**The relationship between a short cervix and the risk of PTB was initially interpreted as evidence of diminished cervical strength or competence, but subsequent clinical experience and interventional studies do not support that conclusion. Cerclage is an effective treatment for women with a history of PTB and a short cervix** (see [Chapter 28](#)). Although beneficial for women with a prior PTB whose CL is very short (<15 to 25 mm),<sup>80,81</sup> cerclage treatment does not reduce PTB risk in women with an isolated short cervix (<15 mm) without a

### BOX 29-6 INDICATIONS FOR CERVICAL ULTRASOUND SCREENING IN THE SECOND TRIMESTER

- Any previous pregnancy delivered between 16 and 36 weeks' gestation
- All pregnancies conceived after fertility care
- All women with a history of cervical instrumentation
  - Cervical cone biopsy or loop electrosurgical excision procedure (LEEP)
  - Dilation and curettage for diagnosis or therapeutic indications, including first- and second-trimester pregnancy terminations
- All women with prior genital tract infections or persistently abnormal Papanicolaou smear
- All women with depression, low body mass index (BMI<19.6), or who smoke
- All women whose cervical length is <35 mm on a midtrimester transabdominal ultrasound examination
  - Women with signs or symptoms of preterm parturition in the current pregnancy
  - Vaginal bleeding or spotting without an obvious cause
  - Persistent symptoms of pelvic pressure, cramps, change in vaginal discharge after 16 weeks' gestation

history of PTB,<sup>82</sup> and it actually appears to increase the risk of PTB in women with a twin pregnancy and a short cervix.<sup>82,83</sup> In women with a prior PTB, cerclage is paradoxically most beneficial in those with the shortest CL (<15 mm),<sup>80,81</sup> which suggests that the benefit of cerclage may relate more to protection of exposed membranes than to bolstering cervical strength.

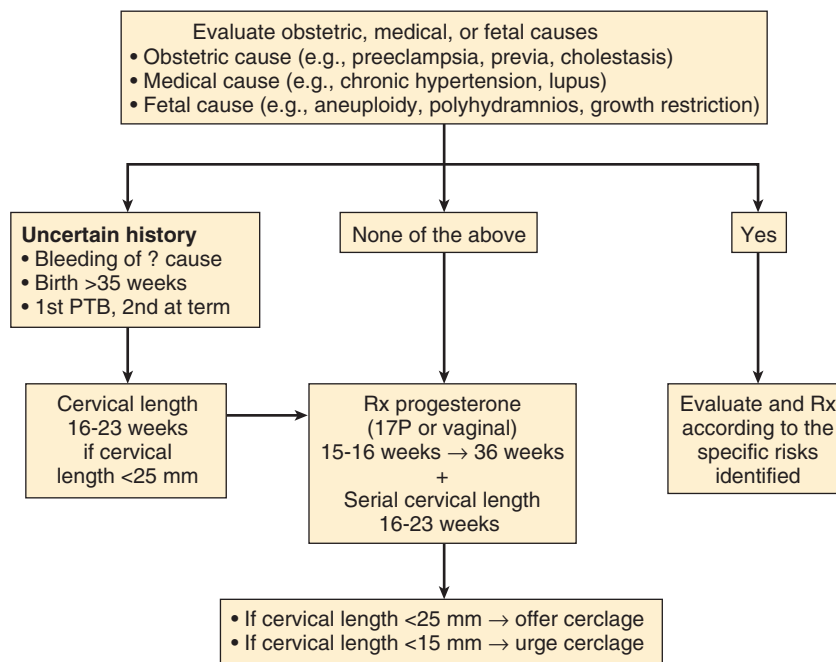

### Clinical Use of Progesterone and Cerclage to Prevent Preterm Birth

The body of evidence that shows progesterone is effective in reducing the risk of PTB in women with a short cervix with or without a history of PTB has influenced the clinical care of women who would previously have been considered to be candidates for prophylactic history-indicated cervical cerclage. Similarly, results from the NICHD Vaginal Ultrasound Cerclage Trial<sup>80</sup> indicate that only 30% of the more than 1000 women with a history of a PTB between 17 and 34 weeks' gestation displayed a CL of 25 mm or less before 24 weeks' gestation when followed with cervical sonography. These observations led to development of the protocol displayed in [Figure 29-11](#).<sup>84</sup> Cerclage is reserved for women with a history of cervical injury, uterine anomaly, and/or progressive cervical shortening to a length below 25 mm despite progesterone therapy. In these patients, cerclage is offered at 25 mm and is strongly urged if the CL is 15 mm or less or membranes are visible.

### Late Preterm Birth

In 2008, 12.3% of births in the United States were preterm, and 71% of these (8.8%) were *late preterm*, occurring between 34<sup>0/7</sup> and 36<sup>6/7</sup> weeks' gestation ([Fig. 29-12](#)). Although these infants fare better than those born before 34 weeks' gestation, they experience substantially increased morbidity and mortality compared with infants born after 37 weeks' gestation, and they account for the overwhelming majority of admissions to the NICU. Approximately 70% of PTBs are spontaneous, but the relative percentage has declined in recent years because indicated PTBs have increased. **Other contributors to the decline in**

- All women receive nutritional and social work counseling at initial visit and as needed thereafter.
- Smoking cessation education and program are provided as needed.
- All women receive nursing education and support at each visit and an invitation to call as needed between visits.

**FIG 29-11** Care algorithm for women with a prior preterm birth (PTB) at 16 to 36 weeks' gestation. Rx, medical treatment. (Courtesy Ohio State University.)

**FIG 29-12** Trends in late-preterm birth, stillbirth, and infant mortality, United States, 1990-2004. (From Ananth CV, Gyamfi C, Jain L. Characterizing risk profiles of infants who are delivered at late preterm gestations: does it matter? *Am J Obstet Gynecol.* 2008;199[4]:329-331.)

the proportion of late spontaneous PTBs that have occurred since 2006 include the decline in multifetal gestations related to fertility care and increased use of progesterone and cervical cerclage. The rise in PTBs between 1990 and 2006 in singletons was almost entirely explained by an increased rate of indicated PTBs between 34 and 36 weeks' gestation. The principal driver of this increase was an increased willingness to consider scheduled birth as a safer option than continuing the pregnancy in women with various pregnancy complications.

The decision to choose indicated PTB over continuation of the pregnancy at any gestational age carries great potential to create, as well as to prevent or reduce, perinatal morbidity and mortality. Unfortunately, the relative risks and benefits of delivery versus expectant management are difficult to weigh accurately, especially in the late preterm period. Before 34 weeks' gestation, clear benefit can be gained by daily increases in fetal maturity. At 34 weeks, the risks of immaturity have been considered to be acceptable in complicated pregnancies, but the morbidity and mortality rates for infants born between 34 and 37 weeks' gestation are higher than previously realized. Reddy and colleagues<sup>85</sup> examined the records of 292,627 late-preterm singleton births and found that 49% were associated with spontaneous labor. Remarkably, no reason was recorded in 23% of late PTBs. In another study,<sup>86</sup> 7.8% of all births and 65.7% of PTBs were late preterm. Of these, 29.8% followed spontaneous labor; 32.3% followed PPROM; 31.8% had an obstetric, maternal, or fetal condition that led to late PTB following induction of labor or cesarean delivery in the absence of labor; and 6.1%

were unknown. Specific guidelines for choosing late PTB in complicated pregnancies are lacking, but recent efforts to document the reasons and track the risks and benefits of these births are expected to help in the future (Table 29-5).<sup>87</sup>

### Primary Prevention of Preterm Birth

**Primary prevention strategies for PTB will require consistent efforts through education and public policy because the public and government currently underestimate the magnitude of the societal burden.** Preconceptional interventions are needed because as many as 50% of PTBs occur in women without known risk factors.

### Public Educational Interventions

Greater awareness of the increased risk of PTB in singleton gestations associated with assisted reproductive technology (ART) could affect attitudes and choices made in fertility care.

Similar strategies to reduce the prevalence of smoking, increase the use of condoms to prevent sexually transmitted infections, and promote recognition and early treatment of depression might all have an eventual effect on PTB rates. Promotion of long-acting reversible contraceptives for women at risk, especially after a preterm delivery, offers a chance to reduce the risk of recurrent PTB.

### Public and Professional Policies

Policies promulgated by fertility specialists intended to reduce the risk of higher-order multiple gestation have been successful in Europe, Australia, and the United States. Rates of triplet and higher-order multiple pregnancies had been rising rapidly in the United States until 1998, when the increase was arrested by voluntary adoption of limitations on the number of ova transferred. The rate of higher-order multiples fell by 50% between 1996 and 2003. A societal approach to improve pregnancy

**TABLE 29-5** GUIDANCE REGARDING TIMING OF DELIVERY WHEN CONDITIONS COMPLICATE PREGNANCY AT 34 WEEKS' GESTATION OR LATER

| CONDITION  | GESTATIONAL AGE* AT DELIVERY  | GRADE OF RECOMMENDATION <sup>†</sup> |
|--|---|--------------------------------------|
| <b>Placental and Uterine Issues</b>  |   |                                      |
| Placenta previa <sup>‡</sup>   | 36-37 wk  | B                                    |
| Suspected placenta accreta, increta, or percreta with placenta previa <sup>‡</sup> | 34-35 wk  | B                                    |
| Prior classical cesarean incision (upper segment uterine incision) <sup>‡</sup>    | 36-37 wk  | B                                    |
| Prior myomectomy necessitating cesarean delivery <sup>‡</sup>                      | 37-38 wk (may require earlier delivery, similar to prior classical cesarean, in situations with more extensive or complicated myomectomy)   | B                                    |
| <b>Fetal Issues</b>  |   |                                      |

| Spontaneous PTB: active preterm labor <sup>‡</sup>  | Delivery if progressive labor or additional maternal or fetal indication                      | B                                    |

From Spong CY, Mercer BM, D'Alton M, et al. Timing of indicated late-preterm and early-term birth. *Obstet Gynecol.* 2011;118(2 Pt 1):323.

\*Gestational age is in completed weeks; thus 34 weeks includes 340/7 weeks through 346/7 weeks.

<sup>†</sup>Grade of recommendation: recommendations or conclusions or both are based on good and consistent scientific evidence (A); based on limited or inconsistent scientific evidence (B); based primarily on consensus and expert opinion (C). The recommendations regarding expeditious delivery for imminent fetal jeopardy were not given a grade. The recommendation regarding severe preeclampsia is based largely on expert opinion; however, higher-level evidence is not likely to be forthcoming because this condition is believed to carry significant maternal risk with limited potential fetal benefit from expectant management after 34 weeks.

<sup>‡</sup>Uncomplicated, thus no fetal growth restriction, superimposed preeclampsia, and so on. If these are present, the complicating conditions take precedence, and earlier delivery may be indicated.

<sup>§</sup>Maintenance antihypertensive therapy should not be used to treat gestational hypertension.

ETB, early-term birth at 37<sup>0/7</sup> weeks through 38<sup>6/7</sup> weeks; EXIT, ex utero intrapartum treatment; LPTB, late-preterm birth at 34<sup>0/7</sup> weeks through 36<sup>6/7</sup> weeks; PPROM, preterm premature rupture of the membranes; PTB, preterm birth.

outcomes has been adopted in most European countries, where policies to protect pregnant women include minimum paid pregnancy leave, time off for prenatal visits, exemption from night shifts, and protection from workplace hazards. The European Programme of Occupational Risks and Pregnancy Outcome (EUROPOP) study of such policies found that **risk of PTB was increased among women who worked more than 42 hours per week (OR, 1.33; CI, 1.1 to 1.6) and who were required to stand for more than 6 hours per day (OR, 1.26; CI, 1.1 to 1.5).**

### Social Determinants of Health

Racial disparities in health are not confined to perinatal medicine but rather are reflected throughout the life span. The increased rates of many illnesses in black and other disadvantaged groups are being addressed by the public health community through **the social determinants of health: (1) promotion of school attendance and completion, (2) food security, (3) neighborhood nutritional programs, (4) job fairs, and (5) an increasing role for hospital and health providers as local leaders.**<sup>88</sup>

### SUMMARY

Preterm birth is a syndrome, the final result of several pathways that often overlap to initiate parturition. Obstetric interventions to reduce infant morbidity, such as antenatal glucocorticoids and antibiotics for group B

streptococcal prophylaxis, are effective tertiary therapies but have no opportunity to reduce the incidence of PTB. Detection of pregnancies at risk through careful review of prior pregnancies, selective or universal use of cervical ultrasound screening to identify candidates for progesterone therapy, and selective use of cerclage are welcome advances. Adherence to protocols for timing of scheduled births and documentation of indications for iatrogenic PTB are needed to further reduce the rate of stillbirth while limiting the associated morbidity of late PTB.

### KEY POINTS

- ◆ More than 70% of fetal, neonatal, and infant morbidity and mortality occurs in infants born preterm.
- ◆ The rate of PTB peaked in 2006 as the result of the increased use of assisted reproductive technology, ultrasound dating, and indicated preterm births. It has since declined largely because of the adoption of fertility practices to reduce the multifetal gestations associated with infertility treatment.
- ◆ Major risk factors for PTB are a history of previous preterm delivery, multifetal gestation, and bleeding after the first trimester of pregnancy; however, most women who deliver preterm have no apparent risk factors; therefore every pregnancy is potentially at risk.

- ◆ sPTB is a syndrome in which the parturition process may be initiated by one or more pathways that culminate in cervical ripening, decidual activation, uterine contractions, and ruptured membranes.
- ◆ Four interventions have been shown to reduce perinatal morbidity and mortality: (1) transfer of the mother and fetus to an appropriate hospital before PTB; (2) administration of maternal antibiotics to prevent neonatal Group B *Streptococcus* infection; (3) administration of maternal corticosteroids to reduce neonatal RDS, IVH, and neonatal mortality; and (4) administration of maternal magnesium sulfate at the preterm delivery at less than 32 weeks to reduce the incidence of cerebral palsy.
- ◆ The risk of recurrent PTB may be reduced in women with a prior PTB with 17- $\alpha$ -hydroxyprogesterone caproate and in women with a short cervix (<20 mm) by administration of prophylactic supplemental progesterone. Cervical cerclage should be reserved for women with a prior PTB and a short cervix.

**Membrane rupture that occurs spontaneously before the onset of labor is described as premature rupture of the membranes (PROM) regardless of the gestational age at which it occurs.** PROM complicates about 8% to 10% of pregnancies. Preterm PROM that occurs before 37 weeks' gestation affects about 1% of deliveries overall, and birth certificate data suggest that it is over twofold more common in blacks.<sup>1</sup> Like preterm labor and cervical insufficiency, PROM is considered a cause of spontaneous preterm birth. The relative contribution of PROM to prematurity appears to vary greatly among patient populations, affecting about 10% of preterm births in national databases but over 20% in certain high-risk populations. Its frequency appears to have declined during the past decade.<sup>2-5</sup>

**PROM at any gestational age is associated with brief latency from membrane rupture to delivery and also increased risks for perinatal infection and umbilical cord compression due to oligohydramnios.** Because of this, term and preterm PROM are significant causes of perinatal morbidity and mortality. When PROM occurs at term, the risk is low for severe neonatal complications with delivery of a noninfected and non-asphyxiated infant. Clinical management should be directed toward delivery. Although complications can occur, delivery at 32 to 36 weeks' gestation is generally associated with good infant outcomes, particularly if the fetus has documented pulmonary maturity. Given the risks of continued pregnancy and anticipated brief latency, delivery of the mature fetus is generally warranted, particularly at 34 weeks' gestation or later. At 32 to 33 weeks' gestation, the immature fetus may benefit from measures to accelerate fetal maturation and to prolong the pregnancy. With immediate delivery after preterm PROM at 23 to 31 weeks' gestation, the risk is significant for newborn complications that can be reduced through adequate delay of delivery. In the absence of contraindications, management is directed toward

continuing the pregnancy with attention to potential complications that include umbilical cord compression, intrauterine infection, and abruptio placentae. When PROM occurs before the limit of viability, newborn death is inevitable with immediate delivery. Although conservative management may still result in a previsible delivery, some women will benefit from extended latency with delivery of a potentially viable infant. **Regardless of the gestational age, the patient should be well informed regarding the potential maternal, fetal, and neonatal complications of PROM and preterm birth.** These issues are discussed in detail in this chapter.

## FETAL MEMBRANE ANATOMY AND PHYSIOLOGY

The fetus develops within the amniotic sac, which is surrounded like a balloon by the fetal membranes. These membranes consist of a thin amnion layer that lines the amniotic cavity and a thicker outer chorion directly apposed to the maternal decidua. The amnion fuses to the chorion near the end of the first trimester of pregnancy, and these layers are subsequently attached by a collagen-rich connective tissue zone. For the remainder of the pregnancy, the fetal membranes include a single cuboidal amnion epithelium with subjacent compact and spongy connective tissue layers and a thicker chorion that consists of reticular and trophoblastic layers. Together, the amnion and chorion are stronger than either layer independently; individually, the amnion has greater tensile strength than the chorion.

As the pregnancy progresses, changes in collagen content and type, intercellular matrix, and cellular apoptosis result in structural weakening of the fetal membranes. Membrane remodeling is more evident near the internal cervical os and can be stimulated by thrombin-mediated increases in matrix metalloproteinases (e.g., MMP-1, MMP-2, MMP-9) and decreased levels of tissue inhibitors of matrix metalloproteinases (e.g., TIMP-1, TIMP-3) within the membranes, as well as increased poly (ADP-ribose) polymerase (PARP) cleavage.<sup>6-8</sup> Contractions subject the amniochorionic membranes to additional physical strain that can lead to membrane rupture. Should the fetal membranes not rupture before labor, advancing cervical dilation decreases the work needed to cause membrane rupture over the internal cervical os. **Preterm PROM likely results from a variety of factors that ultimately lead to accelerated membrane weakening through an increase in local cytokines and an imbalance in the interaction between MMPs and TIMPs, increased collagenase and protease activity, or other factors that cause increased intrauterine pressure (e.g., polyhydramnios).**<sup>5-9</sup>

## ETIOLOGY OF PREMATURE RUPTURE OF THE MEMBRANES

A number of risk factors have been associated with the occurrence of preterm PROM. Among these are low socioeconomic status, uterine overdistension, second- and third-trimester bleeding, low body mass index (BMI), nutritional deficiencies of copper and ascorbic acid, maternal cigarette smoking, cervical conization or cerclage, pulmonary disease in pregnancy, connective tissue disorders (e.g., Ehlers-Danlos syndrome), and preterm labor or symptomatic contractions in the current gestation. Each risk factor, individually or in concert, could lead to PROM through the mechanisms outlined above. However, the ultimate

clinical cause of membrane rupture is often not apparent, and many at-risk patients will deliver at term without PROM.

**Preterm PROM has also been linked to infections that involve the urogenital tract.** *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and *Trichomonas vaginalis* have each been associated with preterm PROM.<sup>10</sup> Although vaginal group B  $\beta$ -hemolytic *Streptococcus* (GBS) colonization does not appear to be associated with preterm PROM, cervical colonization may be. **GBS bacteriuria is associated with preterm PROM and low-birth-weight infants.**<sup>11,12</sup> Although bacterial vaginosis has been linked to spontaneous preterm births, including preterm PROM, it is unclear whether bacterial vaginosis is the inciting condition that facilitates ascent of other bacteria to the upper genital tract, or whether it is simply a marker of maternal susceptibility to abnormal genital tract colonization.<sup>13</sup> Bacterial invasion can facilitate membrane rupture through direct release of proteases and also through stimulation of a host inflammatory response that results in the elaboration of local cytokines, MMPs, and prostaglandins. Histologic studies of the membranes after preterm PROM often demonstrate significant bacterial contamination along the chorio-decidual interface with minimal involvement of the amnion.<sup>14</sup> Further evidence that links preterm PROM and genital tract infection is that these women have a high incidence of positive amniotic fluid cultures (25% to 35%) even in the absence of clinically suspected intrauterine infection.<sup>15,16</sup> Although some of these findings may reflect ascending infection subsequent to membrane rupture, it is probable that **ascending bacterial colonization and infection are integral to the pathogenesis of preterm PROM in many cases.**

**Although the onset of vaginal fluid leakage is an acute event, evidence shows that the factors and events that lead to membrane rupture are sometimes subacute or even chronic.** Women with a prior preterm birth (PTB), especially because of PROM, are at increased risk for PTB due to PROM in future pregnancies. Studies have also suggested associations exist between maternal inflammatory proteins, genotype, and spontaneous preterm birth (sPTB) due to preterm labor or PROM.<sup>17,18</sup> Further, asymptomatic women with a short cervical length in the second trimester are at increased risk for preterm PROM occurring many weeks later.<sup>19</sup>

## PREDICTION AND PREVENTION OF PRETERM PREMATURE RUPTURE OF THE MEMBRANES

Once preterm PROM occurs, delivery is often required or inevitable. Optimally, prevention of PROM would offer the best opportunity to avoid its complications. **Prior PTB and especially prior preterm PROM (PPROM) have been associated with PPROM in a subsequent pregnancy.**<sup>20</sup> **The risk of recurrence increases with decreasing gestational age of the index PTB.** Those with a prior delivery near the limit of viability (23 to 27 weeks) have a 27.1% risk of subsequent PTB. Those with a prior history of PTB due to PROM have a 3.3-fold higher risk for PTB due to PROM (13.5% vs. 4.1%) and a 13.5-fold higher risk for PPROM before 28 weeks' gestation (1.8% vs. 0.13%) in a subsequent pregnancy ( $P < .01$  for each). In an analysis from a prospective evaluation of PTB prediction, nulliparas and women with prior deliveries were evaluated separately because those without a prior birth lacked important historic information available to those with a prior term or preterm birth.<sup>19</sup> In that study, multivariable analysis revealed medical complications (including pulmonary disease in pregnancy), work during

pregnancy, recent symptomatic uterine contractions, and bacterial vaginosis to be significant markers for subsequent PTB in nulliparas when assessed at 22 to 24 weeks' gestation (Table 30-1). **Among women with prior deliveries, prior PTB due to preterm labor or PROM and a positive cervicovaginal fetal fibronectin (fFN) screen were statistically significant clinical markers for subsequent PPROM after controlling for other factors.** Short cervical length (<25 mm) identified by transvaginal ultrasound and low maternal BMI (<19.8 kg/m<sup>2</sup>) were associated with an increased risk for subsequent PROM in both nulliparas and multiparas. Nulliparas with a positive cervicovaginal fFN and a short cervix had a 16.7% risk for PTB due to PPROM. **Among multiparas, women with a prior PTB due to PROM, a short cervix on ultrasound, and positive cervicovaginal fFN screen had a 31-fold higher risk for PROM with delivery before 35 weeks' gestation (25% vs. 2.3%) than those without risk factors (Table 30-2).**

†Short cervix, cervix length <25 mm on transvaginal ultrasound at 22 to 24 weeks' gestation.

fFN, fetal fibronectin; PROM, premature rupture of the membranes.

Unfortunately, clinical risk-assessment systems identify only a small fraction of women who will ultimately deliver preterm. Although clinical and ancillary testing has increased our ability to identify women at increased risk because of potentially modifiable factors—such as cigarette smoking, poor nutrition, urinary tract and sexually transmitted infections, pulmonary disease, and severe polyhydramnios—it is unknown whether modification of these in a given patient will reduce the risk for PROM. Regardless, women at risk for PTB due to PROM based on clinical findings can be counseled regarding the symptoms of membrane rupture and contractions and can be encouraged to seek medical care should symptoms occur. Regarding ancillary testing, progesterone therapy has been recommended for prevention of PTB in asymptomatic women with a short cervix, and thus cervical length (CL) screening has potential value for both predictive and therapeutic reasons.<sup>21</sup> Alternatively, routine fFN screening has similar predictive value to CL measurement, but no effective intervention can be offered based on the results. Thus routine fFN testing after PTB due to PROM is not recommended. **Current evidence supports 17- $\alpha$ -hydroxyprogesterone caproate (17-P) treatment for women with a prior PTB due to PROM or preterm labor and also supports treatment with vaginal progesterone for asymptomatic women with a short cervical length.**<sup>21-23</sup> Data regarding the value of vitamin C supplementation in preventing PROM are conflicting and are not generally supportive. In one study, such treatment was associated with a lower risk (7.7% vs. 24.5%;  $P = .02$ ).<sup>24</sup> Secondary analysis of another study suggested that treatment with vitamin C and E did not reduce sPTB or late preterm birth due to PROM but was associated with less frequent PTB due to PROM before 32 weeks' gestation.<sup>25</sup> However, a review of studies in which vitamin C was given alone or in combination with other supplements suggests a negative impact on membrane strength and an increased risk for PTB.<sup>26,27</sup> **Because of these findings, vitamin C supplementation to prevent PPROM is not currently recommended.**

## CLINICAL COURSE AFTER PREMATURE RUPTURE OF THE MEMBRANES

### Maternal Risks

Hallmarks of PROM include a brief latency from membrane rupture to delivery. On average, latency increases with decreasing gestational age at membrane rupture. At term, half of expectantly managed gravidas deliver within 5 hours and 95% deliver within 28 hours of membrane rupture.<sup>28</sup> Of all women with PROM before 34 weeks, 93% deliver in less than 1 week. After excluding those who require delivery soon after admission, 50% to 60% of those conservatively managed and treated with antibiotics for pregnancy prolongation will deliver within 1 week of membrane rupture.<sup>29</sup> Only a small proportion of women with membrane rupture ( $\leq 5\%$ ) can anticipate cessation of fluid leakage. About 86% of those with leakage after amniocentesis will resealed.<sup>30,31</sup>

## RISKS OF PREMATURE RUPTURE OF THE MEMBRANES

### Maternal Risks

**Chorioamnionitis is the most common maternal complication after PPROM.** This risk increases as the duration of membrane rupture becomes more prolonged and decreases with

advancing gestational age at PROM.<sup>32</sup> The risks of chorioamnionitis and endometritis increase with decreasing gestational age at PROM and also in different patient populations (13% to 60% for chorioamnionitis and 2% to 13%, for endometritis).<sup>33,34</sup> **Abruptio placentae can cause PROM or can occur subsequent to membrane rupture, and it affects 4% to 12% of these pregnancies.<sup>35</sup> Uncommon but serious complications of PROM managed conservatively near the limit of viability include retained placenta and hemorrhage, requiring dilation and curettage (12%); maternal sepsis (0.8%); and maternal death (0.14%).<sup>36</sup>**

### Fetal and Neonatal Risks

**Fetal complications after membrane rupture include infection and fetal distress due to umbilical cord compression or placental abruption.** Umbilical cord compression due to oligohydramnios is not uncommon after PROM. Frank or occult umbilical cord prolapse can also occur, particularly with fetal malpresentation. Because of these factors, women with PROM have a higher risk for cesarean delivery for nonreassuring fetal heart rate (FHR) patterns than those with isolated preterm labor (7.9% vs. 1.5%). **Fetal death complicates 1% to 2% of cases of conservatively managed PROM.<sup>29</sup>**

**The frequency and severity of neonatal complications after PROM vary inversely with gestational age at membrane rupture and at delivery.** Respiratory distress syndrome (RDS) is the most common serious newborn complication after PPROM at any gestational age. Necrotizing enterocolitis (NEC), intraventricular hemorrhage (IVH), and sepsis are common with early PTB but are relatively uncommon when PPROM and delivery occur near term. Serious perinatal morbidities with delivery remote from term can lead to long-term sequelae such as chronic lung disease (CLD), visual or hearing difficulties, intellectual disabilities, developmental and motor delay, cerebral palsy, and death. Although specific data are not available for those who deliver after PPROM, general community-based survival and morbidity data suggest that long-term morbidities and death are uncommon with delivery after about 32 weeks' gestation.<sup>37</sup> It is controversial whether gestational age-specific mortality is increased for preterm infants who deliver after PPROM.<sup>38,39</sup>

**PPROM increases the risk of neonatal sepsis twofold over that seen after PTB due to preterm labor with intact membranes.<sup>40</sup>** Neonatal infection can result from the same organisms present in the amniotic fluid, or from others, and it can present as acute congenital pneumonia, sepsis, or meningitis. Late-onset bacterial or fungal infections can also occur. Accumulating evidence suggests that fetal and neonatal infection and inflammation are associated with an increased risk for long-term neurologic complications. Cerebral palsy and cystic periventricular leukomalacia (PVL), as well as cognitive impairment and death and neurodevelopmental impairment in extremely preterm infants, have been linked to chorioamnionitis, which is more commonly seen after PPROM and is more likely with conservative management after membrane rupture.<sup>41,42</sup> Elevated amniotic fluid cytokines and fetal systemic inflammation have also been associated with PPROM, PVL, and cerebral palsy.<sup>43</sup> **Although no data suggest that immediate delivery on admission with PROM will avert these sequelae, these findings highlight the importance of restricting conservative management after PROM to circumstances in which there is the potential to reduce neonatal morbidity through either antenatal corticosteroid**

**administration or extended pregnancy prolongation for fetal maturation.**

**Pulmonary hypoplasia is a severe complication of oligohydramnios in the second trimester that results from a lack of terminal bronchiole and alveolar development during the canalicular phase of pulmonary development.<sup>44</sup>** It is most accurately diagnosed pathologically using radial alveolar counts and lung weights.<sup>45</sup> Clinical findings, such as a small chest circumference with severe respiratory distress and persistent pulmonary hypertension in the newborn, and radiographic findings—small, well-aerated lungs with a bell-shaped chest and elevation of the diaphragm—are also supportive of the diagnosis. Whether because of fluid efflux and tracheobronchial collapse after membrane rupture or through loss of intrinsic factors within the tracheobronchial fluid, pulmonary hypoplasia develops over weeks after membrane rupture. Pulmonary hypoplasia complicated an average of about 6% of cases in series of midtrimester PROM and carries a 70% mortality rate.<sup>46</sup> Its incidence is inversely correlated with gestational age at membrane rupture, and it complicates nearly 50% of cases with membrane rupture before 19 weeks and prolonged latency.<sup>44,47</sup> The frequency of pulmonary hypoplasia can be as high as 74% to 82% with PROM at 15 to 16 weeks, persistent oligohydramnios, and a latency of 28 days.<sup>48</sup> Lethal pulmonary hypoplasia rarely occurs with PROM after 26 weeks' gestation (0% to 1.4%).<sup>49</sup> However, other pulmonary complications such as pneumothorax and pneumomediastinum related to poor pulmonary compliance and high ventilatory pressures can occur with lesser degrees of this condition. Restriction deformities occur in about 1.5% of infants delivered after conservative management after midtrimester PROM but complicate up to 27% of fetuses with prolonged oligohydramnios.<sup>36,50</sup>

### DIAGNOSIS OF PREMATURE RUPTURE OF THE MEMBRANES

The diagnosis of PROM involves clinical history and physical examination as well as laboratory evaluation in some cases.

**The diagnosis of membrane rupture is confirmed by the presence of the following findings:**

- Visualization of amniotic fluid passing from the cervical canal *or*
- Vaginal sidewall or posterior fornix pH of more than 6.0 to 6.5 *and*
- Microscopic arborized crystals ("ferning"), owing to the interaction of amniotic fluid proteins and salts, from dried vaginal secretions obtained by swabbing the posterior fornix with a sterile swab.

False-positive pH results may occur with blood or semen contamination, alkaline antiseptics, or bacterial vaginosis. Cervical mucus can yield a false-positive ferning pattern; however, the crystals appear as more of a floral pattern. The fern pattern in samples heavily contaminated with blood is atypical and appears more "skeletonized." Prolonged leakage with minimal residual fluid can result in a false-negative result on visual inspection or pH or ferning testing. If the diagnosis is equivocal after initial testing, the patient can be placed in a Trendelenburg position and reexamined after a few hours. The diagnosis of membrane rupture can be made unequivocally by ultrasound-guided dye amnioinfusion (1 mL indigo carmine plus 9 mL sterile saline), followed by observation for passage of dye onto a perineal pad. **Although oligohydramnios without evident fetal urinary**

**tract malformations or fetal growth restriction may be suggestive of membrane rupture, ultrasound alone is not definitive.**

Noninvasive cervicovaginal markers such as fFN, alpha-fetoprotein, prolactin, human chorionic gonadotropin (hCG), placental  $\alpha$ -microglobulin 1 (PAMG-1), and insulin-like growth factor-binding protein 1 (IGFBP-1) have been studied for their ability to confirm or exclude membrane rupture, but most are unavailable for clinical use. Such testing is unnecessary when the diagnosis is confirmed clinically. Further, although membrane rupture can be confirmed by the presence of PAMG-1 in cervicovaginal secretions, and the test's accuracy is relatively unaffected by the presence of blood,<sup>51</sup> it has also been found to be present in nearly one third of laboring women and in 1 of 20 nonlaboring women without suspected membrane rupture.<sup>52</sup>

## MANAGEMENT OF PREMATURE RUPTURE OF THE MEMBRANES

### General Considerations

**Management of PROM is based primarily on an individual assessment of the estimated risk for fetal and neonatal complications should conservative management or delivery be pursued. The risks for maternal morbidity should also be considered, particularly when PROM occurs before the limit of potential viability** (currently 23 weeks' gestational age). Regional factors may impact the potential risks and benefits of conservative management. In populations where the risk of intrauterine infection is high and the potential for extended latency without complications is low, the focus will tend to be on acceleration of fetal maturation, prevention of intrauterine infection, and delivery if fetal benefit from prolonged latency is not anticipated. Alternatively, in populations at low risk for intrauterine infection and with higher potential for prolonged latency, conservative management may be appropriate at a more advanced gestational age.

The diagnosis of membrane rupture is confirmed and the duration of membrane rupture is determined to assist the pediatric caregivers with subsequent management decisions. The patient is assessed for fetal presentation, contractions, findings suggestive of intrauterine infection, and evidence of fetal well-being. GBS carriage is ascertained, if available, from a recent anovaginal culture performed within the previous 5 weeks.

**In general, digital cervical examinations should be avoided until it is determined that delivery is inevitable because such examination has been associated with a shortening of latency from membrane rupture to delivery.**<sup>53</sup> Visualization of the cervix during a sterile speculum examination offers helpful information regarding cervical dilation and effacement. Brown and colleagues<sup>54</sup> found visual estimation to be within 1 cm of digitally determined cervical dilation in 64% and within 2 cm in 84% of examinations, whereas visually estimated cervical effacement was within 1 cm in 83% of cases. In addition to providing confirmatory evidence of membrane rupture, sterile speculum examination can provide the opportunity to inspect for cervicitis and to obtain appropriate cervical and vaginal cultures.

The benefit of narrow-spectrum intrapartum prophylaxis with intravenous (IV) penicillin G (5 million U and then 2.5 to 3 million U every 4 hr) or ampicillin (2 g IV, then 1 g IV every 4 hr) to prevent vertical transmission and early-onset neonatal

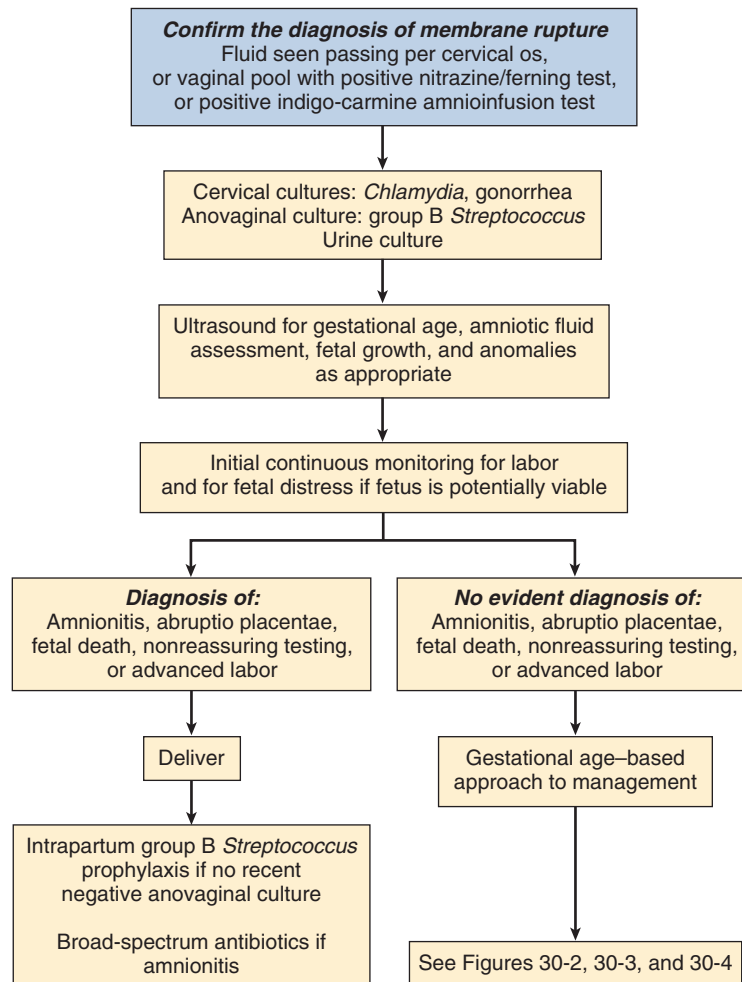

GBS sepsis from maternal GBS carriers has been well established, and the Centers for Disease Control and Prevention (CDC) published a revised guideline for the prevention of perinatal group B streptococcal disease in November 2010.<sup>55,56</sup> Current indications for intrapartum GBS prophylaxis and alternative antibiotic regimens for those with a penicillin allergy are discussed in Chapter 54. Known GBS carriers with PROM at any gestation and those with PPROM and unknown GBS status should receive intrapartum prophylaxis regardless of prior antibiotic treatment. GBS carriers with PROM and chorioamnionitis should receive broad-spectrum intrapartum antibiotic therapy, including agents effective against GBS. If chorioamnionitis is not suspected clinically and there is a recent negative anovaginal culture for GBS, intrapartum antibiotics should not be administered because of the potential for selection of resistant organisms should neonatal sepsis occur.<sup>57</sup>

Although practice varies regarding the management of PPROM, general consensus has been reached in regard to some issues. Gestational age should be established based on clinical history and earliest ultrasound assessment where available (Fig. 30-1). Ultrasound should be performed to assess fetal growth and position, residual amniotic fluid volume, and gross fetal abnormalities that might cause polyhydramnios and PROM. Those with advanced labor, intrauterine infection, significant vaginal bleeding, or nonreassuring fetal testing are best delivered. **If conservative management of PPROM is to be pursued, the patient should be admitted to a facility capable of providing emergent delivery for placental abruption, fetal malpresentation in labor, and fetal distress due to umbilical cord compression or in utero infection. The facility should also be capable of providing 24-hour neonatal resuscitation and intensive care because conservative management should generally be performed only when significant risk for neonatal morbidity and mortality is present.** If the need for transfer to a tertiary care facility is anticipated, this should occur early in the course of management to avoid emergent transfer once delivery is imminent or complications arise.

### Management of Premature Rupture of the Membranes at Term

Despite some past controversy, studies have found that induction with oxytocin after PROM at term does not increase the risks for perinatal infection or cesarean delivery.<sup>28,58-61</sup> In fact, the largest prospective study to date has found that oxytocin induction after PROM at term reduces the duration of membrane rupture after PROM (median, 17.2 vs. 33.3 hr), and the frequencies of chorioamnionitis (4% vs. 8.6%) and postpartum fever (1.9% vs. 3.6%;  $P \leq .008$  for each), without increasing cesarean deliveries (13.7% vs. 14.1%) or neonatal infections (2% vs. 2.8%).<sup>28</sup> An additional benefit of early oxytocin induction in this trial was a reduction in neonatal antibiotic therapy (7.5% vs. 13.7%;  $P < .001$ ). Meta-analysis of 12 studies that comprised a total of 6814 women and studied early delivery versus expectant management for PROM at term confirmed less frequent chorioamnionitis and endometritis with planned delivery, with no increases in cesarean delivery or neonatal infection.<sup>62</sup> Fewer infants in the early delivery group required neonatal intensive care unit (NICU) or special care admission. Analysis of studies of prostaglandin versus oxytocin induction after PROM at or near term found increased chorioamnionitis (odds ratio [OR], 1.51; 95% confidence interval [CI], 1.07 to 2.12), neonatal infection (OR, 1.63; 95% CI, 1 to 2.66), and a

**FIG 30-1** Initial assessment and management of women with preterm premature rupture of the membranes. (From Mercer BM. Preterm premature rupture of the membranes: diagnosis and management. *Clin Perinatol*. 2004;31:765.)

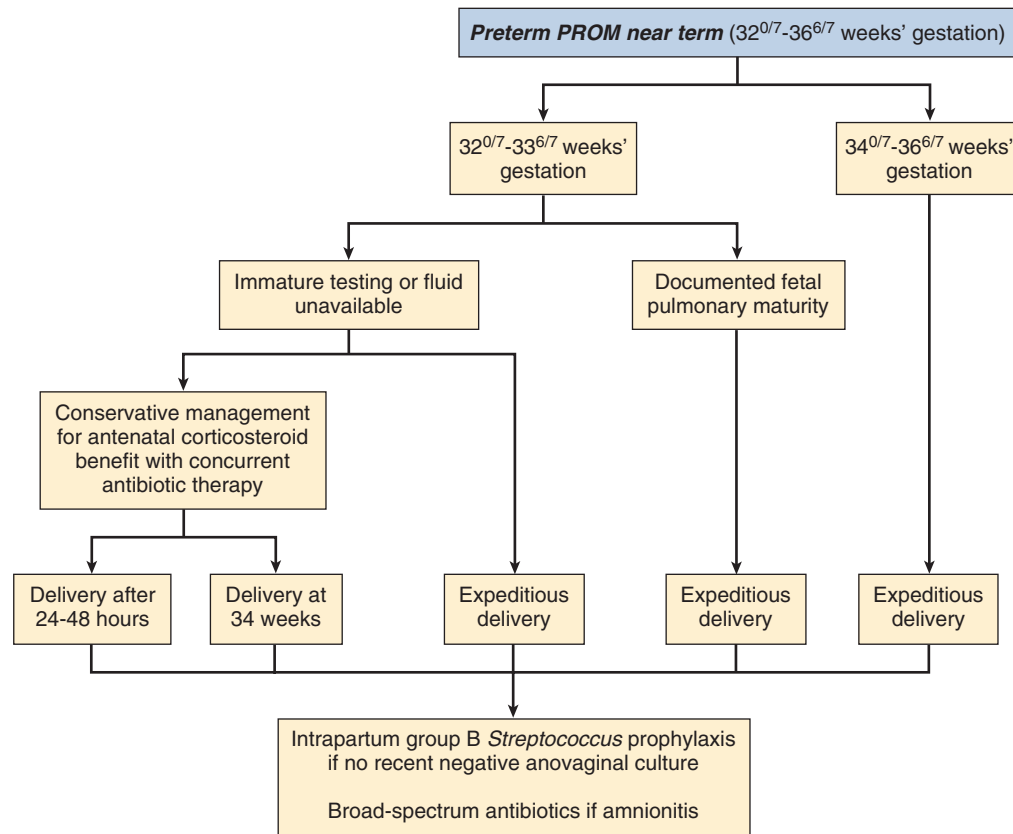

prolonged NICU stay (OR, 1.43; 95% CI, 1.07 to 1.91) without improvement in cesarean delivery rates (OR, 0.92; 95% CI, 0.73 to 1.16) with prostaglandin treatment.<sup>63</sup> This meta-analysis was dominated by the TermPROM trial,<sup>28</sup> which found shorter latency from membrane rupture to delivery with oxytocin than with prostaglandin therapy (median, 17.2 vs. 23 hours;  $P < .001$ ). Taken together, these data suggest that **women with PROM at term should be offered early delivery, generally with a continuous oxytocin infusion, to reduce the risk for maternal and neonatal complications.** Adequate time for latent phase of labor should be allowed. During labor, transcervical amnioinfusion of warm normal saline solution may prove useful if significant umbilical cord compression is suspected and immediate delivery is not required.<sup>64,65</sup>

### Management of Preterm Premature Rupture of the Membranes Near Term (32 to 36 Weeks)

Severe acute newborn complications are uncommon when preterm birth occurs between 34 and 36 weeks' gestation. Antenatal corticosteroids for fetal maturation and magnesium sulfate for fetal/neonatal neuroprotection are not usually administered in this gestational age range.<sup>37</sup> Alternatively, **conservative**

**management after PROM at 34 to 36 weeks' gestation only briefly prolongs pregnancy while increasing the likelihood of chorioamnionitis** (16% vs. 2%;  $P = .001$ ) without preventing neonatal complications.<sup>66,67</sup> A recent multicenter study regarding this issue suggested conservative management of women without GBS colonization to be preferable because newborn complications were not reduced with early delivery after PROM at 34 to 37 weeks' of gestation.<sup>68,69</sup> Whereas chorioamnionitis was twofold more common (5.6% vs. 2.3%,  $P = .045$ ), conservative management was associated with less frequent newborn hypoglycemia and hyperbilirubinemia. **As such, conservative management of PROM that occurs at 34 to 37 weeks might be an option if the risk of intrauterine infection is considered to be low.**

**Management of the woman with PROM at 32 to 33 weeks' gestation is more controversial because pulmonary and other gestational age-dependent complications can occur, but the likelihood of survival at this gestation is high and long-term complications are uncommon.** Neerhoff and colleagues<sup>67</sup> found modest benefits in the duration of newborn hospital stay and the frequency of hyperbilirubinemia with conservative management at 32 to 33 weeks' gestation. Alternatively, two prospective trials that compared early delivery and conservative management of PROM near term have provided useful

**FIG 30-2** Management algorithm for preterm premature rupture of the membranes (PROM) near term (32 to 36 weeks' gestation). (From Mercer BM: Preterm premature rupture of the membranes: diagnosis and management. *Clin Perinatol.* 2004;31:765.)

insights. Cox and coworkers found conservative management of PROM at 30 to 33<sup>6/7</sup> weeks' gestation to increase latency only briefly (59% vs. 100% delivered within 48 hr;  $P < .001$ ).<sup>70</sup> In a study of PROM at 32 to 36<sup>6/7</sup> weeks' gestation, Mercer and colleagues<sup>71</sup> observed only a 24-hour increase in latency with conservative management (36 vs. 14 hours;  $P < .001$ ). However, both studies noted that conservative management increased the risk for chorioamnionitis (15% vs. 2%,  $P = .009$  and 27.7% vs. 10.9%,  $P = .06$ , respectively) without evident reductions in newborn complications. Secondary analysis of those with PROM at 32 to 33<sup>6/7</sup> weeks' gestation in the latter trial revealed similar trends regarding latency, infection, and infant morbidities.<sup>72</sup> The potential for umbilical cord compression during conservative management of PROM is highlighted by one stillbirth and the high incidence of nonreassuring FHR patterns found on intermittent monitoring in these studies.<sup>70,71</sup>

**At 32 to 33 weeks' gestation, it can be helpful to assess fetal pulmonary maturity and to treat with antenatal corticosteroids those pregnancies without documented fetal maturity.** Either vaginal pool or amniocentesis specimens can be used for testing. Because of the increased potential for inadvertent fetal or umbilical cord puncture during amniocentesis when the amniotic fluid volume is decreased, **vaginal pool specimen collection is preferable if an adequate specimen can be obtained.** If amniocentesis is required, color Doppler imaging can be helpful in differentiating umbilical cord loops from a small residual fluid pocket. Pulmonary phospholipids are not present in lavage fluid from the vagina when the membranes are intact.<sup>73</sup> Studies of women with ruptured membranes have

found a high concordance rate (89% to 100%) between specimens collected vaginally and by amniocentesis for pulmonary phospholipids such as lecithin, phosphatidylglycerol (PG), phosphatidylinositol, phosphatidylethanolamine, and phosphatidylserine.<sup>74</sup> Lewis and associates<sup>75</sup> found no cases of RDS among infants delivered after a mature PG result from vaginal pool fluid. Similarly, in a study of vaginally collected samples, Russell and associates<sup>76</sup> found no cases of RDS after a mature lecithin-to-sphingomyelin (L/S) ratio or PG result. The presence of PG on perineal pad-collected fluid is predictive of fetal pulmonary maturity (97.8%), and its absence is predictive of pulmonary immaturity (33.7%).<sup>77</sup> The lamellar body count (LBC;  $\geq 50,000$  is considered mature) may be performed from vaginally collected amniotic fluid specimens and has been shown by some to have a high predictive value for fetal pulmonary maturity.<sup>78</sup> Amniotic fluid pulmonary maturity testing can be confounded by the presence of contaminants such as blood and meconium (see Chapter 11). Realistically, delivery should be considered if significant blood or meconium is present in a vaginal pool or an amniocentesis specimen after PROM.

Based on the available data, early delivery should be pursued when PROM occurs at 34 to 36 weeks' gestation (Fig. 30-2). The infant delivered after PROM at 30 to 33 weeks' gestation is at risk for infectious and other gestational age-dependent morbidities, but evidence of fetal pulmonary maturity at 32 to 33<sup>6/7</sup> weeks' gestation suggests a low risk for complications with immediate delivery. Because of the increased risk for infectious morbidity and potential for occult umbilical cord compression with conservative management, **delivery should be initiated**

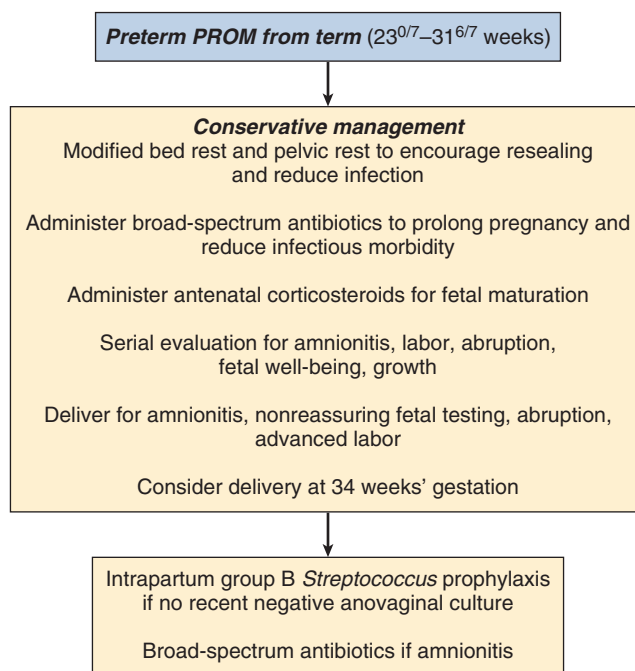

before complications ensue if there is documented fetal pulmonary maturity after PROM at 32 to 33 weeks. If fetal pulmonary maturity is not evident on testing, or if amniotic fluid cannot be obtained for testing, conservative management with antenatal corticosteroid administration for fetal maturation and antibiotic therapy to reduce the risk for infection (see below) is appropriate. The issue of continued conservative management versus delivery after steroid treatment is a matter of opinion. Pragmatically, if elective delivery is planned within 1 week, it is unlikely that prolonging the pregnancy further will offer more opportunity for significant additional fetal maturation, and delivery should be considered after steroids have been administered. Alternatively, if several weeks of conservative management are to be attempted, there may be benefit to continuing the pregnancy.

### Management of Preterm Premature Rupture of the Membranes Remote From Term (23 to 31 Weeks)

Infants born at 23 to 31 weeks' gestation are at increased risk for perinatal death, and survivors commonly suffer acute and long-term complications. Pregnancy prolongation can reduce these risks, and because of this, inpatient conservative management is generally attempted unless intrauterine infection, significant vaginal bleeding, placental abruption, or advanced labor is evident or fetal testing becomes nonreassuring. Fetal malpresentation, funic presentation, human immunodeficiency virus (HIV), and primary herpes simplex virus (HSV) are examples of exceptions that might warrant expeditious delivery because of the increased potential for fetal death or infection with prolonged membrane rupture.

During conservative management, initial care generally consists of prolonged continuous FHR and maternal contraction monitoring for evidence of umbilical cord compression and occult contractions and to establish fetal well-being. If initial testing is reassuring, the patient can be transferred to an inpatient ward for modified bed rest (Fig. 30-3). Because the fetus with PPROM remote from term is at risk for heart rate abnormalities resulting from umbilical cord compression, fetal assessment should be performed at least daily. More frequent or continuous monitoring may be appropriate if intermittent FHR decelerations are present but findings are otherwise reassuring. Although both nonstress and biophysical profile testing have the ability to confirm fetal well-being in the setting of PPROM, FHR monitoring offers the opportunity to identify periodic heart rate changes and allows concurrent evaluation of uterine activity. Biophysical profile (BPP) testing may be confounded by the presence of oligohydramnios but can be helpful should the nonstress test (NST) result be equivocal (see Chapter 11). **Although a low initial amniotic fluid index is associated with shorter latency and an increased risk for chorioamnionitis, it does not accurately predict who will ultimately develop these complications and should not be used in isolation to make management decisions.** Prolonged bed rest in pregnancy may increase the risk for deep venous thrombosis (DVT).<sup>79</sup> Preventive measures such as leg exercises, antiembolic stockings, and/or prophylactic doses of subcutaneous heparin should be considered during conservative management of PROM (see Chapter 45).

Twofold to fourfold increases in perinatal mortality, IVH, and neonatal sepsis have been reported in infants born after

**FIG 30-3** Management algorithm for preterm premature rupture of the membranes (PROM) remote from term (23 to 31 weeks' gestation). (From Mercer BM. Preterm premature rupture of the membranes: diagnosis and management. *Clin Perinatol*. 2004;31:765.)

chorioamnionitis compared with gestational age-matched controls born to noninfected mothers.<sup>33</sup> **The clinical diagnosis is made when maternal fever** (temperature  $\geq 38^{\circ}\text{C}$  [ $100.4^{\circ}\text{F}$ ]) **with uterine tenderness and maternal or fetal tachycardia are identified in the absence of another evident source of infection. The maternal white blood cell (WBC) count can be helpful if clinical findings are equivocal.** An increase in the WBC count from a baseline level obtained on admission is suggestive of infection but may be artificially elevated if antenatal corticosteroids have been administered within 5 to 7 days. If additional confirmation of intrauterine infection is required, **amniocentesis may be helpful.**<sup>15,80</sup> A positive amniotic fluid culture is also supportive of a clinical suspicion of clinical chorioamnionitis (sensitivity, 65% to 85%; specificity, 85%), but the clinical diagnosis will likely become clear during the 48 hours needed to achieve a culture result. An **amniotic fluid glucose** concentration below 16 to 20 mg/dL (sensitivity and specificity, 80% to 90% for positive culture) or a **Gram stain positive for bacteria** are supportive of a clinically suspicious diagnosis of chorioamnionitis and can be rapidly obtained. However, the presence of WBCs only in amniotic fluid is not diagnostic of intrauterine infection after PROM. Elevated amniotic fluid interleukin levels have also been associated with an increased risk for early delivery and perinatal infectious morbidity, but cytokine analyses are not readily available in most clinical laboratories,<sup>80</sup> which limits their utility in clinical practice. **Once chorioamnionitis is diagnosed, broad-spectrum antibiotics should be initiated and delivery should be pursued.**

### Corticosteroid Administration

A single course of antenatal corticosteroids, either betamethasone (12 mg intramuscularly [IM] every 24 hr for two doses) or

dexamethasone (6 mg IM every 12 hours for four doses) before anticipated preterm birth has been shown to reduce the risks for RDS, IVH, NEC, perinatal death, and long-term neurologic morbidities. **Meta-analysis regarding antenatal corticosteroid administration after PPROM has confirmed steroid therapy to significantly reduce the risks for RDS (20% vs. 35.4%), IVH (7.5% vs. 15.9%), and NEC (0.8% vs. 4.6%) without increasing the risks for maternal (9.2% vs. 5.1%) or neonatal (7.0% vs. 6.6%) infection.**<sup>81</sup>

Repeated courses of antenatal corticosteroids after PPROM have been associated with increased newborn infection in some studies and have not been consistently associated with improvements in newborn outcomes.<sup>82</sup> Ghidini and colleagues<sup>83</sup> found less IVH and chorioamnionitis but no reduction in the risk for RDS with repeated antenatal corticosteroid doses. Alternatively, Abbasi and associates<sup>82</sup> observed a lower risk for RDS with more than one course of antenatal corticosteroids after PROM (34.9% vs. 45.2%). Given the potential risks and the lack of clear data supporting the benefit of repeated weekly antenatal corticosteroid administration, such treatment does not appear warranted. It remains to be determined whether a single repeat “rescue” course could benefit the woman who receives an initial course of antenatal corticosteroids after PROM near the limit of viability but then remains pregnant through 30 to 33 weeks’ gestation.

### Antibiotic Administration

The goal of antibiotic therapy during conservative management of PPROM remote from term is to treat or prevent ascending infection in order to prolong pregnancy and reduce perinatal infectious and gestational age–dependent morbidity. Meta-analyses have summarized a large number of randomized controlled clinical trials in this regard.<sup>84,85</sup> These evaluations suggest that **antibiotic treatment significantly prolongs latency after membrane rupture and reduces chorioamnionitis, and treatment also reduces the frequencies of newborn complications that include neonatal infection, the need for oxygen or surfactant therapy, and IVH.** Several published trials offer valuable insights regarding the potential role of adjunctive antibiotics in this setting. The National Institutes of Child Health and Human Development Maternal Fetal Medicine Units (NICHD-MFMU) Research Network studied women with PPROM remote from term (24 to 32 weeks, 0 days’ gestation).<sup>86,87</sup> Participants received 48 hours of broad-spectrum IV therapy (ampicillin 2 g every 6 hours and erythromycin 250 mg every 6 hours), followed by 5 days of oral (PO) therapy (amoxicillin 250 mg every 8 hours and enteric-coated erythromycin base 333 mg every 8 hours) or a matching placebo. GBS carriers in both study arms received ampicillin for 1 week and then again in labor. Antibiotic treatment doubled the likelihood of remaining undelivered after 7 days, and this benefit persisted up to 3 weeks after randomization, suggesting that antibiotics successfully treat, rather than just suppress, subclinical infection. Antibiotics improved neonatal health by reducing the number of babies with one or more major infant complications from 53% to 44% (composite morbidity: death, RDS, early sepsis, severe IVH, severe NEC;  $P < .05$ ) and also reduced individual newborn complications, including RDS (40.5% vs. 48.7%), stage 3 or 4 NEC (2.3% vs. 5.8%), patent ductus arteriosus (11.7% vs. 20.2%), and CLD (bronchopulmonary dysplasia: 20.5% vs. 13.0%;  $P < .05$  for each). Regarding individual infectious morbidities, antibiotics reduced the frequencies of

chorioamnionitis overall (32.5% vs. 23%), and also neonatal sepsis (8.4% vs. 15.6%) and pneumonia (2.9% vs. 7%), among those who were not GBS carriers ( $P \leq .04$  for each). In a second multicenter placebo-controlled trial, Kenyon and colleagues<sup>88</sup> studied oral therapy with erythromycin, amoxicillin–clavulanic acid, or both for up to 10 days after PPROM before 37 weeks’ gestation. In summary, erythromycin prolonged latency only briefly (not significant at 7 days) but did reduce the need for supplemental oxygen (31.1% vs. 35.6%) and the frequency of positive blood cultures (5.7% vs. 8.2%;  $P = .02$  for both). Amoxicillin–clavulanic acid prolonged pregnancy (43.3% vs. 36.7% undelivered at 7 days) and reduced the need for supplemental oxygen (30.1% vs. 35.6%) but increased the risk for NEC (1.9% vs. 0.5%;  $P \leq .05$  for each). Long-term follow-up of infants delivered within this trial revealed no evident differences between antibiotic and control groups.<sup>89</sup> Subsequent studies have attempted to determine whether the duration of antibiotic therapy could be shortened but are of inadequate size and power to evaluate infant outcomes adequately.

In summary, **there is a role for a 7-day course of parenteral and oral antibiotic therapy with erythromycin and amoxicillin-ampicillin during conservative management of PROM remote from term, to prolong latency and to reduce infectious and gestational age–dependent neonatal complications. Extended-spectrum ampicillin–clavulanic acid treatment is not recommended because it may be harmful.**

### Magnesium Sulfate for Neuroprotection

**Administration of magnesium sulfate before early PTB will improve long-term infant outcomes and is recommended for anticipated deliveries before 32 weeks’ gestation after PPROM** regardless of attempts at conservative management.<sup>90,91</sup> In a large multicenter trial that studied this issue, 92% of participants had PROM before 32 weeks’ gestation, and treatment was effective in preventing moderate/severe cerebral palsy (1.9% vs. 3.9%,  $P = .03$ ) and cerebral palsy overall (4.2% vs. 7.3%,  $P = .004$ ) by 2 years of age.<sup>91</sup> Magnesium sulfate was administered as a bolus of 6 g followed by an infusion of 2 g/hr for 12 hours if undelivered (or continued for imminent delivery). Retreatment was attempted for those initially undelivered and those who subsequently delivered before 34 weeks gestation.

### Tocolysis

Limited evidence suggests that prophylactic tocolysis, administered after PPROM and before the onset of contractions, can prolong pregnancy briefly.<sup>92</sup> However, therapeutic tocolysis initiated only after the onset of contractions has not been shown to prolong latency after PPROM. A report from the National Institutes of Health (NIH) collaborative study on antenatal steroids suggested an association between tocolytic treatment after PPROM and subsequent neonatal RDS, but subsequent small prospective studies have found neither an increase nor a decrease in neonatal complications with such tocolytic treatment.<sup>93</sup> Although it is plausible that tocolysis could facilitate initial uterine quiescence to allow additional time for antibiotic and corticosteroid benefits, no studies have been done of therapy with traditional tocolytic agents after PPROM in which concurrent antenatal corticosteroid and antibiotic treatments were given. Further, weekly progesterone treatment failed to prolong latency after PROM in a recent small, randomized controlled trial.<sup>94</sup> Pending further study, **tocolysis and progesterone**

therapy are not recommended during conservative management of PPROM.

### Cervical Cerclage

PPROM is a common complication after cervical cerclage placement, and it affects about one in four elective cerclages and half of emergent procedures.<sup>95</sup> Retrospective studies reveal that perinatal complications are similar to PROM without a cerclage if the stitch is removed on admission.<sup>96</sup> A single randomized controlled study of cerclage removal after PROM was discontinued when futility calculations determined that the power of the study would not be met. The investigation revealed no improvement in latency (56.3% vs. 45.8% delivered within 1 week,  $P = .59$ ) and no improvement in newborn outcomes with cerclage retention. Despite being 1.7-fold more common in the study population, cerclage retention was not significantly associated with more frequent chorioamnionitis (41.7% vs. 25%,  $P = .25$ ).<sup>97</sup> Retrospective studies that compared stitch removal and retention after PPROM have been small but have yielded consistent patterns.<sup>98,99</sup> Each has found insignificant trends toward increased maternal infections and only brief pregnancy prolongation; one study noted increased infant mortality and death due to sepsis when the cerclage was retained after PROM.<sup>98</sup> Because **no well-controlled study has found cerclage retention to improve newborn outcomes after PROM, early cerclage removal is recommended when PROM occurs.** The risks and benefits of short-term cerclage retention during antenatal corticosteroid are unknown.

### Herpes Simplex Virus

Neonatal HSV infection most commonly results from direct maternal-fetal transmission during delivery, with newborn infection rates of 34% to 80% after primary and 1% to 5% after secondary maternal infection.<sup>100</sup> When neonatal HSV infection occurs, the infant mortality rate is 50% to 60%, and up to 50% of survivors will suffer serious sequelae.<sup>101</sup> Based on small case series of women with an active maternal genital HSV infection by Gibbs and colleagues<sup>102</sup> ( $n = 9$ ) and Nahmias and colleagues ( $n = 26$ ), both in 1971, the accepted belief has been that extended latency after membrane rupture ( $>4$  to 6 hours) is associated with an increased risk for newborn infection. Major and coworkers<sup>103</sup> have reported on a case series of 29 gravidas managed expectantly with PROM before 32 weeks' gestation with active recurrent HSV lesions. Latency after membrane rupture ranged from 1 to 35 days, and cesarean delivery was performed if active lesions were present at the time of delivery. None of the infants delivered under this regimen developed neonatal herpes infection. **These data support conservative management of PROM complicated by recurrent maternal HSV infection when the likelihood of infant mortality and long-term complications with early delivery is high.** Prophylactic treatment with antiviral agents (e.g., acyclovir) to reduce viral shedding and the frequency of recurrences is prudent under this circumstance.

### Management of Previa Premature Rupture of the Membranes

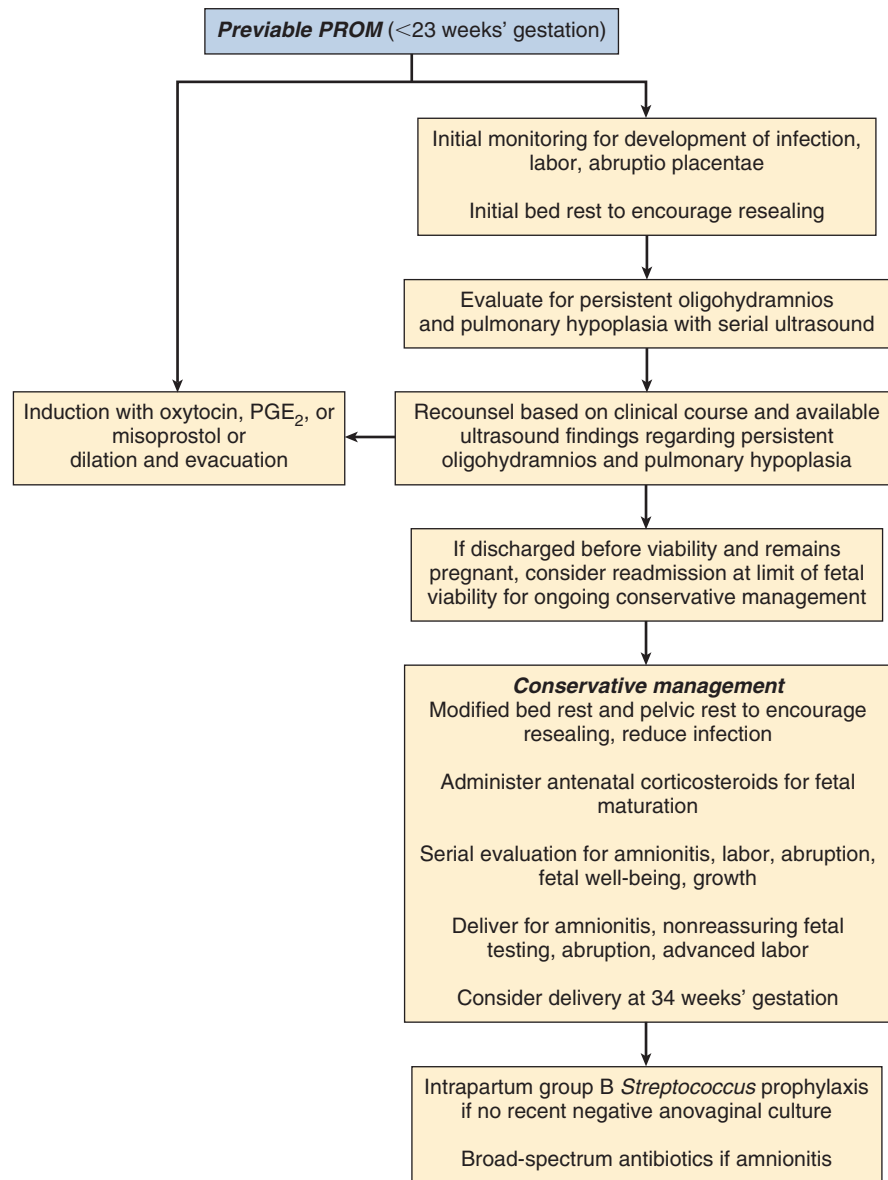

The cause of PROM before the limit of viability has implications for the anticipated pregnancy outcome and can be helpful in guiding counseling and management. Previa PROM subsequent to **second-trimester amniocentesis** is likely related to continued leakage of fluid through a small membrane

defect without concurrent infection. Under this circumstance it is likely that the membranes will reseat, and extended pregnancy can be anticipated. Alternatively, previable PROM subsequent to **second-trimester bleeding**, oligohydramnios, or an elevated maternal serum alpha-fetoprotein level more likely reflects an abnormality of placentation and has a poorer prognosis. The patient with previable PROM and no indication for immediate delivery should be counseled regarding the potential risks and benefits of conservative management. Counseling should include a realistic appraisal of fetal and neonatal outcomes and the risks for maternal complications.

Most available data regarding women with PPROM near the limit of viability are derived from retrospective studies. **In a review of PPROM that occurred at or before 24 weeks' gestation, Waters and Mercer<sup>36</sup> found median latency to range from 6 to 13 days.** Another recent evaluation found that 38% delivered within 1 week and 69% delivered within 5 weeks after previable PROM.<sup>104</sup> **Other maternal risks during conservative management of PROM at 24 weeks or less include chorioamnionitis (35%), abruptio placentae (19%), retained placenta (11%), and endometritis (14%).<sup>37</sup> Maternal sepsis (0.8%) and death (1 in 619 pregnancies overall) are rare but serious complications.** Conservative management can also lead to maternal muscle wasting, bone demineralization, and DVT due to prolonged bed rest. Overall, infant survival after conservatively managed previable PROM occurs in 44% of cases, but this varies with gestational age at membrane rupture (14.4% before 22 weeks vs. 57.7% at 22 to 24 weeks). Stillbirth is common and complicates up to 23% to 53% of cases. Neonatal complications include pulmonary hypoplasia (19%), RDS (66%), grade III or IV intraventricular hemorrhage (5%), sepsis (19%), and NEC (4%) as well as long-term complications such as bronchopulmonary dysplasia (29%), stage III retinopathy of prematurity (5%), and contractures (3%). Prediction of individual outcomes is difficult because of the inability to predict the ultimate gestational age at delivery in any given case.

A potential management scheme for PROM before the limit of viability is presented in [Figure 30-4](#). **Consensus has not yet been reached regarding the advantages of inpatient versus outpatient management for the patient who elects conservative management after previable PROM.** The benefits of an initial period of inpatient observation may include bed rest and pelvic rest to increase the opportunity for membrane resealing as well as early identification of infection, fetal demise, and abruptio. A number of novel treatments, including amnioinfusion and fibrin-platelet-cryoprecipitate or Gelfoam sealing of the membranes, have been preliminarily investigated.<sup>105-108</sup> The risks and benefits of these aggressive interventions have not been adequately studied to suggest that such therapy be incorporated into routine clinical practice. **Typically, women with previable PROM who have been managed as outpatients are readmitted to the hospital once the pregnancy reaches the limit of viability.** Administration of antenatal corticosteroids for fetal maturation is appropriate at the limit of viability because early delivery is still anticipated.

During conservative management, serial ultrasound studies performed every 1 to 2 weeks can evaluate for reaccumulation of amniotic fluid and interval pulmonary growth. Although persistent severe oligohydramnios is a strong marker for subsequent development of lethal pulmonary hypoplasia, serial fetal biometric evaluation (e.g., lung length,

**FIG 30-4** Management algorithm for previable premature rupture of the membranes (PROM) before the limit of potential viability (currently 23 weeks' gestation). PGE<sub>2</sub>, prostaglandin E<sub>2</sub>. (From Mercer BM. Preterm premature rupture of the membranes: diagnosis and management. *Clin Perinatol.* 2004;31:765.)

three-dimensional lung volume, chest circumference) and ratios that adjust for overall fetal size (thoracic-abdominal circumference, thoracic circumference–femur length) can demonstrate a lack of fetal pulmonary growth over time and have a high predictive value for lethal pulmonary hypoplasia.<sup>44,47,109,110</sup> Studies of pulmonary artery and ductus arteriosus waveform modulation with fetal breathing movements have shown some promise but can be technically difficult to perform.

Some women will choose to not undertake the potential risks for maternal complications after previable PROM either after initial counseling or with evidence of developing pulmonary hypoplasia. Delivery can be accomplished by labor induction with vaginal prostaglandin E<sub>2</sub>, prostaglandin E<sub>1</sub> (misoprostol), high-dose IV oxytocin, or dilation and evacuation. The optimal approach depends on patient characteristics (e.g., gestational age, evident chorioamnionitis, prior cesarean delivery), available facilities, and physician experience.

### SUMMARY

The potential for significant perinatal complications exists when PROM occurs at term or before term. Early delivery of the patient with PROM at or near term can reduce the risk for perinatal infections without increasing the likelihood of operative delivery. Careful conservative management of PROM remote from term offers the potential to reduce infectious and gestational age–dependent morbidities. Early transfer to a facility capable of providing urgent obstetric and neonatal intensive care is important should adequate facilities not be available locally. Regardless of the management approach, infants who deliver after PPROM and after PROM before the limit of potential viability are at high risk for perinatal complications, many of which cannot be avoided with current technology and management algorithms.

## KEY POINTS

- ◆ PROM complicates about 8% to 10% of pregnancies and is a significant cause of gestational age-dependent and infectious perinatal morbidity and mortality.
- ◆ Latency from membrane rupture to delivery is typically brief and decreases with increasing gestational age at membrane rupture.
- ◆ Chorioamnionitis is common after PPRM and increases in frequency with decreasing gestational age at membrane rupture.
- ◆ Women with a prior preterm birth due to PROM have a 3.3-fold higher risk for subsequent preterm birth due to PROM and a 13.5-fold higher risk for PPRM before 28 weeks' gestation.
- ◆ Some potentially preventable causes of PPRM include urogenital tract infections, poor maternal nutrition with a low body mass index ( $<19.8 \text{ kg/m}^2$ ), and cigarette smoking.
- ◆ Vaginally collected amniotic fluid can reliably predict the presence of fetal pulmonary maturity after PPRM.
- ◆ Conservative management after PPRM with documented fetal pulmonary maturity near term (32 to 36 weeks) prolongs latency only briefly but increases the risk for perinatal infection and does not improve neonatal outcomes.
- ◆ Antenatal corticosteroid administration and limited duration broad-spectrum antibiotic administration have been shown to reduce newborn complications when given in the setting of PROM remote from term.
- ◆ Cervical cerclage retention after PPRM has not been shown to improve neonatal outcomes.
- ◆ Lethal pulmonary hypoplasia is common after PROM that occurs before 20 weeks and can be predicted with serial ultrasound assessment of lung and chest growth.

Hypertensive disorders are among the most common medical complications of pregnancy; the reported incidence is between 5% and 10%,<sup>1,2</sup> although incidence varies among different hospitals, regions, and countries. These disorders are a major cause of maternal and perinatal mortality and morbidity worldwide.<sup>3</sup> The term *hypertension in pregnancy* is commonly used to describe a wide spectrum of patients who may have only mild elevations in blood pressure (BP) or severe hypertension with dysfunction of various organ systems. The clinical manifestations in these patients may be similar (e.g., hypertension, proteinuria); however, they may result from different underlying causes such as chronic hypertension, renal disease, or pure preeclampsia (PE). The three most common forms of hypertension that complicate pregnancy are (1) gestational hypertension, (2) preeclampsia, and (3) chronic essential hypertension.

## DEFINITIONS

### Gestational Hypertension

Hypertension may be present before pregnancy, or it may be diagnosed for the first time during pregnancy. In addition, in some women, hypertension may become evident only during labor or during the postpartum period. For clinical purposes, women with hypertension may be classified into one of the three categories listed above; these are described further in [Table 31-1](#).<sup>1,2</sup> Recently, the diagnosis of PE and its subtypes have been expanded and revised by the members of the American College of Obstetricians and Gynecologists (ACOG) Task Force on Hypertension in Pregnancy<sup>1</sup>:

- Systolic BP greater than 140 mm Hg but less than 160 mm Hg *or*
- Diastolic BP greater than 90 mm Hg but less than 110 mm Hg *and*
- These pressures must be observed on at least two occasions 4 hours apart but no more than 7 days apart.<sup>4</sup>

### Severe Hypertension

*Severe hypertension* refers to sustained elevations in systolic BP to at least 160 mm Hg and/or in diastolic BP to at least 110 mm Hg for at least 4 hours or once if the patient is receiving

oral antihypertensive agents or received intravenous (IV) antihypertensive medications prior to the 4-hour period.

### Proteinuria

Proteinuria may also be present before pregnancy, or it may be newly diagnosed during pregnancy. The definition of proteinuria is the same no matter when it occurs:

- Greater than 0.3 g in a 24-hour urine collection or protein/creatinine (P/C) ratio greater than 0.3. If it is not possible to measure 24-hour protein or P/C ratio, *proteinuria* can be defined as a dipstick measurement of at least 1+ on two occasions.
- Protein excretion in the urine increases in normal pregnancy from approximately 5 mg/dL in the first and second trimesters to 15 mg/dL in the third trimester. These low levels are not detected by dipstick. The concentration of urinary protein is influenced by contamination with vaginal secretions, blood, bacteria, or amniotic fluid. It also varies with urine specific gravity and pH, exercise, and posture.
- Proteinuria usually appears after hypertension in the course of the disease process, but in some women, it may appear before hypertension.

### Edema

*Edema* is defined as excessive weight gain (>4 lb [1.8 kg] in 1 week) in the second or third trimester, and it may be the first sign of the potential development of PE. However, 39% of patients with eclampsia do not have edema.

### Preeclampsia and Eclampsia

**Preeclampsia is gestational hypertension (GH) plus proteinuria.** [Box 31-1](#) lists criteria for diagnosis of GH and PE. The ACOG Task Force on Hypertension in Pregnancy Group classifies PE based on whether it has severe features. The term *mild preeclampsia* has been removed from the ACOG classification system and should not be used in clinical practice.

**It is recognized that some women with GH may have undiagnosed chronic hypertension, whereas others will subsequently progress to develop the clinical syndrome of preeclampsia.**<sup>5</sup> In general, the likelihood of progression to PE

**TABLE 31-1** HYPERTENSIVE DISORDERS OF PREGNANCY

| CLINICAL FINDINGS             | CHRONIC HYPERTENSION | GESTATIONAL HYPERTENSION* | PREECLAMPSIA               |
|-------------------------------|----------------------|---------------------------|----------------------------|
| Time of onset of hypertension | <20 wk               | >20 wk                    | Usually in third trimester |
| Degree of hypertension        | Mild or severe       | Mild                      | Mild or severe             |
| Proteinuria*                  | Absent               | Absent                    | Usually present            |
| Cerebral symptoms             | May be present       | Absent                    | Present in 30%             |
| Hemoconcentration             | Absent               | Absent                    | Severe disease             |
| Thrombocytopenia              | Absent               | Absent                    | Severe disease             |
| Hepatic dysfunction           | Absent               | Absent                    | Severe disease             |

\*Defined as 1+ or more (or protein/creatinine ratio >0.30) by dipstick testing on two occasions or 300 mg or more in a 24-hour urine collection or protein.

**BOX 31-1 CRITERIA FOR MILD GESTATIONAL HYPERTENSION IN HEALTHY PREGNANT WOMEN**

- Systolic blood pressure  $>140$  mm Hg but  $<160$  mm Hg and diastolic blood pressure  $>90$  mm Hg but  $<110$  mm Hg
- Proteinuria of  $<300$  mg per 24-hr collection
- Platelet count of  $>100,000/\text{mm}^3$
- Normal liver enzymes
- Absent maternal symptoms
- Absent intrauterine growth restriction and oligohydramnios by ultrasound

**FIG 31-1** Rate of progression from gestational hypertension to preeclampsia by gestational age at diagnosis. (Data from references 5, 6, 7, and 8.)

depends on gestational age at time of diagnosis, with higher rates if the onset of hypertension is before 35 weeks' gestation (Fig. 31-1).<sup>5-8</sup>

**Criteria for Preeclampsia or Gestational Hypertension With Severe Features**

*Preeclampsia*, or *gestational hypertension with severe features*, is defined when either disorder is present in association with any of the following abnormalities:

- Systolic BP greater than 160 mm Hg or diastolic BP greater than 110 mm Hg on two occasions at least 4 hours apart while the patient is on bed rest or once if the patient has received prior antihypertensive therapy. Prompt treatment is recommended for severe BP values that are sustained for longer than 30 minutes.
- New-onset persistent cerebral symptoms (headaches) or visual disturbances
- Impaired liver function as indicated by abnormally elevated liver enzymes (at least twice the upper limit of normal [ULN]); severe, persistent right upper quadrant or epigastric pain that is unresponsive to medications and not accounted for by an alternative diagnosis; or both
- Pulmonary edema
- Thrombocytopenia (platelet count  $<100,000/\mu\text{L}$ )
- Progressive renal insufficiency (serum creatinine  $>1.1$  mg/dL)

It is important to note that the amount of proteinuria, presence of oliguria, and presence of intrauterine growth restriction (IUGR) or fetal growth restriction (FGR) by ultrasound have been removed as criteria for the diagnosis of severe disease.

**TABLE 31-2** RECOMMENDED CRITERIA TO DIAGNOSE PREECLAMPSIA IN WOMEN WITH PREEXISTING MEDICAL CONDITIONS

| CONDITION   | CRITERIA NEEDED  |
|---|--|
| Hypertension only   | Proteinuria of $\geq 300$ mg per 24 hr or thrombocytopenia   |
| Hypertension plus proteinuria (renal disease or class F diabetes) | Worsening severe hypertension plus proteinuria and either new onset of symptoms, thrombocytopenia, or elevated liver enzymes |

*Eclampsia* is defined as the occurrence of seizures after the second half of pregnancy not attributable to other causes.<sup>9</sup>

**Chronic Hypertension**

*Chronic hypertension* is defined as hypertension present prior to pregnancy or that is diagnosed before 20 weeks of gestation. Hypertension that persists for more than 3 months postpartum is also classified as chronic hypertension.<sup>2,3</sup>

**Chronic Hypertension With Superimposed Preeclampsia**

Women with chronic hypertension may develop superimposed preeclampsia, which increases morbidity for both the mother and fetus. The diagnosis of superimposed PE is based on one or both of the following findings: development of *new-onset proteinuria*, defined as the urinary excretion of 0.3 g or more of protein in a 24-hour specimen or a P/C ratio greater than 0.3 in women with hypertension and no proteinuria before 20 weeks' gestation; *or*, in women with hypertension and proteinuria before 20 weeks, severe exacerbation in hypertension plus development of symptoms *or* thrombocytopenia and abnormal liver enzymes (Table 31-2).<sup>1,10,11</sup>

The ACOG Task Force report on hypertension in pregnancy recommended that **superimposed preeclampsia** be stratified into two groups to guide management: (1) *superimposed preeclampsia*, defined as a sudden increase in blood pressure that was previously well controlled or escalation of antihypertensive medications to control BP, or (2) *new-onset proteinuria* ( $>300$  mg/24-hour collection or a P/C ratio  $>0.3$ ), or a sudden and sustained increase in proteinuria in a woman with known proteinuria before conception or early in pregnancy.

A diagnosis of **superimposed preeclampsia with severe features** should be made in the presence of any of the following: (1) severe-range BP ( $>160$  mm Hg systolic or  $>110$  mm Hg diastolic) despite escalation of antihypertensive therapy; (2) persistent cerebral symptoms such as headaches or visual disturbances; (3) significant increase in liver enzymes (at least two times the ULN concentration for a particular laboratory); (4) thrombocytopenia (platelet count  $<100,000/\mu\text{L}$ ); or (5) new-onset and/or worsening renal insufficiency.

**Gestational Hypertension**

**Gestational hypertension is the most frequent cause of hypertension during pregnancy.** The incidence ranges between 6% and 29% in nulliparous women<sup>2,4,12</sup> and between 2% and 4% in multiparous women.<sup>2</sup> The incidence is markedly increased in patients with multiple gestations.<sup>13-15</sup> In general, most cases of GH develop at or beyond 37 weeks' gestation, and thus the overall pregnancy outcome is usually similar to that seen in women with normotensive pregnancies (Table 31-3).<sup>4,5,12</sup>

FIG 31-2 Maternal manifestations in preeclampsia. CNS, central nervous system; DIC, disseminated intravascular coagulation; HELLP, hemolysis, elevated liver enzymes, and low platelets.

However, women with mild GH have higher rates of induction of labor.<sup>4</sup>

Maternal and perinatal morbidities are substantially increased in women with severe GH.<sup>2,4</sup> Indeed, these women have increased risk for morbidity compared with women with mild PE. The rates of abruptio placentae, preterm delivery (at <37 and 35 weeks), and small-for-gestational-age (SGA) infants in these women are similar to those seen in women with PE and severe features.<sup>2,16</sup> It remains unclear whether this increase in preterm delivery is secondary to scheduled early delivery according to physician preference or whether it occurs because of a disease process.

## PREECLAMPSIA

Preeclampsia is a form of hypertension that is unique to human pregnancy. The clinical findings of PE can manifest as either a maternal syndrome (Fig. 31-2) or a fetal syndrome (Fig. 31-3).<sup>17-19</sup> In practice, the maternal syndrome of PE represents a clinical spectrum with major differences between near-term PE without demonstrable fetal effects and PE that is associated with low birthweight and preterm delivery.<sup>17,20</sup> PE is clearly a heterogeneous condition for which the pathogenesis may be different in women with various risk factors.<sup>17,20,21</sup> The pathogenesis of PE in nulliparous women may be different than that in women with preexisting vascular disease, multifetal gestations, diabetes mellitus, or previous PE. In addition, the

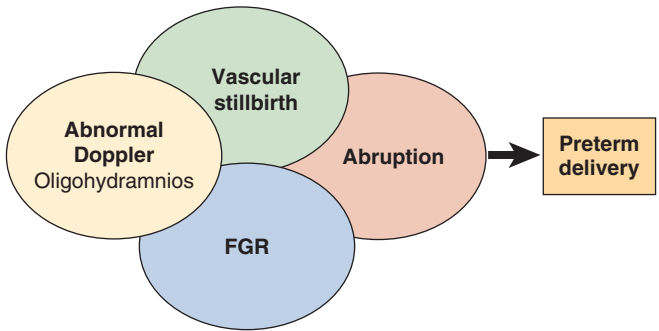

FIG 31-3 Fetal manifestations of preeclampsia. FGR, fetal growth restriction.

pathophysiology of early-onset PE may be different than that of PE that develops at term, during labor, or in the postpartum period.<sup>17,20,21</sup>

The incidence of preeclampsia ranges between 2% and 7% in healthy nulliparous women.<sup>2,4,12</sup> In these women, PE is generally mild, with the onset near term or during labor (75% of cases), and the condition conveys only a minimally increased risk for adverse fetal outcome.<sup>2,4,12</sup> In contrast, the incidence and severity of PE are substantially higher in women with multifetal gestation,<sup>10,13,15,22</sup> chronic hypertension,<sup>10,11</sup> previous PE,<sup>23-28</sup> pregestational diabetes mellitus,<sup>10,29,30</sup> or preexisting thrombophilias.<sup>31</sup>

## Atypical Preeclampsia

The criteria for atypical preeclampsia include gestational proteinuria or FGR plus one or more of the following symptoms of preeclampsia: hemolysis, thrombocytopenia, elevated liver enzymes, early signs and symptoms of preeclampsia-eclampsia earlier than 20 weeks, and late postpartum preeclampsia-eclampsia (>48 hours postpartum).

### Capillary Leak Syndrome: Facial Edema, Ascites and Pulmonary Edema, and Gestational Proteinuria

Hypertension is considered to be the hallmark for the diagnosis of preeclampsia. However, in some patients with PE, the disease may manifest as either a capillary leak (proteinuria, facial and vulvar edema, ascites, pulmonary edema); excessive weight gain, particularly during the second and early third trimester; or a spectrum of abnormal hemostasis with multiple-organ dysfunction. These women usually present

**FIG 31-4** Vulvar edema in severe preeclampsia.

with clinical manifestations of atypical preeclampsia, such as proteinuria with or without facial edema, vulvar edema (Fig. 31-4), excessive weight gain (>4 lb/wk), ascites, or pulmonary edema in association with abnormalities in laboratory values or presence of symptoms but without hypertension.<sup>32</sup> Therefore we recommend that women with capillary leak syndrome with or without hypertension be evaluated for platelet, liver enzyme, and renal abnormalities. Those with symptoms such as new onset of unrelenting severe headache, severe visual disturbances, or abnormal blood tests should be considered to have PE.<sup>32</sup>

### Gestational Proteinuria

It is generally agreed that urine dipstick protein measurements should be performed at each prenatal visit after 20 weeks' gestation. *Gestational proteinuria* is defined as urinary protein excretion of at least 300 mg per 24-hour timed collection, P/C ratio greater than 0.3, or persistent proteinuria ( $\geq 1+$  on dipstick on at least two occasions at least 4 hr apart).<sup>1,3</sup> In addition, new-onset proteinuria greater than 2+ on one occasion is strongly associated with proteinuria of greater than 300 mg in 24 hours. The exact incidence of gestational proteinuria progressing to preeclampsia is unknown; however, isolated gestational proteinuria was identified in 4% of women enrolled in two multicenter trials.<sup>33,34</sup> In addition, these studies reported that 4.3% to 7% of patients had combined GH and gestational proteinuria. Thus it appears that at least one third of women with gestational proteinuria may progress to PE.<sup>33,34</sup> Indeed, some authors have suggested that gestational proteinuria alone may herald the early manifestations of impending preeclampsia.<sup>33,35</sup> **In the absence of other pathology, the patient should be treated as having potential PE and requires evaluation for the presence of symptoms; evaluation should include blood tests and frequent monitoring of BP (at least twice per week or, alternatively, ambulatory home BP measurements), and the patient should be educated about the signs and symptoms of PE. In addition, women in whom convulsions develop in association with hypertension and proteinuria during the first half of pregnancy should be considered to have eclampsia until proven otherwise. These women should undergo ultrasound**

### BOX 31-2 RISK FACTORS FOR PREECLAMPSIA

- Nulliparity
- Age >40 years
- Pregnancy with assisted reproduction
- Interpregnancy interval >7 years
- Family history of preeclampsia
- Woman born small for gestational age
- Obesity/gestational diabetes mellitus
- Multifetal gestation
- Preeclampsia in previous pregnancy
- Poor outcome in previous pregnancy
- Fetal growth restriction, placental abruption, fetal death
- Preexisting medical-genetic conditions
- Chronic hypertension
- Renal disease
- Type 1 (insulin-dependent) diabetes mellitus
- Antiphospholipid antibody syndrome
- Factor V Leiden mutation

**examination of the uterus to rule out molar pregnancy or hydropic/cystic degeneration of the placenta.** Measurement of uterine artery Doppler flow, which shows the classic “notching” characteristic of increased resistance in the placenta of patients with PE, is also recommended.<sup>32</sup>

### Risk Factors for Preeclampsia

Several factors have been identified with increased risk for preeclampsia (Box 31-2). **Generally, PE is considered a disease of primigravid women.** The risk increases in those who have limited sperm exposure with the same partner before conception.<sup>17,20,36</sup> The protective effects of long-term sperm exposure with the same partner might provide an explanation for the high risk for PE in women younger than 20 years old. A previous abortion (spontaneous or induced) or a previous normal pregnancy with the same partner is associated with a lower risk for PE. However, this protective effect is lost with a change of partner or with prolonged interval between pregnancies.<sup>37</sup>

Both Scandinavian and U.S. studies have confirmed the importance of paternal factors as a contributor to PE as well as an interpregnancy interval greater than 7 years.<sup>38,39</sup> Using whole population data, Lie and colleagues<sup>39</sup> demonstrated that men who fathered one preeclamptic pregnancy were nearly twice as likely to father a preeclamptic pregnancy with a different woman (odds ratio [OR], 1.8; 95% confidence interval [CI], 1.2 to 2.6 after adjustment for parity), regardless of whether the new partner had a history of a preeclamptic pregnancy. Thus mothers had a substantially increased risk in their second pregnancy (2.9%) if their partner had fathered a preeclamptic first pregnancy with another woman. This risk was nearly as high as the average risk among primigravid women.<sup>39</sup>

Recent advances in assisted reproductive technology (ART) have been associated with an increased risk for preeclampsia.<sup>14,15,40</sup> Among the factors cited are a greater proportion of women older than 40 years, infertile women during their first gestation, multifetal gestation, obese women with polycystic ovary syndrome (PCOS), and women who become pregnant with donated gametes or embryos.<sup>40</sup> The use of donated gametes can influence the maternal-fetal immune interaction. In addition, infertile women with recurrent miscarriage are also reported to be at increased risk for PE.<sup>41</sup>

Obesity reflected as increased body mass index (BMI) heightens the risk for preeclampsia.<sup>42</sup> The worldwide increase in obesity

### BOX 31-3 THEORIES ASSOCIATED WITH THE ETIOLOGY OF PREECLAMPSIA

- Abnormal trophoblast invasion or poor implantation
- Imbalance in angiogenesis
- Coagulation abnormalities
- Vascular endothelial damage
- Cardiovascular maladaptation
- Immunologic maladaptation
- Genetic predisposition
- Exaggerated inflammatory response
- Increased oxidative stress

is thus likely to lead to a rise in the frequency of PE.<sup>43,44</sup> Obesity has a strong link to insulin resistance, which is also a risk factor for PE. The exact mechanism by which obesity or insulin resistance is associated with PE is not well understood.

Earlier studies found an overall higher rate of thrombophilia in women with PE compared with controls.<sup>31</sup> Recently, a number of reports have failed to reproduce these findings.<sup>45-46</sup> The disparity in results may reflect the heterogeneity of the women being studied. In the largest series of preeclamptic women with thrombophilia, women had increasing risk for very early onset, severe disease (delivery before 28 weeks) compared with those who did not have thrombophilia.<sup>31</sup>

### Pathophysiology

The etiology of preeclampsia remains unknown. Many theories have been suggested, but most of them have not withstood the test of time. Some of the theories still under consideration are listed in [Box 31-3](#).<sup>17, 47-50</sup>

During normal pregnancy, impressive physiologic changes occur in the uteroplacental vasculature and in the cardiovascular system. These changes are most likely induced by the interaction of the fetal (parental) allograft with maternal tissue. The development of mutual immunologic tolerance in the first trimester is thought to lead to important morphologic and biochemical changes in the systemic and uteroplacental maternal circulation.

### Uterine Vascular Changes

**The human placenta receives its blood supply from numerous uteroplacental arteries that are developed by the action of migratory interstitial and endovascular trophoblasts into the walls of the spiral arterioles. This transforms the uteroplacental arterial bed into a low-resistance, low-pressure, high-flow system.** The conversion of the spiral arterioles of the nonpregnant uterus into the uteroplacental arteries has been termed *physiologic changes*.<sup>50,51</sup> In a normal pregnancy, these trophoblast-induced vascular changes extend all the way from the intervillous space to the origin of the spiral arterioles that represent the radial arteries in the inner one third of the myometrium. **It is suggested that these vascular changes are effected in two stages, “the conversion of the decidual segments of the spiral arterioles by a wave of endovascular trophoblast migration in the first trimester and the myometrial segments by a subsequent wave in the second trimester.”**<sup>52,53</sup> **This process is reportedly associated with extensive fibrinoid formation and degeneration of the muscular layer in the arterial wall.** These vascular changes result in the conversion of about 100 to 150 spiral arterioles into distended, tortuous, and

funnel-shaped vessels that communicate through multiple openings into the intervillous space.

In contrast, pregnancies complicated by preeclampsia or by FGR demonstrate inadequate maternal vascular response to placentation. In these pregnancies, the previously mentioned vascular changes are usually found only in the decidual segments of the uteroplacental arteries. Hence the myometrial segments of the spiral arterioles continue to exhibit their characteristic musculoelastic architecture, thereby leaving them responsive to hormonal influences.<sup>50,52</sup> Additionally, the number of well-developed arterioles is smaller than that found in normotensive pregnancies.

**It has been postulated that this defective vascular response to placentation is due to inhibition of the second wave of endovascular trophoblast migration that normally occurs from about 16 weeks’ gestation onward. These pathologic changes may have the effect of curtailing the increased blood supply required by the fetoplacental unit in the later stages of pregnancy and may correlate with the decreased uteroplacental blood flow seen in most cases of preeclampsia.**<sup>50</sup> Frusca and associates<sup>52</sup> studied placental bed biopsy specimens obtained during cesarean delivery from normal pregnancies ( $n = 14$ ), preeclamptic pregnancies ( $n = 24$ ), and chronic hypertensive pregnancies only ( $n = 5$ ). Biopsy specimens from the preeclamptic group demonstrated abnormal vascular changes in every case, and 18 had acute atherosclerotic changes. In contrast, 13 of the 14 specimens from normotensive pregnancies had normal vascular physiologic changes. In addition, they found that the mean birthweight was significantly lower in the group with atherosclerosis than it was in the other group without such findings. It is important to note that these vascular changes may also be demonstrated in a significant proportion of normotensive pregnancies complicated by FGR. Meekins and associates<sup>53</sup> demonstrated that endovascular trophoblast invasion is not an all-or-none phenomenon in normal and preeclamptic pregnancies. These authors observed that morphologic features found in one spiral artery may not be representative of all vessels in a placental bed.

### Vascular Endothelial Activation and Inflammation

The mechanism by which placental ischemia leads to the clinical syndrome of PE is thought to be related to the production of placental factors that enter the maternal circulation and result in endothelial cell dysfunction.<sup>47-49,54</sup> **Soluble fms-like tyrosine kinase 1 (sFlt-1) is a protein produced by the placenta. It acts by binding to the receptor-binding domains of vascular endothelial growth factor (VEGF), and it also binds to placental-like growth factor (PLGF). Increased levels of this protein in the maternal circulation results in reduced levels of free VEGF and free PLGF with resultant endothelial cell dysfunction.**<sup>54</sup>

**Maternal serum and placental levels of sFlt-1 are increased in pregnancies complicated by preeclampsia values above seen during normal pregnancies.** Maynard and coworkers<sup>55</sup> demonstrated that soluble placenta-derived VEGF receptor (sFlt-1)—an antagonist of VEGF and PLGF—is unregulated in PE, which leads to increased systemic levels of sFlt-1 that fall after delivery. Increased circulating sFlt-1 in PE is associated with decreased circulating levels of free VEGF and PLGF and results in endothelial dysfunction. The magnitude of increase in sFlt levels correlates with disease severity,<sup>56</sup> which lends further

support to VEGF–soluble Flt balance and represents one of the final common pathophysiologic pathways.

First-trimester PLGF levels are decreased in future preeclamptic pregnancies and in pregnancies complicated by FGR, whereas sFlt levels do not differ from controls.<sup>57</sup> Again, these data are compatible with decidual angiogenic growth factors, in particular PLGF, as being essential for early placental development (PLGF is low in both FGR and preeclampsia), with a later involvement of sFlt as a fetal rescue signal steering the maternal response; that is, the degree of maternal systemic hypertension. This hypothesis is supported by Levine and colleagues,<sup>56</sup> who demonstrated that during the last 2 months of pregnancy in normotensive controls, the level of sFlt-1 increased and the level of PLGF decreased.

Levine and associates<sup>58</sup> investigated urinary PLGF levels in pregnant women with and without PE and found that among normotensive pregnant women, urinary PLGF increased during the first two trimesters, peaked at 29 to 32 weeks, and decreased thereafter. Among women who ultimately developed PE, the pattern of urinary PLGF was similar, but levels were significantly reduced beginning at 25 to 28 weeks. Particularly large differences were seen among those who subsequently developed early-onset PE and in those who delivered SGA infants.<sup>58</sup> A similar study suggested that urinary angiogenic factors can identify women with severe PE.<sup>59</sup>

During the past decade, our understanding of the molecular basis for the pathophysiologic abnormalities in preeclampsia has reached an unprecedented level. Clear appreciation now exists for the role of cell adhesion molecules (CAMs) and angiogenic proteins and for activation of the inflammatory system in the pathogenesis of microvascular dysfunction in women with PE.<sup>47,48,56</sup> Evidence also suggests an exaggerated inflammatory response (abnormal cytokine production and neutrophil activation) in women with the clinical findings of PE.<sup>49</sup> However, this enhanced inflammatory response is absent before the development of PE.<sup>60</sup>

Recent studies that have confirmed increased levels of asymmetric dimethylarginine at 23 to 25 weeks in pregnant women who develop PE have emphasized the importance of the nitric oxide–cyclic guanosine monophosphate (cGMP) pathway.<sup>61,62</sup> Endothelial dysfunction and inappropriate endothelial cell activation associated with alterations in nitric oxide levels in PE explains most typical clinical manifestations, including the increased endothelial cell permeability and increased platelet aggregation.<sup>63</sup>

### Genetics and Genetic Imprinting

According to the genetic conflict theory, fetal genes are selected to increase the transfer of nutrients to the fetus, whereas maternal genes are selected to limit transfer in excess of some optimal level.<sup>17,20</sup> The phenomenon of genomic imprinting means that a similar conflict exists within fetal cells between genes that are maternally derived and those that are paternally derived. The conflict hypothesis suggests that placental factors (fetal genes) act to *increase* maternal BP, whereas maternal factors act to *reduce* BP.<sup>20</sup> Endothelial cell dysfunction may have evolved as a fetal rescue strategy to increase nonplacental resistance when the uteroplacental blood supply is inadequate.

Nilsson and associates<sup>64</sup> published a model that suggests a heritability estimate of 31% for PE and 20% for GH. It is unlikely that one major PE gene will be found because such a gene would be selected against through evolution, unless it also

carried a major reproductive advantage. It is more likely that a rapidly growing number of susceptibility genes will be uncovered and that many of these will be found to interact with the maternal cardiovascular-hemostatic system or in the regulation of maternal inflammatory responses.<sup>65</sup> These loci segregate with different populations,<sup>66</sup> and it should be noted that these loci only explain a relatively small percentage of the overall cases of PE. In addition, although these linkage studies indicate maternal susceptibility, they do not exclude the additional involvement of fetal genes.<sup>66</sup> **Another important consideration regarding the genetics of PE is the confounding effect of the so-called fetal origins of adult disease hypothesis, which suggests that a hostile intrauterine environment for a female fetus would form the basis for the insulin resistance syndrome with its associated endothelial dysfunction and, as such, that it would lead to an increased risk for PE (see Chapter 5).**<sup>20</sup>

Epigenetic features and imprinting are also involved in the pathogenesis of PE.<sup>66,67</sup> Further evidence of the role of imprinting was recently suggested by Oudejans and van Dijk<sup>66</sup> and Nafee and associates.<sup>67</sup>

### Changes in Prostanoids

Several investigators have described levels of the various prostaglandins and their metabolites throughout pregnancy. They have measured the concentrations of these substances in plasma, serum, amniotic fluid, placental tissues, urine, and cord blood. The data have been inconsistent, which reflects differences in methodology.<sup>68,69</sup> During pregnancy, prostanoid production increases in both maternal and fetoplacental tissues. Prostacyclin is produced by the vascular endothelium and in the renal cortex. It is a potent vasodilator and inhibitor of platelet aggregation. Thromboxane A<sub>2</sub> (TXA<sub>2</sub>) is produced by the platelets and trophoblasts; it is a potent vasoconstrictor and platelet aggregator. Hence, these eicosanoids have opposite effects and play a major role in regulating vascular tone and vascular blood flow. **An imbalance in prostanoid production or catabolism has been suggested as being responsible for the pathophysiologic changes in preeclampsia.** However, the precise role by which prostaglandins are involved in the etiology of PE remains unclear.<sup>20</sup>

### Lipid Peroxide, Free Radicals, and Antioxidants

Evidence is accumulating that lipid peroxides and free radicals may be important in the pathogenesis of preeclampsia.<sup>40,50,70</sup> Superoxide ions may be cytotoxic to the cell by changing the characteristics of the cellular membrane and producing membrane lipid peroxidation. Elevated plasma concentrations of free radical oxidation products precede the development of PE. In addition, some studies reported lower serum antioxidant activity in patients with PE than in those with normotensive pregnancies.<sup>17,20</sup>

Much of the controversy about oxidative stress is related to the nonspecificity of the markers. A recent study by Moretti and associates<sup>71</sup> measured oxidative stress “on line” in exhaled breath (not subjective to in vitro artifacts) and confirmed greater oxidative stress in women with PE compared with nonpregnant controls and those who had uncomplicated pregnancies.

### Diagnosis of Preeclampsia

**Preeclampsia is a clinical syndrome that embraces a wide spectrum of signs and symptoms that have been clinically**

**observed to develop alone or in combination. Elevated BP is the traditional hallmark for diagnosis of the disease.** The diagnosis of PE and the severity of the disease process are generally based on maternal BP. Many factors may influence the measurement of BP, including the accuracy of the equipment used, the size of the sphygmomanometer cuff, duration of the rest period before recording, posture of the patient, and the Korotkoff phase used (phase IV or phase V for diastolic BP measurement). **It is recommended that all BP values be recorded with the woman in a sitting position for ambulatory patients or in a semireclining position for hospitalized patients.**<sup>2,3,18,19</sup> The right arm should be used consistently, and the arm should be in a roughly horizontal position at heart level. For diastolic BP measurements, both phases—muffling sound and disappearance sound—should be recorded. This is very important because the level measured at phase IV is about 5 to 10 mm Hg higher than that measured at phase V. A rise in BP has been used by several authors as a criterion for the diagnosis of hypertension in pregnancy. This definition is usually unreliable because a gradual increase in BP from the second to third trimester is seen in most normotensive pregnancies. Villar and Sibai<sup>72</sup> prospectively studied BP changes during the course of pregnancy in 700 young primigravidas and found that 137 patients (19.6%) had PE. The sensitivity and positive predictive values for PE of a threshold increase in diastolic BP of at least 15 mm Hg on two occasions were 39% and 32%, respectively. The respective values for a threshold increase in systolic pressures were 22% and 33%.

Three recent studies from New Zealand,<sup>73</sup> the United States,<sup>74</sup> and Turkey<sup>75</sup> investigated pregnancy outcomes in women with a rise in diastolic BP of more than 15 mm Hg but an absolute diastolic level below 90 mm Hg compared with gravidas who remained normotensive. The New Zealand report<sup>73</sup> and a Turkish study<sup>75</sup> included women with elevated BPs without proteinuria, whereas the American investigation<sup>74</sup> included women with an increased diastolic pressure by 15 mm Hg or more plus proteinuria ( $\geq 300$  mg/24 hours). Overall, pregnancy outcomes were similar among women who remained normotensive and those who demonstrated a rise in diastolic pressure of 15 mm Hg or higher but did not reach 90 mm Hg. The use of a specific rise in BP over baseline as a diagnostic criterion is principally influenced by two factors: gestational age at time of first observation and frequency of BP measurements. Thus a 15 mm Hg rise in diastolic BP is unreliable to diagnose PE.

### Prediction of Preeclampsia

A review of the world literature reveals that more than 100 clinical, biophysical, and biochemical tests have been recommended to predict or identify the patient at risk for future development of preeclampsia.<sup>76-84</sup> **The results of the pooled data for the various tests and the lack of agreement among serial tests suggest that none of these clinical tests is sufficiently reliable for use as a screening test in clinical practice.**<sup>28</sup>

Numerous biochemical markers have been proposed to predict which women are destined to develop PE. These biochemical markers were generally chosen on the basis of specific pathophysiologic abnormalities that have been reported in association with PE. Thus these markers have included markers of placental dysfunction, endothelial and coagulation activation, angiogenesis, and markers of systemic inflammation. However, the results of various studies to evaluate the reliability of these markers in predicting PE have been inconsistent, and many of

these markers suffer from poor specificity and predictive values that are too low for routine use in clinical practice.<sup>80-88</sup>

**During the past decade, several prospective and nested case-control studies have found that certain maternal risk factors, biophysical clinical factors, and serum biomarkers obtained in the first trimester are associated with subsequent development of hypertensive disorders of pregnancy (HDP), GH, or PE.**<sup>79-83,89,90</sup> These studies evaluated the use of these factors or markers alone or in combination, and they provided detection rates for various subtypes of hypertension and PE with a false-positive rate (FPR) of either 5% or 10%. Overall, neither the maternal factors nor the serum biomarkers, either alone or combined, had an adequate detection rate for either all HDPs or GH or PE developing at 37 weeks of gestation or later. In the same studies, using maternal factors and mean arterial pressure (MAP) in the first trimester, the detection rate for PE before 34 weeks was 73%, and for PE before 37 weeks, it was 60% with an FPR of 10%. Using data from the Maternal-Fetal Medicine Foundation, the use of combined maternal factors and biophysical and biochemical markers increased the detection rate to 95% for PE that required delivery before 34 weeks of gestation and 77% for PE that required delivery at before 37 weeks of gestation with an FPR of 10%.<sup>90</sup> However, the positive predictive value (PPV) for such a screen remained less than 10%. In addition, these studies were conducted in a heterogeneous group of women at various risks for HDP and PE. A recent study by Giguère and colleagues<sup>91</sup> evaluated combined maternal factors and serum markers measured in the first trimester in 7929 women who were at very low risk for GH (2.7%) and PE (1.8%). In those with PE, the incidence was 0.2% at less than 34 weeks and 1.2% at less than 37 weeks of gestation. They found that a clinical model that included maternal risk factors, BMI, and MAP had a detection rate of 54% and a PPV of 3% with an FPR of 10% for preeclampsia at less than 37 weeks of gestation, whereas a full model that also included serum biomarkers had a detection rate of 39% and a PPV of 2% for PE at less than 37 weeks of gestation.

**Based on the results of this study and other reports in recent years, it is clear that evaluation of maternal clinical factors and other biophysical and biomarkers measured in the first trimester is useful only for the prediction of those who will ultimately progress to PE that will require delivery prior to 34 weeks of gestation.** However, given the poor PPV for PE before 34 weeks and the poor detection rates for all cases of GH and PE, the clinical indications for a PE screening test in the first trimester remain unclear. **Currently, no prospective studies or randomized trials have evaluated the benefits and risks of first-trimester screening for prediction of PE. Until then, the use of such tests for screening should remain investigational.**<sup>92</sup>

Doppler ultrasound is a useful method to assess uterine artery blood flow velocity in the second trimester. An abnormal uterine artery velocity waveform is characterized by a high resistance index or by the presence of an early diastolic notch (unilateral or bilateral).<sup>77,78,81</sup> **Pregnancies complicated by abnormal uterine artery Doppler findings in the second trimester are associated with more than a sixfold increase in the rate of PE.**<sup>77</sup> However, the sensitivity of an abnormal uterine artery Doppler for predicting PE ranges from 20% to 60% with a PPV of 6% to 40%.<sup>77,81</sup> **Current data do not support Doppler studies for routine screening of pregnant women for PE, but uterine artery Doppler could be beneficial as a screening test**

**BOX 31-4 INTERVENTIONS USED TO PREVENT PREECLAMPSIA**

- High-protein and low-salt diet
- Nutritional supplementation (protein)
- Calcium
- Magnesium
- Zinc
- Fish and evening primrose oil
- Antihypertensive drugs, including diuretics
- Antithrombotic agents
- Low-dose aspirin
- Dipyridamole
- Heparin
- Vitamins E and C
- Sildenafil

in women at very high risk for PE if an effective preventive treatment should become available.

The ACOG task force report on hypertension in pregnancy recommends only using risk factors for identifying women considered at increased risk for PE.<sup>1,3</sup>

**Prevention of Preeclampsia**

Numerous clinical trials describe the use of various methods to prevent or reduce the incidence of preeclampsia.<sup>28,92</sup> Because the etiology of the disease is unknown, these interventions have been used in an attempt to correct theoretic abnormalities in PE. A detailed review of these trials is beyond the scope of this chapter; however, the results of these studies have been the subject of several recent systemic reviews.<sup>92</sup> **In short, randomized trials have evaluated protein or salt restriction; zinc, magnesium, fish oil, or vitamin C or E supplementation; the use of diuretics and other antihypertensive agents; and the use of heparin to prevent PE in women with various risk factors. These trials have had limited sample sizes, and results have revealed minimal to no benefit.** Some of the methods studied are summarized in [Box 31-4](#).

**Calcium Supplementation**

The relationship between dietary calcium intake and hypertension has been the subject of several experimental and observational studies. Epidemiologic studies have documented an inverse association between calcium intake and maternal BP and the incidences of PE and eclampsia. The BP-lowering effect of calcium is thought to be mediated by alterations in plasma renin activity and parathyroid hormone.

Thirteen clinical studies (15,730 women) have compared the use of calcium with no treatment or with a placebo in pregnancy. These trials differ in the populations studied (low risk or high risk for hypertensive disorders of pregnancy), study design (randomization, double-blind, or use of a placebo), gestational age at enrollment (20 to 32 weeks' gestation), sample size in each group (range, 22 to 588), dose of elemental calcium used (156 to 2000 mg/day), and the definition of hypertensive disorders of pregnancy used.

In the Cochrane review, calcium supplementation was associated with reduced hypertension (relative risk [RR], 0.65; 95% CI, 0.53 to 0.81) and reduced PE (RR, 0.45; 95% CI, 0.31 to 0.65), particularly for those at high risk and with low baseline dietary calcium intake; for those with adequate calcium intake, the difference was not statistically significant. No side

effects of calcium supplementation have been recorded in the trials reviewed. **In contrast, a recent evidence-based review by the U.S. Food and Drug Administration (FDA) concluded that "the relationship between calcium and risk of hypertension in pregnancy is inconsistent and inconclusive, and the relationship between calcium and the risk of pregnancy-induced hypertension and preeclampsia is highly unlikely."** At present, the benefit of calcium supplementation for PE prevention in women with low dietary calcium intake remains unclear.<sup>28</sup> It is also important to note that none of the published randomized trials included women with high-risk factors such as previous PE, chronic hypertension, twins, or pregestational diabetes mellitus.<sup>28</sup> **Based on available data, the author does not recommend using calcium supplementation for the prevention of PE.**

**Antiplatelet Agents Including Low-Dose Aspirin**

Preeclampsia is associated with vasospasm and activation of the coagulation-hemostasis systems. Enhanced platelet activation plays a central role in the previously mentioned process and reflects abnormalities in the thromboxane-prostacyclin balance. Hence, several authors have used pharmacologic manipulation to alter the previously mentioned ratio in an attempt to prevent or ameliorate the course of PE.

Aspirin inhibits the synthesis of prostaglandins by irreversibly acetylating and inactivating cyclooxygenase (COX). In vitro, platelet COX is more sensitive to inhibition by low doses of aspirin (<80 mg) than vascular endothelial COX. This biochemical selectivity of low-dose aspirin appears to be related to its unusual kinetics, which result in presystemic acetylation of platelets exposed to higher concentrations of aspirin in the portal circulation.

Most randomized trials for the prevention of PE have used low-dose aspirin (LDA; 50 to 150 mg/dL). **The rationale for recommending LDA prophylaxis is the theory that the vasospasm and coagulation abnormalities in preeclampsia are caused partly by an imbalance in the TXA<sub>2</sub>/prostacyclin ratio.**<sup>20,28</sup>

Recently, the Perinatal Antiplatelet Review of International Studies (PARIS) collaborative group performed a meta-analysis of the effectiveness and safety of antiplatelet agents, predominantly aspirin, for the prevention of PE. Thirty-one trials that involved 32,217 women are included in this review, and a 10% reduction was seen in the risk for PE associated with the use of antiplatelet agents (RR, 0.90; 95% CI, 0.84 to 0.96). For women with a previous history of hypertension or PE ( $n = 6107$ ) who were assigned to antiplatelet agents, the relative risk for developing PE was 0.86 (95% CI, 0.77 to 0.97). No significant differences were found between treatment and control groups in any other measures of outcome. **The reviewers concluded that antiplatelet agents, largely LDA, have small to moderate benefits when used for prevention of PE.** LDA was also found to be safe. However, more information is clearly required to assess which women are most likely to benefit from this therapy, when treatment is optimally started, and what dose to use.<sup>28</sup>

Several studies have evaluated the efficacy of aspirin in the prevention of PE in high-risk pregnancies as determined by Doppler ultrasound or other risk factors when aspirin was used early in pregnancy. A meta-analysis suggested that LDA improves pregnancy outcome in these women when aspirin is started before 16 weeks' gestation. However, this review has numerous flaws in design and data analysis. A large multicenter study

**TABLE 31-4** LOW-DOSE ASPIRIN IN HIGH-RISK WOMEN: NATIONAL INSTITUTE OF CHILD HEALTH AND HUMAN DEVELOPMENT TRIAL

| ENTRY CRITERIA                  | N    | PREECLAMPSIA (%) |          |
|---------------------------------|------|------------------|----------|
|                                 |      | ASPIRIN*         | PLACEBO* |
| Normotensive and no proteinuria | 1613 | 14.5             | 17.7     |
| Proteinuria and hypertension    | 119  | 31.7             | 22.0     |
| Proteinuria only                | 48   | 25.0             | 33.3     |
| Hypertension only               | 723  | 24.8             | 25.0     |
| Insulin-dependent diabetes      | 462  | 18.3             | 21.6     |
| Chronic hypertension            | 763  | 26.0             | 24.6     |
| Multifetal gestation            | 678  | 11.5             | 15.9     |
| Previous preeclampsia           | 600  | 16.7             | 19.0     |

Data from Caritis SN, Sibai BM, Hauth J, et al, for the National Institute of Child Health and Human Development. Low-dose aspirin therapy to prevent preeclampsia in women at high risk. *N Engl J Med*. 1998;338:701.

\*No difference was reported for any of the groups regarding the rate of preeclampsia.

sponsored by the National Institute of Child Health and Human Development (NICHD) included 2539 women with pregestational insulin-treated diabetes mellitus, chronic hypertension, multifetal gestation, or PE in a previous pregnancy and showed no beneficial effect from LDA in such high-risk women (Table 31-4).

During the past three decades, several randomized controlled trials (RCTs) and systematic reviews evaluated the benefits and risks of using LDA in pregnancy for the prevention of PE and its complications in women with one or more of the risk factors listed above. The results of the RCTs were conflicting, and the systematic reviews were inconclusive.<sup>93</sup> This is not surprising given that the published trials and those included in various reviews differed in regard to the enrolled study populations (minimal risk to extremely high risk for PE, preterm birth, FGR, and perinatal death), gestational age at enrollment (12 to 32 weeks), dose of aspirin utilized (50 to 150 mg/day), number of study subjects and number of centers in each trial, definition of PE and adverse perinatal outcomes, and whether the systemic review included unplanned subgroup analysis.<sup>93</sup>

The U.S. Preventive Services Task Force (USPSTF) recently published a report on LDA for the prevention of morbidity and mortality from preeclampsia.<sup>94</sup> The report contained an exhaustive review of published trials regarding the efficacy and safety of LDA in pregnancy for the prevention of PE and other adverse perinatal outcomes in women considered at high risk for PE. The review considered 15 randomized trials (8 quality) in women at increased risk for PE to evaluate maternal and perinatal benefits and 13 randomized trials (8 quality) to evaluate the incidence of PE. Preeclampsia incidence in women considered at increased risk ranged from 8% to 30%. In addition, two large observational studies were included to evaluate the safety of LDA use in pregnancy.

**In women considered at increased risk for preeclampsia, the USPSTF members found that LDA administered after 12 weeks' gestation reduced the risk of PE by an average of 24% (pooled relative risk [PRR], 0.76; 95% CI, 0.62 to 0.95), reduced the average risk of preterm birth by 14% (PRR, 0.86; 95% CI, 0.76 to 0.98), and reduced the risk of FGR by 20% (PRR, 0.80; 95% CI, 0.65 to 0.99).** In addition, they found that the magnitude of risk reduction with LDA for the above

complications was dependent on baseline risk for PE in the study population. Contrary to the results of other systematic reviews, they found that the beneficial effects of LDA were not dependent on the dose of LDA, and they were evident when LDA was used between 12 and 28 weeks' gestation. Moreover, they found that LDA did not increase the risk of bleeding complications (abruptio placentae, postpartum hemorrhage, neonatal intracerebral hemorrhage) or perinatal death. Based on results of this review, the **Task Force members recommended that women considered at increased risk for PE—that is, those with a history of PE, preexisting chronic hypertension or renal disease, pregestational diabetes, autoimmune disease, or multifetal gestation—should receive LDA (81 mg/day) starting at 12 to 28 weeks until delivery to reduce the likelihood of developing subsequent PE, preterm birth, or FGR.**

However, such recommendation is in contrast to that of the ACOG Task Force on Hypertension in Pregnancy, which recommended LDA only to women with prior PE that resulted in delivery at less than 34 weeks or to those with prior recurrent PE.

### Heparin or Low-Molecular-Weight Heparin

Several observational studies and randomized trials have evaluated the prophylactic use of low-molecular-weight heparin (LMWH) for the prevention of PE and other adverse pregnancy outcomes. The results of these studies were the subject of several recent reviews. Two recent large randomized trials conducted in Italy<sup>95</sup> and in Canada<sup>96</sup> revealed that prophylactic LMWH does not reduce the rate of PE in women at high risk for this complication. In addition, a meta-analysis of published trials demonstrated no benefit from LMWH.<sup>97</sup> **Therefore it is the authors' opinion that LMWH should not be used for PE prevention.**

### Vitamins C and E

Reduced antioxidant capacity, increased oxidative stress, or both in the maternal circulation and in the placenta have been proposed to play a major role in the pathogenesis of PE. Consequently, several trials were designed using vitamins C and E for the prevention of PE. The first trial suggested a beneficial effect from pharmacologic doses of vitamins E and C in women identified as being at risk for PE by means of abnormal uterine Doppler flow velocimetry. However, the study had limited sample size and must be confirmed in other populations. **In contrast, several randomized trials with large sample sizes in women at low risk and very high risk for PE found no reduction in the rate of PE with vitamin C and E supplementation (Table 31-5).**<sup>29,98-103</sup>

### Laboratory Abnormalities in Preeclampsia

Women with preeclampsia may exhibit a symptom complex that ranges from minimal BP elevation to derangements of multiple-organ systems. The renal, hematologic, and hepatic systems are most likely to be involved.

### Renal Function

Renal plasma flow and glomerular filtration rate (GFR) increase during normal pregnancy. These changes are responsible for a fall in serum creatinine, urea, and uric acid concentrations.<sup>98</sup> In PE, vasospasm and glomerular capillary endothelial swelling (glomerular endotheliosis) lead to an average reduction in GFR of 25% below the rate for normal pregnancy. Serum creatinine

is rarely elevated in PE, but uric acid can be increased. In a study of 95 women with severe PE, Sibai and associates reported a mean serum creatinine of 0.91 mg/dL, a mean uric acid of 6.6 mg/dL, and a mean creatinine clearance of 100 mL/min.

The clinical significance of elevated uric acid levels in preeclampsia-eclampsia has been confusing. Hyperuricemia is associated with renal dysfunction, especially decreased renal tubular secretion, and has been consistently associated with glomerular endotheliosis. In addition, it has been linked with increased oxidative stress in PE. **Despite the fact that uric acid levels are elevated in women with PE, this test is not sensitive or specific for the diagnosis of PE or for predicting adverse perinatal outcome.**

Elevated uric acid levels above 6 mg/dL are often found in women with normotensive multifetal pregnancies. As a result, some authors have suggested that to secure a diagnosis of PE based on elevated uric acid values, the upper limit should be adjusted for those with multiple gestation. Elevated uric acid values are also found in women with acute fatty liver of pregnancy and underlying renal disease; therefore **it is suggested that uric acid values not be used for the diagnosis of PE or as an indication for delivery in women with PE.**

### Hepatic Function

The liver is not primarily involved in preeclampsia, and hepatic involvement is observed in only 10% of women with severe PE. Fibrin deposition has been found along the walls of hepatic sinusoids in preeclamptic patients with no laboratory or histologic evidence of liver involvement. When liver dysfunction does occur in PE, mild elevation of serum transaminases is most common. Bilirubin is rarely increased in PE, but when elevated, the indirect fraction predominates. Elevated liver enzymes are a feature of the hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome, a variant of severe PE.

### Hematologic Changes

Many studies have evaluated the hematologic abnormalities in women with preeclampsia. **Plasma fibrinogen, D-dimer levels, and circulating thrombin-antithrombin complexes are higher in women with PE than in normotensive gravidas. In contrast, plasma antithrombin III activity is decreased.** These findings indicate enhanced thrombin generation.

Plasma fibrinogen rises progressively during normal pregnancy. In general, plasma fibrinogen levels are rarely reduced in women with PE in the absence of placental abruption.

**Thrombocytopenia is the most common hematologic abnormality in women with severe PE. It is correlated with the severity of the disease process and the presence or absence of placental abruption.** In a study of 1414 women with

hypertension during pregnancy, Burrows and Kelton found a platelet count of less than 150,000/mm<sup>3</sup> in 15% of cases.

Leduc and associates studied the coagulation profile—the platelet count, fibrinogen, prothrombin time (PT), and partial thromboplastin time (PTT)—in 100 consecutive women with severe PE. A platelet count lower than 150,000/mm<sup>3</sup> was found in 50% of the women, and a count lower than 100,000/mm<sup>3</sup> was found in 36%. Thirteen women had a fibrinogen level of less than 300 mg/dL, and two had prolonged PT and PTT as well as thrombocytopenia on admission. These researchers found **the admission platelet count to be an excellent predictor of subsequent thrombocytopenia and concluded that fibrinogen levels, PT, and PTT should be obtained only in women with a platelet count of less than 100,000/mm<sup>3</sup>.** A recent study by Barron confirmed these observations in more than 800 women with hypertension in pregnancy.

### Hemolysis, Elevated Liver Enzymes, and Low Platelets (HELLP) Syndrome

Considerable debate surrounds the definition, diagnosis, incidence, etiology, and management of HELLP syndrome.<sup>104</sup> Patients with such findings were previously described by many investigators. Weinstein considered it a unique variant of PE and coined the term *HELLP syndrome* for this entity. Barton and associates performed liver biopsies in patients with PE and HELLP syndrome, and periportal necrosis and hemorrhage were the most common histopathologic findings. In addition, they found that the extent of the laboratory abnormalities in HELLP syndrome, including the platelet count and liver enzymes, did not correlate with hepatic histopathologic findings.

### LABORATORY CRITERIA FOR DIAGNOSIS

**Various diagnostic criteria have been used for HELLP. Hemolysis, defined as the presence of microangiopathic hemolytic anemia, is the hallmark of the triad of HELLP syndrome.**<sup>104</sup>

The classic findings of microangiopathic hemolysis include an abnormal peripheral smear (schistocytes, burr cells, echinocytes), elevated serum bilirubin (indirect form), low serum haptoglobin levels, elevated lactate dehydrogenase (LDH) levels, and a significant drop in hemoglobin levels. A significant percentage of published reports included patients who had no evidence of hemolysis; hence, these patients will not fit the criteria for HELLP syndrome.<sup>104</sup> In some studies in which hemolysis is described, the diagnosis is suspect because it has been based on the presence of an abnormal peripheral smear (no description of type or degree of abnormalities) or elevated LDH levels (threshold of 180 to 600 U/L).

No consensus exists in the literature regarding the liver function test to be used or the degree of elevation in these tests to

diagnose elevated liver enzymes. In his original report, Weinstein mentioned abnormal serum levels of aspartate transaminase (AST), abnormal alanine transaminase (ALT), and abnormal bilirubin values; however, specific levels were not suggested. In subsequent studies in which elevated liver enzymes were described, either AST or ALT, the values considered to be abnormal ranged from 17 to 72 U/L.<sup>104</sup> In clinical practice, many of these values are considered normal or slightly elevated.

Low platelet count is the third abnormality required to establish the diagnosis of HELLP syndrome; no consensus has been reached among various published reports regarding the diagnosis of thrombocytopenia. The reported cut-off values have ranged from 75,000/mm<sup>3</sup> to 279,000/mm<sup>3</sup>, and a level of less than 100,000/mm<sup>3</sup> is most often cited.<sup>104</sup>

Many authors have used elevated total LDH (usually >600 U/L) as a diagnostic criteria for hemolysis. Of the five isoforms of LDH, only two of them—LDH<sub>1</sub> and LDH<sub>2</sub>—are released from ruptured red blood cells. In most women with severe preeclampsia-eclampsia, the elevation in total LDH is probably caused mostly by liver ischemia. Therefore many authors advocate that elevated bilirubin values (indirect form), abnormal peripheral smear, or a low serum haptoglobin level should be part of the diagnostic criteria for hemolysis.

Based on a retrospective review of 302 cases of HELLP syndrome, Martin and colleagues devised the following classification based on the nadir of the platelet count. **Class 1 HELLP syndrome was defined as a platelet nadir below 50,000/mm<sup>3</sup>, class 2 as a platelet nadir between 50,000 and 100,000/mm<sup>3</sup>, and class 3 as a platelet nadir between 100,000 and 150,000/mm<sup>3</sup>.** These classes have been used to predict the rapidity of recovery postpartum, maternal-perinatal outcome, and the need for plasmapheresis.

**Hemolysis**, defined as the presence of microangiopathic hemolytic anemia, is the hallmark of HELLP syndrome. The role of disseminated intravascular coagulation (DIC) in preeclampsia is controversial. **Most authors do not regard HELLP syndrome to be a variant of DIC because coagulation parameters such as PT, PTT, and serum fibrinogen are normal.**<sup>85</sup> However, the diagnosis of DIC can be difficult to establish in clinical practice. When sensitive determinants of this condition are used—such as antithrombin III, fibrinopeptide A, fibrin monomer, D-dimer,  $\alpha_2$ -antiplasmin, plasminogen, prekallikrein, and fibronectin—many patients have laboratory values consistent with DIC. Unfortunately, these tests are time consuming and are not suitable for routine monitoring. Consequently, less sensitive parameters are often used. Sibai and associates defined DIC as the presence of thrombocytopenia, low fibrinogen levels (plasma fibrinogen <300 mg/dL), and fibrin split products above 40 mg/mL. These authors noted the presence of coagulopathy in 21% of 442 patients with HELLP syndrome. They

also found that most cases occurred in women who had antecedent placental abruption or peripartum hemorrhage, and it occurred in all four women in their study who had subcapsular liver hematomas. In the absence of these complications, the frequency of DIC was only 5%.

**In view of the previously mentioned diagnostic problems, we recommended that uniform and standardized laboratory values be used to diagnose HELLP syndrome.**<sup>104</sup> Plasma haptoglobin and bilirubin values should be included in the diagnosis of hemolysis. In addition, the degree of abnormality of liver enzymes should be defined as a certain number of standard deviations (SDs) from the normal value for each hospital population. Our laboratory criteria to establish the diagnosis are presented in [Box 31-5](#).

### CLINICAL FINDINGS

The reported incidence of HELLP syndrome in preeclampsia has been variable, which reflects the differences in diagnostic criteria. **The syndrome appears to be more common in white women and is also more common in preeclamptic women who have been managed conservatively.**<sup>104</sup>

Early detection of HELLP syndrome can be a challenge in that many women present with nonspecific symptoms or subtle signs of PE. The various signs and symptoms reported are not diagnostic of PE and may also be found in women with severe preeclampsia-eclampsia without HELLP syndrome.<sup>104</sup> Right upper quadrant or epigastric pain and nausea or vomiting have been reported with a frequency ranging from 30% to 90% ([Table 31-6](#)). Most women gave a history of malaise typical of a nonspecific viral-like syndrome for several days before presentation, which led one investigator to suggest performing laboratory investigations (complete blood count [CBC] and liver enzymes) in all pregnant women with suspected PE who have

### BOX 31-5 CRITERIA TO ESTABLISH THE DIAGNOSIS OF HELLP SYNDROME

Hemolysis (as least two of these):

- Peripheral smear (schistocytes, burr cells)
- Serum bilirubin ( $\geq 1.2$  mg/dL)
- Low serum haptoglobin

Severe anemia unrelated to blood loss

Elevated liver enzymes

- Aspartate transaminase or alanine transaminase at least twice the ULN
- Lactate dehydrogenase twice or more of the ULN

Low platelets (<100,000/mm<sup>3</sup>)

HELLP, hemolysis, elevated liver enzymes, and low platelets; ULN, upper limit of normal.

**TABLE 31-6 SIGNS AND SYMPTOMS IN WOMEN WITH HELLP SYNDROME**

- Systemic lupus erythematosus
- Antiphospholipid antibody syndrome
- Thrombotic thrombocytopenic purpura
- Viral hepatitis

HELLP, hemolysis, elevated liver enzymes, and low platelets.

these symptoms during the third trimester.<sup>104</sup> Headaches are reported by 33% to 61% of the patients, whereas visual changes are reported in about 17%. A small subset of patients with HELLP syndrome may present with symptoms related to thrombocytopenia, such as bleeding from mucosal surfaces, hematuria, petechial hemorrhages, or ecchymosis.

Although most patients have hypertension (82% to 88%; see Table 31-6), it may be only mild in 15% to 50% of the cases and absent in 12% to 18%. Most of the patients (86% to 100%) have proteinuria by dipstick examination, although it has been reported to be absent in 13% of cases.

**DIFFERENTIAL DIAGNOSIS**

The presenting symptoms, clinical findings, and many of the laboratory findings in women with HELLP syndrome overlap with a number of medical syndromes, surgical conditions, and obstetric complications; therefore the differential diagnosis of HELLP syndrome should include any of the conditions listed in Box 31-6. Because some women with HELLP syndrome may present with gastrointestinal, respiratory, or hematologic symptoms in association with elevated liver enzymes or low platelets in the absence of hypertension or proteinuria, many initially are misdiagnosed as having other conditions such as upper respiratory infection, hepatitis, cholecystitis, pancreatitis, acute fatty liver of pregnancy (AFLP), or immune thrombocytopenic purpura (ITP).<sup>104</sup> Conversely, some women with other conditions—such as thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome (HUS), systemic lupus erythematosus (SLE), sepsis, or catastrophic antiphospholipid antibody syndrome—may be erroneously diagnosed as having HELLP syndrome. In addition, PE may occasionally be superimposed on one of these disorders, which further contributes to the diagnostic difficulty. Because of the remarkably similar clinical and laboratory findings of these disease processes, even the most experienced clinician can face a difficult diagnostic challenge. Therefore efforts should be made to attempt to identify an accurate diagnosis, given that management strategies may be different among these conditions. It is important to emphasize that affected women may have a variety of unusual signs and symptoms, none of which are diagnostic of severe PE. **Pregnant women with probable PE who present with atypical symptoms should have a CBC, a platelet count, and liver enzyme determinations irrespective of maternal BP findings.**

Occasionally, the presence of this syndrome is associated with hypoglycemia that leads to coma, severe hyponatremia, and cortical blindness. A rare but interesting complication of HELLP syndrome is transient nephrogenic diabetes insipidus. Unlike *central diabetes insipidus*, which results from the diminished or absent secretion of arginine vasopressin by the hypothalamus, *transient nephrogenic diabetes insipidus* is characterized by a resistance to arginine vasopressin mediated by excessive vasopressinase. It is postulated that elevated circulating vasopressinase may result from impaired hepatic metabolism of the enzyme.

**MANAGEMENT OF HELLP SYNDROME**

Management of preeclamptic women who present with HELLP syndrome is highly controversial.<sup>104</sup> Consequently, several therapeutic modalities have been described in the literature to treat or reverse HELLP syndrome. Most of these modalities are similar to those used in the management of severe PE remote from term (Box 31-7).

The clinical course of women with true HELLP syndrome is usually characterized by progressive and sometimes sudden deterioration in the maternal condition.<sup>104</sup> Because the presence of this syndrome has been associated with increased rates of maternal morbidity and mortality, many authors consider its presence to be an indication for immediate delivery. **There is also a consensus of opinion that prompt delivery is indicated if the syndrome develops beyond 34 weeks' gestation or earlier if obvious multiorgan dysfunction, DIC, liver infarction or hemorrhage, renal failure, suspected abruption, or nonreassuring fetal status are apparent.** Delivery is also indicated if the syndrome develops before 23 weeks' gestation.<sup>1,104</sup>

On the other hand, **considerable disagreement exists about the management of women with HELLP syndrome at or before 34 weeks of gestation when the maternal condition is stable, except for mild to moderate abnormalities in blood tests, and fetal condition is reassuring.** In such patients, some authors recommend the administration of corticosteroids to accelerate fetal lung maturity followed by delivery after 24 hours,<sup>104</sup> whereas others recommend prolonging pregnancy until the development of maternal or fetal indications for delivery or until achievement of fetal lung maturity. Some of the measures used in these latter cases have included one or more of the following: bed rest, antihypertensive agents, antithrombotic agents (LDA, dipyridamole), plasma volume expanders (crystalloids, albumin, fresh frozen plasma [FFP]), and corticosteroids (prednisone, prednisolone, dexamethasone, or betamethasone).<sup>104</sup>

**EXPECTANT MANAGEMENT OF HELLP SYNDROME**

**Few large case series describe expectant management of women with true HELLP, partial HELLP, or severe PE with isolated liver enzyme elevation. In general, these reports suggest that transient improvement in laboratory values or pregnancy prolongation from a few days to a few weeks is possible in a select group of women with HELLP syndrome. It is important to note that most of the patients included in these studies were ultimately delivered within 1 week of expectant management.**<sup>104</sup>

Investigators from the Netherlands have reported their experience with expectant management in women with HELLP syndrome before 34 weeks' gestation. Visser and Wallenburg reported the use of plasma volume expansion using invasive hemodynamic monitoring and vasodilators in 128 women with

**BOX 31-7 THERAPEUTIC MODALITIES USED TO TREAT OR REVERSE HELLP SYNDROME**

## Plasma volume expansion

- Bed rest
- Crystalloids
- Albumin 5% to 25%

## Antithrombotic agents

- Low-dose aspirin
- Dipyridamole
- Heparin
- Antithrombin III

## Immunosuppressive agents

- Steroids

## Miscellaneous

- Fresh-frozen plasma infusions
- Exchange plasmapheresis
- Dialysis

Modified from Sibai BM. The HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets): much ado about nothing? *Am J Obstet Gynecol.* 1990;162:311.

HELLP, hemolysis, elevated liver enzymes, and low platelets.

HELLP syndrome before 34 weeks' gestation. Magnesium sulfate and steroids were not used in such women. Twenty-two of the 128 patients were delivered within 48 hours; the remaining 102 patients had pregnancy prolongation for a median of 15 days (range, 3 to 62 days). Fifty-five of these 102 women had antepartum resolution of HELLP syndrome, with a median pregnancy prolongation in these women of 21 days (range, 7 to 62 days). No maternal deaths or serious maternal morbidity was reported. However, 11 of the 128 pregnancies (8.6%) resulted in fetal death at 25 to 34.4 weeks, and 7 neonatal deaths (5.5%) at 27 to 32 weeks' gestation were reported.

Van Pampus and coworkers reported the use of bed rest, antihypertensive medication, and salt restriction in 41 women with HELLP syndrome before 35 weeks' gestation. Fourteen women (34%) were delivered within 24 hours; in the remaining 27 women, pregnancy was prolonged a median of 3 days (range, 0 to 59 days). Fifteen of these 27 women showed complete normalization of the laboratory values. No serious maternal morbidities were noted, but 10 fetal deaths were reported at 27 to 35.7 weeks' gestation.

The study by Ganzevoort and colleagues included 54 women with HELLP syndrome at the time of enrollment. In a subsequent publication, the same authors compared maternal and perinatal complications in these women to the respective outcomes in women without HELLP. They found that the median number of days of pregnancy prolongation and maternal and perinatal complications were similar between the two groups.

One randomized, double-blind trial compared prednisolone ( $n = 15$ ) to placebo ( $n = 16$ ) in patients with HELLP syndrome before 30 weeks' gestation. Prednisolone was given intravenously twice a day. The primary outcome measures were the entry-to-delivery interval and the number of "recurrent HELLP" exacerbations in the antepartum period. The mean entry-to-delivery interval was similar between the two groups (6.9 days for prednisolone and 8 days for placebo). Three cases of liver hematoma or rupture were reported, along with one maternal death in the placebo group. The perinatal mortality rate was similar between the two groups (20% in the prednisolone group and 25% in the placebo group).

The results of these studies suggest that expectant management is possible in a very select group of women with suspected HELLP syndrome before 34 weeks' gestation. However, despite pregnancy prolongation in some of these cases, the overall perinatal outcome was not improved compared with fetuses at a similar gestational age who were delivered within 48 hours after the diagnosis of HELLP syndrome.

Confounding variables make it difficult to evaluate any treatment modality proposed for this syndrome. Occasionally, some patients without true HELLP syndrome may demonstrate antepartum reversal of hematologic abnormalities following bed rest, use of corticosteroids, or plasma volume expansion. However, most of these patients experienced deterioration in either maternal or fetal condition within 1 to 10 days after conservative management. It is doubtful that such limited pregnancy prolongation will result in improved perinatal outcome, and maternal and fetal risks are substantial.<sup>104</sup>

In summary, the results of these studies suggest that expectant treatment is possible in a select group of women with HELLP syndrome before 34 weeks' gestation. However, the number of women who were studied in these reports is inadequate to evaluate maternal safety; therefore such treatment should be considered experimental. In addition, most experts—including members of the ACOG Task Force—recommend delivery of such patients after completion of a course of corticosteroids for fetal lung maturity or if the gestational age is less than 24 weeks.<sup>1,3</sup>

**CORTICOSTEROIDS TO IMPROVE PREGNANCY OUTCOME IN WOMEN WITH HELLP SYNDROME**

It is well established that antenatal glucocorticoid therapy reduces neonatal complications and neonatal mortality in women with severe PE at 34 weeks' gestation or less (see [Chapter 29](#)). The recommended regimens of corticosteroids for the enhancement of fetal maturity are betamethasone (12 mg intramuscularly every 24 hours, two doses) or dexamethasone (6 mg intramuscularly every 12 hours, four doses). These regimens have been identified as the most appropriate for this purpose because they readily cross the placenta and have minimal mineralocorticoid activity. However, it is unclear whether the same or different regimens are beneficial in women with HELLP syndrome.

Corticosteroids have been suggested as safe and effective drugs for improving maternal and neonatal outcome in women with HELLP or partial HELLP syndrome. A review of the literature reveals substantial differences in methodology, time of administration, and drug selection among investigators who advocate the use of corticosteroids in women with HELLP syndrome. Different regimens of steroids have been suggested for preventing respiratory distress syndrome (RDS) as well as to accelerate maternal recovery in the postpartum period.<sup>104</sup> The regimens of steroids used included intramuscular betamethasone (12 mg/12 hr or 24 hours apart on two occasions) or IV dexamethasone (various doses at various time intervals) or a combination of the two. Some studies used steroids only in the antepartum period (for 24 hours, 48 hours, repeat regimens, or chronically for weeks until delivery). In other studies, steroids were given for 48 hours before delivery and then were continued for 24 to 48 hours postpartum, whereas others recommend their administration only in the postpartum period.<sup>104</sup>

Some randomized trials have compared the use of high-dose dexamethasone to either no treatment or betamethasone in

Modified from Katz L, de Amorim MM, Figueiroa JN, Pinto e Silva JL. Postpartum dexamethasone for women with hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome: a double-blind, placebo-controlled, randomized clinical trial. *Am J Obstet Gynecol.* 2008;198:283.

\*Each patient may have more than one complication.

women with presumed HELLP syndrome. These studies were summarized in a review by Sibai.<sup>104</sup> **The results of these studies demonstrated improved laboratory values and urine output in patients receiving dexamethasone but found no differences in serious maternal morbidity.** In addition, the number of patients studied was limited, and neither of these small studies used a placebo.

More recently, three randomized, double-blind placebo trials were conducted to evaluate dexamethasone versus placebo in women with antepartum and postpartum HELLP syndrome. Two of the trials were multicenter, and one was a single-center trial. The results of the two large, multicenter trials are summarized in Tables 31-7 and 31-8. Overall, these trials revealed no maternal benefit of using dexamethasone in women with HELLP syndrome.<sup>105</sup> **It is my opinion that corticosteroids should only be used for 48 hours to accelerate fetal lung maturity in women who have reached 24 to 34 weeks' gestation. In addition, it is recommended that dexamethasone not be used to treat maternal symptoms of HELLP syndrome either beyond 34 weeks or in the postpartum period.**<sup>1,3</sup>

#### MATERNAL AND PERINATAL OUTCOME

The presence of HELLP syndrome is associated with an increased risk for maternal death (1%) and increased rates of maternal morbidities such as pulmonary edema (8%), acute renal failure (3%), DIC (15%), abruptio placentae (9%), liver hemorrhage or failure (1%), acute respiratory distress syndrome (ARDS), sepsis, and stroke (<1%).<sup>104</sup> Pregnancies complicated by HELLP syndrome are also associated with

HELLP, hemolysis, elevated liver enzymes, and low platelets.

increased rates of wound hematomas and the need for transfusion of blood and blood products.<sup>104</sup> The rate of these complications depends on the population studied, the laboratory criteria used to establish the diagnosis, and the presence of associated preexisting medical conditions (chronic hypertension, lupus) or obstetric complications (abruptio placentae, peripartum hemorrhage, fetal demise, eclampsia).<sup>104</sup> The development of HELLP syndrome in the postpartum period also increases the risk for renal failure and pulmonary edema. The presence of placental abruption increases the risk for DIC, pulmonary edema, and renal failure and also increases the need for blood transfusions. Patients who have a large volume of ascites appear to have a high rate of cardiopulmonary complications. Finally, women who meet all the criteria suggested for diagnosis will have higher rates of maternal complications than those who have partial HELLP or elevated liver enzymes only (Table 31-9).

**It is generally agreed that perinatal mortality and morbidity are substantially increased in pregnancies complicated by**

the HELLP syndrome. The reported perinatal death rate in recent series ranged from 7.4% to 34%, and this high perinatal death rate is mainly experienced at a very early gestational age (<28 weeks) in association with severe FGR or placental abruption.<sup>104</sup> It is important to emphasize that neonatal morbidities in these pregnancies are dependent on gestational age at time of delivery, and they are similar when corrected for gestational age to those in preeclamptic pregnancies without the HELLP syndrome. The rate of preterm delivery is about 70%, and 15% occur before 28 weeks' gestation. As a result, these infants have a high rate of acute neonatal complications.

The HELLP syndrome may develop antepartum or postpartum. Analysis of 442 cases studied by Sibai and associates revealed that 309 (70%) had evidence of the syndrome antepartum, whereas 133 (30%) developed the condition postpartum. Four maternal deaths were reported, and morbidity was frequent (Table 31-10).

In the postpartum period, the time of onset of the manifestations can range from a few hours to 7 days, but most develop within 48 hours postpartum. Thus **laboratory assessment for potential HELLP syndrome should be considered during the first 48 hours postpartum in women with significant hypertension or symptoms of severe PE.** Eighty percent of the women who develop HELLP syndrome postpartum had PE before delivery, whereas 20% had no evidence of PE during either the antepartum or intrapartum periods. It is my experience that patients in this group are at increased risk for

the development of pulmonary edema and acute renal failure (Table 31-11). The differential diagnosis should include exacerbation of SLE, TTP, and HUS.

### RECOMMENDED MANAGEMENT

The clinical course of women with HELLP syndrome is usually characterized by progressive and sometimes sudden deterioration in maternal and fetal condition. Therefore **patients with a suspected diagnosis of HELLP syndrome should be hospitalized immediately and observed in a labor and delivery unit (Fig. 31-5).** Such patients should be managed as if they have PE with severe features and should initially receive IV magnesium sulfate as prophylaxis against convulsions and antihypertensive medications to maintain systolic BP below 160 mm Hg or diastolic BP below 105 mm Hg.<sup>104</sup> This can be achieved with a 5-mg bolus dose of hydralazine repeated as needed every 20 minutes for a maximal dose of 25 mg/hour. BP is recorded every 20 minutes during therapy and every hour once the desired values are achieved. If hydralazine does not lower BP adequately, or if maternal side effects such as tachycardia or headaches develop, another agent such as labetalol or nifedipine can be used.

The recommended dose of labetalol is 20 to 40 mg given intravenously every 10 minutes for a maximum of 300 mg, and the dose of nifedipine is 10 to 20 mg orally every 20 minutes for a maximum dose of 50 mg within an hour. During the observation period, maternal and fetal conditions should be followed carefully.

The recommended regimen of magnesium sulfate is a loading dose of 6 g given over 20 minutes, followed by a maintenance dose of 2 g/hr as a continuous IV solution. Magnesium sulfate is initiated at the beginning of the observation period and is then continued during labor and for at least 24 hours postpartum. In those with abnormal renal function (oliguria or serum creatinine  $\geq 1.2$  mg/dL), the dose of magnesium sulfate should be reduced and perhaps even discontinued.

Once the diagnosis of HELLP syndrome is confirmed, a decision must be made regarding the need for delivery (see Fig. 31-5). Women with HELLP syndrome at less than 35 weeks' gestation should be referred to a tertiary care facility if their condition is stable. The first priority is to assess and stabilize the maternal condition, particularly BP and coagulation abnormalities. The next step is to evaluate fetal status with the use of fetal heart rate (FHR) monitoring, biophysical profile (BPP), or Doppler assessment of fetal vessels. Finally, a decision must be made as to whether delivery should be initiated or delayed for

**TABLE 31-10** SERIOUS MATERNAL COMPLICATIONS IN 442 PATIENTS WITH HELLP SYNDROME

48 hours to allow the full benefit of corticosteroids. **Thus in practice, prompt delivery is undertaken in all patients with true HELLP syndrome except in those with a gestational age between 24 to 34 weeks with stable maternal and fetal conditions.** These latter patients are given betamethasone and are generally then delivered within 24 hours after the last dose of corticosteroids. Maternal and fetal conditions are assessed continuously during this time. In some of these women, transient improvement in maternal laboratory values may be seen; however, delivery is still recommended despite such improvement.<sup>104</sup>

#### INTRAPARTUM MANAGEMENT

The presence of HELLP syndrome is not an indication for immediate cesarean delivery, and such an approach might prove detrimental for both mother and fetus. The decision to perform a cesarean delivery should be based on gestational age, fetal condition, the presence of labor, and the cervical Bishop score. Elective cesarean delivery is recommended for all women with HELLP syndrome before 30 weeks' gestation who are not in labor and have a Bishop score of less than 5. Elective cesarean delivery is also undertaken for those with HELLP syndrome complicated by FGR or oligohydramnios, particularly if the gestational age is less than 32 weeks in the presence of an unfavorable cervical Bishop score (Box 31-8).

Women in labor and those whose membranes have ruptured are allowed to deliver vaginally in the absence of obstetric complications. When induction is indicated, labor is initiated with either oxytocin infusion or prostaglandins in patients with a gestational age of more than 30 weeks, irrespective of the amount of cervical dilation or effacement. A similar approach is used for those at 30 weeks' gestation or less if the cervical Bishop score is at least 5.

Maternal pain relief during labor and delivery can be provided by intermittent use of small doses of systemic opioids. Local infiltration anesthesia can be used for all vaginal deliveries if an episiotomy or repair of a laceration is necessary. The use of a pudendal block is contraindicated in these patients because of the risk for bleeding and hematoma formation into this area.

#### BOX 31-8 INDICATIONS AND MANAGEMENT DURING CESAREAN DELIVERY IN HELLP SYNDROME

##### Indications for Cesarean Delivery

- Nonreassuring fetal status
- Abnormal fetal presentation
- Gestation <30 weeks and Bishop score <5
- Gestation <32 weeks with IUGR or oligohydramnios and Bishop score <5
- Known subcapsular liver hematoma
- Suspected abruptio placentae

##### Management During Cesarean Delivery

- General anesthesia for platelet count <75,000/mm<sup>3</sup>
- Transfuse 6 U of platelets if count <40,000/mm<sup>3</sup>
- Insert subfascial drain
- Secondary skin closure or leave subcutaneous drain
- Observe for bleeding from upper abdomen before closure

HELLP, hemolysis, elevated liver enzymes, and low platelets; IUGR, intrauterine growth restriction.

Epidural anesthesia is also contraindicated, particularly if the platelet count is less than 75,000/mm<sup>3</sup>. **Therefore general anesthesia is the method of choice for cesarean delivery in most thrombocytopenic women.** O'Brien and coworkers assessed the impact of glucocorticoid administration on the use of epidural anesthesia in 37 women with partial HELLP syndrome who had a platelet count of less than 90,000/mm<sup>3</sup> before steroid administration. They found that administration of corticosteroids in these patients increased the use of epidural anesthesia, particularly in those who achieved a latency period of 24 hours before delivery (8 of 14 in the steroid group vs. 0 of 10 in the group that did not receive steroids;  $P = .006$ ).

**Platelet transfusions are indicated either before or after delivery in all patients with HELLP syndrome in the presence of significant bleeding—such as subcapsular hematoma of the liver, ecchymosis, bleeding from gums, oozing from**

**FIG 31-6** Subfascial drains used at the time of cesarean section.

puncture sites and wounds, or intraperitoneal bleeding—and in all those with a platelet count less than  $20,000/\text{mm}^3$ . However, repeated platelet transfusions are generally not necessary because of the short half-life of the transfused platelets in such patients. Correction of thrombocytopenia is also important before any surgery. Administration of 6 units of platelets is recommended in all patients with a platelet count less than  $40,000$  to  $50,000/\text{mm}^3$  before intubation if cesarean delivery is needed. Generalized oozing from the incision site can occur during surgery or in the immediate postpartum period because of the continued drop in platelet count in some patients. The risk for hematoma formation at these sites is about 20%, and some prefer to use a vertical skin incision for this reason, whereas others use a subfascial drain and keep the skin incision open for at least 48 hours in women who require cesarean delivery (Fig. 31-6).<sup>104</sup>

#### POSTPARTUM MANAGEMENT

After delivery, patients with HELLP syndrome should receive close monitoring of vital signs, fluid intake and output, laboratory values, and pulse oximetry for at least 48 hours. IV magnesium sulfate prophylaxis is generally continued for 48 hours, and antihypertensive drugs are used if the systolic BP is at least 155 mm Hg or if the diastolic BP is at least 105 mm Hg. **In general, most women will show evidence of resolution of the disease process within 48 hours after delivery. However, some patients—especially those with placental abruption complicated by DIC, severe thrombocytopenia (platelet count  $<20,000/\text{mm}^3$ ), or severe ascites or those with significant renal dysfunction—may show delayed resolution or even deterioration in their clinical condition.** Such patients are at risk for the development of pulmonary edema from transfusion of blood and blood products, fluid mobilization, and compromised renal function. These patients are also at risk for acute tubular necrosis and may require dialysis and intensive monitoring for several days. Some authors have suggested that such patients might benefit from plasmapheresis or plasma transfusions. In practice, most of these women will recover with supportive therapy only. **If the patient continues to deteriorate for more than 72 hours after delivery, however, or shows improvement in laboratory values and then starts to show thrombocytopenia and abnormal liver enzymes again, a diagnosis of TTP/HUS should be considered. In such cases, plasmapheresis is indicated.**

**FIG 31-7** Computed tomographic scan of the liver demonstrates hepatic infarct.

The clinical and laboratory findings of HELLP syndrome may first appear during the postpartum period.<sup>104</sup> In these women, the time of onset of the manifestations ranges from a few hours to 7 days, although most develop within 48 hours postpartum.<sup>104</sup> Hence, all postpartum women and their health care providers should be educated to be aware of the signs and symptoms of HELLP syndrome. Management of patients with postpartum HELLP syndrome should be similar to that in the antepartum period, including the use of magnesium sulfate.

#### Hepatic Complications in HELLP Syndrome

**Marked elevations in serum aminotransferases ( $>1000$  to  $2000$  IU/L) are not typical of uncomplicated HELLP syndrome; however, when they do occur, the possibility of hepatic infarction and subcapsular hematoma of the liver must be considered.** The differential diagnosis should also include AFLP, abruptio placentae with DIC, acute cholecystitis with sepsis, viral hepatitis, and TTP. In addition to the signs and symptoms of PE, physical examination findings consistent with peritoneal irritation and hepatomegaly may be present.

#### HEPATIC INFARCTION

Marked elevation in serum aminotransferases (usually 1000 to 2000 IU/L or higher) and LDH (usually 10,000 to 20,000 IU/L) associated with right upper quadrant pain and fever is characteristic of hepatic infarction; this diagnosis can be confirmed by hepatic imaging (Fig. 31-7). Follow-up imaging after delivery typically demonstrates resolution of the infarcts. These women may have underlying antiphospholipid antibody syndrome.<sup>104</sup>

#### HEPATIC HEMATOMA AND RUPTURE

**HELLP syndrome may be complicated by hepatic rupture with the development of a hematoma beneath the Glisson capsule (Fig. 31-8).** Histology of the liver adjacent to the rupture shows periportal hemorrhage and fibrin deposition along with a neutrophilic infiltrate suggestive of hepatic PE. The hematoma may remain contained or it may rupture, with resulting

Liver hematoma at 40 weeks  
Pleural effusions, intubation

**FIG 31-8** Computed tomographic scan of liver demonstrates subcapsular hematoma at presentation and 2 weeks postpartum.

hemorrhage into the peritoneal cavity. Women who develop a hepatic hematoma typically have abdominal pain, and many have severe thrombocytopenia, shoulder pain, nausea, and vomiting. The aminotransferases are usually modestly elevated, but values of 4000 to 5000 IU/L can occasionally be seen. If hepatic rupture occurs, swelling of the abdomen from hemoperitoneum and shock rapidly ensue.

**The management of a contained hematoma is to support the patient with volume replacement and blood transfusion, as needed, with consideration for percutaneous embolization of the hepatic arteries.** If the size of the hematoma remains stable and the laboratory abnormalities are resolving, the patient may be discharged home with outpatient follow-up. It may take months for the hematoma to resolve completely.

Surgical repair has been recommended for hepatic hemorrhage without liver rupture. This complication, however, can be managed conservatively in patients who remain hemodynamically stable. Management should include close monitoring of hemodynamics and coagulation status. Serial assessment of the subcapsular hematoma with ultrasound or computed tomography (CT) is necessary, as is immediate intervention for rupture or worsening of maternal status. It is important with conservative management to avoid exogenous sources of trauma to the liver—such as abdominal palpation, convulsions, or emesis—and to use care in transportation of the patient. Indeed, any sudden increase in intraabdominal pressure could potentially lead to rupture of the subcapsular hematoma (Fig. 31-9).

**Rupture of a subcapsular hematoma of the liver is a life-threatening complication of HELLP syndrome.** Profound hypovolemic shock in a previously hypertensive patient is the hallmark of hematoma rupture. In most instances, rupture involves the right lobe and is preceded by the development of a parenchymal hematoma. Patients frequently present with shoulder pain, shock, evidence of massive ascites, respiratory difficulty, pleural effusions, and often with a dead fetus. Ultrasound or CT of the liver should be performed to rule out the presence of subcapsular hematoma of the liver and to assess for the presence of intraperitoneal bleeding. Paracentesis can confirm intraperitoneal bleeding.

**The presence of ruptured subcapsular liver hematoma that results in shock is a surgical emergency that requires acute multidisciplinary treatment (Box 31-9).** Resuscitation should consist of massive transfusions of blood, correction of coagulopathy with FFP and platelets, and immediate laparotomy.

**FIG 31-9** Subcapsular hematoma in a patient with hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome.

A team experienced in liver trauma surgery should be consulted. If hepatic rupture is suspected, an incision in the upper abdomen is necessary for adequate surgical exposure. A lower abdominal midline incision can be extended superiorly. If a Pfannenstiel incision was used for operative delivery, a separate upper abdominal midline incision should be made to maximize visualization of the upper abdomen and liver. Options at laparotomy include packing and drainage, surgical ligation of the hemorrhaging hepatic segments, embolization of the hepatic artery to the involved liver segment, and loose suturing of the omentum or surgical mesh to the liver to improve integrity. Shrivastava and associates in a case report described the successful use of an argon-beam coagulator to obtain hemostasis from a ruptured liver hematoma in a patient with HELLP syndrome, although previous experience with this modality was unsuccessful. **Even with appropriate treatment, maternal and fetal mortality is almost 50%. Mortality is most commonly associated with exsanguination with coagulopathy and sepsis.** Initial survivors are at increased risk for developing ARDS, pulmonary edema, liver failure, and acute renal failure in the postoperative period.

Reck and colleagues reviewed cases with HELLP syndrome–associated liver rupture (4 patients from their center in Germany and 49 identified from a MedLine literature search covering 1990 to 1999). Despite surgical interventions, HELLP syndrome–associated liver rupture carried a mortality rate of

### BOX 31-9 MANAGEMENT OF PATIENTS WITH DOCUMENTED SUBCAPSULAR HEMATOMA OF THE LIVER

#### General Considerations

1. Inform the blood bank about the potential need for large amounts of packed red blood cells, fresh-frozen plasma, and platelet concentrate.
2. Ensure consultation with a general or vascular surgeon.
3. Avoid direct and indirect manipulation of the liver.
4. Arrange for close monitoring of hemodynamic status.
5. Administer intravenous magnesium sulfate to prevent seizures.

#### Unruptured Hematoma

- Conservative management
- Correct coagulopathy
- Serial computed tomography scans or ultrasound

#### Expanding or Ruptured Hematoma

- Massive transfusions
- Immediate laparotomy

#### Minimal Bleeding

- Observation
- Draining area with closed suction

#### Severe Bleeding

- Application of laparotomy sponges as packs for pressure
- Embolization of the hepatic artery to the involved liver segment
- Surgical ligation of hemorrhaging hepatic segment
- Loosely sutured omentum or surgical mesh to the liver to improve integrity
- Argon beam coagulator to liver surface
- Hepatic lobectomy
- Hepatectomy and temporary portocaval shunt followed by liver transplantation

39% (19 of 49) in their review. The main causes of death were hemorrhagic shock ( $n = 11$ ) and multiorgan failure ( $n = 7$ ). Based on their review, these authors suggested an interdisciplinary approach for patients with ruptured liver or hepatic failure that includes the use of temporary packing of the liver to control bleeding. In those patients with hepatic failure or uncontrollable hepatic hemorrhage, they noted that a liver transplantation as a last-resort measure must be considered.

#### LIVER TRANSPLANTATION FOR INTRACTABLE HEMORRHAGE

For women with intractable hemorrhage despite the previously described interventions, and for those with necrosis with subsequent liver failure, liver transplantation has been successful in case reports and case series. Shames and colleagues queried the Organ Procurement and Transplantation Network database regarding liver transplantations performed for complications from HELLP syndrome. Eight deceased donor liver transplantations were identified in the United States with this indication between October 1987 and November 2003. At the time of their review, six of the eight patients were alive, whereas two maternal deaths occurred within 1 month of transplantation. In addition, two patients required retransplantation. Based on the results of their review, these authors presented an algorithm in which liver transplantation is considered for patients with complicated HELLP syndrome, including ongoing, uncontrolled hemorrhage or liver necrosis and failure. **From our experience**

and review of the literature, we have developed a management plan of hepatic hematoma associated with HELLP syndrome. This plan emphasizes the potential for transfusion of large amounts of blood and blood products and the need for aggressive intervention if rupture of the hematoma is suspected (see Box 31-9). We recommend that 30 units of packed red blood cells, 20 U of FFP, 30 to 50 U of platelets, and 20 to 30 U of cryoprecipitate be available if rupture of a subcapsular hematoma is suspected.

We agree with the observations of others that a stable patient with an unruptured subcapsular hematoma should be conservatively managed. Constant monitoring must continue during this management, however, because patients can rapidly become unstable after rupture of the hematoma. Survival clearly is associated with rapid diagnosis and immediate medical or surgical stabilization, so these patients should be managed in an intensive care unit (ICU) with close monitoring of hemodynamic parameters and fluid status to avoid the potential for pulmonary edema or respiratory compromise.

Postpartum follow-up for patients with subcapsular hematoma of the liver should include serial CT, magnetic resonance imaging (MRI), or ultrasonography until the defect resolves. Although the data on subsequent pregnancy outcome after a subcapsular hematoma of the liver in pregnancy are limited, we have managed three such patients who have had subsequent normal maternal and fetal outcomes, and Wust and coworkers reported the successful outcome of four subsequent pregnancies in three women with a history of hepatic rupture and PE or HELLP syndrome.

#### Hemodynamic Monitoring in Preeclampsia

The cardiovascular hemodynamics of preeclampsia have been investigated over the years by many authors who have used various techniques for measurement of BP, cardiac output, pulmonary capillary wedge pressure (PCWP), and central venous pressure (CVP).

Hemodynamic findings in women with PE are variable. A review of the English literature demonstrates considerable disagreement regarding one or more of the hemodynamic parameters studied. This lack of agreement has been attributed to differences in the definition of PE, variable severity and duration of the disease process, presence of underlying cardiac or renal disease, techniques used to measure cardiac output and BP, and therapeutic interventions applied before obtaining the various measurements. In addition, the dynamic minute-to-minute fluctuation of the cardiovascular parameters studied makes it difficult to standardize the conditions under which these observations are made, which limits the value of a single measurement.

Invasive techniques have been used by many authors to study the hemodynamic findings in untreated women with severe PE. The reported cardiac index ranged from a low of 2.8 to a high of 4.8 L/m<sup>2</sup> per minute, and the reported PCWP ranged from a low of 3.3 to a high of 12 mm Hg. The findings suggest that cardiac index and PCWP are either low or normal in severe PE. The reported CVP values also ranged from 2 to 6 mm Hg. **The findings demonstrate that treated patients with PE have normal to high cardiac index, normal to high systemic vascular resistance index, and normal to high PCWP.**

In summary, variable hemodynamic findings accompany PE. Moreover, the clinical utility of invasive hemodynamic monitoring in PE is debatable. Most of the invasive monitoring data indicate that both cardiac output and systemic vascular

resistance appear to be elevated in women with severe PE. This finding suggests that the problem in PE is a systemic vascular resistance that is inappropriately high for the level of cardiac output. Both the PCWP and the CVP appear to be in the low to normal range; however, no correlation is found between the two values.

### Antepartum Management of Gestational Hypertension–Preeclampsia GESTATIONAL HYPERTENSION

**Women with gestational hypertension–preeclampsia (GH-PE) are at risk for progression to severe hypertension, PE with severe features, HELLP syndrome, or eclampsia.<sup>1-8</sup> The risks are increased with a lower gestational age at the time of diagnosis,<sup>3-8</sup> and therefore these patients require close observation of maternal and fetal conditions.** Maternal evaluations require weekly prenatal visits; education about reporting preeclamptic symptoms; and evaluation of CBC, platelet count, liver enzymes, and serum creatinine.<sup>1-3</sup> Fetal evaluation includes ultrasound examination of fluid and estimated fetal weight at the time of diagnosis and weekly or twice weekly nonstress tests (NSTs) and evaluation of amniotic fluid volume (AFV).<sup>1,3</sup> Restriction of dietary salt and physical activity has not proved beneficial in the management of these patients.<sup>1-3</sup> Additionally, **the results of several randomized trials reveal that control of maternal BP with antihypertensive drugs does not improve pregnancy outcome in these women.**

**In the absence of progression to severe disease, women with GH-PE can continue pregnancy until 37 weeks' gestation.** During labor and immediately postpartum, they do not require seizure prophylaxis because the rate of eclampsia in these women is less than 1 in 500.<sup>1,2</sup>

The Hypertension and Preeclampsia Intervention Trial At Term (HYPITAT) was a multicenter, open-label RCT conducted at 6 academic and 32 nonacademic hospitals in the Netherlands. It included 756 women with a singleton pregnancy at a gestational age between 36<sup>0/7</sup> weeks and 41<sup>0/7</sup> weeks who had mild GH ( $n = 496$ ) or nonsevere GH ( $n = 246$ ); 377 were randomized to induction, 379 to expectant monitoring. **The primary outcome was a composite of adverse maternal outcomes: progression to severe disease or HELLP syndrome, eclampsia, pulmonary edema, placental abruption, postpartum hemorrhage, thromboembolic disease, or death.** Secondary outcomes were a composite of adverse neonatal outcomes and rate of cesarean delivery. No cases of maternal, fetal, or neonatal death and no cases of eclampsia or abruption were reported in either group. **However, women randomized to the induction group had a significant reduction in the primary outcome (31% vs. 44%; RR, 0.71; 95% CI, 0.59 to 0.86) mainly because of differences in the rates of severe hypertension.** No differences were found in the overall secondary outcomes; however, subgroup analysis revealed significant differences in the primary outcomes in the group enrolled with mild PE (33% vs. 54%; RR, 0.61; 95% CI, 0.45 to 0.8) but not in those with mild GH (31% vs. 38%; RR, 0.81; 95% CI, 0.63 to 1.03). Unfortunately, the sample size was inadequate to answer the question in those with nonsevere GH only. Moreover, in the induction group, the rate of cesarean delivery was lower in nulliparous women and in those with a cervical Bishop score of less than 2, which refutes the belief that induction of labor in these women increases the rate of cesarean delivery. Results of this trial are summarized in Tables 31-12 and 31-13.

**TABLE 31-12** MATERNAL OUTCOME IN RANDOMIZED TRIAL COMPARING INDUCTION AND EXPECTANT MONITORING IN MILD GESTATIONAL HYPERTENSION–PREECLAMPSIA

### HOSPITALIZATION

In the past, management of these women has involved hospital bed rest for the duration of pregnancy with the belief that such management diminishes the frequency of progression to severe disease and allows rapid intervention in the event of sudden disease progression, including the development of placental abruption, eclampsia, or hypertensive crisis. However, these complications are extremely rare among compliant women with mild hypertension or nonsevere hypertension and absent symptoms. In addition, the results of two randomized trials in women with GH and several observational studies in **women with mild hypertension and nonsevere PE suggest that most of these women can be safely managed at home or in a day care facility provided they undergo frequent maternal and fetal evaluation.**<sup>1-3</sup>

### BED REST

**Complete or partial bed rest for the duration of pregnancy is often recommended for women with nonsevere hypertension–PE. No evidence to date suggests that this practice improves pregnancy outcome.** In addition, no published randomized

trials have compared complete bed rest and restricted activity in the management of women with PE. On the other hand, prolonged bed rest for the duration of pregnancy increases the risk for thromboembolism. The ACOG Task Force report recommends that bed rest not be used in management of GH-PE.<sup>1</sup>

### BLOOD PRESSURE MEDICATIONS

Several randomized trials have described the use of antihypertensive drugs compared with no treatment or a placebo in the management of women with nonsevere hypertension or PE remote from term. Overall, these trials revealed lower rates of progression to severe disease with no improvement in perinatal outcome.<sup>1-3</sup> Of note, the sample size of these trials is inadequate to evaluate differences in FGR, abruptio placentae, perinatal death, or maternal outcome. **It is recommended that antihypertensive medications not be used routinely to control mild levels of hypertension.**

### FETAL AND MATERNAL SURVEILLANCE

It is universally agreed that fetal testing is indicated during expectant management of women with GH or PE.<sup>1-3</sup> Most authorities in the United States recommend daily fetal movement counting (FMC) in association with either an NST or BPP to be performed at the time of diagnosis and serially thereafter until delivery (1 to 2 times per week).<sup>1-3</sup> Because uteroplacental blood flow may be reduced in some of these women, ultrasound estimation of fetal weight and amniotic fluid status is also recommended at the time of diagnosis and serially thereafter, with the frequency depending on findings. Doppler flow velocimetry is recommended in the presence of suspected IUGR.<sup>1,3</sup> The frequency of these tests is usually dependent on the severity of hypertension or PE, gestational age at the time of diagnosis, and fetal growth findings. Most clinical series suggest testing once weekly in women with GH or PE, twice weekly if fetal growth delay is suspected, and daily during expectant management of women with PE without severe features at less than 32 weeks' gestation. However, no large prospective studies have assessed outcomes of these monitoring techniques in women with GH or PE.

**Maternal surveillance is indicated in all women with GH and PE. The goal of monitoring in women with GH is to observe progression of the condition to severe hypertension or to PE.<sup>1-3</sup> In women with PE, the goal is early detection of progression to PE with severe features.** In those with severe features, the goal is to detect the development of organ dysfunction; therefore all such women should be evaluated for

symptoms of organ dysfunction such as severe headaches, visual changes, altered mentation, right upper quadrant or epigastric pain, nausea or vomiting, and shortness of breath.<sup>1-3</sup> In addition, they should undergo laboratory testing for serum creatinine, platelet count, and liver enzymes. **Coagulation function tests are not necessary in the presence of a normal platelet count and liver enzymes. The frequency of laboratory testing will depend on the initial findings, the severity of the maternal condition, and the ensuing clinical progression.**

### RECOMMENDED MANAGEMENT

The primary objective of management in women with GH-PE must always be safety of the mother and then delivery of a mature newborn that will not require intensive and prolonged neonatal care. This objective can be achieved by formulating a management plan that takes into consideration the severity of the disease process, gestational age, maternal and fetal status at the initial evaluation, presence of labor, and the wishes of the mother.

#### HYPERTENSION OR PREECLAMPSIA WITHOUT SEVERE FEATURES

Once the diagnosis of GH or PE is made, subsequent management will depend on the results of maternal and fetal evaluation (Fig. 31-10). **In general, women with disease that develops at 37 weeks' gestation or later should undergo induction of labor.**

In women who remain undelivered, close maternal and fetal evaluation are essential. These women are instructed to eat a regular diet with no salt restriction and to restrict their activity, but complete bed rest is not advised. Diuretics and antihypertensive medications are not used because of the potential to mask the diagnosis of severe disease.<sup>1</sup> At the time of initial and subsequent visits, women are educated and instructed about reporting symptoms of severe PE. **Those who are managed as outpatients are also advised to come to the hospital or outpatient facility immediately if they develop abdominal pain, significant headache, uterine contractions, vaginal spotting, or decreased fetal movement.**

In women with nonsevere GH, fetal evaluation should include an NST and an ultrasound examination of estimated fetal weight (EFW) and AFV using the amniotic fluid index (AFI). If the results are normal, repeat testing is performed every week as previously described.

Maternal evaluation includes weekly measurements of hematocrit, platelet count, serum creatinine, and liver function tests.

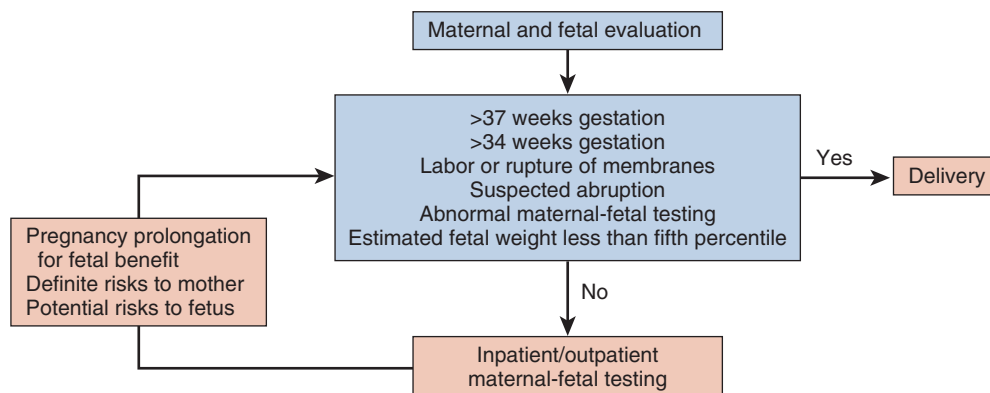

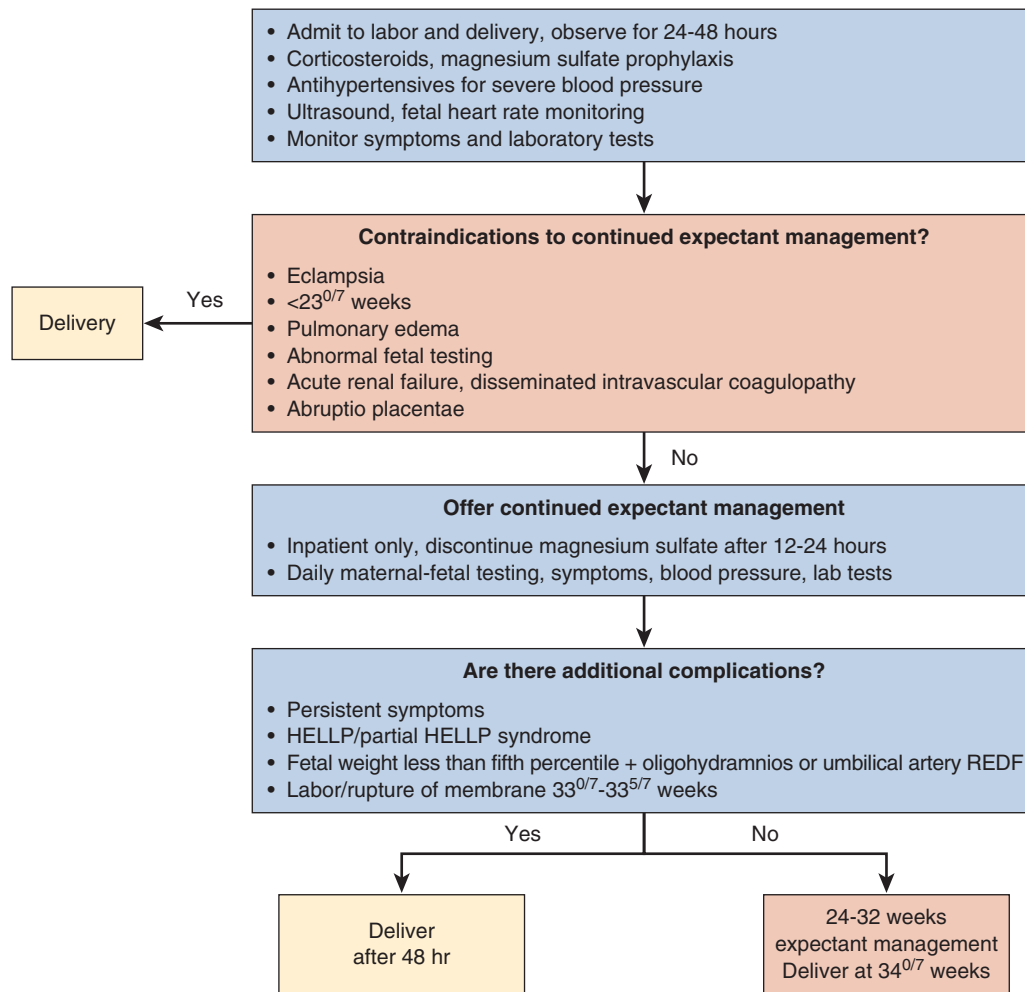

FIG 31-10 Management plan for patients with gestational hypertension-preeclampsia.

**FIG 31-11** Management plan for patients with preeclampsia with severe features before 34 weeks' gestation. HELLP, hemolysis, elevated liver enzymes, and low platelets; REDF, reversed end-diastolic flow.

The women are usually seen twice a week for evaluation of maternal BP, urine protein by dipstick or P/C ratio (GH only), and symptoms of impending eclampsia. This evaluation is extremely important for early detection of progression to severe disease. The onset of maternal symptoms and/or a sudden increase in BP to severe values requires prompt hospitalization for close evaluation.

**In women with PE at less than 37 weeks' gestation but at more than 32 weeks, outpatient management can be considered for reliable patients with a systolic BP of 155 mm Hg or less or diastolic BP of 105 mm Hg or less and no symptoms. Women who do not satisfy these criteria are hospitalized, particularly those with PE before 32 weeks.** During ambulatory management, women are instructed to have limited activity at home and are given instructions about prompt reporting of symptoms of severe disease; these women are then seen twice weekly. Fetal evaluation includes daily FMC, twice-weekly NST, and serial ultrasound evaluation of fetal growth and AFV. If disease progression is evident—that is, if a significant increase in BP to levels above the threshold mentioned previously, new onset of symptoms, evidence of abnormal blood tests, or abnormal fetal growth are apparent—these women are hospitalized for the duration of pregnancy. Women managed in the hospital receive similar maternal and fetal evaluations. Obstetric management is summarized in [Figure 31-11](#).

#### PREECLAMPSIA WITH SEVERE FEATURES

The incidence of preeclampsia with severe features ranges from 0.6% to 1%.<sup>105</sup> Pregnancies complicated by PE with severe features are associated with serious maternal and perinatal complications, particularly preterm delivery, FGR, placental abruption, and perinatal death ([Table 31-14](#)). As a result, knowledge of the anticipated maternal, fetal, and neonatal risks is essential for appropriate counseling and management.

#### Expectant Management

The clinical course of PE with severe features may be characterized by progressive deterioration in both maternal and fetal conditions. **Because these pregnancies have been associated with increased rates of maternal morbidity and mortality and with significant risks for the fetus (growth restriction, hypoxemia, and death), it is generally agreed that all such patients should be delivered if the disease develops after 34 weeks' gestation.** Prompt delivery is also indicated when eclampsia is imminent—when persistent, severe symptoms do not respond to treatment—or in the presence of multiorgan dysfunction or severe IUGR (<5th percentile) in association with abnormal umbilical artery Doppler studies, such as reversed end-diastolic flow (REDF) or severe oligohydramnios (largest vertical pocket <2 cm), suspected placental abruption, nonreassuring fetal testing, gestational age less than 24 weeks, or fetal demise.<sup>1-3,105</sup>

\*Included women with previous preeclampsia. The other studies included only nulliparous women.

<sup>†</sup>Rates for delivery at <34 wk.

NR, not reported; SGA, small for gestational age.

Although delivery is beneficial to the mother, it must be weighed against the risks associated with prematurity. In the past, it was believed that infants born prematurely to severely preeclamptic women had lower rates of neonatal mortality and morbidity compared with infants of similar gestational age born to nonpreeclamptic women. This belief was based on the clinical impression that fetuses of preeclamptic women have accelerated lung and neurologic maturation as a result of stress in utero. Reduced risk for prematurity-associated neonatal morbidity has never been documented in case-control studies. In contrast, **several recent case-control investigations have demonstrated that premature infants born after PE with severe features have similar neonatal complications and mortality and have higher rates of admission to neonatal ICUs compared with other premature infants of similar gestational age. In addition, the results of case-controlled studies reveal that fetuses of preeclamptic women do not exhibit accelerated lung or neurologic maturation.**<sup>104</sup>

During expectant management, women should be aware that the decision to continue such management will be made on a daily basis and that the median time of pregnancy prolongation is **7 days with a range of 2 to 35 days.** Only three randomized trials have compared a policy of early elective delivery after corticosteroids with a policy of delayed delivery.<sup>105</sup> One trial was conducted in South Africa and included patients at a gestational age of 26 to 34 weeks, one United States trial included women at 28 to 32 weeks, and a recent trial from Latin American countries included patients with a gestational age of 28 to 34 weeks. The first two studies totaled 133 women and revealed improved neonatal outcome in those who had delivery delayed, whereas the multicenter Latin American study revealed no perinatal benefits and increased maternal morbidity. Nevertheless, the results of retrospective and observational studies of more than 2000 women suggest that **expectant management is associated with reduced short-term neonatal morbidity in a select group of women with a gestational age between 24 and 32 weeks.**<sup>1,3,104</sup>

In the past, uncertainty surrounded the efficacy and safety of corticosteroids administered to women with PE with severe features before 34 weeks' gestation. A prospective double-blind randomized trial of 218 women with severe PE with a gestational age between 26 and 34 weeks receiving either betamethasone ( $n = 110$ ) or placebo ( $n = 108$ ) reported a significant reduction in the rate of RDS (RR, 0.53; 95% CI, 0.35 to 0.82) in the steroid-treated group. Corticosteroid use also was associated with a reduction in the risks for neonatal intraventricular hemorrhage (RR, 0.35; 95% CI, 0.15 to 0.86), neonatal infection (RR, 0.39; 95% CI, 0.39 to 0.97), and neonatal death (RR, 0.5; 95% CI, 0.28 to 0.89). However, no differences were noted

in maternal complications between the two groups. Thus **the data support the use of steroids to reduce neonatal complications in women with severe PE at 34 weeks' gestation or less.**

### Recommended Management of Preeclampsia With Severe Features

**The presence of severe disease mandates immediate hospitalization in labor and delivery. IV magnesium sulfate is begun to prevent convulsions, and antihypertensive medications are administered to lower severe levels of hypertension (systolic pressure  $\geq 160$  mm Hg and/or diastolic pressure  $\geq 110$  mm Hg). The aim of antihypertensive therapy is to keep the systolic pressure between 140 and 155 mm Hg and the diastolic pressure between 90 and 105 mm Hg. During the observation period, maternal and fetal conditions are assessed, and a decision is made regarding the need for delivery (see Fig. 31-11). Those with a gestational age of 24 to 34 weeks are given corticosteroids to accelerate fetal lung maturity. Maternal evaluation includes monitoring of BP, intake and urine output, cerebral status, and the presence of persistent severe epigastric pain, tenderness, labor, or vaginal bleeding. Laboratory evaluation includes a platelet count, liver enzymes, and serum creatinine. Fetal evaluation includes continuous fetal heart monitoring, a BPP, and ultrasound assessment of fetal growth and AFV. Patients with resistant severe hypertension despite maximal doses of IV labetalol (300 mg within an hour) plus maximum doses of hydralazine (25 mg) or oral rapid-acting nifedipine (50 mg) or persistent cerebral symptoms while on magnesium sulfate are delivered irrespective of gestational age.**

After the initial evaluation, the need for immediate delivery versus the potential neonatal benefit and the relative maternal and fetal risks of expectant management should be determined.<sup>33</sup> Women who develop eclampsia, pulmonary edema, or documented or suspected placental abruption; those with DIC or moderate to severe renal dysfunction (serum creatinine  $\geq 1.5$  mg/dL); and those with gestational age less than 23<sup>0/7</sup> weeks' gestation should be delivered after maternal stabilization. In addition, those with a nonreassuring FHR tracing (repetitive decelerations) and those with a persistent BPP of 4 or less should be delivered promptly.<sup>33</sup> Women with a fetus between 23<sup>0/7</sup> and 23<sup>6/7</sup> weeks should receive extensive counseling about the minimal neonatal benefit and high maternal complications from expectant management, and treatment should be individualized.

**For pregnancies at 24<sup>0/7</sup> weeks or greater without any indication for prompt delivery, corticosteroids are administered to accelerate fetal lung maturity.<sup>33</sup> With a gestational age between 33<sup>0/7</sup> to 33<sup>6/7</sup> weeks, severe FGR with absent or reversed umbilical artery diastolic flow, largest amniotic fluid**

vertical pocket less than 2 cm, preterm labor or premature rupture of the membranes (PROM), HELLP syndrome or partial HELLP syndrome, or persistent symptoms—such as headaches, visual changes, epigastric or right upper quadrant pain, nausea, or vomiting—the fetus should be delivered no later than 24 hours after the last dose of corticosteroids. These gravidas should remain on magnesium sulfate with continuous monitoring of uterine contractions and FHR until delivery.

Women with a pregnancy between 24<sup>0/7</sup> and 32<sup>6/7</sup> weeks' gestation with stable maternal and fetal conditions during the initial 24-hour observation period are considered candidates for expectant management (see Fig. 31-11). In these women, magnesium sulfate is generally discontinued after 24 hours with transfer to a high-risk antepartum floor for close observation. Because of the potential for rapid deterioration in maternal and fetal conditions during expectant management, these women should generally be managed in a tertiary care hospital with adequate maternal and neonatal intensive care facilities. They should be cared for in consultation with a maternal-fetal medicine specialist, and the mother should receive counseling from a neonatologist.<sup>33</sup>

Oral antihypertensive medications are used as needed to keep systolic BP between 140 and 155 mm Hg and diastolic BP between 90 and 105 mm Hg.<sup>33</sup> Oral labetalol and oral calcium channel blockers (nifedipine or nicardipine) have been commonly used in reported studies. **My regimen consists of an initial dose of labetalol of 200 mg every 8 hours to be increased up to 800 mg every 8 hours (600 to 2400 mg/day) as needed. If the maximal dose is inadequate to achieve the desired BP goal, short-acting oral nifedipine is added with an initial dose of 10 mg every 6 hours and is subsequently increased up to 20 mg every 4 hours (40 to 120 mg/day).** An alternative regimen may include the long-acting (XL) version of nifedipine (30 to 60 mg) every 8 hours. During titration of oral antihypertensive agents, if the patient has persistent severe hypertensive episodes (systolic BP  $\geq 160$  mm Hg and/or diastolic BP  $\geq 105$  mm Hg), BP should be assessed every 15 minutes. If the BP remains in the severe range after 60 minutes, the patient should be transferred to the labor and delivery unit for more intensive monitoring and treatment with IV medications such as hydralazine or labetalol. **Patients with resistant severe hypertension after maximal doses of IV hydralazine (25 mg) or labetalol (300 mg) should receive magnesium sulfate and be delivered. In addition, patients who develop persistent severe hypertension despite combined maximal doses of oral labetalol (2400 mg/day) plus short-acting nifedipine (120 mg/day) or nifedipine XL (180 mg/day) should also be considered for delivery.**

Maternal assessment includes frequent evaluation of symptoms such as new onset of severe headaches that do not respond to repeated doses of analgesics, blurred or double vision or inability to see, confusion, persistent nausea, vomiting, epigastric or right upper quadrant pain, shortness of breath, uterine activity, and vaginal bleeding. In addition, intake and output should be closely monitored.<sup>33</sup>

Laboratory assessment includes daily testing of the CBC with platelet count, transaminases, LDH, and serum creatinine levels.<sup>32</sup> Coagulation studies are obtained only if thrombocytopenia or suspicion of abruption is present.

Fetal assessment includes daily fetal kick counts, at least daily NST with uterine activity monitoring with a BPP if the NST

is nonreactive, and twice-weekly amniotic fluid assessment (see Chapter 11).<sup>33</sup> Ultrasound assessment of fetal growth is performed every 2 weeks.<sup>33</sup> Severe oligohydramnios (largest vertical pocket  $< 2$  cm) is considered an indication for delivery in women with a gestational age of more than 30 weeks irrespective of other fetal testing results. In those at 30 weeks or less of gestation, pregnancy may be continued with a reassuring NST, BPP, and umbilical artery Doppler studies. Umbilical artery Doppler studies are performed weekly, and they should be done more often when FGR is suspected or when testing reveals abnormal diastolic flow or severe oligohydramnios. If umbilical artery diastolic flow is absent, Doppler studies should be performed daily.

**In general, most patients with preeclampsia without severe features managed expectantly will require delivery within 2 weeks, but some patients may continue their pregnancies for several weeks. It is important to emphasize that this therapy is appropriate only in a select group of patients and should be undertaken in a facility with adequate maternal and neonatal intensive care facilities.** Once the decision is made for delivery, magnesium sulfate should be administered in labor and for at least 24 hours postpartum.<sup>33</sup>

### Intrapartum Management

The goals of management of women with gestational hypertension-preeclampsia are early detection of FHR abnormalities and progression from mild to severe disease and prevention of maternal complications. Pregnancies complicated by PE, particularly those with severe disease or FGR, are at risk for reduced fetal reserve and placental abruption.<sup>2</sup> Therefore women with PE should receive continuous monitoring of FHR and uterine activity. The presence of uterine tachysystole or recurrent FHR decelerations may be the first sign of placental abruption in these women.

**Some women with GH-PE progress to severe disease as a result of changes in cardiac output and stress hormones during labor.** Therefore women with GH-PE should have BP recordings every hour and should be assessed for symptoms suggestive of severe disease. Those who develop severe hypertension or symptoms should be managed as patients with PE with severe features.

Maternal pain relief during labor and delivery can be provided by either systemic opioids or segmental epidural anesthesia. **Epidural analgesia is considered to be the preferred method of pain relief in women whose GH and PE are nonsevere.** Although no unanimity of opinion exists regarding the use of epidural anesthesia in women with PE with severe features, evidence suggests that epidural anesthesia is also safe in these women. A randomized trial of 116 women with severe PE who received either epidural analgesia or patient-controlled analgesia (PCA) reported no differences in cesarean delivery rates, and the group who received epidural had significantly better pain relief during labor.

The use of either epidural, spinal, or combined techniques of regional anesthesia is considered by most obstetric anesthesiologists to be the method of choice during cesarean delivery. **In women with PE with severe features, general anesthesia carries the risk for aspiration and failed intubation owing to airway edema, and it is associated with marked increases in systemic and cerebral pressures during intubation and extubation.**<sup>1</sup> Women with airway or laryngeal edema may require awake intubation under fiberoptic observation with the availability of immediate tracheostomy. Changes in systemic

**FIG 31-12** Retinal ischemia and injury in severe preeclampsia. **A**, Scattered, yellowish opaque lesions of the retinal pigment epithelium. **B**, Fluorescein angiograms showing patchy delayed filling of the choriocapillaris.

and cerebral pressures may be attenuated by pretreatment with labetalol or nitroglycerine injections. It is important to recognize that regional anesthesia is contraindicated in the presence of coagulopathy or severe thrombocytopenia (platelet count  $<50,000/\text{mm}^3$ ).

### Prevention of Eclamptic Seizures

**Magnesium sulfate is the drug of choice to prevent convulsions in women with preeclampsia. The results of recent randomized trials revealed that magnesium sulfate is superior to placebo or no treatment for prevention of convulsions in women with PE with severe features.** The overall results of these four trials demonstrate that magnesium sulfate prophylaxis, compared with placebo (two trials, 10,795 women), nimodipine (one trial, 1750 women), and no treatment (one trial, 228 women) in severe PE is associated with a significantly lower rate of eclampsia (RR, 0.39; 95% CI, 0.28 to 0.55). Results from one of the largest randomized trials to date, that of 10,141 women with PE in 33 nations (largely in the Third World), has been recently reported. Almost all the enrolled patients had severe disease by U.S. standards: 50% received antihypertensives before randomization, 75% received antihypertensives after randomization, and the remainder had severe PE or imminent eclampsia. Among all enrolled women, the rate of eclampsia was significantly lower in those assigned to magnesium sulfate (0.8% vs. 1.9%; RR, 0.42; 95% CI, 0.29 to 0.60). However, among the 1560 women enrolled in the western world, the rates of eclampsia were 0.5% in the magnesium group versus 0.8% with placebo, a difference that was not significant (RR, 0.67; 95% CI, 1.19 to 2.37).

Two randomized placebo-controlled trials evaluated the efficacy and safety of magnesium sulfate in women with mild PE. One of these trials included 135 women, and the other included only 222 women. No instances of eclampsia were reported in either group in both of these trials. In addition, **the findings of both studies revealed that magnesium sulfate does not affect either the duration of labor or the rate of cesarean delivery.** However, neither of these studies had an adequate sample size to address the efficacy of magnesium sulfate to prevent convulsions. Therefore **whether magnesium sulfate treatment benefits women with mild PE remains unclear.**

### Control of Severe Hypertension

The objective of treating acute and sustained severe hypertension that lasts more than 60 minutes is to prevent cerebrovascular

and cardiovascular complications such as encephalopathy, hemorrhage, and congestive heart failure (CHF) and to prevent retinal injury (Fig. 31-12).<sup>1,2</sup> For ethical reasons, no randomized trials have been done to determine the level of hypertension to treat in order to prevent these complications. Antihypertensive therapy is recommended by some for sustained systolic BP values of 160 mm Hg or more and for sustained diastolic values of 110 mm Hg or more. Some experts recommend treating diastolic levels of 105 mm Hg, and still others use a mean arterial BP of 130 mm Hg or more.<sup>1,2</sup> The definition of *sustained hypertension* is not clear and ranges from 30 minutes to 2 hours.

**I recommend that antihypertensive medications are indicated with sustained elevations in systolic BP to levels of 160 mm Hg or greater and/or when diastolic BP is 105 mm Hg or higher for at least 60 minutes.**<sup>33</sup> If the desired target of BP level is not achieved after maximum doses of IV medications are used, I recommend the insertion of an arterial line with the initiation of a continuous IV administration of medications such as nicardipine, nitroprusside, labetalol or nitroglycerine. This may require admitting the patient to an intensive care facility. Several antihypertensive medications can be used to treat severe hypertension in PE. The most commonly recommended medications include IV bolus doses of hydralazine, bolus doses of labetalol, or oral nifedipine (rapid-acting tablets or long-acting capsules). Other antihypertensive medications recommended for treatment of severe hypertension have included IV nicardipine and mini boluses of diazoxide.

Despite the extensive literature on the subject, it remains unclear which is the ideal antihypertensive medication to use in the acute control of hypertension in women with severe PE. The results of a recent meta-analysis of relevant randomized trials found that parenteral hydralazine was associated with more adverse effects compared with other antihypertensives; however, such a finding was not confirmed in a recent large randomized trial. **Based on the available evidence, hydralazine, labetalol, or nifedipine can be used to treat severe hypertension in PE.**<sup>2,3,33</sup> **The provider should be familiar with the dosage to be used, the expected response, and potential side effects of each of these drugs.** Both hydralazine and nifedipine are associated with tachycardia and headaches and thus are not the first drugs of choice in patients with a heart rate above 100 beats/min. In such case, labetalol is preferred. Labetalol, however, should be avoided in patients with moderate to severe asthma, bradycardia (heart rate  $<60$  beats/min), and in those with CHF. Compared with other antihypertensive medications, nifedipine

has the advantage of increased renal blood flow with an associated increase in urine output.<sup>33</sup> Thus it may be the drug of choice in those with decreased urine output and for treatment of severe hypertension in the postpartum period.<sup>33</sup> In the past, there has been a theoretic concern that the combined use of magnesium sulfate and nifedipine in patients with severe PE can result in excessive hypotension and neuromuscular blockade. However, a recent review on this subject found that therapy with both magnesium sulfate and nifedipine does not increase the risk for the previously described complications in women with PE. Nevertheless, if neuromuscular blockade develops in these patients, this can be easily reversed by the administration of 1 g of IV calcium gluconate.

**For the treatment of severe hypertension in pregnancy, the recommended dosage is IV hydralazine given as bolus injections of 5 to 10 mg every 20 minutes for a maximal dose of 25 mg in 60 minutes. The recommended dose of labetalol is 20 to 80 mg intravenously every 10 minutes for a maximal dose of 300 mg; and the dosage of nifedipine is 10 to 20 mg orally every 20 minutes for a maximal dose of 50 mg within 60 minutes.**<sup>33</sup> Sustained BP values of 160 mm Hg systolic or more or 105 to 110 mm Hg diastolic or more for at least 60 minutes require therapy intrapartum. It is important to emphasize that BP recordings during labor that utilize electronic equipment may not be reliable for lack of a standardized cuff position and for the effects of labor and pain. Therefore BP recordings should be accurately measured and then confirmed with a sphygmomanometer prior to the use of acute IV medications to treat severe sustained systolic hypertension. For women with severe thrombocytopenia and sustained systolic values greater than 150 mm Hg or diastolic readings greater than 100 mm Hg are the recommended thresholds for therapy.<sup>33</sup> **For this author, the first-line agent is IV labetalol, and if maximal doses are ineffective, hydralazine can be added. Oral nifedipine is my first choice in the postpartum period.**

### Mode of Delivery

No randomized trials have compared the optimal method of delivery in women with GH-PE. A plan for vaginal delivery should be attempted in all women with disease without other indications for cesarean delivery and in most women with severe disease, particularly those beyond 30 weeks' gestation.<sup>1,2,17</sup> The decision to perform a cesarean delivery should be based on gestational age, fetal condition, presence of labor, and cervical Bishop score. In general, the presence of PE with severe features is not an indication for cesarean delivery per se.

**No randomized trials have compared the optimal methods of delivery in patients with severe hypertension or severe PE.** The method for delivery will depend on gestational age, cervical Bishop score, and fetal condition. The cesarean delivery rate among reported studies<sup>33</sup> in patients as less than 34 weeks' gestation ranged from 66% to 96% with the higher rates for patients with onset prior to 28 weeks' gestation. This high cesarean delivery rate is expected considering that a deterioration in either fetal or maternal condition is the indication for delivery during expectant management (high rates of severe FGR, oligohydramnios, nonreassuring fetal status, abnormal presentation, and maternal complications).<sup>33</sup> Thus, a very small percentage of these patients will be considered candidates for medical induction of labor.

Several retrospective studies have evaluated induction of labor in patients with PE before 34 weeks' gestation and absent any

contraindication for induction. However, most of the women included in these studies had a gestational age beyond 32 weeks at the time of induction, and only two of these studies included data on patients earlier than 28 weeks undergoing induction of labor.<sup>33</sup> Both of these studies reported a cesarean delivery rate above 95% and thus recommended elective cesarean delivery in such patients.

**In general, the decision to perform a cesarean delivery versus a trial of labor in such patients should be individualized and based on one or more of the following factors: fetal gestational age, fetal presentation, presence or absence of severe FGR, oligohydramnios, results of umbilical artery Doppler, BPP, FHR monitoring, presence of labor, and cervical Bishop score. On the basis of the available data, we recommend cesarean delivery for all women with a gestation of less than 28 weeks and for those with severe FGR, severe oligohydramnios, BPP of 4 or less, or reverse umbilical artery Doppler flow at less than 32 weeks of gestation.**

### Postpartum Management

During the immediate postpartum period, women with PE should receive close monitoring of BP and of symptoms consistent with severe disease, and accurate measurements of fluid intake and urinary output should be obtained.

These women often receive large amounts of IV fluids during labor as a result of prehydration before the administration of epidural analgesia, and IV fluids are given during the administration of oxytocin and magnesium sulfate in labor and postpartum. In addition, during the postpartum period, mobilization of extracellular fluid leads to increased intravascular volume. As a result, **women with severe PE—particularly those with abnormal renal function, capillary leak, or early-onset disease—are at increased risk for pulmonary edema and exacerbation of severe hypertension postpartum. Careful evaluation of the volume of IV fluids, oral intake, blood products, and urine output are advised in addition to monitoring by pulse oximetry and chest auscultation.**<sup>2,33</sup>

In general, most women with GH become normotensive during the first week postpartum.<sup>1,2</sup> In contrast, in women with PE, hypertension often takes longer to resolve. In addition, in some women with PE, an initial decrease in BP is seen immediately postpartum, followed by development of hypertension again between days 3 and 6. Moreover, a recent study found that resolution of hypertension and proteinuria may take up to 1 year postpartum. Oral antihypertensive drug treatment is recommended if the systolic BP is at least 150 mm Hg or if the diastolic BP is at least 100 mm Hg. Various agents may be used. A common regimen is to prescribe oral nifedipine, 10 mg every 6 hours, or long-acting nifedipine.<sup>33</sup> If the BP is well controlled and maternal symptoms are absent, the woman is discharged home with instructions for daily BP measurements by a home-visiting nurse for the first week postpartum or longer if necessary. Antihypertensive medications are discontinued if the BP remains below the hypertensive levels for at least 24 hours. Recently, some authors have suggested that 5 days of oral furosemide therapy (20 mg/dL) enhances recovery and reduces the need for antihypertensive therapy in women with severe disease.

**Severe hypertension or PE with severe features may develop for the first time during the postpartum period. Hence, postpartum women should be educated about the signs and**

symptoms of severe hypertension or PE. These women are at increased risk for eclampsia, pulmonary edema, stroke, and thromboembolism. Therefore medical providers and personnel who respond to patient phone calls should be educated and instructed about symptoms of severe postpartum hypertension. Women who have persistent new-onset severe headaches that do not respond to maximum doses of analgesics or who have persistent severe visual changes or new-onset epigastric pain with nausea or vomiting and those with sustained severe hypertension require evaluation and potential hospitalization. Some women may require magnesium sulfate for at least 24 hours and antihypertensive therapy. If neurologic symptoms exist or the symptoms do not respond to magnesium sulfate and lowering of maternal BP, brain imaging is undertaken to rule out the presence of cerebral pathology.

### Maternal and Perinatal Outcomes With Preeclampsia

Maternal and perinatal morbidity is substantially increased in women with severe GH. Indeed, these women have higher morbidity rates than women with mild preeclampsia.<sup>19</sup> In addition, the rates of placental abruption, preterm delivery (at less than 37 and 35 weeks), and rates of SGA infants in these pregnancies are similar to those observed in women with PE with severe features. However, whether this increase in rate of preterm delivery is a result of early delivery chosen by the physician or because of the disease process itself remains unknown. Therefore these women should be managed as if they had severe PE.<sup>33</sup>

**Maternal and perinatal outcomes in PE are usually dependent on one or more of the following four factors: (1) gestational age at onset of PE and at the time of delivery, (2) the severity of the disease process, (3) the presence of multifetal gestation, and (4) the presence of preexisting medical conditions such as pregestational diabetes, renal disease, or thrombophilias.**

PE with severe features is also associated with an increased risk for maternal mortality (0.2%) and increased rates of maternal morbidity (5%), such as convulsions, pulmonary edema, retinal ischemia and injury (see Fig. 31-12), acute renal or liver failure, liver hemorrhage, DIC, and stroke. These complications are usually seen in women who develop PE before 32 weeks' gestation and in those with preexisting medical conditions.

### Counseling Women Who Have Had Preeclampsia in Prior Pregnancies

We examined the pregnancy outcomes and incidences of PE in subsequent pregnancies and the frequency of chronic hypertension and diabetes mellitus in women who had severe PE (287 women) or eclampsia (119 women) in their first pregnancies (aged 11 to 25 yr) compared with 409 women (aged 12 to 25 yr) who remained normotensive during their first pregnancies. Each woman had at least one subsequent pregnancy (range, 1 to 11) and was followed for a minimum of 2 years (range, 2 to 24). **No significant difference was reported in the incidences of diabetes mellitus in the two groups (1.3% vs. 1.5%), but the incidence of chronic hypertension was significantly higher in the PE patients (14.8% vs. 5.6%;  $P < .001$ ). This difference became even greater for women followed more than 10 years (51% vs. 14%;  $P < .001$ ). The incidence of severe PE was also significantly higher in the second pregnancies (25.9% to 4.6%) and in the subsequent pregnancies (12.2% to 5.0%) of women with PE.**

In a later report, subsequent pregnancy outcome and long-term prognosis were studied in 108 women who had **severe PE in the second trimester**. These women were followed for a minimum of 2 years (range, 2 to 12 years) and had a total of 169 subsequent pregnancies. Fifty-nine subsequent pregnancies (35%) were normotensive, and 110 (65%) were complicated by PE. **Overall, 21% of all subsequent pregnancies were complicated by severe PE in the second trimester.** In addition, these women had a higher risk for developing chronic hypertension; the highest incidence was in those who had recurrent severe PE in the second trimester (55%).

Hnat and associates<sup>23</sup> reported subsequent pregnancy outcome in women with previous PE enrolled in a multicenter trial. The rate of recurrent PE was 17%. The authors also noted that these women had a high rate of severe PE and poor perinatal outcome. In addition, even in those who remained normotensive in their subsequent pregnancy, the likelihood of adverse pregnancy outcome (preterm delivery, SGA infants, and perinatal death) was greater.

Some women with PE remote from term may have placental abruption. The risk for this complication is increased significantly in those with PE before 34 weeks' gestation and particularly in those who have PE in the second trimester. **For women with PE complicated by placental abruption, the risk for abruption in subsequent pregnancies ranges from 5% to 20%.**

Pregnancy outcome and long-term prognosis were studied in 37 women with PE complicated by pulmonary edema, and 18 of these women had subsequent pregnancies. Ten of the 18 were normotensive, 4 were complicated by chronic hypertension, and 4 were had PE; 1 of the latter women also had pulmonary edema.

Pregnancy outcome and remote prognosis were also studied in 18 women with severe PE complicated by acute renal failure. All 18 had acute tubular necrosis, 9 of whom required dialysis, and 2 died within 8 weeks after birth. All women had serial evaluation of renal function, urine microscopic testing, and electrolyte studies at the onset of acute renal failure and during follow-up. All 16 surviving patients had normal renal function on long-term follow-up (average, 4 years). Four of the 16 women had seven subsequent pregnancies: one ended in miscarriage, one was complicated by PE at 35 weeks, and five were term pregnancies without complications.

**Women with a history of HELLP syndrome are at increased risk for all forms of PE in subsequent pregnancies (Table 31-15). In general, the rate of PE in subsequent pregnancies is about 20%, with significantly higher rates if the onset of HELLP syndrome is during the second trimester. The rate of recurrent HELLP syndrome ranges from 2% to 19%, and the most reliable data suggest a recurrence risk of less than 5%.** This lower rate of 5% has been recently confirmed by the results of a systemic review. Because of the previously mentioned risks, these women are informed that they are at increased risk for adverse pregnancy outcomes (preterm delivery, FGR, placental abruption, and fetal death) in subsequent pregnancies and therefore require close monitoring during subsequent gestations. At present, **no preventive therapy is available for recurrent HELLP syndrome.** Case series describe subsequent pregnancy outcomes in women with previous ruptured liver hematomas. We have followed three such women through four subsequent pregnancies without complications. Other authors have reviewed the literature and have reported on several such women, who

Modified from Sibai BM. Diagnosis, controversies, and management of HELLP syndrome. *Obstet Gynecol.* 2004;103:981.

\*HELLP (hemolysis, elevated liver enzymes, and low platelets) at 28 weeks' or less in a previous pregnancy.

had subsequent uneventful pregnancies under close maternal and fetal observation.

Liver function tests were studied in 54 women at a median of 31 months (range, 3 to 101 months) after pregnancies complicated by the HELLP syndrome. Serum levels of AST, LDH, and conjugated bilirubin were found to be normal. However, total bilirubin levels were elevated in 11 (20%) of the studied women. The authors of this report suggested the possibility that a dysfunction of the bilirubin-conjugating mechanism represents a risk factor for the development of this syndrome.

Two reports describe long-term renal function after HELLP syndrome. One of the reports included 23 patients whose pregnancies were complicated by HELLP syndrome and acute renal failure: 8 of these women had 11 subsequent pregnancies, 9 of which resulted in term gestation. All 23 women also had normal BP and renal function at an average follow-up of 4.6 years (range, 0.5 to 11 years). The other study compared renal function after at least 5 years after HELLP syndrome in 10 patients with the respective findings in 22 patients with previous normotensive gestation. No differences were reported in renal function tests between the two groups. These findings suggest that the development of HELLP syndrome with or without renal failure does not affect long-term renal function.

### Remote Prognosis

Women with PE should also be counseled regarding future cardiovascular risks and risks for underlying renal disease. **Evidence suggests that women with PE remote from term are at particular increased risk for chronic hypertension later in life.** In addition, these patients—particularly those with recurrent PE—are more likely to have underlying renal disease. In a recent report, 86 Japanese women who had severe hypertension, severe proteinuria, or both during pregnancy had a postpartum renal biopsy. The authors found that women who had gestational proteinuria or PE before 30 weeks' gestation were more likely to have had underlying renal disease.

Several recent studies suggested that women who develop PE may be at increased risk for coronary artery disease later in life. Indeed, many of the risk factors and pathophysiologic abnormalities of PE are similar to those of coronary artery disease. Ramsey and associates demonstrated for the first time, using laser Doppler imaging in vivo, impaired microvascular function in women 15 to 25 years of age following a pregnancy complicated by PE. Thus microvascular dysfunction, which is associated with insulin resistance, may be a predisposing vascular mechanism for both coronary heart disease and PE. In addition, pregnancies complicated by PE are at increased risk for stroke later in life. **Therefore pregnancies complicated by PE may identify women at risk for vascular disease in later life and may provide the opportunity for lifestyle and risk-factor modification to alter their risk for complications.**

### ECLAMPSIA

**Eclampsia is the occurrence of convulsions or coma unrelated to other cerebral conditions with signs and symptoms of preeclampsia.** Early writings of both the Egyptians and Chinese warned of the dangers of convulsions encountered during pregnancy. Hippocrates noted that headaches, convulsions, and drowsiness were ominous signs associated with pregnancy. The term *eclampsia* appeared in a treatise on gynecology written by Varandaeus in 1619. Clonic spasms in association with pregnancy were described by Pew in 1694. In 1772, De la Motte recognized that prompt delivery of pregnant women with convulsions favored their recovery.

**Eclampsia is defined as the development of convulsions or unexplained coma during pregnancy or postpartum in patients with signs and symptoms of PE.** In the western world, the reported incidence of eclampsia ranges from 1 in 2000 to 1 in 3448 pregnancies. The reported incidence is usually higher in tertiary referral centers, with multifetal gestation, and in those without prenatal care.<sup>12</sup>

### Pathophysiology

The pathogenesis of eclamptic convulsions continues to be the subject of extensive investigation and speculation. Several theories and pathologic mechanisms have been implicated as possible etiologic factors, but none of these has been proved conclusively. It is not clear whether the pathologic features in eclampsia are a cause or an effect of the convulsions.<sup>86</sup>

### Diagnosis

**The diagnosis of eclampsia is secure in the presence of generalized edema, hypertension, proteinuria, and convulsions. However, women in whom eclampsia develops exhibit a wide spectrum of signs that range from severe hypertension, severe proteinuria, and generalized edema to absent or minimal hypertension, no proteinuria, and no edema.**<sup>86</sup> Hypertension is considered the hallmark for the diagnosis of eclampsia. The hypertension can be severe ( $\geq 160$  mm Hg systolic or  $\geq 110$  mm Hg diastolic), as in 20% to 54% of cases,<sup>16,86</sup> or it can be mild (systolic BP between 140 and 160 mm Hg or diastolic BP between 90 and 110 mm Hg), as in 30% to 60% of cases.<sup>12,86</sup> However, in 16% of cases, hypertension may be absent.<sup>16</sup> In addition, severe hypertension is more common in patients who develop antepartum eclampsia (58%) and in those who develop eclampsia at 32 weeks' gestation or later (71%).<sup>16</sup> Moreover, hypertension is absent in only 10% of women who develop eclampsia at or before 32 weeks' gestation.<sup>16</sup>

**The diagnosis of eclampsia is usually associated with proteinuria** (at least 1+ on a dipstick).<sup>16,86</sup> In a series of 399 women with eclampsia, substantial proteinuria ( $\geq 3+$  on a dipstick) was present in only 48% of the cases, whereas proteinuria was absent in 14% of the cases.<sup>16</sup> Abnormal weight gain in excess of 2 lb/

wk (with or without clinical edema) during the third trimester might be the first sign before the onset of eclampsia. However, edema was absent in 26% of 399 eclamptic women studied.<sup>16</sup>

Several clinical symptoms are potentially helpful in establishing the diagnosis of eclampsia. These include persistent occipital or frontal headaches, blurred vision, photophobia, epigastric or right upper quadrant pain, and altered mental status. Women had at least one of these symptoms in 59% to 75% of the cases (Table 31-16). Headaches are reported by 50% to 75% of patients, whereas visual changes are reported in 19% to 32% of patients.<sup>86</sup> These symptoms may occur before or after the onset of convulsions.<sup>86</sup>

Time of Onset of Eclampsia

The onset of eclamptic convulsions can be during the antepartum, intrapartum, or postpartum period. The reported frequency of antepartum convulsions among recent series has ranged from 38% to 53% (Table 31-17),<sup>16</sup> whereas the frequency of postpartum eclampsia has ranged from 11% to 44%.<sup>16</sup> Although most cases of postpartum eclampsia occur within the first 48 hours, some cases can develop beyond 48 hours postpartum and have been reported as late as 23 days postpartum.<sup>16</sup> In the latter cases, an extensive neurologic evaluation may be required to rule out the presence of other cerebral pathology.<sup>86</sup>

Almost all cases of eclampsia (91%) develop in the third trimester (≥28 weeks).<sup>16</sup> The remaining cases occur between 21 and 27 weeks' gestation (7.5%) or at or before 20 weeks' gestation (1.5%).<sup>16</sup> Eclampsia that occurs before the twentieth week of gestation is generally associated with molar or hydropic degeneration of the placenta with or without a coexistent fetus.<sup>32,86</sup> Although rare, eclampsia can occur during the first half of pregnancy without molar degeneration of the placenta.<sup>32,86</sup> These women may be misdiagnosed as having hypertensive encephalopathy, a seizure disorder, or TTP. Women in whom convulsions develop in association with hypertension and proteinuria during the first half of pregnancy should be

considered to have eclampsia until proved otherwise.<sup>32</sup> These women should have an ultrasound examination to rule out molar pregnancy or hydropic degeneration of the placenta, and they also should have an extensive neurologic and medical evaluation to rule out another pathologic process.

Late postpartum eclampsia is defined as eclampsia that occurs more than 48 hours but less than 4 weeks after delivery. Historically, eclampsia was believed not to occur more than 48 hours after delivery. However, several recent reports have confirmed the existence of late postpartum eclampsia.<sup>86</sup> These women have signs and symptoms consistent with PE in association with convulsions.<sup>32,86</sup> Some women demonstrate a clinical picture of PE during labor or immediately postpartum (56%), whereas others demonstrate these clinical findings for the first time more than 48 hours after delivery (44%). Of interest is the fact that late-postpartum eclampsia developed despite the use of prophylactic magnesium sulfate during labor and for at least 24 hours postpartum in previously diagnosed preeclamptic women.<sup>86</sup> Therefore women in whom convulsions develop in association with hypertension or proteinuria or with headaches or blurred vision after 48 hours of delivery should be considered to have eclampsia and initially treated as such.<sup>32</sup>

Cerebral Pathology

Autoregulation of the cerebral circulation is a mechanism for the maintenance of constant cerebral blood flow during changes in BP, and it may be altered in eclampsia. Through active changes in cerebrovascular resistance at the arteriolar level, cerebral blood flow normally remains relatively constant when cerebral perfusion pressure ranges between 60 and 120 mm Hg. In this normal range, vasoconstriction of cerebral vessels occurs in response to elevations in BP, whereas vasodilation occurs as BP is lowered. Once cerebral perfusion pressure exceeds 130 to 150 mm Hg, however, the autoregulatory mechanism fails. In extreme hypertension, the normal compensatory vasoconstriction may become defective, and cerebral blood flow increases. As a result, segments of the vessels become dilated, ischemic, and increasingly permeable. Thus exudation of plasma occurs and gives rise to focal cerebral edema and compression of the vessels, which results in a decreased cerebral blood flow.<sup>86</sup> Hypertensive encephalopathy, a possible model for eclampsia, is an acute clinical condition that results from abrupt severe hypertension and subsequent significant increases in intracranial pressure. Because this is an acute disturbance in the hemodynamics of cerebral arterioles, morphologic changes in anatomy may not be uniformly evident in pathologic material. Several autopsy findings that are relatively constant include cerebral swelling and fibrinoid necrosis of vessel walls.

The cause of eclampsia is unknown, and many questions regarding the pathogenesis of its cerebral manifestations remain unanswered. Cerebral pathology in cortical and subcortical

white matter in the form of edema, infarction, and hemorrhage (microhemorrhage and intracerebral parenchymal hemorrhage) is a common autopsy finding in patients who die of eclampsia. However, although autopsy series provide information regarding the central nervous system (CNS) abnormality in patients who die of eclampsia, this information is not necessarily indicative of the CNS abnormality present in most patients who survive this condition.<sup>86</sup> The diagnosis of eclampsia is not dependent on any single clinical or diagnostic neurologic findings. Focal neurologic signs such as hemiparesis or an unconscious state are rare in cases of eclampsia reported from countries in the developed world.<sup>86</sup> **Although eclamptic patients may initially manifest a variety of neurologic abnormalities—including cortical blindness, focal motor deficits, and coma—fortunately, most have no permanent neurologic deficits.**<sup>16,86</sup> These neurologic abnormalities are probably due to a transient insult, such as hypoxia, ischemia, or edema.

Several neurodiagnostic tests—such as electroencephalography (EEG), CT, cerebral Doppler velocimetry, MRI, and cerebral angiography (both traditional and MRI angiography)—have been studied in women with eclampsia. In general, the EEG is acutely abnormal in most eclamptic patients; however, these abnormalities are not pathognomonic of eclampsia. In addition, the abnormal EEG findings are not affected by the use of magnesium sulfate. Moreover, lumbar puncture is not helpful in the diagnosis and management of eclamptic women. The results of CT and MRI studies reveal the presence of edema and infarction within the subcortical white matter and adjacent gray matter mostly in the parietooccipital lobes (Box 31-10). Cerebral angiography and Doppler velocimetry suggest the presence of vasospasm.

On the basis of cerebral imaging findings, attention has been directed to hypertensive encephalopathy as a model for the CNS abnormalities in eclampsia. The two conditions share many clinical, radiologic, and pathologic features. Normal cerebral blood flow autoregulation fails in patients with hypertensive encephalopathy and in some patients with eclampsia.<sup>86</sup> **Two theories have been proposed to explain these cerebral abnormalities, forced dilation and vasospasm,<sup>86</sup> and the forced dilation theory suggests that the lesions in eclampsia are caused by loss of cerebrovascular autoregulation.**

Recently, MRI and apparent diffusion coefficient mapping were used to characterize the relative frequency of vasogenic and cytotoxic edema in two small series of eclamptic women; cerebral edema (mostly vasogenic) was present in up to 93% to 100%. However, concurrent foci of infarction evidenced by

reduced apparent diffusion coefficient (restricted diffusion) were present in 6 of 27 eclamptic women studied by Zeeman and colleagues and in 3 of 17 eclamptic and preeclamptic women studied by Loureiro and associates. In addition, 5 of the 6 women reported by Zeeman and colleagues had persistent abnormalities on repeat MRI testing 6 to 8 weeks later, which suggests these lesions might not be reversible. Moreover, 4 of the 17 women reported by Loureiro and associates had persistent MRI abnormalities at a median of 8 weeks of follow-up.

**In summary, cerebral imaging findings in eclampsia are similar to those found in patients with hypertensive encephalopathy.** The classic findings are referred to as *posterior reversible encephalopathy syndrome* (PRES); Figure 31-13 demonstrates such a lesion. This syndrome is also seen in patients with reversible cerebral vasoconstriction syndrome and is usually seen in patients who present in the postpartum period with signs and symptoms similar to eclampsia. The diagnosis is confirmed by angiogram (Fig. 31-14). **Cerebral imaging is not necessary for the diagnosis and management of most women with eclampsia; however, it is indicated for patients with focal neurologic deficits or prolonged coma. In these patients, hemorrhage and other serious abnormalities that require specific pharmacologic therapy or surgery must be excluded. Cerebral imaging may also be helpful in patients who have an atypical presentation for eclampsia** (onset before 20 weeks' gestation or more than 48 hours after delivery and eclampsia refractory to adequate magnesium sulfate therapy). Advances in MRI and magnetic resonance angiography (MRA), as well as in cerebral vascular Doppler velocimetry, may aid our understanding regarding the pathogenesis and may improve long-term outcome of this condition.<sup>86</sup>

### Differential Diagnosis

The presenting symptoms, clinical findings, and many of the laboratory findings overlap with a number of medical and

#### BOX 31-10 REPORTED COMPUTED TOMOGRAPHY SCAN AND MAGNETIC RESONANCE IMAGING FINDINGS IN COMPLICATED ECLAMPSIA

- Diffuse white matter low-density areas
- Patchy areas of low density
- Occipital white matter edema
- Loss of normal cortical sulci
- Reduced ventricular size
- Acute hydrocephalus
- Cerebral hemorrhage
  - Intraventricular hemorrhage
  - Parenchymal hemorrhage (high density)
- Cerebral infarction
  - Low-attenuation areas
  - Basal ganglia infarctions

#### BOX 31-11 DIFFERENTIAL DIAGNOSIS OF ECLAMPSIA

- Hypertensive encephalopathy
- Seizure disorder
- Hypoglycemia, hyponatremia
- Posterior reversible encephalopathy syndrome (PRES; see Fig. 31-13)
- Thrombotic thrombocytopenic purpura
- Postdural puncture syndrome
- Vasculitis, angiopathy
- Amniotic fluid embolism
- Cerebrovascular accident
- Hemorrhage
- Ruptured aneurysm or malformation
- Arterial embolism, thrombosis
- Cerebral venous thrombosis
- Hypoxic ischemic encephalopathy
- Angiomas

surgical conditions.<sup>32</sup> For convulsions that develop in association with hypertension or proteinuria during pregnancy or immediately postpartum, the most common cause is eclampsia. Rarely, other etiologies that produce convulsions in pregnancy or postpartum may mimic eclampsia.<sup>86</sup>

These diagnoses are particularly important in the presence of focal neurologic deficits, prolonged coma, or atypical eclampsia. In addition, in some patients, GH or PE may develop in association with disorders such as connective tissue disease, thrombophilias, seizure disorder, or hypertensive encephalopathy, which further contributes to the diagnostic difficulty. Therefore an effort should be made to identify an accurate diagnosis given that management strategies may differ among these conditions (Box 31-11).

### Maternal and Perinatal Outcome

Eclampsia is associated with a slightly increased risk for maternal death in developed countries (0% to 1.8%),<sup>86</sup> but

the maternal mortality rate may be as high as 14% in developing countries. The high maternal mortality reported from developing countries occurs primarily among patients who have had multiple seizures outside the hospital and those without prenatal care. In addition, this high mortality rate could be attributed to the lack of resources and intensive care facilities needed to manage maternal complications from eclampsia. Of 4024 pregnancy-related deaths reported from 1979 to 1992, a total of 790 (19.6%) were considered to have been caused by PE-eclampsia, and 49% of these 790 were considered to have been related to eclampsia. In this series, the risk for death from PE or eclampsia was higher for women older than 30 years, those without prenatal care, and black women; **the greatest risk for death was found among women with pregnancies at or before 28 weeks' gestation.**

Pregnancies complicated by eclampsia are also associated with increased rates of maternal morbidities such as placental abruption (7% to 10%),<sup>86</sup> DIC (7% to 11%),<sup>86</sup> pulmonary edema (3% to 5%), acute renal failure (5% to 9%), aspiration pneumonia (2% to 3%), and cardiopulmonary arrest (2% to 5%).<sup>86</sup> ARDS and intracerebral hemorrhage are rare complications in series of eclamptic patients reported from the developed world. It is important to note that maternal complications are greatest among women who develop antepartum eclampsia, particularly among those who develop eclampsia remote from term.<sup>86</sup>

Perinatal mortality and morbidity remain high in eclamptic pregnancies. The reported perinatal death rate in recent series ranged from 5.6% to 11.8%.<sup>86</sup> This high perinatal death rate is related to prematurity, placental abruption, and severe FGR.<sup>86</sup> The rate of preterm delivery is about 50%, and about 25% of cases occur before 32 weeks' gestation.<sup>86</sup>

### Is Eclampsia Preventable?

Prevention of eclampsia requires knowledge of its etiology and pathophysiology and of methods to predict patients at high risk for development of convulsions. However, as discussed earlier, the pathogenesis of eclampsia is largely unknown. Prevention of eclampsia can be *primary*, by preventing the development and/or progression of PE, or it can be *secondary*, by using pharmacologic agents that prevent convulsions in women with established PE. Prevention can also be *tertiary*, by preventing subsequent convulsions in women with established eclampsia.

Current management schemes designed to prevent eclampsia are based on early detection of GH or PE and subsequent use of preventive therapy in such women. **Some of the recommended preventive therapies have included close monitoring (in-hospital or outpatient), use of antihypertensive therapy to keep maternal BP below a certain level** (less than severe range or to normal values), **timely delivery, and prophylactic use of magnesium sulfate during labor and immediately postpartum in those considered to have PE.** These management schemes assume that the clinical course in the development of eclampsia is characterized by a gradual process that begins with progressive weight gain, followed by hypertension (mild to severe) and proteinuria, with the subsequent onset of premonitory symptoms, and ending with the onset of generalized convulsions or coma.<sup>86</sup> This clinical course may be present in some women who develop eclampsia in developed countries. However, recent data from large series of eclamptic women from the United States and Europe indicate that about **20% to 40% of eclamptic women do not have any premonitory signs or**

**symptoms before the onset of convulsions.**<sup>16</sup> In many of these cases, the onset of convulsions is abrupt and does not follow an indolent progression from mild to severe disease before the onset of eclampsia.<sup>86</sup>

It is also assumed that appropriate and timely standard preventive therapy will prevent eclampsia in virtually all patients with GH-PE.<sup>86</sup> The efficacy of in-hospital management of patients with GH or PE for the prevention of eclampsia has not been evaluated in randomized trials. Moreover, data from retrospective studies from developed countries indicate that about 50% of eclamptic women develop their first convulsion while in the hospital under “close medical supervision.”<sup>86</sup> Thus early and prolonged hospitalization of women with mild hypertension or PE may not prevent most cases of eclampsia.

Several randomized trials have described the use of antihypertensive drugs versus no treatment or a placebo in the treatment of women with mild hypertension or PE. Overall, these trials revealed lower rates of progression to severe disease. However, the study design and the sample size of these trials is inadequate to evaluate potential benefits regarding prevention of eclampsia.

Prophylactic magnesium sulfate is recommended only for women who are hospitalized with the established diagnosis of PE.<sup>1-3</sup> Its use is recommended only during labor and for 12 to 24 hours' postpartum<sup>1-3</sup>; therefore it can be expected to have a potential effect in preventing eclampsia that develops only during this time (40% of total).

Several randomized trials have compared the efficacy of magnesium sulfate with other anticonvulsive agents for the prevention of recurrent seizures in women with eclampsia. In these trials, **magnesium sulfate was compared with diazepam, phenytoin, and a lytic cocktail. Overall, these trials revealed that magnesium sulfate was associated with a significantly lower rate of recurrent seizures** (9.4% vs. 23.1%; RR, 0.41; 95% CI, 0.32 to 0.51) **and a lower rate of maternal death** (3% vs. 4.8%; RR, 0.62; 95% CI, 0.39 to 0.99) **than that observed with other agents.**

The low incidence of eclampsia in developed countries is probably related to prevention of cases of eclampsia in women with a classic presentation and with a classic progression from mild to severe PE.<sup>86</sup> As a result, most eclamptic cases described in reported series from the United States and Europe have an atypical presentation (abrupt onset, development of convulsions while receiving prophylactic magnesium sulfate, or onset of convulsions beyond 48 hours after delivery).<sup>86</sup> Indeed, most eclamptic convulsions in these series developed in hospitalized women, and in some of these women, the onset of convulsions was not preceded by warning signs or symptoms.<sup>86</sup> Overall, the percentage of eclampsia considered unpreventable in these series ranged from 31% to 87%.<sup>86</sup>

### Transport of the Eclamptic Patient

During the past 20 years, a marked reduction has been seen in the incidence of eclampsia. Consequently, most obstetricians have little or no experience in the management of eclampsia. A recent survey of a random sample of obstetricians from all 50 states indicated that about 50% of obstetricians in private practice had not seen an eclamptic patient during the past year.

**Because management of the eclamptic patient requires the availability of neonatal and obstetric ICUs and personnel with special expertise, it is recommended that eclamptic women at term be cared for only at level II or III hospitals**

**with adequate facilities and with consultants from other specialties.** For those eclamptic patients who are remote from term, referral should be made to a tertiary care center. The following steps should be taken before transfer of these critically ill patients:

1. The referring physician or nurse should consult with the physician at the perinatal center regarding the referral and appropriate treatment. All maternal records, including prenatal data and a detailed summary of the patient's condition, should be transmitted.
2. BP should be stabilized, and convulsions should be controlled.
3. Adequate prophylactic anticonvulsive medications should be given. An accepted regimen is 4 or 6 g IV magnesium sulfate as a loading dose over 20 minutes.
4. Maternal laboratory assessment (CBC with platelet count, liver enzymes) and fetal monitoring should be undertaken.

Patients should be sent in an ambulance with medical personnel in attendance for proper management in cases of subsequent convulsions.

### Treatment of Eclamptic Convulsions

Eclamptic convulsions are a life-threatening emergency and require proper care to minimize morbidity and mortality. The development of an eclamptic convulsion is frightening to observe. Initially, the patient's face becomes distorted with protrusion of her eyes. This is followed by a congested facial expression. Foam often exudes from the mouth, and the woman usually bites her tongue unless it is protected. Respirations are absent throughout the seizure. The convulsion, which can be divided into two phases, typically continues for 60 to 75 seconds. The first phase, which lasts 15 to 20 seconds, begins with facial twitching and proceeds to the body becoming rigid with generalized muscular contractions. The second phase lasts about 60 seconds and consists of the muscles of the body alternately contracting and relaxing in rapid succession. This phase begins with the muscles of the jaw and rapidly involves the eyelids, other facial muscles, and then all the muscles of the body. Coma follows the convulsion, and the woman usually remembers nothing of the recent events. If she has repeated convulsions, some degree of consciousness returns after each convulsion. She may enter a combative state and may be agitated and difficult to control. Rapid and deep respirations usually begin as soon as the convulsions end. Maintenance of oxygenation is usually not a problem after a single convulsion; the risk for aspiration is low in the well-managed patient.

**Because eclampsia is so frightening, the natural tendency is to attempt to abolish the convulsion. However, drugs such as diazepam should *not* be given in an attempt to stop or shorten the convulsion, especially if the patient does not have an IV line in place and someone skilled in intubation is not immediately available.** If diazepam is used, no more than 5 mg should be given over 60 seconds. Rapid administration of diazepam may lead to apnea, cardiac arrest, or both.

### Prevention of Maternal Injury During the Convulsions

**The first priority in the management of eclampsia is to prevent maternal injury and to support cardiovascular function. During or immediately after the acute convulsive episode, supportive care should be given to prevent serious maternal injury and aspiration, assess and establish airway patency, and ensure maternal oxygenation.** During this time,

the bed's side rails should be elevated and padded; a padded tongue blade is inserted between the teeth (avoid inducing a gag reflex), and physical restraints may also be needed. To minimize the risk for aspiration, the patient should lie in the lateral decubitus position, and vomitus and oral secretions are suctioned as needed.<sup>86</sup> Aspiration may be caused by forcing the padded tongue blade to the back of the throat, stimulating the gag reflex with resultant vomiting.

Adequate oxygenation should be maintained during the convulsive episode because hypoventilation and respiratory acidosis often occur. Although the initial seizure lasts only a few minutes, it is important to maintain oxygenation by supplemental oxygen administration through a face mask with or without an oxygen reservoir at 8 to 10 L/min.<sup>86</sup> After the convulsion has ceased, the patient begins to breathe again, and oxygenation is rarely a problem. However, maternal hypoxemia and acidosis may develop in women who have had repetitive convulsions, in those with aspiration pneumonia or pulmonary edema, or as a result of a combination of these factors. **It is my policy to use transcutaneous pulse oximetry to monitor oxygenation in all eclamptic patients.** Arterial blood gas analysis is required if the pulse oximetry results are abnormal (oxygen saturation  $\leq 92\%$ ). Sodium bicarbonate is not given unless the pH is below 7.10.

### Prevention of Recurrent Convulsions

The next step in the management of eclampsia is to prevent recurrent convulsions. **Magnesium sulfate is the drug of choice to treat and prevent subsequent convulsions in women with eclampsia.**<sup>86</sup> **A loading dose of 6 g over 15 to 20 minutes is recommended, followed by a maintenance dose of 2 g per hour as a continuous IV solution.** About 10% of eclamptic women have a second convulsion after receiving magnesium sulfate.<sup>86</sup> In these women, another bolus of 2 g magnesium sulfate can be given intravenously over 3 to 5 minutes. An occasional patient will have recurrent convulsions while receiving adequate and therapeutic doses of magnesium sulfate. In this patient, recurrent seizures can be treated with Ativan 2 mg intravenously over 3 to 5 minutes.<sup>86</sup>

Rarely, a woman may experience an eclamptic seizure, lapse into a coma, and die. Magnesium toxicity should be considered in those women who do not regain consciousness. A case report of magnesium sulfate toxicity details the features of this serious complication. Within a few minutes of starting what was supposed to be a magnesium loading dose, 4 g magnesium sulfate in 250 mL saline, the patient went into cardiorespiratory arrest. Immediate resuscitation was performed, including intubation; about half of the loading dose had been given. A coma ensued that was believed to have been caused by an intracerebral accident or eclampsia; the loading dose was continued, and maintenance therapy was started. Initial blood gases were normal, and the electrocardiogram (ECG) was normal 15 minutes after the arrest. The patient's vital signs were stable; however, mechanical ventilatory support was required, and her pupils were non-reactive. Serum electrolytes, glucose, blood urea nitrogen, and creatinine were normal; CT scan of the head and cerebral angiograms were also normal. A magnesium level of 35 mg/dL was reported 3.5 hours later from a blood sample taken through femoral venipuncture at the time of arrest; the magnesium sulfate infusion was stopped immediately. During the first 5 hours after the cardiorespiratory arrest, 1344 mg of magnesium was excreted in the urine. Twelve hours after the arrest, an uncomplicated low vertical cesarean delivery was done for a

**FIG 31-15** Magnesium levels over time in a patient with magnesium toxicity. (From McCubbin JH, Sibai BM, Abdella TN, et al. Cardiopulmonary arrest due to acute maternal hypermagnesemia [letter]. *Lancet*. 1981;1:1058.)

breech presentation. The 3160-g male infant had Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. Maternal and cord blood magnesium levels at delivery were 5.8 mg/dL. Both mother and baby were discharged from the hospital with no apparent sequelae. Of interest, the patient reported she could hear and see what was occurring around her, but she could not make any movements while she was intubated. **Figure 31-15** presents the maternal magnesium levels in this case.

### Control of Severe Hypertension

The next step in the management of eclampsia is to reduce the BP to a safe range. The objectives of treating severe hypertension are to avoid loss of cerebral autoregulation and to prevent CHF without compromising cerebral perfusion or jeopardizing utero-placental blood flow, which is already reduced in many women with eclampsia.<sup>86</sup> Thus **maintaining systolic BP between 140 and 160 mm Hg and diastolic BP between 90 and 105 mm Hg is a reasonable goal. This can be achieved with bolus 5 to 10 mg doses of hydralazine every 20 minutes or labetalol (20 to 40 mg intravenously) every 10 minutes as needed.**<sup>86</sup> Other potent antihypertensive medications, such as sodium nitroprusside or nitroglycerine, are rarely needed in eclampsia. Diuretics are not used except in the presence of pulmonary edema.

### Intrapartum Management of Eclampsia

**Maternal hypoxemia and hypercarbia cause FHR and uterine activity changes during and immediately after a convulsion. The FHR tracing may reveal bradycardia, transient late decelerations, decreased beat-to-beat variability, and compensatory tachycardia. Uterine contractions can increase in frequency and tone.**<sup>86</sup> These changes usually resolve

**spontaneously within 3 to 10 minutes after the termination of convulsions and correction of maternal hypoxemia.** The patient should not be rushed to emergency cesarean delivery based on these findings, especially if the maternal condition remains stable.

In a review of 10 women who had undergone electronic internal fetal monitoring during an eclamptic convulsion, 6 had fetal bradycardia (FHR <120 beats/min) that varied in duration from 30 seconds to 9 minutes. The interval from onset of the seizure to the fall in FHR was 5 minutes. Transitory fetal tachycardia occurred frequently after the prolonged bradycardia. In addition, loss of beat-to-beat variability with transitory late decelerations occurred during the recovery phase. Uterine hyperactivity demonstrated by both increased uterine tone and increased frequency of uterine contractions occurs during an eclamptic seizure. The duration of the increased uterine activity varies from 2 to 14 minutes.

**Fetal outcome is generally good after an eclamptic convulsion. The mechanism for the transitory fetal bradycardia may be a decrease in uterine blood flow caused by intense vasospasm and uterine hyperactivity. The absence of maternal respiration during the convulsion may also result in fetal hypoxia and heart rate changes. Because the FHR pattern usually returns to normal after a convulsion, other conditions should be considered if an abnormal pattern persists.** It may take longer for the heart rate pattern to return to baseline in an eclamptic woman whose fetus is preterm with growth restriction. Placental abruption may occur after the convulsion and should be considered if uterine hyperactivity remains or the bradycardia persists.<sup>86</sup>

**The presence of eclampsia is not an indication for cesarean delivery. The decision to perform a cesarean delivery should be based on gestational age, fetal condition, presence of labor, and cervical Bishop score.**<sup>86</sup> Cesarean delivery is recommended for those with eclampsia before 30 weeks' gestation who are not in labor with an unfavorable cervix (Bishop score <5). Patients in labor or whose membranes have ruptured are allowed to deliver vaginally in the absence of obstetric complications. When labor is indicated, it is initiated with either oxytocin infusions or prostaglandins in all patients with a gestational age at or above 30 weeks, irrespective of the Bishop score. A similar approach is used for those before 30 weeks' gestation if the cervical Bishop score is at least 5.

Maternal pain relief during labor and delivery can be provided by either systemic opioids or epidural anesthesia as recommended for women with severe PE.<sup>2</sup> Either epidural, spinal, or combined techniques of regional anesthesia can be used for cesarean delivery. Regional anesthesia is contraindicated in the presence of coagulopathy or severe thrombocytopenia (platelet count <50,000/mm<sup>3</sup>). In women with eclampsia, general anesthesia increases the risk for aspiration and failed intubation due to airway edema and is associated with marked increases in

systemic and cerebral pressures during intubation and extubation.<sup>86</sup> Women with airway or laryngeal edema may require awake intubation under fiberoptic observation with the availability of immediate tracheostomy. Changes in systemic or cerebral pressures may be attenuated by pretreatment with labetalol or nitroglycerine injections.<sup>86</sup>

### Postpartum Management of Eclampsia

After delivery, women with eclampsia should receive close monitoring of vital signs, fluid intake and output, and symptoms for at least 48 hours. These women usually receive large amounts of IV fluids during labor, delivery, and postpartum. In addition, during the postpartum period, mobilization of extracellular fluid leads to increased intravascular volume. As a result, women with eclampsia, particularly those with abnormal renal function; those with abruptio placentae; and those with preexisting chronic hypertension are at increased risk for pulmonary edema and exacerbation of severe hypertension postpartum.<sup>86</sup> Careful attention to fluid status is essential.

**Parenteral magnesium sulfate should be continued for at least 24 hours after delivery or for at least 24 hours after the last convulsion. If oliguria is present (<100 mL/4 hr), both the rate of fluid administration and the dose of magnesium sulfate should be reduced.** Once delivery has occurred, other oral antihypertensive agents such as labetalol or nifedipine can be used to keep systolic BP below 155 mm Hg and diastolic BP below 105 mm Hg. Nifedipine offers the benefit of improved diuresis in the postpartum period.

### Subsequent Pregnancy Outcomes and Remote Prognosis

**Women with a history of eclampsia are at increased risk for all forms of PE in subsequent pregnancies (Table 31-18).** In general, the rate of PE in subsequent pregnancies is about 25%, with substantially higher rates if the onset of eclampsia was in the second trimester. **The rate of recurrent eclampsia is about 2%.** Because of these risks, these women should be informed that they are at increased risk for adverse pregnancy outcome in subsequent pregnancies. At present, no preventive therapy exists for recurrent antepartum eclampsia.

The long-term effects of eclampsia on maternal BP and neurologic outcome have been the subject of few reports. The findings of these studies revealed that eclampsia did not cause hypertension in women who were normotensive before the eclamptic pregnancy. Two of these studies found that the rate of chronic hypertension on follow-up was significantly higher in those who had eclampsia remote from term compared with those who had eclampsia at or beyond 37 weeks of gestation. In addition, one of these reports revealed that women who had eclampsia as multiparas were at increased risk for death from cardiovascular renal disease. Moreover, these investigations revealed no evidence of neurologic deficit during the follow-up period.

CHRONIC HYPERTENSION

The frequency of chronic hypertension in pregnancy is estimated at 1% to 5%. It is more common in older obese women and in black women. Because of the current trend of childbearing at an older age and the obesity epidemic, it is expected that the incidence of chronic hypertension in pregnancy will continue to rise. During the new millennium, and estimating a prevalence of chronic hypertension during pregnancy of 3%, at least 120,000 pregnant women (3% of 4 million pregnancies) with chronic hypertension will be seen annually in the United States.

Definition and Diagnosis

In pregnancy, *chronic hypertension* is defined as elevated BP that is present and documented before conception. In women whose prepregnancy BP is unknown, the diagnosis is based on the presence of *sustained hypertension before 20 weeks of gestation*, defined as either systolic BP of at least 140 mm Hg or diastolic BP of at least 90 mm Hg on at least two occasions measured at least 4 hours apart.

The diagnosis may be difficult to establish in women with previously undiagnosed chronic hypertension who begin prenatal care after 16 weeks' gestation because physiologic decline in BP occurs at that time. An analysis of pregnancy outcome in 211 patients with mild chronic hypertension suggests that the use of antihypertensive drugs is not necessary to achieve a good pregnancy outcome (Table 31-19). The changes in average MAP throughout the course of pregnancy are summarized in Figure 31-16. This decrease may result in normal BP findings in the second trimester that will eventually increase again during the

third trimester. These women are more likely to be erroneously diagnosed as having GH.

Women with chronic hypertension are at increased risk for superimposed PE. The development of superimposed PE is associated with high rates of adverse maternal and perinatal outcomes.<sup>14</sup> The diagnosis of superimposed PE should be made as described previously based on changes in BP, development of new-onset proteinuria, new-onset symptoms, or changes in laboratory tests.

Etiology and Classification

The etiology and severity of chronic hypertension are important considerations in the management of pregnancy. Chronic hypertension is subdivided into *primary* (essential) and *secondary* hypertension. Primary hypertension is by far the most common type of chronic hypertension seen during pregnancy (90%). In 10% of cases, chronic hypertension is secondary to one or more underlying disorders such as renal disease (glomerulonephritis, interstitial nephritis, polycystic kidneys, renal artery stenosis), collagen vascular disease (lupus, scleroderma), endocrine disorders (diabetes mellitus with vascular involvement, pheochromocytoma, thyrotoxicosis, Cushing disease, hyperaldosteronism), or coarctation of the aorta.

Chronic hypertension during pregnancy can be subclassified as either mild or severe, depending on the systolic and diastolic BP readings. Systolic and diastolic (Korotkoff phase V) BPs of at least 160 mm Hg or 110 mm Hg, respectively, constitute severe hypertension.

For management and counseling purposes, chronic hypertension in pregnancy is also categorized as either low risk or high risk, as described in Figure 31-17. The patient is considered to

be at low risk when she has mild essential hypertension without any organ involvement. The BP criteria are based on measurements at the initial visit irrespective of treatment with antihypertensive medications. For example, if the patient has a BP of 140/80 mm Hg on antihypertensive drugs, she is still classified as low risk. It is important to note that a patient initially classified as low risk early in pregnancy may become high risk if she later develops severe hypertension or PE.

### Maternal and Perinatal Risks

Pregnancies complicated by chronic hypertension are at increased risk for the development of superimposed PE, placental abruption, and fetal growth restriction. The reported rates of PE in the literature in mild hypertension range from 14% to 28% (see Table 31-19).<sup>14</sup> The rate of PE in women with severe chronic hypertension ranges from 50% to 79%. Sibai and associates<sup>14</sup> studied the rate of superimposed PE among 763 women with chronic hypertension followed prospectively at several tertiary medical centers in the United States. The overall rate of superimposed PE was 25%. The rate was not affected by maternal age, race, or presence of proteinuria early in pregnancy; however, it was significantly greater in women who had hypertension for at least 4 years (31% vs. 22%), in those who had PE during a previous pregnancy (32% vs. 23%), and in those whose diastolic BP was 100 mm Hg or higher (42% vs. 24%).<sup>14</sup>

The reported rate of placental abruption in women with mild chronic hypertension has ranged from 0.7% to 2.7% (see Table 31-19). The rate in those with severe or high-risk hypertension may be 5% to 10%. In a recent multicenter study that included 763 women with chronic hypertension, the overall rate of abruption was reported at 1.5%, and the rate was significantly higher in those who developed superimposed PE than in those without this complication (3% vs. 1%,  $P = .04$ ).<sup>14</sup> However, the rate was not influenced by maternal age, race, or duration of hypertension.<sup>14</sup> In addition, the results of a systematic review of nine observational studies revealed that in women with chronic hypertension, the rate of abruption is doubled

(OR, 2.1; 95% CI, 1.1 to 3.9) compared with normotensive patients.

In addition to PE and abruption, women with high-risk chronic hypertension are at increased risk for life-threatening maternal complications such as pulmonary edema, hypertensive encephalopathy, retinopathy, cerebral hemorrhage, and acute renal failure. These risks are particularly increased in women with uncontrolled severe hypertension, significant renal disease early in pregnancy, or left ventricular dysfunction before conception.

Fetal and neonatal complications are also increased in women with chronic hypertension. The risk for perinatal mortality is three to four times greater compared with that of the general obstetric population (OR, 3.4; 95% CI, 3.0 to 3.7). The likelihood of premature delivery and a growth-restricted infant is also increased in women with chronic hypertension. In women with severe chronic hypertension in the first trimester, the reported rates of preterm delivery were 62% to 70%, and the rates of an SGA infant were 31% to 40%. Recently, Sibai and associates<sup>15</sup> reported risk factors for adverse perinatal outcome in a secondary analysis of 763 women with mild chronic hypertension who were enrolled in a multicenter trial that compared low-dose aspirin with a placebo for the prevention of PE. They found that the development of superimposed PE was associated with higher rates of preterm delivery (OR, 3.9; 95% CI, 2.7 to 5.4), neonatal intraventricular hemorrhage (OR, 4.5; 95% CI, 1.5 to 14.2), and perinatal death (OR, 2.3; 95% CI, 1.4 to 4.8). In addition, the presence of proteinuria early in pregnancy was an independent risk factor associated with higher rates of preterm delivery (OR, 3.1; 95% CI, 1.8 to 5.3), an SGA infant (OR, 2.8; 95% CI, 1.6 to 5.0), and neonatal intraventricular hemorrhage (OR, 3.9; 95% CI, 1.3 to 11.6).<sup>14</sup>

### Goals of Antihypertensive Therapy in Pregnancy

In nonpregnant individuals, long-term BP control can lead to significant reductions in the rates of stroke and cardiovascular morbidity and mortality. In contrast to hypertension

**in pregnancy, the duration of therapy is shorter, the benefits to the mother may not be obvious during the short time of treatment, and the exposure to medication will include both mother and fetus. In this respect, the clinician must balance the potential short-term maternal benefits against possible short-term and long-term benefits and risks to the fetus and infant.**

Most women with chronic hypertension during pregnancy have mild, essential, uncomplicated hypertension and are at minimal risk for cardiovascular complications within the short time frame of pregnancy. Several retrospective and prospective studies have been conducted to determine whether antihypertensive therapy in these women improves pregnancy outcome. An overall summary of these studies revealed that regardless of the antihypertensive therapy used, maternal cardiovascular and renal complications were minimal or absent. **No available data suggest that short-term antihypertensive therapy is beneficial for the mother or the fetus in the setting of low-risk hypertension except for a reduction in the rate of exacerbation of hypertension. However, only three trials have had a sufficient sample size to evaluate the risks for superimposed PE and placental abruption.**

Recently, the benefits of tight blood pressure control versus less blood pressure control in women with chronic hypertension in pregnancy were studied in a large multicenter study, the Control of Hypertension in Pregnancy Study (CHIPS). The trial included 736 women with chronic hypertension; 361 were assigned to tight control and 371 were assigned to less tight control. The investigators found no difference between groups in primary outcome (pregnancy loss or high-level neonatal care) or in serious maternal complications. However, women in the less-tight control group had a higher rate of progression to severe hypertension. In contrast, the tight control group had a significantly higher rate of SGA infants (19.7% vs. 13.9%).

No placebo-controlled trials have examined the benefits of antihypertensive therapy in women with severe hypertension in pregnancy, and none are likely to be performed. **Antihypertensive therapy is necessary in women with severe hypertension to reduce the acute risks for stroke, CHF, and renal failure. In addition, control of severe hypertension can permit pregnancy prolongation and thereby improve perinatal outcome. However, no evidence suggests that control of severe hypertension reduces the rate of either superimposed PE or placental abruption.**

No trials have examined the treatment of women with chronic hypertension and other risk factors such as preexisting renal disease, diabetes mellitus, or cardiac disease. On the other hand, evidence from retrospective and observational studies suggests that uncontrolled mild to moderate hypertension may exacerbate target-organ damage during pregnancy in women with renal disease, diabetes mellitus with vascular disease, or left ventricular dysfunction. Therefore some authors recommend aggressive treatment of mild hypertension in these women because of the belief that such management may reduce both short- and long-term cardiovascular complications.

### **Safety of Antihypertensive Drugs in Pregnancy**

The potential adverse effects of most commonly prescribed antihypertensive agents are either poorly established or unclearly quantified. Most of the evidence on harm associated with antihypertensives in pregnancy is limited to case reports. The

interpretation of these reports is difficult because it is impossible to ascertain the exact number of women exposed to antihypertensive drugs during pregnancy. Also, it is likely that the number of published case reports is an underestimate of the actual number of women who experience the reported adverse reaction. This limitation is amplified by the fact that information related to previous exposure during pregnancy is nonexistent. Furthermore, the condition for which pregnant women are treated with antihypertensive drugs can be partially responsible for the adverse fetal and neonatal outcomes.

In general, available information about teratogenicity, except in laboratory animals, is limited and selective. All available data have been obtained from registries such as state Medicaid registry data. Because of absent multicenter randomized trials in women with chronic hypertension, no placebo-controlled evaluations have been done regarding the safety of these drugs when used at the time of conception and throughout pregnancy. At the present time, only minimal data are available to help the clinician evaluate the benefits or risks of most antihypertensive drugs when used in pregnancy. **Nevertheless, the limited data in the literature suggest potential adverse fetal effects, such as oligohydramnios and fetal-neonatal renal failure, when angiotensin-converting enzyme (ACE) inhibitors are used in the second or third trimester.** Similar effects are to be expected with the use of angiotensin II receptor blockers. Therefore these agents should be avoided once pregnancy is established (see [Chapter 8](#)).

**The use of atenolol during the first and second trimesters has been associated with significantly reduced fetal growth along with decreased placental growth and weight. On the other hand, no such effects on fetal or placental growth have been reported with other  $\beta$ -blockers—such as metoprolol, pindolol, and oxprenolol—but data on the use of these agents in early pregnancy are very limited.**

Prospective trials that have examined the effect of either methyldopa or labetalol in women with mild chronic hypertension revealed no adverse maternal or fetal outcomes with the use of these medications. In a large and unique trial in which methyldopa or labetalol was started between 6 and 13 weeks' gestation in patients with chronic hypertension, none of the exposed newborns had major congenital anomalies.

Clinical experience is extensive with the use of thiazide diuretics during pregnancy. The available data suggest that treatment with diuretics in the first trimester and throughout gestation is not associated with an increased risk for major fetal anomalies or adverse fetal-neonatal events. Information is sparse regarding the use of calcium channel blockers in women with mild chronic hypertension; however, **the available evidence suggests that the use of calcium channel blockers, particularly nifedipine, in the first trimester was not associated with increased rates of major birth defects.** The effects of nifedipine on fetal-neonatal outcome were evaluated in a prospective randomized trial of 283 women with mild to moderate hypertension in pregnancy in which 47% of the participants had chronic hypertension. Sixty-six of these women were enrolled between 12 and 20 weeks' gestation. In this study, the use of slow-release nifedipine was not associated with adverse fetal-neonatal outcomes.

The long-term effects on children of mothers exposed to antihypertensive drugs during pregnancy are lacking except for limited information concerning the use of methyldopa and nifedipine. A follow-up study of infants after 7.5 years showed no

long-term adverse effects on development among those exposed to methyl dopa in utero compared with infants not exposed to such treatment. A similar study that examined the effects of slow-release nifedipine after 1.5 years of follow-up demonstrated no adverse effects on development.

### Recommended Management of Chronic Hypertension in Pregnancy

The primary objective in the management of pregnancies complicated by chronic hypertension is to reduce maternal risks and achieve optimal perinatal survival. This objective can be achieved by formulating a rational approach that includes preconception evaluation and counseling, early antenatal care, frequent antepartum visits to monitor both maternal and fetal well-being, timely delivery with intensive intrapartum monitoring, and proper postpartum management.

#### Evaluation and Classification

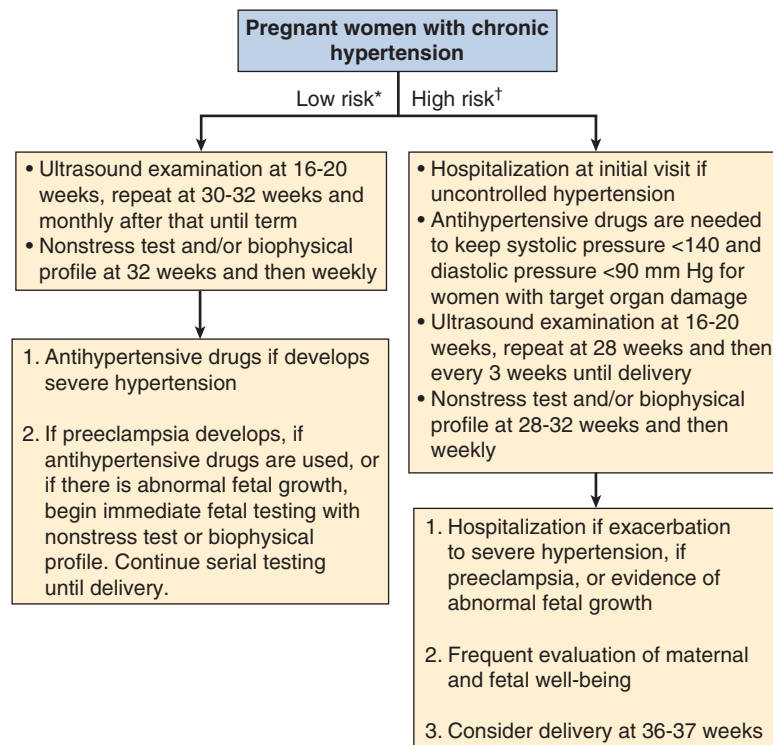

**Women with chronic hypertension should ideally be counseled before pregnancy, when extensive evaluation and complete workup can be undertaken. Assessment of the etiology and severity of the hypertension, as well as the coexistence of other medical illnesses, and ruling out the presence of target-organ damage resulting from long-standing hypertension can be accomplished.** An in-depth history should delineate in particular the duration of hypertension, the use of antihypertensive medications, their type, and the response to these medications. Also, attention should be given to the presence of cardiac or renal disease, diabetes mellitus, thyroid disease, and a history of cerebrovascular accident or CHF. A detailed

obstetric history should include maternal and neonatal outcomes of previous pregnancies and should stress any history of the development of placental abruption, superimposed PE, preterm delivery, FGR, intrauterine fetal death, and neonatal morbidity and mortality.

Laboratory evaluation is obtained to assess the function of different organ systems likely to be affected by chronic hypertension and as a baseline for future assessments. **For all patients, these should include urinalysis, urine culture and sensitivity, 24-hour urine evaluations for protein, electrolytes, CBC, and screening for diabetes.**

**Women with long-standing hypertension for several years, particularly those with a history of poor compliance or poor BP control, should be evaluated for target-organ damage that includes left ventricular hypertrophy, retinopathy, and renal injury. These women should undergo an ECG examination and echocardiography if the ECG is abnormal, ophthalmologic evaluation, and creatinine clearance.**

Selectively, certain tests should be obtained to identify secondary causes of hypertension such as pheochromocytoma, primary hyperaldosteronism, or renal artery stenosis. These conditions require selective biochemical testing and are amenable to diagnosis with either CT or MRI. Pheochromocytoma should be suspected in women with paroxysmal severe hypertension, hyperglycemia, and sweating (see Chapter 43). Primary aldosteronism is extremely rare in pregnancy and should be considered in women with severe hypertension and marked hypokalemia (see Chapter 43). Based on this evaluation, the patient is then classified as having low-risk or high-risk chronic hypertension and is managed accordingly (Fig. 31-18).

**FIG 31-18** Antepartum management of chronic hypertension. Low risk (\*) includes those with controlled hypertension on medication and those not receiving antihypertensive drugs; high risk (†) includes those with uncontrolled hypertension, left ventricular dysfunction, and/or coexisting medical diseases (renal, diabetes mellitus, systemic lupus erythematosus). (From Sibai BM. Chronic hypertension in pregnancy. *Obstet Gynecol*. 2002;100:369.)

### LOW-RISK HYPERTENSION

**Women with low-risk chronic hypertension without superimposed PE usually have a pregnancy outcome similar to that of the general obstetric population.** In addition, discontinuation of antihypertensive therapy early in pregnancy does not affect the rate of PE, abruptio placentae, or preterm delivery in these women. Many clinicians choose to discontinue antihypertensive treatment at the first prenatal visit because most of these women will experience a good pregnancy outcome without such therapy. Although many of these women will not require subsequent pharmacologic therapy, careful management is still essential (see Fig. 31-16). At the time of initial and subsequent visits, women are educated about nutritional requirements, weight gain, and sodium intake (maximum of 2.4 g/day). They are also counseled that consumption of alcohol and smoking during pregnancy can aggravate maternal hypertension and are associated with adverse effects on the fetus such as FGR and abruptio placentae. During each subsequent visit, they are observed closely for early signs of PE and FGR.

Fetal evaluation should include an ultrasound examination at 16 to 20 weeks' gestation, to be repeated at 30 to 32 weeks and monthly thereafter until term. **Antihypertensive treatment with either nifedipine or labetalol is initiated if the patient develops severe hypertension before term.** The development of severe hypertension, PE, or abnormal fetal growth requires immediate fetal testing with NST or BPP. Women who develop severe hypertension require hospitalization, and those with documented FGR by ultrasound examination require intensive surveillance and often delivery. If superimposed PE is diagnosed at or beyond 37 weeks, delivery is undertaken as well. In the absence of these complications, the pregnancy may be continued until 40 weeks' gestation.

### HIGH-RISK HYPERTENSION

Women with high-risk chronic hypertension are at increased risk for adverse maternal and perinatal complications. The likelihood and impact of these complications will depend on the etiology of the hypertension as well as the degree of target-organ damage. Women with significant renal insufficiency (serum creatinine >1.4 mg/dL), diabetes mellitus with vascular involvement (class R/F), severe collagen vascular disease, cardiomyopathy, or coarctation of the aorta should receive thorough counseling regarding the adverse effects of pregnancy before conception. These women should be advised that pregnancy may exacerbate their condition, with the potential for CHF, acute renal failure requiring dialysis, and even death. In addition, perinatal loss and neonatal complications are markedly increased in these women. All such women should be managed by, or in consultation with, a subspecialist in maternal-fetal medicine in association with other medical specialists as needed. In addition, these women must be observed and delivered at a tertiary care center with the appropriate resources for maternal and neonatal care.

**Hospitalization of women with high-risk uncontrolled hypertension at the time of the first prenatal visit is recommended.** This facilitates evaluation of cardiovascular and renal status and also facilitates regulation of antihypertensive medications and other prescribed treatments (e.g., insulin, cardiac drugs, thyroid medications) if needed. Women who receive ACE inhibitors or angiotensin II receptor antagonists should have these medications discontinued under close observation. **Antihypertensive therapy with one or more of the drugs listed in Table 31-20 is subsequently used in all women with systolic**

**TABLE 31-20** DRUGS USED TO TREAT HYPERTENSION IN PREGNANCY

| DRUG  | STARTING DOSE             | MAXIMUM DOSE | COMMENTS   |
|---|---------------------------|--------------|--|
| <b>Acute Treatment of Severe Hypertension</b> |                           |              |  |
| Hydralazine                                   | 5-10 mg IV<br>q20 min     | 20 mg*       | Avoid in cases of tachycardia and persistent headaches |
| Labetalol                                     | 20-40 mg IV<br>q10-15 min | 220 mg*      | Avoid in women with asthma or congestive heart failure |
| Nifedipine                                    | 10-20 mg oral<br>q30 min  | 50 mg*       | Avoid in case of tachycardia and palpitations          |
| <b>Long-Term Treatment of Hypertension</b>    |                           |              |  |
| Methyldopa                                    | 250 mg bid                | 4 g/day      |  |
| Labetalol                                     | 100 mg bid                | 2400 mg/day  |  |
| Nifedipine                                    | 10 mg bid                 | 120 mg/day   |  |
| Thiazide diuretic                             | 12.5 mg bid               | 50 mg/day    |  |

\*If desired blood pressure levels are not achieved, switch to another drug.

**BP of 160 mm Hg or more or diastolic BP of 110 mm Hg or more.** In women without target-organ damage, the aim of antihypertensive therapy is to keep systolic BP between 140 and 150 mm Hg and diastolic BP between 90 and 100 mm Hg. In addition, antihypertensive therapy is indicated in women with mild hypertension plus target-organ damage because of the short-term maternal benefits from lowering BP in such women. In these women, maintaining systolic BP below 140 mm Hg and diastolic BP below 90 mm Hg is advised. In some women, BP may be difficult to control initially, which demands the use of IV therapy with hydralazine or labetalol or oral short-acting nifedipine with doses as described in Table 31-20. For maintenance therapy, the choices are either oral methyldopa, labetalol, slow-release nifedipine, or a diuretic. Methyldopa remains the drug most commonly recommended to treat hypertension during pregnancy; however, it is rarely used in nonpregnant hypertensive women. **The recommended drug of choice for control of hypertension in pregnancy is labetalol, starting at 100 mg twice daily to be increased to a maximum of 2400 mg/day. If maternal BP is not controlled with maximal doses of labetalol, a second drug such as a thiazide diuretic or nifedipine may be added.** For women with diabetes mellitus and vascular disease, oral nifedipine is recommended. Oral nifedipine or a thiazide diuretic is the drug of choice for young black women with hypertension because these women often manifest a low-renin-type hypertension or salt-sensitive hypertension. If maternal BP is adequately controlled with these medications, the patient can continue with the same drug after delivery.

Diuretics are commonly prescribed in women with essential hypertension before conception, although the use of diuretics throughout pregnancy is controversial. Of concern, women who use diuretics from early in pregnancy do not have an increase in plasma volume to the degree expected in normal pregnancy. However, this reduction in plasma volume has not been shown to be associated with an adverse effect on fetal outcome. Therefore it is appropriate to start diuretics as a single agent during pregnancy or to use them in combination with other agents, particularly in women with excessive salt retention. However,

diuretics should be discontinued immediately if superimposed PE develops or with evidence of suspected FGR because of the potential for reduced uteroplacental blood flow secondary to reduced plasma volume in women with these complications.

Early and frequent prenatal visits are the key for successful pregnancy outcome in women with high-risk chronic hypertension. These women need close observation throughout pregnancy and may require serial evaluation of 24-hour urine protein excretion and a CBC with a metabolic profile at least once every trimester. Further laboratory testing can be performed depending on the clinical progress of the pregnancy. During each visit, the woman should be advised about the adverse effects of smoking and alcohol abuse, and she should receive nutritional advice regarding diet and salt intake.

Fetal evaluation should include an ultrasound examination at 16 to 20 weeks' gestation, to be repeated at 28 weeks and subsequently every 3 weeks until delivery. NST or BPP testing is usually started at 28 to 32 weeks and then repeated weekly. **The development of uncontrolled severe hypertension or PE requires maternal hospitalization for more frequent evaluation of maternal and fetal well-being. The development of FGR also requires intensive surveillance, and the development of these complications at or beyond 34 weeks' gestation should be considered an indication for delivery.** In all other women, delivery should be considered at 36 to 37 weeks' gestation after documentation of fetal lung maturity.

### Postpartum Management

Women with high-risk chronic hypertension are at risk for postpartum complications such as pulmonary edema, hypertensive encephalopathy, and renal failure. These risks are particularly increased in women with target-organ involvement, superimposed PE, or placental abruption. **In these patients, BP must be closely controlled for at least 24 hours after delivery.** IV labetalol or hydralazine can be used as needed, and diuretics may be appropriate in women with circulatory congestion and pulmonary edema. This therapy is usually required in those who develop exaggerated and sustained severe hypertension in the first week postpartum.

Oral therapy may be needed to control BP after delivery. In some women, it is often necessary to switch to a new agent such as an ACE inhibitor, particularly in those with pregestational diabetes mellitus and those with cardiomyopathy. Some patients may wish to breastfeed their infant, and all antihypertensive drugs are found in the breast milk, although the milk-to-plasma ratio of these drugs varies. Additionally, the long-term effect of maternal antihypertensive drugs on breastfeeding infants has not been specifically studied. Milk concentrations of methyldopa appear to be low and are considered to be safe. The  $\beta$ -blocking agents (atenolol and metoprolol) are concentrated in breast milk, whereas labetalol and propranolol have low concentrations. Concentrations of diuretic agents in breast milk are low; however, they may induce a decrease in milk production.

Little information is available about the transfer of calcium channel blockers to breast milk, but no side effects are apparent. ACE inhibitors and angiotensin II receptor antagonists should be avoided because of their effects on neonatal renal function, even though their concentrations appear to be low in breast milk (see Chapter 24).

**Finally, in breastfeeding women, the use of methyldopa as a first-line oral therapy is a reasonable choice. If methyldopa is contraindicated, labetalol may be used.**

## HYPERTENSIVE EMERGENCIES IN CHRONIC HYPERTENSION

On rare occasions, pregnant women may present with life-threatening clinical conditions that require immediate control of BP, such as hypertensive encephalopathy, acute left ventricular failure, acute aortic dissection, or increased circulating catecholamines (pheochromocytoma, clonidine withdrawal, cocaine ingestion). Patients at highest risk for these complications include those using multiple drugs to control their hypertension and also women with underlying cardiac or chronic glomerular renal disease, superimposed PE in the second trimester, and placental abruption complicated by DIC. Although a diastolic BP of 115 mm Hg or greater is usually considered a hypertensive emergency, this level is actually arbitrary, and the rate of change of BP may be more important than its absolute level. The association of elevated BP with evidence of new or progressive end-organ damage determines the seriousness of the clinical situation.

### Hypertensive Encephalopathy

Untreated essential hypertension progresses to a hypertensive crisis in up to 1% to 2% of cases for unknown reasons. **Hypertensive encephalopathy is usually seen in patients with a systolic BP above 220 mm Hg or a diastolic BP above 130 mm Hg.** Patients with an acute onset of hypertension may develop encephalopathy at pressure levels that are generally tolerated by those with chronic hypertension. Normally, cerebral blood flow is about 50 mL/min per 100 g tissue. When the BP falls, cerebral arterioles normally dilate, whereas when BP increases, they constrict to maintain constant cerebral blood flow. This mechanism usually remains operative between 60 and 120 mm Hg diastolic BP. **Hypertensive encephalopathy is currently considered to be a derangement of the autoregulation of cerebral arterioles, which occurs when the upper limit of autoregulation is exceeded.** With severe hypertension (130 to 150 mm Hg cerebral perfusion pressure), cerebral blood vessels constrict as much as possible and then reflex cerebral vasodilation occurs. This results in overperfusion, damage to small blood vessels, cerebral edema, and increased intracranial pressure (*breakthrough theory*). Others believe that hypertensive encephalopathy results from an exaggerated vasoconstrictive response of the arterioles that results in cerebral ischemia (*overregulation theory*). Patients who have impaired autoregulation that involves the cerebral arterioles may experience necrotizing arteriolitis, microinfarcts, petechial hemorrhages, multiple small thrombi, or cerebral edema. Typically, hypertensive encephalopathy has a subacute onset over 24 to 72 hours.

During a hypertensive crisis, other evidence for end-organ damage may be present: cardiac, renal, or retinal dysfunction secondary to impaired organ perfusion and loss of autoregulation of blood flow. Ischemia of the retina with flame-shaped retinal hemorrhages, retinal infarcts, or papilledema may occur and can cause decreased visual acuity. Impaired regulation of coronary blood flow and a marked increase in ventricular wall stress may result in angina, myocardial infarction (MI), CHF, malignant ventricular arrhythmia, pulmonary edema, or dissecting aortic aneurysm. Necrosis of the afferent arterioles of the glomerulus results in hemorrhages of the cortex and medulla, fibrinoid necrosis, and proliferative endarteritis that results in elevated serum creatinine ( $>3$  mg/dL), proteinuria, oliguria, hematuria, hyaline or red blood cell casts, and progressive

azotemia. Severe hypertension may result in placental abruption with resultant DIC. In addition, high levels of angiotensin II, norepinephrine, and vasopressin accompany ongoing vascular damage. These circulating hormones increase relative efferent arteriolar tone, which results in sodium diuresis and hypovolemia. Because levels of renin and angiotensin II are increased, the aldosterone level is also elevated. The impact of these endocrine changes may be important in maintaining the hypertensive crisis.

### Treatment of Hypertensive Encephalopathy

The ultimate goal of therapy is to prevent the occurrence of a hypertensive emergency. Patients at risk for a hypertensive crisis should receive intensive management during labor and for a minimum of 48 hours after delivery. Although pregnancy may complicate the diagnosis, once the life-threatening conditions are recognized, pregnancy should not in any way slow or alter the mode of therapy. **The only reliable clinical criterion to confirm the diagnosis of hypertensive encephalopathy is prompt response of the patient to antihypertensive therapy. The headache and sensorium often clear dramatically, sometimes within 1 to 2 hours after the treatment.** The overall recovery may be somewhat slower in patients with uremia and when symptoms have been present for a prolonged period before the therapy is given. Sustained cerebrovascular deficits should suggest other diagnoses.

Patients with hypertensive encephalopathy or other hypertensive crisis should be hospitalized for bed rest. IV lines should be inserted for fluids and medications. Although the tendency is to restrict sodium intake in patients with a hypertensive emergency, volume contraction from sodium diuresis may be present. A marked drop in diastolic BP with a rise in heart rate on standing from the supine position is evidence of volume contraction. Infusion of normal saline solution during the first 24 to 48 hours to achieve volume expansion should be considered. Saline infusion can help decrease the activity of the renin-angiotensin-aldosterone axis and can result in better BP control. Simultaneous repletion of potassium losses and continuous monitoring of BP, volume status, urinary output, ECG readings, and mental status are mandatory. An intraarterial line provides the most accurate BP information. Laboratory studies include a CBC with differential, reticulocyte count, platelets, and blood chemistries. A urinalysis should be obtained for protein, glucose, blood, cells, casts, and bacteria. Assessment for end-organ damage in the CNS, retina, kidneys, and cardiovascular system should be done periodically. Antepartum patients should have continuous fetal monitoring.

### LOWERING BLOOD PRESSURE IN HYPERTENSIVE ENCEPHALOPATHY

**Certain risks are associated with an overly rapid or excessive reduction of elevated BP. The aim of therapy is to lower mean BP by no more than 15% to 25%. Small reductions in BP in the first 60 minutes, working toward a diastolic level of 100 to 110 mm Hg, have been recommended.** Although cerebral blood flow is maintained constantly over a wide range of BPs, autoregulation has a lower and upper limit. In chronically hypertensive women who have a rightward shift of the cerebral autoregulation curve secondary to medial hypertrophy of the cerebral vasculature, lowering BP too rapidly may produce cerebral ischemia, stroke, or coma. Coronary blood flow, renal perfusion, and uteroplacental blood flow also may deteriorate, resulting in

acute renal failure, MI, fetal distress, or death. Hypertension that proves increasingly difficult to control is an indication to terminate the pregnancy. If the patient's outcome appears to be grave, consideration of perimortem cesarean delivery should be made.

**The drug of choice in a hypertensive crisis is sodium nitroprusside.** Other agents such as nitroglycerin, nifedipine, trimetaphan, labetalol, and hydralazine can also be used.

### SODIUM NITROPRUSSIDE

Sodium nitroprusside causes arterial and venous relaxation by interfering with both influx and the intracellular activation of calcium. It is given as an IV infusion of 0.25 to 3  $\mu\text{g/kg/min}$ . The onset of action is immediate, and its effect may last 3 to 5 minutes after discontinuing the infusion. Hypotension caused by nitroprusside should resolve within a few minutes of stopping the infusion because the drug's half-life is so short. If it does not resolve, other causes for hypotension should be suspected.

The effect of nitroprusside on uterine blood flow is controversial. Nitroprusside is metabolized into thiocyanate, which is excreted in the urine. Cyanide can accumulate if production is increased as a result of large doses ( $>10 \mu\text{g/kg/min}$ ) or prolonged administration ( $>48$  hours), or if there is renal insufficiency or decreased metabolism in the liver. Signs of toxicity include anorexia, disorientation, headache, fatigue, restlessness, tinnitus, delirium, hallucinations, nausea, vomiting, and metabolic acidosis. When it is infused at less than 2  $\mu\text{g/kg/min}$ , cyanide toxicity is unlikely. At a maximal dose rate of 10  $\mu\text{g/kg/min}$ , infusion should never last more than 10 minutes. Animal experiments and the few reported cases of nitroprusside use in pregnancy have revealed that **thiocyanate toxicity to mother and fetus rarely occur if it is used in a regular pharmacologic dose.** Tachyphylaxis to nitroprusside usually develops before toxicity occurs. Whenever toxicity is suspected, therapy should be initiated with 3% sodium nitrite at a rate not to exceed 5 mL/min up to a total dose of 15 mL. Then, infusion of 12.5 g of sodium thiosulfate in 50 mL of 5% dextrose in water over a 10 minute period should be started.

### NITROGLYCERIN

Nitroglycerin is an arterial but mostly venous dilator. It is given as an IV infusion of 5  $\mu\text{g/min}$  that is gradually increased every 3 to 5 minutes to titrate BP up to a maximal dose of 100 mg/min. **It is the drug of choice in PE associated with pulmonary edema and for control of hypertension associated with tracheal manipulation.** Side effects such as headache, tachycardia, and methemoglobinemia may develop. It is contraindicated in hypertensive encephalopathy because it increases cerebral blood flow and intracranial pressure.

### KEY POINTS

- ◆ Hypertension is the most common medical complication during pregnancy.
- ◆ Preeclampsia is a leading cause of maternal mortality and morbidity worldwide.
- ◆ The pathophysiologic abnormalities of preeclampsia are numerous, but the etiology is unknown.
- ◆ At present, there is no proven method to prevent preeclampsia. However, low-dose aspirin may have a role in certain women.

- ◆ The HELLP syndrome may develop in the absence of maternal hypertension and proteinuria.
- ◆ Expectant management improves perinatal outcome in a select group of women with severe preeclampsia before 32 weeks' gestation.
- ◆ Magnesium sulfate is the preferred agent to prevent or treat eclamptic convulsions.
- ◆ Rare cases of eclampsia can develop before 20 weeks' gestation and beyond 48 hours postpartum.
- ◆ Antihypertensive agents do not improve pregnancy outcome in women with mild uncomplicated chronic hypertension.
- ◆ Labetalol is the drug of choice for the treatment of chronic hypertension during pregnancy; ACE inhibitors should not be used.

FIG 32-1 Placentation in twin pregnancies.

The increase in multiple births during the past 30 years has been well documented, making multiple gestations one of the most common high-risk conditions encountered by obstetricians. The increase in multiples is due to assisted reproductive technology (ART), as well as older maternal age at childbirth, a known risk factor for spontaneous dizygotic twinning. Over the three decades between 1980 and 2009, the twin birth rate rose by 76%, from 18.9 per 1000 to 33.2 per 1000 births. Until 2004, the twin birth rate rose by approximately 2% each year. However, since 2004, the twin birth rate has remained relatively stable, with a reported rate of 33.1 per 1000 births in 2012.<sup>1</sup> Likewise, rates of triplets and higher-order multiples increased by more than 400% during the 1980s and 1990s, reaching an all-time high in 1998 at a rate of 193.5 per 100,000. Since then, the rate has generally trended downward. The 2012 rate of 124.4 per 100,000 births is the lowest since 1994.<sup>1</sup>

### ZYGOSITY AND CHORIONICITY

Twins can be either monozygotic (MZ) or dizygotic (DZ). *Zygosity* refers to the genetic makeup of the twin pregnancy, and *chorionicity* indicates the pregnancy's placental composition (Fig. 32-1). **Chorionicity is determined by the mechanism of twinning and, in MZ twins, by the timing of embryo division.** Early determination of chorionicity is vital because it is a major factor in determining obstetric risks, management, and outcomes. Because they result from the fertilization of two different ova by two separate sperm, DZ twins always develop dichorionic diamniotic placentation because each blastocyst generates its own chorionic and amniotic sacs. An MZ twin pregnancy is created by the fertilization of one egg by one sperm and subsequent spontaneous cleavage of the fertilized ovum.

TABLE 32-1 DETERMINATION OF MONOZYGOTIC TWIN PLACENTATION

| TIMING OF CLEAVAGE OF FERTILIZED OVUM | RESULTING PLACENTATION     | PERCENTAGE OF MONOZYGOTIC TWINS |
|---------------------------------------|----------------------------|---------------------------------|
| <72 hours                             | Diamniotic dichorionic     | 25-30                           |
| Days 4-7                              | Diamniotic monochorionic   | 70-75                           |
| Days 8-12                             | Monoamniotic monochorionic | 1-2                             |
| ≥Day 13                               | Conjoined                  | Very rare                       |

Thus the type of placentation that develops is determined by the timing of this cleavage (Table 32-1).

**MZ twins are at higher risk for adverse outcomes than are DZ twins. Not only do MZ twins have higher rates of anomalies than DZ twins, they also deliver earlier, have a lower birthweight, and have higher rates of intrauterine and neonatal death.** However, several studies, including one that used DNA analysis to confirm zygosity, have shown that monochorionicity, rather than monozygosity per se, is the determining factor.

### DISTRIBUTION AND CAUSES OF DIZYGOTIC VERSUS MONOZYGOTIC TWINNING

Among natural conceptions, DZ twins arise in about 1% to 1.5% of pregnancies, and MZ twins occur in 0.4% of pregnancies. Rates of spontaneous DZ twinning are greatly affected by maternal age, family history, and race. **The risk for DZ twinning increases with maternal age and peaks at 37 years of age.** Maternal family history, particularly in first-degree relatives, also increases the chance of spontaneous DZ twinning. Paternal family history contributes little or nothing to this risk. Finally, women of African descent have higher rates of DZ twinning than white women, who in turn have higher rates than women of Asian descent. For instance, in Japan, 1 in 250 newborns is a twin, whereas in Nigeria, 1 in 11 babies is a product of a twin gestation.

The causes of DZ twinning are much better understood than the causes of MZ twinning. **DZ twins result from multiple ovulation, which is associated with higher maternal follicle-stimulating hormone (FSH) levels.** FSH levels, and thus rates of DZ twinning, vary with season, geography, maternal age, and body habitus. Increases in DZ twins have been reported in summer months and in locations with more daylight hours and also in taller, heavier, and older mothers. Higher rates of DZ twinning have also been reported following discontinuation of birth control pills, presumably due to a rebound in FSH levels after discontinuation of hormonal suppression.

The causes of MZ twinning are less clear. No naturally occurring animal models for MZ twinning exist except for armadillos, which produce MZ quadruplets or octuplets. It has been proposed that MZ twinning in humans is a teratogenic event. Theories for MZ twinning in humans include fertilization of an "old" ovum with a more fragile zona pellucida or inadequate cytoplasm and with damage to the inner cell mass that leads to two separate points of regrowth and splitting of the fertilized ovum. MZ twinning rates are constant across all variables, with the exception of assisted reproduction. In vitro fertilization

(IVF) and ovulation induction have been shown to produce higher rates of MZ twins. Against a spontaneous rate of 0.4% in the general population, studies have reported rates of MZ twinning more than tenfold higher in pregnancies conceived by assisted fertility. One theory to explain these increased rates of MZ twinning is that injury to the zona pellucida may be responsible for the increased tendency toward iatrogenic zygote splitting.

DIAGNOSIS OF MULTIPLE GESTATIONS

Prenatal ultrasound is invaluable to the early diagnosis of a multiple gestation. Before the advent of routine prenatal ultrasound, many twins were not diagnosed until late in gestation or at delivery. **Using transvaginal ultrasound, separate gestational sacs with individual yolk sacs can be identified as early as 5 weeks from the first day of the last menstrual period, and embryos with cardiac activity can usually be seen by 6 weeks.** Retromembranous collections of blood or fluid or a prominent fetal yolk sac should not be confused with a twin gestation. Another entity that could be confused with a multiple gestation would be a singleton pregnancy with a separate pseudosac in a bicornuate or didelphic uterus. The sonographer must be compulsive in examining the entire uterine cavity in order to avoid underdiagnosing or overdiagnosing a multiple gestation.

Determination of Chorionicity

Accurate determination of chorionicity and amnionicity early in pregnancy is vital to optimal obstetric care. A 2010 editorial argued that “there is no diagnosis of twins” but rather any twin gestation must be further classified at diagnosis as either monochorionic or dichorionic.<sup>2</sup> **Knowledge of chorionicity is essential in counseling patients on obstetric and neonatal risks because chorionicity is a major determinant of pregnancy outcome. Chorionicity is also crucial in making a surveillance and management plan because monochorionic twin gestations require closer surveillance for complications unique to monochorionic placentation, such as twin-twin transfusion syndrome (TTTS).**

**Determination of chorionicity is easiest and most reliable when assessed in the first trimester.** Between 6 and 10 weeks, counting the number of gestational sacs and evaluating the thickness of the dividing membrane is the most reliable method of determining chorionicity (Table 32-2). Two separate

gestational sacs, each containing a fetus, and a thick dividing membrane represent a dichorionic diamniotic pregnancy, whereas one gestational sac with a thin dividing membrane and two fetuses suggests a monochorionic diamniotic pregnancy (Fig. 32-2). For monochorionic gestations, the dividing amniotic membrane may be very difficult to visualize in the first trimester. However, with rare exceptions, the number of amniotic sacs will be the same as the number of yolk sacs, which are relatively easy to count in early gestation.

After 9 weeks, the dividing membranes become progressively thinner, but in dichorionic pregnancies, they remain thicker and easy to identify. **At 11 to 14 weeks’ gestation, sonographic examination of the base of the intertwin membrane for the presence or absence of the lambda, or twin peak, sign provides reliable distinction between a fused dichorionic and a monochorionic pregnancy.** The *twin peak sign* is a triangular projection of tissue that extends beyond the chorionic surface of the placenta (Fig. 32-3). This tissue is insinuated between the layers of the intertwin membrane, is wider at the chorionic surface, and tapers to a point at some distance inward from that surface. This finding is produced by extension of chorionic villi into the potential interchorionic space of the twin membrane where it encounters the placenta of the co-twin; this space exists only in dichorionic pregnancies. The twin peak sign cannot occur in monochorionic placentation because the single continuous chorion does not extend into the potential interamniotic space of the monochorionic diamniotic twin membrane.

**After the early second trimester, determination of chorionicity and amnionicity becomes less accurate, and different techniques are used to assess placentation (Fig. 32-4).** The sonographic prediction of chorionicity and amnionicity should be systematically approached by determining the number of placentae and the sex of each fetus and then by assessing the membranes that divide the sacs. In our own experience we found that using these criteria, **dichorionicity could be determined with 97.3% sensitivity and 91.7% specificity, and monochorionicity with 91.7% sensitivity and 97.3% specificity, in twin gestations first scanned at 22.6 ± 6.9 weeks.**<sup>3</sup> In some pregnancies with monochorionic diamniotic placentation, the dividing membranes may not be sonographically visualized because they are very thin. In other cases, they may not be seen because severe oligohydramnios causes them to be closely apposed to the fetus in that sac. This results in a “stuck twin” appearance, in which the trapped fetus remains firmly held against the uterine wall despite changes in maternal position. In many cases, a small portion of the dividing membrane can be seen extending from a fetal edge to the uterine wall (Fig. 32-5). Diagnosis of this condition confirms the presence of a monochorionic diamniotic gestation, which should be distinguished from a monoamniotic gestation, in which dividing amniotic membranes are absent. In the latter situation, free movement of both twins—and entanglement of their umbilical cords—can be demonstrated.

Determination of Zygosity

If a twin set is monochorionic, monozygosity can be inferred. If twins are different genders, with very rare anecdotal exceptions, they can be assumed to be DZ. It is estimated that based on these two findings, about 55% of all twins’ zygosity can be determined by examination of the babies and placentae. Conversely, 45% of all twins (same-sex dichorionic twins) would need further genetic testing to determine zygosity.

TABLE 32-2    DETERMINATION OF CHORIONICITY AND AMNIONICITY IN FIRST-TRIMESTER PREGNANCIES

| PLACENTATION               | GESTATIONAL SACS | YOLK SACS | AMNIOTIC CAVITIES           |
|----------------------------|------------------|-----------|-----------------------------|
| Dichorionic diamniotic     | 2                | 2         | 2 (thick dividing membrane) |
| Monochorionic diamniotic   | 1                | 2         | 2 (thin dividing membrane)  |
| Monochorionic monoamniotic | 1                | 1*        | 1                           |

\*Although this is nearly always true, there have been case reports of two yolk sacs in early pregnancy in twins later confirmed to be monoamniotic.

**FIG 32-2** **A**, An early first-trimester dichorionic twin gestation. Note the clearly separate gestational sacs, each surrounded by a thick echogenic ring. **B**, A mid first-trimester monochorionic diamniotic twin pregnancy with a very thin, hairlike dividing membrane (MEM, arrow). **C**, An early first-trimester image of a dichorionic triamniotic triplet pregnancy. Note that monochorionic triplets B and C are separated by a very thin membrane, whereas triplet A—with its own placenta—is separated from B and C by a thick membrane.

## MATERNAL AND FETAL RISKS OF MULTIPLE GESTATION

### Maternal Adaptation to Multifetal Gestation

The degree of maternal physiologic adaptation to pregnancy (see Chapter 3) is exaggerated with a multiple gestation. Levels of maternal progesterone, estriol, and human chorionic somatomammotropin (placental lactogen) are higher in multiple gestations than in singletons. This increase in human placental lactogen (hPL) modifies maternal metabolism and is thought to be the cause of the **increased risk for gestational diabetes** seen in multifetal pregnancies. Increased production of multiple placental proteins such as human chorionic gonadotropin (hCG)

**FIG 32-4** Algorithm for determination of chorionicity and amnionicity in the second and third trimesters.

may contribute to clinical conditions such as **a greater risk for hyperemesis**, and it complicates the interpretation of both first- and second-trimester maternal serum screening tests. Cardiovascular adaptations are also greater; both heart rate and stroke volume are increased compared with that of singleton gestations, thus increasing cardiac output. In addition to these cardiac changes, plasma volume expansion and total body water are remarkably increased in twin gestations. Partially as a consequence of increased total body water, colloid oncotic pressure is reduced. Clinical effects of the decreased colloid oncotic pressure are **increased dependent edema and a greater propensity for pulmonary edema**.

Studies using dye excretion have suggested that hepatic clearance capacity is reduced in pregnancy in general and even more so in twin gestation. As described previously, serum protein concentrations are decreased during pregnancy. Although this is partially due to increased total body water, likely some degree of reduced hepatic contribution of serum proteins is present that is again more exaggerated in multifetal gestation compared with singleton pregnancies. Most obvious to patients, marked uterine changes also occur. **By 25 weeks' gestation, the average twin gestation uterine size is equal to a term singleton pregnancy.** By term, the total uterine volume is often 10,000 mL, and the weight of the uterus and its contents can exceed 8 kg. These

**FIG 32-5** The donor twin “stuck” against the anterior uterine wall in a case of twin-twin transfusion syndrome. Note the small portion of membrane visible (arrow) extending from the edge of the fetus to the uterine wall.

changes are even more exaggerated with triplets and higher-order gestations.

### Maternal Morbidity and Mortality

**Virtually every obstetric complication, with the exception of macrosomia and postterm gestation, is more common with multiple gestations, and in general the risk rises proportionally to increasing plurality.** Table 32-3 provides the relative risks for various obstetric complications in twin gestations compared with singletons.<sup>4</sup> In addition to the conditions listed in the table, multiples are associated with higher rates of gestational diabetes and rare but life-threatening conditions such as acute fatty liver and peripartum cardiomyopathy. **Additionally, women pregnant with multiples not only have higher risks for developing certain conditions but also are more likely to have more severe manifestations of those conditions.** For instance, Sibai and associates<sup>5</sup> showed that not only are mothers of twins more likely to develop preeclampsia (relative risk [RR], 2.62; 95% confidence interval [CI], 2.03 to 3.38), but twin mothers with preeclampsia also have higher rates of delivery before 37 weeks and before 35 weeks as well as higher rates of placental abruption and small-for-gestational-age (SGA) infants than singleton mothers with preeclampsia. A large retrospective analysis of 24,781 singleton, 6859 twin, 2545 triplet, and 189 quadruplet pregnancies found an incidence of pregnancy-related hypertensive conditions of 6.5% in singletons, 12.7% in twins, and 20% in triplets and quadruplets.<sup>6</sup> **Atypical presentations of preeclampsia are also more common in multifetal gestations, especially triplets and higher-order multiples.** One retrospective review of 21 triplet and 8 quadruplet pregnancies found that only half of the women who were delivered for preeclampsia had elevated blood pressures before delivery. Furthermore, proteinuria was present in only 3 of 16 women before delivery. Predominant presentations of preeclampsia in this series were laboratory abnormalities (chiefly elevated liver enzymes) and maternal symptoms.<sup>7</sup> One theory for the higher incidence of atypical preeclampsia in women with triplet and higher-order multiples is that the exaggerated hemodynamic changes found in higher-order multiples will mask the “typical” maternal manifestations of preeclampsia.

These increased maternal risks extend to life-threatening morbidity and even mortality. Multiple gestation has been found to be an independent risk factor for intensive care unit (ICU) admission.<sup>8</sup> Finally, **although fortunately still a very rare event, maternal death is also increased in multifetal gestations.** A

**TABLE 32-3** MATERNAL COMPLICATIONS IN MULTIPLE GESTATIONS

|                                 | SINGLETON (n = 71,851) (%) | TWIN (n = 1694) (%) | RR  | 95% CI     |

relative risk of 2.9 (95% CI, 1.4 to 6.1) for maternal death in women pregnant with multiples has been reported.<sup>9</sup>

### Perinatal Morbidity and Mortality

**Multifetal gestations carry significant perinatal risks. Babies who are products of multiple gestations have higher rates of low birthweight (LBW), very low birthweight (VLBW), earlier gestational age at delivery, and higher rates of neonatal and infant death and cerebral palsy (Table 32-4).**<sup>10</sup> One in 8 twins and 1 in 3 triplets are born before 32 weeks' gestation compared with only 2 in 100 singletons. Additionally, the risk for infant death is dramatically higher than in singletons: twins are more than 4 times, triplets 10 times, and quadruplets more than 20 times as likely to die in infancy.<sup>1</sup> Rates of cerebral palsy have been estimated to be 4 to 8 times higher in twins than in singletons and as much as 47 times higher in triplets. Most of this increased risk is attributable to higher rates of early preterm delivery and VLBW in multiple gestations. Notably, although the overall rates of cerebral palsy are higher in twins than in singletons, LBW preterm twins do not have higher rates than similar-weight, gestational age–matched singletons. Interestingly, however, most studies have demonstrated higher rates of cerebral palsy for twins born at term weighing more than 2500 g than for comparable term singletons. This difference is mostly a reflection of the effect of monochorionicity on twin growth and development.

### Fetal Anomalies

**Fetuses in multiple gestations are known to be at increased risk for anatomic abnormalities, although the exact degree of risk is debated.** The largest series<sup>11</sup> available, an international study of more than 260,000 twins, found an increased relative risk for major anomalies of 1.25 (95% CI, 1.21 to 1.28); anomalies were found in all organ systems. This study, however, was not informed on zygosity or chorionicity, and most experts believe that **much of the increased risk for structural anomalies in multiple gestation is associated with MZ twinning.**

A 2009 population-based study<sup>12</sup> from England found that rates of congenital anomalies were 1.7 times more frequent in twins compared with singletons (95% CI, 1.5 to 2.0) and that the relative risk for monochorionic twins was nearly twice that of dichorionic twins (RR, 1.8; 95% CI, 1.3 to 2.5). A Taiwanese series<sup>13</sup> of 844 twin sets compared with 4573 control singletons found a doubling of the relative risk of major congenital malformations in twins compared with singletons. When broken down by zygosity, the relative risks were 1.7 for DZ twins and 4.6 for MZ twins with an anomaly prevalence of 0.6% for singletons, 1% for DZ twins, and 2.7% for MZ twins. Anomalies were concordant in 18% of the MZ twins but in none of the DZ twins. Older studies have shown somewhat higher

overall anomaly rates both for singletons and twins but found similar distributions. Thus **the overall evidence supports an approximately twofold increased risk for congenital anomalies in twins versus singletons, with most of this risk occurring in MZ twins.**

A strong association has been found between MZ twinning and midline structural defects. Nance<sup>14</sup> has presented evidence that a group of birth defects that involve midline structures—including symmelia, holoprosencephaly, exstrophy of the cloaca, and neural tube defects—may be associated with the MZ twinning process. Nance suggests that the MZ twinning process with its attendant opportunities for asymmetry, cytoplasmic deficiency, and competition in utero may favor the discordant expression of midline defects in these gestations.

### ISSUES AND COMPLICATIONS UNIQUE TO MULTIPLE GESTATIONS

#### "Vanishing Twin"

The so-called vanishing twin is a well-known obstetric phenomenon, and this term refers to the **loss of one fetus of a multiple gestation early in pregnancy.** This is typically either asymptomatic or associated with spotting or mild bleeding. Landy and colleagues<sup>15</sup> reported on a series of 1000 first-trimester ultrasounds and found an incidence of twinning of just over 3%. After confirming a twin gestation (two embryos with heartbeats), 21.2% ultimately delivered singletons. In general, if two gestational sacs are confirmed by the first-trimester ultrasound, the chance of delivering twins is 63% for women younger than 30 years and 52% for women 30 years or older. If two embryos with cardiac activity are seen in the first trimester, the chance of a twin birth rises to 90% for women younger than 30 years and 84% for women 30 years or older.<sup>16</sup> Other investigators have shown that, not unexpectedly, the earlier the initial ultrasound, the greater the chance of a vanishing twin phenomenon. Additionally, monochorionic twin gestations are at higher risk for either a vanishing twin or a complete pregnancy loss than are dichorionic twins. A vanishing twin phenomenon is even more common in higher-order multiples. Dickey and colleagues<sup>17</sup> performed an ultrasound at 3.5 to 4.5 weeks postovulation and repeated the scan every 2 weeks until 12 weeks to assess the natural history of early pregnancy in higher-order gestations. Spontaneous loss of one or more sacs occurred in 53% of 132 triplets and in 65% of 23 quadruplets. Most of these losses were recognized earlier than 9 weeks' gestation.

#### First-Trimester Multifetal Pregnancy Reduction

The increasing use of ovulation induction and assisted reproduction has resulted in a growing number of multifetal pregnancies with three or more fetuses. **Because the risk for pregnancy loss,**

**preterm delivery, and long-term physical and neurodevelopmental morbidity for children who are products of multiple gestations is directly proportional to the number of fetuses being carried, first-trimester multifetal pregnancy reduction (MPR) has been advocated as a method to reduce the risks associated with prematurity.** Currently, the method of choice is injection of potassium chloride into the thorax of one or more of the fetuses, most commonly performed transabdominally under real-time sonographic guidance. **Unless reduction of the entire monochorionic component is planned, the use of this technique is contraindicated in monochorionic pregnancies because of the vascular communications within the placenta.**

MPR is an outpatient procedure usually performed between 11 and 13 weeks, and chorionic villus sampling (CVS) can be performed on some or all of the fetuses before the procedure to confirm karyotype if desired. Ultrasound is used to map the location of each fetus, nuchal translucencies should be measured, and prophylactic antibiotics are often administered. Any fetus that appears small for gestational age, anatomically abnormal, abnormal in nuchal translucency measurement, or is known to have a karyotypic abnormality is included among those reduced. If a monochorionic twin component is present in a higher-order multiple gestation, the monochorionic set is generally targeted for reduction. If no abnormalities can be detected, the fetus or fetuses that are technically most accessible are chosen for reduction. In order to minimize the risk for premature rupture of the membranes whenever possible, the fetus whose sac overlies the internal cervical os is not electively reduced. Follow-up ultrasound examinations should be performed to confirm the success of the procedure and to monitor the growth of the remaining fetuses.

In deciding on the appropriateness of MPR for a multifetal pregnancy, the clinician must take into account not only the potential improvement in pregnancy outcome from reducing a higher-order multifetal pregnancy but also the risk of losing the entire desired pregnancy as a result of the procedure. Evans and colleagues<sup>18</sup> published a series of 3513 completed first-trimester MPR procedures from 11 centers in five countries. The overall loss rate was 9.6%, but each of the participating centers showed significant improvement in this parameter as the operators developed more experience. Additionally, loss rates increased steadily from 4.5% to 15.4% as the number of starting fetuses rose from three to six or more.

Stone and colleagues<sup>19</sup> also demonstrated a learning curve evidenced by fewer complications with increasing experience. A 2008 report of the most recent 1000 multifetal reductions (of >2000 procedures performed by their group at that time) found that the overall unintended pregnancy loss rate was 4.7%, a decrease from a 9.5% loss rate in the first 200 procedures at their institution. This 4.7% loss rate is unlikely to drop further because it approximates the baseline risk for pregnancy loss with twins in general. The rates of complete pregnancy loss by starting fetal number were 2.1%, 5.1%, 5.5%, and 11% for twins, triplets, quadruplets, and quintuplets or more, respectively. All patients except two reduced to twins or singletons; complete pregnancy loss rates by finishing fetal number were 3.8% for singletons and 5.3% for twins.

**Although perinatal morbidity and mortality are clearly improved when pregnancies with quadruplets or greater are reduced to smaller numbers, the obstetric and perinatal advantages of reducing triplets to twins remain debatable. A**

2006 meta-analysis attempted to answer this question.<sup>20</sup> The authors collected 893 pregnancies beginning as triplets, of which 411 were expectantly managed and 482 underwent MPR to twins. The rate of pregnancy loss before 24 weeks was higher in the MPR group (8.1% vs. 4.4%;  $P = .036$ ). However, this risk was offset by a lower risk for delivery between 24 and 32 weeks in the MPR group (10.4% vs. 26.7%;  $P < .0001$ ). The authors calculated that 7 reductions are needed to prevent one delivery before 32 weeks, and that 26 reductions would result in one loss before 24 weeks. Thus reducing triplets to twins may be associated with overall improvements in outcome. Since this meta-analysis, several other papers that reported outcomes in triplets reduced to twins have been published. A 2014 retrospective cohort study from the Netherlands compared 86 women with trichorionic triplets reduced to twins with 44 women with ongoing trichorionic triplet pregnancies and 824 women with conceived dichorionic twins. The study found that the median gestational age at delivery for reduced twins was 3 weeks longer than for triplets and 1 week shorter than for primarily conceived twins (36.1 weeks vs. 33.3 weeks vs. 37.1 weeks;  $P < .001$ ). A significant difference was also found in birthweight (2217 g, 1700 g, and 2422 g in reduced twins, triplets, and primary twins, respectively;  $P < .001$ ). However, no difference in survival was reported. In addition, no statistically significant reduction was noted in delivery prior to 24 weeks or prior to 32 weeks in the reduced twins compared with the triplets.<sup>21</sup> Another 2014 paper from Iran reported on 115 ART-conceived triplet pregnancies. Of those 115 triplet pregnancies, 57 were reduced to twins and 58 were not. The reduced pregnancies had a lower risk of preterm labor, higher birthweights, more advanced gestational age at delivery (35.1 vs. 32.4 weeks;  $P = .002$ ), and lower rates of neonatal intensive care unit (NICU) admission. Additionally, they reported lower perinatal mortality in the reduced pregnancies (6% vs. 17.6%;  $P = .007$ ).<sup>22</sup> Of course, it must be considered that inherent in a reduction procedure from triplets to twins is a one-third mortality rate. Offering the option of a multifetal reduction procedure to patients carrying triplets is medically reasonable, but whether this is perceived as a valuable option by the patient will depend on many factors, including the family's social, financial, ethical, and religious considerations.

## Discordance for Anomalies

When an anomaly is detected in a twin gestation, even in an MZ set, the co-twin is usually normal. The diagnosis of discordance for a major anatomic abnormality places the parents in an extremely difficult position. Management choices include (1) expectant management of both fetuses, (2) termination of the entire pregnancy, or (3) selective termination of the anomalous fetus.

Several issues should be considered when counseling patients about the management of a multiple pregnancy complicated by discordant anomalies. These include (1) severity of the anomaly and certainty of diagnosis, (2) likelihood of survival or intact survival of the anomalous twin, (3) chorionicity, (4) effect of the anomalous fetus on the remaining fetus or fetuses, and (5) the parents' ethical beliefs. It is important to counsel patients if expectant management could result in adverse outcomes for the healthy twin. In dichorionic twins, the main issue is whether the presence of an anomalous co-twin is associated with a significantly increased risk of preterm delivery (e.g., an anomaly with polyhydramnios). For monochorionic twins, the issues are more

complex. In addition to the possibility of preterm birth (PTB) associated with the presence of an anomalous co-twin, intrauterine fetal death (IUFD) of the anomalous fetus clearly has direct implications for the normal co-twin. As discussed elsewhere in this chapter, IUFD of one twin in a monochorionic pair is associated with a high rate of death or neurologic impairment of the co-twin.

Regarding the risk of PTB, the data are conflicting. Several papers have shown an increased risk of preterm delivery compared with twins in which neither fetus has a major structural anomaly.<sup>23-25</sup> A 2009 population-based study using the 1995 through 1997 United States Matched Multiple Births dataset compared more than 3000 normal co-twins of fetuses with nonchromosomal structural anomalies with more than 12,000 control twins unaffected by structural anomalies. They found higher rates of PTB (both <37 and <32 weeks), LBW, and perinatal mortality in the normal co-twins of affected fetuses. However, the differences in mean gestational age at delivery and mean birthweight, although statistically significant, were small (35.0 vs. 35.8 weeks,  $P < .0001$ , and 2265 vs. 2417 g,  $P < .0001$ , respectively).<sup>26</sup> A recent smaller paper did not find an increased risk of preterm delivery in twin pregnancies complicated by a major anomaly in one fetus. Harper and colleagues<sup>27</sup> compared 66 twin pregnancies discordant for anomalies with 1911 structurally normal twin pregnancies and found no difference in median gestational age at delivery (36.0 vs. 35.7 weeks for normal vs. anomalous pregnancies, respectively;  $P = .43$ ).

Some papers have shown a small increased risk of perinatal mortality in normal co-twins of anomalous fetuses.<sup>24,26</sup> However, it should be noted that one of these papers did not have information on chorionicity, and several of the deaths in the other paper were in monochorionic sets. **Consequently, the evidence for an increased risk of perinatal mortality in dichorionic pregnancies discordant for major anomalies is inconclusive.** Other studies, even one of the papers that demonstrated a higher risk of preterm delivery, have not detected any differences in perinatal mortality or neonatal outcomes other than hospital length of stay.<sup>23</sup>

### Selective Termination

Although multiple techniques have been used to effect selective termination (ST) of a single fetus in a multiple gestation, the most common approach in dichorionic gestations is intracardiac injection of potassium chloride.

Evans and colleagues<sup>28</sup> reported the outcomes of 402 ST procedures in dichorionic twins from eight centers in four countries using ultrasound-guided intracardiac injection of potassium chloride. They reported successful ST in 100% of cases and delivery of one or more viable infants in more than 90% of cases. The complete pregnancy loss rate prior to 24 weeks was 7.1%, and no cases of disseminated intravascular coagulation (DIC) or serious maternal complications were reported.

**In monochorionic twins, ST is far more challenging. Ablation of the umbilical cord of the anomalous fetus is needed to avoid back-bleeding through communicating vessels, which may precipitate death or neurologic injury in the remaining normal co-twin.** Selective termination by cord occlusion can be considered in several circumstances involving monochorionic multiple gestations. These include:

1. Severely discordant anomalies
2. Severely discordant growth with high risk for IUFD at previable or perivable gestational ages

3. Twin reversed arterial perfusion (TRAP) sequence
4. Severe TTTS with associated discordant anomaly or in cases in which laser ablation was precluded by position of the fetus and placenta

Each of the above indications is discussed in more detail in the corresponding sections of this chapter.

Bipolar coagulation of the umbilical cord is probably the most commonly used technique, although radiofrequency ablation (RFA), laser coagulation, and ligation of the cord have also been successful. The site for port insertion is chosen according to the position of the placenta and the amniotic sac of the target fetus and its umbilical cord. Preferentially, the other sac is avoided. Sometimes amniotomies are necessary to expand the target sac.

Pregnancy outcomes for the surviving co-twin are relatively favorable after selective cord occlusion. Rossi and D'Addario<sup>29</sup> published a review of the literature regarding umbilical cord occlusion in complicated monochorionic twin pregnancies. They evaluated 12 studies that comprised 345 cases of cord occlusion at median gestational ages between 18 and 24 weeks. The overall survival rate for the remaining twin was 79% and was higher for cases after 18 weeks (89%) than for those undergoing the procedure earlier than 18 weeks (69%) regardless of the indication. Survival rates were 86% after RFA, 82% after bipolar cord coagulation, 72% after laser, and 70% after cord ligation. Long-term follow-up was not available for most studies. However, in one series, the incidence of developmental delay was 8% in 67 infants older than 1 year who underwent evaluation by a pediatrician.<sup>30</sup>

### Intrauterine Fetal Demise of One Twin

Intrauterine fetal demise of one twin occurs most commonly during the first trimester. This phenomenon is known as a *vanishing twin* and was discussed earlier in this chapter. Although it can be associated with vaginal spotting, the loss of one conceptus early in the first trimester is often not clinically recognized, and the prognosis for the surviving twin is generally excellent. **IUFD of one fetus in a multiple gestation in the second or third trimester is much less common and complicates about 2.4% to 6.8% of twin pregnancies, but it can have more severe sequelae for the surviving fetus.** In triplet pregnancies, studies have reported single IUFD rates between 4.3% and 17%.

The etiology of IUFD in a multiple pregnancy may be similar to that for singletons or may be unique to the twinning process. Death in utero may be caused by conditions that affect only the demised twin, such as chromosomal or structural abnormalities, or by more global conditions such as maternal diseases, which put the entire pregnancy at risk. In diamniotic monochorionic pregnancies, IUFD may result from complications of TTTS or twin anemia-polycythemia sequence (TAPS), whereas cord entanglement is a major contributor to IUFD in monoamniotic monochorionic twins. Just as in singletons, however, the etiology of many IUFDs remains elusive.

**Single IUFD in a twin gestation puts the surviving twin in jeopardy.** In twin pregnancies complicated by demise of one twin, intrauterine death of the co-twin is reported in 12% to 15% of monochorionic gestations and in 3% to 4% of dichorionic gestations.<sup>31,32</sup> In a 2006 meta-analysis by Ong and associates<sup>31</sup> of twin pregnancies complicated by a single IUFD, preterm delivery occurred in 68% of monochorionic twins and in 57% of dichorionic twins, figures that include both spontaneous and iatrogenic preterm delivery. A more recent meta-analysis in 2011

by Hillman and colleagues<sup>32</sup> found strikingly similar rates of PTB: 68% for monochorionic and 54% for dichorionic twins. In the Hillman meta-analysis, overall PTB rates did not differ statistically by chorionicity except in the subgroup, in which IUFD occurred between 28 and 33 weeks. In this subgroup, preterm delivery was nearly 5 times more common in monochorionic compared with dichorionic twins (OR, 4.96; 95% CI, 1.6 to 15.8). The authors speculate that this difference may relate to iatrogenic delivery as a result of clinician concern for co-twin demise in monochorionic pregnancies. Neither of these meta-analyses had a control group of twins with two survivors. However, the reported percentages for PTB in the IUFD pregnancies are not markedly different than the 58.8% risk of preterm delivery reported by national vital statistics data for all twin pregnancies.<sup>10</sup> That said, some studies have shown an increased risk of PTB in twin pregnancies complicated by a single IUFD.<sup>33</sup>

**Surviving co-twins of pregnancies complicated by a single IUFD are also at risk for brain injury.** Pharoah and Adi<sup>34</sup> reported on a large cohort of all registered twin births in England and Wales between 1993 and 1995 and found a 20% risk of cerebral impairment in the surviving twins. That paper provided information on gender but not chorionicity or zygosity. The meta-analysis by Hillman and colleagues<sup>32</sup> reported the rate of abnormal postnatal (<4 weeks of delivery) cranial imaging and neurodevelopmental impairment after a single fetal death. Abnormal cranial imaging was found in 34% of monochorionic twins compared with 16% of dichorionic twins (not significant with OR 3.25; 95% CI, 0.66 to 16.10). Neurodevelopmental impairment followed single fetal death in 26% versus 2% for monochorionic and dichorionic twins, respectively (OR, 4.81; 95% CI, 1.4 to 16.6).

Multicystic encephalomalacia is believed to be a precursor to infant and childhood cerebral impairment in many cases; it results in **cystic lesions within the cerebral white matter distributed in areas supplied by the anterior and middle cerebral arteries, and it is associated with profound neurologic handicap** (Fig. 32-6). Patients with monochorionic placentation should thus be counseled about the risk of developing this condition and the resultant cerebral palsy or other serious neurodevelopmental handicap in the surviving twin. Ultrasound examination of the fetal brain may be suggestive of multicystic encephalomalacia but is not always definitive. Antenatal magnetic resonance imaging (MRI) of the fetal brain may also be useful in its detection. We currently offer fetal MRI to all patients with monochorionic placentae approximately 2 to 3 weeks after the demise of one fetus has been detected. If a normal MRI does not definitively rule out brain abnormalities, it is a very positive prognostic finding.

**The most widely accepted hypothesis as to the cause of neurologic injury in surviving co-twins in a monochorionic pregnancy is that significant hypotension occurs at the time of the demise.** After death of the first twin, the resulting low pressure in that twin's circulatory system causes blood from the survivor to rapidly back-bleed into the dead twin through placental anastomoses. If the resulting hypotension is severe, the surviving twin is at risk for both demise and ischemic damage to vital organs. The brain is at particular risk because of its high oxygen requirements. It should be stressed that, because the injury is coincident with the IUFD, rapid delivery of the co-twin following single IUFD in a monochorionic pregnancy will not improve the outcome.

**FIG 32-6** Ultrasound of the fetal brain of a monochorionic twin before (A) and after (B, C) intrauterine fetal death of the co-twin at 20 weeks' gestation. Note the normal brain anatomy in A, the dilation and cystic changes shortly after the co-twin's demise in B, and the residual irregular hydrocephalus and parenchymal loss 12 weeks later in C. B, twin B; NF, nuchal fold.

Until relatively recently, it was thought that intrauterine demise in a monochorionic twin gestation would not cause neurologic injury to its co-twin until at least the mid second trimester. However, in 2003, Weiss and coworkers<sup>35</sup> reported a case of injury to a fetus after IUFD of the co-twin at about 13 weeks. Multicystic encephalomalacia was diagnosed by ultrasound and MRI in the co-twin at 20 weeks. The patient was counseled regarding the likelihood of a poor prognosis and opted for termination. Multicystic encephalomalacia was confirmed pathologically, although the exact timing of the injury could not be determined.

**Other maternal risks exist with single IUFD in a multifetal gestation. Cesarean delivery appears to be increased in these patients, often because of nonreassuring fetal status of the surviving twin.** However, other adverse maternal outcomes such as hemorrhage, infection, and coagulopathy have *not* been found to be increased in twin mothers with a single IUFD.<sup>33</sup> It was originally estimated that the incidence of maternal DIC was 25% when a dead fetus was retained in a multiple gestation. However, only a few isolated cases of laboratory changes consistent with a subclinical coagulopathy have been reported under these circumstances. The estimated 25% incidence is certainly a gross overestimation. It is also reassuring to note that no cases of clinically significant coagulopathy have been reported in the extensive literature on selective termination and multifetal pregnancy reduction.

The optimal management for a single IUFD in multiple gestations is not well established, and recommendations are based mainly on expert opinion. **Clinical management depends on the gestational age, maternal status, or detection of in utero compromise of the surviving fetus or fetuses.** The goal is to optimize the outcome for the survivor while also avoiding unnecessary prematurity. Serial sonographic assessment of the surviving co-twin's growth is indicated, as is antenatal testing. However, when to initiate antenatal testing and the frequency of testing depends on clinical factors such as gestational age at the time of the IUFD.

The 2011 National Institute of Child Health and Human Development (NICHD) and Society for Maternal-Fetal Medicine (SMFM) workshop on timing of indicated late-preterm and early-term birth addressed the issue of a single IUFD in a twin pregnancy. If the IUFD occurs at 34 weeks or beyond, delivery should be considered.<sup>36</sup> In the 2014 Practice Bulletin on Multifetal Gestation, the American College of Obstetricians and Gynecologists (ACOG) gives a similar recommendation, stating that in the absence of other indications, a single IUFD in a twin pregnancy before 34 weeks should not prompt immediate delivery.<sup>37</sup> **In the authors' practices, a single IUFD in a monochorionic diamniotic pregnancy at or after 34 weeks would be an indication for delivery.** In a dichorionic pregnancy, delivery timing would be individualized based on the likely cause of the IUFD, the appropriateness of fetal growth, and fetal testing of the surviving co-twin.

Vaginal delivery is not contraindicated, and cesarean delivery is reserved for routine obstetric indications. Autopsy should be offered for the stillborn fetus but may not be helpful if the demise occurred several weeks earlier. Pathologic examination of the placenta is also recommended. In addition, the pregnancy history should be communicated to the pediatricians caring for the neonate.

## Twin-Twin Transfusion Syndrome

### Etiology

**Twin-twin transfusion syndrome is exclusively a complication of monochorionic multifetal pregnancies. It occurs in 10% to 15% of monochorionic diamniotic gestations and is thus the most common life-threatening complication specific to this type of twinning.** TTTS is characterized by an imbalance of fetal blood flow through communicating vessels across a shared placenta, which leads to **underperfusion of the donor twin and overperfusion of the recipient** (Fig. 32-7). The donor twin develops oligohydramnios, and if it is chronic, intrauterine growth restriction (IUGR) ensues; the recipient

**twin experiences volume overload**, which results in polyhydramnios that leads to uterine overdistension and increased intrauterine pressure, both of which may contribute to an increased risk for preterm labor and preterm premature rupture of the membranes (PPROM). On fetal echocardiography, the recipient demonstrates decreased ventricular function, tricuspid regurgitation, and cardiomegaly. Over time, recipient twins can develop functional right ventricular outflow tract obstruction and pulmonic stenosis. These cardiac abnormalities often progress during pregnancy and persist into the neonatal period.

**TTTS can present at any gestational age, but earlier onset is associated with a poorer prognosis.** If untreated, the reported mortality rates can range from 80% to 100%. Furthermore, if one fetus dies in utero, the surviving twin is at risk for death or multiorgan ischemia from acute exsanguination due to back-bleeding into the circulation of the dead co-twin.

All monochorionic twins share vascular anastomoses and thus exist in a state of constant intertwin transfusion. As noted earlier, however, only a minority develop clinical TTTS. The following pathophysiology has been proposed to explain this observation. In monochorionic placentae, three types of vascular communication are possible: (1) arteriovenous (AV), (2) arterioarterial (AA), and (3) venovenous (VV). AA and VV anastomoses are usually superficial bidirectional anastomoses on the surface of the chorionic plate; however, **AV anastomoses—referred to as deep anastomoses—involve a shared cotyledon, which receives arterial supply from one twin and drains on the venous side to the other twin.** All these anastomoses are identifiable at the chorionic surface. Superficial anastomoses, especially those that are AA, are crucial for maintaining bidirectional flow. According to this hypothesis, an inadequacy of superficial AA and VV anastomoses, which help maintain balanced blood flow, allows TTTS to manifest due to an imbalance of deep AV anastomoses.

### Diagnosis and Staging

**The antenatal diagnosis of TTTS is made by ultrasound. The two classic criteria are monochorionic diamniotic twin gestation and oligohydramnios (deepest vertical pocket [DVP] <2 cm) in one amniotic sac and polyhydramnios (DVP >8 cm) in the other sac.** A staging system for TTTS (Table 32-5) was developed in 1999 by Quintero and colleagues<sup>38</sup> to categorize disease severity and to standardize comparison of different treatment approaches. **Although the Quintero staging is widely used and has proved enormously useful in our understanding of TTTS, many experts have noted its limitations.** The stage does not always progress; and when patients worsen,

**TABLE 32-5** QUINTERO STAGING FOR TWIN-TWIN TRANSFUSION SYNDROME

|           |   |
|-----------|---|
| Stage I   | Oligohydramnios, polyhydramnios sequence. Donor twin bladder visible.   |
| Stage II  | Oligohydramnios, polyhydramnios sequence. Donor twin bladder not visible. Doppler scan normal.  |
| Stage III | Oligohydramnios, polyhydramnios sequence. Donor twin bladder not visible, and Doppler scans abnormal (absent or reversed end-diastolic velocity in the umbilical artery, reversed flow in the ductus venosus, or pulsatile flow in the umbilical vein). |
| Stage IV  | One or both fetuses have hydrops.   |
| Stage V   | One or both fetuses have died.  |

**FIG 32-7** **A**, The placenta of a pregnancy complicated by twin-twin transfusion syndrome. Milk has been injected into an artery on the donor side of the placenta (*black arrow*). It can be seen returning through the venous circulation on that side but is also evident in the venous circulation of the recipient twin (*white arrow*). **B**, The arteriovenous shunt shown in A.

they do not always progress sequentially through the stages. For instance, a pregnancy can become stage 5 (fetal death) without progressing through stage 4 (hydrops); and an atypical stage III TTTS has been described with Doppler abnormalities but with a bladder still visible in the donor. Modifications of Quintero staging have been proposed that incorporate the differences in cardiovascular pathophysiology between donors and recipients. None of these proposed staging alternatives, however, has been validated in prospective studies.

TTTS most commonly presents between 15 and 26 weeks' gestation. Intensive ultrasound surveillance should be performed during this period to allow a timely diagnosis. Because an ultrasound interval of more than 14 days has been associated with a higher stage of TTTS at diagnosis,<sup>39</sup> both ACOG and SMFM endorse an every-2-week ultrasound surveillance schedule for monochorionic diamniotic twins starting around 16 weeks.<sup>37,40</sup>

### Management

**When TTTS is diagnosed, five management options are available: (1) expectant management, (2) septostomy, (3) serial amnioreduction, (4) selective termination/cord occlusion, and (5) fetoscopic laser photocoagulation.** Selective termination is only offered in extreme cases of advanced TTTS. Expectant management is generally not recommended in stage II or greater TTTS because of the poor perinatal outcomes associated with the disorder if untreated. **However, management depends on the gestational age at diagnosis and, despite the previously mentioned limitations of the Quintero staging system, on the severity of the clinical findings.**

### SEPTOSTOMY

**Septostomy involves intentional perforation of the dividing membrane, usually performed with a 20- or 22-gauge needle**

**under ultrasound guidance.** This procedure can, in theory, equalize amniotic fluid volumes (AFVs) between amniotic sacs. The only randomized trial involving this technique compared septostomy with amnioreduction for the treatment of TTTS. The study was terminated early after enrollment of 73 women because the rate of survival of at least one infant was similar in both groups (78% vs. 80%;  $P = .82$ ). The major advantage seen with septostomy was that women randomized to the septostomy group were more likely to require only a single procedure for treatment (64% vs. 46%;  $P = .04$ ).<sup>41</sup> Because septostomy could functionally create an iatrogenic monoamniotic pregnancy with its own inherent risks, the procedure has been criticized and infrequently recommended as a therapeutic option for TTTS.

### SERIAL AMNIOREDUCTION

**In serial reduction amniocentesis, a needle is placed into the polyhydramniotic sac under ultrasound guidance. Amniotic fluid is withdrawn until the fluid volume normalizes** (i.e., DVP <8 cm). Because of the large amount of fluid to be removed, attaching the needle to a closed-system vacuum container is more practical than withdrawing fluid manually. Amnioreduction is repeated as often as necessary to maintain a normal or near-normal AFV. The mechanism by which this procedure restores the amniotic fluid balance is unknown. Removing excessive fluid from the sac with polyhydramnios may result in decreased intraamniotic pressure that in turn may result in increased placental perfusion to the twin with oligohydramnios, especially through thin-walled superficial venous anastomoses with secondary improvement in its AFV. Additionally, normalizing the AFV may help prolong pregnancy by relieving uterine overdistension and pressure on the cervix.

Although no prospective studies are available with which to compare serial amnioreduction with conservative management, **based on observational data, amnioreduction appears to offer a twofold to threefold increase in overall survival compared with no intervention.** The exception may be late-onset (third-trimester) stage I TTTS that remains stable over a 1- to 2-week observation period. A large retrospective cohort study using the International Amnioreduction Registry to analyze 223 sets of twins with TTTS diagnosed prior to 28 weeks' gestation and treated with serial amnioreduction found a live birth rate of 78%, and 60% were alive 4 weeks after birth. IUFD of at least one twin occurred in 31% of the pregnancies. In 14% of cases, IUFD of both babies occurred. Of those babies alive 4 weeks after birth, 24% of the recipients and 25% of the donors had abnormal findings on cranial imaging. Poor prognostic factors for survival were earlier gestational age at diagnosis, no end-diastolic flow in the umbilical arteries, hydrops, LBW, and earlier gestational age at delivery. Complications within 48 hours of the procedure (spontaneous rupture of the membranes, spontaneous delivery, fetal distress, fetal death, and placental abruption) occurred in 15% of patients.<sup>42</sup>

### LASER THERAPY

**Laser ablation of placental anastomoses is the favored treatment option for early-onset TTTS (Fig. 32-8).** In the United States, the use of laser photocoagulation to treat TTTS is restricted to gestations earlier than 26 weeks. **Unlike both serial amnioreduction and septostomy, which are considered palliative procedures, laser ablation is the only therapeutic option that corrects the underlying pathophysiologic aberration that causes TTTS.** Additionally, because laser ablation

**FIG 32-8** **A**, An artery from one twin going to a cotyledon, which is drained by a vein returning to the co-twin (*black arrow*). The cotyledon is also perfused by a small artery from the co-twin (*white arrow*) and is drained by a large vein going also to the co-twin. To preserve this cotyledon for the co-twin, the arterial perfusion to the cotyledon from the other twin is interrupted by laser photocoagulation of the other artery. **B**, The effect of photocoagulation. (Courtesy Timothy M Crombleholme, MD, University of Cincinnati College of Medicine.)

interrupts the vascular anastomoses between the fetuses, it has the advantage of being protective of the surviving twin should one twin succumb in utero.

In this procedure, first described by De Lia, the strategy is to ablate all anastomosing vessels that might connect the fetuses. The procedure is performed percutaneously under local or regional anesthesia. An endoscopic cannula is inserted into the amniotic cavity of the recipient fetus under ultrasound guidance at an angle perpendicular to the presumed vascular equator. The positions of the fetuses, umbilical cord insertions, and placenta are mapped. The operator visualizes the entire vascular equator and coagulates all visible anastomoses. Arteries are distinguishable from veins because they have a darker color and pass over the larger veins. Reduction amniocentesis is usually simultaneously performed. When the placenta is anterior, operative

conditions are more difficult. Special instruments have been developed that include curved sheaths, flexible endoscopes, and a double-insertion technique. Most centers hospitalize patients for 1 or 2 postoperative days, and many experts use perioperative tocolytics and antibiotics.

#### OUTCOMES AFTER LASER THERAPY

In 2004, Senat and colleagues<sup>43</sup> published the results of the Eurofetus trial, a prospective multicenter randomized controlled trial (RCT) of endoscopic laser (semiselective technique) versus serial amnioreduction for the treatment of severe TTTS between 15 and 26 weeks' gestation. Following an interim analysis, the study was stopped after 142 patients had been treated. **Compared with the amnioreduction group, the laser group had a higher likelihood of survival for at least one twin to 28 days of life (76% vs. 56%;  $P = .009$ ) and 6 months of age (76% vs. 51%;  $P = .002$ ).** The median gestational age at delivery was significantly more advanced in the laser group (33.3 vs. 29.0 weeks;  $P = .004$ ). Neonates from the laser group also had a lower incidence of periventricular leukomalacia (PVL) and were more likely to be free of neurologic deficits at 6 months of age (52% vs. 31%;  $P = .003$ ). The authors concluded that **endoscopic laser coagulation of anastomoses is a more effective first-line treatment than serial amnioreduction for severe TTTS diagnosed before 26 weeks' gestation.** Although this study did include patients in all Quintero stages, most (90% of the laser group and 91% of the amnioreduction group) were stage II or III.

An NICHD-sponsored prospective multicenter trial is the only other randomized clinical trial to compare amnioreduction to fetoscopic laser photocoagulation.<sup>44</sup> That trial, in which all patients were Quintero stages II to IV, was stopped early after only 40 patients accrued, mainly because of recruitment difficulties but also because of concern about a trend toward more adverse fetal outcomes affecting the recipient twin in the laser arm. Analysis of the 40 patients showed no difference, either for donors or recipients, in the primary outcome of 30-day neonatal survival (55% in both arms for donors and 45% vs. 30% in the amnioreduction vs. laser arms for recipients;  $P > .5$ ). The increased *fetal* mortality rate among recipients in the laser group was more pronounced in Quintero stage III and IV disease. The investigators concluded that the trial did not conclusively demonstrate the superiority of either treatment modality, although the results were severely limited by the small sample size.

**Subsequently, both a Cochrane review and another meta-analysis that compared laser therapy with serial amnioreduction supported the use of endoscopic laser therapy in the treatment of severe TTTS.** In the Cochrane review, at age 6 years, more children were alive without neurologic abnormality in the laser groups than in the amnioreduction groups (RR, 1.57; 95% CI, 1.05 to 2.34). However, no difference was apparent in overall death between amnioreduction and laser (RR, 0.87; 95% CI, 0.55 to 1.38).<sup>45</sup> The meta-analysis by Rossi and D'Addario<sup>46</sup> found improved overall survival (OR, 2.04; 95% CI, 1.52 to 2.76), decreased neonatal death (OR, 0.24; 95% CI, 0.15 to 0.4), and decreased neurologic morbidity (OR, 0.2; 95% CI, 0.12 to 0.33) with laser therapy compared with serial amnioreduction.

**Short-term complications of laser ablation include placental abruption, PPROM, IUFD, and labor.** In the Eurofetus trial, a 1% to 12% risk was reported for each of these complications in both the laser and amnioreduction groups. Rates of

IUFD, pregnancy loss, and PPROM within 7 days of the procedure were 1.5- to 5-fold higher in the laser group, although these differences did not reach statistical significance.<sup>43</sup> In the NICHD trial,<sup>44</sup> the incidence of PPROM before 28 weeks was 4.8% in the laser arm and 0% in the amnioreduction arm. Maternal complications are not consistently reported in the literature; however, no maternal deaths have been reported in all of the TTTS laser therapy literature, and serious complications such as pulmonary edema or blood transfusion appear to be very rare.

A few investigations have studied the long-term neurologic outcomes of babies treated in utero with laser ablation. Rossi and colleagues<sup>47</sup> performed a meta-analysis of 15 papers that described neurologic outcomes in children who underwent laser photocoagulation for TTTS. For those seven papers that reported neurologic morbidity at birth ( $n = 895$  babies), the incidence was 6.1%. For the nine studies that reported follow-up at 6 to 48 months ( $n = 1255$  babies), the incidence of neurologic impairment was 11.1%, and cerebral palsy was the most frequent neurologic diagnosis (39.7%). Neurologic impairment was identified equally between donors and recipients and between one survivor and two survivors for twin sets. Since publication of this meta-analysis, a long-term follow-up from the Eurofetus trial has been published.<sup>48</sup> This paper showed some improvement in neurologic outcome at age 6 years among 73 children who had undergone laser treatment compared with 47 children who had undergone amnioreduction. The survivors in the laser group had an 82% chance of a normal neurologic exam, compared with 72% in the amnioreduction group ( $P = .12$ ). No difference was reported in neurologic outcomes between donors and recipients.

**The current consensus is that laser ablation of vascular anastomoses is the optimal therapy for Quintero stage II to IV disease before 26 weeks' gestation.** However, controversy exists as to the optimal management of stage I disease. This controversy is based on several observations. First, the prognosis for stage I patients can be quite good without laser surgery. In a series by Taylor and colleagues,<sup>49</sup> 70% of stage I patients treated with either expectant management, amnioreduction, or septostomy remained stable or regressed. O'Donoghue and colleagues<sup>50</sup> reviewed all cases of TTTS at their institution between 2000 and 2006 and identified 46 cases that presented with stage I TTTS, all of which were treated either expectantly or with amnioreduction. They found that 70% either remained stable or regressed. Rossi and D'Addario<sup>51</sup> published a review of the literature that included only stage I TTTS. They reported overall survival rates of 77% after amnioreduction, 85% after laser therapy, and 86% after expectant management. The progression to a more advanced stage was 15% for those pregnancies managed expectantly.

On the other hand, recent studies have shown that even in stage I and II TTTS, the recipient can suffer cardiac dysfunction, something not taken into account by the commonly used Quintero staging system. Michelfelder and associates<sup>52</sup> examined echocardiographic parameters of 42 TTTS patients, of whom 14 were stage I. Of the stage I patients, 57% had ventricular hypertrophy and 14% had atrioventricular valve dysfunction. Because it has been shown that cardiac dysfunction in the recipient improves after laser therapy but not after amnioreduction, this suggests that laser therapy may be the better choice in select patients who present with Quintero stage I TTTS. A single retrospective cohort study<sup>53</sup> published in 2009 directly

compared outcomes in stage I patients treated with laser surgery versus expectant management. Of 50 women who presented with stage I TTTS, 40% underwent laser surgery and 60% were managed either expectantly, or, if maternal symptoms were present, with amnioreduction. Although short-term outcomes (gestational age at delivery and perinatal survival) were not significantly different between the two treatment groups, long-term neurodevelopmental impairment as determined by neurologic examination and neuropsychological developmental testing at a minimum of 2 years of age was decreased in the laser group (0/21 vs. 7/30;  $P = .03$ ). This study raises the question as to whether ongoing neurologic injury is present from mild TTTS even if the disease does not progress and whether this damage could be prevented by interrupting the underlying pathophysiology of TTTS using laser ablation.

**In summary, laser photocoagulation is considered optimal management of stage II and greater TTTS prior to 26 weeks' gestation.** For stage I disease, pending further study, expectant management is reasonable; but some centers offer laser therapy to these women, especially when diagnosis is made in the early second trimester or when evidence of cardiac dysfunction is present. For women diagnosed with TTTS after 26 weeks, either expectant management or serial amnioreduction are recommended, and management decisions should be based on severity of disease. It is important to remember that **even with optimal laser treatment of TTTS, it remains a serious disease with 20% to 50% overall perinatal mortality.**<sup>40</sup>

### SELECTIVE INTRAUTERINE GROWTH RESTRICTION IN MONOCHORIONIC TWIN PREGNANCIES

**Selective IUGR (sIUGR) is defined as growth restriction, most commonly an estimated fetal weight below the 10th percentile of one twin with appropriate growth in the co-twin but without full criteria for TTTS.** This condition has been reported in 10% to 15% of monochorionic diamniotic gestations and frequently presents at relatively early gestational ages, although sIUGR can also occur in dichorionic pregnancies. However, the course of early-onset sIUGR in a monochorionic pregnancy differs from early-onset IUGR in a singleton or dichorionic twin gestation. Umbilical artery (UA) Doppler findings cannot be interpreted in the same way as in singleton or dichorionic gestations because the waveforms represent not only the effects of placental insufficiency but also the influence of intertwin vascular communications. Usually the latency period is longer from abnormal Dopplers to delivery in monochorionic twins. Additionally, the initial UA Doppler findings (stage of sIUGR, see below) usually remain unchanged; that is, if Dopplers are initially normal, they rarely worsen, and a good prognosis is likely. In monochorionic compared with dichorionic twins, sIUGR is also associated with a higher frequency of abnormalities such as a two-vessel cord and marginal or velamentous cord insertions.

Gratacós and associates<sup>54</sup> have proposed a **classification system for sIUGR** based on UA Doppler findings. Type I is characterized by positive diastolic flow in the growth-restricted fetus, type II by persistently absent or reversed end-diastolic flow, and type III by intermittently absent or reversed end-diastolic flow. The cyclical pattern of intermittently abnormal Doppler flow is believed to be caused by transmitted waveforms from the larger to the smaller twin's cord due to the existence of

large AA anastomoses. Pregnancies with type III sIUGR are reported to have both more frequent, as well as larger diameter, AA anastomoses than either uncomplicated monochorionic twin pregnancies or pregnancies with type I or II sIUGR.<sup>54</sup> Based on the type I through III classification system, Gratacós and associates<sup>54</sup> reported on 134 monochorionic diamniotic pregnancies complicated by sIUGR diagnosed before 26 weeks (39 type I, 30 type II, 65 type III). They reported unexpected IUFD of the smaller twin in 2.6%, 0%, and 15.4% of cases of type I, type II, and type III sIUGR, respectively. The corresponding numbers for IUFD of the normally grown twin were 2.6%, 0%, and 6.2%. Mean gestational ages at delivery for type I, type II, and type III sIUGR, were 35.4 weeks, 30.7 weeks, and 31.6 weeks, respectively. It should be noted that in 9 cases of type II and 4 cases of type III sIUGR, cord occlusion of the IUGR twin was performed for the benefit of the normally grown twin in the face of deterioration of the growth-restricted twin's status. Consequently, the above numbers do not necessarily represent the natural history of early-onset type II and III sIUGR in monochorionic twins. However, a study from Japan of expectantly managed sIUGR cases in monochorionic diamniotic gestations does provide some insight into the natural history of the disorder. Ishii and colleagues<sup>55</sup> reported on 23 type I, 27 type II, and 13 type III sIUGR pregnancies. Mean gestational age at delivery was 36 weeks, 28 weeks, and 31 weeks for types I through III, respectively. IUFD of the smaller twin occurred in 4.3%, 22.2%, and 15.4% of cases, respectively, and in the larger twin in 4.3%, 22.2%, and 0% of cases, respectively. In the Ishii study, the incidence of neurologic morbidity for the larger twin was 0%, 11.1%, and 38.5% for types I through III, respectively. For the smaller twin, the corresponding numbers were 4.3%, 14.8%, and 23.1%.

As evidenced by the above data, the prognosis for expectantly managed type I sIUGR is generally good, so close observation is preferred. The prognosis for type II and III sIUGR is much more guarded. **Three management options are available for type II and III early-onset sIUGR in a monochorionic twin pregnancy:**

1. Careful expectant management with an effort to maximize outcome for both twins
2. Cord occlusion of the IUGR twin, thus sacrificing the IUGR fetus to protect the larger twin from injury as a result of acute intertwin transfusion associated with smaller co-twin demise
3. Laser photocoagulation to physically separate the shared fetal circulations to help protect the larger co-twin from injury or death in the event of the smaller twin's demise

Detailed discussion of management options is beyond the scope of this chapter. The reader is referred to an excellent review article by Valsky and associates.<sup>56</sup>

### TWIN ANEMIA-POLYCYTHEMIA SEQUENCE

**Twin anemia-polycythemia sequence (TAPS) refers to the occurrence of a chronic and severe hemoglobin discordance in a monochorionic diamniotic twin pair in the absence of other criteria for TTTS.** Prenatally, the diagnosis is made by middle cerebral artery (MCA) Doppler multiples of the median (MoM) of 1.5 or more in one twin and MoM of 0.8 or less in the other twin without amniotic fluid discordance that meets TTTS criteria. However, some experts have proposed an alternative criteria for the anemic twin; specifically, an MCA Doppler of MoM of 1.0 or less. Postnatally, criteria for anemia

**TABLE 32-6** STAGING SYSTEM FOR TWIN ANEMIA-POLYCYTHEMIA SEQUENCE

| STAGE | FINDING   |
|-------|---|
| 1     | Donor MCA-PSV >1.5 MoM and recipient MCA-PSV <1.0   |
| 2     | Donor MCA-PSV >1.7 MoM and recipient MCA-PSV <0.8 MoM without other signs of fetal compromise |
| 3     | Stage 1 or 2, with critically abnormal Doppler ultrasound*                                    |
| 4     | Hydrops of donor  |
| 5     | IUFD of one or both fetuses   |

\*Absent or reversed end-diastolic flow in umbilical artery, pulsatile flow in umbilical vein, increased pulsatility index or reversed flow in the ductus venosus.  
IUFD, intrauterine fetal demise; MCA, middle cerebral artery; MoM, multiples of the median; PSV, peak systolic velocity.

and polycythemia are hemoglobin of 11 g/dL or less with reticulocytosis in the donor and hemoglobin of 20 g/dL or more in the recipient. A TAPS classification system has been proposed that is similar to the Quintero system for TTTS (Table 32-6).<sup>57</sup> Isolated TAPS can occur spontaneously in monochorionic pregnancies with an observed frequency of 3% to 5%, but it has been reported more commonly as a complication of laser photocoagulation for TTTS. Postlaser TAPS has been reported up to 13% of laser-treated TTTS cases.

The cause of TAPS is thought to be the presence of only a few, very small AV anastomoses, which allow a slow transfusion of blood from the donor to the recipient. AA anastomoses are believed to be important in equilibrating the blood flow between twins and consequently are seen in 80% of uncomplicated monochorionic diamniotic gestations. In contrast, AA anastomoses are seen in only about 25% of TTTS pregnancies and are even more rare (11%) in pregnancies complicated by TAPS. Because of the possibility of TAPS, an MCA peak systolic flow velocity should be considered in the screening of all monochorionic multifetal pregnancies.

**Ideal management of TAPS is not yet clear, but intrauterine transfusions—both intraperitoneal and intravenous (IV)—and laser treatment have been reported with good success. Expectant management is also a reasonable option.** Regardless of management, survival rates for twins in a pregnancy complicated by TAPS have been reported to range from 75% to 100%. In utero intervention is not proven to be associated with clear differences in survival or long-term outcomes. The reader is also referred to two excellent reviews on TAPS by Slaghekke and coworkers<sup>57</sup> and by Baschat and Oepkes.<sup>58</sup>

**Monoamniotic Twins**

**Monoamniotic twinning is an uncommon form of MZ twinning in which both fetuses occupy a single amniotic sac. Monoamniotic twins account for only 1% of all MZ pregnancies.** Interestingly, as in conjoined twins, there is a female predominance: 55% to 74% of monoamniotic twin sets are reported to be female, although the reason for this difference is unclear.<sup>59-63</sup> **Historically, perinatal mortality rates for monoamniotic twins have been reported to approach 50%, attributed to premature delivery, growth restriction, and congenital anomalies** (seen in up to 25% of monoamniotic twin pregnancies) **but mostly to umbilical cord entanglement and cord accidents** (Fig. 32-9). Some degree of umbilical cord entanglement is present in virtually every monoamniotic twin pregnancy. More recent series of prenatally diagnosed cases suggest improved perinatal outcomes with mortality rates in the range of 7% to

**FIG 32-9** Entangled cords found during emergent cesarean delivery in a case of monochorionic monoamniotic twins at 32 weeks. Both babies did well.

20%<sup>60-64</sup> and as low as 2.4% to 2.8% when fetuses with anomalies are excluded.<sup>65,66</sup> **This improvement is likely due to prenatal diagnosis, use of antenatal corticosteroids, increased fetal surveillance, and elective early delivery.** Because cord accidents are the primary cause of fetal death, most management protocols emphasize intense fetal surveillance to identify significant umbilical cord constriction before fetal loss.

Rodis and coworkers<sup>64</sup> reviewed 13 cases of monoamnioticity at one tertiary care center over a 10-year period. All patients underwent serial ultrasound examinations and antenatal fetal surveillance two to seven times per week starting between 24 and 26 weeks' gestation, and 62% of the pregnancies were delivered for abnormal fetal testing. If undelivered earlier, all patients were delivered by cesarean delivery by 35 weeks' gestation. No fetal deaths were reported, and the mean gestational age at delivery was 32.9 weeks. Compared with 77 sets of monoamniotic twins from the literature that had not been diagnosed prenatally, these patients had a 71% reduction in the relative risk for perinatal mortality.

A more recent study evaluated the impact of routine hospitalization for fetal monitoring on perinatal survival and neonatal morbidity in a multicenter retrospective cohort study of 96 monoamniotic twin gestations.<sup>61</sup> Of 87 women with both twins surviving at 24 weeks, 43 patients were admitted electively at a median gestational age of 26.5 weeks for **inpatient surveillance and fetal testing two to three times daily**. The remaining 44 women were followed as outpatients with fetal testing one to three times weekly. None of the hospitalized patients experienced an IUFD, but 14.8% (13 of 88) of the fetuses of mothers followed as outpatients were stillborn. Statistically significant improvements in birthweight, gestational age at delivery, and neonatal morbidity were also noted among the electively

hospitalized women. Two other smaller studies<sup>67,68</sup> have also compared inpatient with outpatient management and have found similar results. These studies suggest that **improved neonatal survival and decreased perinatal morbidity are achievable with monoamniotic twins admitted electively for daily fetal monitoring after viability, and we recommend offering hospital admission to all women with monoamniotic twins.**

The timing of admission should be the gestational age at which the mother would desire delivery for evidence of fetal compromise, generally 24 to 28 weeks. We obtain preadmission consultation with a neonatologist to discuss complications from prematurity at various gestational ages. After admission, we prophylactically administer antenatal corticosteroids because of the possibility of emergent delivery.

Some institutions perform continuous fetal monitoring in women electively admitted for monoamniotic twins. In actual practice, however, true continuous monitoring is never achievable. Quinn and colleagues<sup>69</sup> reviewed over 10,000 hours of fetal monitoring of monoamniotic twins and found that both fetuses were successfully monitored only 51.6% of the time. **We do not perform continuous monitoring, rather we recommend fetal heart rate (FHR) monitoring two or three times per day for 1 to 2 hours.** Although cord accidents cannot be predicted, FHR monitoring may reveal an increasing frequency of variable decelerations. If these are identified, continuous monitoring is recommended along with emergency delivery for worsening or nonreassuring fetal status. In the absence of nonreassuring fetal testing, the timing of elective delivery is not well established by prospective data. Multiple papers over the past 10 years have demonstrated a continued risk of sudden IUFD throughout gestation. Because of this continuing risk of unexpected fetal death, **most experts perform elective delivery following the administration of antenatal corticosteroid therapy between 32 and 34 weeks' gestation. Delivery at 32 to 34 weeks is associated with a low risk of serious neonatal morbidity counterbalanced against the unpredictable continuing IUFD risk.** Van Mieghem and colleagues<sup>62</sup> evaluated fetal and neonatal outcomes in 193 monoamniotic twin pairs managed

at eight European university hospitals between 2003 and 2012. In this study, the overall risk of fetal death was 18.1%, but of the 144 gestations with 2 live fetuses at 26 weeks' gestation, only 8 fetal deaths were reported. They compared the risk of IUFD to the risk of neonatal morbidity/mortality and calculated that the risk of IUFD exceeded the risk of a nonrespiratory neonatal complication at 32 weeks 4 days gestation. These researchers concluded that with close fetal surveillance instituted between 26 and 28 weeks of gestation and delivery at 33 weeks of gestation, the risk of stillbirth—as well as the risk of neonatal death or serious complication—is minimized.

**The 2011 NICHD and SMFM workshop that addressed timing of indicated late-preterm and early-term birth recommended delivery of monoamniotic twins at 32 to 34 weeks.**<sup>36</sup>

The 2014 ACOG Practice Bulletin on multifetal gestation also acknowledges the limitations of the available evidence on management and delivery timing for monoamniotic twin gestations, but it states that delivery between 32 and 34 weeks is reasonable.<sup>37</sup>

Cesarean delivery has been recommended to eliminate the risk of intrapartum cord accidents, although vaginal delivery of these patients is not entirely contraindicated if careful fetal monitoring is performed. On the other hand, there have been case reports of a nuchal cord affecting the first twin being cut to facilitate delivery, only to discover that the cut cord actually belonged to the second twin. Given this issue and a high incidence of intrapartum nonreassuring fetal testing, **most experts recommend cesarean delivery for monoamniotic twin pregnancies.**

### Twin Reversed Arterial Perfusion Sequence

The TRAP sequence, also known as *acardiac twinning*, is a malformation that occurs only in monochorionic pregnancies with a frequency of about 1 per 30,000 deliveries and 1 in 100 monochorionic twins. An acardiac twin is an extremely malformed fetus with either no heart at all or only rudimentary cardiac tissue in association with multiple other developmental abnormalities (Fig. 32-10). In about one third of acardiac twins,

**FIG 32-10** Acardiac twin. (Courtesy Dr. James Wheeler, Department of Surgical Pathology, Hospital of the University of Pennsylvania, Philadelphia.)

the karyotype has been found to be abnormal. A two-vessel cord is present in two thirds of acardiac twins, and polyhydramnios has been reported in around 70% of cases. The co-twin, referred to as the *pump twin*, is generally normal, although a 9% risk of aneuploidy has been reported.<sup>70</sup>

**Patients with TRAP sequence have a monochorionic placenta with vascular anastomoses that sustain the life of the acardiac twin.** The acardiac twin is perfused via direct UA-UA anastomosis at the placental surface. Blood flows from the normal pump twin's UAs back to the placenta. Then through this UA anastomosis, deoxygenated blood flows directly to the acardiac twin without passing through a placental capillary bed. In the acardiac twin's umbilical arteries, flow is thus retrograde, creating the TRAP sequence. **This poorly oxygenated blood preferentially perfuses the acardiac twin's lower body, contributing to the bizarre anomalies seen in acardiac fetuses.**

Antenatal diagnosis by ultrasound of an acardiac fetus coexisting with a normal co-twin is fairly straightforward, but **color Doppler is essential.** The only other entity in the differential diagnosis is an IUFD of one twin. However, continued growth of the abnormal, presumed dead twin rules this out, as does demonstration of umbilical blood flow in the presumed dead twin by color Doppler. Additionally, retrograde flow can be demonstrated to occur through the UAs.

The acardiac twin clearly has no chance of survival, but its presence is not innocuous for the normal pump twin. The pump twin is at increased risk for in utero cardiac failure and preterm delivery. In the absence of intervention, mortality rates of 50% or higher have been reported.<sup>71</sup> **The estimated weight of the acardiac twin** (calculated using the formula  $1.2L^2 - 1.7L = \text{weight in grams}$ , where  $L$  is the longest dimension) **relative to the normal twin is an important prognostic factor.** Moore and colleagues<sup>71</sup> reported on a series of 49 pregnancies complicated by TRAP sequence. Other than four therapeutic amniocenteses, none of the pregnancies underwent invasive therapies. They reported 90% preterm delivery, 40% polyhydramnios, and 30% cardiac failure of the normal pump twin when the weight ratio of the acardiac to normal pump twin was more than 70%, compared with 75% preterm delivery, 30% polyhydramnios, and 10% cardiac failure for the normal pump twin when the weight ratio was less than 70%. In that same series, no pump twins had cardiac failure when the weight ratio was less than 50%. Among all 49 cases in the series, the mean gestational age at delivery was 29 weeks, and the mean birthweight of the pump twin was 1378 g.

**When faced with a monochorionic pregnancy complicated by TRAP sequence, three options are available: (1) expectant management, (2) delivery, or (3) interruption of the vascular communication between the twins.** Many experts use a ratio of weight of acardiac twin to weight of pump twin of 0.5 (50%) as a criterion for invasive intervention. Other factors that suggest a need for intervention are hydrops, polyhydramnios, and abdominal circumference of the acardiac twin greater than or equal to that of the pump twin.

Expectant management is reasonable in the absence of poor prognostic features, and good survival rates have been reported (88% in one series) when the weight ratio of the acardiac to pump twin is 50% or less.<sup>72</sup> If expectant management is undertaken, weekly surveillance that includes fetal echocardiography is recommended. Delivery may be indicated if signs of cardiac decompensation are noted at a viable gestational age. In the face

of poor prognostic features remote from term, interruption of the vascular communication between the twins should be considered. This intervention is most commonly performed between 16 and 26 weeks. Current treatment modalities include occlusion of the acardiac twin's umbilical cord by bipolar cord coagulation, laser ablation, or RFA. The optimal treatment approach has not yet been definitively determined.

A recent meta-analysis of intrafetal laser treatment for TRAP sequence found an 82% survival rate for the pump twin. The median gestational age at delivery was 37 weeks and 1 day.<sup>73</sup> A report by the North American Fetal Therapy Network (NAFTNet)<sup>74</sup> on outcomes for all patients ( $n = 98$ ) who underwent RFA for TRAP at NAFTNet institutions between 1998 and 2008 found an 80% overall survival to 30 days of life for pump twins with a median gestational age at delivery of 37 weeks 0 days.

## Conjoined Twins

**Conjoined twins are another rare complication of MZ twinning. They are believed to occur when a single embryo incompletely divides between 13 and 15 days after fertilization instead of splitting earlier.** This event gives rise to monochorionic monoamniotic placentation with conjoined fetuses, and it occurs with a frequency of about 1 in 50,000 pregnancies. Most conjoined twins are female, with a reported female/male ratio of 2:1 or 3:1.

Conjoined twins are classified according to their site of union. The most common location is the chest (thoracopagus), followed by the anterior abdominal wall (omphalopagus), the buttocks (pygopagus), the ischium (ischiopagus), and the head (cephalopagus; Fig. 32-11 and Videos 32-1 and 32-2). Organs are shared to varying degrees. Major congenital anomalies of one or both twins are common, and polyhydramnios is present in almost half of the reported cases of conjoined twins.

**The mortality rate is high,** as evidenced by a retrospective case series from the Children's Hospital of Philadelphia.<sup>75</sup> That series identified an incidence of 28% intrauterine death, 54% early neonatal death, and 18% overall survival among 14 sets of conjoined twins managed at their institution between 1996 and 2002. Another series<sup>76</sup> of 36 sets of conjoined twins from a single center in Brazil between 1998 and 2010 reported similar results: after excluding the nearly 40% who underwent termination of pregnancy, the survival rate was 13.6%.

**Ultrasound can establish this diagnosis in utero as early as the first trimester based on visualization of monoamniocity and a bifid fetal pole.** Three-dimensional ultrasound, color Doppler, fetal echocardiography, and MRI can be used to complement two-dimensional ultrasound imaging to confirm the diagnosis, determine the extent of organ sharing, and definitively classify the type of conjoined twinning. If the diagnosis is confirmed before viability, pregnancy termination should be offered. **If the patient desires expectant management, she should be counseled that the prognosis for survival and successful separation depends on the degree of organ and vascular sharing between the two fetuses, especially the heart.** Multimodality fetal evaluation as previously described should be used prenatally to survey fetal anatomy. **To optimize postnatal management, patients with conjoined twins should be cared for by a multidisciplinary team during the antenatal period, including maternal-fetal medicine specialists, neonatologists, pediatric anesthesiologists, pediatric surgeons, and appropriate pediatric subspecialists.**

**FIG 32-11** **A** and **B**, Late first-trimester images of thoracopagus conjoined twins. This twin set had one trunk with two parallel spinal columns (**A**) leading to two separate necks and heads (**B**). **C** and **D**, Cephalopagus conjoined twins with a single cranium but two separate spines, conjoined to the level just above the pelvis. (This case is depicted in Videos 32-1 and 32-2.)

If any evaluation and treatment beyond palliation is planned, patients with conjoined twins should deliver at a tertiary care facility where neonatal and pediatric specialists with experience in the care of conjoined twins are available. Cesarean delivery near term will be necessary to minimize maternal and fetal injury. For conjoined twins, a mean gestational age at delivery of 34 to 35 weeks has been reported.<sup>75,76</sup> If the twins are believed to be nonviable and are believed to be small enough to pass through the birth canal without traumatizing the mother, vaginal delivery can be considered. In the above mentioned series from Brazil, all conjoined twins at less than 27 weeks' gestation were delivered vaginally.

**Of conjoined twins who are deemed appropriate for and survive to undergo elective separation, survival rates approach 80%.** If conjoined twins require emergent separation, however, survival rates are much lower, around 25% to 30%.<sup>77</sup> Although the long-term follow-up of conjoined twins who have undergone successful surgical separation is limited, the data seem favorable. Survivors frequently require additional surgeries following the initial separation, but many achieve educational levels similar to their singleton peers.

## ANTEPARTUM MANAGEMENT OF MULTIFETAL PREGNANCY

### Maternal Nutrition and Weight Gain

**The two factors that most influence pregnancy outcome are gestational age at delivery and the adequacy of fetal growth.** Nutritional status during gestation is closely linked to both these outcomes. The increased physiologic stress of a multifetal pregnancy demands **a 10% higher maternal resting energy expenditure.** To meet this heightened metabolic expenditure, multiple gestations require modification of the caloric intake and weight gain recommendations established for singleton pregnancies. **The higher risks of LBW, PTB, and neonatal complications in twin pregnancies create a situation in which enhancement of maternal nutrition has the potential to provide tremendous positive impact.**

Both total maternal weight gain and the timing of that weight gain are critical to optimizing twin birthweight and perinatal outcomes. Luke and colleagues<sup>78</sup> have shown **that weight gain before 28 weeks accounts for 80% of the effects of maternal weight gain on infant birthweights.** Underscoring this point,

**TABLE 32-7** RECOMMENDED RATES OF MATERNAL WEIGHT GAIN IN TWIN PREGNANCIES

| GESTATIONAL AGE PERIOD | UNDERWEIGHT (BMI <19.8) | NORMAL WEIGHT (BMI 19.8-26) | OVERWEIGHT (BMI 26.1-29) | OBESE (BMI >29) |
|------------------------|-------------------------|-----------------------------|--------------------------|-----------------|
| Early (<20 wk)         | 1.25-1.75 lb/wk         | 1-1.5 lb/wk                 | 1-1.25 lb/wk             | 0.75-1 lb/wk    |
| Mid (21-28 wk)         | 1.5-1.75 lb/wk          | 1.25-1.75 lb/wk             | 1-1.5 lb/wk              | 0.75-1.25 lb/wk |
| Late (≥29 wk)          | 1.25 lb/wk              | 1 lb/wk                     | 1 lb/wk                  | 0.75 lb/wk      |

**TABLE 32-8** 2009 INSTITUTE OF MEDICINE RECOMMENDATIONS FOR WEIGHT GAIN IN PREGNANCY

| PREPREGNANCY BMI | BMI (kg/m <sup>2</sup> ) WHO CRITERIA | TOTAL WEIGHT GAIN SINGLETON (lb) | TOTAL WEIGHT GAIN TWINS (lb) |
|------------------|---------------------------------------|----------------------------------|------------------------------|
| Underweight      | <18.5                                 | 28-40                            | No recommendations made      |
| Normal weight    | 18.5-24.9                             | 25-35                            | 37-54                        |
| Overweight       | 25.0-29.9                             | 15-25                            | 31-50                        |
| Obese            | ≥30.0                                 | 11-20                            | 25-42                        |

From Rasmussen KM, Yaktine AL, editors. *Institute of Medicine (Committee to Reexamine IOM Pregnancy Weight Guidelines, Food and Nutrition Board and Board on Children, Youth, and Families). Weight Gain During Pregnancy: Reexamining the Guidelines*. Washington, DC: National Academies Press; 2009. BMI, body mass index; WHO, World Health Organization.

these researchers demonstrated that even when weight gain is appropriate after 24 weeks, suboptimal gain before 24 weeks is still associated with earlier delivery and poor intrauterine growth. Body mass index (BMI)–specific weight gain patterns associated with ideal twin pregnancy outcomes, defined as a birthweight of 2850 to 2950 g at 36 weeks or later, are summarized in Table 32-7. Although the BMI categories used are slightly different from current BMI definitions, the differences in recommended weight gain by BMI category can easily be appreciated. Compared with singleton gestations, **these recommended rates of weight gain are more than double early in pregnancy (0 to 20 weeks), about 50% higher during mid-pregnancy (20 to 28 weeks), and about 25% higher late in gestation (28 to 38 weeks).**<sup>79</sup>

The crucial role of early weight gain and the pronounced benefits of appropriate weight gain in underweight women suggest that **early weight gain provides improved maternal nutrient stores for use later in pregnancy when fetal demands increase. Additionally, optimal maternal nutrition and weight gain early in pregnancy may enhance placental growth**, thus providing a better ongoing nutrient supply to the babies. Both of these mechanisms may explain why adequate weight gain in late pregnancy after inadequate gain in early pregnancy does not provide complete recovery in either fetal growth or outcomes. The implementation of these nutritional principles as part of an enhanced nutritional clinical program for twins at the University of Michigan was associated with improvements in virtually all important obstetric and neonatal outcomes in a prospective cohort trial.<sup>80</sup>

Using the data published by Luke and colleagues but with slight changes in the BMI categories, the Institute of Medicine (IOM) issued new BMI-specific weight-gain recommendations for twin pregnancy in 2009; these recommendations are summarized in Table 32-8. Several studies have examined perinatal outcomes using the IOM recommendations for maternal weight gain and have found improved outcomes among women who meet the IOM weight-gain goals. For instance, Fox and coworkers<sup>81</sup> retrospectively studied a cohort of 297 twin pregnancies from a private maternal-fetal medicine practice, applying the 2009 IOM guidelines to compare pregnancy outcomes between those women who achieved or failed to achieve these

recommendations. They found that women with a prepregnancy BMI in the normal or overweight categories who met the weight-gain recommendations demonstrated significantly better outcomes. **Normal-weight women who achieved the IOM weight-gain recommendations had significantly larger babies and a greater likelihood of babies weighing more than 2500 g.** Overweight women who met the weight-gain recommendations had more advanced gestational ages at delivery and a heavier weight of the larger twin. Both normal-weight and overweight women who met weight-gain goals had reductions in both overall and spontaneous PTB. Notably, the IOM guidelines do not provide a specific weight-gain recommendation for women with an underweight prepregnancy BMI who are pregnant with twins. However, because the singleton literature clearly demonstrates that underweight women benefit the most from optimal gestational weight gain, special attention should be given to nutritional counseling and achievement of weight-gain goals in this population.

Although increased maternal weight gain during pregnancy is associated with improved outcomes, maternal weight retention and its long-term health effects are also a concern. Therefore in the setting of multiple gestation, emphasis should be placed on appropriate weight gain, while avoiding gains that exceed the IOM recommendations.

### Spontaneous Preterm Birth

Patients with a multiple gestation are at significant risk for preterm labor and delivery. **Refining the risk for PTB in each individual patient improves pregnancy management by selecting those patients who may benefit most from increased surveillance and interventions while simultaneously minimizing unnecessary interventions in lower-risk women.**

The use of ultrasound transvaginal cervical length (TVCL) measurements and fetal fibronectin (fFN) sampling can help stratify PTB risk in multiple gestations. A 2010 meta-analysis that included 21 studies with a total of 3523 women pregnant with twins found that in asymptomatic women, **a TVCL of 20 mm or less between 20 and 24 weeks' gestation was the best predictor of PTB before 32 and before 34 weeks.** A TVCL of 20 mm or less increased the probability of birth before 32 weeks from 6.8% to 42.4% and increased the risk of birth before

34 weeks from 15.3% to 61.9%. At a gestational age of 20 to 24 weeks, a TVCL of 25 mm or less increased the risk of delivery before 32 weeks from 3.5% to 25.8%, and it increased the risk of delivery before 37 weeks from 41.2% to 75.5%. A TVCL of 25 mm or more reduced the risk of delivery before 28 weeks to 1.4% and the risk of delivery before 37 weeks to 36.8%.<sup>82</sup>

In addition to the absolute cervical length (CL), **the degree of change in the cervical length over time may also be an important predictor of PTB in twins.** Fox and coworkers<sup>83</sup> studied a historical cohort of 121 asymptomatic twin pregnancies who had two TVCL measurements taken 2 to 6 weeks apart between 18 and 24 weeks' gestation. They found that CL shortening of 20% or more over this interval was associated with a greater risk for PTB before 28, 30, 32, and 34 weeks compared with women whose CL remained stable (15.8% vs. 1% at <28 weeks, 15.8% vs. 2% at <30 weeks, 31.6% vs. 5% at <32 weeks, and 36.8% vs. 12.9% at <34 weeks; all *P* values  $\leq .03$ ). Most striking was the fact that this association with PTB remained significant even when patients with a CL less than 25 mm were excluded.

Fetal fibronectin has also been studied as a predictor of spontaneous PTB risk in multifetal pregnancies. A 2010 meta-analysis<sup>84</sup> that included 15 studies with a total of 1221 women found that **in symptomatic mothers of twins, fFN had good predictive value.** A positive fFN in this setting increased the risk of delivery within 7 days of testing from 7.7% to 24.5%, and a negative result decreased the risk of delivery within 7 days to 1.6%.

**The use of these tests can help guide management decisions, such as frequency of office visits or whether work or activity restriction is prudent.** Identification of a patient at particularly high risk for preterm delivery based on her CL, fFN, or a combination of the two can allow for heightened surveillance and may permit timely interventions such as tocolysis or steroid administration. On the other hand, documentation of an above-average (>35 mm) or stable CL in midgestation can allow both patient and physician to feel comfortable with a patient continuing with her normal activities, avoiding the temptation to implement unnecessary restrictions or interventions.

Unfortunately, although studies such as those mentioned above allow us to determine which multiple gestations are at greatest risk for spontaneous PTB, limited options are available to prevent PTB. Of note, however, few PTB prevention studies have been carried out in the highest-risk multiple gestations based on transvaginal CLs or a positive fFN. The following section discusses the relative merits of proposed interventions to prevent spontaneous PTB in multiple gestations.

### Bed Rest and Hospitalization

A Cochrane review<sup>85</sup> analyzed seven randomized trials that included 713 women and 1426 babies and concluded that **routine hospitalized bed rest was not associated with a decrease in PTB in multifetal pregnancies.** A trend toward fewer LBW babies was noted (RR, 0.92; 95% CI, 0.85 to 1.00), although this trend did not extend to VLBW infants. Because no evidence suggests that routine hospitalization is beneficial for patients with multiples, these women should be hospitalized only for the same obstetric indications as singletons. **For asymptomatic twin pregnancies in women with a reassuring CL and no prior history of PTB, we do not recommend either cessation of work or rest at home.**

### Tocolysis

**Prophylactic tocolysis has been evaluated in multiple gestations and was not found to be effective.** In contrast, short-term use of agents for acute tocolysis in preterm labor is helpful to gain time for administration of corticosteroids to enhance fetal lung maturity and allow transport to a tertiary care facility. Tocolytic use in multiple gestations, however, must be accompanied by careful monitoring of the maternal condition. Because of the exaggerated maternal cardiovascular adaptations to a multiple gestation, women pregnant with multiples are predisposed to cardiopulmonary complications, most notably pulmonary edema. This risk is heightened with  $\beta$ -adrenergic agents and when tocolytics are used in combination with corticosteroids and intravenous fluids. **In 2011, the U.S. Food and Drug Administration (FDA) issued a boxed warning on terbutaline, stating that it should not be used in an injectable form beyond 48 to 72 hours to treat preterm labor—and that it should not be used at all in an oral form—because of the potential for serious maternal cardiovascular problems and death.** Because of the FDA warning and known higher risks of tocolysis in multifetal pregnancies, use of terbutaline in multiple gestations should be discouraged. **At our institution, intravenous magnesium sulfate is used as a first-line acute tocolytic.** When needed in patients before 32 weeks' gestation, we add oral indomethacin for 48 hours. After 32 weeks, we have also used short-acting nifedipine for tocolysis, assuming the maternal blood pressure tolerates its use.

### Progesterone

#### INTRAMUSCULAR 17-HYDROXYPROGESTERONE CAPROATE

After 17-hydroxyprogesterone caproate (17-OH-P) was shown to be effective in reducing recurrent PTB in singletons, there was interest in using it in populations with other risk factors for spontaneous preterm delivery, such as multiple gestations. Numerous RCTs have been done using 17-OH-P in doses that range from 250 mg weekly, the dose proven effective in singleton gestations, to 500 mg twice weekly in multifetal gestations. Most of the twin populations were unselected, but one study<sup>86</sup> enrolled only women with a TVCL of 25 mm or less. **None of these studies have shown any benefit associated with the use of 17-OH-P in multiple gestation.**<sup>86-90</sup> An interesting dilemma arises when caring for a woman pregnant with multiples who has had a prior singleton spontaneous PTB. Unfortunately, no data exist to inform decision making on whether to offer weekly 17-OH-P in this scenario.

#### VAGINAL PROGESTERONE

Vaginally administered progesterone has been shown in multiple studies to be beneficial in prolonging gestation in singleton pregnancies with a short cervix. Vaginal progesterone is recommended by ACOG as a management option in asymptomatic women with a singleton gestation and incidentally identified CL of 20 mm or less prior to 24 weeks of gestation. The 2007 trial by Fonseca and associates<sup>91</sup> examined the effect of nightly vaginal progesterone in women with a short midgestation CL and included twin gestations, although twins made up only 10.4% (*n* = 13) of the placebo group and 8.8% (*n* = 11) of the treatment group. This study randomized women with a transvaginal CL of 15 mm or less at a median of 22 weeks' gestation to either 200 mg of vaginal progesterone or placebo. They found that administration of nightly vaginal progesterone decreased spontaneous delivery before 34 weeks from 34.3% to 19.2%

( $P < .05$ ). In the subgroup of twin gestations, vaginal progesterone was associated with a similar reduction in preterm delivery, although the difference did not reach statistical significance because of the small sample size. Since publication of that paper, multiple RCTs have examined the use of vaginal progesterone gel 90 mg daily or vaginal micronized progesterone suppositories in doses that ranged from 100 to 400 mg daily in women pregnant with multiples.<sup>92-97</sup> **None of the studies that enrolled only multiple gestations showed an improvement in the primary outcome, but the study by Cetingoz and colleagues<sup>93</sup> that enrolled women at high risk for PTB (of whom 40% in the placebo group and 48.7% in the daily 100-mg micronized vaginal progesterone group had twins) found a statistically significant increase in the risk of delivery before 37 weeks (3.48; 95% CI, 1.16 to 10.46), but not before 34 weeks, in twin gestations in which the mother received placebo compared with those who received progesterone.<sup>93</sup>** None of these studies enrolled the highest-risk multiple gestations based on TVCL or other factors such as prior spontaneous PTB.

Two meta-analyses have been published that help distill the results of these various studies that have examined the use of intramuscular and vaginal progesterone in multifetal gestations. The first is a 2012 meta-analysis of individual patient data by Romero and colleagues<sup>98</sup> that included five trials of vaginal progesterone in women with an asymptomatic short cervix in the midtrimester. Overall, the five trials included 775 women and 827 infants. **In the subgroup of women with a twin gestation, the investigators found a nonsignificant 30% reduction in the rate of PTB before 33 weeks in women given progesterone compared with those who received placebo (RR, 0.70; 95% CI, 0.34 to 1.44), and a statistically significant reduction in composite adverse neonatal outcomes (RR, 0.52; 95% CI, 0.29 to 0.93).**

The more recent individual patient data meta-analysis evaluated the effectiveness of progesterone in improving twin pregnancy outcomes and included 13 trials with 3768 women and 7536 babies.<sup>99</sup> The primary outcome was a composite of perinatal mortality and severe neonatal morbidity. The results demonstrated no reduction in adverse outcome with either 17-OH-P or vaginal progesterone in the overall analysis. However, in a subgroup analysis of women with twins and a TVCL of 25 mm or less who received vaginal progesterone, a statistically significant reduction was seen in adverse perinatal outcome (RR, 0.56; 95% CI, 0.42 to 0.75) when TVCL was measured prior to 24 weeks.

**The authors' interpretation of the available literature on progesterone to prevent PTB in twins is that no evidence is available to support the use of intramuscular 17-OH-P in any multifetal gestation, nor should any form of progesterone be used in unselected multiple pregnancies. However, although more study is needed to confirm this finding, because of the evidence of neonatal benefit in twin pregnancies with a TVCL of 25 mm or less, vaginal progesterone should be offered to these women. Evidence is insufficient to support a specific dose or to support gel versus a micronized progesterone suppository.**

### Cerclage

Results of studies using cervical cerclage to prolong pregnancy in multiple gestations have been disappointing. **Prophylactic cerclage has been studied and was found to be ineffective in both twins and triplets.** Even in the presence of cervical

shortening, no clear benefit of cerclage placement in patients with twins has been demonstrated. Newman and coworkers<sup>100</sup> prospectively followed 147 twin pregnancies in women who underwent transvaginal ultrasonographic CL measurements between 18 and 26 weeks' gestation. Cerclage was offered to all 33 women with a transvaginal cervical length of 25 mm or less, and a cerclage was placed in 21 women. No differences were reported between the cerclage and no-cerclage groups with regard to length of gestation, birthweight, delivery before 34 weeks, PPRM, or VLBW. A 2005 meta-analysis of ultrasound-indicated cerclage found that in the subgroup with twins, cerclage placement was actually associated with a statistically significant increase in birth before 35 weeks (75% vs. 36%).<sup>101</sup> Because cerclage is a surgical procedure that may be associated with adverse sequelae for both the mother and her fetuses, it is recommended that **cerclage placement in multiple gestations be restricted to women with either a strongly suggestive history of cervical insufficiency or objectively documented cervical insufficiency based on physical examination. Neither prophylactic nor ultrasound-indicated cerclage are of benefit in multifetal gestations.**

### Pessary

In the last few years, there has been renewed interest in pessary placement for prevention of spontaneous PTB. The Cervical Pessary in Pregnant Women with a Short Cervix (PECEP) study, an RCT of pessary versus expectant management in singleton pregnancies with a TVCL less than 25 mm at a mean gestational age of 22 weeks, showed a reduction in birth before 34 weeks as well as an improvement in neonatal outcomes in the pessary group.<sup>102</sup> Pessary use has also been studied in a prospective RCT of multifetal gestations conducted in 40 centers in the Netherlands. The ProTWIN trial<sup>103</sup> randomized 813 women pregnant with multiple gestations, of which 98% were twins, to either expectant management or pessary placement. Fifty-five percent of women in both groups were nulliparous, and only 7% in the pessary group and 6% in the control group had a prior spontaneous PTB. TVCL was measured between 16 and 22 weeks. Only 1% of women in both groups had funneling, and the median TVCL was 43.6 mm in the pessary group and 44.2 mm in the control group. **In the overall analysis, no difference was seen in neonatal outcomes; gestational age at delivery; or delivery before 28 weeks, 32 weeks, or 37 weeks between women randomized to pessary and those randomized to expectant management.** The study had originally included a planned a priori analysis of all women with TVCL less than 25 mm, but because very few women met this criterion, that analysis was changed to TVCL below the 25th percentile. When the analysis was restricted to women with TVCL below the 25th percentile, which corresponded to 38 mm, median gestational age at delivery was longer in the pessary group than in the control group (36.4 vs. 35.0 weeks,  $P < .05$ ). Pessary use was associated with a reduced risk of delivery before 28 weeks (OR, 0.23; 95% CI, 0.06 to 0.87) and before 32 weeks (OR, 0.49; 95% CI, 0.24 to 0.97) but not before 37 weeks (OR, 0.82; 95% CI, 0.54 to 1.24) in the group of women with TVCL below the 25th percentile. Additionally, among women with a shorter cervix at enrollment, the risk of a composite adverse neonatal outcome was decreased in the pessary group (OR, 0.40; 95% CI, 0.19 to 0.83). The results of this study show that pessary placement is not effective in prolonging gestation or improving outcomes when used routinely in twin pregnancies, but **the subgroup analysis of women**

with TVCL below the 25th percentile suggests that pessary could be effective in women pregnant with twins who also have a short cervix. In the 2014 Practice Bulletin on Multifetal Gestation, ACOG cites the ProTWIN study and concludes that “based on available evidence, the use of prophylactic cervical pessary is not recommended in multifetal pregnancies.”<sup>37</sup> Further study is needed to determine whether pessary use could be of value in multifetal pregnancies with a short cervix, a population in which evidence-based interventions are lacking.

### Antenatal Testing

**Multiple gestations are at increased risk for uteroplacental insufficiency, IUGR, and stillbirth; for this reason, antenatal surveillance in the form of nonstress tests (NSTs) or biophysical profiles (BPPs) is often performed.** Retrospective data show that both NSTs and BPPs can effectively detect compromised twin gestations and can be interpreted the same as in singletons. However, any recommendations on specific surveillance protocols are based on expert opinion, because no prospective data are available upon which to base a recommendation. ACOG does not recommend antenatal testing for uncomplicated dichorionic twins, but the 2014 ACOG practice bulletin on antenatal testing does list monochorionicity as an indication, although no specific testing schedule is suggested.<sup>104</sup> In the United States, most institutions perform weekly or twice weekly antenatal testing on monochorionic twins starting at around 32 to 34 weeks. Although ACOG does not list dichorionic twins as an indication for routine antenatal testing, the authors feel it is reasonable to perform routine weekly NSTs or BPPs in this population, in part because of the limitations in detection of IUGR. The 2009 NICHD reevaluation of antenatal testing does not specify by chorionicity, but they list weekly testing at 32 weeks as a reasonable strategy for twins with normal fetal growth.<sup>105</sup> **At the authors’ institutions, weekly NST or BPP is initiated at 32 weeks for monochorionic diamniotic twins and at 34 weeks for dichorionic twins.** More frequent or earlier onset of testing is initiated for twins with additional complications such as IUGR, discordant growth, or underlying maternal medical disorders such as diabetes or hypertension.

Even fewer data are available for triplet and higher-order multiple gestations. However, because the stillbirth risk increases with increasing plurality, it is reasonable to begin antenatal testing earlier for triplets than for twins. **The 2009 NICHD document lists initiation of antenatal testing at 28 weeks as a reasonable strategy for triplets.**<sup>105</sup> **We preferentially perform BPPs instead of NSTs in triplets or higher plurality because of the difficulty in consistently and efficiently obtaining and interpreting NSTs with more than two fetuses.**

### Fetal Growth Surveillance

Although ultrasound is an imperfect predictor of fetal weight, it is the only method available for assessing individual fetal growth in multiple gestations. Data indicate that **twins grow at the same rate as singletons until 30 to 32 weeks gestation, after which their growth velocity slows compared with singletons.**<sup>106-108</sup> A study that used 1991 to 1995 National Center for Health Statistics data found that singleton, twin, and triplet birthweights prior to 28 weeks gestation were similar regardless of plurality. However, by 30 weeks gestation, differences in birthweights began to be identified. By 32 weeks, the

median birthweight in twins and triplets was reduced by 300 g and 450 g, respectively, compared with singletons.<sup>106</sup> A retrospective study in Scotland studied all twins ( $n = 131$ ) delivered at a single institution between 1994 and 1996. Each pregnancy had ultrasounds every 2 to 3 weeks after 24 weeks to assess fetal growth, and growth velocities were calculated. The study found that biparietal diameter (BPD) and abdominal area growth velocities slowed significantly after 30 weeks. This slowing of growth was present regardless of whether the pregnancy subsequently delivered preterm.<sup>107</sup> A prospective longitudinal study of 162 twin pregnancies that underwent ultrasound assessment of fetal growth every 2 weeks starting at 16 weeks gestation reported slowing of growth velocities for BPD, femur length (FL), and abdominal circumference (AC) after 32 weeks.<sup>108</sup>

Formulas developed specifically for ultrasound estimation of twin fetal weights have been studied, but these twin formulas have not proven to be superior to standard singleton formulas typically used. **It is recommended that twin fetal weights should be estimated using singleton formulas, taking into account multiple biometric parameters. Additionally, because growth is a dynamic process, patients with multifetal gestations should be followed throughout pregnancy. It is recommended that all patients with twins undergo ultrasound evaluation of fetal growth at least every 4 weeks after 20 weeks and more frequently if IUGR or growth discordance is suspected. Additionally, ultrasounds should be performed every 2 weeks in monochorionic twins beginning at 16 weeks to screen for TTTS.**

### Discordant Growth

**Significant discordance in weight between twins is most commonly defined as a greater than 20% difference in actual or estimated twin weights** (the difference between the weights divided by the weight of the larger twin). In a cohort of 293 twin pregnancies, birthweight discordance of 10%, 15%, 20%, and 25% was reported in 48.8%, 34.5%, 23.5%, and 18.8% of twin pregnancies, respectively.<sup>109</sup> Because DZ twins are genetically distinct, they might easily be programmed to have obviously different weights at birth. There are, however, several pathologic situations in which either monochorionic or dichorionic twins may develop substantial weight differences. These include TTTS, the combination of an anomalous fetus with a normal co-twin, umbilical cord abnormalities that affect a single twin, and selective IUGR that affects only one twin. Although it has been argued that twin weight discordance is not concerning if both babies’ estimated weights remain appropriate for gestational age, discordance, especially when severe, suggests the possibility of clinically significant growth restriction.

Although it is generally agreed that weight discordance in twins should be calculated, the degree of discordance that confers an increased risk of adverse outcomes is subject to debate. The ESPRiT trial prospectively followed twin pregnancies with serial sonography, including growth assessments every 2 weeks. Analyzing data for 977 twin pregnancies, they found that perinatal morbidity and mortality increased with birthweight discordance above 18%. This threshold remained the same regardless of chorionicity after cases of TTTS were excluded.<sup>110</sup> Adverse perinatal outcome was roughly twofold higher (hazard ratio [HR], 2.1; 95% CI, 1.6 to 2.8) in twins with discordance of 18% or more, even when both twin weights were appropriate for gestational age. The hazard ratio for adverse perinatal outcome rose more than fourfold (HR, 4.5; 95% CI,

1.8 to 10.8) if one twin in a discordant pair was growth restricted, defined as below the 5th percentile in birthweight.

Another recent retrospective cohort study that involved 895 dichorionic and 250 monochorionic pregnancies reported different results. All pregnancies were cared for at a single tertiary care center between 1990 and 2008. Exclusion criteria were monoamniocity, TTTS, structural anomalies and, importantly, growth-restricted twins (birthweight below the 10th percentile). The study found that a birthweight discordance of 20% or more did not affect outcome in appropriately grown dichorionic gestations. However, in monochorionic twins, a birthweight discordance of 20% or more was associated with an increased risk of delivery before 34 weeks and before 28 weeks and with a higher risk of admission to the NICU. The paper concluded that when neither twin was growth restricted, growth discordance was a risk factor for adverse perinatal outcomes only in monochorionic twin gestations.<sup>111</sup>

Most of the available literature on twin weight discordance and associated outcomes has used birthweight, rather than discordance, in estimated fetal weight (EFW). Of course, ultrasound estimation of fetal weight is the only information available to guide antenatal management. Khalil and associates<sup>109</sup> compared sonographically estimated fetal weights and fetal growth discordance to actual birthweights that occurred within 48 hours of the ultrasound. Ultrasound correctly identified growth discordance ( $\geq 10\%$ ,  $\geq 15\%$ ,  $\geq 20\%$ , and  $\geq 25\%$ ) in 69% to 86% of cases, with greater accuracy at the extremes of growth discordance. **Because ultrasound diagnosis of fetal growth discordance and IUGR is imperfect, we recommend using the presence of EFW discordance of 20% or more as an indication for heightened surveillance even when neither fetus meets criteria for IUGR. This recommendation applies to both dichorionic and monochorionic twins, but more caution should be used in monochorionic gestations with the same degree of estimated growth discordance compared with a dichorionic pregnancy.** Based on the ESPRiT study data, using a cutoff of 18% or more discordance would also be reasonable.

## SPECIALIZED TWIN CLINICS

The value of specialized twin clinics has been described. **In these clinics, where women carrying twins are seen at regular intervals by the same obstetric team, several advantages accrue. Patients are followed by a small group of focused caregivers and benefit from the accumulated experience of a specialized service.** Two studies have examined the effects of such clinics and have found improvements in outcomes. One study demonstrated reduced rates of VLBW babies, NICU admissions, and perinatal mortality,<sup>112</sup> whereas the other showed improvements in gestational age and birthweight and reduced rates of PPROM, preterm labor and delivery, preeclampsia, and LBW and VLBW infants as well as reductions in NICU admissions and individual complications such as respiratory distress syndrome (RDS), necrotizing enterocolitis (NEC), and retinopathy of prematurity (ROP).<sup>113</sup> Although they lack a prospective randomized design, these studies suggest that intensive education, multidisciplinary care, and surveillance combined with careful attention to maternal nutrition and weight gain can improve outcomes in twin pregnancies. Figure 32-12 outlines a reasonable management algorithm for antepartum care unique to twin gestations.

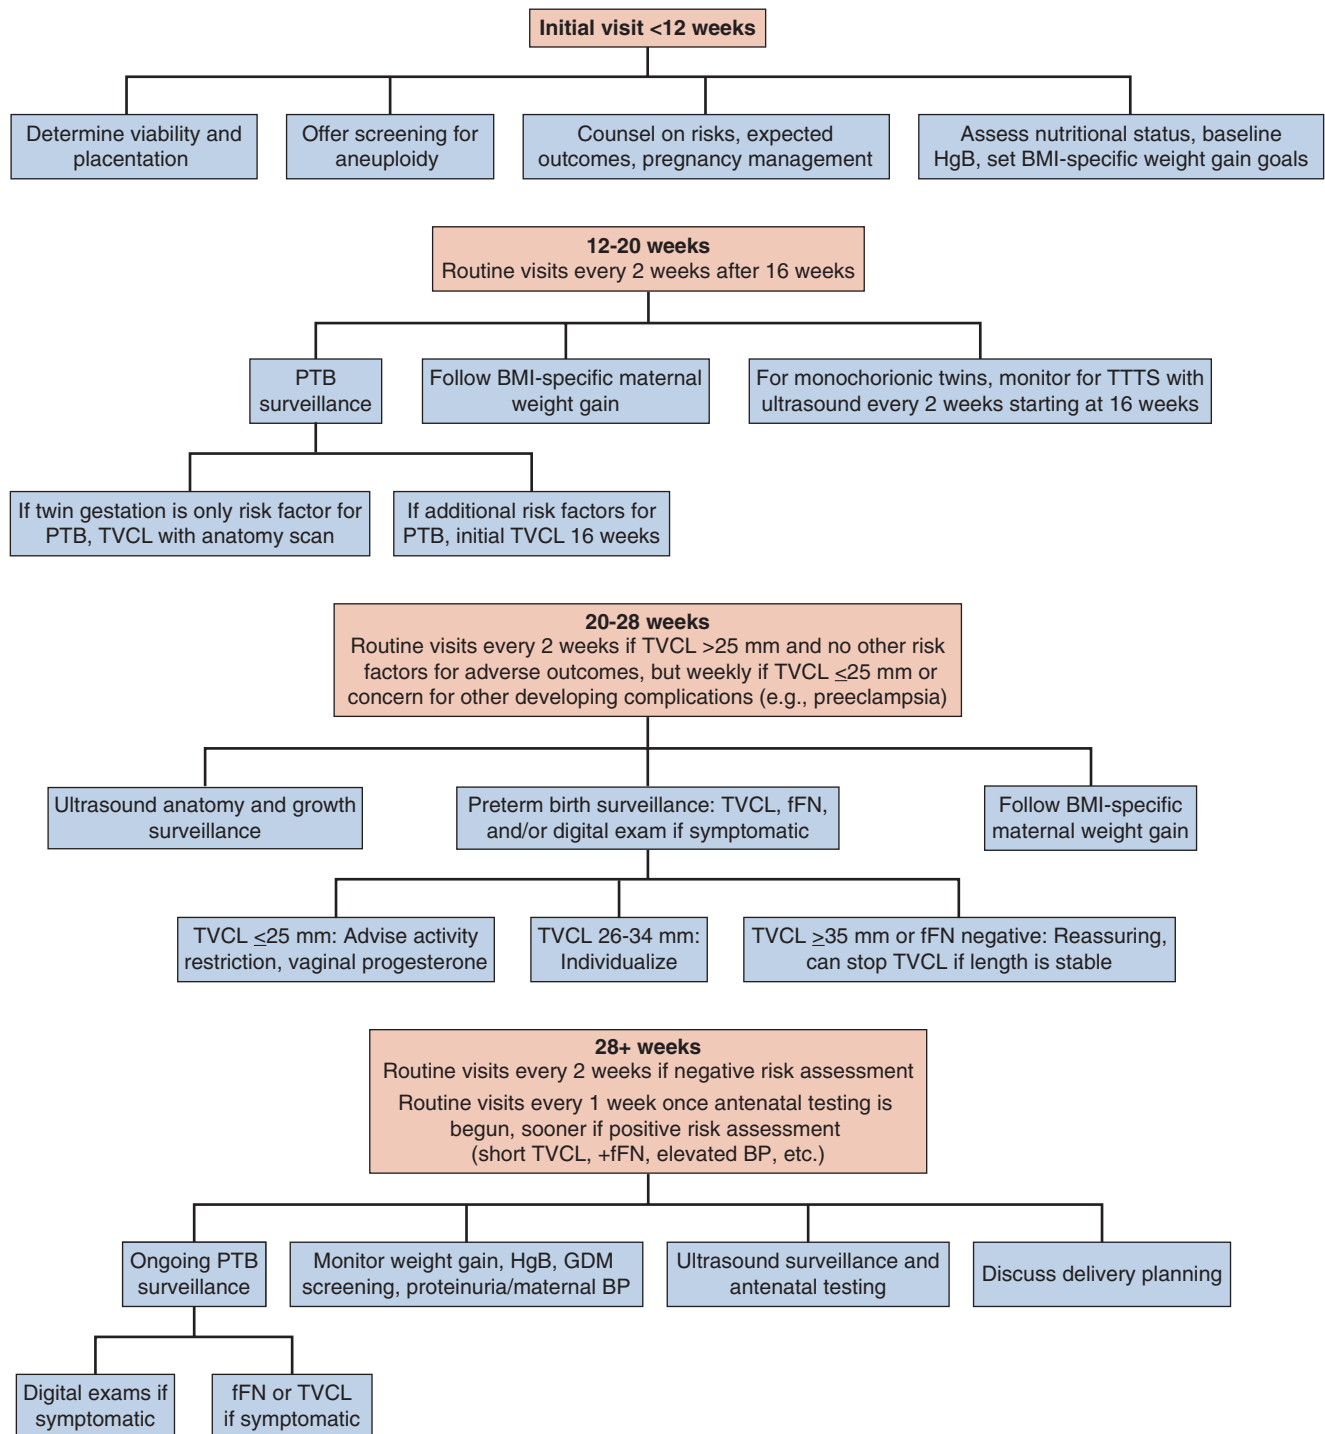

## TIMING OF DELIVERY IN MULTIPLE GESTATIONS

Concern over preterm delivery in twin pregnancies sometimes overshadows decision making regarding the appropriate timing of delivery for mothers with a multiple gestation who remain pregnant at or near term. **Numerous population-based studies suggest that the nadir of perinatal complications occurs at earlier gestational ages in multiple gestations compared with singletons.**

Unfortunately, the hypothesis that elective early delivery of twins leads to better outcomes has not been subjected to rigorous prospective study. Until recently the only randomized study of elective early delivery of twins was an underpowered Japanese study, with only 17 women in the induction group and 19 in the expectant management group. Women with both uncomplicated dichorionic and monochorionic pregnancies and a cephalic first twin were randomized at 37 weeks to either labor induction or expectant management. No differences were apparent in birthweight, Apgar score, or cesarean delivery rate, and no fetal deaths occurred in either group.<sup>114</sup> More recently, Dodd and associates<sup>115</sup> performed a randomized trial of delivery timing at term for uncomplicated twin pregnancies. Two hundred thirty-five women with uncomplicated dichorionic or monochorionic diamniotic twins were randomized to delivery at 37 weeks ( $n = 116$ ) versus at or after 38 weeks ( $n = 119$ ). Recruitment was stopped well short of the sample-size goal of 460 women due to insufficient funding. The study found a decreased rate of the primary outcome, which was a composite of adverse neonatal outcomes, in the 37-week delivery group (4.7% vs. 12.2%; RR, 0.39; 95% CI, 0.20 to 0.75;  $P = .005$ ). However, this apparent improvement in overall outcome was solely a result of a decrease in birthweight below the 3rd percentile (3.0% vs. 10.1%;  $P = .004$ ). No difference was reported in any other individual infant outcome, nor were differences found in maternal outcomes or mode of delivery. The difference in mean birthweight between groups was statistically significant (2.74 kg vs. 2.83 kg in the 37-week vs. the greater than 38-week groups, respectively;  $P = .01$ ) but arguably clinically insignificant. For this reason, as well as the fact that the study was significantly underpowered, the question of optimal delivery timing for uncomplicated twins remains unanswered. Furthermore, it is unlikely that a trial to definitively answer this question would ever be feasible to perform.

As mentioned previously, numerous population-based studies suggest a perinatal benefit associated with the early delivery of twins. Kahn and colleagues<sup>116</sup> reviewed nearly 300,000 twin pairs and found 39 weeks to be the point of intersection that minimized both the fetal and neonatal death rates. They found that the prospective risk for stillbirth in twins equaled that of postterm singletons by 36 to 37 weeks' gestation. Another analysis by Sairam and associates<sup>117</sup> evaluated more than 4000 multiple pregnancies, of which more than 99% were twins, and found that the fetal death rate at 39 weeks' gestation in a twin pregnancy exceeded that of a postterm singleton pregnancy. Twins at 37 to 38 weeks' gestation had stillbirth rates equivalent to those of postterm singletons.

**Given consistent evidence of increased risk in twin pregnancies that extend past 38 to 39 weeks' gestation (analogous to a postdate singleton gestation), a rational delivery approach would be elective delivery at 38 weeks in well-dated, uncomplicated dichorionic twin pregnancies (Fig. 32-13).** Allowing

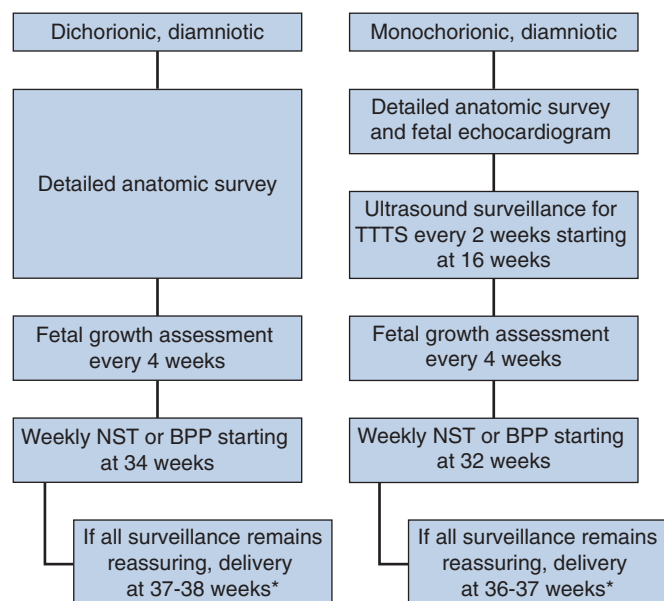

**FIG 32-12** Suggested algorithm for antepartum management of twin gestations. BMI, body mass index; BP, blood pressure; fFN, fetal fibronectin; GDM, gestational diabetes mellitus; Hct, hematocrit; HgB, hemoglobin; PTB, preterm birth; TVCL, transvaginal cervical length; TTTS, twin-twin transfusion syndrome.

a dichorionic twin gestation to go past 38 weeks requires convincing evidence of normal fetal growth, amniotic fluid volume, and fetal testing as well as a patient desire to extend the pregnancy. **Prolongation of a twin pregnancy past 39 weeks is not advisable because of clear risk without any known benefit.** Unfortunately, few of these population-based studies differentiated between dichorionic and monochorionic pregnancies, and further studies were needed to define the optimal

delivery timing for monochorionic twins; this evidence will be discussed below.

Of course, the timing of delivery in the face of either maternal or fetal complications is influenced by severity and clinical judgment and will require modification of the guidelines outlined in [Figure 32-13](#). For instance, an IUGR twin or a pregnancy with significant discordance in EFWs may be an indication for earlier delivery even if all other testing is normal. Likewise, poorly

\*Aim for the end of this range

**FIG 32-13** Antenatal surveillance and delivery timing for uncomplicated diamniotic twins. This figure applies only to uncomplicated twins. If any fetal or maternal complications exist, more frequent ultrasounds and antenatal testing, as well as earlier delivery, may be indicated. BPP, biophysical profile; NST, nonstress test; TTTS, twin-twin transfusion syndrome.

controlled maternal conditions such as diabetes, preeclampsia, lupus, or sickle cell disease may warrant preterm delivery even if fetal growth is appropriate.

### Monochorionic Diamniotic Twins: Special Considerations Regarding Delivery Timing

Although monochorionic gestations share all the same increased risks as dichorionic twins—for instance, elevated risk of preterm labor and preeclampsia—monochorionic twins also have unique risks such as TTTS, TAPS, and selective IUGR; consequently, they also have a higher risk of stillbirth. Additionally, **many investigators have expressed recent concern for an elevated risk of stillbirth even in apparently uncomplicated monochorionic diamniotic twins in the late-preterm/early-term period.**

The first paper to formally raise this concern was a 2005 retrospective analysis<sup>118</sup> from the United Kingdom that reviewed 151 uncomplicated monochorionic pregnancies. The patients underwent ultrasound evaluation for fetal growth, amniotic fluid, and UA Dopplers every 2 weeks. The study reported a prospective risk of stillbirth after 32 weeks of 4.3% (1 in 23). Since publication of that paper, over a dozen studies on stillbirth risk and optimal delivery timing for monochorionic diamniotic twins have been published. Most show a lower stillbirth risk than reported in the Barigye paper. The results of these studies are conflicting, and differences in antenatal surveillance regimens, as well as inclusion or exclusion of certain complications, make synthesis of the information difficult. A 2013 meta-analysis<sup>119</sup> of nine studies reported the risk of stillbirth per monochorionic diamniotic pregnancy at 32, 34, and 36 weeks of gestation to be 1.6%, 1.3%, and 0.9%, respectively. Four of the nine studies had a dichorionic control group. Compared with the uncomplicated dichorionic pregnancies, the odds ratio for stillbirth per

monochorionic diamniotic pregnancy at 32, 34, and 36 weeks of gestation was 4.2 (95% CI, 1.4 to 12.6), 3.7 (95% CI, 1.1 to 12.0), and 8.5 (95% CI, 1.6 to 44.7), respectively. Importantly, this meta-analysis did not include several very recent papers with a much lower reported risk of stillbirth in otherwise uncomplicated monochorionic diamniotic twins. **The authors' own data**, a retrospective cohort study of all twins (601 dichorionic and 167 monochorionic pregnancies) delivered at or after 34 weeks at a single tertiary care center from 1987 to 2010, was published in 2014. All twins received ultrasounds for fetal growth and AFV at least every 4 weeks and weekly NSTs starting at 32 weeks for monochorionic twins and at 34 weeks for dichorionic twins. **Delivery of uncomplicated dichorionic and monochorionic twins was recommended at 38 and 37 weeks, respectively. The prospective risk of IUFD at 34 or more weeks' gestation for dichorionic twins was 0.17% (a single stillbirth) and 0.0% for monochorionic twins. Composite neonatal morbidity was calculated and was found to decrease with each advancing gestational week ( $P < .0001$ ). The nadir of composite neonatal morbidity occurred between 36 weeks 0 days and 36 weeks 6 days gestation for monochorionic twins and between 37 weeks 0 days and 37 weeks 6 days gestation for dichorionic twins.**<sup>120</sup>

The first organization to formally recommend differences in delivery timing by chorionicity was the 2011 NICHD and SMFM publication on timing of indicated late-preterm and early-term birth. They recommended delivery of uncomplicated dichorionic twins at 38 weeks and uncomplicated monochorionic diamniotic twins between 34 and 37 weeks.<sup>36</sup> The 2014 Practice Bulletin on Multifetal Gestations is the most recent ACOG publication to address twin delivery timing, and it offers a similar recommendation for delivery at 38 weeks for uncomplicated dichorionic gestations and between 34 and 37<sup>67</sup> weeks for uncomplicated monochorionic diamniotic twins.<sup>37</sup>

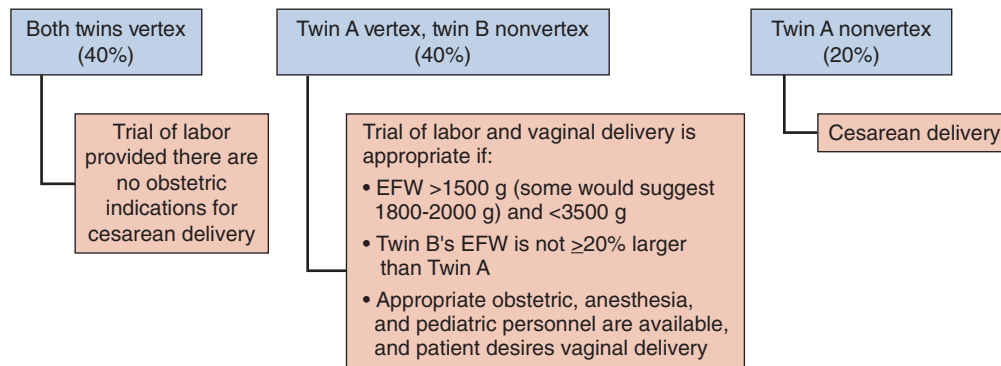

In our experience, intensive fetal surveillance can minimize unexpected third-trimester stillbirth in monochorionic pregnancies. This allows prolongation of uncomplicated monochorionic pregnancy to 36 to 37 weeks, which significantly reduces composite neonatal morbidity. Taking into account the risks of both stillbirth and neonatal morbidity, a reasonable approach to surveillance and planned delivery for uncomplicated monochorionic diamniotic gestations is outlined in Figure 32-13.

### Timing of Delivery With Triplets

Triplets are clearly at very high risk for PTB. However, in a review of more than 15,000 triplet pregnancies, as many as 15% of triplets were undelivered at 36 weeks. That same study found that the point of intersection between a falling neonatal death rate and a rising stillbirth rate occurred at 36 weeks' gestation.<sup>116</sup> **Most experts agree that it is reasonable to offer delivery of uncomplicated triplets anytime between 35 and 36 weeks.**

### MODE OF DELIVERY IN MULTIPLE GESTATIONS

A number of factors must be considered when determining the mode of delivery for patients with multifetal gestations. These variables include the gestational age, estimated weights of the fetuses, their positions relative to each other, the availability of real-time ultrasound on the labor floor and in the delivery room, and the ability to monitor each twin independently during the

**FIG 32-14** Algorithm for mode of delivery in diamniotic twins. (Monoamniotic twins should have cesarean delivery.) EFW, estimated fetal weight.

entire intrapartum period. Carefully considering all these variables is essential because multiple gestations are inherently at higher risk during the intrapartum period. The recent available literature on mode of delivery in twin gestations is summarized below.

All combinations of intrapartum twin presentations can be classified into three groups: (1) twin A vertex, twin B vertex; (2) twin A nonvertex, twin B either vertex or nonvertex; and (3) twin A vertex, twin B nonvertex. In a series of 362 twin deliveries presented by Chervenak and associates,<sup>121</sup> these presentations were found in 42.5%, 19.1%, and 38.4% of cases, respectively. Each scenario is discussed in turn, and recommendations are summarized in [Figure 32-14](#).

### Vertex-Vertex Twins

**A trial of labor and vaginal delivery is appropriate for all vertex-vertex twin gestations, regardless of gestational age or estimated fetal weight.** No clear benefit to routine cesarean delivery of vertex-vertex twins has been found in the literature, including VLBW deliveries. However, it is important to note that the presentation of the second twin may change in 5% to 10% of cases after delivery of the presenting twin. The obstetrician should always discuss this possibility with the patient before delivery, and the obstetric team should always have a clear plan for the management of an unexpected nonvertex second twin.

### Nonvertex Presenting Twin

**Twin pregnancies with a nonvertex presenting twin are nearly always managed by cesarean delivery.** Historically, this was because of a fear of interlocking fetal heads during delivery of breech-vertex twins. However, interlocking fetuses are exceedingly rare. More concerning is extension of the fetal head of the presenting breech twin, which predisposes to a more difficult breech extraction and risk of cervical spine injury. Currently, in an era in which nearly all singleton breech fetuses are delivered by elective cesarean delivery (see [Chapter 17](#)), cesarean delivery is also the optimal mode of delivery for twin pregnancies with a nonvertex-presenting fetus.

### Vertex-Nonvertex Twins

Although the route of delivery for the previous two scenarios is noncontroversial, the management of patients whose twins are in a vertex-breech or vertex-transverse lie is subject to significant debate. When the second twin is nonvertex after delivery of the first twin, the two options for vaginal delivery are breech extraction or external cephalic version (ECV). Although ECV is an acceptable strategy, it has been shown to be associated with more

delivery complications and higher rates of cesarean delivery than breech extraction.<sup>122</sup> **Thus, provided the obstetrician is sufficiently trained in breech extraction and the fetus is of appropriate size, breech extraction is the preferable option for achievement of vaginal delivery with a nonvertex second twin** (see [Chapter 17](#)).

Some obstetricians have voiced concerns regarding the safety of breech extraction and have questioned whether outcomes are equivalent to cesarean delivery. Chervenak and colleagues<sup>121</sup> cite several older references in which depressed Apgar scores and increased perinatal mortality rates were associated with vaginal breech delivery of the second twin. However, in the same report, the authors analyze their own extensive experience, along with a review of the published literature, and conclude that breech extraction of a second twin is a safe and appropriate option if the EFW is more than 2000 g. Although the data supported the safety of breech extraction for babies who weigh more than 1500 g, the investigators chose 2000 g—rather than 1500 g—to allow for the margin of error of an ultrasound-estimated fetal weight.

The safety of breech extraction for second twins is supported by what was until recently the only randomized trial of cesarean delivery versus breech extraction. Rabinovici and associates<sup>123</sup> randomized 66 women with vertex-nonvertex twins of more than 35 weeks' gestation to vaginal delivery with breech extraction or cesarean delivery. They found no differences in neonatal outcomes and no cases of birth trauma or neonatal death. Not surprisingly, maternal febrile morbidity was greater in the cesarean delivery group.

Several other large case series and cohort studies have also supported the safety of breech extraction of second twins. Gocke and colleagues<sup>122</sup> retrospectively analyzed 136 sets of vertex-nonvertex twins with a birthweight higher than 1500 g in whom delivery of the second twin was managed by primary cesarean delivery, ECV, or primary breech extraction. No differences were noted in the incidence of neonatal mortality or morbidity among the three delivery modes, although ECV was associated with a higher failure rate than breech extraction along with a higher rate of nonreassuring FHR patterns, cord prolapse, and compound presentation. The authors concluded that primary breech extraction of a second nonvertex twin weighing more than 1500 g is a reasonable alternative to either cesarean delivery or ECV. Fishman and coworkers<sup>124</sup> and Greig and colleagues<sup>125</sup> examined the records of more than 1200 twin gestations and concluded that no evidence supported cesarean delivery for nonvertex second twins who weighed more than 1500 g. In fact, Greig's data did not show poorer outcomes even for babies who

weighed less than 1500 g delivered by breech extraction. Nonetheless, **most experts recommend avoidance of breech extractions on second twins with EFWs of less than 1500 g.**

Two recent retrospective studies on mode of delivery for twins lend further support to the safety of breech extraction for second twins under appropriate circumstances and with experienced operators. Both studies were conducted in single institutions with strict protocols for active second-stage management and immediate breech extraction of the nonvertex second twin. Schmitz and colleagues<sup>126</sup> performed a retrospective cohort study of 758 consecutive twin sets at more than 35 weeks' gestation with a cephalic-presenting twin. The investigators found that the neonatal composite morbidity for the second twin did not differ between planned cesarean and planned vaginal delivery. The second, more recent study by Fox and coworkers<sup>127</sup> examined a retrospective cohort of 287 twin pregnancies from a single tertiary care academic medical center. Once again, following a strict second-stage management protocol, all nonvertex second twins underwent immediate breech extraction, and all nonengaged vertex second twins were delivered by immediate internal podalic version and subsequent breech vaginal delivery. The study found no difference in the rates of 5-minute Apgar scores lower than 7 or a cord pH lower than 7.2 between the planned vaginal delivery ( $n = 130$ ) and planned cesarean delivery groups ( $n = 157$ ). Both of these studies were retrospective and were conducted in a single center by experienced obstetricians using a strict protocol for second-stage management.

Another recent multicenter prospective study revealed similar results. In a prespecified secondary analysis of the ESPRiT study, Breathnach and colleagues<sup>128</sup> analyzed perinatal outcomes by mode of delivery in 971 diamniotic twin pregnancies delivered at eight centers in Ireland. Decisions on timing and mode of delivery were deferred to the lead clinician managing each case and were not prespecified by the study protocol. Of those 971 pregnancies, 441 (45%) were deemed to be appropriate for trial of labor. Of those 441 women, 338 (77%) had a successful vaginal delivery of both twins. The most common indication for cesarean delivery during a trial of labor was arrest of the first stage of labor. Breech extraction of the second twin was performed in 29% of those 338 successful vaginal deliveries, and no differences were found in perinatal outcomes by planned mode of delivery. When they analyzed predictors of successful vaginal delivery for both babies, only multiparity and spontaneous conception were independently associated with successful vaginal birth. Four percent of women who underwent a trial of labor had vaginal delivery of the first twin and cesarean delivery of the second twin.

In 2013, a large randomized trial of delivery mode in twin pregnancies was published. This multicenter, multinational study randomized 2804 women pregnant with diamniotic twins and a cephalic-presenting first twin between 32 weeks 0 days and 38 weeks 6 days gestation to either planned cesarean or planned vaginal delivery. **The primary outcome was a composite of fetal or neonatal death or serious morbidity.** In the planned cesarean delivery group, 89.9% of women underwent cesarean delivery of both babies, and in the planned vaginal delivery group, 56.2% had successful vaginal delivery of both twins. In the planned vaginal group, 4.2% of women underwent vaginal delivery of the first twin and cesarean delivery of the second twin. The paper does not state how many women had vaginal breech delivery of the second twin, but 36.4% of the planned vaginal delivery group had twins in cephalic/noncephalic presentation

at the time of delivery. **The results showed no difference in the primary outcome between the planned cesarean delivery and the planned vaginal delivery groups, nor were differences in maternal morbidity found between the groups.** In a planned subgroup analysis, no difference was found in the primary outcome based on the presentation of the second twin (cephalic vs. noncephalic). When the data were analyzed by birth order, second twins did have a higher risk of the primary outcome (OR, 1.9; 95% CI, 1.34 to 2.69); however, cesarean delivery was not protective.<sup>129</sup>

The above retrospective and prospective data on mode of delivery in diamniotic twin gestations with a cephalic-presenting first twin, including two randomized trials, show that **in selected women under appropriate conditions and with experienced obstetricians and supporting staff, no benefit to routine cesarean delivery is evident.** However, the importance of operator training and experience for safe vaginal delivery of twins cannot be underestimated, particularly when the second twin is in a nonvertex presentation. During the past decade, concerns about outcomes associated with singleton breech deliveries have led to virtual abandonment of vaginal delivery of breech-presenting singletons. As a consequence, **fewer obstetricians are acquiring or maintaining the skills needed to safely perform vaginal breech deliveries.**

### Triplets

Although vaginal delivery is an option for patients with triplets, no large prospective studies have established its safety. Adequate monitoring of three fetuses throughout labor and delivery is challenging. **As a result, elective cesarean delivery of patients with three or more live fetuses of viable gestational age is in most cases the optimal management strategy.** Vaginal delivery of triplets should probably be restricted to those cases with EFWs greater than 1800 g, at least the first two triplets in a cephalic presentation, and obstetricians experienced in such deliveries.

## INTRAPARTUM MANAGEMENT OF TWIN VAGINAL DELIVERY

**Safe vaginal delivery of multiples requires careful preparation and multidisciplinary cooperation among obstetrics, anesthesia, nursing, and neonatology or pediatrics.** On admission to labor and delivery, both fetal presentations should be confirmed by ultrasound. If a recent (<1 to 2 weeks) ultrasound-estimated fetal weight for both babies is not available, this should be obtained and documented. As discussed earlier, knowledge of the presentation, gestational age, and estimated weight of each twin permits the establishment of a plan regarding the anticipated route of delivery. Additionally, the discussion between obstetric providers and the patient regarding mode of delivery should be thoroughly documented in the medical record.

**If a trial of labor is elected, both fetuses should be continuously monitored.** Although the woman may labor in a standard room, the delivery itself is best performed in an operating room (OR) in the event that general anesthesia or cesarean delivery is emergently needed. **We typically transfer the patient to the OR bed for delivery. Epidural anesthesia for labor and delivery is also advisable and is advocated by ACOG.**<sup>37</sup> The pain control afforded by an epidural enhances maternal cooperation, allows a wider range of obstetric procedures to be performed

### BOX 32-1 CHECKLIST FOR MANAGEMENT OF VAGINAL DELIVERY OF TWINS

#### Personnel and Location

- Availability of a fully staffed operating room for the delivery with staff capable of performing an emergency cesarean delivery
- Skilled obstetric attendants present
- Anesthesiologist present at delivery
- Sufficient neonatal personnel for resuscitation of two infants

#### Supplies

- Equipment to continuously monitor both fetuses throughout labor and delivery
- Portable ultrasound for intrapartum use
- Premixed oxytocin
- Methergine, 15-methyl PGF<sub>2α</sub>, and misoprostol for postpartum hemorrhage
- Nitroglycerin and terbutaline for uterine relaxation
- Obstetric forceps and vacuum (including Piper forceps for aftercoming head)
- Blood products

quickly, and is available for anesthesia if emergent cesarean delivery becomes necessary. Box 32-1 provides a list of personnel and equipment that should be prepared for each planned vaginal delivery of a multiple gestation.

### Time Interval Between Deliveries

Historically, many investigators have considered the time interval between delivery of the first and second babies to be an important intrapartum variable that affects the outcome of twin pregnancies. After delivery of the first twin, uterine inertia may develop, the umbilical cord of the second twin can prolapse, and placental abruption may occur; each of these poses a risk to the undelivered second twin. In addition, the cervix can constrict, making rapid delivery of the second twin extremely difficult if nonreassuring fetal status develops. **Many reports have suggested that the interval between deliveries should ideally be 15 minutes or less and certainly not more than 30 minutes.** Most of the data in support of this view, however, were obtained before the advent of continuous and dual intrapartum fetal monitoring capability.

Rayburn and associates<sup>130</sup> reported the outcome of 115 second twins delivered vaginally at or beyond 34 weeks' gestation after the vertex delivery of their co-twin. Continuous monitoring of the FHR was performed in all cases. Oxytocin was used if uterine contractions subsided within 10 minutes after delivery of the first twin. In this series, 70 second twins were delivered within 15 minutes of the first twin, 28 within 16 to 30 minutes, and 17 more than 30 minutes later. The longest interval between deliveries was 134 minutes. All of these infants survived, and none had a traumatic delivery. All 17 of the neonates delivered beyond 30 minutes had 5-minute Apgar scores between 8 and 10. In another series reported by Chervenak and colleagues,<sup>131</sup> when the FHR of the second twin was monitored with ultrasound visualization throughout the period between twin deliveries, no relationship was found between the length of the interdelivery interval and low 5-minute Apgar scores.

**Although some second twins may require rapid delivery, most can be safely followed with FHR surveillance and can remain undelivered for substantial periods of time. This less**

**hurried approach when the second twin is not demonstrating signs of nonreassuring fetal status may reduce the incidence of both maternal and fetal trauma associated with difficult deliveries performed to meet arbitrary deadlines.**

### SUMMARY

The patient who carries more than one fetus presents a formidable challenge to the obstetrician. The elevated maternal risk and perinatal morbidity and mortality seen in multiple gestations, compared with singletons, are due to a variety of factors, many of which cannot currently be altered. However, extraordinary technologic advances during the past 25 years have given us new insights into problems peculiar to multifetal pregnancies and has provided tools with which to detect and treat those problems. Early diagnosis of multiple gestations, determination of chorionicity, and serial surveillance with ultrasound and antenatal testing offer the potential for administering specialized regimens to selected patients, which we believe will lead to a beneficial impact on the outcome of those pregnancies.

### KEY POINTS

- ◆ Twinning is one of the most common high-risk conditions in all of obstetrics. Both maternal and perinatal morbidity and mortality are significantly higher in multifetal gestations than in singleton pregnancies.
- ◆ Chorionicity is a critical determinant of pregnancy outcome and management, and as such it should be ascertained by ultrasound as early in gestation as possible.
- ◆ Monochorionic pregnancies are at higher risk than dichorionic pregnancies and have increased rates of spontaneous abortion, congenital anomalies, IUGR, and IUFD in addition to a 10% to 15% risk for TTTS, a complication unique to monochorionic pregnancies.
- ◆ Multiple gestations benefit from specialized care, which includes attention to maternal nutrition and weight gain, serial assessment of fetal growth by ultrasound, and careful surveillance for signs of preterm labor.
- ◆ Routine bed rest, prophylactic tocolytics, prophylactic cerclage, prophylactic progesterone, and prophylactic pessary have not been shown to be effective in prolonging multiple gestations. However, none of these interventions has been adequately studied in the highest-risk women based on prior obstetric history or current short cervical lengths.
- ◆ The nadir of perinatal complications and an increase in stillbirth risk occurs earlier in twin gestations than in singletons. Uncomplicated dichorionic twins appear to have the best outcomes between 37 and 38 weeks, and uncomplicated monochorionic diamniotic twin outcomes are best when delivery occurs between 36 and 37 weeks. We recommend scheduled delivery at the later end of this range.
- ◆ Monoamniotic twin outcomes are best when managed with a combination of prophylactic antenatal corticosteroids, hospitalization for daily fetal assessment, and elective cesarean delivery between 32 and 34 weeks.

- ◆ Mode of delivery should take into account gestational age, fetal presentations, estimated weights, and the experience and skill of the obstetrician; a trial of labor is appropriate when both twins are vertex.
- ◆ Mode of delivery should be individualized for vertex-nonvertex twins, and cesarean delivery is optimal when the presenting twin is nonvertex.

The identification of pregnancies at risk for preventable perinatal handicap is a primary goal of the obstetric care provider. Pregnancies in which adverse intrauterine conditions result in failure of the fetus to reach its growth potential constitute such a high-risk group. Next to prematurity, intrauterine growth restriction (IUGR) is the second leading cause of perinatal mortality.

Compared with appropriately grown counterparts, perinatal mortality rates in growth-restricted neonates are 6 to 10 times greater; perinatal mortality rates as high as 120 per 1000 for all cases of IUGR and 80 per 1000 after exclusion of anomalous infants have been reported. As many as 53% of preterm stillbirths and 26% of term stillbirths are growth

**restricted.** In survivors, the incidence of intrapartum asphyxia may be as high as 50%.<sup>1</sup> Prevention of some perinatal complications that lead to adverse outcomes in growth-restricted fetuses is possible with appropriate prenatal identification and management. This chapter reviews normal and disturbed fetal growth, the definition of abnormal fetal growth, the impact of fetal growth restriction, and the incorporation of this knowledge into screening, diagnosis, and management of these high-risk pregnancies. *Intrauterine growth restriction* (IUGR), *fetal growth restriction* (FGR), and *small for gestational age* (SGA) are terms frequently used interchangeably when describing the small fetus.

## REGULATION OF FETAL GROWTH

Fetal growth is regulated at multiple levels and requires successful development of the placental interface between maternal and fetal compartments. In the early first trimester, anchoring villi that originate from the cytotrophoblast connect the decidua to the uterus and thereby establish placental adherence. This allows formation of vascular connections between the maternal circulation and the intervillous space so that increasing quantities of placental secretory products can reach the maternal circulation (see Chapter 1).

The villous trophoblast becomes the primary placental site of maternal-fetal exchange. By 16 weeks' gestation, the maternal microvillous and fetal basal layer are only 4 microns apart, posing little resistance to passive diffusion. Elaboration of active transport mechanisms for three major nutrient classes—glucose, amino acids, and free fatty acids—and an increase in the villous surface area raise the capacity and efficiency of active transplacental transport. Vascular throughput across the placenta also increases in the maternal and fetal compartments. Extravillous cytotrophoblast invasion of the maternal spiral arteries results in progressive loss of the musculoelastic media, a process paralleled on the fetal side by continuous villous vascular branching. **This results in significant reduction of blood flow resistance in the uterine and umbilical vessels, which converts both circulations into low-resistance, high-capacitance vascular beds.** Owing to these developments, as much as 600 mL/min of maternal cardiac output reaches a placental exchange area of up to 12 m<sup>2</sup> at term. In the fetal compartment this is matched with a blood flow volume of 200 to 300 mL/kg/min throughout gestation. This magnitude of maternal blood flow is necessary to ensure maintenance of placental function that is energy intensive and consumes as much as 40% of the oxygen and 70% of the glucose supplied. Optimal fetal growth and development depends on a magnitude of maternal nutrient and oxygen delivery to the uterus that leaves sufficient surplus for fetal substrate utilization.

**Of the actively transported primary nutrients, glucose is the predominant oxidative fuel, whereas amino acids are major contributors to protein synthesis and muscle bulk.** Glucose and, to a lesser extent, amino acids drive the insulin-like growth factors axis and therefore stimulate longitudinal fetal growth.

Concurrent development and maturation of the fetal circulation as a conduit for nutrient and waste delivery allows preferential partitioning of nutrients in the fetus. Nutrient- and oxygen-rich blood from the primitive villous circulation enters the fetus via the umbilical vein. The ductus venosus (DV) is the first vascular partitioning shunt encountered. Through modulation in DV shunting, the proportion of umbilical venous blood

distributed to the liver and heart changes with advancing gestation. **Near term, 18% to 25% of umbilical venous flow shunts through the DV to reach the right atrium in this high-velocity stream; 55% reaches the dominant left hepatic lobe, and 20% reaches the right liver lobes (Fig. 33-1).** The differences in direction and velocity of blood entering the right atrium ensures that nutrient-rich blood is distributed to the left ventricle, myocardium, and brain while low-nutrient venous return is distributed to the placenta for reoxygenation and waste exchange. **This process of blood distribution is referred to as preferential streaming.**<sup>2</sup> In addition to this overall distribution of left- and right-sided cardiac output, several organs can modify local blood flow to meet oxygen and nutrient demands by autoregulation.

When the milestones in maternal, placental, and fetal development are met, placental and fetal growth progress normally. The metabolic and vascular maternal adaptations promote a steady and enhanced nutrient delivery to the uterus, and placental transport mechanisms allow for efficient bidirectional exchange of nutrients and waste. **Placental and fetal growth across the three trimesters are characterized by sequential cellular hyperplasia, hyperplasia plus hypertrophy, and lastly, by hypertrophy alone.** Placental growth follows a sigmoid curve that plateaus in midgestation preceding exponential third-trimester growth of the fetus. During this exponential fetal growth phase of 1.5% per day, initial weight gain is due to longitudinal growth and muscle bulk and therefore correlates with glucose and amino acid transport. **Eighty percent of fetal fat gain is accrued after 28 weeks' gestation, providing essential body stores in preparation for extrauterine life.** From 32 weeks onward, fat stores increase from 3.2% of fetal body weight to 16%, which accounts for the significant reduction in body water content.<sup>3</sup>

Several possible mechanisms may challenge compensatory capacity of the maternal-placental-fetal unit to such an extent that failure to reach the growth potential may be the end result.

## DEFINITION AND PATTERNS OF FETAL GROWTH RESTRICTION

**Normal fetal growth involves hyperplasia and hypertrophy on a cellular level. Disturbance of fetal growth dynamics can lead to a reduced cell number, cell size, or both, ultimately resulting in abnormal weight, body mass, or body proportion at birth.** The classification of abnormal growth has evolved significantly over the last century. From its modern origins in 1919 when Yippon was the first to label neonates with a birthweight below 2500 g as “premature” to the description of individualized growth potential, the recognition of the SGA neonate has advanced significantly. With the advent of ultrasound, the recognition and study of fetal growth abnormalities extended into the prenatal period. It is important to note that several definitions that describe abnormal growth are used interchangeably in the obstetric and pediatric literature, but they do not necessarily describe the same population.

The terminology for classifying fetal growth disorders has specifically expanded over the last four decades, which has led to confusion among the various terms used. **From the 1960s, growth has been classified by the absolute birthweight value as low birthweight (LBW; <2500 g), very low birthweight (VLBW; <1500 g), extremely low birth weight (ELBW; <1000 g), or macrosomia (>4000 g).** Subsequently, studies by

**FIG 33-1** Fetal umbilical and hepatic venous circulation. The arrows indicate the direction of blood flow, and the color shows the oxygen content (red = high, purple = medium, blue = low). DV, ductus venosus; EPV, extrahepatic portal vein; FO, foramen ovale; GB, gallbladder; HV, hepatic vein; IVC, inferior vena cava; LPV, left portal vein; PS, portal sinus; RA, right atrium; RPV, right portal vein; UV, umbilical vein. (From Mavrides E, Moscoso G, Carvalho JS, et al. The anatomy of the umbilical, portal and hepatic venous systems in the human fetus at 14-19 weeks of gestation. *Ultrasound Obstet Gynecol.* 2001;18:598.)

Lubchenco, Usher, Battaglia, and others demonstrated that only the comparison of the actual birthweight to the expected weight in a population at the same gestational age identified small neonates at risk for adverse outcome. Adopting this concept of “light” and “heavy” for gestational age served as an introduction of population-based reference ranges for birthweight in the 1970s and allowed classification of growth by the birthweight percentile. **This resulted in the currently accepted classification of birthweight as very small for gestational age (VSGA; <3rd percentile), small for gestational age (SGA; <10th percentile), average for gestational age (AGA; 10<sup>th</sup> to 90th percentile), or large for gestational age (LGA; >90th percentile).** Although birthweight percentiles are superior in identifying the small neonate, they fail to account for proportionality of growth and the growth potential of the individual. Therefore neonates with a normal birthweight percentile but abnormal body proportion as a result of differential growth delay may be missed. Similarly, birthweight percentiles do not distinguish between the small neonate normally grown given his or her genetic potential and the neonate that is growth restricted because of a disease process.

The detection of abnormal body mass or proportions is based on anthropometric measurements and ratios that are relatively

independent of sex and race and, to a certain extent, gestational age and therefore also the traditional birthweight percentiles. **The ponderal index** ([birthweight in grams/crown heel length]<sup>3</sup> × 100) **has a high accuracy for the identification of SGA and macrosomia.** The ponderal index correlates more closely with perinatal morbidity and mortality than traditional birthweight percentiles, but it may miss the proportionally small and lean growth-restricted neonate. Several studies are currently underway to determine the most appropriate statistical methods to calculate the personalized growth potential across ethnicities. It is anticipated that these will improve the accurate prenatal identification of the SGA fetus.

The classification of abnormal growth during fetal life marks a significant advance because it opens the possibility of prenatal detection that leads to preventive or therapeutic management. The concept of percentiles has been adapted to the ultrasound biometry of the fetus. Accordingly, parameters of head, abdominal, and skeletal growth are related to population-based reference ranges. The prenatal diagnosis of FGR based on ultrasound biometry is described in detail below.

In addition to the detection of smaller individual measurements and lower weight, **two principal patterns of disturbed fetal growth have been described: asymmetric and**

**symmetric. In the *asymmetric growth pattern*, somatic growth (e.g., the abdominal circumference [AC] and lower body) shows a significant delay, whereas there is relative or absolute sparing of head growth. In the *symmetric growth pattern*, body and head growth are similarly affected.** Asymmetric growth patterns result from two processes. First, liver volume is reduced because of depletion of glycogen stores as the result of limited nutrient supply, which leads to a decrease in AC. Second, elevations in placental blood flow resistance increase right cardiac afterload and promote diversion of the cardiac output toward the left ventricle because of the parallel arrangement of the fetal circulation and the presence of central shunts. Blood and nutrient supply to vital structures in the upper part of the body thus increase, presumably resulting in relative “head sparing.” Symmetrically restricted fetal growth typically results when interference with the growth process results in decreased cell numbers and cell size, typically resulting from a first-trimester insult. As a result, all parts of the body are equally affected, which produces uniformly small growth.

The pattern of fetal growth depends on the underlying cause of growth delay and on the timing and duration of the insult. **Uteroplacental insufficiency is typically associated with asymmetric fetal growth delay owing to the aforementioned mechanisms. Aneuploidy, nonaneuploid syndromes, and viral infections either disrupt the regulation of growth processes or interfere with growth at the stage of cell hyperplasia. This typically results in a symmetric growth delay.** Specific conditions such as skeletal dysplasia may produce distinct growth patterns by their differential impacts on axial and peripheral skeletal growth. Because growth is dynamic, the pattern of growth restriction may evolve in the course of gestation. Placental disease may initially present with relative head sparing but eventually progresses to symmetric growth delay as placental insufficiency worsens. Alternatively, the acute course of a fetal viral illness may temporarily result in arrested growth with subsequent resumption of a normal growth pattern.

Although the definition and classification of FGR has significantly evolved, research is still ongoing. Small fetal and neonatal sizes have to be considered as a physical sign rather than a specific disease that warrants further investigation of underlying causes. Given that the term *small for gestational age* simply identifies a fetus below a specific weight cutoff without identifying any underlying cause, the SGA designation will be used for this chapter when no underlying cause is evident. The terms *intrauterine growth restriction* and *fetal growth restriction* imply that some pathologic process has prohibited attainment of genetic growth potential, and these terms will be used accordingly in this chapter with a focus on underlying placental pathology. From the perspective of the managing obstetrician, prenatal identification of IUGR is most relevant because it allows appropriate prospective fetal management. Conversely, prenatal identification of the constitutionally small fetus will allow the obstetrician to reassure the patient. To formulate a uniform approach to prenatal detection and perinatal management, an understanding of the maternal and fetal impact of placental insufficiency is essential.

## ETIOLOGIES OF INTRAUTERINE GROWTH RESTRICTION

The precise mechanisms by which various conditions interfere with normal placentation and culminate in either pregnancy loss

or IUGR are of great importance. **Conditions that result in FGR broadly consist of maternal, uterine, placental, and fetal disorders.** These conditions result in growth delay by affecting nutrient and oxygen delivery to the placenta (maternal causes), nutrient and oxygen transfer across the placenta (placental causes), and fetal nutrient uptake or regulation of growth processes (fetal causes). In clinical practice, considerable overlap may occur between the conditions that determine manifestation, progression, and outcome.

**Maternal causes of FGR include vascular disease such as hypertensive disorders of pregnancy, diabetic vasculopathy, collagen vascular disease, and thrombophilia and chronic renal disease. Abnormalities of the fetus and/or placenta can also result in FGR.** Chromosomal abnormalities, congenital malformations, and genetic syndromes have been associated with less than 10% of cases of IUGR.<sup>4</sup> Similarly, although long recognized as a cause of growth restriction, intrauterine infection also accounts for less than 10% of all cases. **However, genetic and infectious etiologies are of special importance because perinatal and long-term outcomes are ultimately determined by the underlying condition, with little potential impact through perinatal interventions.**

Growth restriction has been observed in 53% of cases of trisomy 13 and in 64% of cases of trisomy 18 and may be manifest as early as the first trimester. Other conditions that may present with FGR include skeletal dysplasia and de Lange syndrome. The online database of inheritance in man lists over 100 genetic syndromes that may be associated with FGR. Of the infectious agents, herpes, cytomegalovirus (CMV), rubella, and *Toxoplasma gondii* are well-documented causes of symmetric IUGR.

The common causes of IUGR are listed in [Box 33-1](#). Recognition of these is important in planning the diagnostic workup for specific underlying conditions.

**Although it is beyond the scope of this chapter to discuss the spectrum of clinical consequences, it needs to be**

### BOX 33-1 ETIOLOGIES AND RISK FACTORS FOR INTRAUTERINE GROWTH RESTRICTION

#### Maternal

- Hypertensive disease
- Pregestational diabetes
- Cyanotic cardiac disease
- Autoimmune disease
- Restrictive pulmonary disease
- High altitude (>10,000 feet)
- Tobacco/substance abuse
- Malabsorptive disease/malnutrition
- Multiple gestation

#### Fetal

- Teratogenic exposure
- Fetal infection
- Genetic disorders
- Structural abnormalities

#### Placental

- Primary placental disease
- Placental abruption and infarction
- Placenta previa
- Placental mosaicism

**FIG 33-2** **A**, Uterine artery flow-velocity waveforms. Normal trophoblast invasion results in a low-resistance, high-capacitance placental vascular circulation that can be documented with uterine artery Doppler velocimetry. The flow-velocity waveform in **A** was obtained at 24 weeks' gestation and shows high diastolic flow velocities. Such a flow pattern indicates successful trophoblast invasion. **B**, The second waveform shows lower diastolic velocities and an early diastolic notch (asterisks). This flow pattern is reflective of increased blood flow resistance in the spiral arteries and downstream placental vascular bed. Persistence of notching beyond 24 weeks' gestation is associated with an increased risk of fetal growth restriction and/or hypertensive disorders of pregnancy.

recognized that the diagnosis and prognosis of FGR in twin pregnancies is critically determined by the chorionicity (see Chapter 32). *Selective intrauterine growth restriction (sIUGR)* is a specific term applied to FGR that occurs in monochorionic twins. The prognosis and risk profile can be determined based on the umbilical artery flow pattern.<sup>5</sup>

## MATERNAL AND FETAL MANIFESTATIONS OF INTRAUTERINE GROWTH RESTRICTION

The impact and clinical manifestations of placental insufficiency depend on the gestational age at onset and the severity and type of the placental disease. Early interference with normal placentation affects all levels of placental and fetal development and culminates in the most severe clinical picture, which may result in miscarriage or early stillbirth. If sufficient supply to the placental mass can be established, further placental differentiation may be possible, but suboptimal maternal adaptation to pregnancy and deficient nutrient delivery pose limitations. If adaptive mechanisms permit ongoing fetal survival, early-onset growth restriction with its many fetal manifestations develops. If placental disease is mild or successful compensation has occurred, the consequences of nutrient shortage may remain largely subclinical, only to be unmasked through their restrictive effect on exponential fetal growth in the second to third trimester. In these cases, late-onset growth delay, a decrease in adipose tissue, or abnormal body proportions at birth may be the consequence.

### Maternal Impacts

Placental dysfunction affects several aspects of maternal adaptation to pregnancy. Associations between poor placentation with suboptimal maternal volume expansion, increased vascular reactivity, and a “flat” curve on the glucose tolerance test have been described. Abnormalities of placental vascular development are of special interest because they can be detected by Doppler ultrasound of the uterine arteries and frequently predate clinical

disease (Fig. 33-2). When trophoblast invasion remains confined to the decidual portion of the myometrium, maternal spiral and radial arteries fail to undergo the physiologic transformation into low-resistance vessels, which is generally expected by 22 to 24 weeks. Maternal placental floor infarcts, fetal villous obliteration, and fibrosis each increase placental blood flow resistance, producing a maternal-fetal placental perfusion mismatch that decreases the effective exchange area. With progressive vascular occlusion, fetoplacental flow resistance is increased throughout the vascular bed, and eventually, metabolically active placental mass is reduced. The diagnostic and screening utility of ultrasound findings suggestive of such pathology are discussed below.

### Fetal Impacts

When placental dysfunction compromises nutrient delivery and triggers fetal mobilization of hepatic glycogen stores, physical manifestation of growth delay becomes clinically apparent. In addition to the cardinal sign of FGR, metabolic, endocrine, hematologic, cardiovascular, and behavioral manifestations of placental insufficiency have been described that relate to the severity and duration of placental dysfunction. Of these, cardiovascular and central nervous system (CNS) responses are best studied because their noninvasive assessment is readily achieved by multivessel Doppler, gray-scale ultrasonography, and fetal heart rate (FHR) analysis and can therefore be utilized for fetal surveillance. Appreciating the variety of fetal manifestations helps to understand the potential limitations of antenatal surveillance and provides a basis on which to appreciate the possible short- and long-term impacts of placental insufficiency.

**Metabolic manifestations** occur early in growth-restricted fetuses. This is because with mild to moderate decline in uterine nutrient delivery, fetal supply is compromised first, whereas placental nutrition is preferentially maintained. With progression of placental insufficiency, nutrient deficits become universal and result in decreased fetal and placental size. Accordingly, with mild restrictions in oxygen and glucose supply, fetal demands

are still met by increased fractional extraction. **When uterine oxygen delivery falls below a critical value** (0.6 mmol/min/kg fetal body weight in sheep), **fetal oxygenation begins to fall and is eventually accompanied by fetal hypoglycemia.** The initially mild hypoglycemia results in a blunted fetal pancreatic insulin response that allows gluconeogenesis from hepatic glycogen stores. The minimal hepatic glycogen stores in the fetus are quickly depleted as glucose and lactate are preferentially diverted to the placenta. An increasing nutrient deficit leads to worsening fetal hypoglycemia, which decreases the maintenance of fetal oxidative metabolism and placental nutrition. With a more significant limitation of oxidative metabolism associated with downregulation of placental transport mechanisms and intensifying hypoglycemia, the use of other fetal energy sources becomes necessary, and more widespread metabolic consequences ensue. Limitation of amino acid transfer and breakdown of endogenous muscle protein to obtain gluconeogenic amino acids depletes branched-chain and other essential amino acids.<sup>6</sup> Simultaneously, lactate accumulates because of the limited capacity for oxidative metabolism. Placental transfer of fatty acids loses its selectivity, particularly for essential fatty acids. Reduced utilization leads to increased fetal free fatty acid and triglyceride levels with a subsequent failure to accumulate adipose stores. In this setting of advancing malnutrition, cerebral and cardiac metabolism of lactate and ketones is upregulated to remove these accumulating products of anaerobic metabolism. Acid-base balance can be maintained as long as acid production is met by sufficient buffering capacity of fetal hemoglobin and an equal disposition by the various organs. **Thus metabolic compromise progresses from simple hypoglycemia, hypoxemia, and decreased levels of essential amino acids to overt hypoaminoacidemia, hypercapnia, hypertriglyceridemia, and hyperlactacidemia. The lactate production is exponentially correlated to the degree of acidemia that generally results from this metabolic state.**<sup>7</sup> A summary of metabolic responses is provided in Table 33-1.

**Fetal endocrine manifestations** of placental insufficiency are relevant because they are responsible for the downregulation of growth and developmental processes. Decreases in fetal glucose and amino acids indirectly downregulate insulin and insulin-like growth factors (IGFs) I and II as the principal endocrine regulators of longitudinal growth. Leptin-coordinated deposition of fat stores is similarly affected. In addition, pancreatic cellular dysfunction becomes evident through a decreased insulin/glucose ratio and impaired fetal glucose tolerance. Significant elevations of corticotropin-releasing hormone (CRH), adrenocorticotrophic hormone (ACTH), and cortisol and a decline in active vitamin D and osteocalcin all correlate with the severity of placental dysfunction. **These hormonal imbalances are believed to have additional negative impacts on linear and growth, bone mineralization, and the potential for postpartum catch-up growth.**

In growth-restricted fetuses, declining function at all levels of the thyroid axis correlates to the degree of hypoxemia. Thyroid gland dysfunction may develop as indicated by low levels of thyroxine and triiodothyronine despite elevated thyroid-stimulating hormone (TSH) levels. In other instances, central production of TSH may be responsible for fetal hypothyroidism. Finally, downregulation of thyroid hormone receptors may limit the biologic activity of circulating thyroid hormones in specific target tissues such as the developing brain.<sup>8</sup>

**TABLE 33-1** SUMMARY OF METABOLIC RESPONSES TO PLACENTAL INSUFFICIENCY

| SUBSTRATE                     | CHANGE   |
|-------------------------------|--|
| Glucose                       | Decreased proportional to the degree of fetal hypoxemia  |
| Amino acids                   | Significant decrease in branched-chain amino acids (valine, leucine, isoleucine) as well as lysine and serine; in contrast, hydroxyproline is elevated. The decrease in essential amino acids is proportional to the degree of hypoxemia.<br>Elevated amniotic fluid glycine to valine ratio<br>Elevations in amniotic fluid ammonia with a significant positive correlation with the fetal ponderal index |
| Fatty acids and triglycerides | Decrease in long-chain polyunsaturated fatty acids (docosahexaenoic and arachidonic acids), decrease in overall fatty acid transfer only with significant loss of placental substance<br>Hypertriglyceridemia due to decreased utilization<br>Lower cholesterol esters   |
| Oxygen and carbon dioxide     | Degree of hypoxemia proportional to villous damage; correlates significantly with hypercapnia, acidemia and hypoglycemia, and hyperlactacidemia  |

Elevations in serum glucagon, adrenaline, and noradrenaline and stimulation of the fetal glucocorticoid axis have immediate effects that promote the mobilization of hepatic glycogen stores and peripheral gluconeogenesis. However, persistent alterations of these hormones may have a causative relationship with the development of diabetes and vascular complications in adult life.

**Fetal hematologic responses to placental insufficiency are important because they initially provide a compensatory mechanism for hypoxemia and acidemia but eventually become contributory to the escalation of placental vascular dysfunction.** Fetal hypoxemia is a trigger for erythropoietin release and stimulation of red blood cell (RBC) production through both medullary and extramedullary sites, which results in polycythemia.<sup>9</sup> Oxygen-carrying capacity and the buffering capacity are thus increased through the elevation in hemoglobin count. If extramedullary hematopoiesis is increasingly induced by prolonged tissue hypoxemia and/or acidosis, the nucleated red blood cell (NRBC) count rises owing to the escape of these cells from these sites. **Thus elevated NRBC counts correlate with metabolic and cardiovascular status and are independent markers for poor perinatal outcome.** In advanced placental insufficiency, more complex hematologic abnormalities supervene that may result from dysfunctional erythropoiesis, placental consumption of platelets, and vitamin and iron deficiency. Subsequently, fetal anemia and thrombocytopenia are observed, particularly in fetuses with marked elevation of placental blood flow resistance and evidence of intraplacental thrombosis, which suggests a causative relationship. **Increase in whole blood viscosity, decrease in RBC membrane fluidity, and platelet aggregation may be important precursors in the acceleration of placental vascular occlusion and dysfunction.**<sup>10</sup>

**Growth-restricted fetuses also show evidence of immune dysfunction at the cellular and humoral level.** Decreases in immunoglobulin, absolute B-cell counts, total white blood cell (WBC) counts, and neutrophil, monocyte, and lymphocyte subpopulations—as well as selective suppression of T-helper and cytotoxic T cells—are all related to the degree of acidemia. These immune deficiencies explain the higher susceptibility of growth-restricted neonates to infection after delivery.

**Fetal cardiovascular responses** to placental insufficiency can be subdivided into early and late based on the degree of deterioration of cardiovascular status and the associated derangement of fetal acid-base balance (see below).<sup>11</sup> **Early responses are typically adaptive in nature and result in preferential nutrient streaming to essential organs.** The combination of elevated placental blood flow resistance and impaired transplacental gas transfer has several effects on the fetal circulation. Normally, nutrient-rich oxygenated blood enters the fetus via the umbilical vein and reaches the liver as the first major organ. One of the earliest cardiovascular signs of placental insufficiency is a decrease in the magnitude of umbilical venous flow volume. In response to these changes in umbilical venous nutrition content and blood flow volume, the proportion of umbilical venous blood diverted through the ductus venosus toward the fetal heart increases.<sup>12</sup> This change in venous shunting across the DV increases the proportion of nutrient-rich umbilical venous blood that bypasses the liver and reaches the left side of the heart through the foramen ovale.<sup>13</sup> Because of the presence of central shunts at the level of the foramen ovale and ductus arteriosus, differential changes in downstream blood flow resistance can affect the proportion of cardiac output delivered through each ventricle (Fig. 33-3). Elevation of blood flow resistance in the pulmonary vascular bed and subdiaphragmatic circulation (lower body and placenta) increase right ventricular afterload. A drop in cerebral blood flow resistance decreases left ventricular afterload. As a consequence, **shunting of nutrient-rich blood from the DV through the foramen ovale to the left side of the heart increases, and left ventricular output rises in relation to the right cardiac output.**<sup>14</sup> At the aortic isthmus, blood coming from the right ventricle through the ductus arteriosus is diverted toward the aortic arch, thereby supplementing this central shift in cardiac output from right to left. **This relative shift in cardiac output toward the left ventricle that results in increased blood flow to the myocardium and brachiocephalic circulation has been termed *redistribution*, which indicates a compensatory mechanism in response to placental insufficiency.**

**Late circulatory responses** are associated with deterioration of cardiovascular status and are predominantly observed in early-onset growth delay, which requires delivery prior to 34 weeks.<sup>15</sup> **Redistribution is only effective as long as adequate forward cardiac function is maintained.** Marked elevations in placental blood flow resistance and progressive placental insufficiency can lead to an impairment of cardiac function. When this occurs, several aspects of cardiovascular homeostasis can be affected. **Ineffective preload handling and elevation in central venous pressure may result from ineffective redistribution, a measurable decline in cardiac output, and a decline in cardiac forward function.** The hallmark of this advancing deterioration in cardiovascular state is loss of diastolic forward flow in the umbilical circulation and a marked decline of forward flow in the venous system.<sup>16</sup> **Finally, myocardial dysfunction and cardiac dilatation may result in holosystolic tricuspid insufficiency and spontaneous FHR decelerations, followed by fetal demise.**<sup>17</sup>

Fetal organs also have the ability to regulate their individual blood flow through autoregulation. Such autoregulatory mechanisms have been identified in the myocardium, adrenal glands, spleen, liver, celiac axis, mesenteric vessels, and kidneys. These autoregulatory mechanisms are evoked at different levels of compromise and their effect is

**TABLE 33-2** ARTERIAL AND VENOUS DOPPLER INDICES

| INDEX  | CALCULATION  |
|--|--|
| <b>Arterial Doppler Indices</b>  |  |
| Systolic/diastolic (S/D) ratio   | $\frac{\text{Systolic peak velocity}}{\text{Diastolic peak velocity}}$                               |
| Resistance index (RI)  | $\frac{\text{Systolic} - \text{End-diastolic peak velocity}}{\text{Systolic peak velocity}}$         |
| Pulsatility index (PI)   | $\frac{\text{Systolic} - \text{End-diastolic peak velocity}}{\text{Time averaged maximum velocity}}$ |
| <b>Venous Doppler Indices</b>  |  |
| Inferior vena cava preload index   | $\frac{\text{Peak velocity during atrial contraction}}{\text{Systolic peak velocity}}$               |
| Ductus venosus preload index   | $\frac{\text{Systolic} - \text{Diastolic peak velocity}}{\text{Systolic peak velocity}}$             |
| Inferior vena cava and ductus venosus pulsatility index for veins (PIV)    | $\frac{\text{Systolic} - \text{Diastolic peak velocity}}{\text{Time averaged maximum velocity}}$     |
| Inferior vena cava and ductus venosus peak velocity index for veins (PVIV) | $\frac{\text{Systolic} - \text{Atrial contraction peak velocity}}{\text{Diastolic peak velocity}}$   |
| Percentage reverse flow  | $\frac{\text{Systolic time averaged velocity}}{\text{Diastolic time averaged velocity}} \times 100$  |

typically complementary to central blood flow redistribution by enhancing perfusion of vital organs as long as cardiovascular homeostasis is maintained. A summary of Doppler findings and their physiologic significance in the context of placental insufficiency is provided in Table 33-2.

**Fetal behavioral responses to placental insufficiency and characteristics of the FHR** reflect developmental status and undergo significant changes with advancing gestation. Progressive sophistication of fetal behavior and increasing variation of the FHR reflect differentiation of central regulatory centers and expansion of central processing capability. **Normally, behavioral milestones progress from the initiation of gross body movements and fetal breathing in the first trimester to coupling of fetal behavior (e.g., heart rate reactivity) and integration of rest-activity cycles into stable behavioral states (states 1 through 4 F) by 28 to 32 weeks' gestation (see Chapter 11).** A steady decrease in baseline heart rate that reflects increasing vagal tone accompanies these developments. In addition, short- and long-term variability and variation, as well as the amplitude of accelerations, increase with advancing gestation, which reflects increased central processing. **With the completion of these milestones, heart rate reactivity by traditional criteria is present in 80% of fetuses by 32 weeks' gestation.** Differences in maturational state and behavioral state, disruption of neural pathways, and declining oxygen tension may all modulate or even abolish fetal behavior or heart rate characteristics.

Because variations of fetal behavior and the FHR may be due to several factors, observation of several variables over a sufficient length of time is necessary to separate physiologic from pathologic variation. Biophysical profile (BPP) scoring quantifies fetal behavior by assessing tone, movement, breathing activity, and

**FIG 33-3** Schematic presentation of the fetal circulation. This figure illustrates the serial partitioning of nutrient- and oxygen-rich blood reaching the fetus via the umbilical vein. The first partition at the level of the ductus venosus distributes the majority of umbilical venous blood to the liver. Umbilical venous blood that continues toward the heart is partitioned toward the left ventricle (LV) at the foramen ovale. This blood supplies the brain and upper part of the body via the brachiocephalic circulation and the myocardium via the coronary circulation. A minor proportion of blood from the right ventricle (RV) supplies the lungs, and the remainder continues through the ductus arteriosus toward the aorta. At the aortic isthmus bloodstreams coming from the aorta are partitioned based on the relationship of blood flow resistance in the brachiocephalic and subdiaphragmatic circulations. Whereas net forward flow is maintained under physiologic conditions, diastolic flow reversal occurs when brachiocephalic resistance falls and/or subdiaphragmatic (placental) resistance rises. Finally, the major proportion of descending aortic blood is partitioned at the umbilical arteries to return to the placenta for respiratory and nutrient exchange. LA, left atrium; RA, right atrium. (From Baschat AA. The fetal circulation and essential organs—a new twist to an old tale. *Ultrasound Obstet Gynecol.* 2006;27:349.)

FHR reactivity in an observation period of at least 30 minutes (see [Chapter 11](#)). Amniotic fluid volume (AFV) assessment has traditionally been a part of the BPP. From the second trimester onward, AFV is primarily related to fetal urine production and therefore renal perfusion (see [Chapter 35](#)). **Thus AFV assessment provides an indirect assessment of renal/vascular status and constitutes the main longitudinal monitoring**

**component of the BPP** (see below). **Visual FHR analysis is associated with interobserver and intraobserver variability.** These are circumvented by computerized cardiotocography (cCTG) analysis of the fetal heart rate. The cCTG assesses short-term, long-term, and mean minute variation and periods of high variation in addition to traditional FHR parameters that also allow longitudinal observations.

**In growth-restricted fetuses with chronic hypoxemia and mild placental dysfunction, the primary CNS response is a delay in all aspects of CNS maturation.**<sup>18</sup> With the help of computerized research tools, a delay in behavioral development has been documented under such circumstances. The combination of delayed central integration of FHR control, decreased fetal activity, and chronic hypoxemia results in a higher baseline heart rate with lower short- and long-term variation (on computerized analysis) and delayed development of heart rate reactivity.<sup>19</sup> These maturational differences in FHR parameters are particularly evident between 28 and 32 weeks.

Despite the maturational delay of some aspects of CNS function, several centrally regulated responses to acid-base status are still preserved. Therefore the growth-restricted fetus still maintains behavioral responses to a decline in acid-base status independently of the cardiovascular status. **In contrast, the declining AFV that commonly accompanies the sequential loss of biophysical variables appears to be related to renal blood flow and the degree of vascular redistribution.**<sup>20</sup>

With worsening fetal hypoxemia, a decline in global fetal activity initiates the cascade of late behavioral responses characteristic of placental insufficiency.<sup>21</sup> With further deepening hypoxemia, fetal breathing movement ceases.

Gross body movements and tone decrease further until they are no longer observed in the traditional examination period.<sup>22,23</sup> **Traditional FHR variables are frequently abnormal by this time. Reduction of global fetal activity and loss of fetal coupling** (absence of heart rate reactivity and fetal breathing movements) **are typically observed at a mean pH between 7.10 and 7.20.** Loss of tone and movement is characteristic as the pH drops further. Late decelerations of the FHR may develop because of a relative drop in oxygen tension that exceeds 8 torr (see Chapter 15). Spontaneous decelerations as a result of direct depression of cardiac contractility or “cardiac” late decelerations typically herald fetal demise.

## DIAGNOSTIC TOOLS IN FETAL GROWTH RESTRICTION

**Fetal growth restriction is a syndrome marked by failure of the fetus to reach its growth potential with consequences related to the underlying disorder as well as the severity of fetal disease.** Because IUGR may be the consequence of many underlying etiologies, the differential diagnosis always includes maternal disease, placental insufficiency, aneuploidy, nonaneuploid syndromes, and viral infection. For appropriate patient counseling and choice of management options, comprehensive prenatal evaluation must go beyond the assessment of fetal size, utilizing a diagnostic approach aimed at identifying the underlying causes. **After confirming small fetal size, stratification into three patient groups is of particular importance. The first group consists of constitutionally small but otherwise normal fetuses.** These will not usually require any intervention and therefore do not need antenatal surveillance. **The second group consists of fetuses with aneuploidy, nonaneuploid syndromes, or viral infection.** In these conditions, prognosis is largely determined by the underlying disease, with little potential for impact by perinatal interventions. Sensitive and knowledgeable counseling of the parents about the likely prognosis in these conditions is especially important in such cases. **The third group consists of fetuses with placental disease in which progressive deterioration of the fetal condition worsens the**

**prognosis.** This subset of patients is most likely to benefit from fetal surveillance and subsequent intervention. Although gray-scale ultrasonography provides important clues to the presence of IUGR, the liability of preterm delivery and iatrogenic complications is great if the diagnosis is based solely on biometry. Although maternal disease is readily apparent through a history and physical examination, the accurate evaluation of a possible fetal disorder and stratification of risk requires the integration of several diagnostic modalities that evaluate fetal, placental, and amniotic fluid characteristics.<sup>24-26</sup>

## Fetal Biometry

Ultrasound criteria have emerged as the diagnostic standard used in the identification of FGR. For this purpose, sonographic measurements of fetal bony and soft structures are related to reference ranges for gestation. The primary measurements utilized to evaluate fetal growth include those of the fetal head, abdominal circumference, and long bones. The most important calculated ultrasound variable of fetal growth is the sonographically estimated fetal weight (SEFW), and numerous investigators have identified distinct fetal ultrasound parameters that are useful in the calculation of the SEFW.<sup>27</sup> All of the techniques incorporate an index of abdominal size as a variable contributing to the estimation of fetal weight. **Population-specific formulae have been derived to generate reference limits that generally have 95% confidence limits that deviate approximately 15% around the actual value.**

Accurate estimation of fetal growth from these fetal measurements requires knowledge of the gestational age as a reference point to calculate percentile ranks. **An estimated date of confinement (EDC) should be based on the last menstrual period when the sonographic estimate of gestational age is within the predictive error** (7 days in the first, 14 days in the second, and 21 days in the third trimester). **Once the EDC is set by this method or by a first-trimester ultrasound, it should not be changed because such practice interferes with the ability to diagnose IUGR.**

**Measurement of the biparietal diameter (BPD) alone is a poor tool for the detection of IUGR.** The physiologic variation in size inherent with advancing gestation is high. The majority of growth-restricted fetuses who present with asymmetric growth restriction and delayed flattening of the cranial growth curve would be detected relatively late. Factors that interfere with a technically adequate measurement of the BPD include alterations of the cranial shape by external forces (oligohydramnios, breech presentation) and direct anteroposterior position of the fetal head.

The head circumference (HC) is not subject to the same extrinsic variability as the BPD. The measurement technique is important because calculated HC measurements are systematically smaller than those directly measured, thus the nomogram selected should be based on measurements obtained using the same methodology. As a screening tool for IUGR, the HC poses a similar problem as the BPD in that two thirds of IUGR fetuses with asymmetric growth pattern would be detected late.

The transcerebellar diameter (TCD) is one of the few soft tissue measurements that correlate well with gestational age, being relatively spared from the effects of mild to moderate uteroplacental dysfunction.<sup>28</sup> Whether its measurement offers any advantage over bony measurements in the assessment of compromised fetal growth is controversial.

**FIG 33-4** Growth chart in a case of asymmetric intrauterine growth restriction (IUGR). Although head circumference is preserved, abdominal circumference growth falls off early in the third trimester. For this reason, the head/abdomen (H/A) ratio shown in the lower right corner of the graph becomes elevated. SD, standard deviation. (From Chudleigh P, Pearce JM. *Obstetric Ultrasound*. Edinburgh: Churchill Livingstone; 1986.)

**FIG 33-5** Growth chart in a case of symmetric intrauterine growth restriction (IUGR). Note the early onset of both head circumference and abdominal circumference growth restriction. For this reason, the head/abdomen (H/A) ratio shown in the lower right corner remains normal. SD, standard deviation. (From Chudleigh P, Pearce JM. *Obstetric Ultrasound*. Edinburgh: Churchill Livingstone; 1986.)

The AC is the single best measurement for the detection of IUGR.<sup>29</sup> The most accurate AC is the smallest directly measured circumference obtained in a perpendicular plane of the upper abdomen at the level of the hepatic vein between fetal respirations. The AC percentile has both the highest sensitivity and negative predictive value for the sonographic diagnosis of IUGR whether defined postnatally by birthweight percentile or ponderal index. **Using the 10th percentiles as cutoffs, the AC has a higher sensitivity (98% vs. 85%) but lower positive predictive value (PPV) than the SEFW (36% vs. 51%). Its sensitivity is further enhanced by serial measurements at least 14 days apart.**<sup>30</sup> Because of its high sensitivity, some type of abdominal measurement should be part of every sonographic growth evaluation. However, because the AC reflects fetal nutrition, it should be excluded from the calculation of the composite gestational age after the early second trimester.

Calculation of the ratio between the head and abdominal circumference (HC/AC ratio) has been proposed as a tool to increase detection of the fetus with asymmetric growth restriction (Figs. 33-4 and 33-5). In the normally growing fetus, the HC/AC ratio exceeds 1.0 before 32 weeks' gestation, is approximately 1.0 at 32 to 34 weeks' gestation, and falls below 1.0 after 34 weeks' gestation. In fetuses with asymmetric growth restriction, the HC remains larger than that of the body and results in an elevated HC/AC ratio,<sup>31</sup> whereas the ratio remains normal in symmetric IUGR, in which both direct measurements are equally affected (see Figs. 33-4 and 33-5). Using the HC/AC

ratio, 70% to 85% of growth-restricted fetuses are detected, with a reduction in false-negative diagnoses. Thus even when determined in the latter part of pregnancy, a single set of measurements can be very helpful in evaluating the status of fetal growth. **However, both the sensitivity and the PPV of the HC/AC ratio for growth restriction does not equal either the AC percentile or the SEFW.**<sup>32</sup>

When measurement of the HC is difficult because of fetal position, comparisons can be made of the femur length (FL)—which is relatively spared in asymmetric IUGR—to the AC. **The FL/AC ratio is 22 at all gestational ages from 21 weeks to term; therefore this ratio can be applied without knowledge of the gestational age. An FL/AC ratio greater than 23.5 suggests IUGR.**

Several formulae have been devised to calculate the SEFW. Using a multifactorial equation and a measurement of abdominal size, a weight can be predicted and related to gestational age. Formulae that incorporate the FL may increase the accuracy of in utero weight estimation for the fetus with IUGR. Because the SEFW cannot be measured directly but is calculated from a combination of directly measured parameters, the error in the estimate is increased. **The accuracy of most formulae ( $\pm 2$  standard deviations [SDs]) is  $\pm 10\%$ , and none has proven superior to the first devised by Warsof and reported by Sheppard.** As noted earlier, the SEFW has a lower sensitivity but higher PPV than the AC and does not add to the AC percentile for the diagnosis of IUGR. However, an SEFW below the 10th

percentile provides a graphic image that makes it easy for both patient and referring physician to conceptualize. **Therefore use of the estimated fetal weight (EFW) has become the most common method for characterizing fetal size and thereby growth abnormalities.**

### Reference Ranges That Define Fetal Growth

An absolute threshold to define IUGR can be applied to any of the fetal biometric parameters. These criteria have been statistically defined, rather than outcome based, and use either a threshold percentile ranking (nonnormative data) or a number of standard deviations below the mean (normative data) as cutoffs. **Small for gestational age is defined as a birthweight below the population 10th percentile corrected for gestational age. However, this cutoff has also been the most widely used criterion for defining growth restriction at birth.** This definition has also been adopted for the prenatal period by using an SEFW below the 10th percentile as an indicator of IUGR. Because such an approach is purely based on a weight threshold, it can only serve as a screen for the identification of the small fetus at risk for adverse outcomes. **Approximately 70% of infants with a birthweight below the 10th percentile are normally grown (i.e., constitutionally small) and are not at risk for adverse outcomes because they present one end of the normal spectrum for neonatal size.**<sup>33</sup> **The remaining 30% consist of infants who are truly growth restricted and are at risk for increased perinatal morbidity and mortality.** When the cutoff for an abnormal birthweight is adjusted to the 3rd percentile, the proportion of true growth-restricted infants identified increases, whereas some with milder forms of IUGR will be missed. The principal advantage of a lower percentile cutoff is the identification of fetuses at greatest need for antenatal surveillance. This is further emphasized by the increased mortality for birthweights through the 15th percentile with an odds ratio of 1.9 for mortality in newborns with birthweights between the 10th and 15th percentiles. Because the percentile cutoffs to define abnormal growth continue to be a matter of debate, risk assessment based on weight alone is further hampered by discrepancies between the SEFW and the actual birthweight. Live birthweight criteria do not appropriately describe SEFWs, and **a significant association of preterm birth with FGR is apparent.**<sup>34</sup> The weights of preterm infants are not normally distributed as they are at term, which produces a significant discrepancy between birthweight-defined growth curves and SEFW-defined growth curves in preterm gestation.<sup>35</sup> **SEFW growth curves are generated from patient samples that represent the entire obstetric population at any gestational age. In contrast, preterm live birth normative data tables reflect only those individuals who have delivered under abnormal circumstances.** Thus the SEFW growth curves consistently demonstrate higher fetal weights over the range of preterm gestation than do birthweight-generated growth curves. **Therefore use of an SEFW cutoff below the 10th percentile is more appropriate to define abnormal fetal growth because the ability to identify fetuses at greater perinatal risk is increased.**<sup>36</sup> For the AC, a cutoff of the 2.5 percentile is appropriate because reference ranges are based on a cross section of small, appropriately grown preterm and term newborns. However, because reference limits are based on healthy women delivering appropriately nourished neonates at term, less than the 10th percentile cutoff is consistent with IUGR.

Because of the limitation of population-based reference ranges to assess fetal growth, **individualized growth models have been proposed by several investigators.**<sup>1,37</sup> The obvious advantage is the lack of dependency on population-based normative data and the ability to detect a true, singularly defined growth restriction even with EFWs above the 10th percentile for the population. Some of these models require three sequential sonograms. This includes baseline biometry in the second trimester, a second sonogram to establish growth potential for an individual morphometric parameter, and a third scan to identify a growth abnormality. Because this approach is cumbersome in clinical practice, other models have been developed that account for variables that contribute the majority of the variance to newborn size. These include early pregnancy weight, maternal height, ethnic group, parity, and sex.<sup>1</sup> Using these variables and fetal growth patterns, the estimated size of a fetus of a given mother can be projected at term and estimated at any specific point in gestation. Deviations from this projected growth pattern can then be recognized. Overall, the diagnostic advantages of these individualized growth models has been questioned when compared with the sequential comparison of the percentile ranking of individual or composite growth parameters to population-based growth curves.

Fetal growth, as opposed to fetal size, is a dynamic process that requires more than a single evaluation for its estimation. The appropriate observation interval for the evaluation of fetal growth has been based on the assumptions that growth is continuous, rather than sporadic, and that the identification of growth is limited by the technical capability of the ultrasound equipment used to measure the fetus. **The recommended interval between ultrasound evaluations of fetal growth is 3 weeks because shorter intervals increase the likelihood of a false-positive diagnosis.**

**In summary, the ability to correctly identify growth-restricted fetuses at risk for adverse outcome by weight estimates alone is limited. Individualized or sequential growth assessment performs better than a single measurement of fetal size. Improved stratification of risk requires the integration of additional diagnostic tests.**

### Fetal Anatomic Survey

The sonographic survey of fetal anatomy may provide a clue to the underlying etiology of IUGR. The anatomic survey should focus on markers of aneuploidy, nonaneuploid syndromes, and fetal infection as well as structural malformations. The relationship between aneuploidy and fetal anomalies such as omphalocele, diaphragmatic hernia, congenital heart defects, and sonographic markers such as echogenic bowel, nuchal thickening, and abnormal hand positioning are discussed in [Chapter 9](#). Abnormalities of skull contour, thoracic shape, or disproportional shortening of the long bones may be suggestive of a skeletal dysplasia. Markers for viral infection may be nonspecific but include echogenicity and calcification in organs such as the brain and liver.<sup>38</sup> Identification of any of these abnormalities on ultrasound may help to establish a differential diagnosis and can impact the prognosis.

### Amniotic Fluid Assessment

From the second trimester onward, regulation of AFV is primarily dependent on fetal urine output, production of pulmonary fluid, and fetal swallowing (see [Chapter 35](#)). **Placental dysfunction and fetal hypoxemia both may result in decreased**

**perfusion of the fetal kidneys with subsequent oliguria and decreasing AFV.**<sup>39</sup> Although the accuracy of ultrasound in the assessment of actual AFV is poor, two techniques are used that can provide important diagnostic and prognostic information.<sup>40</sup> A vertical pocket of amniotic fluid measuring 1 cm or more was historically considered indicative of an adequate fluid volume. Criteria for AFV assessment were subsequently broadened. A 2-cm vertical pocket was considered *normal*, 1 to 2 cm was *marginal*, and less than 1 cm was *decreased*. Alternatively, AFV may be assessed by the sum of vertical pockets from the four quadrants of the uterine cavity. This four-quadrant amniotic fluid index (AFI) nomogram (see Fig. 33-3) is compared with gestational reference ranges. **Despite the availability of these numerical methods for estimating the AFV, an overall clinical impression of reduced amniotic fluid may be most important.** Ultrasound criteria for a subjectively reduced AFV include a maximum vertical pocket less than 3 cm, the fetus in a flexion attitude with limited room for movement, a small or empty bladder and stomach, and molding of the uterus around the fetal body. In addition, movement of the transducer frequently generates uterine contractions, which may be associated with variable decelerations.

Overall, estimation of AFV in itself is a poor screening method for IUGR or fetal acidemia. However, in clinical practice, it is an important diagnostic and prognostic tool. Oligohydramnios may be the first sign of FGR detected on ultrasonography preceding an assessment for lagging fetal growth. If gestational age is known, ultrasound assessment of fetal growth based on the HC, AC, FL, and SEFW can be performed. **If gestational age is unknown, measurements of the FL/AC ratio and a single amniotic fluid pocket have to be used because they are independent of gestational age. Up to 96% of fetuses with fluid pockets less than 1 cm may be growth restricted.**<sup>41</sup> When growth delay is already suspected, assessments of AFV can help with a differential diagnosis. In the setting of small fetal size, abundant AFV suggests aneuploidy or fetal infection, whereas normal or decreased amniotic fluid is compatible with placental insufficiency. **The volume of amniotic fluid also has prognostic significance for the course of labor.** Groome and colleagues<sup>42</sup> demonstrated that oligohydramnios associated with fetal oliguria is associated with a higher rate of intra-partum complications that may be attributed to reduced placental reserve.

### Doppler Velocimetry

Similar to the assessment of AFV, the role of Doppler velocimetry in the management of FGR is unique because it serves as a diagnostic, as well as a monitoring, tool. Doppler flow-velocity waveforms may be obtained from arterial and venous vascular beds in the fetus. **Arterial Doppler waveforms provide information on downstream vascular resistance, which may be altered because of structural changes in the vasculature or regulatory changes in vascular tone. The systolic/diastolic (S/D) ratio, the resistance index (RI), and the pulsatility index (PI) are the three Doppler indices most widely used to analyze arterial blood flow resistance** (see Table 33-2). An increase in blood flow resistance manifests with a relative decrease in end-diastolic velocity that results in an increase in all three Doppler indices. Of these, the pulsatility index has the smallest measurement error and narrower reference limits. With extreme increases in blood flow resistance, end-diastolic forward flow velocity may be absent or reversed, referred

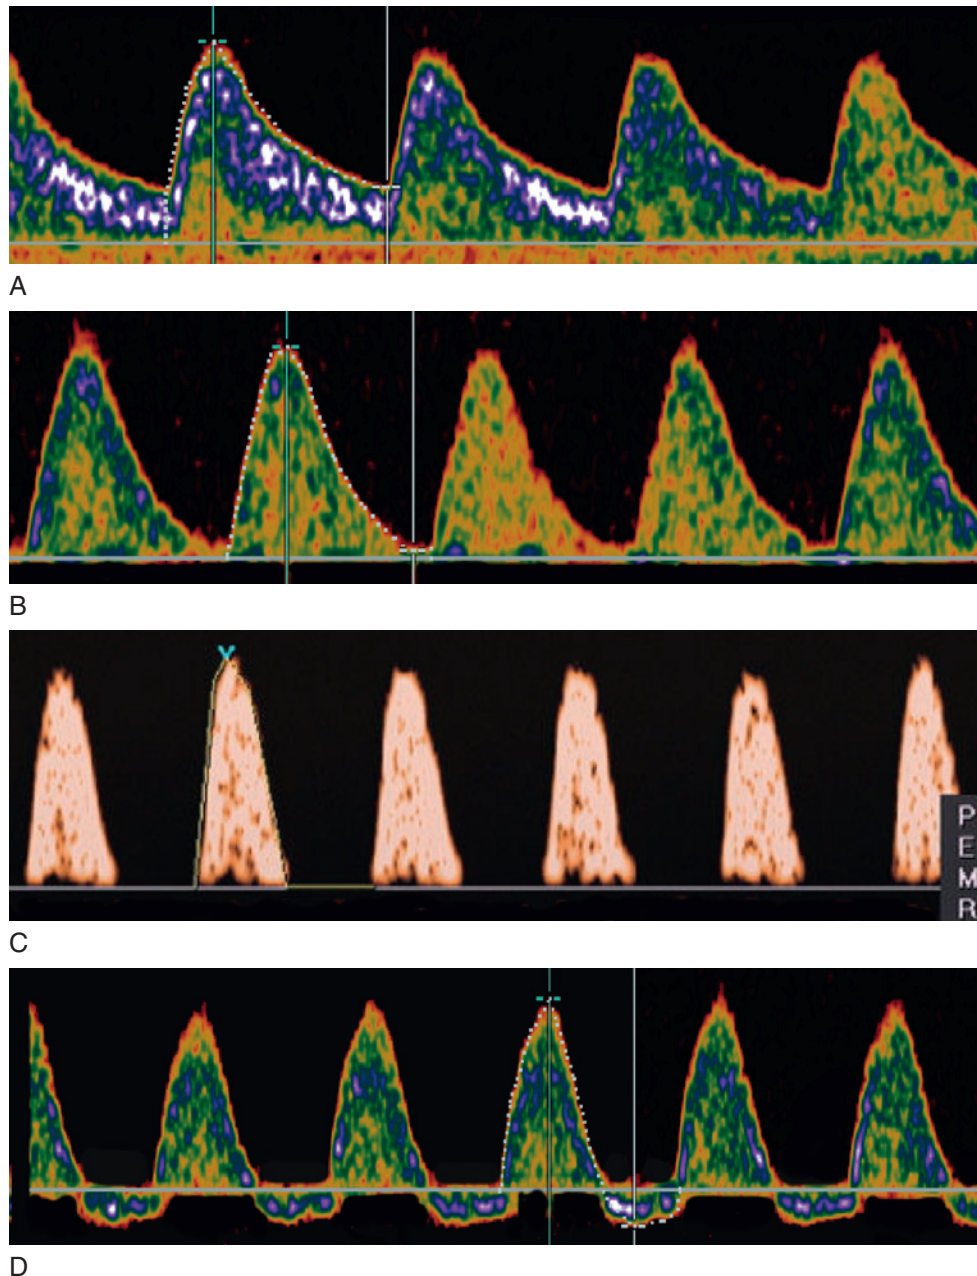

to as *absent end-diastolic velocity* (AEDV) or *reversed end-diastolic velocity* (REDV; Fig. 33-6).

**Venous Doppler parameters complement evaluation of fetal cardiovascular status by providing an assessment of cardiac forward function.** Forward blood flow in the venous system is determined by cardiac compliance, contractility, and afterload and is characterized by a triphasic flow pattern that reflects pressure volume changes in the atria throughout the cardiac cycle.<sup>43</sup> The descent of the AV ring during ventricular systole and passive diastolic ventricular filling generates the systolic and diastolic peaks respectively (the S-wave and the D-wave). The sudden increase in right atrial pressure with atrial contraction in late diastole causes a variable amount of reverse flow that produces a second trough after the D-wave (the a-wave; Fig. 33-7). The magnitude of forward flow during the atrial systole varies considerably in individual veins, and reversal may be physiologic in the inferior vena cava and hepatic veins but is always abnormal in the ductus venosus. **Multiple venous Doppler indices have been described to characterize this complex waveform without any clear advantages of individual indices** (see Table 33-2).

**The vessels that are of primary importance in the differential diagnosis of placental dysfunction are the umbilical artery (UA) and the middle cerebral artery (MCA). Randomized trials and meta-analyses confirm that the combined use of fetal biometry and UA Doppler significantly reduces perinatal mortality and iatrogenic intervention because documentation of placental vascular insufficiency effectively separates growth-restricted fetuses that require surveillance and possible intervention from constitutionally small fetuses.**<sup>44,45</sup>

A free umbilical cord loop is examined with continuous or pulsed Doppler ultrasound far from the fetal and placental insertions. Most current ultrasound equipment allows concurrent use of color and pulsed Doppler with improved reproducibility of measurements. **Vascular damage that affects approximately 30% of the placenta produces elevations in the Doppler index.** More marked abnormalities result in umbilical artery AEDV or REDV. **Milder forms of placental vascular dysfunction, especially near term, may not produce elevation of UA blood flow resistance sufficient to be detectable by traditional Doppler methods.**<sup>46</sup> If placental gas exchange is significantly impaired, resulting in fetal hypoxemia, a decrease in MCA Doppler resistance may occur (Fig. 33-8). Another Doppler index frequently used clinically to detect this condition is the ratio between UA pulsatility as an index of vasoconstriction in the placenta and MCA pulsatility as an index of vasodilation in the fetal brain. In milder forms of placental disease with near minimal increase in UA blood flow resistance, the cerebroplacental Doppler ratio (CPR) may decrease. Grammellini and coworkers demonstrated that a value below 1.08 identified small fetuses at risk for adverse outcome. **Subsequently, Bahado-Singh and coworkers<sup>47</sup> indicated that the predictive accuracy of the CPR decreased after 34 weeks' gestation. This is presumably attributable to an increasing number of growth-restricted fetuses who may have normal UA blood flow resistance near term but demonstrate isolated "brain sparing" as the only sign of placental insufficiency of oxygen transfer. These fetuses are at risk for adverse outcomes.**

Because of the variable presentation of IUGR across gestation, comprehensive Doppler assessment of placental function should include the umbilical and middle cerebral arteries. For the UA,

**FIG 33-6** Umbilical artery flow-velocity waveforms. **A**, The normal umbilical artery flow-velocity waveform has positive end-diastolic velocities that increase toward term, reflecting a falling blood flow resistance in the villous vascular tree. **B**, Moderate abnormalities in the villous vascular structure raise the blood flow resistance and are associated with a decline in end-diastolic velocities. When a significant proportion of the villous vascular tree is abnormal, end-diastolic velocities may be absent (**C**) or even reversed (**D**).

an abnormal test result is defined as a Doppler index measurement of greater than 2 SDs above the gestational age mean and/or a loss of end-diastolic velocity. As with growth curves, it is best to use nomograms developed from a local or comparable population. For the CPR and also for the MCA, a greater than 2-SD decrease of the index is considered abnormal. In a setting of small fetal size, these findings identify those fetuses at greatest risk for adverse outcome (Figs. 33-9 to 33-12).

### Invasive Testing

Several invasive tests for the evaluation of the fetus with suspected growth restriction have been described. From a clinical

standpoint, only a few studies are of critical importance. These include maternal toxoplasmosis, other infections, rubella, CMV, and herpes infection (TORCH) serology and invasive fetal testing to obtain amniotic fluid and/or fetal blood for karyotyping or microarray analysis to rule out a chromosomal abnormality such as trisomies 13, 18, or 21 or a submicroscopic deletion or duplication (Table 33-3). Trisomy 18 may present with the unusual combination of growth restriction and polyhydramnios (see Chapter 10). If the diagnosis of a lethal anomaly can be made with certainty, cesarean delivery for fetal distress is unnecessary and may be prevented. Viral polymerase chain reaction (PCR) studies can be performed if clinical

**FIG 33-7** Venous flow-velocity waveform. A typical venous flow-velocity waveform is shown. The triphasic waveform (systole [S], diastole [D], atrial contraction [a]) reflects volume flow changes during the cardiac cycle. With descent of the atrioventricular valves during ventricular systole, intraatrial pressures fall, and increased forward flow during the S-wave is observed. A temporary decrease in forward flow occurs when the atrioventricular valve ring ascends at the end of ventricular systole, producing the first trough in the flow-velocity waveform. When atrial pressures exceed intraventricular pressures, the atrioventricular valves open, resulting in the rapid influx of blood into the ventricles. The associated increase in venous flow results in the D-wave. With initiation of a new cardiac cycle, atrial contraction results in a sharp rise in intraatrial pressure and a decline in venous forward flow. This second trough is called the *a*-wave because it is produced by atrial contraction.

suspicion is based on the ultrasound examination or the maternal history.

In summary, ultrasound examination is the primary diagnostic tool for the evaluation of fetal growth. In the presence of risk factors and clinical conditions associated with IUGR, a comprehensive gray-scale ultrasound examination of fetal anatomy along with biometry and an assessment of amniotic fluid characteristics is required. In the absence of routine clinical indications, ultrasound screening of these high-risk pregnancies should be performed in the first or early second trimester for dating and again at 32 to 34 weeks. If small fetal size is documented, Doppler ultrasound of the umbilical and middle cerebral arteries and invasive tests when indicated are of critical importance to identify fetuses most likely to benefit from antenatal surveillance and perinatal interventions. A diagnostic algorithm that utilizes this combination of test parameters is depicted in Figure 33-13.<sup>48</sup>

## SCREENING AND PREVENTION OF FETAL GROWTH RESTRICTION

Fetal growth restriction as a disease entity fulfills several criteria that potentially justify a screening program. It is a common clinical problem with an identifiable predisease state that leaves enough time for potential interventions. Although treatment options in utero are limited (see below), interventions that improve outcome exist. The various screening methods that have been proposed include identification of risk factors in addition to serum and ultrasound tests.

**FIG 33-8** Middle cerebral artery flow-velocity waveform. **A**, The normal middle cerebral artery flow pattern has relatively little diastolic flow. With progressive placental dysfunction, an increase in the diastolic velocity results in a decrease in the Doppler index (brain sparing). **B**, With brain sparing, the systolic downslope of the waveform becomes smoother so that the waveform almost resembles that of the umbilical artery. The associated rise in the mean velocity results in a marked decline in the Doppler index.

**FIG 33-9** Umbilical artery (UA) pulsatility index with advancing gestational age. Displayed are the reference ranges (mean and 95% confidence interval).

**FIG 33-12** Ductus venosus (DV) pulsatility index for veins with advancing gestational age. This graph displays the gestational reference range (mean and 95% confidence interval) of the ductus venosus pulsatility index for veins calculated from cross-sectional data in 232 normal singleton fetuses.

**FIG 33-10** Middle cerebral artery (MCA) pulsatility index with advancing gestational age. The graph shows the mean and 95% confidence intervals.

**FIG 33-11** Cerebroplacental Doppler ratio with advancing gestational age. This graph displays the gestational reference range (mean and 95% confidence interval) of the cerebroplacental ratio based on paired measurements of the middle cerebral and umbilical artery pulsatility indices.

**TABLE 33-3** CHROMOSOMAL ABNORMALITIES AND INTRAUTERINE GROWTH RESTRICTION

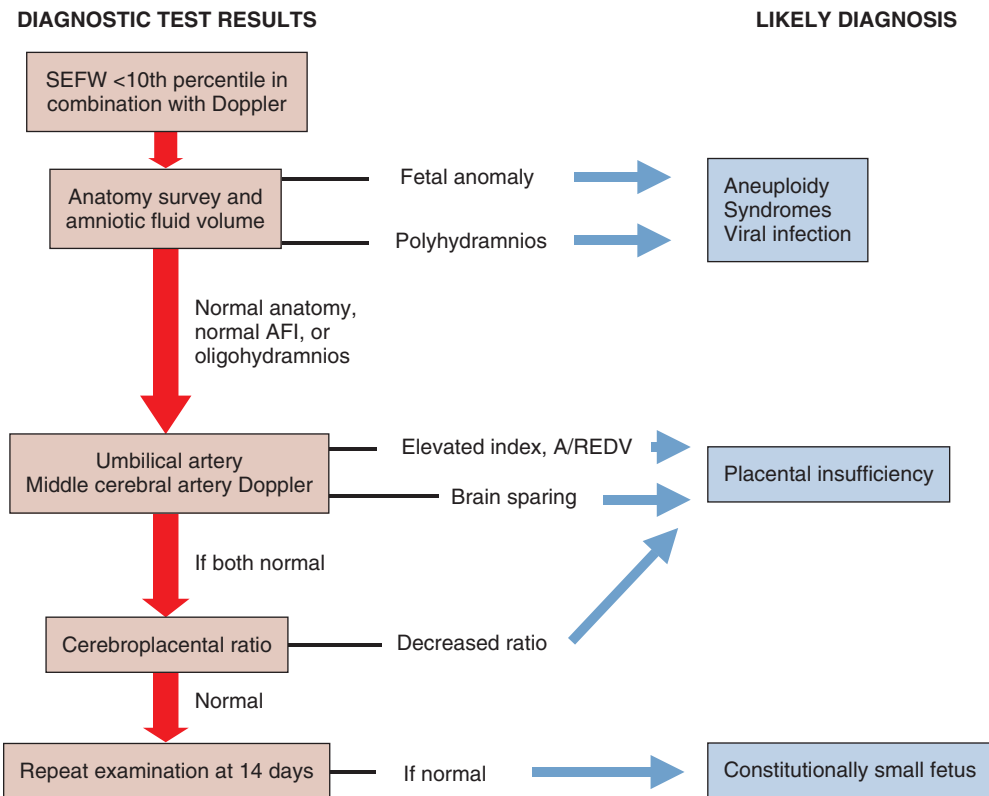

| ULTRASOUND FINDINGS PRESENT |         |            | ABNORMAL KARYOTYPE |
|-----------------------------|---------|------------|--------------------|
| IUGR                        | ANOMALY | HYDRAMNIOS |                    |
| X                           |         |            | 12/180 (7%)        |
| X                           | X       |            | 18/57 (32%)        |
| X                           |         | X          | 6/22 (27%)         |
| X                           | X       | X          | 7/15 (47%)         |

IUGR, intrauterine growth restriction.

## Maternal History

A history of poor pregnancy outcome is clearly correlated with the subsequent delivery of a growth-restricted infant. **A prior birth of a growth-restricted infant is the obstetric factor most often associated with the subsequent birth of a growth-restricted infant.** These study populations did include women with underlying medical problems. A retrospective study of 83 multigravidas who had delivered growth-restricted infants noted that the perinatal wastage from their 200 prior pregnancies was 41%. This striking figure, which includes spontaneous abortions as well as neonatal and intrauterine deaths, points to the significance of poor obstetric history as a risk factor for IUGR. **The history of delivery of a growth-restricted infant in the first pregnancy is associated with a 25% risk of delivering a second infant below the 10th percentile.** After two pregnancies complicated by IUGR, the risk is increased fourfold for birth of a subsequent growth-restricted infant. When all indices of risk have been applied, the one third of patients considered at highest risk for delivering a growth-restricted infant actually deliver over 60% of infants identified as growth restricted. The two thirds of women not considered at risk for delivering a growth-restricted infant contribute to one third of deliveries with a birthweight below the 10th percentile. The majority of these babies are considered constitutionally small.

**FIG 33-13** An integrated diagnostic approach to the fetus with suspected fetal growth restriction. This figure displays a decision tree following the evaluation of fetal anatomy, amniotic fluid volume, and umbilical and middle cerebral artery Doppler. The most likely clinical diagnosis based on the test results is presented on the right-hand side. A high index of suspicion for aneuploidy and viral and nonaneuploid syndromes needs to be maintained at all times. AFI, amniotic fluid index; A/REDV, absent/reversed end-diastolic flow; SEFW, sonographically estimated fetal weight. (Data from Unterscheider J, Daly S, Geary MP, et al. Optimizing the definition of intrauterine growth restriction: the multicenter prospective PORTO Study. *Am J Obstet Gynecol.* 2013;208:290.e1-e6.)

### Maternal Serum Analytes

At least four hormone/protein markers measured in the maternal sera during the early second trimester are associated with subsequent IUGR. These include serum estriol, human placental lactogen (hPL), human chorionic gonadotrophin (hCG), and alpha-fetoprotein (AFP). Elevated maternal serum alpha-fetoprotein (MSAFP) and elevated hCG levels in the second trimester are considered markers of abnormal placentation and have been associated with an increased risk for IUGR.<sup>49</sup> Most studies conclude that a **single, unexplained elevated value of 2 to 2.5 multiples of the median (MoM) raises the risk of growth restriction fivefold to tenfold.**

Several first-trimester serum analytes associated with early abnormalities in placenta angiogenesis and development have been identified. These show significant differences in their distribution among pregnancies at risk of developing early-onset preeclampsia or FGR prior to 34 weeks' gestation. Of these markers, **a decrease in the pregnancy-associated plasma protein A (PAPP-A) or the placental growth factor (PIGF) have shown the most consistent predictive performance.** The advantage of PAPP-A is the current commercial availability as part of the first-trimester screen for aneuploidy. In this setting, a decrease in the PAPP-A below 0.8 MoM is associated with an increased risk for subsequent placental dysfunction.

### Clinical Examination

From the early second trimester on, each antenatal visit includes the measurement of the distance between the maternal uterine

fundus and the symphysis pubis. **After 20 weeks' gestation, the normal symphyseal-fundal height in centimeters approximates the weeks' gestation after allowances for maternal height and fetal station. After 20 weeks' gestation, a lag of the symphyseal-fundal height of 4 cm or more suggests growth restriction.** The reported sensitivities of symphyseal fundal height screening for IUGR range from 27% to 85%, and the PPVs range from 18% to 50%. Although the measurement of the symphyseal fundal height is a poor screening tool for the detection of IUGR, **the accuracy of subsequent ultrasound prediction of IUGR is enhanced if clinical suspicion of IUGR is based on a lagging fundal height.**

### Maternal Doppler Velocimetry

**Abnormal uterine artery flow-velocity waveforms are a manifestation of delayed trophoblast invasion that are highly associated with gestational hypertensive disorders, IUGR, and fetal demise.<sup>50</sup>** Therefore, Doppler velocimetry of the uterine arteries has been examined for its usefulness in predicting pregnancies destined to produce a growth-restricted fetus. In women with hypertensive disorders, the presence of an elevated uterine artery S/D ratio (>2.6) and/or diastolic notching increased the risk for IUGR and stillbirth (see Fig. 33-17). **The changes in uterine artery flow patterns precede those observed in the umbilical artery and antedate FGR.** Subsequent studies used various cutoffs to define an abnormal test result. These include S/D ratios above 2.18 at 18 weeks, RI above 0.58 at 18 to 24 weeks, PI above the 95th percentile

(1.45) at 22 to 24 weeks, or the presence of notches. The screen positive rate ranges between 5% and 13% according to the gestational age and the criterion used to define an abnormal test result. In low-risk patients, a uterine artery Doppler resistance profile that is high, persistently notched, or both identifies women at high risk for preeclampsia and IUGR, with sensitivities and PPVs as high as 72% and 35%, respectively, when performed between 22 and 23 weeks' gestation. Uterine artery Doppler is better at predicting severe, rather than mild, disease. The likelihood ratio of abnormal uterine artery impedance for the development of IUGR was 3.7 with higher sensitivity for severe early-onset forms. Meta-analysis of the utility of uterine artery Doppler in the prediction of intrauterine death yields a likelihood ratio of 2.4 for patients with an abnormal result. Combining uterine artery Doppler velocimetry with other tests can improve screening sensitivities. The combination of abnormal second-trimester maternal uterine artery Doppler velocimetry and maternal glucose tolerance testing that demonstrate a "flat" response results in a PPV of 94% and a sensitivity of 54% for FGR. The presence of a normal uterine artery flow-velocity waveform bears a high negative predictive value, with a likelihood ratio of 0.5 and 0.8 for the development of preeclampsia and IUGR, respectively.

### Integrated Approach to Screening

Several markers reflect early failure of normal placental development in the first trimester. One marker is abnormal maternal cardiovascular adaptation to pregnancy, which results in a delay in the physiologic drop of mean arterial blood pressure (BP). Deficient trophoblast invasion is associated with a slower than anticipated drop in uterine artery blood flow resistance, and placental expression of analytes that relate to normal development is altered. When these markers are considered in isolation, their prediction of subsequent placental dysfunction is inaccurate. Therefore **an integrated screening algorithm has been developed that uses multiple independent risk factors that include a prior history of preeclampsia, maternal first-trimester body mass index (BMI), BP, uterine artery pulsatility index, and the PAPP-A MoM.** This combined model is capable of predicting early-onset preeclampsia or FGR with 80% to 90% sensitivity and a 5% to 10% false-positive rate. Although the predictive accuracy of this algorithm needs to be confirmed in a variety of population settings, this approach offers the important advantage of early stratification of risk with potential for intervention.

### Preventive Strategies

**Efforts to prevent FGR have been disappointing.** Low-dose aspirin has been extensively evaluated as a possible preventive agent for improving placental vascular development by virtue of its inhibitory action on platelet aggregation. However, whereas the use of aspirin in the second trimester has been found to be safe, initiation of therapy in the second trimester improves neither placental function nor long-term outcome. Because subsets of patients with a poor obstetric history appear to derive a benefit from aspirin, the utility of first-trimester uterine artery screening with subsequent aspirin therapy has been investigated. The choice of target population profoundly affects the utility of this approach. Although low-risk patients derive little benefit, high-risk patients—those with thrombophilia, hypertension, or a past history of either preeclampsia or IUGR—given low-dose aspirin because of bilateral uterine artery notching at 12 to 14

weeks experience an 80% reduction of placental disease compared with placebo-matched controls. However, only women who were initiated on aspirin before 16 weeks' gestation derive a 50% to 60% reduction in the relative risk for development of preeclampsia or FGR.<sup>51</sup>

**It appears prudent to regard poor obstetric history, unexplained elevations in second-trimester MSAFP, flat oral glucose tolerance curves, and abnormal second-trimester uterine artery Doppler velocimetry as important risk factors for IUGR that warrant further investigation when the clinical suspicion of IUGR arises and/or maternal preeclampsia develops. Such patients should undergo ultrasound estimation of fetal size and a full diagnostic workup if these factors are confirmed.**

## MANAGEMENT IN CLINICAL PRACTICE

Before developing a management plan, it is important that the major underlying etiologies have been addressed by a comprehensive diagnostic workup as described above. **It is worth stressing that the majority of fetuses thought to be growth restricted are constitutionally small and require no intervention. Approximately 15% exhibit symmetric growth restriction attributable to an early fetal insult for which there is no effective therapy. Here, an accurate diagnosis is essential. Finally, approximately 15% of small fetuses have growth restriction as a result of placental disease or reduced uteroplacental blood flow.** Once the diagnosis of placental insufficiency has been made, appropriate therapeutic options may be explored. However, ongoing assessment of fetal growth and parameters of fetal well-being is a more critical component of clinical management in defining the intervention thresholds when the balance of fetal versus neonatal risks favors delivery.

### Therapeutic Options

Elimination of contributors such as stress, smoking, and alcohol and drug use is advocated. Tobacco smoke contains a number of substances that are vasoactive and can cause vasoconstriction. Anecdotally, the authors have observed cases of IUGR with absent end-diastolic flow in the umbilical artery in which diastolic flow returned upon cessation of maternal smoking. Non-specific therapies include bed rest in the left lateral decubitus position to increase placental blood flow. Although an inadequate diet has not been clearly established as a cause of growth restriction in the United States, dietary supplementation may be helpful in those with poor weight gain or low prepregnancy weight. In patients with chronic malnutrition, improved fetal growth has been reported with total parenteral nutrition. Consideration should be given to hospitalized bed rest, which has the advantages of positive enforcement of rest and facilitation of daily fetal testing. The decision for inpatient versus outpatient management is based on the severity of the maternal and/or fetal condition and the local standard of care.

**Maternal hyperoxygenation** has been examined in several studies for potential benefits in the treatment of the compromised growth-restricted fetus. Studies by several groups confirm that maternal hyperoxygenation can raise the fetal cord blood pO<sub>2</sub>.<sup>52</sup> Techniques used included administration of 55% oxygen by face mask or 2.5 L/min by nasal prong. Prolongation of pregnancy from the first recognition of the compromised fetal condition ranged from 9 days to 5 weeks. However, fetal growth velocity was not improved. In addition, fetuses subjected to

oxygen therapy had more hypoglycemia, thrombocytopenia, and disseminated intravascular coagulation (DIC) compared with controls. The primary role of maternal hyperoxygenation may reside in the safe short-term prolongation of pregnancy to allow the administration of corticosteroids to reduce the risk of neonatal respiratory distress syndrome (RDS) and intraventricular hemorrhage (IVH) in anticipation of a preterm delivery. There may also be benefit by gaining additional time in utero for improved survival and fetal maturity.

**Maternal hyperalimentation** as a means of intrauterine feeding of the growth-restricted fetus is an attractive therapeutic concept. Increasing the maternal concentration of amino acids leads to an increased umbilical uptake of some amino acids to the fetus, but no change is seen in the three essential amino acids: lysine, histidine, and threonine. These data further support that total parenteral nutrition can reverse abnormal fetal growth secondary to maternal nutritional deprivation. However, it does not overcome abnormal placental function. Outcomes are neither improved in animal models nor in human pregnancies. Therefore maternal hyperalimentation only plays a role in patients in whom malnutrition has been established as the underlying cause of growth delay.

**Maternal volume expansion** as a therapeutic concept is based on the observation that poor maternal blood volume status is associated with adverse pregnancy outcome.<sup>53</sup> In a small group of centrally monitored women with abnormal placental Doppler studies, volume expansion was associated with reappearance of umbilical artery end-diastolic velocities and a significant improvement of neonatal survival.

**Low-dose aspirin** in combination with dipyridamole administered from 16 weeks' gestation was first reported in 1987 by Wallenburg and Rotmans to significantly reduce the incidence of FGR in women with a history of recurrent IUGR. Women receiving therapy had a rate of FGR of 13%, compared with 61% in an untreated control group. No treated woman had a child with severe growth restriction (birthweight <2.3 percentile) compared with 27% in the untreated group. **In 1997, a meta-analysis of the efficacy of low-dose aspirin (50 to 100 mg/day) demonstrated a significant reduction in the frequency of IUGR when low-dose aspirin was used. A dose-dependent relationship is apparent: higher doses (100 to 150 mg/day) were significantly more effective in preventing IUGR than were lower doses (50 to 80 mg/day).**

Two recent randomized trials illustrate important considerations regarding the use of aspirin to prevent preeclampsia and IUGR. In a study of patients randomized at 24 weeks' gestation based on the uterine artery flow-velocity waveform, low-dose aspirin was not associated with any improvement in placental function or perinatal outcome. Conversely, in patients with a poor obstetric history (thrombophilia, hypertension, history of either preeclampsia or IUGR) randomized at 12 to 14 weeks based on the uterine artery flow-velocity waveforms, those who received aspirin experienced an 80% reduction in placental disease compared with placebo-matched controls. **Therefore it appears that aspirin works best in patients with significant risk factors for IUGR and that the therapeutic optimal window to commence aspirin therapy lies between 12 and 16 weeks' gestation when branching angiogenesis of the placenta is ongoing.**

Although the overall safety of aspirin has been documented in a large patient population, concerns about a possible association with abdominal wall defects have been raised with

administration in the early first trimester. Therefore, **we suggest deferral of indicated therapy until completion of organogenesis at 12 weeks' gestation.** Selected patients who present in the second trimester may still derive benefit from aspirin, and patients should be counseled on an individualized basis. Aspirin prophylaxis can be discontinued at any point after 34 weeks' gestation because bleeding risks at delivery and during regional anesthesia outweigh the benefits of prolonging gestation.

**Corticosteroids** are a universally available antenatal therapeutic option that positively affects outcome by enhancing lung maturation and preventing IVH. The impact of prenatal glucocorticoid administration on the neonatal complication rate in the growth-restricted newborn has recently been examined by Bernstein and coworkers<sup>35</sup> in a study of 19,759 newborns between 500 and 1500 g. After controlling for a different set of confounding variables, **this study demonstrated a significant reduction in neonatal RDS, IVH, and death when prenatal glucocorticoids were administered.** These benefits were not qualitatively different from those observed in appropriately sized newborns. **Other studies have also refuted that the "stress" of the intrauterine condition enhances maturation and protects against prematurity.** In contrast, a smaller study demonstrated no benefit to neonatal outcome when perinatal glucocorticoids were used. Although these studies indicate the need for randomized comparison of management, they also clearly show no benefit from the omission of antenatal corticosteroids. **We recommend administration of a complete 48-hour course of antenatal steroids to any growth-restricted fetus when delivery is anticipated before 34 weeks' gestation, if this can be safely accomplished.**

When corticosteroids are administered, it is important to account for their effect on fetal testing parameters when interpreting antenatal surveillance results. Betamethasone, for example, temporarily reduces FHR variation on days 2 and 3 after the first injection, together with a 50% decrease in fetal body movements and a near cessation of fetal breathing movements. Subsequently, the number of fetuses with abnormal BPP scores increases significantly by 48 hours after steroid administration, with a return to the preadministration state at 72 hours.<sup>54</sup> In contrast, maternal and fetal Doppler findings are not affected to the same degree during this period. A transient decrease in the MCA blood flow resistance has been reported 48 hours after betamethasone administration.

## ASSESSMENT OF FETAL WELL-BEING

Once the diagnosis of FGR has been made and the differential diagnostic options have been explored, fetal assessment is instituted (see [Chapter 11](#)). **Serial ultrasound evaluations of fetal growth are continued every 3 to 4 weeks and should include determinations of the BPD, HC/AC ratio, fetal weight, and AFV.** The institution of antenatal surveillance is a critical component in the management of the growth-restricted fetus. The goal is to avoid stillbirth and optimize the timing of delivery, which requires consideration of the appropriate intervention threshold and the choice of the appropriate surveillance intervals. Relationships between fetal testing parameters and subsequent outcome determine the balance between fetal and neonatal risks and therefore define intervention thresholds. In contrast, changes in the rate of clinical progression determine the surveillance interval for patients where delivery is not yet indicated. Growth-restricted fetuses are at risk for worsening placental

function, subsequent deterioration of acid-base status, decompensation, stillbirth, and long-term adverse health outcomes into adulthood. Although prevention of long-term morbidity is an attractive goal, information is insufficient on its relationships with prenatal variables to direct management with long-term outcomes in mind. Of the many short-term outcomes that have been related to fetal status, only a few are presently of clinical relevance. Fetal acidemia and major neonatal complications have a significant impact on subsequent neurodevelopment, whereas the combination of fetal and neonatal deaths determines the overall perinatal mortality.<sup>55</sup> **The likelihood of fetal acidemia and stillbirth is therefore the strongest fetal criterion for intervention. In contrast, gestational age-specific expectations for neonatal complications and survival force conservative management.** Whereas neonatal complications are typically multifactorial and not accurately predicted prenatally, anticipation of fetal risks remains as the primary goal. Therefore antenatal surveillance tests need to predict fetal acid-base status, rate of anticipated progression, and the resulting risk for deterioration and stillbirth. The monitoring tools available to achieve this include the traditional nonstress test (NST), contraction stress test, (CST), BPP scoring, and Doppler sonography.

### Maternal Monitoring of Fetal Activity

Maternal monitoring of fetal activity has been used extensively in Great Britain, Scandinavia, and Israel for the assessment of pregnancies complicated by IUGR. **Fetal activity charting in pregnancies complicated by FGR predicts subsequent distress in labor.**<sup>56</sup> A simple technique for monitoring fetal movement is the minimum requirement of 10 movements in a 2-hour period. If this criterion is not met, additional testing is warranted. In an outpatient setting, maternal kick counts or fetal activity counts (FAC) supplement medically administered antenatal surveillance. In compliant patients with an appropriate level of awareness of fetal movements, it may also be helpful in modifying monitoring intervals as fetal deterioration occurs.

### Fetal Heart Rate Analysis

The traditional NST is a visually analyzed record of the FHR baseline, variability, and episodic changes. Normal FHR characteristics are determined by gestational age, maturational and functional status of central regulatory centers, and oxygen tension. A “reactive” NST exhibits two 15-beat accelerations above the baseline maintained for 15 seconds in a 30-minute monitoring period. When the NST is analyzed as part of the five-component BPP score, reactivity criteria that account for gestational age are applied (see below). **Irrespective of the context, a “reactive” NST indicates absence of fetal acidemia at the moment of the FHR recording. Many growth-restricted fetuses with a normal heart rate tracing can have low-normal pO<sub>2</sub> values, but acidemia is virtually excluded by a reactive NST. Heart rate reactivity also correlates highly with a fetus not in immediate danger of intrauterine demise. Nonreactive NST results, on the other hand, are often falsely positive and require further evaluation. The development of repetitive decelerations may reflect fetal hypoxemia or cord compression as a result of the development of oligohydramnios and has been associated with a high perinatal mortality rate.**<sup>57</sup>

The CST is an additional option for testing placental respiratory reserve.<sup>58</sup> Positive CST results have been reported in 30% of pregnancies complicated by proven growth restriction. **In one**

**study, 30% of growth-restricted infants had nonreactive NST results, and 40% had positive CST results.**<sup>59</sup> **Ninety-two percent of IUGR infants with a nonreactive positive pattern exhibited perinatal morbidity. However, a 25% to 50% false-positive rate has been associated with the CST by some investigators. A possible role for the CST may be evaluation of placental reserve prior to induction in IUGR fetuses in whom vaginal delivery is attempted.**

Marked intraobserver and interobserver variability of visual FHR analysis has been identified as a potential factor affecting the prediction of fetal status. Currently, traditional FHR parameters and short- and long-term variation of the heart rate in milliseconds, length of episodes with low and high variation, and the rate of signal loss can be assessed by computerized analysis. The objective assessment of these variables circumvents the issue of observer variability, and a direct correlation between FHR variation and pO<sub>2</sub> in the umbilical vein as assessed at cordocentesis prior to the onset of labor has been documented. **A computerized documentation of a mean minute variation below 3.5 msec has been reported to predict an umbilical artery cord pH less than 7.20 with over 90% sensitivity. In addition, FHR variation usually decreases gradually in the weeks that precede the appearance of late decelerations and fetal hypoxemia and is therefore the most useful computerized FHR parameter for longitudinal assessment in IUGR.** As with the traditional NST, gestational age, time of day, and the presence of fetal rest-activity cycles also need to be taken into account in the interpretation of computerized results. Wide normal ranges are apparent for FHR patterns and their variations, but the individual fetus shows a certain intrafetal consistency throughout gestation. For monitoring of trends, each fetus should therefore serve as its own control, using recordings of standardized duration and appropriate reference ranges.

In summary, **a visually reactive FHR provides assurance of fetal well-being at the time of analysis.** Whereas the traditional NST is most sensitive in the prediction of fetal normoxemia, computerized analysis appears to be superior in the prediction of hypoxemia and acidemia. Once traditional reactivity is lost, computerized analysis of heart rate variation is a potential tool available for ongoing longitudinal analysis. Computerized FHR analysis is more widely used in Europe. FHR analysis itself does not assess the severity of disease and most importantly does not anticipate the rate of deterioration; therefore frequency of surveillance cannot be based on FHR testing. To address these issues, additional fetal tests are available.

### Amniotic Fluid Volume

**In the context of fetal surveillance, assessment of AFV provides an indirect measure of vascular status. A relationship between oligohydramnios and progressive deterioration of arterial and venous Doppler studies has been documented in growth-restricted fetuses and prolonged pregnancies.**

Therefore declining AFV is suggestive of ineffective downstream delivery of cardiac output and allows some form of longitudinal monitoring even in the absence of Doppler studies. **If the NST is reactive, a concurrent assessment of the AFV constitutes the modified biophysical profile (MBPP) and provides assurance of fetal well-being if both parameters are normal.** Interventions based on twice-weekly MBPP scores result in similar perinatal outcomes as with weekly contraction stress testing and therefore have largely replaced the latter. **When the FHR is nonreactive, relying on a normal AFV assessment**

alone is inadequate, and a full BPP that incorporates multiple parameters of fetal well-being should be done because of its superior performance in identifying jeopardized fetuses.

### Biophysical Parameters

The five-component fetal BPP was developed by Manning and colleagues and has been widely used in the surveillance of growth-restricted fetuses. A graded system is applied to categorize fetal tone, movement, breathing movement, heart rate reactivity, and a maximum amniotic fluid pocket as *normal* (2 points) or *abnormal* (0 points). If used in the context of the BPP, fetal heart rate reactivity criteria that account for gestational age are used. **Reactivity has been defined prior to 32 weeks' gestation as accelerations greater than 10 beats/min sustained for more than 10 seconds; between 32 to 36 weeks' gestation, accelerations greater than 15 beats/min sustained for more than 15 seconds; and after 36 weeks' gestation, accelerations greater than 20 beats/min sustained for more than 20 seconds.** In anatomically normal fetuses, the presence of the dynamic variables is related to physiologic variations in maturation and behavioral state as well as acid-base status. Vintzileos and coworkers have demonstrated that four components of the BPP are affected at different levels of hypoxemia and acidemia. The earliest manifestations of abnormal fetal biophysical activity consist of the loss of heart rate reactivity along with the absence of fetal breathing. This is followed by decreased fetal tone and movement in association with more advanced acidemia, hypoxemia, and hypercapnia. **Because of the relationship between AFV and vascular status, amniotic fluid assessment provides the only marker of chronic hypoxemia and is the only longitudinal monitoring component of the BPP.**

Growth-restricted fetuses preserve acute central responses to acid-base status despite their maturational delay and are at risk for oligohydramnios. **The five-component BPP accounts best for physiologic and individual variations in behavior and therefore remains closely related to arterial pH in fetuses with IUGR without anomalies from 20 weeks onward.<sup>60</sup>** An abnormal score of 4 or less is associated with a mean pH of less than 7.20, and sensitivity in the prediction of acidemia is 100% for a score of 2 or less. A normal score and normal AFV indicate the absence of fetal acidemia at the time of testing. Longitudinal observations in growth-restricted fetuses have shown that the BPP deteriorates late and often rapidly.<sup>20</sup> Whereas an abnormal BPP is associated with escalating risks for stillbirth and perinatal mortality, a normal score allows no anticipation of fetal deterioration and stillbirth.

**In summary, assessment of fetal biophysical variables provides an accurate measure of fetal status at the time of testing. In the patient with a nonreactive NST, a full five-component BPP must be performed.** As a back-up test for a nonreactive FHR test, the BPP leads to lower rates of intervention, when compared with the CST, without jeopardizing perinatal outcome. In the presence of normal AFV, a normal BPP of 8 (–2 for a nonreactive NST) or 10 is reassuring of fetal well-being. Nevertheless, in the absence of knowledge about placental vascular status, the rate of progression cannot be anticipated and may require even daily testing in severe IUGR. The development of oligohydramnios is concerning and frequently requires modification of management or delivery. The knowledge of fetal Doppler status is complementary to BPP because it improves

the anticipation of fetal deterioration and provides an additional means to assess fetal state.<sup>61</sup>

### Doppler Ultrasound

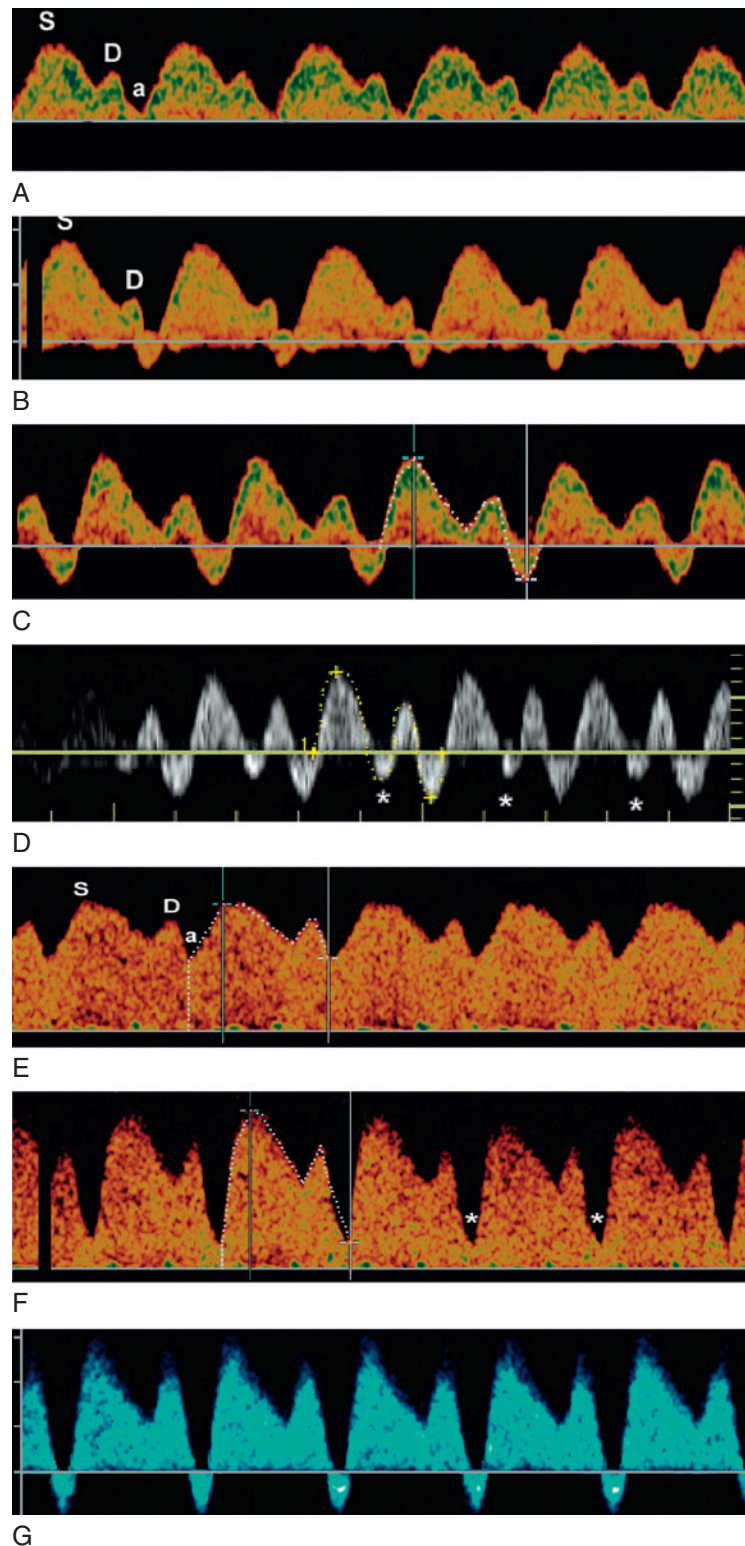

Doppler parameters are influenced by several variables that include vascular histology and tone and fetal blood pressure. Placental respiratory function is related to the integrity of the villous vasculature, and a decrease in arterial  $pO_2$  can trigger autoregulatory adjustments of vascular smooth muscle tone. As diagnostic tools, elevated umbilical artery blood flow resistance and/or MCA brain sparing provide evidence of placental dysfunction. The utility of Doppler ultrasound in the assessment of fetal well-being is based on the relationship between Doppler parameters with metabolic status, rate of disease progression, and the risk for stillbirth. **This utility is greatest for early-onset growth restriction, which is associated with more marked Doppler abnormalities than late-onset disease that requires delivery after 34 weeks, especially in early-onset placental dysfunction.<sup>18,62</sup>** Distinction between early and late fetal vascular responses to placental insufficiency provides a useful framework within which to estimate these risks.

**Early responses to placental insufficiency** are observed in mild placental vascular disease when umbilical artery end-diastolic velocity is still present. A decrease in the CPR provides an early and sensitive marker of redistribution of cardiac output that often precedes overt growth delay by up to 2 weeks. The reduction of fetal growth velocity generally mirrors the elevation in umbilical artery blood flow resistance and is followed by decreasing MCA impedance (brain sparing). The nadir of cerebral blood flow resistance is typically reached after a median of 2 weeks and is followed by an increase in aortic blood flow impedance.<sup>63</sup> **Early cardiovascular responses are considered compensatory because they occur at a time when cardiac function is normal, and they are typically accompanied by preferential perfusion of vital organs and the placenta. Although the fetus may be hypoxemic, the risk for acidemia is low.**

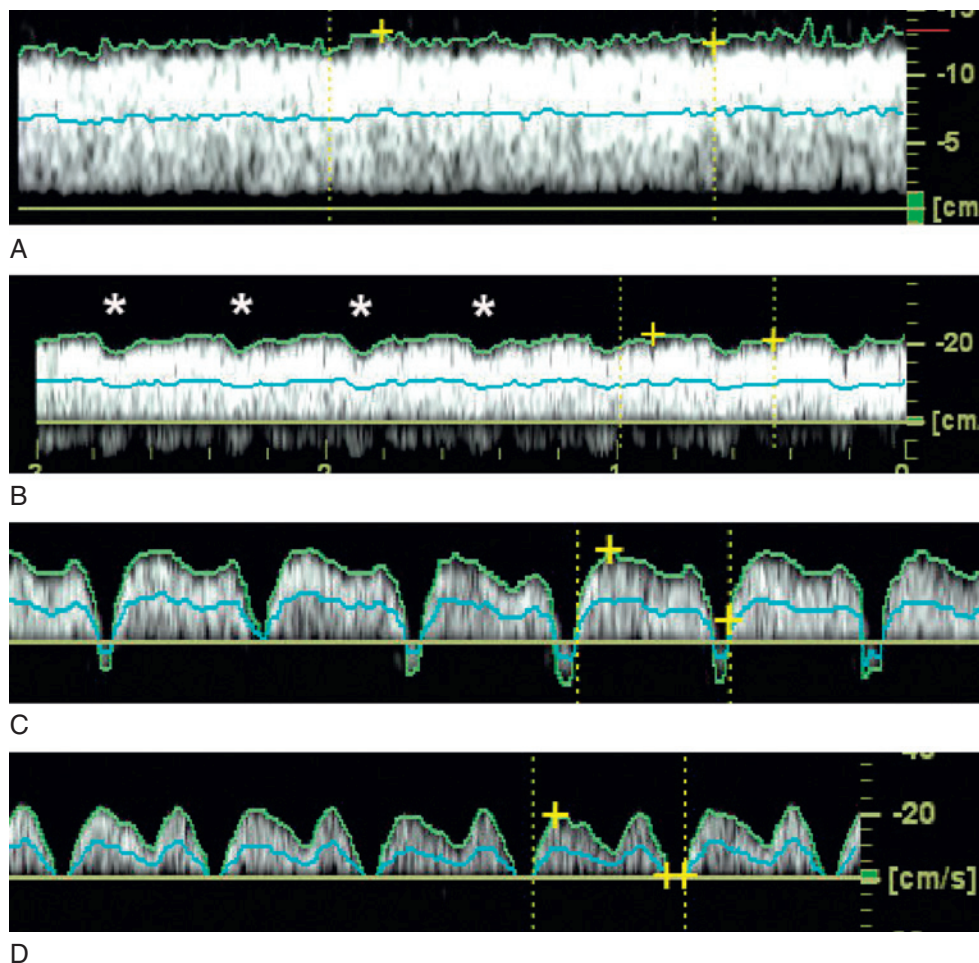

**Late responses to placental insufficiency** are observed when accelerating placental disease results in loss or reversal of umbilical artery end-diastolic velocity, and when fetal deterioration becomes evident through parallel elevations in placental blood flow resistance and venous Doppler indices. **Although the development of abnormal venous blood flows has been documented in many veins, the precordial veins—including the ductus venosus, the inferior vena cava, and the umbilical vein—are typically utilized in clinical practice (Figs. 33-14 and 33-15).** When fetal compromise accelerates, a further steady rise is seen in umbilical blood flow resistance; venous Doppler indices escalate over a wide range, and the development of oligohydramnios and metabolic acidemia is characteristic of ineffective downstream delivery of cardiac output.<sup>64</sup> In the final stages of compromise, cardiac dilatation with holosystolic tricuspid insufficiency, complete fetal inactivity, short-term heart rate variation below 3.5 ms, and spontaneous “cardiac” late decelerations of the FHR can be observed as preterminal events (Fig. 33-16).<sup>65</sup>

In the past, the major focus of Doppler studies for the assessment of fetal health has been the umbilical circulation. The association between an elevation in Doppler blood flow indices in the UA, increased disturbance of placental perfusion, and the deterioration of fetal acid-base status proportional to the degree of the Doppler abnormality has been demonstrated by several

**FIG 33-14** Normal and abnormal precordial venous flow-velocity waveforms. The inferior vena cava and ductus venosus are the most commonly evaluated precordial veins, whereas the umbilical venous flow-velocity waveform is predominantly assessed qualitatively. **A**, The inferior vena cava shows the typical triphasic pattern with systolic and diastolic peaks (S, D, respectively). **B**, The a-wave may be reversed under physiologic conditions. **C**, An abnormal inferior vena cava flow-velocity waveform shows a relative decrease in forward flow during the first trough, the D-wave, and the a-wave. **D**, Under extreme circumstances, flow may be reversed during the first trough (*asterisks*). **E**, In contrast to the inferior vena cava, the ductus venosus has antegrade blood flow throughout the cardiac cycle with forward velocities during the S-, D-, and a-waves. **F**, A decrease in atrial systolic forward velocities (*asterisks*) is the first sign of abnormality and results in an increased Doppler index. **G**, With marked elevation of central venous pressure, blood flow may reverse during atrial systole.

**FIG 33-15** Normal and abnormal umbilical venous flow velocity. Umbilical venous blood flow is usually constant (**A**). Monophasic umbilical venous pulsations (asterisks) may be observed with moderate elevations of placental blood flow resistance and/or oligohydramnios (**B**). Retrograde propagation of increased central venous pressure first results in biphasic and then triphasic pulsations (**C** and **D**, respectively).

investigators. In the fetal compartment, elevation of the UA Doppler index is observed when approximately 30% of the fetal villous vessels are abnormal. Absence or even reversal of UA end-diastolic velocity can occur when 60% to 70% of the villous vascular tree is damaged.<sup>66</sup> Incidences of intra-uterine hypoxia that range from 50% to 80% in fetuses with absent end-diastolic flow have been reported. The benefit of UA Doppler in management has been documented in randomized controlled trials and meta-analyses. In these studies, when used in conjunction with standard antepartum testing, UA Doppler was associated with a decrease of up to 38% in perinatal mortality, antenatal admissions, inductions of labor, and cesarean deliveries for fetal distress in labor in women considered at high risk. However, several studies that have examined the cerebral and especially the venous circulation have provided greater insight into the relationships between Doppler abnormality and outcome. Previous work has reported that development of umbilical venous pulsations in fetuses with absent end-diastolic velocities in the UA was associated with a fivefold increase in mortality. Arduini and colleagues<sup>67</sup> demonstrated that gestational age at onset, maternal hypertension, and the development of pulsations in the umbilical venous velocities were significantly correlated with the interval of time between diagnosis and delivery for late decelerations of the FHR. Subsequently, several studies have confirmed that fetuses

with abnormal arterial velocities who also developed abnormal precordial venous velocities had a higher morbidity and mortality than fetuses without abnormal venous flow.<sup>68</sup> These studies and subsequent analyses confirm that fetal Doppler assessment based on the UA alone is no longer appropriate, particularly in the setting of early-onset IUGR prior to 34 weeks. Incorporation of MCA and venous Doppler provide the best prediction of acid-base status, risk of stillbirth, and the anticipated rate of progression.

In growth-restricted fetuses with an elevated Doppler index in the UA, brain sparing in the presence of normal venous Doppler parameters is typically associated with hypoxemia but a normal pH. Elevation of venous Doppler indices, either alone or in combination with umbilical venous pulsations, increases the risk for fetal acidemia. This association is strengthened by serial elevations of the ductus venosus Doppler index. Depending on the cutoff (2 vs. 3 SD) and the combinations of veins examined, sensitivity for prediction of acidemia ranges from 70% to 90%, and specificity from 70% to 80%. **Abnormal venous Doppler parameters are the strongest Doppler predictors of stillbirth. Even among fetuses with severe arterial Doppler abnormalities (e.g., AEDV or REDV), the risk of stillbirth is largely confined to those fetuses with abnormal venous Dopplers.**<sup>68</sup> The likelihood of stillbirth increases with the degree of venous Doppler abnormality. Particularly ominous

**FIG 33-16** Longitudinal progression of antenatal testing variables. This figure displays trends in arterial and venous Doppler parameters (DAO, descending aorta; DV, ductus venosus; IVC, inferior vena cava; MCA, middle cerebral artery; PI, pulsatility index; PIV, pulsatility index for veins; UA, umbilical artery), amniotic fluid index (AFI), and computerized fetal heart rate short-term variation (STV) in relation to delivery expressed as standard deviation for growth-restricted fetuses delivered before 32 weeks' gestation. The graph demonstrates that arterial Doppler parameters may be abnormal for more than 5 weeks prior to delivery, whereas venous Doppler parameters and the short-term variation deteriorate in the week prior to delivery for fetal indications. (From Hecher K, Bilardo CM, Stigter RH, et al. Monitoring of fetuses with intrauterine growth restriction: a longitudinal study. *Ultrasound Obstet Gynecol.* 2001;18:564.)

venous Doppler findings are absence or reversal of the ductus venosus a-wave and biphasic/triphasic umbilical venous pulsations. In the setting of a 25% stillbirth rate in a population with preterm severe IUGR, these Doppler findings have a 65% predictive sensitivity and 95% specificity.<sup>69</sup>

Although neonatal morbidity is primarily determined by gestational age at delivery, and neonatal mortality is the product of several factors, both of these outcomes are also related to fetal Doppler studies. Arterial redistribution and brain sparing are not associated with a significant rise in major neonatal complications. In contrast, a 2-SD elevation of the DV Doppler index is associated with a threefold increase in neonatal complications, and further escalation of DV Doppler indices leads to an elevenfold increase in this relative risk. **The neonatal mortality rate in fetuses with absent or reversed UA end-diastolic velocity ranges from 5% to 18% when the venous Doppler indices are normal. Elevation of the DV Doppler index greater than 2 SDs doubles this mortality rate, although predictive sensitivity is only 38% with a specificity of 98%.**

In summary, Doppler evaluation of the umbilical, cerebral, and precordial vessels of the growth-restricted fetus provides important diagnostic and prognostic information. Fetal acidemia and the risk of stillbirth are high with progressive elevation of venous Doppler indices. **Advancing Doppler abnormalities indicate acceleration of disease and require increased frequency of fetal monitoring. In growth-restricted fetuses, Doppler evaluation is complementary to all other surveillance modalities.**

### Invasive Fetal Testing

In the past, direct determination of fetal acid-base status by cordocentesis was often performed with fetal karyotyping.

Nicolini and colleagues examined 58 growth-restricted fetuses using cordocentesis for acid-base evaluation in addition to karyotyping. They found significant differences in pH, partial pressure of carbon dioxide ( $pCO_2$ ),  $pO_2$ , and the base equivalent in fetuses with no evidence of end-diastolic flow by UA Doppler velocimetry. However, they observed no relationship between acid-base determination and perinatal outcome. Pardi and colleagues<sup>70</sup> examined umbilical blood acid-base status in 56 growth-restricted fetuses and demonstrated an association between acid-base status and the results of cardiotocographic and UA Doppler waveform analysis. If both FHR and Doppler studies were normal, neither hypoxemia nor acidemia was noted. When both tests were abnormal, 64% of the growth-restricted fetuses demonstrated abnormal acid-base analysis. The prognostic significance of these abnormalities remains unclear. Lack of benefit, the complication rate, accuracy of noninvasive assessment of fetal acid-base status, and finally the availability for rapid karyotyping techniques from amniocytes all mean that **cordocentesis is rarely necessary today.**

### Anticipating the Progression to Fetal Compromise

The anticipation of clinical progression is a critical component in the management of the fetus with IUGR because it determines fetal surveillance intervals as well as the timing for intervention. Although deterioration of fetal status is manifested in all surveillance modalities, accelerating disease is best anticipated by AFV status and arterial and venous Doppler parameters (Fig. 33-17). **However, the gestational age at onset has an important impact on the clinical presentation and, accordingly, on the diagnosis and management of FGR. In early-onset growth delay (prior to 34 weeks' gestation), the significantly decreased survival rates—as well as the higher mortality following immediate delivery—places special emphasis on safe pregnancy prolongation in these situations.<sup>71,72</sup> Late-onset FGR (presenting after 34 weeks' gestation) does not typically pose a dilemma for delivery timing because delivery thresholds can be low given the lower neonatal risks. However, late-onset FGR is a significant clinical problem that contributes to over 50% of unanticipated stillbirths at term.<sup>73</sup> Therefore a more pressing issue in term pregnancies is the recognition of growth-restricted fetuses, rather than the timing of their delivery (see earlier sections on diagnostic tools and clinical examination).** Once the fetus with IUGR has been identified, recognizing the important differences in management helps to clarify the nature of decisions that need to be based on the results of the surveillance examination. The principal choices that need to be made at each monitoring visit are whether intervention is needed and the interval to the next visit. The intervention threshold is based on the balance of fetal and neonatal risks, and it is high at early gestation given the high neonatal morbidity but successively decreases as gestation advances. The monitoring interval is often empirically defined but needs to be shortened if fetal signs of deterioration are present that indicate an acceleration of the disease. This in turn requires an appreciation of the typical pattern of progression in early- and late-onset FGR.<sup>11,74</sup>

Umbilical artery Doppler alone provides inaccurate prediction because progression to abnormal FHR parameters is highly variable and may range from 0 to 49 days, as reported in a study by Farine and coworkers. In general, early-onset IUGR that presents prior to 28 weeks' gestation is associated with more

**FIG 33-17** Progression of compromise in various monitoring systems. This figure summarizes the early and late responses to placental insufficiency. Doppler variables in the placental circulation precede abnormalities in the cerebral circulation. Fetal heart rate (FHR), amniotic fluid volume (AFV), and biophysical profile score (BPS) are still normal at this time, and computerized analysis of fetal behavioral patterns is necessary to document a developmental delay. With progression to late responses, venous Doppler abnormality in the fetal circulation is characteristic and often precedes the sequential loss of fetal dynamic variables and frequently accompanies the decline in AFV. The decline in biophysical variables shows a reproducible relationship with acid-base status. Because the BPS is a composite score of five variables, an abnormal BPS less than 6 often develops late and may be sudden. Absence or reversal of the ductus venosus a-wave, decrease of the short-term variation (STV) of the computerized FHR analysis, spontaneous late decelerations, and an abnormal BPS are the most advanced testing abnormalities. If adaptation mechanisms fail and the fetus remains undelivered, stillbirth ensues. CPR, cerebroplacental ratio.

significant placental vascular problems that produce marked Doppler changes. In contrast, IUGR that presents near term is typically associated with milder placental disease and therefore more subtle Doppler findings. Decreasing AFV and behavioral responses are preserved throughout gestation irrespective of Doppler status. Accordingly, longitudinal progression and clinical findings may vary based on gestational age and may be further modulated by maternal disease.<sup>75</sup> Beyond 34 weeks, when the UA waveform may be normal or near normal, assessment of the MCA flow-velocity waveform and/or the CPR may be necessary to provide an estimate of placental disease and direct the frequency of testing.<sup>47</sup> In fetuses with elevated placental blood flow resistance, onset of MCA brain sparing or a decline in the AFI indicate accelerating disease. Once brain sparing is established, the next level of deterioration occurs when UA end-diastolic velocity is lost and parallel elevations in placental blood flow resistance and precordial venous Doppler

indices are observed. Although this may happen after several weeks, the anticipation of such deterioration may require twice-weekly, rather than weekly, testing. When accelerating fetal compromise occurs, it is associated with a further rise in umbilical blood flow resistance (leading to REDV), whereas venous Doppler indices escalate over a wide range of distribution (see Fig. 33-15). **Studies by Baschat, Ferrazzi, Hecher, and Bilardo indicate that 40% of preterm growth-restricted fetuses that deteriorate in utero have an increased DV Doppler index the week prior to delivery (Figs. 33-18 and 33-19; see also Fig. 33-16).** On the day of delivery, an additional 20% deteriorated further. Elevations of precordial venous Doppler indices also precede sudden deterioration of the BPP by a median of 1 week in fetuses with elevated UA blood flow resistance. These findings have an important impact on testing frequency. For example, in a preterm growth-restricted fetus where venous Doppler indices are elevated, a BPP of 10 does not provide assurance that fetal

**FIG 33-18** Early and late Doppler findings in growth-restricted fetuses. This figure displays cumulative onset time curves of Doppler abnormalities for each fetal vessel examined. Middle cerebral artery (MCA) brain sparing and umbilical artery (UmA) absent end-diastolic flow (AEDF) are observed up to 16 days before delivery. Ao PSV, aortic peak systolic velocity; DV, ductus venosus; PA PSV, pulmonary artery peak systolic velocity; REDF, reverse end-diastolic flow; S/a, ratio of maximum forward velocity during ventricular systole and atrial systole. (Modified from Ferrazzi E, Bozzo M, Rigano S, et al. Temporal sequence of abnormal Doppler changes in the peripheral and central circulatory systems of the severely growth-restricted fetus. *Ultrasound Obstet Gynecol.* 2002;19:140.)

**FIG 33-19** Sequential deterioration of Doppler and biophysical parameters. This figure shows the percentage of abnormal Doppler findings in individual vessels and the incidence of a biophysical profile score (BPS) below 6 in the last week prior to delivery represented by the lines. A/REDF, absent or reversed end-diastolic flow; DV, ductus venosus; IVC, inferior vena cava; MCA, middle cerebral artery; UA, umbilical artery; UV, umbilical vein. Deterioration of Doppler findings precedes decline in biophysical profile score. (From Baschat AA, Gembruch U, Harman CR. The sequence of changes in Doppler and biophysical parameters as severe fetal growth restriction worsens. *Ultrasound Obstet Gynecol.* 2001;18:571.)

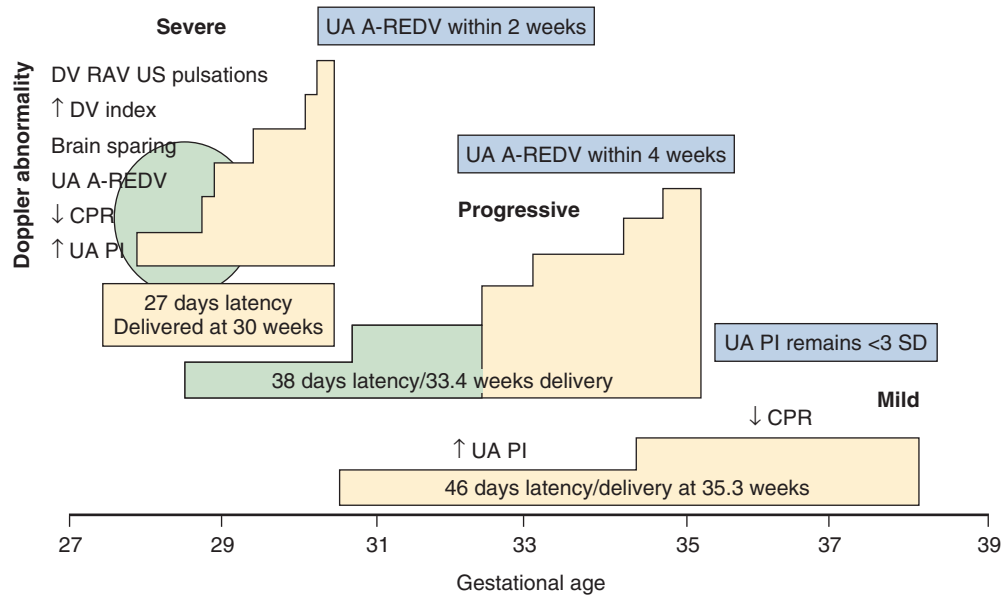

status will remain stable for the following week. In fact, a sizeable proportion of these fetuses may have a BPP score of less than 6 after a median time of just 1 day.<sup>20</sup> Therefore, thrice-weekly or even daily testing may be necessary in such fetuses. This is illustrated in a study by Divon and coworkers in which the authors performed a daily BPP in fetuses with absent UA end-diastolic velocity. Delivery was indicated for maternal reasons, a BPP

below 6, oligohydramnios, documented lung maturity, or a gestational age beyond 36 weeks' gestation. No stillbirths and no cord artery pH below 7.20 were reported using this intensive monitoring approach.

More recent work reported through the Prospective Observational Trial to Optimize Pediatric Health in IUGR (PORTO) study identifies one of the challenges in Doppler evaluation of the severely growth-restricted fetus prior to 34 weeks' gestation.<sup>48</sup> **Pregnancies at increased risk of adverse outcome were those with an abnormal UA Doppler study and, in particular, those with an EFW below the third percentile with or without oligohydramnios.** However, after approximately 31 weeks, it appears that these growth-restricted fetuses do not follow a dominant pattern or sequence of Doppler abnormalities as seen earlier in gestation, and it cannot be predicted what Doppler abnormality pattern a given fetus will follow prior to an abnormal biophysical test. However, it remains clear that by the time severe venous Doppler changes are detected, the fetus is frequently acidemic.<sup>46</sup> Of note, a substantial number of fetuses with absent UA flow were managed as inpatients and were not included in the PORTO trial after 30 weeks' gestation.

The clinical progression in Doppler and biophysical abnormalities is observed in approximately 70% to 80% of growth-restricted fetuses prior to 34 weeks' gestation.<sup>11,20</sup> Two rates of progression have been described that can be anticipated based on the UA end-diastolic velocity (EDV). In pregnancies in which UA EDV is lost within the first 2 weeks of diagnosis, deterioration to venous Doppler and biophysical abnormalities within 4 weeks is common (Fig. 33-20). If UA EDV is maintained for longer periods, deterioration may not occur for 6 weeks after diagnosis. In late-onset growth restriction that presents beyond 34 weeks' gestation, several other presentations are possible. UA blood flow resistance may be normal, and brain sparing may be observed as the only Doppler sign of perceived hypoxemia that requires an increase in surveillance frequency to twice weekly.<sup>15</sup> Alternatively, Doppler findings may be normal, and oligohydramnios and/or a decline of biophysical variables may be the only signs of placental insufficiency. On a similar note, the speed of progression may vary significantly in these different clinical scenarios, and persistence of normal umbilical Doppler parameters for up to 9 weeks before new-onset brain sparing is observed is not unusual. In recognition of these variable time scales and patterns of deterioration, it is evident that **the combination of several testing modalities is more likely to provide evidence of deterioration. If BPP scoring is used, particular attention needs to be placed on the amniotic fluid, because this is the only component that reflects longitudinal progression. The most comprehensive approach that addresses cardiovascular and behavioral responses in IUGR fetuses across all gestational ages has been described as "integrated fetal testing."**

**Integrated fetal testing utilizes a surveillance approach to pregnancies with IUGR that requires familiarity with the combined assessment of the five-component BPP and arterial and venous Doppler studies.<sup>77</sup> Doppler examination includes evaluation of the UA, MCA, DV, and free umbilical vein flow-velocity waveform. The testing is always supplemented with maternal assessment of fetal movement ("kick counts"). Surveillance is initiated no earlier than 24 weeks' gestation. In fetuses with elevated UA pulsatility, positive end-diastolic flow, and absence of any additional abnormality, weekly BPP is performed along with multivessel Doppler**

**FIG 33-20** Two rates of progression can be anticipated based on the umbilical artery (UA) end-diastolic velocity (EDV). Losing UA EDV within the first 2 weeks of diagnosis commonly leads to deterioration to venous Doppler and biophysical abnormalities within 4 weeks (middle section of the figure). However, UA EDV can be maintained for longer periods, and deterioration may not occur for 6 weeks after diagnosis (bottom section of figure). A-REDV, absent/reversed end-diastolic velocity; CPR, cerebroplacental ratio; DV, ductus venosus; PI, pulsatility index; RAV, reverse atrial systolic velocity; US, ultrasound.

monitoring studies every 2 weeks. With the onset of brain sparing, Doppler monitoring intervals are shortened to weekly visits. In fetuses with an AFI of less than 5 cm or AEDV in the umbilical artery, surveillance intervals are shortened to every 3 to 4 days. With elevation of the DV Doppler index to less than 2 SD, testing frequency is increased to every 2 to 3 days. Further escalation of the DV Doppler index may require daily testing, and inpatient admission may be prudent based on local practice. Any change in maternal condition, especially the development of preeclampsia, calls for reassessment of fetal status irrespective of the last examination result (Fig. 33-21).

### TIMING OF DELIVERY

In the absence of definitive fetal therapy, proper timing of delivery is often the critical management issue when dealing with the growth-restricted fetus. In principle, the decision for delivery always weighs fetal risks against risks that can be anticipated as a result of delivery. The risks of prematurity are of primary concern and make management of the preterm growth-restricted fetus particularly challenging. Typically, the decline in neonatal mortality is greatest between 24 and 28 weeks, whereas morbidity declines progressively thereafter toward 32 weeks. Although surprisingly few randomized management studies address the issue of delivery timing in IUGR, the Growth Restriction Intervention Trial (GRIT) clarified several important points.<sup>78</sup> This prospective multicenter study randomized more than 500 women with complicating FGR into immediate versus delayed delivery when their managing physicians were unsure about the timing of delivery. In the conservatively managed group, delivery was delayed until a point when their managing obstetricians were no longer unsure about the need to deliver or when fetal testing became overtly normal. With a median delay of 4.5 days, no significant differences in short-term outcome were identified

between the two groups (Table 33-4). The perinatal mortality with early delivery was associated with a higher rate of neonatal deaths, whereas delaying delivery increased the risk for stillbirth. Delivery timing also had little effect on neurodevelopment at 2 years of age. However, in the subset of fetuses delivered before 32 weeks, a trend toward poor neurodevelopment was primarily attributable to neonatal complications that occurred as a result of prematurity. In 2010, Walker and colleagues<sup>79</sup> reported on the 6- to 13-year GRIT study outcomes and found the two groups to be similar for cognitive, language, behavior, and motor ability (half of original cohort). This suggests that neurologic impairment may already be set by the time the fetus with IUGR reaches the point of delivery. Other observational studies have also addressed the impact of gestational age on perinatal morbidity. In prenatally identified growth-restricted fetuses, the effect of gestational age overshadows all other perinatal variables. After 27.0 weeks, when survival and intact survival first exceed 50%, a birthweight below 550 g is associated with a high risk for neonatal death.<sup>80,81</sup> It appears that fetal deterioration of venous Doppler parameters begins to have an independent impact on neonatal survival from 28 weeks onward as postpartum morbidities become less frequent with advancing gestation.<sup>72</sup> Gestational age is also an important factor affecting perinatal mortality in patients who remain undelivered. More recent data from the Trial of Randomized Umbilical and Fetal Flow in Europe (TRUFFLE) study<sup>82</sup> confirm the trend of improved outcome with advancing gestational age. This was a randomized clinical trial of delivery of severely growth-restricted fetuses based on either FHR monitoring, early DV changes, or late DV changes (absent or reversed a-wave; see Fig. 33-14). In contrast to prior studies, the neonatal outcomes are significantly better, which has been attributed to a standardized management approach and improvement of neonatal care in the last decade.<sup>83</sup> A recently published 2-year follow-up study showed that

| IUGR UNLIKELY   |  |   |
|---|--|---|
| Normal AC, AC growth rate and HC/AC ratio<br>UA, MCA Doppler, BPS, and AFV normal   | Asphyxia extremely rare<br>low risk for intrapartum distress   | Deliver for obstetric or maternal factors only, follow growth                         |

**FIG 33-21** Integrated fetal testing and management protocol. The management algorithm for pregnancies complicated by intrauterine growth restriction (IUGR) is based on the ability to perform arterial and venous Doppler as well as a full five-component biophysical profile score (BPS). AC, abdominal circumference; AFV, amniotic fluid volume; A/REDV, absent/reversed end-diastolic velocity; CPR, cerebroplacental ratio; DV, ductus venosus; HC, head circumference; MCA, middle cerebral artery; NST, nonstress test; NICU, neonatal intensive care unit; tid, three times daily; UA, umbilical artery. (From Baschat AA, Hecher K. Fetal growth restriction due to placental disease. *Semin Perinatol.* 2004;28:67.)

**liveborn fetuses delivered on the basis of late DV changes (absent or reversed a-wave) demonstrated a reduction in neuroimpairment.**<sup>84</sup>

Frigoletto has previously emphasized that the majority of fetal deaths in IUGR occur after the 36th week of gestation and before the onset of labor. The Disproportionate Intrauterine Growth Intervention Trial at Term (DIGITAT) randomized trial<sup>85</sup> illustrates that neonatal morbidity is still a concern until 38 weeks' gestation. For these reasons, a definite delivery indication other than the presence of suspected growth delay is required prior to 38 weeks' gestation.<sup>85</sup> One limitation of the DIGITAT trial was a lack of UA and MCA Doppler assessment or integration in the study.

These investigations illustrate several points that are of critical importance in the management of pregnancies complicated by IUGR today. Patients need to be aware that growth-restricted fetuses have different viability thresholds and neonatal risk

statistics than their appropriately grown counterparts. The major risk for the undelivered growth-restricted fetus is progression of hypoxemia to acidemia and stillbirth. Delivery is therefore typically indicated when the risk for these complications is high or there is no added benefit from prolongation of pregnancy. In the preterm growth-restricted fetus, **the risk for acidemia and stillbirth is highest when repetitive late decelerations are observed in association with oligohydramnios and/or anhydramnios, when the BPP is below 6, when the DV Doppler index elevation escalates beyond 3 SDs, or when reversal of the DV a-wave is observed with accompanying umbilical venous pulsations.** In the growth-restricted fetus beyond 37 weeks, risks of unanticipated stillbirth increase when brain sparing, loss of heart rate reactivity, or a decrease in the AFV are observed.<sup>15</sup> A recent study from the Washington University group<sup>86</sup> demonstrated that although the overall risk of stillbirth is low in fetuses beyond 37 weeks, an increase in stillbirth risk

Data from The GRIT study group. A randomised trial of timed delivery for the compromised preterm fetus: short term outcomes and Bayesian interpretation. *BJOG*. 2003;110:27; and Thornton JG, Hornbuckle J, Vail A, et al; The GRIT study group: Infant well-being at 2 years of age in the Growth Restriction Intervention Trial (GRIT): multicentred randomized trial. *Lancet*. 2004;364:513.

occurs with each advancing week for ongoing pregnancies. Thus they recommend delivery of the IUGR fetus at 37 to 38 weeks. The study is limited by its retrospective nature and that the growth-restricted fetuses that died in utero may not have been identified and followed with Doppler or antenatal testing.

### General Considerations

Surveillance and management considerations are most challenging in preterm pregnancies, which places the highest demand on the accuracy of fetal testing before 34 weeks' gestation. Once FGR is suspected or anticipated, appropriate fetal testing and daily maternal assessment of fetal activity should be instituted. Ultrasound examinations to assess fetal growth should be scheduled every 2 to 4 weeks. As long as studies show continued fetal head growth and testing results remain reassuring, no intervention is required. An understanding of the strengths and limitations of individual surveillance tests in this context is important. The NST and fetal dynamic variables (fetal breathing, movement, and tone) provide assurance of fetal well-being at the time of testing. Because the traditional NST is frequently nonreactive in preterm fetuses, it is often inadequate as a stand-alone test of fetal well-being. A combination of UA Doppler and a five-component BPP are the surveillance tests of choice in preterm growth-restricted fetuses that circumvent this limitation of the NST alone. In the presence of UA end-diastolic velocity, normal AFV, and a normal BPP, weekly testing is sufficient. Testing frequency is adjusted according to fetal status with strict criteria for delivery as indicated above. In preterm growth-restricted fetuses in which timing of delivery is most critical, the combination of multiple modalities, including arterial and venous Doppler, offers the most comprehensive approach to assess fetal well-being.<sup>61,87</sup> Such integrated fetal testing is suggested for centers experienced with the performance of these studies. In the preterm growth-restricted fetus who presents before 34 weeks' gestation, consideration should always be given to administration of steroids if necessary, with continuous FHR monitoring and oxygen supplementation. Beyond 34 weeks' gestation, an amniocentesis to assess lung maturity to direct timing of

delivery should be considered. Delivery at 38 weeks is an option that should be discussed in all pregnancies complicated by SGA because of the difficulties in accurately identifying fetal deterioration at this gestational age. Even with optimal management, there may be a yet undefined background morbidity that is predetermined by the condition and not amenable to treatment.

The following recommendations regarding the timing of delivery of the SGA fetus are made with the understanding that these guidelines are primarily based on retrospective studies, registries, and expert opinion; definitive randomized clinical studies are otherwise lacking or inconclusive. These guidelines are consistent with those produced by the American College of Obstetricians and Gynecologists (ACOG).

### Between 24 and 29 Weeks' Gestation

Between 24 and 27 weeks' gestation, a growth-restricted fetus is periviable, and interventions are typically undertaken for maternal conditions such as severe preeclampsia. Thresholds for fetal indications should be high, which requires strong evidence of fetal compromise and risk of stillbirth. Management is frequently individualized, and a multidisciplinary approach is helpful in stressing that outcome may be poor even with maximal support in the neonatal intensive care unit (NICU). Parents need to be aware that despite maximum management and effort, perinatal mortality exceeds 50%.<sup>80,81</sup> Based on retrospective studies, 29 weeks' gestation may be an important milestone to reach. Gestational age appears to be the strongest predictor of intact survival until 29 weeks, and 94% of perinatal mortality has been reported to occur prior to 29 weeks' gestation.<sup>80,88</sup> Delivery triggers can be considered to be any one or a combination of FHR tracing with decelerations, BPP of 4 or less, or reverse a-wave in the ductus venosus, a marker of fetal acidemia.

### Between 29 and 34 Weeks' Gestation

Fetal indications for delivery should be based on firm evidence of fetal compromise with an attempt to complete a course of antenatal corticosteroids whenever possible. Indications may include any one or combination of FHR tracing with decelerations, BPP of 4 or less, or absent or reverse a-wave in the ductus venosus.

### Between 34 and 37 Weeks' Gestation

Between 34 and 37 weeks' gestation, lower delivery thresholds are acceptable and may include absent fetal growth (in particular arrested head growth), oligohydramnios, documented lung maturity on amniocentesis, Doppler evidence of accelerating disease, and maternal comorbidity.

### Beyond 37 Weeks

If an SGA fetus has continued appropriate interval growth, normal Doppler studies, normal AFV, normal antepartum testing, and no maternal comorbidities, this may represent a normal or constitutionally small fetus. Delivery may be accomplished between 38 to 39 weeks' gestation.

## DELIVERY

The premature growth-restricted fetus requires the highest level of NICU care; therefore predelivery transport to an appropriate institution is recommended in all cases of early-onset IUGR.

**Because many growth-restricted infants suffer intrapartum asphyxia, intrapartum management demands continuous FHR monitoring. In principle the route of delivery is determined by the severity of the fetal and maternal condition, along with other obstetric factors.** Cesarean delivery without a trial of labor is indicated when the risks of vaginal delivery are unacceptable to the mother and fetus. These circumstances include prelabor evidence of fetal acidemia, spontaneous late decelerations, or late decelerations with minimal uterine activity. In addition, absent and reversed end-diastolic flow in the UA is associated with a high incidence of fetal intolerance of labor. Thus cesarean delivery is often required and should be considered for these severely growth-restricted fetuses. In the instance of less abnormal fetal test results, typically in the setting of a more advanced gestational age, selection of the route of delivery is based on the Bishop score, AFV, and difficulty anticipated in inducing labor. The presence of IUGR has been considered a relative contraindication to the use of prostaglandin for cervical preparation by some authors. If cervical ripening is considered, preinduction oxytocin challenge testing may be helpful in determining the likelihood and safety of vaginal delivery. Pharmacologic or mechanical ripening of the cervix, coupled with labor in the left lateral decubitus position with supplemental oxygen, increases the likelihood of a successful vaginal delivery. During labor, a tracing without late decelerations is predictive of a good outcome in cases complicated by IUGR. However, **with late decelerations, the incidence of asphyxia in growth-restricted infants is far greater than in normally grown infants.**

## OUTCOME

IUGR can transiently and/or permanently impair neonatal well-being. The potential effects of this condition at birth and from complications that occur in the neonatal period have been most extensively studied. However, additional effects of this perinatal period on intermediate and long-term health are starting to emerge. Recently, a new area of research into the fetal origin of maternal diseases has also pointed out how exposure to a hostile intrauterine environment can be a predisposing factor for the development in adulthood of cardiovascular diseases and endocrine disturbances (see Chapter 5). An understanding of these outcomes will become important when the focus of management strategies shifts from the prevention of fetal and neonatal morbidity to the improvement of intermediate- and long-term development. Studies that examine the relationship between FGR and postdelivery outcomes are therefore best separated into those that focus on short-term outcomes and those that focus on long-term outcomes.

## Short-Term Outcomes

Initial reports that evaluated the association between FGR and neonatal morbidity suggested the possibility of a protective effect of IUGR, with reduced occurrence of RDS and IVH. Subsequent studies do not support these early assumptions. No differences were found in indices of fetal lung maturity and the frequency of the need for ventilator support comparing gestational age-matched SGA and AGA fetuses. Most recently, several large trials suggest that RDS, necrotizing enterocolitis (NEC), IVH, clotting disorders, and multiorgan failure are significantly more likely to occur in growth-restricted neonates.<sup>89,90</sup> Mortality rates are uniformly higher when IUGR is present. These data

should put to rest the notion that FGR is associated with any reduction in newborn illness. Additional neonatal morbidities that must be anticipated include meconium aspiration, hypoglycemia, and electrolyte abnormalities.

**Meconium aspiration** occurs more frequently in IUGR than in appropriately grown infants and is largely observed after 34 weeks. Gasping in utero in response to asphyxia appears to contribute to this problem. Historically, careful suctioning of the nasopharynx and oropharynx with the DeLee catheter at delivery was used to decrease the incidence of this complication; however, more recent data show that this is not the case. Clearing of the airway can be accomplished at delivery by direct laryngoscopy and aspiration by an experienced pediatrician. **To effect immediate attention to the many potential neonatal problems, appropriate pediatric support should be present in the delivery room when an infant suspected of being growth restricted is to be delivered.**

**Hypoglycemia** is frequently observed in growth-restricted infants owing to their inadequate glycogen reserves and a gluconeogenic pathway that is less sensitive to hypoglycemia than that of the normally grown infant.<sup>89</sup> In anticipation of this risk for hypoglycemia, frequent blood glucose monitoring should be instituted in all growth-restricted infants. **Hypocalcemia**, another well-recognized problem in IUGR, may be the result of relative hypoparathyroidism, a result of intrauterine acidosis.

Hyperphosphatemia secondary to tissue breakdown may also contribute. Frequent calcium monitoring is essential because symptoms are nonspecific and are similar to those associated with hypoglycemia.

Hyponatremia that results from impaired renal function is also frequently reported in growth-restricted infants. The renal complications associated with IUGR may be attributed to asphyxia, which can produce central nervous system injury and can lead to inappropriate antidiuretic hormone (ADH) secretion.<sup>89</sup>

Neonates with growth restriction are at risk for polycythemia, anemia, thrombocytopenia, and complex hematologic derangements that may be problematic well beyond delivery.<sup>10</sup> **Polycythemia** is observed three to four times more frequently in the growth-restricted infant than in weight-matched controls. Polycythemia results from hypoxia-stimulated production of red blood cells (RBCs) and from transfer of blood volume from the placental to the fetal circulation in the face of intrauterine asphyxia. Thus these infants produce more RBCs that are shunted to them if hypoxia occurs during labor. Polycythemia leads to increased RBC breakdown, accounting in part for the high incidence of **hyperbilirubinemia** in these infants. Polycythemia is a criterion for, but does not necessarily lead to, hyperviscosity, which can result in capillary bed sludging and thrombosis. Multiple organ systems can be affected and can lead to pulmonary hypertension, cerebral infarction, and NEC. Anemia can be observed in preterm fetuses with growth restriction with markedly abnormal placental blood flow studies, and thrombocytopenia frequently accompanies the anemia. The risk for thrombocytopenia is increased more than tenfold if UA end-diastolic velocity is absent. The cause for these abnormalities could involve a combination of dysfunctional erythropoiesis coupled with placental consumption of platelets and RBCs. Neonates with such complex hematologic abnormalities are frequently unable to sustain their blood cell counts despite repeated substitution of blood products.

**Hypothermia** is another common problem for the growth-restricted infant and results from decreased body fat stores secondary to intrauterine malnourishment.<sup>89</sup> If unrecognized and untreated, hypothermia can contribute to the metabolic deterioration of an already unstable growth-restricted infant.

Finally, growth-restricted neonates are at increased risk for perinatal death in light of the multiple complications that may arise in the fetal and neonatal periods. The range of reported perinatal mortality is variable but depends clearly on the level of perinatal management received: infants who received optimal intrapartum and neonatal management have a lower perinatal mortality than age-matched controls who did not have such intensive care.<sup>90</sup>

### Long-Term Outcomes

Following delivery, the ultimate growth potential for growth-restricted infants appears to be good. The degree of catch-up growth observed in several longitudinal studies suggests that **these infants can be expected to have normal growth curves and a normal, albeit slightly reduced size as adults.** In an 8-year follow-up study of children who weighed less than 1500 g at birth,<sup>91</sup> 75% of growth-restricted infants achieved a height and weight above the 10th percentile. Of infants whose birthweight fell below the 3rd percentile, 60% had reached the 25th percentile for weight at 8 years. However, 50% of the children with small HCs still had HCs below the 10th percentile at the 8-year follow-up visit in spite of their growth in height and weight.<sup>91</sup> Others observed that growth-restricted infants experienced a period of catch-up growth in early infancy but remained near the 25th percentile through age 47 months, and infants with birthweights less than 1250 g remained below the third percentile for height and weight at 1 year in 38% to 46% of cases, respectively.<sup>92</sup> In general, those infants who suffered growth restriction near the time of delivery do tend to catch up. However, those neonates with earlier onset and more longstanding growth restriction in utero continue to lag behind.

The issue of long-term neurologic sequelae remains unresolved. In 1972, Fitzhardinge and Steven<sup>93</sup> evaluated a group of 96 growth-restricted infants and noted that 50% of males and 36% of females had poor school performance and, overall, 25% had minimal cerebral dysfunction. Major neurologic deficits were much less frequent. Other studies have shown low birthweight and short gestation to be risk factors for cerebral palsy. However, **the vast majority of children with cerebral palsy were not growth restricted.**

The positive effect of intrapartum surveillance for the growth-restricted fetus is reflected in the data of Low and colleagues.<sup>94</sup> In a study of 88 growth-restricted infants, they reported no severe neurologic sequelae. They did detect a lag in mental development that was significant in the growth-restricted babies when compared with appropriately grown controls, especially in the group with birthweights less than 2300 g. This study correlates well with other data on LBW babies, showing that **growth-restricted infants with HCs below the 10th percentile have two to three times the number of serious neurologic sequelae of their normocephalic counterparts.** Others have found that term infants with IUGR and HCs less than 2 SD below the mean had significantly poorer performance on intelligence and visual motor development testing at age 7 when compared with their control siblings.<sup>95</sup> In an examination of 7-year-olds who suffered no perinatal complications despite IUGR and who were matched for social class with a control

group, Walther showed an increase in teacher-identified hyperactivity, poor concentration, and clumsiness. In a study of school performance in 8-year-olds matched for socioeconomic status, Robertson and colleagues demonstrated a tendency toward hyperactivity in preterm growth-restricted children compared with control groups. Low and colleagues<sup>96</sup> have shown that in 9- to 11-year-olds, only FGR and socioeconomic status contributed independently to the presence of learning deficits. Intrapartum fetal asphyxia assessed by UA base deficit was not associated with learning deficits in this group of children.

Few studies have related neurodevelopment to a full complement of antenatal surveillance parameters. A study of predominantly preterm growth-restricted infants that evaluated 2-year developmental outcomes reported **gestational age at delivery, birthweight, and reversal of UA end-diastolic velocity as the main determinants of motor and neurosensory morbidity.** Interestingly, fetal deterioration of venous Doppler or biophysical parameters did not have a statistical impact on neurodevelopment.<sup>97</sup>

The pattern that emerges from evaluation of these data emphasizes that **neurologic outcome depends on the degree of growth restriction, especially the impact on head growth, its time of onset, the gestational age of the infant at birth, and the postnatal environment.** An early intrauterine insult between 10 and 17 weeks' gestation could limit neuronal cellular multiplication and would obviously have a profound effect on neurologic function. In the third trimester, brain development is characterized by glial multiplication, dendritic arborization, establishment of synaptic connections, and myelination—all of which continue during the first 2 years of life. Recovery after a period of impaired growth in the third trimester is therefore more likely to occur. Thus **the preterm appropriately grown infant has more normal neurologic development and fewer severe neurologic deficits than its preterm growth-restricted counterpart.** Developmental milestones and neurologic development of mature infants with IUGR and mature infants of normal birthweight are similar. Presumably, this also reflects heightened physician awareness of the growth-restricted infant that allows detection, appropriate antepartum management, intrapartum therapy, and early pediatric intervention. The premature growth-restricted infant suffers from increased susceptibility to intrauterine asphyxia and all of the neonatal complications of the premature infant in addition to those of the infant with IUGR. **If growth restriction is associated with lagging head growth before 26 weeks, even mature infants have significant developmental delay at 4 years of age.**

The long-term impacts at age 6 to 13 years of age were reported for the GRIT study. In the absence of any specific delivery triggers, the cognitive development was identical in both groups. In summary, these findings are concerning, which emphasizes the fact that the intrauterine environment has significant impact on neurodevelopment *before* management issues at delivery arise and, accordingly, it is unlikely that intervention trials will demonstrate a large impact of delivery timing on neurodevelopment.<sup>97</sup>

**Gestational programming of growth-restricted fetuses has received considerable attention over the past 10 to 15 years. Infants born growth restricted have an increased risk of metabolic syndrome, obesity, hypertension, diabetes, and stroke from coronary artery disease. For a more in-depth review of fetal programming and long-term adult outcomes from IUGR, the reader is referred to Chapter 5.**

## KEY POINTS

- ◆ Although the terms IUGR, FGR, and SGA are used interchangeably, IUGR and FGR identify pathologically small fetuses, whereas SGA indicates a fetus below a specific cutoff without designation of pathology.
- ◆ IUGR is a major cause of perinatal morbidity, perinatal mortality, and both short-term and life-long morbidities.
- ◆ Although IUGR is currently defined by fetal size alone, the four primary underlying etiologies—aneuploidy, viral infection, nonaneuploid syndromes, and placental insufficiency—produce quite different outcomes.
- ◆ Identification of growth restriction as a result of placental insufficiency requires a comprehensive diagnostic workup that includes measurement of the fetal abdominal circumference in combination with umbilical artery Doppler studies, exclusion of fetal anomalies, and possibly invasive testing to detect aneuploidy and viral infection.
- ◆ The combination of a small abdominal circumference, normal anatomy, low or normal amniotic fluid volume, and abnormal umbilical artery Doppler is strongly suggestive of placental insufficiency.
- ◆ Because mortality resulting from fetal growth restriction can be reduced with appropriate antenatal surveillance, all pregnancies at risk for IUGR should be carefully monitored.
- ◆ Deterioration of fetal biophysical and cardiovascular parameters follows a relatively predictable pattern, progressing from early to late changes that can be used for the prediction of fetal acid-base imbalance and the risk for stillbirth.
- ◆ Antenatal surveillance in preterm IUGR requires the combination of several testing modalities to provide fetal assessment of sufficient precision to guide intervention.
- ◆ In preterm gestations complicated by IUGR, the threshold for delivery is critically influenced by gestational age.

## NOMENCLATURE

Exposure to foreign red cell antigens invariably results in the production of anti-red cell antibodies in a process known as *red cell alloimmunization*, formerly termed *isoimmunization*. The expression *sensitization* can be used interchangeably with *Rhesus alloimmunization*. The active transport of

these antibodies across the placenta during pregnancy results in fetal anemia, hyperbilirubinemia, and ultimately hydrops fetalis. Before the advent of obstetric ultrasound, the perinatal effects of maternal red cell alloimmunization could be recognized only after birth in the affected neonate. Thus the neonatal consequences of maternal red cell alloimmunization came to be known as *hemolytic disease of the newborn* (HDN). Because the peripheral blood smear of these infants demonstrated a large percentage of circulating immature red cells known as *erythroblasts*, the newborn entity was also known as *erythroblastosis fetalis*. Today, ultrasound and fetal blood sampling (FBS) make the detection of the severely anemic fetus a reality. For this reason, **the term *hemolytic disease of the fetus and newborn* (HDFN) would appear more appropriate to describe this disorder.**

## HISTORIC PERSPECTIVES

The first case of HDFN was probably described by a midwife in 1609 in the French literature: a twin gestation in which the first fetus was stillborn and the second twin developed jaundice and died soon after birth.<sup>1</sup> In 1932, Diamond<sup>2</sup> proposed that the clinical entities of erythroblastosis fetalis, icterus gravis neonatorum, and hydrops fetalis represented different manifestations of the same disease. Seven years later, Levine and Stetson<sup>3</sup> described an antibody in a woman who gave birth to a stillborn fetus. The patient experienced a severe hemolytic transfusion reaction after later receiving her husband's blood. In 1940, Landsteiner and Weiner<sup>4</sup> injected red blood cells from rhesus monkeys into rabbits. The antibody isolated from these rabbits was used to test human blood samples from whites, and agglutination was noted in 85% of individuals. The following year Levine and colleagues<sup>5</sup> were able to demonstrate a causal relationship between Rhesus D (RhD) antibodies in RhD-negative women and HDFN in their offspring.

The advent of therapy for HDFN began in 1945 with the description by Wallerstein<sup>6</sup> of the technique of neonatal exchange transfusion. Later Liley<sup>7</sup> proposed the use of amniotic fluid bilirubin assessment as an indirect measure of the degree of fetal hemolysis. Sir William Liley's major contribution to the story of rhesus disease was the introduction of the fetal intraperitoneal transfusion (IPT).<sup>8</sup> He learned from a visiting fellow who had returned from Africa that the infusion of red blood cells into the peritoneal cavity of children with sickle-cell disease produced normal-appearing red blood cells on peripheral blood smear. Liley realized that he had previously inadvertently entered the peritoneal cavity of fetuses at the time of amniocentesis, based on the marked contrast in the yellow hue of the ascitic fluid as compared with amniotic fluid. He postulated that purposeful entry into the fetal peritoneal cavity could be accomplished. After three unsuccessful attempts that resulted in fetal demises, the fourth fetus was delivered at 34<sup>1/7</sup> weeks' gestation after undergoing two successful IPTs. Early attempts at IPT used fluoroscopy for needle guidance. With the introduction of real-time ultrasound in the early 1980s, IPT became a safer procedure as fluoroscopy was abandoned. Charles Rodeck<sup>9</sup> is credited with the first intravascular fetal transfusion (IVT) using a fetoscope to guide the transfusion needle into a placental plate vessel. Just 1 year later, investigators in Denmark performed the first ultrasound-guided IVT using the intrahepatic portion of the umbilical vein.<sup>10</sup>

The 1990s saw the introduction of genetic techniques using amniocentesis to determine fetal red cell typing.<sup>11</sup> The turn of the century brought the noninvasive detection of fetal anemia through Doppler ultrasound of the fetal middle cerebral artery (MCA) and the use of fetal typing through cell-free DNA in maternal plasma.<sup>12,13</sup>

## INCIDENCE

**The advent of the routine administration of antenatal and postpartum rhesus immune globulin (RhIG) has resulted in a marked reduction in cases of red cell alloimmunization secondary to the RhD antigen.** The Centers for Disease Control and Prevention (CDC) last required the reporting of rhesus alloimmunization as a medical complication of pregnancy on U.S. birth certificates in the year 2002.<sup>14</sup> In that year, the most recent for which epidemiologic data are available, the incidence was reported to be 6.7 cases of rhesus alloimmunization per 1000 live births.

**Clearly, a shift to other red cell antibodies associated with HDFN has occurred as a result of the decreasing incidence of RhD alloimmunization.** In a series of over 8000 pregnant patients between 2007 and 2011, a positive screen for an antibody associated with HDFN was found in 1.2% of samples.<sup>15</sup> Anti-E was the most common antibody encountered; RhD antibody accounted for only 19% of the significant antibodies (Fig. 34-1).

## PATHOPHYSIOLOGY

Although the placenta was once thought to be an absolute barrier to the transfer of cells between the maternal and fetal compartments, we now appreciate that the placental interface allows for the bidirectional movement of both intact cells and free DNA. The putative "grandmother theory" of rhesus red cell alloimmunization probably occurs more commonly than first

**FIG 34-1** Incidence of maternal anti-red cell antibodies associated with hemolytic disease of the fetus and newborn (HDFN) at a tertiary care institution between 2007 and 2011. E, M, D, K, and C are antibodies. (Modified from Smith HM, Shirey RS, Thoman SK, Jackson JB. Prevalence of clinically significant red blood cell alloantibodies in pregnant women at a large tertiary care facility. *Immunohematology*. 2013;29:127-130.)

thought. In this paradigm, maternal RhD-positive red cells gain access to the circulation of the RhD-negative fetus at the time of delivery. **As many as one fourth of RhD-negative babies have been shown to be immunized in early life as a result of their delivery.**<sup>16,17</sup> The immune response of an Rh-negative individual to RhD-positive red cells has been characterized into one of three groups: (1) responders, (2) hyporesponders, and (3) nonresponders. About 60% to 70% of individuals are *responders* who develop an antibody to relatively small volumes of red cells; in these individuals, the probability of immunization increases with escalating volumes of cells. A small percentage of responders can be called *hyperresponders* in that they will be immunized by very small quantities of red cells. The second group of individuals (10% to 20%), *hyporesponders*, can be immunized only by exposure to very large volumes of cells. Finally, the 10% to 20% of individuals who remain appear to be *nonresponders*.

**In most cases of red cell alloimmunization, a fetomaternal hemorrhage (FMH) occurs in the antenatal period or, more commonly, at the time of delivery.** If a maternal ABO blood type incompatibility exists between the mother and her fetus, anti-A and/or anti-B antibodies lyse the fetal cells in the maternal circulation and destroy the RhD antigen.<sup>18,19</sup> Even if this protective effect is not present, **only 13% of deliveries of RhD-positive fetuses result in RhD alloimmunization in RhD-negative women who do not receive RhIG.** The vast majority of RhD-alloimmunized women produce an immunoglobulin G (IgG) response as their initial antibody. *Responders* may represent a group of individuals who had their initial exposure to the RhD antigen at birth because of FMH.<sup>17</sup> After a sensitizing event, the human antiglobulin anti-D titer can usually be detected after 5 to 16 weeks. However, approximately half of alloimmunized patients are *sensitized*. In this scenario, an antibody screen will be negative, but memory B lymphocytes are present that can create an anti-D antibody response. When faced with the challenge of a subsequent pregnancy involving an RhD-positive fetus, the anti-D titer becomes detectable.

The anti-D immune response is the best characterized of the anti-red cell antibodies associated with HDFN. In one third of cases, only subclass IgG1 is produced; in the remainder of cases, a combination of IgG1 and IgG3 subclasses is found.<sup>20</sup> **Anti-D IgG is a nonagglutinating antibody that does not bind complement. This results in a lack of intravascular hemolysis; sequestration and subsequent destruction of antibody-coated red cells in the fetal liver and spleen are the mechanism of fetal anemia.** Most studies have not detected a relationship between a specific maternal human leukocyte antigen (HLA) type and susceptibility to become alloimmunized to RhD.<sup>21</sup> However, sensitized women with high titers of anti-D are more likely to exhibit the DQB1\*0201 and DR17 alleles compared with women who have low titers.<sup>22</sup> Fetal sex may also play a significant role in the fetal response to maternal antibodies. **RhD-positive male fetuses are 13 times more likely than their female counterparts to become hydropic and are 3 times more likely to die of their disease.**<sup>23</sup>

Anemia results in several important physiologic changes in the fetus. Reticulocytosis from the bone marrow can be detected by FBS once the hemoglobin deficit exceeds 2 g/dL compared with norms for gestational age; erythroblasts are released from the fetal liver once the hemoglobin deficit reaches 7 g/dL or greater.<sup>24</sup> In an effort to increase oxygen delivery to peripheral tissues, fetal cardiac output increases and 2-3 diphosphatidylglycerol (DPG) levels are enhanced.<sup>25,26</sup> Tissue hypoxia appears as anemia progresses despite these physiologic changes. An increased umbilical artery lactate level is noted when the fetal hemoglobin falls below 8 g/dL, and increased venous lactate can be detected when the hemoglobin level falls below 4 g/dL.<sup>27</sup> **Hydrops fetalis, the accumulation of extracellular fluid in at least two body compartments, is a late finding in cases of fetal anemia. Its exact pathophysiology is unknown.** Enhanced hepatic erythropoietic function with subsequent depressed synthesis of serum proteins has been proposed as the explanation for the lower serum albumin levels that have been detected.<sup>28</sup> Colloid osmotic pressure appears decreased.<sup>29</sup> However, experimental animal models in which fetal plasma proteins have been replaced with saline did not produce hydrops.<sup>30</sup> An alternative hypothesis is that tissue hypoxia due to anemia enhances capillary permeability. In addition, iron overload due to ongoing hemolysis may contribute to free radical formation and endothelial cell dysfunction.<sup>31</sup> Central venous pressures do appear elevated in the hydropic fetus with HDFN. This may cause a functional blockage of the lymphatic system at the level of the thoracic duct as it empties into the left brachiocephalic vein.<sup>29</sup> This theory is supported by reports of poor absorption of donor red cells infused into the intraperitoneal cavity in cases of hydrops.<sup>32</sup>

## RHESUS ALLOIMMUNIZATION AND FETAL/NEONATAL HEMOLYTIC DISEASE OF THE NEWBORN

### Genetics

Initial concepts on the genetics of the Rh antigens proposed the presence of three distinct genes.<sup>33</sup> Newer DNA techniques have allowed for the localization of the Rh locus to the short arm of chromosome 1.<sup>34</sup> **Only two genes were identified, an *RHD* gene and an *RHCE* gene.** Each gene is 10 exons in length with 96% homology. These genes presumably represent a duplication of a common ancestral gene. Production of two distinct proteins

**FIG 34-2** Schematic of Rh gene locus on chromosome 1. The homozygous RhD-positive state, heterozygous RhD-positive state, RhD-negative with heterozygosity for the *Rhd* pseudogene, and RhD-negative with heterozygosity for the *RHCCdes* gene are demonstrated. (Modified from Moise KJ. Hemolytic disease of the fetus and newborn. In Creasy RK, Resnik R, Iams J, eds. *Maternal-Fetal Medicine: Principles and Practice*, ed 5. Philadelphia: Elsevier; 2004.)

from the *RHCE* gene probably occurs as a result of alternative splicing of messenger RNA.<sup>35</sup> One nucleotide difference, cytosine to thymine, in exon 2 of the *RHCE* gene results in a single amino acid change of a serine to proline. This causes the expression of the *C* antigen as opposed to the *c* antigen.<sup>36</sup> A single cytosine-to-guanine change in exon 5 of the *RHCE* gene, producing a single amino acid change of a proline to alanine, results in formation of the *e* antigen instead of the *E* antigen.

The gene frequency found in different ethnic groups can be traced to the Spanish colonization in the fifteenth and sixteenth centuries. Populations native to certain land masses have a less than 1% incidence of RhD negativity—Eskimos, Native Americans, Japanese, and Chinese individuals. The Basque tribe in Spain is noted to have a 30% incidence of Rh negativity. This may well be the origin of the *RHD* gene deletion that is the most common genetic basis of the RhD-negative state in whites (Fig. 34-2). Whites of European descent exhibit a 15% incidence of RhD negativity, whereas an 8% incidence is found in blacks and Hispanics of Mexico and Central America. This latter incidence probably reflects ethnic diversity secondary to Spanish colonization of the New World.

Further study of the *RHD* gene has revealed significant heterogeneity. Several of these genetic modifications result in a lack of expression of the RhD phenotype. Although these individuals may have an aberrant RhD gene present, serologic methods do not detect the RhD antigen on the surface of the red cells. One such example is the *RHD* pseudogene, which has been found in 69% of South African blacks and 24% of American blacks (see Fig. 34-2).<sup>37</sup> In this situation, all 10 exons of the *RHD* gene are present. However, translation of the gene into a messenger RNA (mRNA) product does not occur owing to the presence of a stop codon in the intron between exons 3 and 4. Thus, no RhD protein is synthesized, and the patient is serologically RhD

negative. Similarly, the *RHCcdes* gene has been detected in 22% of American blacks. It appears to contain exons 1, 2, 9, and 10 as well as a portion of exon 3 of the original *RHD* gene, with other exons being duplicated from the *RHCE* gene. In the Taiwanese population of RhD-negative individuals, five different exons of the *RHD* gene were evaluated.<sup>38</sup> Seventeen percent of individuals had all five exons detected, and an additional 135 demonstrated the presence of at least one of the five exons tested.

## PREVENTION OF RhD HEMOLYTIC DISEASE IN THE FETUS AND NEWBORN

### History

The history of rhesus prophylaxis can be traced to three unique individuals. Vincent Freda was an obstetric resident who developed an interest in HDFN.<sup>39</sup> He was allowed to spend part of the fourth year of his residency at Columbia Presbyterian Medical Center in the laboratory of Alexander Weiner, one of the first investigators to identify the “Rh factor.” When Freda returned to Columbia, he went on to establish a serology laboratory and later organized the Rh Antepartum Clinic in 1960. A seat on the hospital transfusion committee became vacant, and in an unprecedented move based on his interest, the chairman of obstetrics and gynecology, Howard C. Taylor, Jr., appointed Freda to this position even though he had not completed his residency. The chairman of pathology responded with the appointment of John Gorman to the committee, a resident in pathology with an interest in blood banking. It is here that these two individuals met and developed the collaboration that would one day end in the introduction of RhIG. In 1906, Theobald Smith<sup>40</sup> found that guinea pigs given excess passive antibody failed to become immunized to diphtheria toxin. Freda and Gorman proposed that anti-D could be used in a similar fashion to prevent alloimmunization after delivery. They enlisted the aid of William Pollack, a senior protein chemist at Ortho Diagnostics, who developed an IgG globulin fraction from high-titered donor plasma. An initial grant application to the National Institutes of Health was rejected; however, funding was secured from the New York City Health Research Council on a second attempt. This was followed by a year’s negotiations with lawyers in the state capital to allow the investigators to perform their clinical trials at the Sing Sing prison in New York beginning in 1961 (John Gorman; personal communication, 2009). Nine RhD-negative male volunteers were injected monthly with RhD-positive cells for five successive months.<sup>41</sup> Four of the men were immunized with intramuscular RhIG 24 hours before the injection of the red cells. Four of the five controls became alloimmunized to RhD, whereas none of the treated individuals developed anti-RhD antibodies. Their second experiment involved 27 inmates at Sing Sing, 13 controls and 14 treated. Red cells were given intravenously. However, the warden of Sing Sing would not allow the investigators to return on any fixed schedule that would enable the prisoners to know the time and day of their revisit. He was concerned that this exact foreknowledge could involve the prisoners in an escape plan. The investigators gladly accepted this limitation as they reasoned that pregnant women who delivered over a weekend would probably not receive RhIG until Monday, up to 72 hours after delivery, owing to the closure of blood banks on weekends, as was commonly practiced at the time. None of the men who received RhIG were alloimmunized, whereas 8 of 13 controls developed anti-RhD antibodies. After two additional experiments at Sing Sing in this

second group of individuals, Freda and Gorman<sup>41</sup> went on to conduct a clinical trial in postpartum women at Columbia Presbyterian Medical Center starting in March of 1964. Of the 100 patients that received RhIG, none became sensitized, as compared with a rate of 12% sensitization to RhD in the control group. In a follow-up study in these patients in their next pregnancy, none of the treated patients developed antibodies; 5 of 10 controls were alloimmunized and delivered infants affected by HDFN.

A parallel track of investigation was being undertaken by a group of British researchers in Liverpool. This group reasoned that the natural protective effect of ABO incompatibility between a mother and her fetus in preventing the formation of anti-D antibody could be used as a preventative strategy. A preparation of plasma that contained anti-D IgM was formulated and was administered intravenously to male volunteers.<sup>42</sup> Although initial short-term antibody studies were promising, eventually 8 of 13 treated men became immunized to RhD, compared with only 1 of 11 controls. After the publication of the initial work of Freda and colleagues<sup>43</sup> describing the use of a gamma globulin fraction of the plasma, the British group visited the New York investigators and obtained a sample of their gamma globulin preparation. The Liverpool group<sup>44</sup> began their clinical trial in postpartum women with evidence of FMH by Kleihauer-Betke (KB) stain in April 1964, and they were subsequently credited for the first publication of a successful clinical trial in women.

An observational trial in Canada was initiated and determined that the baseline rate of antenatal sensitization to RhD was 1.8%.<sup>45</sup> Between 1968 and 1974, a trial of antenatal prophylaxis using injections of 300 µg of RhIG at 28 and 34 weeks’ gestation followed. As compared with the previous observational study, none of the women demonstrated the development of anti-D antibodies. In a subsequent investigation that involved RhIG administered only at 28 weeks’ gestation, only 0.18% of women became sensitized.

In 1968, RhIG was approved by the Division of Biologics Standards of the National Institutes of Health for general clinical use in the United States as RhoGAM (Ortho-Clinical Diagnostics, Inc.). **Recommendations for use during the immediate postpartum period were set forth by the American College of Obstetricians and Gynecologists (ACOG)<sup>46</sup> in 1970. The Food and Drug Administration (FDA) approved the use of antenatal RhIG in 1981. Routine antenatal prophylaxis at 28 to 29 weeks’ gestation was proposed by ACOG later that same year.<sup>47</sup>**

### Preparations

**Four polyclonal products derived from human plasma are currently available in the United States for the prevention of RhD alloimmunization.** Two of the products (RhoGAM [Kedron Biopharma] and HyperRho S/D [Grifols USA]) can only be given intramuscularly because they are derived from human plasma through Cohn cold ethanol fractionation, a process that results in contamination with IgA and other plasma proteins. The remaining two products (WinRho-SDF, [Can-gene Corporation] and Rhophlac [CSL Behring]) are prepared through sepharose column and ion-exchange chromatography, respectively. At present, all available products are subject to solvent detergent treatment to inactivate enveloped viruses; many manufacturers also use an additional micropore filtration step to further reduce the chance for viral contamination.

Additionally, thimerosal, a mercury preservative used to prevent bacterial and fungal contamination, has been removed from all RhIG products used in the United States.

The dwindling resource of plasma donors for RhIG manufacture has led to the search for a synthetic product. Several monoclonal anti-D antibodies and a synthetic polyclonal immune globulin consisting of 25 recombinant anti-D antibodies have been developed but are still being studied in human clinical trials. In the future, one of these products may replace the current polyclonal products derived from human plasma.

## Indications

**All pregnant patients should undergo determination of blood type and an antibody screen at the first prenatal visit.** In the past, all Rh negative patients underwent additional testing to see if they were *Du positive*. This terminology was later changed to classify these patients as *weak Rh positive* individuals. In one series of 500 pregnant patients, this occurred in 1% of whites, 2.6% of blacks, and 2.7% of Hispanics.<sup>48</sup> The recommendation in the past was that these individuals should be considered Rh positive, and RhIG was not indicated.<sup>48</sup> Subsequent research found that the *weak D* individuals can belong to one of two groups; some of these patients have intact D antigens that are expressed in reduced numbers on the surface of the red cells (Fig. 34-3). These individuals are *not* at risk for rhesus alloimmunization. **In others with a weak D phenotype, the individual has inherited a gene that results in a variant expression of the D antigen. In these cases, one or more of the D antigen epitopes are missing, and the patient can become alloimmunized to these missing portions of the D antigen. Severe HDFN has been reported in these cases when a maternal antibody develops to the missing epitope.<sup>49</sup> Although clinical trials have not been undertaken, the current recommendation is that these patients should receive RhIG.**

Confusion can arise depending on when and where the patient undergoes red cell typing. Standards from the American Association of Blood Banks (AABB) recommend that reagents that detect weak D should *not* be used for prenatal typing.<sup>50</sup> This guideline results in all weak D patients being called Rh negative and subsequently receiving antenatal RhIG. Newer monoclonal

reagents used in an indirect antiglobulin test that can detect weak D are used at blood donor centers. These reagents are used to be sure that weak D blood is not administered to an Rh-negative recipient, resulting in a potential for alloimmunization. This will result in the same individual, now a blood donor, being called *RhD positive*—very confusing to the patient and to the clinician.

More recently, a work group of the AABB and the College of American Pathologists has suggested that weak D types 1, 2, and 3 can be managed as if they are RhD positive with no need for RhIG.<sup>51</sup> *RHD* genotyping would be required in all pregnant patients to identify this subgroup with weak D. This proposal has not yet been adopted by ACOG.

**If there is no evidence of anti-D alloimmunization in the RhD-negative woman, the patient should receive 300 µg of RhIG at 28 weeks of gestation.<sup>48</sup>** The 2% background incidence of RhD alloimmunization in the antenatal period can be expected to decline to 0.1%. In the United Kingdom, an antenatal protocol of administering 100 µg (500 IU) of RhIG at 28 and 34 weeks is used in primigravida women.<sup>52</sup> Limited resources have not allowed for extension of this protocol to all subsequent pregnancies. The issue of repeating an antibody screen at 28 weeks before the administration of RhIG is controversial. A recent study of over 2000 women found an incidence of sensitization prior to 28 weeks' gestation to occur in only 0.099% of pregnancies.<sup>53</sup> In addition, the authors of this study did not find the practice to be cost-effective. Although ACOG leaves the decision to repeat the antibody screen up to the obstetric provider, the AABB and the U.S. Preventative Services Task Force recommend that a repeat screen be obtained before antenatal RhIG.<sup>50,54</sup> If a repeat antibody screen is to be undertaken, a maternal blood sample can be drawn at the same office visit as the RhIG injection. Although the administration of the exogenous anti-D will eventually result in a weakly positive titer, this will not occur in the short interval of several hours due to the slow absorption from the intramuscular site.

A new paradigm is developing in antenatal prophylaxis. Early studies in pregnant women carrying a male fetus indicated that 3% of the circulating cell-free fetal DNA (ccfDNA) in the maternal circulation in the first trimester is fetal in origin; this increases to 6% by the third trimester.<sup>55</sup> The source of this DNA appears to be apoptosis of placental villi. Fetal DNA is rapidly cleared from the maternal circulation with a mean half-life of 16 minutes after cesarean delivery; after vaginal delivery, fetal free DNA is cleared by 100 hours.<sup>56,57</sup> The presence of fetal *RHD* DNA sequences in the maternal circulation was first reported by Lo and colleagues.<sup>13</sup> Clinical assays for the determination of the fetal RhD status were subsequently developed. Approximately 40% of Rh-negative pregnant women will carry an Rh-negative fetus; thus rhesus immune globulin would not be indicated in the antepartum period if this can be accurately determined.

Screening of RhD-negative pregnant patients to determine whether antepartum RhIG should be undertaken is routinely now practiced in Denmark and the Netherlands as well as in regions of Sweden, France, and England.<sup>58</sup> In some of these situations, ccfDNA screening was implemented as part of a new antepartum prophylaxis program because of the limited availability of RhIG. However, in the United States, plasma collected from sensitized male volunteer donors is used to manufacture RhIG. Therefore the availability of RhIG is unrestricted. Others

\*A = high, B = moderate, C = low.

have argued that the potential for infection with prions and other viruses supports an ethical approach to limiting antenatal RhIG to only those patients who need it.<sup>59</sup> A cost-neutral strategy would appear to be the optimal approach to the implementation of ccfDNA. Several studies have determined that the break-even costs of ccfDNA testing would range from \$29 to \$119 for the saved doses of RhIG to offset the costs of evaluating all RhD-negative pregnant women.<sup>60,61</sup> In addition, even at an accuracy of 99%, as many 3000 patients in the United States would be misdiagnosed with an RhD-negative fetus, when the fetus is actually RhD positive. These cases would result in missed opportunities for the prevention of antenatal alloimmunization and an estimated 21 new cases of Rh alloimmunization annually. Continuation of the practice of obtaining cord serology at birth would allow these “misses” to be correctly diagnosed at the time of delivery when postpartum RhIG is indicated. Currently, the use of ccfDNA to guide antenatal RhIG use is not a guideline from any major U.S. organization, although this may change in the near future.

**Although not well studied, level A scientific evidence has been cited by ACOG to address additional indications for the antepartum administration of RhIG.<sup>48</sup> These include spontaneous miscarriage, elective abortion, ectopic pregnancy, genetic amniocentesis, chorionic villus sampling, and FBS (Table 34-1).** A dose of 50 µg of RhIG is effective until 13 weeks' gestation owing to the small volume of red cells in the fetoplacental circulation. However, most hospitals and offices do not stock this dose of RhIG because the cost is equivalent to that of the standard dose of 300 µg.

The use of RhIG in other scenarios that involve the possibility of FMH are lacking. However, most experts agree that such events as hydatidiform mole, threatened miscarriage, fetal death in the second or third trimester, blunt trauma to the abdomen, and external cephalic version warrant strong consideration for the use of RhIG.<sup>48</sup>

**The practice of evaluating a persistent maternal anti-D titer as an indication that additional RhIG is not required after an antenatal event is to be discouraged.** Although the precise mechanism for the protective effect of RhIG is unknown, an excess amount of exogenous antibody in relation to the volume of RhD-positive red cells in the maternal circulation is essential for effective prophylaxis. Both animal and human studies have demonstrated that a low level of RhIG can actually enhance the chance for alloimmunization.<sup>18</sup> In the words of Vincent Freda, “The rule of thumb should be to administer Rh immune globulin when in doubt, rather than to withhold it.”

Because the half-life of RhIG is approximately 16 days, 15% to 20% of patients receiving it at 28 weeks' gestation have a very low anti-D titer (usually 2 or 4) at the time of admission for labor at term.<sup>62</sup> In North America, the current recommendation is to administer 300 µg of RhIG within 72 hours of delivery if umbilical cord blood typing reveals an RhD-positive infant.<sup>50</sup> This is sufficient for protection from sensitization due to an FMH of 30 mL of fetal whole blood. In the United Kingdom, 100 µg is given at delivery. Approximately 1 in 1000 deliveries will be associated with an excessive FMH; risk factors identify only 50% of these cases.<sup>63</sup> **Both ACOG and AABB now recommend routine screening of all women at the time of delivery for excessive FMH.** A qualitative yet sensitive test for FMH, the *rosette test*, is first performed. Results return as positive or negative; a negative result warrants administration of a standard 300 µg dose of RhIG. If the rosette is positive, a KB stain or fetal cell stain using flow cytometry is undertaken to quantitate the amount of the FMH. The AABB then recommends that the percentage of fetal blood cells be multiplied by a factor of 50 (to account for an estimated maternal blood volume of 5000 mL) to calculate the volume of the FMH. This volume is divided by 30 to determine the number of vials of RhIG to be administered. A decimal point is rounded up or down for values greater than 0.5 or less than 0.5, respectively. Because this calculation includes an inaccurate estimation of the maternal blood volume, one additional vial of RhIG is added to the calculation. As an example, a 3% KB stain is calculated to indicate a 150-mL FMH. Dividing this number by 30 yields five vials of RhIG with one additional vial added; therefore the blood bank would prescribe 6 vials of RhIG (a total of 1800 µg) for this patient. However, a recent survey by the American College of Pathologists of its member blood banks noted that even following these guidelines, an inadequate dose of RhIG was recommended in 9% of cases and an excessive dose was recommended in 12% of cases.<sup>64</sup>

No more than 5 mL RhIG should be administered by the intramuscular route in one 24-hour period. Should a large dose of RhIG be necessary, an alternative method would be to give the calculated dose using one of the intravenous (IV) preparations of RhIG now available. Doses of up to 600 µg (3000 IU) can be administered every 8 hours until the total dose has been achieved. **Should RhIG be inadvertently omitted after delivery, some protection has been proven with administration within 13 days; recommendations have been made to administer it as late as 28 days after delivery.<sup>63</sup>** If delivery is planned within 48 hours of amniocentesis for fetal lung maturity, RhIG can be deferred until after delivery. **If delivery occurs less than 3 weeks from the administration of RhIG used for antenatal indications such as external cephalic version, a repeat dose is unnecessary unless a large FMH is detected at the time of delivery.<sup>50</sup>**

Failed prophylaxis after the appropriate dose of RhIG is administered is rare. However, once postpartum administration is undertaken, the anti-D antibody screen may remain positive for up to 6 months. Anti-D that persists after this time is likely to be the result of sensitization.

Administration of RhIG after a postpartum tubal ligation is controversial. The possibility of a new partner in conjunction with the availability of in vitro fertilization would seem to make the use of RhIG in these situations prudent. In some cases, RhD-negative red cells may be in short supply if the patient presents after major trauma such as a motor vehicle accident with the need for massive transfusion. In these cases, RhD-positive blood could not be used as a life-saving alternative if the patient is alloimmunized to RhD through her previous delivery. RhIG is not effective once alloimmunization to the RhD antigen has occurred. At present, prophylactic immune globulin preparations to prevent other forms of red cell alloimmunization such as anti-K1 do not exist.

## Diagnostic Methods

### Maternal Antibody Determination

**Once a maternal antibody screen reveals the presence of an anti-D antibody, a titer is the first step in the evaluation of the RhD-sensitized patient during the first affected pregnancy.** Previous titer methodologies using albumin or saline should no longer be used because they detect varying levels of IgM antibody. The pentamer structure of this class of antibody does not allow for transplacental passage; therefore, the contribution of IgM to the titer quantitation has no clinical relevance. **The human antiglobulin titer** (indirect Coombs test) **is used to determine the degree of alloimmunization because it measures the maternal IgG response.** Most titer values in the obstetric literature are reported as dilutions (e.g., 1:32). By blood-banking convention, however, titer values should be reported as the reciprocal of the last tube dilution that demonstrates a positive agglutination reaction, that is, a final dilution of 1:16 is equivalent to a titer of 16.

Variation in results between laboratories is not uncommon because many commercial laboratories use enzymatic treatment of red cells to prevent failed detection of low titer samples. This method causes a marked elevation in titer as compared with the use of nonenzymatic treated cells. Because standard tube methodology uses red cell agglutination as the indicator reaction, subjective interpretation of end points by the laboratory technologist accounts for the variation in results. In addition, inherent subtle differences in the indicator red cell preparations may play a role because their shelf life is only 1 month, and serial titers may require the use of different reagent lots. For these reasons, serial titers should be run in tandem using stored sera from the previous draw.

In the same laboratory, the titer should not vary by more than one dilution if the two samples are run in tandem. Thus an initial titer of 8 that returns at 16 does not represent a true increase in the amount of antibody in the maternal circulation. In addition, the clinician should be aware that newer gel micro-column assays will result in higher titers than conventional tube testing. In one study, the mean titer was 3.4-fold increased with gel technology.<sup>65</sup> **A critical titer is defined as the anti-red cell titer associated with a significant risk for hydrops fetalis.** When this is present, further fetal surveillance is warranted. This value will vary with institution and methodology; however, in

**most centers, a critical titer for anti-D between 8 and 32 is usually used.**

In the United Kingdom, quantitation of anti-D is undertaken through the use of an automated technique using a device known as the *AutoAnalyzer*. Red cell samples are mixed with agents to enhance agglutination by the anti-D antibodies. Agglutinated cells are separated from nonagglutinated cells and are then lysed. The amount of released hemoglobin is then compared with an international standard; results are reported as international units per milliliter. Levels of less than 4 IU/mL are rarely associated with HDFN; a maternal anti-D level of less than 15 IU/mL has been associated with only mild fetal anemia.<sup>66</sup>

### Fetal Blood Typing

**Several techniques have been used to determine the fetal blood type if the patient's partner is determined to be heterozygous for the involved red cell antigen. In 50% of cases in which the fetus is found to be antigen negative, further maternal and fetal testing is unnecessary.** Historically, initial attempts at fetal testing in these cases used serology on blood obtained by ultrasound-directed cordocentesis. Unfortunately, this technique placed half of the antigen-negative fetuses at a 1% to 2% chance of procedure-related loss (see Chapter 10). Investigators went on to use chorionic villus sampling to obtain genetic material for detection of the *RHD* gene. However, the major disadvantage of this method is that disruption of the chorion villi during the procedure can result in FMH and a rise in maternal titer, thereby worsening the fetal disease.<sup>67</sup> Therefore this procedure should be discouraged unless the patient plans to terminate all antigen-positive fetuses detected. In 1990, amniocentesis was described as a reliable method for assessing the fetal blood type through DNA testing.<sup>11</sup> **This method has now been replaced in almost all countries, including the United States, by the use of fetal *RHD* determination using cffDNA.** In addition, the test can be performed with reliable results as early as 10 weeks' gestation.<sup>68</sup>

**The initial step in determining the fetal RhD type involves an assessment of paternity and paternal zygosity.** Once undertaken using serologic testing and population statistics, molecular techniques can now be used to accurately determine the paternal genotype at the *RHD* locus.<sup>69</sup> However, some authorities have argued that issues with paternity can be averted by omitting this step and testing every pregnancy with cffDNA for fetal *RHD* determination.

**In a recent series of more than 1000 patients, cffDNA testing for *RHD* was found to be accurate in 99% of cases.**<sup>70</sup>

An *RHD* positive result on free DNA testing can be considered reliable because *RHD* positive genetic material cannot be from a maternal source. An RhD-negative result with cffDNA is more problematic. If fetal DNA fails to amplify in a background of overwhelming maternal DNA in the plasma, an *RHD* negative result will be obtained. One internal control that can be used is the detection of the *SRY* gene found in male fetuses. The presence of this gene in free DNA indicates that fetal DNA is present, and an *RHD* negative result is reliable.<sup>62</sup> In the case of a female fetus, the presence of single nucleotide polymorphisms (SNPs) not found in the maternal white cells can be used as an internal control.<sup>71</sup> If different polymorphisms than those found in the mother are noted in the plasma sample, these are of paternal origin; thus fetal DNA is present. In this situation, the finding of an *RHD* negative fetus can be considered reliable. **In the cases with an inconclusive result, a repeat maternal**

sample can be submitted or amniocentesis can be undertaken to determine the fetal *RHD* status.

### Amniocentesis to Follow the Severity of Hemolytic Disease of the Fetus and Newborn

Historically, amniocentesis was routinely used in the alloimmunized pregnancy to measure the amount of bilirubin ( $\Delta OD_{450}$ ) as an indirect indication of the degree of fetal hemolysis. Results were plotted on specialized curves first introduced by William Liley<sup>71</sup> and later modified by John Queenan.<sup>72</sup> **The advent of noninvasive testing for fetal anemia with middle cerebral artery MCA Doppler (see below) has now replaced serial amniocenteses for  $\Delta OD_{450}$ .**

### Fetal Blood Sampling

Ultrasound-directed FBS—also known as *percutaneous umbilical blood sampling*, *cordocentesis*, and *funipuncture*—allows direct access to the fetal circulation to obtain important laboratory values such as fetal blood type, hematocrit, direct Coombs test, reticulocyte count, and total bilirubin. Although serial FBS was once proposed as a primary method of fetal surveillance after a maternal critical titer is reached, it has been associated with a 1% to 2% rate of fetal loss and up to a 50% risk for FMH with subsequent worsening of the alloimmunization.<sup>73</sup> For these reasons, **FBS is reserved for patients with elevated peak systolic MCA Doppler velocities.**

### Ultrasound

**Perhaps the greatest advance in the management of the alloimmunized pregnancy has been the use of ultrasound.** Gestational age can be accurately established to evaluate fetal parameters that vary with gestational age such as the peak systolic MCA Doppler velocities. *Hydrops fetalis* is defined as the presence of extracellular fluid in at least two fetal compartments. Often, ascites is the first sign of impending hydrops, with scalp edema and pleural effusions noted with worsening anemia. **When hydrops is present, fetal hemoglobin deficits of 7 to 10 g/dL from the mean hemoglobin value for the corresponding gestational age can be expected.**<sup>74</sup> Unfortunately, this represents the end-stage state of fetal anemia. Survival with intrauterine transfusion (IUT) is markedly reduced in these cases. In addition, **the early second-trimester fetus can be severely anemic without signs of hydrops.**<sup>75</sup> Therefore many investigators have sought alternative ultrasound parameters that could predict the early onset of anemia. In one large series, fetal abdominal circumference (AC), head/abdomen circumference (HC/AC) ratio, intraperitoneal volume, intrahepatic and extrahepatic umbilical venous diameter, and placental thickness failed to accurately predict a fetal hemoglobin deficit of greater than 5 g/dL from the mean.<sup>76</sup> Because the fetal liver and spleen represent sites of extramedullary hematopoiesis and the destruction and sequestration of sensitized red cells in cases of severe HDFN, enlargement of these organs has been evaluated. Both splenic perimeter and hepatic length correlate with the degree of fetal anemia. However, neither has gained widespread acceptance for noninvasive fetal surveillance in red cell alloimmunization.

**The severely anemic fetus exhibits an increased cardiac output in an effort to enhance oxygen delivery to peripheral tissues.**<sup>26</sup> In addition, fetal anemia is associated with a lower blood viscosity that produces fewer shearing forces in blood vessels; this results in increased blood velocities. Using these principles, **Doppler ultrasound has been used to study the**

**FIG 34-4** Power Doppler image of the fetal circle of Willis. Arrows point to locations where the pulsed Doppler gate should be placed for obtaining the fetal peak middle cerebral artery Doppler velocity.

**FIG 34-5** Pulsed Doppler of the peak systolic velocity. The blue arrow at the top of figure indicates the location of the pulsed Doppler gate; the white arrow indicates the measurement using on-board software of a peak velocity of 56.25 cm/sec.

**peak systolic velocity (PSV) in the fetal MCA to predict fetal anemia. A value of greater than 1.5 multiples of the median (MoM) for the corresponding gestational age predicts moderate to severe fetal anemia with a sensitivity of 88% and a negative predictive rate of 89%.<sup>12</sup>**

**Serial MCA Doppler studies are now the mainstay of surveillance for fetal anemia in the red cell alloimmunized pregnancy.** Careful attention to technique is paramount in using this method of surveillance. Because the anteroposterior axis of the fetal head typically lies in a transverse plane, the examiner can use either fetal MCA vessel for interrogation. First, the anterior wing of the sphenoid bone at the base of the skull is located. Color or power Doppler is then used to locate the MCA (Fig. 34-4). The angle of insonation is maintained as close to zero as possible by positioning the ultrasound transducer on the maternal abdomen (Figs. 34-5 and 34-6). The MCA vessel closer to the maternal abdominal wall is usually studied, although the posterior vessel will give equivalent results.<sup>77</sup> Angle-correction software is not typically used, although studies have demonstrated that its use can still result in an accurate determination of the MCA velocity.<sup>78</sup> The Doppler gate is then placed in the proximal MCA where the vessel arises from the carotid siphon. Measurements in the more distal aspect of the vessel will be

**FIG 34-6** Correct determination of the fetal peak middle cerebral artery Doppler velocity.

**FIG 34-7** Serial middle cerebral artery (MCA) Doppler studies in one patient who required intrauterine transfusion (IUT). Hct, hematocrit; MoM, multiples of the median.

inaccurate because reduced peak velocities will be obtained. The fetus should be in a quiescent state during the Doppler examination because accelerations of the fetal heart rate can result in a decrease in the PSV, especially late in the third trimester.<sup>79</sup> Several authorities have reported transient decreases in the peak MCA velocity after the administration of antenatal steroids to enhance fetal lung maturity. This effect usually lasts for 24 to 48 hours after the last dose.

MCA measurements can be obtained reliably as early as 18 weeks' gestation. Studies are repeated every 1 to 2 weeks depending on the trend (Fig. 34-7). Values should be converted to MoM using Internet-based calculators (e.g., [www.perinatology.com](http://www.perinatology.com)).

## CLINICAL MANAGEMENT

The approach using the available diagnostic tools is based on the patient's history of fetal or neonatal manifestations of HDFN. **As a general rule, the patient's first RhD-sensitized pregnancy involves minimal fetal/neonatal disease; but subsequent gestations are associated with worsening degrees of anemia.**

## First Affected Pregnancy

Once sensitization to the RhD antigen is detected, maternal titers are repeated every month until approximately 24 weeks; titers are repeated every 2 weeks thereafter (Fig. 34-8). If paternity is assured, blood is drawn from the patient's partner to determine his *RHD* status and zygosity (DNA testing). Once a critical maternal titer is reached (usually 32), serial MCA Doppler studies are initiated at approximately 24 weeks' gestation. These are then repeated every 1 to 2 weeks depending on their trend. In cases of a heterozygous paternal phenotype or questionable paternity, cffDNA testing should be sent to a DNA reference laboratory to determine the fetal RhD status. In the case of an RhD-negative paternal blood type or a fetal *RHD* negative genotype, further maternal and fetal monitoring is unwarranted as long as paternity is assured.

If presence of an *RHD* positive fetus is evident (homozygous paternal phenotype or *RHD* positive fetus by DNA testing), serial fetal surveillance is indicated. If an MCA Doppler returns at greater than 1.5 MoM, cordocentesis should be undertaken at an experienced referral center, with blood readied for IUT if the fetal hematocrit is less than 30%.

## Previously Affected Fetus or Infant

If the patient has a history of a previous perinatal loss related to HDFN, a previous need for IUT, or a previous need for neonatal exchange transfusion, she should be referred to a tertiary care center with experience in the management of the severely alloimmunized pregnancy. In these cases, maternal titers are *not* predictive of the degree of fetal anemia. In the case of a heterozygous paternal phenotype or questionable paternity, cffDNA analysis to determine the fetal *RHD* status is indicated. Amniocentesis can be used after 15 weeks' gestation to determine the status of the fetal red cell antigen in cases of other maternal antibodies such as anti-Kell. Serial MCA Doppler measurements should begin at 18 weeks' gestation and should be repeated every 1 to 2 weeks.

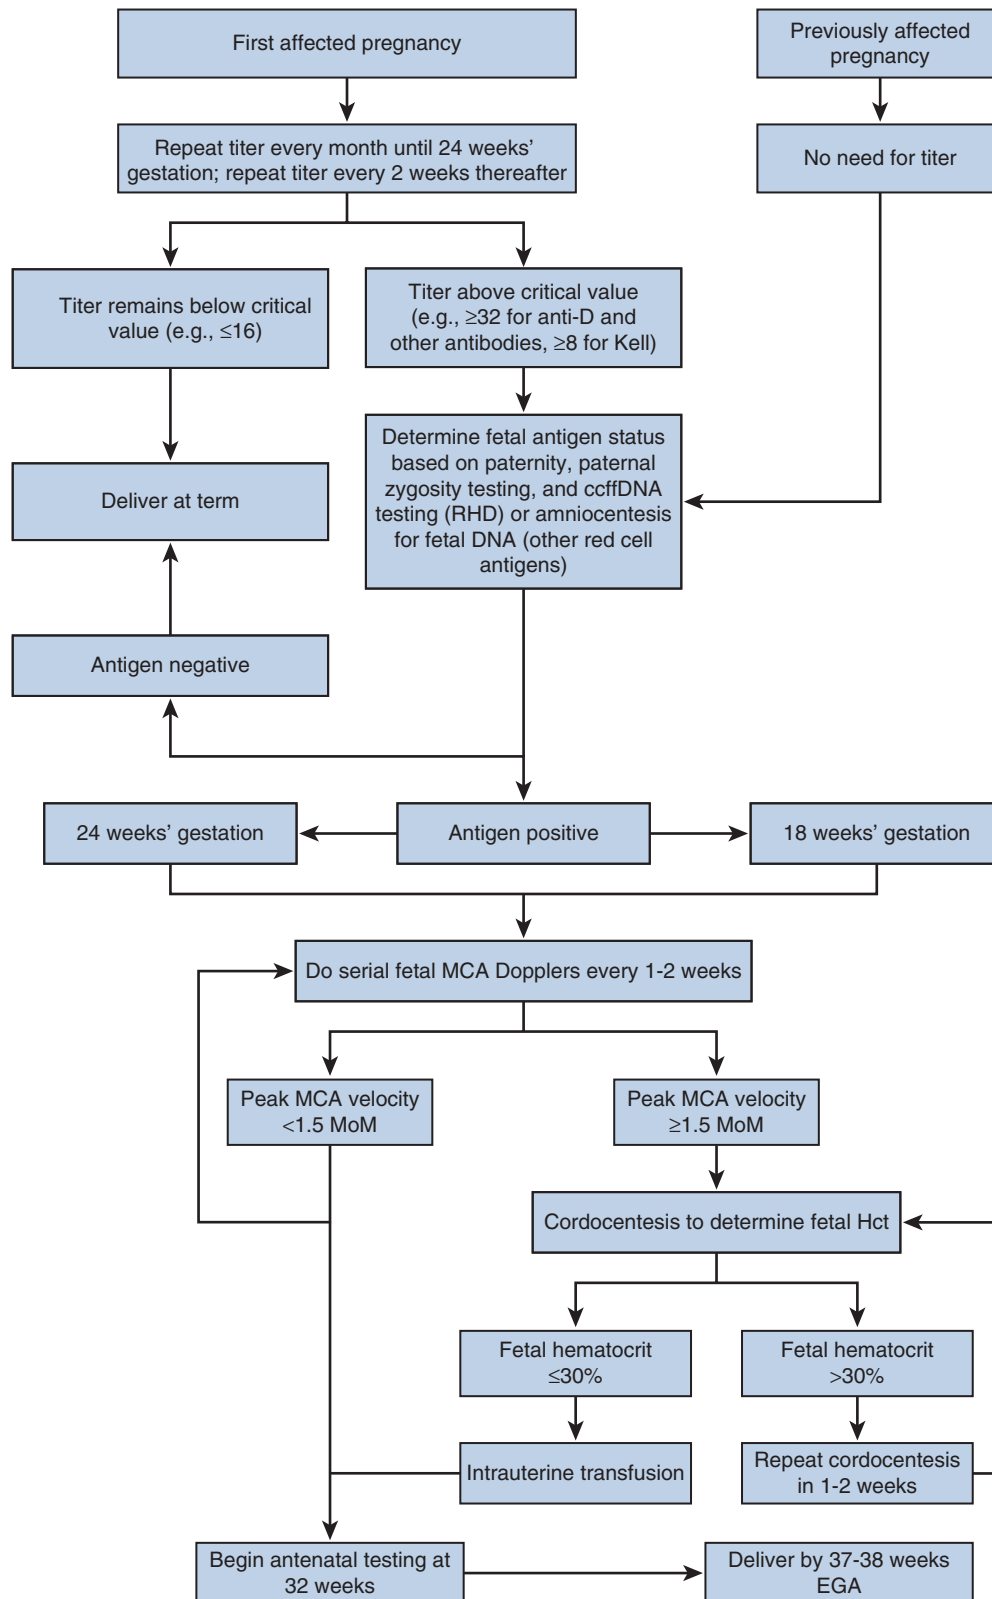

## INTRAUTERINE TRANSFUSION

### Technique

IUTs today are performed under continuous ultrasound guidance with direct infusions of red blood cells into the umbilical cord vessels or into the intrahepatic portion of the umbilical vein of the fetus.<sup>80</sup> Some centers continue to use the intraperitoneal approach as part of a combined technique with an intravascular transfusion (IVT) in an effort to create a reservoir of red cells between procedures.<sup>81</sup>

Typically, a freshly donated, cytomegalovirus (CMV)-negative unit of type O, RhD-negative red blood cells is cross-matched to a maternal blood sample. Extended cross-matching to the mother can decrease the chance of new antibody formation. The unit is leukoreduced and irradiated with 25 Gy to prevent graft-versus-host reaction. It is then washed and packed to a final hematocrit of approximately 75% to 80% to prevent volume overload in the fetus.

The patient is admitted to the labor and delivery unit as an outpatient. The procedure is typically performed in the operating room, especially when a viable gestational age has been reached should an emergency delivery be necessary. The skin is prepped with hexachlorophene, and sterile drapes are applied. A long-acting local anesthetic is administered, and conscious sedation may help alleviate the patient's anxiety. A 20-gauge

**FIG 34-8** Algorithm for clinical management of a patient with red cell alloimmunization. EGA, estimated gestational age; Hct, hematocrit; MCA, middle cerebral artery; MoM, multiples of the median.

procedure needle (a 22-gauge needle is used for gestations <22 weeks) is introduced into the amniotic cavity and then into the umbilical vein under continuous ultrasound guidance. In the case of an anterior placenta, the needle is passed through the placental mass into the cord root. With a posterior placentation, the cord insertion into the placenta is preferred because this represents a site of immobility compared with a “floating” loop of cord. A sample of fetal blood is obtained for an initial hematocrit. Optimally, the sample is processed as a spun hematocrit or through the use of an automated hemocytometer located in the operating room. A short-term paralytic agent such as vecuronium (0.01 mg/kg of estimated fetal weight [EFW]) is administered into the umbilical vein, causing cessation of fetal movement. A short-acting narcotic such as fentanyl (2 to 3 µg/kg EFW) can also be used and can be mixed with the vecuronium.<sup>82</sup> Paralysis is almost immediate and lasts 2 to 3 hours. The amount of packed red blood cells to be infused is based on the EFW determined by ultrasound. Using a donor unit hematocrit of 78%, a factor of 0.02 multiplied by the EFW in grams will calculate the dose of red cells to be administered to raise the fetal hematocrit by 10%.<sup>83</sup> Red cells are actively infused through the use of a syringe and sterile tubing connected to the donor unit. Once the predetermined volume of blood is infused, a small aliquot of blood is obtained to measure the hematocrit, as well as the percentage of fetal versus adult hemoglobin-containing red cells, through either a KB stain or flow cytometry. A final fetal hematocrit of 40% is targeted. After the first IUT, subsequent procedures can be empirically scheduled at 14-day intervals until suppression of fetal erythropoiesis is noted. This usually occurs by the third IUT. Thereafter, the interval for repeat procedures can be determined based on the decline in hematocrit for the individual fetus, usually a 3- to 4-week interval. **The PSV in the MCA has been shown to be useful in timing the second IUT.** After the second procedure, the MCA Doppler loses its validity in predicting fetal anemia, perhaps due to the changing rheology of the transfused adult red cells that make up the majority of the fetal red mass after serial IUTs.<sup>84</sup> The final IUT procedure is usually not performed past 35 weeks' gestation, and the patient is scheduled for delivery approximately 3 weeks later. The administration of oral phenobarbital (30 mg tid) for 10 days prior to delivery has been shown in one retrospective study to decrease the need for neonatal exchange transfusions for hyperbilirubinemia by 75%.<sup>85</sup>

**Severely anemic fetuses in the early second trimester do not tolerate the acute correction of their hematocrit to normal values.**<sup>86</sup> In these situations, the initial hematocrit should not be increased by more than fourfold at the time of the first procedure. A repeat IUT is then performed within 48 hours to correct the fetal hematocrit into the normal range.<sup>87</sup>

## Complications and Outcome

**Complications from IUT are uncommon.** The total procedure-related perinatal loss was 3.8% of fetuses and 1.2% of procedures in one series of over 300 procedures.<sup>88</sup> Survival after IUT varies with the center, its experience, and the presence of hydrops fetalis. **An overall survival rate of 91% has been reported in one series of over 1400 procedures.**<sup>89</sup> The presence of fetal hydrops, particularly if this does not resolve after several IUTs, has been associated with a lower rate of perinatal survival.<sup>90</sup> Preterm premature rupture of the membranes (PPROM) and chorioamnionitis occur rarely. Fetal bradycardia is usually

transient, particularly when there is inadvertent puncture of the umbilical artery, and responds to removal of the procedure needle. Progression to fetal distress with the need for emergency delivery increases with advancing gestation and may complicate as many as 5% of procedures after 32 weeks' gestation.<sup>91</sup>

## Neonatal Transfusions

The practice of prolonging the gestation of the treated fetus with HDFN until near term has resulted in a virtual absence of the need for neonatal exchange transfusions. Typically, these infants are born with a virtual absence of reticulocytes with a red cell population that consists mainly of transfused red cells. The blood bank may be confused if cord blood at delivery is submitted for neonatal red cell typing—the neonate will be typed as O, RhD-negative, reflecting the antigen status of the donor blood used for the IUTs. Elevated levels of circulating maternal antibodies in the neonatal circulation in conjunction with suppression of the fetal bone marrow production of red cells often results in the need for neonatal red cell “top-up” transfusions after discharge from the nursery; this occurs in approximately 50% of infants near 1 month of age.<sup>92</sup> **Therefore these children should be followed weekly with hematocrits and reticulocyte counts until recovery of hematopoietic function is evident.** Typically, only one neonatal transfusion is required, although a maximum of up to three has been reported. Supplemental iron therapy in these infants is unnecessary because they have excess levels of stored iron due to previous hemolysis in utero and lysis of red cells from the IUTs. Supplemental folate therapy (0.5 mg/day) should be considered.

## Neurologic Outcome

Going forward, more data should be available to counsel the patient regarding long-term neonatal outcomes because fetuses with severe anemia and hydrops are likely to survive today secondary to the use of IUTs. **A study of almost 300 children treated with IUTs for HDFN found an overall incidence of neurodevelopmental impairment of 4.8%.**<sup>93</sup> Severe hydrops was associated with an elevenfold increase in neurologic problems.

Elevated levels of bilirubin have been associated with hearing loss in the neonate. Therefore, newborn screening for hearing loss would appear to be warranted in children with HDFN. Follow-up screening at 1 and 2 years of age should be considered.

## OTHER TREATMENT MODALITIES

Before the advent of the IUT, maternal plasmapheresis represented one of the few therapeutic modalities for severe HDFN. Most literature reports include single cases or relatively small case series. Despite these limitations, a review<sup>94</sup> of the published cases reveals a perinatal survival rate of 69%. Intravenous immune globulin (IVIG) has also been used effectively as the sole antenatal treatment for HDFN. Hydrops fetalis was less likely to occur, and the onset of anemia occurred later in pregnancies treated with IVIG. **Some experts have proposed a combined approach in patients with a previous perinatal loss in the early second trimester when technical limitations make the success of IUT unlikely.**<sup>95</sup> Plasmapheresis is started at 12 weeks' gestation and repeated three times in that week. The maternal titer should be expected to be reduced by 50%.

IVIg is then given to replace the globulin fraction removed by plasmapheresis in the form of a 2 g/kg loading dose after the third plasmapheresis; this is followed by 1 g/kg/week of IVIg until 20 weeks' gestation.

### FUTURE THERAPEUTIC OPTIONS

Patients with high anti-red cell titers and recurrent perinatal loss in the second trimester have few options other than artificial insemination with red cell antigen-negative donor semen, surrogate pregnancy, or preimplantation diagnosis (if the father is heterozygous). **Peptides associated with the proliferation of T-helper cells in the development of antibody to the RhD antigen and monoclonal anti-D blocking antibodies are currently being investigated to ameliorate an established anti-D response, thereby preventing severe HDFN in a subsequent pregnancy.**<sup>96,97</sup> Proteasome inhibitors used in the suppression of antibodies in transplant rejection and in cases of multiple myeloma may prove useful for suppression of RhD alloimmunization prior to pregnancy.<sup>98</sup>

### HEMOLYTIC DISEASE OF THE FETUS AND NEWBORN DUE TO NON-RhD ANTIBODIES

Antibodies to the red cell antigens Lewis, I, M, and P are often encountered through antibody screening during prenatal care. Because these antibodies are typically of the IgM class, they are not associated with HDFN.<sup>99</sup>

However, antibodies to more than 50 other red cell antigens have been reported to be associated with HDFN (Table 34-2). **More important, only three antibodies—anti-RhD, anti-Rhc, and anti-Kell (K1)—cause significant enough fetal hemolysis that treatment with IUT is considered necessary.** In one series from a tertiary care center for IUT in the Netherlands, 85% of cases involved anti-D; 10%, anti-K1; and 3.5%, anti-c. In addition, one case each of anti-E, anti-e, and anti-Fy<sup>a</sup> was also reported.<sup>100</sup>

#### Rhc

Anti-c antibody should be considered equivalent to anti-D regarding its potential to cause HDFN. In one report, 25% of

Modified from Moise KJ. Hemolytic disease of the fetus and newborn. In Creasy RK, Resnik R, Iams J, eds. *Maternal-Fetal Medicine: Principles and Practice*, ed 5. Philadelphia: Elsevier; 2004.

antigen-positive fetuses were noted to have severe HDFN, 7% were hydropic, and 17% required IUTs for therapy.<sup>101</sup>

### RhC, RhE, and Rhe

RhC, RhE, and Rhe antibodies are often found in low titer in the alloimmunized patient with anti-D. Their presence may be additive to the fetal hemolytic effect of anti-D.<sup>102</sup> When they occur alone, mild HDFN is usually the clinical course. Only a handful of case reports have indicated the need for treatment with IUT with each of these antibodies.<sup>100,103</sup>

### Duffy

The Duffy antigen system consists of two antigens, Fy<sup>a</sup> and Fy<sup>b</sup>. Only anti-Fy<sup>a</sup> has been associated with mild HDFN.<sup>104</sup>

### Kidd

The Kidd antigen system consists of two antigens, Jk<sup>a</sup> and Jk<sup>b</sup>. Rare cases of mild HDFN have been reported.

### Kell

The Kell antigen system includes 23 different members. Antibodies to at least nine of the Kell antigens have been associated with HDFN. The most common of these is Kell (also designated *K*, *K1*) and cellano (*k*, *K2*). Additional antibodies that have been reported to be causative for HDFN include -Penny (*Kp<sup>a</sup>*, *K3*), -Rautenberg (*Kp<sup>b</sup>*, *K4*), -Peltz (*Ku*, *K5*), -Sutter (*Js<sup>a</sup>*, *K6*), -Matthews (*Js<sup>b</sup>*, *K7*), -Karhula (*U<sup>k</sup>*, *K10*) and -K22.<sup>95</sup> Unlike the case of other hemolytic antibodies, fetal anemia due to Kell (anti-K1) sensitization is thought to be secondary to not only hemolysis but also to suppression of fetal erythropoiesis.<sup>105</sup>

**The majority of cases of K1 sensitization are secondary to previous maternal blood transfusion, usually as a result of postpartum hemorrhage in a previous pregnancy. Because 92% of individuals are Kell negative, the initial management of the K1-sensitized pregnancy should entail paternal red cell typing and genotype testing.** If the paternal typing returns K1-negative (kk) and paternity is assured, no further maternal testing is undertaken. The majority of Kell-positive individuals will be heterozygous (Table 34-3). Amniocentesis can be used to determine the fetal genotype in these cases because cffDNA for fetal Kell typing is currently only available in Europe. **A**

**lower maternal critical antibody value of 8 has been proposed to begin fetal surveillance.<sup>106</sup> Serial MCA Doppler studies have proven effective in detecting fetal anemia.<sup>107</sup>**

### KEY POINTS

- ◆ Alloimmunization to the RhD, Kell (K1), and Rhc red cell antigens is the main cause for severe HDFN.
- ◆ Despite the widespread use of RhIG, approximately six cases of RhD alloimmunization occur annually per 1000 live births in the United States.
- ◆ *Hydrops fetalis* is defined as extracellular fluid in two fetal compartments; it represents the end-stage of fetal anemia in HDFN.
- ◆ The rhesus D, C, c, E, and e antigens are coded by two genes located on the short arm of chromosome 1.
- ◆ The rule of thumb should be to administer RhIG when in doubt, rather than to withhold it.
- ◆ A critical maternal antibody titer can be used in the first affected pregnancy to decide when to begin further fetal testing.
- ◆ The fetal peak systolic MCA Doppler velocity can be used to determine the onset of fetal anemia.
- ◆ In the case of a heterozygous paternal phenotype for a particular red cell antigen, fetal typing can be undertaken through cffDNA in maternal plasma for the *RHD* gene; fetal DNA typing for other red cell antigens can be obtained through amniocentesis.
- ◆ Intravascular fetal intrauterine transfusions are the mainstay of fetal therapy with an overall perinatal survival of greater than 90%.
- ◆ Except in cases of alloimmunization to Kell antigens, irregular red cell antibodies in pregnancy should be managed in a similar fashion to RhD.

## OVERVIEW

**Abnormalities of amniotic fluid volume (AFV) raise the concern for an underlying fetal or maternal complication during pregnancy or fetal/neonatal compromise. The perinatal mortality rate (PMR) approaches 90% to 100% with severe oligohydramnios in the second trimester and can exceed 50% with significant polyhydramnios in midpregnancy.<sup>1-5</sup>** Although these two extreme conditions are rare, other less drastic examples are more common and can impact pregnancy outcome. Efforts to study abnormalities of amniotic fluid (AF) are complicated by the fact that despite over 30 years of research in various human and animal models, little is known about the processes involved in normal AFV regulation. Many of the disease states associated with the extremes of AFV are better understood than the physiologic processes that maintain the normal state.

This chapter explores what is known about the normal mechanisms that effect the production and removal of AF, including fetal urination, swallowing, lung liquid, and intramembranous absorption. The normal changes in AFV and composition across

gestation are reviewed, as well as AFV abnormalities that include oligohydramnios and polyhydramnios, along with the possible underlying causes and treatment modalities.

## AMNIOTIC FLUID VOLUME

Attempts to measure true AFV are difficult because of obvious limitations. To measure the actual volume of AF, an inert dye must be injected into the amniotic cavity via amniocentesis, and samples of amniotic fluid must be obtained to determine a dilution curve. Although the dye injection technique is considered the gold standard for determining actual AFV and is compared with other methods of estimating AFV, such as ultrasound, it is impractical to utilize an invasive test to assess AFV in clinical practice.

Despite these limitations, Brace and Wolf<sup>6</sup> identified all published measurements of AFV in 12 studies with 705 individual AFV measurements; for each week of gestation, wide variation was seen in AFV (Fig. 35-1). The greatest variation occurred at 32 to 33 weeks of gestation, when the normal range was 400 to 2100 mL (5th to 95th percentile); this represents a wide normal range. One of the most interesting findings of the Brace and Wolf study is that **from 22 through 39 weeks of gestation, the average volume of AF (black dots on Fig. 35-1) remained unchanged despite an increase in fetal weight from about 500 g to 3500 g, a sevenfold increase.<sup>6</sup>** Using the dye dilution technique, others found that the normal range was less and the peak AFV occurred at 40 weeks of gestation, instead of 30 to 38 weeks.<sup>7</sup> These studies suggest **the AFV is closely regulated throughout pregnancy.**

## Ultrasound Assessment of Amniotic Fluid Volume

Ultrasound has largely replaced clinical assessment of AFV based on the Leopold maneuver or fundal height measurements. However, AF disorders should be suspected when the uterus measures too large or too small for the gestational age. **Polyhydramnios may be present if the maternal uterus is large for gestational age (LGA) or if the fetus cannot be easily palpated**

**FIG 35-1** Nomogram showing amniotic fluid volume as a function of gestational age. The black dots are the mean for each 2-week interval. Percentiles are calculated from a polynomial regression equation and standard deviation of residuals. (From Brace RA, Wolf EJ. Normal amniotic fluid volume throughout pregnancy. *Am J Obstet Gynecol.* 1989;161:382.)

or is ballotable. The diagnosis of oligohydramnios is a consideration when the fundal height is small for gestational age (SGA) or the fetus is easily palpated.

Early ultrasound estimations of AFV were made by measuring the maximum vertical pocket (MVP) of AF.<sup>8</sup> Chamberlain and colleagues<sup>9</sup> and Mercer and colleagues<sup>10</sup> found that perinatal morbidity and mortality rates were increased with an MVP of less than 1 cm and 0.5 cm, respectively. These lower values of the MVP identified at-risk fetuses, but the low sensitivity for identifying the majority of pregnancy complications associated with oligohydramnios was unacceptable and prompted other investigators to select higher cut-off values.

Subsequently, Phelan and others<sup>11-13</sup> proposed a four quadrant assessment of AF referred to as the *amniotic fluid index* (AFI). After 20 weeks, the uterus is divided into four equal quadrants, as shown in Figure 35-2. The deepest pocket of AF is measured in each quadrant, making sure that the ultrasound transducer is perpendicular to the floor and that fetal body parts and umbilical cord do not interfere with the vertical measurement (Fig. 35-3). The sum of the MVP in each quadrant equals the AFI.<sup>13</sup> Moore and Cayle<sup>13</sup> performed a cross-sectional study of 791 normal pregnancies; the 5th and 95th percentile of the AFI varied for each gestational age. At the 95th percentile, the AFI at 35 to 36 weeks' gestation was 24.9 cm, and it was 19.4 cm at 41 weeks' gestation. The variation in the AFI at the 5th percentile was less than that of the 95th percentile, but it still varied by as much as 2.5 cm. Finally, the investigators reported the interobserver and intraobserver variation to be 3.1% and 6.7%, respectively, which is acceptable for this commonly performed procedure. Comparing the ultrasound estimation of the AFV by the AFI (Fig. 35-4) with the actual measured volume (see Fig. 35-1) demonstrates very similar appearing curves.

Studies that have compared estimates of AFV by ultrasound (MVP and AFI) with actual measurements taken by the dye-dilution technique demonstrate that MVP and AFI

**FIG 35-2** Schematic diagram of the technique for measuring the four-quadrant amniotic fluid index.

measurements are poor predictors of actual AFV. Dildy and colleagues<sup>14</sup> found that the AFI overestimated the actual volume in 88% of cases at lower volumes, and it underestimated the actual volume in 54% of cases at higher volumes. However, this difference should not alter clinical practice. Magann and colleagues<sup>15</sup> reported a sensitivity of 10% (specificity 96%) for an AFI measurement of less than 5 cm (oligohydramnios), and the sensitivity was 5% (specificity 98%) for MVP up to 2 cm. For cases of suspected polyhydramnios, an AFI greater than 20 cm had a sensitivity of 29% (specificity 97%), as did an MVP of greater than 8 cm (specificity 94%). The MVP method had fewer false-positive tests compared with the AFI.<sup>15</sup> Based on these findings, the authors concluded that the MVP is superior

**FIG 35-3** Ultrasound image demonstrates measurement of the maximum vertical pocket (MVP) within the uterus by holding the transducer perpendicular to the floor and determining the MVP of amniotic fluid in centimeters.

**FIG 35-4** Amniotic fluid index (AFI) plotted with gestational age. The black line denotes the 50th percentile; red and green lines, the 5th and 95th percentiles; and the orange and black lines, +2 standard deviations (2.5th and 97.5th percentiles). (From Moore TR, Cayle JE. The amniotic fluid index in normal human pregnancy. *Am J Obstet Gynecol.* 1990;162:1168.)

to the AFI.<sup>16</sup> In contrast, Moore<sup>17</sup> found the AFI superior to the MVP for identifying cases of oligohydramnios but found the two methods similar at predicting polyhydramnios. In a recent review, Moise<sup>18</sup> found that the MVP was superior to the AFI in diagnosing oligohydramnios using an MVP less than 2 cm. **Although the MVP appears to be the preferred method to diagnose oligohydramnios near term, the vast majority of research on ultrasound measurement of AFV utilizes the AFI.**

Differences in ultrasound technique, specifically the pressure of the transducer on the maternal abdomen, can affect the accuracy of the ultrasound measurement of AF. Low pressure

can result in a higher AFI, compared with moderate pressure, whereas high pressure on the maternal abdomen can result in a decrease in the AFI measurement. **Despite overwhelming evidence that current ultrasound methods are poor predictors of abnormal AFV, clinical practice continues to include the use of weekly or twice-weekly ultrasound estimates of AFV to assess fetal status.**

For many years, investigators have tried with mixed success to demonstrate the utility and applicability of ultrasound estimation of AFV in relation to perinatal outcome. Early work by Chamberlain and colleagues<sup>9</sup> found that **when the MVP was less than 1 cm, a marked increase was seen in perinatal morbidity and mortality that persisted even after correcting for birth defects.**

## AMNIOTIC FLUID FORMATION

### Fetal Urine

**The main source of AF is fetal urination.** In the human, the fetal kidneys begin to make urine before the end of the first trimester, and production of urine increases until term. Many different animal models have been used to study fetal urine production. The fetal sheep provides an excellent model for comparative human study owing to its similar fetal weight at term, its sufficient size to allow catheter placement, and the fact that the sheep fetus has a low risk of premature labor after catheter placement. In the fetal sheep, urine production has been reported to be approximately 200 to 1200 mL/day in the last third of pregnancy.<sup>19-21</sup> Efforts to measure human fetal urine production have been accomplished by ultrasound measurements of the change in fetal bladder volume over time. Wladimiroff and Campbell<sup>22</sup> initially measured three dimensions of the fetal bladder every 15 minutes and reported a human fetal urine production rate of 230 mL/day at 36 weeks of gestation, which increased to 655 mL/day at term. Others found similar volumes using the same technique. Interestingly, using the same technique but measuring the change in volume every 2 to 5 minutes, Rabinowitz and colleagues<sup>23</sup> found fetal urine production to be much greater than previously predicted (1224 mL/day). This was confirmed by three-dimensional (3-D) ultrasound and computer modeling.<sup>24</sup> Fetal urine-production rates from several studies are shown in Figure 35-5.<sup>22,23,25-28</sup>

**Human fetal urine-production rate appears to be approximately 1000 to 1200 mL/day at term, which suggests that the entire AFV is replaced more frequently than every 24 hours.**

### Lung Liquid

**Fetal lung liquid also plays an important role in AF formation.** For years, it was presumed that actual movement of AF into the fetal lungs occurred; however, recent data offer no support for this concept.<sup>29,30</sup> In fact, throughout gestation, the fetal lungs produce fluid that exits the trachea and is either swallowed or leaves the mouth and enters the amniotic compartment. In fetal sheep experiments, the lungs have been reported to produce volumes of up to 400 mL/day, with 50% being swallowed and 50% exiting via the mouth.<sup>31-35</sup> Although we do not have direct measurements in humans, the presence of surfactant in the AF near term provides evidence for the outward flow of lung liquid. During normal fetal life, fetal breathing movements provide a “to-and-fro” movement of AF into and out of the trachea, upper lungs, and mouth with a net outward movement of fetal lung liquid into the AF.<sup>36</sup>

**FIG 35-5** Normal changes in fetal urine flow rates across gestation. Lines represent mean values for six studies in the literature,<sup>35-40</sup> whose first authors are shown. The highest line is data from Rabinowitz and colleagues and represents bladder volume measurements every 5 minutes, instead of every 15 minutes, as is the case for the other five studies. (Studies referenced from Gilbert WM, Brace RA: Amniotic fluid volume and normal flows to and from the amniotic cavity. *Semin Perinatol.* 1993;7:150.)

**FIG 35-6** Change in maternal and fetal plasma and in amniotic fluid osmolality across gestation. (From Gilbert WM, Moore TR, Brace RA. Amniotic fluid volume dynamics. *Fetal Med Review.* 1991;3:89.)

## AMNIOTIC FLUID REMOVAL

### Fetal Swallowing

**In the human, fetal swallowing begins early in gestation and contributes to the removal of AF.** In the fetal sheep, swallowing has mostly been measured in the latter half of pregnancy and appears to increase with increasing gestational age. Sherman and colleagues<sup>37</sup> reported that the ovine fetus swallows volumes of 100 to 300 mL/kg/day in episodes that last 2 minutes. In the term ovine fetus, that volume represents a daily swallowing rate of 350 to 1000 mL/day for a 3.5-kg fetus. This is obviously more than the adult sheep, which drinks 40 to 60 mL/kg daily.

Many different techniques have been used to determine swallowing rates in the animal model, including repetitive sampling of injected dye and actual flow probe measurements.<sup>19,37</sup> For obvious reasons, actual measurement of human fetal swallowing is much more difficult. Human fetal swallowing was studied in the distant past by injecting radioactive chromium-labeled erythrocytes and Hypaque (Amersham Health, Princeton, NJ) into the amniotic compartment, and swallowing rates of 72 to 262 mL/kg/day were found in studies in the 1960s.<sup>29,38</sup> Abramovich<sup>39</sup> injected colloidal gold into the human amniotic compartment and found that fetal swallowing increased with advancing gestational age. He also found similar swallowing rates to those previously reported.<sup>38</sup> Obviously, similar studies could not be performed today, but this information is helpful in our understanding of human fetal swallowing. **Fetal swallowing does not remove the entire volume of fluid that enters the amniotic compartment from fetal urine production and lung liquid; therefore other mechanisms of AF removal such as intramembranous absorption must occur.**

### Intramembranous Absorption

One major stumbling block to the understanding of AFV regulation was the discrepancy in volume between fetal urine and lung-liquid production and its removal by swallowing. If the measurements and estimates of AF production and removal were accurate, at least 500 to 750 mL/day of excess fluid would enter the amniotic compartment, which should have resulted in acute polyhydramnios. This does not occur under normal conditions (see Fig. 35-1); therefore a second route for AF removal has been suggested, namely the intramembranous pathway.<sup>24,40-43</sup> This process describes the movement of water and solutes between the amniotic compartment and the fetal blood, which circulates through the fetal surface of the placenta. The large osmotic gradient (Fig. 35-6) between AF and fetal blood provides a substantial driving force for the movement of AF into the fetal blood. Intramembranous absorption has been described in detail in the fetal sheep and has also been demonstrated in the rhesus monkey fetus.<sup>43</sup> Several anecdotal studies suggest that intramembranous absorption also occurs in humans. Heller<sup>44</sup> and Renaud and colleagues<sup>45</sup> each injected labeled amino acids into the amniotic compartments of women, who were shortly thereafter delivered by cesarean section. Both groups found high levels of the amino acids concentrated in the placenta within 45 minutes of injection. They concluded that the amino acids had to have been absorbed by some route other than swallowing in order to explain the rapid absorption into the fetal circulation within the placenta. **Intramembranous absorption could easily explain this movement. This route of absorption is now being actively investigated, and researchers have noted that 200 to 500 mL/day leaves the amniotic compartment under normal physiologic conditions.**<sup>40,41,46</sup> In addition, it has been reported that absorption through the intramembranous pathway can increase almost tenfold under experimental conditions in sheep.<sup>47</sup> Figure 35-7 summarizes all currently identified avenues for fluid entry and exit from the amniotic compartment and measured or estimated volumes. The flow of fluid into and out of the amniotic

**FIG 35-7** All known pathways for fluid and solute entry and exit from the amniotic fluid in the fetus near term. Arrow size is relative to associated flow rate. Solid red arrows represent directly measured flows, whereas the blue arrows represent estimated flows. The numbers represent volume flow in milliliters per day. The curved portion of the double arrow represents lung fluid that is directly swallowed after leaving the trachea, whereas the straight portion represents lung fluid that enters the amniotic cavity from the mouth and nose. (From Gilbert WM, Moore TR, Brace RA. Amniotic fluid volume dynamics. *Fetal Med Review*. 1991;3:89.)

cavity appears to be in a state of balance. Recent work on the mechanisms associated with intramembranous absorption suggests that four intramembranous transport mechanisms act in concert and include (1) a unidirectional bulk transport of AF and solutes out of the AF into the fetal circulation, (2) passive bidirectional diffusion of solutes, (3) passive bidirectional water movement, and (4) unidirectional transport of lactate into the AF.<sup>46</sup> In spite of these new findings, overall AFV regulation still needs further investigation.

## OLIGOHYDRAMNIOS

The incidence of oligohydramnios varies depending on which definition is used; reported rates vary between 1% and 3%.<sup>48</sup> The incidence of oligohydramnios is much higher (19% to 20%) among women undergoing antepartum testing for an underlying maternal or fetal indication.<sup>16</sup> Three studies reported actual measurements of AFV for oligohydramnios from less than 200 mL to 500 mL.<sup>6,49,50</sup> With the advent of ultrasound estimation of AFV, multiple thresholds have been reported.<sup>3,8</sup> **In clinical practice, an MVP less than 1 to 2 cm or an AFI less than 5 cm are commonly used as criteria for the diagnosis of oligohydramnios.**

Chamberlain and colleagues<sup>9</sup> reported a fiftyfold increase in PMR for pregnancies with an MVP of less than 1 cm. This report was instrumental in raising concern about the risk of stillbirth and neonatal mortality in the presence of oligohydramnios. A second, less often reported finding of that study was that 40% of the cases with oligohydramnios also had other confounding factors such as intrauterine growth restriction (IUGR), maternal hypertensive disorders, and congenital malformations. Other investigators have reported that oligohydramnios in the prolonged pregnancy has an increased risk of meconium staining of the AF, fetal distress in labor, and low 1-minute Apgar scores.<sup>48</sup>

The PMR approaches 100% when the AFV is greatly decreased early in pregnancy, especially in midpregnancy.<sup>1-3</sup> The cause of the decrease or absence of AF largely determines the perinatal

### BOX 35-1 FETAL AND MATERNAL CAUSES OF OLIGOHYDRAMNIOS

#### Fetal Conditions

- Renal agenesis
- Obstructed uropathy
- Spontaneous rupture of the membranes
- Premature rupture of the membranes
- Abnormal placentation
- Prolonged pregnancy
- Severe intrauterine growth restriction

#### Maternal Conditions

- Dehydration-hypovolemia
- Hypertensive disorders
- Uteroplacental insufficiency
- Antiphospholipid syndrome

outcome (Box 35-1). With renal agenesis, virtually 100% of newborns die because of pulmonary hypoplasia. **AF is required for fetal lung development during certain periods of early and mid gestation.** If premature rupture of the membranes (PROM) results in a loss of all AF, neonatal survival will vary based on the gestational age when the membranes ruptured and whether intraamniotic infection was the cause of the membrane rupture.<sup>51</sup> Oligohydramnios can also occur with maternal conditions such as hypertensive disorders or the antiphospholipid syndrome (APS). In these cases, if the fetus is large enough to survive outside of the uterus, there may be little impact on perinatal outcome other than the consequences of prematurity.<sup>51</sup>

A common incidental finding is the existence of a low AFI in an otherwise normal pregnancy. Because the diagnosis of oligohydramnios has been associated with poor perinatal outcomes, many women who are at or near term are sent to labor and delivery to be considered for induction solely because of a low AFI. Frequently, their cervical examination is unfavorable for induction, and an induction is attempted in spite of this; often this ends in a cesarean delivery for failed induction. **Although the evidence for induction in the prolonged pregnancy is solid (see Chapter 36), the term or preterm patient with isolated oligohydramnios may not need immediate delivery.** Having said this, borderline oligohydramnios has been found to be a predictor of SGA newborns with an increase in admissions to the neonatal intensive care unit (NICU) but no other significant morbidities.<sup>52</sup> Lagrew and colleagues<sup>53</sup> reported that 41% of women with oligohydramnios, as determined by the AFI, had a normal AFI 3 to 4 days later. They also found that a normal AFI measurement was valid for 1 week, which suggests that the test need not be repeated more often except in certain high-risk situations. Magann and colleagues<sup>16</sup> examined 1001 high-risk women who underwent antepartum testing. They found that those with an AFI of less than 5 cm (19% of cases) had similar outcomes to those whose AFI was in the normal range, and these researchers concluded that an AFI of less than 5 cm was not an indication for delivery.<sup>16</sup> Rainford and colleagues<sup>54</sup> examined 232 women at more than 37 weeks of gestation who had an AFI of less than 5 cm (19%). They found outcomes to be no worse when compared with those whose AFI was in the normal range. In fact, the risk of meconium staining of the AF was found to be increased (35% vs. 16%) in the normal group.<sup>54</sup> Finally, Casey and colleagues<sup>48</sup> examined 6423 women at more than 34 weeks' gestation with an AFI of less than 5 cm and found an

increase in intrauterine fetal death (IUID), admissions to the NICU, neonatal death, low birthweight (LBW), and meconium aspiration syndrome (MAS) compared with women with an AFI of greater than 5 cm. If the birth defects and IUGR were removed, no difference was seen in admissions to the NICU, neonatal death, or respiratory distress syndrome (RDS).<sup>48</sup> This suggests that IUGR and birth defects contributed to the increased morbidity and mortality, not the oligohydramnios. **All cases with oligohydramnios should be evaluated for evidence of IUGR and should be followed with antepartum testing.**

### Evaluation and Treatment of Oligohydramnios

**When the diagnosis of oligohydramnios is made in the second trimester, it is vitally important to obtain a complete history and physical exam and to perform a targeted ultrasound to help identify a cause** (see Box 35-1). The patient should be questioned for any history consistent with rupture of the membranes, leakage of clear or bloody fluid, or wetness of her underwear. If there is a question of possible rupture of the membranes (ROM), a sterile speculum examination should be performed in an attempt to obtain fluid that can be examined for evidence of rupture. Specific tests include evidence of ferning on microscopy examination, a neutral pH on nitrazine paper, and pooling of fluid in the posterior vagina. Commercial tests are also available that screen for ROM: these include AmniSure (Qiagen, Hilden, Germany) and ROM Plus (Clinical Innovations, Murray, Utah), which check for certain proteins from the AF in the vagina. These tests reportedly have a higher sensitivity and specificity than either the fern or nitrazine tests. Next, a targeted ultrasound should be performed to assess the amount of AF present; evaluate fetal anatomy, including the kidneys and bladder; and determine appropriate interval growth. If the fetus is normally grown with kidneys and bladder visualized, more often than not, the amniotic membrane has ruptured prematurely (PROM). If kidneys and bladder cannot be seen, the diagnosis is most likely renal agenesis. Renal agenesis is uniformly fatal, whereas PROM can have a reasonable prognosis if it occurs after fetal viability and if infection is not present.

Although severe oligohydramnios has an increased PMR later in the third trimester, it is still not as high as earlier in pregnancy.<sup>3,48,55</sup> Other studies have reported similar increases in perinatal mortality associated with oligohydramnios, but most have not corrected for other underlying medical conditions.<sup>8</sup> Because of the increase in perinatal morbidity and mortality associated with oligohydramnios in prolonged pregnancy, delivery is recommended (see Chapter 36). As discussed earlier, the patient who presents with isolated oligohydramnios in the third trimester may be a candidate for expectant management.<sup>16,48,54</sup>

**Several investigators have attempted to treat oligohydramnios with the oral administration of water in the hope of “hydrating” the fetus through the mother.** Animal studies have demonstrated that a close relationship exists between the hydration status of the mother and the fetus.<sup>56,57</sup> Attempts to dehydrate the mother have resulted in dehydration of the fetus, and in some cases vice versa. In human pregnancies, Goodlin and colleagues<sup>58</sup> found that the maternal intravascular volume was low in cases of idiopathic oligohydramnios, and that by increasing the maternal intravascular volume, the oligohydramnios resolved. In a randomized study, the oral administration of water increased the AFI in women with oligohydramnios.<sup>59</sup> The treatment group that drank 2 L of water within 4 hours of a repeat AFI measurement had a significantly greater increase in

AFI on repeat testing (6.3 cm) than the control group (5.1 cm).<sup>59</sup> A follow-up study of women with a normal AFI demonstrated that the amount of water ingested could increase or decrease their AFI.<sup>60</sup> As illustrated in Table 35-1, the AFI significantly increased in the oral hydration group compared with the control group. The control group was given what was thought to be a “normal” volume of water to drink, but the AFI actually decreased and urine osmolality increased. This suggests that the mothers were actually dehydrated during the control portion of the study. **Both groups demonstrated that the AFI can be influenced by increasing or decreasing water intake orally.**

Many other studies have shown a similar improvement in AFV with either oral or intravenous administration of water and/or crystalloids.<sup>61-63</sup> In a prospective randomized trial of women with an AFI between 6 and 24 cm, the patients were either hydrated with 1 L of water over 1 hour and placed in the left lateral recumbent position or were not orally hydrated but were placed in the left lateral recumbent position. AFI was measured every 15 minutes for 90 minutes. Both groups saw a similar increase in the AFI at 15 and 30 minutes, but the hydration group saw a further increase at 45 minutes, which suggests that oral hydration—and simple bed rest alone, but to a lesser extent—can improve the AFI.<sup>63</sup> Several researchers have reported success in improving AFV in women with oligohydramnios by the injection of a crystalloid solution into the amniotic compartment during an amniocentesis.<sup>64</sup> Most of these studies, however, have been case reports; because no large prospective studies have been performed, the routine use of this approach for cases of severe oligohydramnios in mid gestation cannot be justified.

### Oligohydramnios in Labor

Almost 30 years ago, Gabbe and colleagues<sup>65</sup> worked with fetal monkeys and noted that when AF was removed from the amniotic compartment, variable decelerations in the fetal heart rate developed. These decelerations resolved when the AF was replaced, suggesting that cord compression was the cause of the decelerations. Since that time, multiple investigators have studied amnioinfusion as a technique by which to treat variable decelerations in labor. **Although most report a decrease in the frequency of variable decelerations, few have demonstrated any decrease in perinatal morbidity or mortality or in the cesarean delivery rate.**<sup>66-69</sup> Amnioinfusion has been studied as a possible therapy in the case of thick meconium. In several small

prospective studies, it has been shown to improve neonatal outcomes, including meconium visualized below the newborn vocal cords and meconium aspiration syndrome.<sup>70-73</sup> Sadovsky and colleagues<sup>74</sup> found that with the randomization of women with greater than light meconium to a control or amnioinfusion treatment group, 29% of control newborns had meconium below the umbilical cords, whereas none of the treated newborns did. A meta-analysis of the therapeutic use of amnioinfusion for thick meconium demonstrated a reduction (odds ratio [OR] 0.3; 95% confidence interval [CI], 0.19 to 0.46) in meconium below the vocal cords at delivery.<sup>75</sup> A more recent, multicenter, randomized trial of 1998 women in labor at 36 weeks' gestation or later with thick meconium did not find that amnioinfusion reduced the risk of moderate or severe meconium aspiration syndrome or perinatal death.<sup>76</sup> **Based on this large multicenter trial, ACOG recommends against routine prophylactic amnioinfusion for the dilution of meconium-stained amniotic fluid.**<sup>77</sup>

## POLYHYDRAMNIOS

The incidence of polyhydramnios is 1% to 2%. The earlier in gestation polyhydramnios occurs and the greater the amount of fluid, the higher the perinatal morbidity and mortality.<sup>4</sup> Ultrasound assessment of the MVP or AFI is used to confirm the diagnosis of polyhydramnios.

Many authors define *polyhydramnios* as an MVP of greater than 8 cm, whereas others use an AFI of 25 cm or greater. Hill and colleagues<sup>78</sup> divided their patients with polyhydramnios into three groups: *mild* (MVP 8 to 11 cm, 79% of cases), *moderate* (MVP 12 to 15 cm, 16.5%), and *severe* (MVP ≥16 cm, 5%). Overall, the perinatal mortality rate was 127.5/1000, which corrected to 58.8/1000 when lethal malformations were excluded. This value is markedly increased over the background rate. A specific cause was identified in only 16% of the pregnancies with mild, 90% with moderate, and 100% with severe polyhydramnios. Fetal and maternal conditions associated with polyhydramnios are shown in Box 35-2. In a follow-up study, Many and colleagues<sup>79</sup> examined 275 women with polyhydramnios to determine whether its degree had any influence on the rate of prematurity. Although excessive AF did not impact the rate of prematurity, the presence of anomalies or diabetes mellitus was associated with an increased risk of preterm delivery.<sup>80</sup> **Severe polyhydramnios in the second trimester has a significant PMR due to prematurity or aneuploidy.**<sup>81,82</sup> Pregnancy complications associated with polyhydramnios have been reported to increase the risk for placental abruption and postpartum hemorrhage as a result of overdistension or rapid deflation of the uterus, and this should be taken into consideration in the plan of care.

## Evaluation and Treatment of Polyhydramnios

The pregnant woman who presents with a rapidly enlarging uterus in mid pregnancy, with or without preterm labor, needs to be evaluated by an ultrasound examination to measure the AFV and assess fetal anatomy. Esophageal atresia with or without tracheoesophageal fistula can present with early-onset severe polyhydramnios due to an obstruction of swallowing. Other gastrointestinal obstructions such as duodenal atresia may result in polyhydramnios.<sup>78</sup> When a structural defect is seen in a fetus with polyhydramnios, consideration should be given to performing an amniocentesis for microarray analysis (see Chapter 10).

### BOX 35-2 FETAL AND MATERNAL CAUSES OF POLYHYDRAMNIOS

#### Fetal Conditions

##### Congenital anomalies

- Gastrointestinal obstruction, central nervous system abnormalities, cystic hygroma, nonimmune hydrops, sacrococcygeal teratoma, cystic adenoid malformations of lung

##### Aneuploidy

##### Genetic disorders

- Achondrogenesis type 1-B
- Muscular dystrophies
- Bartter syndrome

##### Twin-to-twin transfusion syndrome

##### Infections

- Parvovirus B-19

##### Placental abnormalities

- Chorioangioma

#### Maternal Conditions

##### Idiopathic

##### Poorly controlled diabetes mellitus

##### Fetomaternal hemorrhage

Another common cause of acute, severe polyhydramnios in the second trimester is the twin-to-twin transfusion syndrome (TTTS; see Chapter 32). The ultrasound findings associated with TTTS are marked polyhydramnios of the receiving twin and absent AFV or marked oligohydramnios of the donor twin. **When polyhydramnios occurs in the third trimester of pregnancy, it is usually mild and is not associated with a structural defect.**<sup>78</sup> Although the vast majority of cases in the third trimester are idiopathic, the other causes of polyhydramnios must be excluded (see Box 35-2).

In many cases, polyhydramnios may be transient. Mild or transient polyhydramnios is usually idiopathic and has a favorable prognosis.<sup>83</sup> However, complications of pregnancy are greater when the AFV remains markedly elevated during pregnancy, including preterm delivery (2.7-fold increase), preeclampsia (2.7-fold increase), IUFD (7.7-fold increase), and neonatal demise (7.7-fold increase). In such cases, antenatal and maternal surveillance is warranted.

A meta-analysis of 43 studies found that polyhydramnios (AFI >24 cm or MVP >8 cm) was predictive of macrosomia with an OR of 11.5 (95% CI, 4.1 to 32.9), which suggests that this should be taken into account when considering delivery options.<sup>84</sup> Treatment options for patients with polyhydramnios are usually tailored to the underlying cause. With mild idiopathic polyhydramnios—in which the workup is negative, and follow-up ultrasound demonstrates persistent polyhydramnios—antepartum testing with fetal kick counts or nonstress tests may be prudent. Antepartum surveillance is recommended for women with polyhydramnios and poorly controlled diabetes mellitus.

**With severe polyhydramnios associated with preterm labor, one medical treatment option involves the administration of a prostaglandin inhibitor such as indomethacin, which decreases fetal urine production.**<sup>85-87</sup> This effect occurs within 5 hours of starting the medication and decreases the AFV within 24 hours.<sup>85,86,88</sup> Although indomethacin has been shown to be relatively safe when given over a short period of time, such as 72 hours, prolonged use may be associated with

risks to the fetus such as premature closure, narrowing of the ductus arteriosus within the fetal heart, and renal abnormalities in the newborn period.<sup>86,87</sup> Complications related to indomethacin use worsen with advancing gestational age, and such treatment beyond 31 to 32 weeks of gestation should be avoided.<sup>88</sup> The use of repetitive amnioreductions, in which amniocentesis is performed and large volumes (1 to 5 L) of AF are removed through plastic tubing into a vacuum bottle, does prolong pregnancies in a number of cases but may need to be repeated on a regular basis.<sup>5,88</sup>

### KEY POINTS

- ◆ Amniotic fluid is dynamic, with large volume flows into and out of the amniotic compartment each day.
- ◆ Clinical estimates of actual AFV based on ultrasound measurements of the AFI or MVP are not accurate in predicting true volume.
- ◆ In the presence of IUGR or a prolonged gestation, oligohydramnios is associated with significant increases in perinatal morbidity and mortality.
- ◆ Preterm or term isolated oligohydramnios is not associated with an increase in perinatal morbidity or mortality with an otherwise normal fetus.
- ◆ Early-onset or severe polyhydramnios is associated with aneuploidy, congenital malformations, preterm delivery, and an increased perinatal mortality rate.
- ◆ The cause of mild polyhydramnios, especially in the latter part of the third trimester, is usually idiopathic or related to diabetes mellitus and has little impact on perinatal survival.
- ◆ AFV as estimated by the AFI may be expanded with increased maternal oral ingestion of water and/or bed rest in the left lateral recumbent position.
- ◆ Short-term use of indomethacin decreases fetal urine production and can reduce AFV within 24 hours of administration; prolonged use should be avoided because of the risk of premature closure of the ductus arteriosus and renal abnormalities in the newborn.

Obstetricians have long recognized the detrimental effects of preterm delivery, but for the last century, there has also been concern for pregnancies that have gone beyond the normal period of gestation. Early descriptions from prolonged pregnancies described a large fetus and resulted in a difficult delivery with an increased risk of stillbirth.<sup>1</sup> Later descriptions suggested that a postterm fetus not only could be large but also small for gestational age.<sup>2</sup> These concerns led some to adopt a practice of inducing labor to avoid complications in prolonged pregnancies. This practice was variable, and somewhat controversial, because the upper limit of pregnancy was not well defined and the risks were inconsistent. **More recent studies show a small but significantly increased risk in perinatal morbidity and mortality in postterm pregnancies, and hence, postterm pregnancy is one of the most common reasons for induction of labor in the United States.**

## DEFINITION

The American College of Obstetricians and Gynecologists (ACOG), International Federation of Gynecology and Obstetrics (FIGO), and the World Health Organization (WHO) have defined a **postterm pregnancy** as a **gestation that has completed or gone beyond 42 weeks or 294 days, from the first day of the last menstrual period (LMP).**<sup>3-5</sup> This gestational age cutoff has been used for several decades and was first suggested based on early studies that reported an increased risk of fetal death at 42 weeks and beyond.<sup>6</sup> However, in view of more recent perinatal mortality data derived from accurately dated pregnancies, **it would be reasonable to conclude that the gestational age that warrants clinical concern should be 41 weeks.**

Many terms have been used in the literature, including *postmature*, *postdates*, *prolonged*, and *postterm*. These terms have been used with varying definitions, which has led to some confusion regarding proper terminology. Recently ACOG and the Society for Maternal-Fetal Medicine (SMFM) has endorsed the use of new terminology recommended by the Defining Term Pregnancy Workgroup to decrease confusion among physicians, patients, and researchers and to designate gestational ages at higher risk.<sup>7-8</sup> Pregnancies are now designated to be “early term” if they are 37<sup>0/7</sup> weeks through 38<sup>6/7</sup> weeks. Full term is defined at 39<sup>0/7</sup> weeks through 40<sup>6/7</sup> weeks. **Pregnancies are to be designated as “late term” if they are 41<sup>0/7</sup> weeks through 41<sup>6/7</sup> weeks. Postterm will continue to be defined as 42<sup>0/7</sup> weeks and beyond.**

## INCIDENCE

**According to the vital statistics reported by the Centers for Disease Control and Prevention (CDC), the overall incidence of postterm pregnancies was 5.6% in 2012 and has not significantly changed compared with previous years.**<sup>9</sup> Other published studies have shown varying frequency of postterm pregnancies depending on the population studied. The

incidence of prolonged pregnancies in European countries also varies widely, with rates as low as 0.4% in Austria and as high as 7% in Denmark and Sweden.<sup>10</sup> These differences are most likely explained by different approaches for managing pregnancies beyond the estimated date of delivery (EDD) and different criteria for gestational age dating.

## ETIOLOGY

**The etiology of the majority of pregnancies that are late term or postterm is unknown, but some pregnancies may be defined as late term or postterm as the result of an error in dating.** It is common practice to assign an EDD based on the LMP. This practice has been proven by several studies to be unreliable and may have led to the incorrect classification of a pregnancy as late term or postterm.<sup>11</sup>

Understanding the events that lead to parturition in human gestation may help to provide clues to the pathophysiology in prolonged pregnancies. **Parturition is the result of a complex interplay among the mother, fetus, and placenta.**<sup>12</sup> The mechanism in human gestation is unknown but may be similar to that of other mammals. In sheep, the hypothalamic-pituitary-adrenal (HPA) axis is important in the timing of birth. The release of corticotropin-releasing hormone (CRH) from the fetal brain results in the secretion of adrenocorticotrophic hormone (ACTH) from the pituitary gland and cortisol from the adrenal gland.<sup>13</sup> The increase in cortisol parallels an increase in the secretion of prostaglandin and estrogens and a fall in progesterone.<sup>13</sup> Decreases in progesterone and increases in prostaglandins are known triggers of uterine myometrium. Further support for the role of the HPA axis in the initiation of labor is seen in studies with hypophysectomized sheep; disruption of the HPA axis results in prolonged pregnancy.<sup>14</sup> More recent studies have proposed a similar involvement of the HPA axis in human gestation, and its dysregulation may play a role in prolonged pregnancies.

Early studies likened anencephaly to the hypophysectomized sheep. It is hypothesized that the absence of the fetal brain in the anencephalic fetus may result in a similar dysfunction of the HPA axis and may lead to prolonged gestation. Epidemiologic studies of anencephalic pregnancies have observed prolongation of pregnancy.<sup>15</sup> These findings support current thinking that the interaction between the fetal brain and placenta plays an important role in triggering labor.

Pregnancies complicated by placental sulfatase deficiency, an X-linked recessive disorder characterized by the absence of the enzyme steroid sulfatase, are marked by abnormally low estriol levels and, in general, fail to go into spontaneous labor.<sup>16</sup> This is an example of a genetic etiology for prolonged pregnancy and lends further support to the important role of the placenta in the initiation of labor.

**A number of observational studies have identified risk factors for postterm pregnancy including primigravidity, prior postterm pregnancy, male fetus, obesity, and a genetic predisposition.**<sup>17-23</sup> A 10-year cohort study of births in Norway failed to find a strong association of risk factors with postterm pregnancy but may have had a bias toward nondetection.<sup>17</sup> Intergenerational studies suggest a genetic predisposition for postterm pregnancy. Mothers who themselves were postterm also have an increased risk of prolonged pregnancy. Twin studies have found higher rates of concordance for postterm pregnancy among female twins, compared with male twins, implicating a maternal influence on the risk for prolonged pregnancy.<sup>22</sup>

## DIAGNOSIS

**The diagnosis of truly late term and postterm pregnancy is based on accurate gestational dating.** The three most commonly used methods to determine the EDD are (1) knowledge of the date of the LMP, (2) knowledge of the timing of intercourse, and (3) early ultrasound assessment. Other methods have been described but are rarely used in contemporary practice, including the determination of uterine size, quickening, ability to detect fetal heart tones by Doppler auscultation, and fundal height measurement. In most cases, the date of conception is rarely known and therefore is infrequently used to determine gestational age. The EDD is most commonly assigned based on the first day of the LMP, but this assumes that conception occurs on the fourteenth day of the menstrual cycle. This method can be very inaccurate because the timing of ovulation is variable among an individual's menstrual cycles and between individuals.<sup>24,25</sup> Basing gestational age solely on the LMP generally results in an overestimation of gestational age and may result in a higher frequency of induction of labor for presumed postterm pregnancy.

**The use of ultrasound to determine the accuracy of gestational dating based on the LMP is superior to the use of the LMP alone. The EDD is most accurately determined if the crown-rump length is measured in the first trimester with an error of  $\pm 5$  to 7 days.** Boyd and colleagues<sup>26</sup> showed that the incidence of patients whose pregnancy exceeded 293 days was 7.5% based on menstrual dating and declined to 2.6% when dates were determined by early sonographic examination. A similar conclusion was reached by Gardosi and associates,<sup>27</sup> who evaluated 24,675 spontaneous, normal singleton deliveries and showed a decline in the postterm (>294 days) pregnancy rate from 9.5% when pregnancies were dated by LMP to 1.5% when ultrasound dating was used. These authors also reported that about 72% of routine labor inductions at 42 weeks' gestation were not indicated because they were performed before the patients reached 42 weeks based on ultrasound assessment of gestational age. Similarly, Nguyen and coworkers<sup>28</sup> evaluated 14,805 spontaneous deliveries with a reliable LMP and showed that ultrasound dating reduced the proportion of deliveries beyond 294 days of gestation by 39% (from 7.9% to 5.2%). Bennett and colleagues<sup>29</sup> confirmed these findings in a prospective, randomized study of 218 women and found fewer postterm inductions of labor in women dated by a first-trimester sonogram when compared with women whose dates were established by second-trimester sonography.

## PERINATAL MORBIDITY AND MORTALITY

Numerous studies have evaluated the risk to the fetus in late-term and postterm pregnancies. Early descriptive studies found that pregnancies that continued past their EDD had an increased risk of fetal death. In 1963, McClure<sup>6</sup> found a twofold increase in "fetal distress" at 42 weeks with an increase in operative deliveries and surmised that 42 weeks constituted a significant risk to the fetus and proposed intervening with induction of labor or cesarean delivery to avoid the risk of fetal death. Early studies were likely fraught with inaccurate dating and inconsistent definitions of postterm pregnancy. Lastly, it is important to note that these studies included pregnancies complicated by fetal anomalies, intrauterine growth restriction (IUGR), and mothers with coexisting medical conditions, all of which increase the risk of fetal demise.

More recent observational studies that have evaluated the risk of perinatal mortality at each gestational week show an increased risk as gestational age advances beyond the EDD.<sup>30-32</sup> Divon and associates<sup>33</sup> evaluated fetal and neonatal mortality rates in 181,524 accurately dated full-term, late-term, and postterm pregnancies. A significant increase in fetal mortality was detected from 41 weeks' gestation onward (odds ratios [ORs] of 1.5, 1.8, and 2.9 at 41, 42, and 43 weeks, respectively). Campbell and colleagues<sup>17</sup> performed a multivariate analysis of factors associated with perinatal death among 65,796 singleton postterm births ( $\geq 294$  days). Three variables were identified as independent predictors of perinatal mortality: (1) birthweight lower than the 10th percentile for gestational age had a relative risk (RR) of 5.7 and a 95% confidence interval (CI) of 4.4 to 7.4; (2) maternal age 35 years or greater had an RR of 1.88 and a 95% CI of 1.2 to 2.9; and (3) birthweight at the 90th percentile for gestational age or above was associated with a modest protective effect for perinatal death (RR, 0.51; 95% CI, 0.26 to 1.0).

Many of these studies have used perinatal mortality rate (PMR), which has been suggested by Smith<sup>34</sup> and others to be an inappropriate assessment of risk to the fetus. The denominator in the calculation of the PMR is the number of deliveries.<sup>34-37</sup> As stated by Smith,<sup>34</sup> "Estimating the probability of an event requires that the number of events (numerator) be divided by the number of subjects at risk for that event (denominator)." Therefore it seems logical to calculate fetal mortality as fetal deaths per 1000 ongoing pregnancies, rather than per 1000 deliveries. When Hilder and colleagues<sup>35</sup> used ongoing pregnancies in a large retrospective study that included 171,527 births, higher rates of stillbirth were found. A nadir was seen at 41 weeks, but compared with 37 weeks' gestation, an eightfold increase in stillbirths at 43 weeks was reported (Fig. 36-1). Using the Scottish birth registry, Smith<sup>37a</sup> also found a significant increase in the risk of stillbirth from 37 weeks (0.4/1000) to 43 weeks (11.5/1000).

Several studies have examined the association of perinatal morbidity with postterm pregnancy. Clausson and colleagues<sup>38</sup> evaluated a large Swedish database of term and postterm (defined as  $\geq 294$  days) singleton, normal neonates and showed that postterm pregnancies were associated with an increased frequency of neonatal convulsions, meconium aspiration syndrome, and Apgar scores of less than 4 at 5 minutes (Table 36-1). Tunon and associates<sup>39</sup> compared neonatal intensive care unit (NICU) admission rates among 10,048 term pregnancies and 246 postterm pregnancies ( $\geq 296$  days by both scan and LMP dates). Postterm pregnancy was associated with a significant increase in NICU admissions (OR, 2.05; 95% CI, 1.35 to 3.12).

Guidetti and colleagues<sup>40</sup> reported an increased incidence of perinatal morbidity at 41 weeks' gestation or greater. Maternal and fetal complications were evaluated in a large ( $n = 45,673$ ) retrospective cohort study by Caughey and Musci.<sup>41</sup> These authors documented a significant increase in the rate of intrauterine fetal death (IUFD) beyond 41 weeks. They concluded that risks to both the mother and the infant increase as pregnancy progresses beyond 40 weeks' gestation.

Oligohydramnios

Oligohydramnios is a common finding in postterm pregnancies; it is presumably the result of fetal hypoxemia, which may result in altered renal perfusion and decreased urine production.<sup>42</sup>

FIG 36-1 The summed mortality at each gestation for the rate of stillbirth (red), neonatal death (blue), and postneonatal death (green) expressed per 1000 ongoing pregnancies. (Modified from Hilder L, Costeloe K, Thilaganathan B. Prolonged pregnancy: evaluating gestation specific risks of fetal and infant mortality. *BJOG*. 1998;105:169.)

TABLE 36-1 NEONATAL MORBIDITY IN POSTTERM AVERAGE AND SGA INFANTS

| COMPLICATIONS                     | TERM AGA NEONATES* |
|-----------------------------------|--------------------|
| <b>Convulsions</b>                |                    |
| Term SGA                          | 2.3 (1.6-3.4)      |
| Postterm AGA                      | 1.5 (1.2-2.0)      |
| Postterm SGA                      | 3.4 (1.5-7.6)      |

\*Values are presented as odds ratios (confidence interval).  
AGA, average for gestational age; SGA, small for gestational age.

Doppler studies of renal blood flow are conflicting.<sup>43,44</sup> Thus the etiology of oligohydramnios in postterm pregnancies is still debated.

Regardless of the pathophysiology of oligohydramnios in postterm pregnancies, in a setting of oligohydramnios, the risk of perinatal morbidity and mortality is increased.<sup>45</sup> The importance of oligohydramnios was identified by Leveno and coworkers,<sup>46</sup> who used its presence to explain the increased incidence of abnormal antepartum and intrapartum fetal heart rate (FHR) abnormalities seen in prolonged pregnancies. These authors suggested that prolonged FHR decelerations that represented cord compression preceded 75% of cesarean deliveries for fetal jeopardy. The association between a reduced amniotic fluid

index (AFI) and variable decelerations is well documented and is likely related to cord compression.<sup>47,48</sup> Meconium passage in amniotic fluid has also been associated with oligohydramnios, and it is postulated that the hypoxemia may result in rectal sphincter relaxation. Some studies have shown meconium-stained fluid as high as 29% in postterm pregnancies complicated by oligohydramnios.<sup>49</sup> See [Chapter 35](#) for further discussion of oligohydramnios.

A prospective, blinded observational study of 1584 pregnancies was performed by Morris and colleagues<sup>50</sup> to assess the usefulness of ultrasound assessment of amniotic fluid in the prediction of adverse outcome in prolonged pregnancies. The authors demonstrated that an AFI of less than 5 cm, but not a single deepest vertical pocket less than 2 cm, was significantly associated with birth asphyxia or meconium aspiration. In addition, a significant association was found between an AFI of less than 5 cm and fetal distress in labor, cord arterial pH less than 7.0, and low Apgar scores.

The presence of oligohydramnios is often cited as an indication for delivery of pregnancies that reach term gestation or beyond. Importantly, no large, prospective, randomized studies have documented the benefits of delivery in this setting. **Still, given the well-described association between oligohydramnios and adverse pregnancy outcome at or beyond term, delivery is a reasonable choice for patients with oligohydramnios.**

### Fetal Growth

**The risk of macrosomia has been shown to increase with advancing gestational age,** although the majority of prolonged pregnancies are appropriately grown. In a sample of 7000 pregnancies between 39 and 42 weeks, McLean and coworkers<sup>51</sup> found an increase in both fetal weight and head circumference. Eden and associates<sup>52</sup> observed that, compared with term pregnancies, postterm pregnancies have a twofold increase in the risk for macrosomia; and in these pregnancies, macrosomia was associated with a greater risk of operative delivery and shoulder dystocia leading to fetal injury.

Chervenak and colleagues<sup>54</sup> investigated the use of ultrasound to evaluate the estimated fetal weight (EFW) in pregnancies greater than 41 weeks and also found an increased incidence of fetal weight greater than 4000 g. They also showed an increase in the risk of cesarean delivery (22%) because of protracted and arrested labors when compared with nonmacrosomic infants (10%;  $P < .01$ ). The positive and negative predictive values were 70% and 87%, respectively. However, a similar study of pregnancies at 41 weeks or greater found an absolute error of approximately 8% and a positive predictive value of 64% when ultrasound was used to estimate fetal weight within 1 week of delivery.<sup>54</sup> **ACOG<sup>53</sup> has warned that the diagnosis of fetal macrosomia by ultrasound is not precise and that early induction of labor or cesarean delivery has not been shown to reduce the morbidity associated with fetal macrosomia.**

### Postmaturity

**Postmaturity, another complication of prolonged pregnancies, occurs in approximately 10% to 20% of such pregnancies.**<sup>55-57</sup> The “postmature” infant has decreased subcutaneous fat and lacks lanugo and vernix. The features are similar to those of IUGR, and some authors believe that postmaturity is really another manifestation of IUGR. Postmaturity is also associated with an increased incidence of meconium-stained fluid.

### Meconium

Meconium-stained fluid can be seen at any gestational age, although several studies have documented a significantly increased risk of meconium-stained fluid in postterm pregnancies. Meconium aspiration is a serious neonatal condition that results in decreased lung compliance, abnormal production of surfactant, and a chemical pneumonitis (see [Chapter 22](#)).

## MATERNAL COMPLICATIONS

**Prolonged pregnancies are also associated with significant risk to the mother.** Not only is anxiety significant as the pregnancy advances beyond the EDD but the risk of maternal morbidity during the intrapartum period is also increased. Caughey and colleagues<sup>58</sup> studied 119,254 women who delivered at 37 weeks and beyond and found an increased risk in significant perineal laceration (OR, 1.19; 95% CI, 1.09 to 1.22), chorioamnionitis (OR, 1.32; 95% CI, 1.21 to 1.44), endomyometritis (OR, 1.46; 95% CI, 1.14 to 1.87), postpartum hemorrhage (OR, 1.21; 95% CI, 1.10 to 1.32), and cesarean delivery (OR, 1.28; 95% CI, 1.20 to 1.36). The indications for cesarean delivery in this study were nonreassuring FHR and cephalopelvic disproportion.

## MANAGEMENT

**Accurate assessment of gestational age is paramount in the management of late-term and postterm pregnancies.** When ultrasound is used to confirm menstrual dating, the incidence of late-term and postterm pregnancies and unnecessary interventions are decreased.<sup>59</sup> Because late-term and postterm pregnancies have an increased risk of fetal mortality, modern management includes the use of antenatal fetal surveillance and carefully timed intervention.

### Antenatal Surveillance

**Given the increased risk of stillbirth, antenatal surveillance is recommended in the management of prolonged and post-term pregnancies.** Testing options for fetal surveillance include monitoring of fetal kick counts, nonstress test (NST), contraction stress test (CST), biophysical profile (BPP), and modified biophysical profile (NST and AFI). Few data are available with adequate power to assess the timing of initiation or frequency of fetal testing in prolonged pregnancies. **However, based on the studies on perinatal morbidity and mortality discussed above, it would seem prudent to initiate fetal testing no later than 41 weeks of gestation.** A number of small studies suggest that twice-weekly antepartum testing is superior to once a week in prolonged pregnancies. Johnson and associates<sup>60</sup> reported results on twice-weekly testing with BPP in 293 patients followed beyond 42 weeks. No stillbirths were observed in this small series.

No large randomized controlled trials (RCTs) have compared different modalities of fetal surveillance in prolonged pregnancies. One RCT of 145 pregnancies beyond 42 weeks compared BPP with modified BPP (mBPP).<sup>61</sup> This study found a significant increase in abnormal testing in the mBPP group (42% vs. 20.5%, OR, 3.5; 99% CI, 1.3 to 9.1) but no difference in cord blood gases and neonatal outcome between the two groups. Studies have not shown one modality of antepartum surveillance to be superior to another.<sup>61</sup>

**ACOG proposed that amniotic fluid volume (AFV) should be assessed when surveillance is initiated for late-term**

**pregnancies because oligohydramnios has been associated with abnormal fetal heart tracings, umbilical cord compression, and meconium-stained fluid.** Chamberlain and coworkers<sup>62</sup> studied 7582 complicated pregnancies and found an increase in the risk of fetal demise with decreased amniotic fluid.

A paucity of data are available to demonstrate improved neonatal outcomes in postterm pregnancies when testing is used. Still, given the well-described increase in stillbirth in postterm pregnancies, **ACOG currently recommends the initiation of fetal surveillance at 41 weeks or beyond with assessment of AFW.**<sup>3</sup>

Umbilical artery Doppler measurements are sometimes used in cases of suspected placental insufficiency, and hence it might be imagined that this modality could be useful in postterm pregnancies. However, umbilical artery Doppler measurements have not been shown to be useful in the management of prolonged pregnancies.<sup>63</sup>

### Expectant Management Versus Induction of Labor

Until the recent ACOG guidelines, expectant management was acceptable when the cervix was unfavorable. **New evidence, as discussed below, supports the induction of labor after 42<sup>0/7</sup> weeks and by 42<sup>6/7</sup> weeks to decrease the risk of perinatal morbidity and mortality,** and it may be considered for pregnancies between 41<sup>0/7</sup> weeks and 41<sup>6/7</sup> weeks.

Several clinical trials have compared induction of labor to expectant management in pregnancies that have progressed beyond their EDD. Hannah and associates<sup>64</sup> performed one of the largest clinical trials, wherein 3407 pregnant women were randomized at 41 weeks to induction or expectant management with fetal surveillance. Delivery was indicated if the pregnancy reached 44 weeks or if fetal compromise was evident. No difference was reported in the perinatal mortality and neonatal morbidity, although the rate of cesarean delivery was increased in the expectantly managed group. No cases of fetal demise were reported in the induction group, and two were reported in the expectantly managed group.

Another RCT of 440 uncomplicated pregnancies performed by the National Institute of Child Health and Human Development (NICHD) Network of Maternal-Fetal Medicine Units compared induction at 42 weeks versus expectant management until cervical effacement, dilation, or evidence of fetal compromise was apparent.<sup>65</sup> The primary outcome was perinatal or maternal death or a composite of variables for perinatal morbidity. Secondary outcomes for this trial included cesarean delivery, maternal infection, blood transfusion, severe variable or late decelerations, and a 5-minute Apgar score less than 4. No differences were detected in primary outcome or rates of cesarean delivery. The study concluded that either induction or expectant management at 42 weeks was deemed acceptable practice.

More recently, Sanchez-Ramos and colleagues<sup>66</sup> published a meta-analysis that included 16 RCTs and 6588 patients and found a 20% rate of cesarean delivery in uncomplicated pregnancies induced at 41 weeks compared with 22% in the expectantly managed group. A nonsignificant but numerically lower perinatal mortality rate was reported for the induction group (0.09% vs. 0.33%, OR, 0.41; 95% CI, 0.14 to 1.18). They also found no differences in NICU admission and meconium aspiration.

The most recent Cochrane review,<sup>67</sup> updated in 2012, is a meta-analysis of 22 RCTs. The review included 9383 patients and looked at the potential benefits or harms of labor induction

at or beyond 40 weeks' gestation versus expectant management. The primary outcome was perinatal mortality, which included IUFD and neonatal death in the first week of life. Labor induction was associated with a small but significant reduction in perinatal death (RR, 0.31; 95% CI, 0.12 to 0.88) with no impact on the rate of cesarean delivery (RR, 0.89; 95% CI, 0.81 to 0.97). **This Cochrane meta-analysis suggests that induction may yield slightly improved perinatal outcomes.**

### Labor Induction

Several studies have addressed membrane sweeping as a method for labor induction in an attempt to reduce the occurrence of postterm pregnancies (see Chapter 13). Membrane sweeping is the digital separation of the membranes from the lower uterine segment during a cervical examination. This practice is thought to increase the levels of endogenous prostaglandin, which results in uterine contractions. An RCT conducted by de Miranda and colleagues<sup>68</sup> enrolled 742 patients at 41 weeks' gestation and randomized them to serial sweeping of membranes every 48 hours until 42 weeks, or until labor was initiated, or to no intervention. They found a decrease in the risk of postterm pregnancy in the first group; 23% were postterm (RR, 0.57; 95% CI, 0.46 to 0.71) compared with 41% in the no-intervention group. The number needed to treat (NNT) for this trial was six patients. Previously published trials have not shown a significant difference, but these studies limited membrane sweeping to a single episode.<sup>69,70</sup> The most recent Cochrane review of trials that enrolled pregnant patients from 38 to 41 weeks to membrane sweeping found a reduced rate of pregnancies that continued past 41 weeks' gestation, with an NNT of eight patients.<sup>71</sup> Although this practice may be effective in some pregnant patients, the procedure is known to cause maternal discomfort and bleeding. Also, evidence is limited regarding membrane sweeping in women colonized with group B *Streptococcus*. **Thus patients who can consider this option should be selected carefully and counseled appropriately.**

Some have attempted to predict the likelihood of successful induction using transvaginal ultrasound of the cervix and fetal fibronectin. Pandis and colleagues<sup>72</sup> compared Bishop score with ultrasound cervical assessment and found cervical length to be more predictive of a successful labor induction than Bishop score (with a sensitivity and specificity of 87% and 71% vs. 58% and 27%, respectively). Although the results of this study are promising, transvaginal ultrasound assessment of the cervix to predict induction success is not commonly used. Attempts to evaluate the role of a fetal fibronectin in cervical secretions as a predictor of the onset of spontaneous labor have been inconclusive. In fact, Rozenberg and associates<sup>73</sup> have shown that the spontaneous onset of labor within 7 days of evaluation is predicted by a Bishop score greater than 7 and a cervical length less than 25 mm but not with a positive fetal fibronectin (fFN).

Prostaglandins are most commonly used for labor induction in patients with an unfavorable cervix or a Bishop score less than 6. Studies have shown both misoprostol (prostaglandin E1 [PGE<sub>1</sub>]) and dinoprostone (prostaglandin E2 [PGE<sub>2</sub>]) to be efficacious in postterm pregnancy, and either preparation is acceptable.<sup>64,65,74</sup>

### LONG-TERM NEONATAL OUTCOMES

A paucity of information exists on neonates born at 42 weeks and later. Ting and coworkers<sup>75</sup> evaluated a population enrolled

in the Collaborative Perinatal Study in Philadelphia and found that surviving children could not be differentiated from their matched controls either physically or mentally. Shime and colleagues<sup>76</sup> found similar results in children followed at 1 and 2 years of age. They assessed intelligence by the Griffiths Mental Development Scale and found no difference when these children were compared with those from term births. **Based on these small and older studies, no difference in long-term neonatal outcome is apparent.**

## MULTIPLE GESTATION

**No defined gestational age cutoff has been established to define a prolonged pregnancy in twin, triplet, or higher-order multiples.** The average gestation lengths for twin, triplet, and quadruplet pregnancies are 36, 33, and 29 weeks, respectively. The nadir of stillbirth occurs at 38 weeks for twins and at 35 weeks for triplets, and it is unknown for quadruplets and higher-order multiples.<sup>77</sup> Intuitively, because we use rates of perinatal mortality to define these cutoffs for singletons, we should do the same for multiple gestations. No current strategies have been recommended as these pregnancies approach the above gestational ages, although **it would seem reasonable to utilize antenatal testing as these gestational ages approach and to accomplish delivery at the nadir of stillbirth risk** (see Chapter 32).

### KEY POINTS

- ◆ Ultrasonography, preferably done in the first trimester, is the most accurate method with which to establish the EDD.
- ◆ No gestational cutoff has been established by which to define a prolonged pregnancy in multiple gestations. The risk for stillbirth increases after 38 weeks in twins and after 35 weeks in triplets.
- ◆ Late-term and postterm pregnancies are associated with an increased risk for perinatal morbidity and mortality, oligohydramnios, macrosomia, postmaturity, and maternal morbidity.
- ◆ It seems prudent to initiate antenatal fetal surveillance at 41 weeks in a normal, uncomplicated pregnancy in the absence of IUGR.
- ◆ Antenatal fetal surveillance at 41 weeks should include an mBPP at least once a week.
- ◆ If the cervix is favorable at 41 weeks, induction of labor can be considered.
- ◆ Delivery after 42<sup>0/7</sup> weeks and by 42<sup>6/7</sup> weeks is recommended based on the small but increased risk of perinatal morbidity and mortality.
- ◆ Either prostaglandin preparation, PGE<sub>1</sub> or PGE<sub>2</sub>, can be used for induction of the postterm pregnancy.

**Cardiovascular adaptations to pregnancy are well tolerated by healthy young women.** However, these adaptations are of such magnitude that they can significantly compromise women with abnormal or damaged hearts. Without accurate diagnosis and appropriate care, heart disease in pregnancy can be a significant cause of maternal mortality and morbidity. Under more optimal conditions, many women with significant disease can experience good outcomes and should not necessarily be discouraged from becoming pregnant. This chapter develops an understanding of cardiovascular physiology as a basis for care of

the pregnant woman with heart disease. Although published experience with more common conditions can be used to support these principles, information regarding many other conditions is limited to case reports. Data from case reports may, however, be biased toward more complicated cases with more adverse outcomes. The best care for women with heart disease is usually achieved from a thorough understanding of maternal cardiovascular physiology, knowledge of existing literature, and extensive clinical experience brought by a multidisciplinary team of clinicians.

## MATERNAL HEMODYNAMICS

*Hemodynamics* refers to the relationship between blood pressure, cardiac output, and vascular resistance. Blood pressure is measured by auscultation, use of an automated cuff, or directly with an intraarterial catheter. Cardiac output is measured by dilutional techniques that require central venous access, by Doppler or two-dimensional (2-D) echocardiographic techniques, or by electrical impedance. Peripheral resistance is calculated using Ohm's law:

$$TPR = (MAP \times 80) / CO$$

where *TPR* is total peripheral resistance (in  $\text{dyne} \cdot \text{sec} \cdot \text{cm}^{-5}$ ), *MAP* is mean arterial pressure (in millimeters of mercury [mm Hg]), and *CO* is cardiac output (in liters per minute).

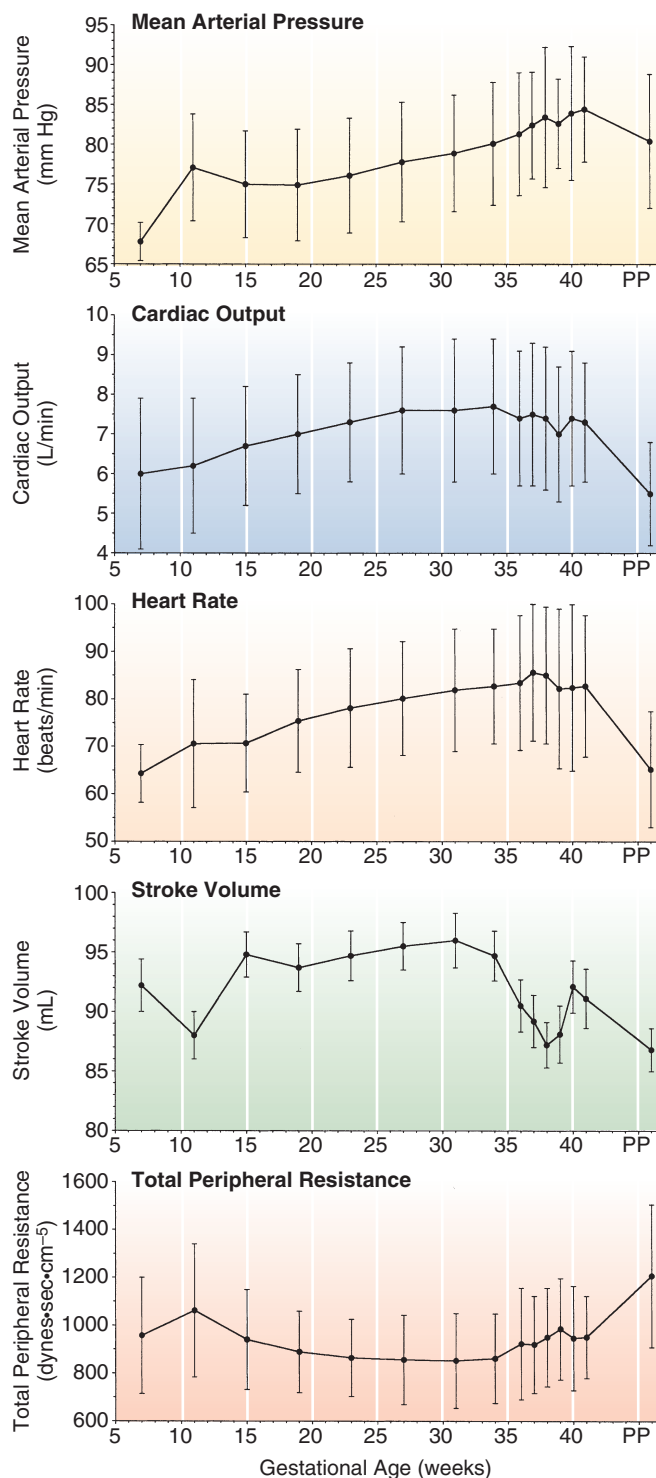

Pregnancy and events unique to pregnancy, such as labor and delivery, are associated with significant and frequently predictable changes in these parameters. The hemodynamic changes of pregnancy, although well tolerated by an otherwise healthy woman, may be tolerated poorly by a woman with significant cardiac disease. Therefore the importance of understanding these changes and placing them in the context of a specific cardiac lesion cannot be overstated.

The maternal hemodynamics of 89 nulliparous women who remained normotensive throughout pregnancy are described in Figure 37-1.<sup>1</sup> MAP falls sharply in the first trimester and reaches a nadir by midpregnancy. Thereafter blood pressure increases slowly and reaches near nonpregnant levels by term. Cardiac output rises throughout the first and second trimesters and reaches a maximum by the middle of the third trimester. **In the supine position, a pregnant woman in the third trimester may experience significant hypotension as a result of venocaval occlusion by the gravid uterus.** In normal pregnancy, venocaval occlusion may produce symptoms such as diaphoresis, tachycardia, or nausea but will rarely result in significant complications. Fetal heart rate (FHR) decelerations may be observed but usually resolve when the mother, often spontaneously, shifts to a more comfortable position. Women with significant right or left ventricular outflow obstruction, such as aortic stenosis, may seriously decompensate in the supine position as a result of poor ventricular filling. Cardiac output (CO) is the product of heart rate (HR) and stroke volume (SV):

$$CO = HR \times SV$$

HR and SV increase as pregnancy progresses to the third trimester. After 32 weeks, SV falls, with the maintenance of CO becoming more and more dependent on HR. Vascular resistance falls in the first and early second trimesters. The magnitude of the fall is sufficient to offset the rise in CO, which results in a net decrease in blood pressure.

**Labor, delivery, and the postpartum period are times of acute hemodynamic changes that may result in maternal decompensation.** Labor itself is associated with pain and anxiety, and tachycardia is a normal response. Significant catecholamine release increases afterload. Each uterine contraction acutely redistributes 400 to 500 mL of blood from the uterus to the central circulation. In Figure 37-2, Robson and colleagues<sup>2</sup> describe the hemodynamic changes associated with unmedicated labor. **HR, blood pressure, and CO all increase with uterine contractions, and the magnitude of the change increases as labor advances.** Obstructive cardiac lesions impede the flow of blood through the heart, blunting the expected rise

**FIG 37-1** Changes in hemodynamic parameters throughout pregnancy (mean  $\pm$  standard deviation). PP, postpartum.

in CO at the expense of increasing pulmonary pressures and pulmonary congestion. In Figure 37-3, intrapartum hemodynamic changes of a patient with aortic stenosis and a peak gradient of 160 mm Hg are shown.<sup>3</sup> In this individual, pulmonary pressures rise in parallel with uterine contractions.

Immediately after delivery, blood from the uterus is returned to the central circulation. In normal pregnancy, this compensatory mechanism protects against the hemodynamic effects that

**FIG 37-2** Changes in hemodynamic parameters at three different points during labor ( $\leq 3$  cm, 4–7 cm, and  $\geq 8$  cm). Each line represents the change in an individual subject. B, before contraction; C, during contraction. (From Robson S, Dunlop W, Boys R, Hunter S. Cardiac output during labour. *BMJ*. 1987;295:1169.)

may accompany postpartum hemorrhage. **In the context of cardiac disease, this acute centralization of blood may increase pulmonary pressures and pulmonary congestion.**<sup>4</sup> During the first 2 postpartum weeks, extravascular fluid is mobilized, diuresis ensues, and vascular resistance increases, returning to nonpregnant norms. Decompensation during postpartum fluid mobilization is common in women with mitral stenosis. Volume loading coupled with vasoconstriction may also unmask maternal cardiomyopathy. Unsuspected cardiac disease may be diagnosed when a woman returns to the emergency department several days postpartum with dyspnea and oxygen desaturation. Maternal CO usually normalizes by 2 weeks postpartum.

**Three key features of the maternal hemodynamic changes in pregnancy are particularly relevant to the management of**

**women with cardiac disease: (1) increased CO, (2) increased HR, and (3) reduced vascular resistance.** In conditions such as mitral stenosis, in which CO is relatively fixed, the drive to achieve an elevated CO may result in pulmonary congestion. If a patient has an atrial septal defect (ASD), the incremental increase in systemic flow associated with pregnancy will be magnified in the pulmonary circulation to the extent that pulmonary flow exceeds systemic flow. If, for example, a shunt ratio of 3:1 is maintained in pregnancy, pulmonary flow may be as high as 20 L/min and may be associated with increasing dyspnea and potential desaturation.

Many cardiac conditions are HR dependent. Flow across a stenotic mitral valve is dependent on the proportion of time in diastole. Tachycardia reduces left ventricular (LV) filling and CO. Coronary blood flow is also dependent on the length of diastole. Patients with aortic stenosis have increased wall tension and therefore increased myocardial oxygen requirements. Tachycardia reduces coronary perfusion time in diastole while simultaneously further increasing myocardial oxygen requirements, and the resulting imbalance between oxygen demand and supply may precipitate myocardial ischemia. Patients with complex congenital heart disease (CHD) can experience significant tachyarrhythmias. The increasing HR in pregnancy may be associated with a worsening of tachyarrhythmias.

Reduction in vascular resistance may be beneficial to some patients, and afterload reduction reduces cardiac work. Cardiomyopathy, aortic regurgitation, and mitral regurgitation all benefit from reduced afterload. Alternatively, patients with intracardiac shunts, in which right and LV pressures are nearly equal when the patient is not pregnant, may reverse their shunt during pregnancy and may desaturate because of right-to-left shunting.

### Blood Volume

Very early in the first trimester, pregnant women experience an expansion of renal blood flow and glomerular filtration rate (GFR). Filtered sodium increases by about 50%. Despite physiologic changes that would promote loss of salt and water and contraction of blood volume, **the pregnant woman will expand her blood volume by 40% to 50%.** In part, the stimulation to retain fluid may be a response to the fall in vascular resistance and reduction in blood pressure. The renin-angiotensin system is activated, and the plasma concentration of aldosterone is elevated. Although the simplicity of this explanation is attractive, the actual process is probably much more complicated.

As plasma volume expands, the hematocrit falls, and hematopoiesis is stimulated. Red cell mass will expand from 18% to 25% depending on the status of individual iron stores. Physiologic anemia with a maternal hematocrit between 30% and 35% does not usually complicate pregnancy in the context of maternal heart disease. More significant anemia, however, may increase cardiac work and induce tachycardia. Microcytosis due to iron deficiency may impair perfusion of the microcirculation of patients who are polycythemic because of cyanotic heart disease; this is because microcytic red blood cells are less deformable. Iron and folate supplementation may be appropriate.

In a similar fashion, serum albumin concentration falls by 22% despite an expansion of intravascular albumin mass by 20%. **As a result, serum oncotic pressure falls in parallel by 20% to about 19 mm Hg.**<sup>5</sup> In normal pregnancy, intravascular fluid balance is maintained by a fall in interstitial oncotic pressure. However, if LV filling pressure becomes elevated or if pulmonary vascular integrity is disrupted, pulmonary edema

**FIG 37-3** Hemodynamic monitoring of a patient with severe aortic stenosis in labor. BP, blood pressure; ECG, electrocardiogram; FHR, fetal heart rate; HR, heart rate; PAP, pulmonary artery pressure. (From Easterling T, Chadwick H, Otto C, Benedetti T. Aortic stenosis in pregnancy. *Obstet Gynecol.* 1988;72:113.)

will develop earlier in the disease process than in nonpregnant women.

## DIAGNOSIS AND EVALUATION OF HEART DISEASE

Many women with heart disease have been diagnosed and treated before pregnancy. For example, in women with prior surgery for CHD, detailed historic information may be available. Others report only that they have a murmur or “a hole in their heart.” Alternatively, heart disease may be diagnosed for the first time during pregnancy owing to symptoms precipitated by increased cardiac demands.

**The classic symptoms of cardiac disease are palpitations, shortness of breath with exertion, and chest pain. Because these symptoms also may accompany normal pregnancy, a careful history is needed to determine whether the symptoms are out of proportion to the stage of pregnancy.** Symptoms are of particular concern in a patient with other reasons to suspect underlying cardiac disease, such as being native to an area where rheumatic heart disease is prevalent.

A systolic flow murmur is present in 80% of pregnant women, most likely because of the increased flow volume in the aorta and pulmonary artery. Typically, a flow murmur is grade 1 or 2, midsystolic, loudest at the cardiac base, and not associated with any other abnormal physical examination findings. A normal physiologic split second heart sound is heard in patients with a flow murmur. **Any diastolic murmur and any systolic murmur that is loud (grade 3/6 or higher) or radiates to the carotids**

**should be considered pathologic.** Careful evaluation for elevation of the jugular venous pulse, peripheral cyanosis or clubbing, and pulmonary crackles is needed in women with suspected cardiac disease.

**Indications for further cardiac diagnostic testing in pregnant women include a history of known cardiac disease, symptoms in excess of those expected in a normal pregnancy, a pathologic murmur, evidence of heart failure on physical examination, or arterial oxygen desaturation in the absence of known pulmonary disease.** The preferred next step in evaluation of pregnant women with suspected heart disease is trans-thoracic echocardiography. A chest radiograph is helpful only if congestive heart failure (CHF) is suspected. An electrocardiogram (ECG) may be nonspecific but could show changes suggestive of the underlying heart disease, such as right ventricular (RV) hypertrophy and biatrial enlargement, seen in patients with significant mitral stenosis. If symptoms are consistent with a cardiac arrhythmia, an event monitor or 24-hour ECG monitor may be indicated. Rarely, cardiac catheterization is needed for full diagnosis of valvular disease or CHD. The exception is an acute coronary syndrome during pregnancy, in which the risk for radiation exposure with cardiac catheterization is small compared with the benefit of early diagnosis and early revascularization to prevent myocardial infarction (MI).

Echocardiography provides detailed information on cardiac anatomy and physiology that allows optimal management of women with heart disease. Basic data obtained on echocardiography include left ventricular ejection fraction, pulmonary artery systolic pressure, qualitative evaluation of RV systolic function,

**FIG 37-4** Changes in B-type natriuretic protein in a patient across two pregnancies.

and evaluation of valve anatomy and function. When valvular stenosis is present, the pressure gradient ( $\Delta P$ ) across the valve is calculated from the **Doppler-derived velocity ( $v$ ) of flow across the valve ( $\Delta P = 4v^2$ )**. Similarly, pulmonary artery systolic pressure can be calculated from the maximal Doppler velocity obtained across a tricuspid regurgitant jet.

Aortic valve area is calculated using the continuity equation. Stroke volume (SV) is calculated from the product of the cross-sectional area of the left ventricular outflow tract (LVOT) and the time-velocity integral derived from Doppler evaluation of the outflow tract. A time-velocity integral is then derived from the stenotic valve. Because the LVOT and the aortic valve are in continuity, SVs across each are equal. Therefore valve area can be derived by dividing the SV by the aortic valve time-velocity integral. Mitral valve area is measured directly by 2-D planimetry or by the Doppler pressure half-time method. In patients with congenital disease, detailed evaluation of anatomy and previous surgical repair is possible. When complex CHD is present or when image quality is suboptimal, transesophageal imaging provides improved image quality. Cardiac magnetic resonance imaging (MRI) may be used to define complex anatomy that is not well evaluated by echocardiography, but caution must be taken with magnetic resonance contrast agents such as gadolinium.

Serum levels of B-type ( $\beta$ ) natriuretic peptide (BNP) and N-terminal pro-BNP (NT-proBNP) rise in response to volume loading conditions and have been used outside pregnancy as predictors of adverse outcomes in patients with cardiac disease. Serum levels of BNP of 100 pg/mL or less and NT-proBNP of 125 pg/mL or less have been demonstrated to have strong negative predictive values for adverse cardiac outcomes in pregnant women with heart disease.<sup>6,7</sup> In our practice, we use BNP to identify potentially adverse effects of volume loading in pregnancy and to guide therapy. **Figure 37-4** describes the course of serum BNP levels across two pregnancies in a woman with hypertrophic cardiomyopathy. The time frame of each of the pregnancies is easily identifiable by a marked rise in BNP, and the impact of the initiation and dose adjustments in diuretic therapy with furosemide can be identified by sharp reductions in BNP.

## GENERAL CARE

Management of cardiac disease in pregnancy is frequently complicated by unique social and psychological concerns. Women who had CHD as children may have experienced multiple

### BOX 37-1 STRUCTURED ASSESSMENT OF CARDIAC SYMPTOMS

How many flights of stairs can you walk up with ease?

Two? One? None?

- Do you have pain when your heart races?

hospitalizations and may be fearful of the medical environment. Some have been cautioned against pregnancy and therefore never expected to bear children. Women with rheumatic heart disease have frequently lived outside the traditional medical care system owing to conditions of poverty, immigration, and cultural differences. Care must be exercised to facilitate their access to care and their comfort with the environment of care. Their practitioner must be patient but persistent in the face of deviations from more traditional standards of compliance and medical care.

**Deterioration in cardiac status during pregnancy is frequently insidious.** Continuity of care with a single provider facilitates early intervention before overt decompensation. Regular visits should include particular attention to heart rate, weight gain, and oxygen saturation. An unexpected increase in weight may indicate the need for more aggressive outpatient therapy. A fall in oxygen saturation often precedes a clearly abnormal chest examination or radiograph. Regular use of a structured history of symptoms (**Box 37-1**) alerts the physician to a change in condition. A regular review of symptoms also educates patients and reinforces their collaborative roles as “partners in care.”

The physiologic changes of pregnancy are usually continuous; therefore they offer adequate time for maternal compensation despite cardiac disease. **Intercurrent events superimposed on pregnancy in the context of maternal heart disease are usually responsible for acute decompensation.** During the antepartum period, the most common of these are febrile episodes. Screens for bacteriuria and vaccination against influenza and pneumococcus (*Streptococcus pneumoniae*) are appropriate. Patients should be instructed to report symptoms of upper respiratory infection, particularly fever. Many women with heart disease—but especially adolescents, recent immigrants, and those living in poverty—are also at risk for iron deficiency. Prophylaxis against anemia with iron and folate supplementation may decrease cardiac work.

One strategy is described in **Box 37-2**; these general principles for care are similar for most cardiac diagnoses. **Physiologically, the ideal labor for a woman with heart disease is short and pain free.** Although induction of labor facilitates organization of care and early pain control, shortening the duration of pregnancy by 1 or 2 weeks at the cost of a 2- or 3-day induction of labor is not worthwhile. Induction of labor with a favorable cervix is therefore preferred. Some patients with severe cardiac disease benefit from invasive hemodynamic monitoring with an arterial catheter and a pulmonary artery catheter. These methods are discussed in detail later. Cesarean delivery is usually reserved for obstetric indications. The American Heart Association (AHA) does not recommend routine antibiotic prophylaxis for the prevention of endocarditis, although it is optional in

### BOX 37-2 STANDARD CARDIAC CARE FOR LABOR AND DELIVERY

1. Accurate diagnosis
2. Mode of delivery based on obstetric indications
3. Medical management initiated early in labor
  - Prolonged labor avoided
  - Induction with a favorable cervix
4. Maintenance of hemodynamic stability
  - Invasive hemodynamic monitoring when required
  - Initial, compensated hemodynamic reference point
  - Specific emphasis based on particular cardiac condition
5. Avoidance of pain and hemodynamic responses
  - Epidural analgesia with narcotic/low-dose local technique
6. Consideration for prophylactic antibiotics when at risk for endocarditis
7. Avoidance of maternal pushing
  - Caudal block for dense perineal anesthesia
  - Low forceps or vacuum delivery
8. Avoidance of maternal blood loss
  - Proactive management of the third stage
  - Early but appropriate fluid replacement
9. Early volume management postpartum
  - Often careful but aggressive diuresis

high-risk patients having a vaginal delivery. Because bacteremia is common at the time of vaginal delivery and cesarean delivery,<sup>8</sup> many practitioners will provide antibiotic prophylaxis in all patients at risk. In contrast to AHA recommendations, compelling arguments in support of broad use of antibiotic prophylaxis have been made, citing limited large-scale studies that support the recommendations and the high cost and risk associated with endocarditis.<sup>9</sup>

Women with significant heart disease should be counseled before pregnancy regarding the risk of pregnancy, interventions that may be required, and potential risks to the fetus. However, women with significant uncorrected disease often present with an ongoing established pregnancy. In this situation, the risks and benefits of termination of pregnancy versus those of continuing a pregnancy should be addressed. **The decision to become pregnant or carry a pregnancy in the context of maternal disease is a balance of two forces: the objective medical risk, including the uncertainty of that estimate, and the value of the birth of a child to an individual woman and her partner.** The first goal of counseling is to educate the patient. Only a few cardiac diseases represent an overwhelming risk for maternal mortality: Eisenmenger syndrome, pulmonary hypertension with RV dysfunction, and Marfan syndrome with significant aortic dilation and severe LV dysfunction. Most other conditions require aggressive management and significant disruption in lifestyle. Intercurrent events such as antepartum pneumonia or obstetric hemorrhage pose the greatest risk for initiating life-threatening events; fastidious care can reduce, but does not eliminate, the risk for these events. Maternal CHD increases the risk for CHD in the fetus from 1% to about 4% to 6%.<sup>9,10</sup> Marfan syndrome and some forms of hypertrophic cardiomyopathy are inherited as autosomal-dominant conditions, and offspring of these women carry a 50% chance of inheriting the disease. The second goal of counseling is to help each woman integrate the medical information into her individual value system and her individual desire to become a mother. Many

women with significant but manageable heart disease choose to carry a pregnancy. The basis for decisions regarding their care should be individualized.

### Risk-Scoring Strategies

Pregnancy in women with heart disease is associated with increased risks for deterioration of maternal cardiac status and adverse pregnancy outcomes. **These risks include maternal arrhythmias, heart failure, preterm birth, fetal growth restriction, and a small but significant risk of maternal and fetal mortality.** Accurate quantification of maternal and fetal risks should be used to counsel patients and to direct care. Three risk models have been suggested.

The Cardiac Disease in Pregnancy (CARPREG) score was derived from a prospective descriptive study of 562 pregnant women with cardiac disease that included congenital or acquired lesions and arrhythmias.<sup>11</sup> The scoring system was created to estimate the risk of experiencing a primary cardiac event. The predictors in this scoring system include (1) a prior cardiac event—heart failure, transient ischemic attack, or stroke before pregnancy; (2) baseline New York Heart Association (NYHA) class greater than II or cyanosis; (3) mitral valve area less than 2 cm<sup>2</sup>, aortic valve area less than 1.5 cm<sup>2</sup>, or peak LVOT gradient greater than 30 mm Hg by echocardiography; and (4) reduced systemic ventricular systolic function with an ejection fraction (EF) of less than 40%.

The ZAHARA (*Zwangerschap bij Aangeboren Hartafwijkingen* [Pregnancy In Congenital Heart Disease]) score was derived from a nationwide database of 1302 pregnant women with CHD.<sup>12</sup> Predictors identified to be associated with maternal cardiac complications included (1) prior arrhythmia, (2) NYHA class III or IV, (3) LVOT gradient greater than 50 mm Hg or aortic valve area less than 1.0 cm<sup>2</sup>, (4) mechanical valve prosthesis, (5) systemic atrioventricular (AV) valve regurgitation (moderate/severe), (6) pulmonary AV valve regurgitation (moderate to severe), (7) cardiac medication prior to pregnancy, and (8) cyanotic heart disease, both corrected and uncorrected. This study also externally validated the prior CARPREG study and noted that the CARPREG score overestimated the risk.

The modified World Health Organization (WHO) classification uses four categories determined largely by diagnosis: *class I* includes uncomplicated, mild pulmonary stenosis; *class II* comprises unoperated ASD, ventricular septal defect (VSD), and repaired tetralogy of Fallot; *class III* includes mechanical valves, systemic right ventricle, Fontan circulation, unrepaired cyanotic heart disease, other complex CHD, Marfan syndrome with an aorta 40 to 45 mm in width or bicuspid aortic valve with an aorta 45 to 50 mm; and *class IV* describes pulmonary hypertension/Eisenmenger syndrome, systemic EF less than 30%, systemic dysfunction of NYHA class III or IV, severe mitral stenosis, severe symptomatic aortic stenosis, Marfan syndrome with aorta greater than 45 mm, bicuspid valve with aorta greater than 50 mm, or severe coarctation.<sup>13</sup>

The ZAHARA II study was performed to validate and compare CARPREG, ZAHARA I, and the modified WHO risk models for pregnant women with CHD.<sup>14</sup> ZAHARA II enrolled 213 women and included patients only with congenital structural heart disease. Overall, primary cardiovascular events were observed in 22 of the pregnancies (10.3%). The most frequent events included clinically significant arrhythmias, followed by heart failure and thrombotic events. It was noted that the ZAHARA I and CARPREG scores overestimated risk. The

modified WHO classification performed as the best available risk-assessment model for estimating cardiovascular risk.

From the scoring systems, common features can be identified that individually or collectively may predict adverse outcome. For patients with several risk factors, the impact on outcome may be more than additive, as suggested by the structures of the scoring systems: (1) prior cardiac event, (2) NYHA class III or IV, (3) LVOT obstruction, (4) reduced systemic EF, (5) mechanical prosthesis, (6) moderate to severe AV valve regurgitation, (7) cardiac medications prior to pregnancy, and (8) cyanotic heart disease. The WHO system based on diagnoses incorporates risk associated with pulmonary hypertension and RV dysfunction, severe mitral stenosis, dilated aortas, and single-ventricle repairs not specifically captured by CARPREG or ZAHARA.

Although it seems optimal to be able to assign a direct risk score to a woman when counseling her during pregnancy, all of the studies above highlight the challenge in being able to create the ideal scoring system. Each category of CHD carries varied risks based on maternal hemodynamic and cardiovascular function findings. It is therefore important to understand the different risk scores; although ultimately, the individual cardiovascular functional parameters and overall hemodynamic stability of each patient must be understood to provide the most individualized care for each woman.

## VALVULAR DISEASE

The American College of Cardiology (ACC) and the AHA have published guidelines for the management of valvular heart disease, including some guidelines for management during pregnancy.<sup>15</sup> These guidelines create a general framework for pre-conceptional care and care during pregnancy, realizing that treatment of a specific patient must be individualized.

### Mitral Stenosis

Mitral stenosis is most commonly caused by rheumatic heart disease and is the most common acquired valvular lesion in pregnant women. Valvular dysfunction progresses continuously throughout life. Deterioration may be accelerated by recurrent episodes of rheumatic fever, an immunologic response to group A  $\beta$ -hemolytic *Streptococcus* (GBS) infections. The incidence of rheumatic fever in a population is heavily influenced by conditions of poverty and crowding. These same individuals are at risk for having reduced access and use of health care resources and may present undiagnosed or untreated.

Patients with asymptomatic mitral stenosis have a 10-year survival rate of greater than 80%. Once a patient is significantly symptomatic, the 10-year survival rate without treatment is less than 15%. In the presence of pulmonary hypertension, mean survival falls to less than 3 years. Death is due to progressive pulmonary edema, right-sided heart failure, systemic embolization, or pulmonary embolism.<sup>15</sup>

Stenosis of the mitral valve impedes the flow of blood from the left atrium to the left ventricle during diastole. The normal mitral valve area is 4 to 5 cm<sup>2</sup>. Symptoms with exercise can be expected with valve areas less than or equal to 2.5 cm<sup>2</sup>. Symptoms at rest are expected at less than or equal to 1.5 cm<sup>2</sup>. The left ventricle responds with Starling mechanisms to increased venous return with increased performance, elevating CO in response to demand. The left atrium is limited in its capacity to respond, and therefore **CO is limited by the relatively passive flow of blood through the valve during diastole; increased**

**venous return results in pulmonary congestion rather than increased CO.** Thus the drive for increased CO in pregnancy cannot be achieved, resulting in increased pulmonary congestion. The relative tachycardia experienced in pregnancy shortens diastole, decreases LV filling, and therefore further compromises CO and increases pulmonary congestion.

The diagnosis of mitral stenosis in pregnancy before maternal decompensation is uncommon. Fatigue and dyspnea on exertion are characteristic symptoms of mitral stenosis but are also ubiquitous among pregnant women. Although the presence of a diastolic rumble may suggest mitral stenosis, this finding is subtle and may be overlooked or not appreciated. Not uncommonly, an intercurrent event such as a febrile episode will result in exaggerated symptoms and the diagnosis of pulmonary edema or oxygen desaturation. Under these circumstances, particularly in the context of a patient from an at-risk group, an echocardiogram should be performed to rule out mitral valvular disease.

Echocardiographic diagnosis of mitral stenosis is based on the characteristic appearance of the stenotic, frequently calcified valve. Calculation of valve area from the Doppler pressure half-time method or by 2-D planimetry provides an objective measure of severity. Valve areas of 1 cm<sup>2</sup> or less usually require pharmacologic management during pregnancy and invasive hemodynamic monitoring during labor, whereas those 1.4 cm<sup>2</sup> or less usually require careful expectant management. Left atrial enlargement identifies a patient at risk for atrial fibrillation, subsequent atrial thrombus, and the potential for systemic embolization. Embolic complications have been reported in pregnant women with atrial enlargement without atrial fibrillation. Pulmonary hypertension, a complication of worsening mitral disease, can be diagnosed and quantified with Doppler evaluation of the regurgitant jet across the tricuspid valve. **Elevated pulmonary pressures may be due to hydrostatic forces associated with elevated left atrial pressures or, in more advanced disease, may result from pathologic elevations of pulmonary vascular resistance (PVR).** Hydrostatic pulmonary hypertension may respond to therapy that lowers left atrial pressure. Pulmonary hypertension due to elevated PVR is life threatening in pregnancy and may precipitate right-sided heart failure in the postpartum period.

**Pregnancy does not negatively affect the natural history of mitral stenosis.** Chesley<sup>16</sup> reviewed the medical histories of 134 women with functionally severe mitral stenosis who survived pregnancies between 1931 and 1943. These women lived before modern management of mitral stenosis and therefore represent the natural history of the disease. By 1974, only nine of the cohort remained alive. Their death rate was exponential; during each year of follow-up, the rate for the remaining cohort was 6.3%. Women with subsequent pregnancies had comparable survival to those who did not become pregnant again, allowing the authors to conclude that pregnancy did not negatively affect long-term outcome.

**The goal of antepartum care in the context of mitral stenosis is to achieve a balance between the drive to increase CO and the limitations of flow across the stenotic valve.** Most women with significant disease require diuresis with a drug such as furosemide. In addition,  $\beta$ -blockade reduces heart rate, improves diastolic flow across the valve, and relieves pulmonary congestion. Al Kasab and associates<sup>17</sup> evaluated the impact of  $\beta$ -blockade on 25 pregnant women with significant mitral stenosis. [Figure 37-5](#) describes the functional status of women before pregnancy and during pregnancy before and after

$\beta$ -blockade. The deterioration associated with pregnancy and the subsequent improvement with treatment is evident. Fastidious antepartum care as described earlier should supplement pharmacologic management.

Women with a history of rheumatic valvular disease who are at risk for contact with populations with a high prevalence of streptococcal infection should receive prophylaxis with daily oral penicillin G or monthly benzathine penicillin. Most pregnant women live in close contact with groups of children and usually are considered at risk.

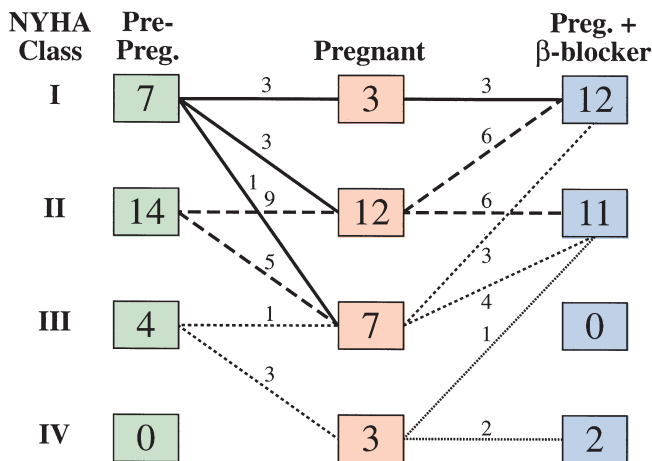

Atrial fibrillation (AF) is a complication associated with mitral stenosis due to left atrial enlargement. Rapid ventricular response to AF may result in sudden decompensation. Digoxin,  $\beta$ -blockers, or calcium channel blockers can be used to control ventricular response. In the context of hemodynamic decompensation, electrical cardioversion may be necessary. Anticoagulation with heparin should be used before and after cardioversion to prevent systemic embolization. Patients with chronic AF and

a history of an embolic event should also undergo anticoagulation. Anticoagulation may be considered in women with a left atrial dimension of 55 mm or greater.

Labor and delivery can frequently precipitate decompensation in patients with critical mitral stenosis. Pain induces tachycardia, and uterine contractions increase venous return and thereby increase pulmonary congestion. Women with critical mitral stenosis frequently cannot tolerate the work of pushing in the second stage. Clark and coworkers<sup>4</sup> described the abrupt elevation in pulmonary artery pressures in the immediate postpartum period associated with return of uterine blood to the general circulation (Fig. 37-6). **Aggressive, anticipatory diuresis will reduce pulmonary congestion and the potential for oxygen desaturation.**

The hemodynamics of women with symptomatic stenosis or a valve area of 1 cm<sup>2</sup> or less may benefit from management with the aid of a pulmonary artery catheter. Ideally, hemodynamic parameters are assessed when the patient is well compensated, early in labor. These findings serve as a reference point to guide subsequent therapy. Pain control is best achieved with an epidural, and heart rate control is maintained through pain control and  $\beta$ -blockade. To avoid pushing, the second stage is shortened with low forceps or vacuum delivery; cesarean delivery is reserved for obstetric indications. Aggressive diuresis is initiated immediately postpartum. In a series of 80 pregnancies managed with a range of severity, the most common complications were pulmonary edema (31%) and arrhythmia (11%). When valve area was 1 cm<sup>2</sup> or less, the rate of pulmonary edema was higher (56%), as was the rate of arrhythmia (33%).<sup>18</sup> These rates will be dependent on the effectiveness of medical management and the timing of presentation and diagnosis.

**Aggressive medical management, including hospital bed rest in selected cases, is sufficient to manage most women with mitral stenosis.** The woman with uncommonly severe disease may require surgical intervention. Although successful valve replacement and open commissurotomy have been reported in pregnancy, they are now rarely needed. Two reports detail successful balloon valvotomy in a series of 40 and 71 women with minimal complications.<sup>19,20</sup> Complications of balloon valvuloplasty outside of pregnancy occur at the following rates:

**FIG 37-5** The effects of  $\beta$ -blockade on functional status of women with mitral stenosis. NYHA, New York Heart Association. (From Al Kasab S, Sabag T, Al Zaibag M, et al. Beta-adrenergic receptor blockade in the management of pregnant women with mitral stenosis. *Am J Obstet Gynecol.* 1990;163:37.)

**FIG 37-6** The changes in pulmonary capillary wedge pressure (PCWP) associated with delivery and subsequent diuresis in women with mitral stenosis. PP, postpartum. (From Clark S, Phelan J, Greenspoon J, et al. Labor and delivery in the presence of mitral stenosis: central hemodynamic observations. *Am J Obstet Gynecol.* 1985;152:384.)

mortality (0.5%), cerebrovascular accident (1%), and mitral regurgitation that requires surgery (2%). Mitral valvuloplasty in pregnancy has been reported with success rates of 95% or greater. The incidence of severe mitral regurgitation that required surgery was 4.6% in the larger series at long-term follow-up; no women required surgery for acute mitral regurgitation during pregnancy. The rate of fetal loss was between 1% and 2%. **Medical management should be clearly exhausted before assuming these risks during pregnancy, when emergent intervention such as valve replacement is more complicated and carries a significant risk to the fetus.**

Rheumatic disease can also affect the aortic valve. In the context of aortic stenosis that is critically dependent on ventricular filling, management of significant mitral stenosis that limits ventricular filling is particularly complicated.

### Mitral Regurgitation

Mitral regurgitation may be due to a chronic progressive process such as rheumatic valve disease or myxomatous mitral valve disease, frequently associated with mitral valve prolapse. As regurgitation increases over time, forward flow is maintained at the expense of LV dilation with eventual impaired contractility. Left atrial enlargement may be associated with AF that should be managed with ventricular rate control and anticoagulation. The patient with chronic mitral regurgitation may remain asymptomatic even with exercise. Preconceptional counseling should include consideration of valve replacement in consultation with a cardiologist. In general, valve replacement is recommended for (1) symptomatic patients, (2) AF, (3) EF less than 60%, (4) LV end-diastolic dimension greater than 40 mm, or (5) pulmonary systolic pressure greater than 50 mm Hg.<sup>15</sup> As discussed later, the benefits of valve replacement before pregnancy must be balanced against the risks associated with a prosthetic valve in pregnancy and the potential for prosthetic valve deterioration in pregnancy. If surgery is required, valve repair—rather than replacement—is preferred when possible to avoid the need for anticoagulation.

**Acute mitral regurgitation in young patients is uncommon and may be associated with ruptured chordae tendineae as a result of endocarditis or myxomatous valve disease.** Without time for LV compensation, forward flow may be severely compromised; urgent valve surgery is usually required. Inotropic LV support and systemic afterload reduction can be used to stabilize the patient.

The hemodynamic changes associated with pregnancy can be expected to have mixed effects. A reduction in systemic vascular resistance (SVR) tends to promote forward flow. The drive to increase CO will exacerbate LV volume overload, and increased atrial dilation may initiate AF. Pulmonary congestion can be managed by careful diuresis with the knowledge that adequate forward flow is usually dependent on a high preload to achieve adequate LV filling. AF should be managed as in the nonpregnant state. An increase in SVR due to progressive hypertension secondary to advancing preeclampsia may significantly impair forward flow and should be treated. Labor and delivery should be managed with standard cardiac care. Catecholamine release that occurs as a result of pain or stress impairs forward flow; therefore particular attention should be paid to LV filling. **Excessive preload results in pulmonary congestion, and insufficient preload will not fill the enlarged left ventricle and will result in insufficient forward flow.** A pulmonary artery catheter can be used to determine appropriate filling pressure in

early labor or before induction. Although a large v-wave may complicate the interpretation of pulmonary artery wedge pressure, the pulmonary artery diastolic pressure can be used as a reference point. Diuresis in the early postpartum period may be required.

Myxomatous mitral valve disease or mitral valve prolapse is a common condition that affects as many as 12% of young women. **In the absence of conditions of abnormal connective tissue such as Marfan or Ehlers-Danlos syndrome and clinically significant mitral regurgitation, women with mitral prolapse can be expected to have uncomplicated pregnancies.** They may experience an increase in tachyarrhythmias that can be treated with  $\beta$ -blockers, and the use of prophylactic antibiotics may be considered at the time of delivery.

### Aortic Stenosis

Most patients who develop calcific stenotic trileaflet aortic valves do so outside their childbearing years (age 70 to 80 years). Patients with bicuspid valves develop significant stenosis after the age of 50 to 60 years. Rheumatic disease can also affect the aortic valve, usually after the development of significant mitral disease. Most pregnant women with significant aortic stenosis have congenitally stenotic valves: bicuspid valves with congenitally fused leaflets, unicuspid valves, or tricuspid valves with fused leaflets.

**The natural history of aortic stenosis is characterized by a long, asymptomatic period.** With increasing outflow obstruction, patients develop angina, syncope, and LV failure. Without valve replacement, only 50% of patients will survive 5 years after the development of angina; 3 years after the development of syncope; and 2 years after the development of LV failure. Although valve replacement is the only definitive treatment for calcific aortic stenosis, valvuloplasty may prove beneficial in some young adults whose valves are not calcified. Medical management of symptomatic patients is not generally efficacious. Mechanical valve replacement requires anticoagulation, which complicates subsequent pregnancies.

Young women with aortic stenosis are usually asymptomatic. Although they may develop increasing exercise intolerance in pregnancy, the progression is insidious and not easily distinguished from the effects of normal pregnancy. The diagnosis is usually made by the auscultation of a harsh systolic murmur. **The murmur can easily be distinguished from a physiologic murmur of pregnancy by its harshness and radiation into the carotid arteries.** Diagnosis is confirmed by echocardiography whereby the pressure gradient across the valve can be measured by Doppler, and the valve area can be calculated with the continuity equation. Many women with significant aortic stenosis experience the expected increase in CO associated with pregnancy.<sup>3</sup> Increased flow across the fixed, stenotic valve results in a proportionately increased gradient across the valve. Although the pressure gradient during pregnancy may be higher than that observed postpartum, these differences are not significant.

Four series of patients with aortic stenosis in pregnancy have been reported.<sup>3,21-23</sup> The reports summarize experiences with wide ranges in severity of disease and management ranging from the 1960s and 1970s to the present. Arias and Pineda<sup>21</sup> described a series of 23 cases managed before 1978 with a maternal mortality rate of 17%. More recent series, however, do not demonstrate this high level of maternal risk.<sup>3,22,23</sup> The potential for serious adverse outcomes reported by Arias should, however, serve as an

indication for intensive management. The rate of mortality should not necessarily be used as an indication for termination or surgical intervention. Pregnant patients have been successfully managed with aortic gradients in excess of 160 mm Hg.<sup>3</sup> In general, patients with a peak aortic gradient of 60 mm Hg or less have had uncomplicated courses. Those with higher gradients require increasingly intensive management.

Aortic valve replacement and balloon valvotomy have been reported during pregnancy. Balloon valvotomy in a young patient without valve calcification can provide significant long-term palliation. Valvotomy before pregnancy may provide an interval of hemodynamic stability sufficient to complete a pregnancy without the complications associated with a mechanical prosthetic valve. **Consideration for valve replacement or valvotomy during pregnancy should be reserved for patients who remain clinically symptomatic despite hospital care.** In general, intervention should not be based solely on a pressure gradient or valve area.

Aortic stenosis is a condition of excess LV afterload. Ventricular hypertrophy increases cardiac oxygen requirements, whereas increased diastolic ventricular pressure impairs coronary perfusion. **Each increases the potential for myocardial ischemia.** The left ventricle requires adequate filling to generate sufficient systolic pressure to produce flow across the stenotic valve. **Given a hypertrophied ventricle and some degree of diastolic dysfunction, the volume-pressure relationship is very steep. A small loss of LV filling results in a proportionately large fall in LV pressure and, therefore, a large fall in forward flow and CO.** The pregnant patient with significant aortic stenosis is very sensitive to loss of preload associated with hemorrhage or epidural-induced hypotension. The window of appropriate filling pressure is narrow. Excess fluid may result in pulmonary edema; insufficient fluid may result in hypotension and coronary ischemia. **In general, pulmonary edema associated with excess preload is much easier to manage than hypotension due to hypovolemia.**

Appropriate antepartum care is described earlier. Given that most aortic stenosis in young women is congenital in origin, fetal echocardiography is indicated. Although some controversy persists, cesarean delivery is generally reserved for obstetric indications. Pain during labor and delivery can be safely managed with regional analgesia using a low-dose bupivacaine and narcotic technique. Dense anesthesia during the second stage can be obtained with minimal hemodynamic complications using a caudal catheter. Patients with gradients above 60 to 80 mm Hg may benefit from the use of a pulmonary artery and arterial catheter during labor. Hospital admission one day before planned induction of labor with a favorable cervix is preferred, and a prolonged induction should be avoided. Pulmonary artery and radial artery catheters, as well as epidural and caudal catheters, are placed. The patient should be gently hydrated overnight to achieve a pulmonary artery wedge pressure (PAWP) of 12 to 15 mm Hg. Some patients with milder disease spontaneously diurese in the face of a volume load such that an elevation in PAWP cannot be achieved. An elevated PAWP serves as a buffer against a loss of preload. If PAWP falls with bleeding or the onset of anesthesia, volume can be administered before a reduction in forward flow occurs. In general, pushing is minimized, and the second stage is shortened with operative vaginal delivery. Antibiotics may be considered for the prevention of endocarditis.

Postpartum patients should be monitored hemodynamically for 24 to 48 hours. Diuresis is usually spontaneous, and the

patient can be allowed to find her predelivery compensated state. When diuresis must be induced to treat pulmonary edema, it should be done gently and carefully. Predelivery hemodynamic parameters should be used as an end point. Some have found that a significant delay in valve replacement in women with quite severe disease is associated with maternal complications.<sup>3</sup> In a larger cohort of women with less severe disease followed for 6 years and compared with a matched cohort who had not been pregnant, women who experienced a pregnancy had a reduction in event-free survival.<sup>24</sup> These observations may be the result of accelerated valve deterioration due to pregnancy. For this reason, valve replacement within weeks of delivery may be indicated.

## Aortic Regurgitation

Aortic regurgitation is most often due to a congenitally abnormal valve. Other causes include Marfan syndrome, endocarditis, and rheumatic disease. As with mitral regurgitation, the left ventricle compensates for decreased forward flow with an increase in LV end-diastolic volume. Afterload reduction prevents progressive LV dilation and is recommended for patients with LV dysfunction or dilation. Valve replacement is generally recommended for (1) NYHA functional class III and class IV symptoms, (2) an EF less than 50%, or (3) an LV end-systolic dimension greater than 50 mm.<sup>12</sup> Acute regurgitation may be due to aortic root dissection or endocarditis and usually represents a medical emergency that requires urgent valve replacement.

**The reduction in vascular resistance associated with pregnancy tends to improve cardiac performance.** If afterload reduction has been achieved with an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin receptor blocker (ARB) before pregnancy, hydralazine or a calcium channel blocker such as nifedipine should be substituted. Modest heart rate elevations should be tolerated, and bradycardia may be associated with increased regurgitation due to prolongation of diastole. Labor and delivery are managed with standard cardiac care, and pulmonary artery catheterization is not usually required. As the hemodynamic changes associated with pregnancy resolve, a rise in vascular resistance should be anticipated and afterload reduction maintained.

## Prosthetic Valves

Definitive therapy for significant valvular disease requires surgical repair or, more commonly, replacement. Mechanical valves are durable but require anticoagulation. When used in a young woman, bioprosthetic valves usually require replacement during her lifetime. Reports of pregnancies associated with prosthetic valves suggest significant variability in outcomes, and these have been reviewed in detail by Elkayam and Bitar<sup>25</sup> and within the 2014 AHA/ACC Valvular Heart Disease Guidelines.<sup>15</sup> Reported outcomes must be interpreted in the context of the cohorts of patients reported and the circumstances of clinical care.

Decisions that surround the timing and choice of valve replacement for a woman of reproductive age are complex. Managing a pregnancy with moderate valve disease may be less complicated than managing a pregnancy with a prosthetic valve. The durability of a mechanical valve has considerable advantages for a young person, but it is associated with more adverse outcomes in pregnancy. **Delay in valve replacement until childbearing is completed is appropriate when the severity of heart disease is believed to be manageable in pregnancy.**

Bioprosthetic valves have relatively low rates of complications in pregnancy. Some women, particularly those with CHD, will

have residual hemodynamic issues associated with their primary condition that are not addressed with valve replacement. The impact of pregnancy on the life of a bioprosthetic valve has been studied.<sup>26</sup> Ten-year graft survival following two pregnancies was 16.7%, compared with 54.8% following a single pregnancy, which suggests that pregnancy may adversely affect the life of a bioprosthetic valve. **Accelerated deterioration of bioprosthetic valves in the setting of pregnancy has been confirmed by several studies.**<sup>25,28-30</sup>

Anticoagulation is required with a mechanical valve. Management of anticoagulation in pregnant women with mechanical prosthetic valves remains very controversial because commonly used anticoagulants have significant maternal and fetal adverse effects, and no single agent is safe throughout all stages of pregnancy. Interpretation of reported outcomes must be made in the context of valve location, thrombogenicity of the particular valve, strategies for anticoagulation and monitoring of effectiveness, and social context including compliance. Mechanical valves in the mitral position will be expected to have more thrombotic complications than those in the aortic position. Older-generation valves, such as Björk-Shiley or Starr-Edwards, may be in place in a pregnant woman and will be more likely to have thrombotic complications. **When strategies for anticoagulation without dose adjustment are used in pregnancy, particularly in the case of heparin therapy, increased thrombotic complications are to be expected. Outcomes are better when clinical care teams are experienced with monitoring and dosing anticoagulation and work to achieve compliance.**

Recommendations regarding anticoagulation in pregnancy for women with mechanical valves have been published by the ACC and AHA,<sup>15</sup> the American College of Chest Physicians,<sup>31</sup> and by Elkayam and Bitar.<sup>25</sup> Each have largely drawn information from the same sources but in doing so have made substantially different recommendations regarding the use of warfarin or heparin. Physicians who care for pregnant women with mechanical heart valves should be familiar with each set of recommendations and should use them for guidance in counseling patients and establishing a plan.

Ideally, patients are evaluated and counseled preconceptionally. An effective plan of birth control is used until a pregnancy is planned; therefore long-acting reversible contraceptives should be considered. Progestin-based systems may reduce menstrual bleeding for women on warfarin. Once a pregnancy is desired, a clear plan for anticoagulation in the first trimester should be in place, with clinical systems available to immediately implement the plan once a pregnancy is identified. Early surveillance for a potential pregnancy is essential.

### First Trimester

Warfarin is clearly teratogenic when used in the first trimester, and its use in pregnancy has been extensively reviewed.<sup>32</sup> A teratogenic window between 6 and 9 gestational weeks has been suggested. Exposure in this timeframe results in an incidence of warfarin embryopathy of approximately 6%. Exposure to less than 5 mg/day has been suggested to decrease the incidence to as low as 3%. If adequate anticoagulation can be maintained with less than 5 mg/day of warfarin, oral anticoagulation could be considered after appropriate counseling. An increase in dosing should be expected in pregnancy and may limit use of this strategy. Many women will choose therapy with low-molecular-weight heparin (LMWH). Conversion can be accomplished

shortly after the first missed period and with confirmation of pregnancy.

### Second and Third Trimester

Management during the second and third trimesters (prior to labor) remains controversial. Treatment with warfarin offers superior anticoagulation compared with heparin therapy. The magnitude of maternal risk assumed with heparin therapy will be dependent on valve type and location and on the quality of anticoagulation achieved. Weight-based dosing, treatment without aggressive monitoring, and noncompliance are associated with unacceptably high rates of thromboembolic complications. Three studies<sup>33-35</sup> have reported a total 35 pregnancies with therapeutic factor Xa levels without thrombotic complications. Three patients experienced complications with subtherapeutic factor Xa levels.

The magnitude of risk to the fetus in the second and third trimesters associated with warfarin exposure is also unclear. Minor levels of dose-dependent neurologic dysfunction with exposure after the first trimester have been reported as have trends for an increased risk for intelligence quotient (IQ score) below 80 (odds ratio [OR], 3.1; 95% confidence interval [CI], 0.8 to 11.6).<sup>32</sup> Preterm labor in the context of anticoagulation with warfarin will be associated with risks for fetal bleeding as well as the potential need for urgent operative delivery, which places the mother at risk for hemorrhage.

The AHA/ACC guidelines recommend treatment with warfarin in the second and third trimesters but suggest that dose-adjusted LMWH is a reasonable option for women who choose not to be on an oral anticoagulant.<sup>15</sup> The American College of Chest Surgeons (ACCS) supports use of dose-adjusted LMWH, dose-adjusted unfractionated heparin (UFH), or warfarin in the second and third trimesters.<sup>31</sup> The review recognizes that “the choice of anticoagulant regimen is so value and preference dependent (risk of thrombosis vs. risk of fetal abnormalities) that we consider the decision to be completely individualized.”

### Labor and Delivery

Prior to delivery, conversion to heparin-based therapy is uniformly recommended. Continuous intravenous (IV) management with UFH or LMWH has been suggested. IV therapy will usually require chronic vascular access and comes with an associated risk for line infection and endocarditis. Treatment is stopped such that delivery can be accomplished without anticoagulation.

### Postpartum

IV heparin is consistently recommended after delivery. Initiating intravenous UFH without a bolus may decrease the risk for bleeding complications, and conversion to warfarin once the risk for bleeding is low is recommended. Avoiding the use of LMWH while bridging to warfarin may also reduce the incidence of bleeding. Oral anticoagulation is not contraindicated with breastfeeding.

Treatment with warfarin to achieve an international normalized ratio (INR) of 2.5 to 3.5 has been recommended.<sup>25</sup> Treatment with LMWH requires careful monitoring and dose adjustment, and the total dose should be expected to increase substantially throughout pregnancy. Substantial variability in anti-factor Xa levels should be expected over a dosing interval and may result in subtherapeutic trough levels.<sup>36</sup> Peak levels of 1.5 IU/mL or less, midinterval levels of approximately 1.0 IU/

mL, and trough levels of 0.6 IU/mL have been recommended.<sup>25</sup> Twice-daily dosing will be required at a minimum, and thrice-daily dosing may be required to achieve an appropriate trough without an excessively high peak concentration. Treatment with intravenous UFH to achieve an activated partial thromboplastin time (aPTT) greater than 2.0 has been recommended<sup>25</sup> in addition to simultaneous treatment with low-dose aspirin.<sup>15</sup>

If valve thrombosis is encountered, thrombolysis should be considered because successful thrombolytic therapy of a clotted valve in pregnancy has been reported. Although thrombolysis is safe and effective for many patients, embolic complications, bleeding, and death have been reported in pregnancy. Surgery such as cesarean delivery cannot be performed in proximity to thrombolytic therapy.

Management of pregnant women with mechanical heart valves is complex. Counseling balances risks of alternative therapies that rely on less than optimal data and the values and risk willingness of individual patients. Management of anticoagulation, whether it be with warfarin or LMWH, is nuanced and relies heavily on clinical experience in monitoring and dose adjustment.

## CONGENITAL HEART DISEASE

**Congenital heart disease is present in 0.7% to 1% of live births and accounts for as many as 30% of infants with birth anomalies.** Before the development of corrective surgery, many children died shortly after birth or in childhood. In 1939, the first patent ductus arteriosus (PDA) was ligated. In 1945, the first Blalock-Thomas-Taussig shunt was performed for palliation of cyanotic heart disease. In 1953, cardiac bypass was introduced. Introduction of surgery under hypothermia in the late 1960s permitted longer and more complex repairs. Of children who survived surgery to correct tetralogy of Fallot between 1955 and 1960, the 23-year survival was 86%, approaching the expected survival rate of 96% for normal children. Before the 1960s, rheumatic heart disease was more common in pregnancy than CHD by a ratio of 4:1. By the 1980s, the ratio was 1:1. Currently, congenital disease is now estimated to exceed rheumatic disease by 4:1. Although most enter pregnancy with known heart disease, some women have their disease first recognized because of the hemodynamic demands of pregnancy.

Increased survival of children with congenital disease has created a population of young women with complex medical and psychosocial conditions entering their childbearing years. Those whose CHD was diagnosed in infancy have frequently experienced multiple cardiothoracic surgeries and extended hospitalizations. They have lived with continued concerns from parents and health care professionals regarding their ongoing health problem. Their childhood has been described as “growing up heart sick.”<sup>37</sup> Some describe a lack of information regarding childbearing and contraception. They “seemed to believe that someone else could and would decide whether they should become pregnant.” Kovacs and coworkers<sup>38</sup> describe the contraception and pregnancy advice women with CHD recall receiving from their health care providers, and in many cases, women received either no information or the information they did receive was inaccurate. **Health care providers should strive to (1) objectively share information regarding reproductive health care; (2) direct decision making toward the patient, rather than toward parents and health care professionals; and (3) improve self-esteem and body image.** When treating CHD

**TABLE 37-1** INCIDENCE OF CONGENITAL HEART DEFECTS IN CHILDHOOD AND IN PREGNANCY

| DEFECT                             | CHILDHOOD (%) | PREGNANCY (%) |
|------------------------------------|---------------|---------------|
| Ventricular septal defect          | 35            | 13            |

during pregnancy, there must be a willingness to acknowledge and address the impact of the patient's disease on her life.

**Table 37-1** summarizes the distribution of CHD in childhood and in pregnancy.<sup>23,39</sup> The spontaneous closure of lesions such as VSD and correction of a patent ductus are reflected by reduced reporting in pregnancy. The increased reporting of aortic stenosis in pregnancy is probably due to a worsening of disease with age and the ease of recognition during pregnancy. The complexity and diversity of CHD confounds our ability to describe the prognosis or a management plan for the breadth of conditions. **Major risks in pregnancy include (1) cyanosis; (2) left (or systemic) ventricular dysfunction and poor functional status; (3) pulmonary hypertension and Eisenmenger syndrome, particularly with RV dysfunction; and (4) severe left (or systemic) outflow tract obstruction.**

Neonatal complications are more likely when pregnant women have heart disease, particularly if one or more of the major risk factors listed above is present.<sup>9,11,23,39</sup> Neonatal outcomes have been most clearly described based on the presence or absence of maternal cyanosis. **Table 37-2** is derived from a report<sup>9</sup> of 482 pregnancies from 233 women with CHD who delivered between 1968 and 1982. The rate of terminations was higher in the group of women with cyanotic heart disease and was particularly high (42%) in those with uncorrected lesions. This reflects the anticipated poor neonatal outcome and maternal risks associated with uncorrected cyanotic disease. It is likely that patients with more severe disease are overly represented in the group of women who chose to terminate, which would bias the group who continued pregnancy toward a better outcome: 86% to 90% of pregnancies without cyanosis ended in a live birth, and 71% with an uncorrected lesion also delivered successfully. Given an expected baseline rate of miscarriage, these

outcomes are good. Corrected cyanotic disease was associated with outcomes comparable to noncyanotic disease. Other adverse neonatal outcomes, including low birthweight, are concentrated among women with uncorrected cyanotic heart disease. In a report of 96 pregnancies among 44 women with cyanotic CHD, 43% resulted in a live birth and spontaneous abortion and stillbirth occurred in 51% and 6%, respectively.<sup>40</sup> Among the live births, 37% were premature. The mean birthweight among those born full term was 2575 g (2100 to 3600 g). A report<sup>23</sup> of 144 pregnancies from women with CHD delivered between 1976 and 1986 details a similar rate of prematurity (35%) with 53% born small for gestational age (SGA, mean birthweight 2400 g  $\pm$  800).

Common maternal complications include CHF and pulmonary edema (4%), arrhythmia (4%), and hypertension (6%). CHF and hypertension were often associated with uncorrected LV outflow obstruction.<sup>9,23</sup> Arrhythmias were observed after surgery in and around atrial or ventricular septa. Maternal death was uncommon, 0 per 482 pregnancies in one series<sup>9</sup> and 1 per 144 pregnancies in a second.<sup>23</sup> Maternal deaths are most commonly reported in association with Eisenmenger syndrome, which is discussed more fully later.

Men and women with CHD are at increased risk for having children with CHD. In a prospective study with aggressive pediatric evaluation, Whittemore and associates<sup>9</sup> estimated the incidence to be as high as 14.2%. In a retrospective study, Rose and coworkers<sup>41</sup> found the risk to be 8.8%. The rate of CHD associated with an affected mother is 2 to 3.5 times that observed with an affected father. **Specific parental defects are not generally associated with the same defect in the child; the risk for cardiac maldevelopment is inherited rather than the risk for a specific defect.** The risk for CHD and the character of the risk should be discussed with an affected mother. In Whittemore's<sup>9</sup> report, 58 of 60 affected infants were diagnosed with relatively benign correctable lesions (ASD, VSD, pulmonary stenosis, aortic stenosis, PDA, or mitral valve prolapse). Only two infants from 372 pregnancies (0.5%) were diagnosed with complex CHD. Gill and colleagues<sup>10</sup> examined the recurrence pattern of CHD in 6640 pregnancies for whom fetal echocardiography was obtained because of a family history of CHD. The recurrence rate was 2.9% (95% CI, 2% to 4%) for mothers with CHD, a rate lower than that reported by others. However, the study is limited to diagnoses established by fetal echocardiography and therefore may underrepresent the true incidence of abnormalities. The type and severity of the cardiac defect seen in the mother did not predict the type or severity of the cardiac defect in the offspring, with a few exceptions. Atrioventricular canal defects, especially those associated with situs abnormalities, had a highly concordant recurrence rate.<sup>10</sup> CHD-associated 22q11.2 deletion (DiGeorge syndrome, velocardiofacial syndrome) will be inherited as an autosomal-dominant condition. Many parents with CHD will not have been previously screened for genetic syndromes; therefore referral for genetic counseling and possible screening should be considered, particularly in the context of conotruncal abnormalities and other associated anomalies. **All women who have CHD should undergo fetal echocardiographic examination at approximately 18 to 22 weeks' gestation.**

Contraceptive counseling should be offered to all women with CHD. **Given the problems experienced growing up with heart disease, contraceptive education should probably be initiated as part of general health care education before the**

**overt need for birth control.** In the context of CHD, complications associated with pregnancy are usually greater than those associated with any form of birth control. Cyanosis, pulmonary hypertension, low CO, dilated cardiac chambers, passive-flow venous conduits (e.g., Fontan), and atrial fibrillation place patients at risk for thrombosis. This small group of women should probably avoid combined estrogen-progestin oral contraceptives. Progestin-only pills are not associated with risk for thrombosis but require regular dosing to achieve optimal efficacy. Parenteral progestins are safe for women with cardiac disease and are extremely effective. They do cause irregular bleeding, which may be significant if the patient is anticoagulated. The intrauterine device (IUD) may also be a suitable choice for women with congenital heart lesions.

### Isolated Septal Defects

**VSDs and ASDs represent greater than 40% of CHD identified in childhood.** In adulthood, 50% of large VSDs (>1.5 cm) lead to the development of Eisenmenger syndrome, and 10% of patients with uncorrected ASDs develop pulmonary hypertension. The management of Eisenmenger syndrome in pregnancy is discussed later.

A harsh S1-coincident systolic murmur that radiates to the left sternal border but not to the carotids suggests the presence of a VSD. The diagnosis can be confirmed by 2-D echocardiography with color-flow Doppler that demonstrates shunting across the ventricular septum. The peak velocity of the jet across the septum can be used to assess the pressure gradient between the ventricles. A high velocity between ventricles indicates a large pressure gradient between the right and left ventricles and the absence of pulmonary hypertension. In the absence of associated cardiac lesions and pulmonary hypertension, the presence of a VSD does not usually complicate pregnancy. Small defects create loud murmurs but are not usually hemodynamically significant, although the high-velocity jet of a small lesion does create a risk for endocarditis.

ASDs are more difficult to diagnose by auscultation. The characteristic finding, a split S<sub>2</sub> that is fixed with respiration, is subtle and usually not appreciated without specific attention. Increased right-sided blood flow secondary to shunting across the defect may create a pulmonary flow murmur that will be augmented in pregnancy. In the absence of other anomalies, the significance of the ASD is related to its size. Hemodynamically significant defects result in left-to-right shunting from the systemic circulation to the pulmonary circulation that causes right atrial and ventricular enlargement. Atrial arrhythmias are commonly associated with atrial enlargement. Increased pulmonary blood flow may result in dyspnea on exertion and restriction of activity. As with VSDs, Eisenmenger syndrome may develop, but this usually occurs at an older age.

Piesiewicz and colleagues<sup>42</sup> reported 54 pregnancies in women with secundum ASDs. **Impaired functional status (NHYA class III or IV) increased from 5.5% in the second trimester to 11.1% in the third trimester.** Although left-to-right shunting was present in all patients in the second trimester, three patients (5.5%) developed bidirectional shunting in the third trimester. One additional patient reversed her shunt. RV diameter and systolic pulmonary artery pressure increased from the second to third trimester (34.1  $\pm$  8.4 mm Hg to 39.1  $\pm$  12.2 mm Hg). Over the same time frame, the pulmonary flow (Q<sub>p</sub>)/systemic flow (Q<sub>s</sub>) ratio decreased. Increased flow associated with pregnancy appears to adversely affect RV function and

pulmonary pressures. The fall in  $Q_p/Q_s$  suggests that the rise in pulmonary pressure is due to increased PVR. The authors also reported supraventricular arrhythmias in 50% of women in the third trimester.

**The patient with a significant VSD or ASD shunt can be expected to normally expand her CO during pregnancy. However, the price of a normal systemic CO is a high pulmonary flow.** The pregnant patient may begin to experience symptoms at rest that she previously noted with exercise. She may also experience an increase in tachyarrhythmias. Heart rate control with a  $\beta$ -blocker may provide symptomatic relief, and early diuresis may benefit the patient postpartum. Elevated pulmonary blood flow associated with pregnancy could accelerate the progression of pulmonary vascular disease. In the absence of associated anomalies, arrhythmias, and pulmonary hypertension, the presence of an ASD does not usually complicate pregnancy.

### Patent Ductus Arteriosus

The diagnosis of a PDA is suggested by the characteristic continuous murmur at the upper left sternal border. Most cases are identified in childhood and are treated with surgical or transcatheter procedures. Of patients with an uncorrected patent ductus, as many as 50% develop Eisenmenger syndrome, usually in childhood. In adults with a small patent ductus, the major risk is endocarditis. **In the absence of Eisenmenger syndrome, pregnancy is not usually complicated.** As with the ASD, the increase in pulmonary blood flow associated with the increase in CO in pregnancy may result in increased dyspnea with exertion and at rest. Early diuresis may benefit the patient postpartum.

### Tetralogy of Fallot

Tetralogy of Fallot is a syndrome of abnormalities that results from malalignment of the conoventricular septum. It is characterized by (1) RV outflow tract (RVOT) obstruction, (2) VSD, (3) overriding aorta, and (4) RV hypertrophy. **Tetralogy of Fallot is the most common cyanotic CHD,** and it was among the first to be successfully surgically palliated by Blalock, Thomas, and Taussig in 1945 and subsequently physiologically repaired. Therefore a significant number of adults with CHD have repaired tetralogy of Fallot. The severity of the clinical presentation in infancy is dependent on the degree of RVOT obstruction. More severe obstruction leads to more significant cyanosis from right-to-left shunting. Surgical repair generally includes closure of a VSD and relief of RVOT obstruction. Some patients with repaired tetralogy of Fallot have near-normal cardiac physiology, but many have residual lesions that may complicate pregnancy.

Some patients had palliative classic Blalock-Thomas-Taussig shunts in infancy using the subclavian artery to connect the systemic circulation with the pulmonary circulation, thus increasing pulmonary blood flow and reducing cyanosis. As a consequence, blood pressures in the arm supplied by the transected artery may not be reflective of aortic pressure. Patients should be asked if one arm is unreliable for blood pressure measurements, or they should be examined to look for evidence of a thoracotomy scar that indicates an affected ipsilateral arm, which should not be used for blood pressure measurements.

Efforts to relieve the RVOT obstruction may be incomplete and may result in persistent pulmonary stenosis. More often, significant pulmonary insufficiency is a consequence of the

transannular patch approach used to enlarge the outflow tract and valve annulus. Several studies have demonstrated that women with severe pulmonary insufficiency and RV dysfunction are more likely to have complications with pregnancy. Balci and colleagues<sup>43</sup> reported a series of 74 women with tetralogy of Fallot who had 157 pregnancies. Eight percent experienced cardiac complications that included supraventricular tachycardia ( $n = 8$ ), heart failure ( $n = 2$ ), and thromboembolism ( $n = 1$ ). The use of cardiac medications prior to pregnancy was identified as an important predictor of cardiovascular events.

**Tetralogy of Fallot is often well tolerated during pregnancy. Preconceptional evaluation should include assessment of right and left ventricular size and function along with the severity of the pulmonary insufficiency or stenosis, with consideration given to repair of severe pulmonary insufficiency before pregnancy if appropriate.**

### Transposition of the Great Arteries

Transposition of the great arteries (TGA) is present in only 5% of pregnant women with CHD but is overrepresented in the publication of case reports and case series. **In complete TGA, systemic venous blood returns to the right atrium and passes through the tricuspid valve, into the RV, and directly into the transposed aorta. Although this is an adequate circulation for fetal life, infants decompensate at birth owing to ineffective systemic circulation.** Some will have an ASD sufficiently large to achieve adequate systemic blood flow and oxygenation; others will require an immediate palliative procedure to open the atrial septum (balloon atrial septostomy).

TGA was first definitively corrected in 1957 with the Senning procedure, then it was standardized in 1964 with the Mustard operation. In both procedures, a baffle is constructed through the left and right atria so that systemic venous return is channeled through the mitral valve into the left ventricle, and pulmonary venous return is directed through the tricuspid valve into the right ventricle (atrial switch operation). With a modest surgical intervention, the right and left pumps are placed in series with physiologic flow of systemic venous return through the pulmonary circulation. **The right ventricle (RV), as the systemic ventricle, must work against systemic resistance, and the tricuspid valve is exposed to systemic pressures. Long-term complications are associated with failure of the systemic RV and arrhythmia.** Of patients who survive the first 30 days after repair, 90% will be alive in 10 years and 87% will be alive in 20 years. After 13 years, only 5% suffer significant disability (NYHA classes II through IV).<sup>44</sup> A more physiologic repair can be achieved when transposition is accompanied by a VSD. The ventricular septum is reconstructed so that the aortic outflow tract lies within the left ventricle, and a conduit is constructed to connect the RV to the pulmonary artery (Rastelli repair). The pulmonary conduit is prone to stenosis with deterioration of the transplanted valve. More recently, a direct surgical switch between the pulmonary artery and the aorta has been performed (arterial switch operation). Given the time when these operations were introduced, fewer young women entering pregnancy will have an atrial repair; however, increasing numbers will have an arterial repair.

The hemodynamic changes of pregnancy will have a mixed impact on a patient with an atrial repair. Increased CO *increases* the volume load on the right heart, and decreased vascular resistance *reduces* afterload on the right heart. [Table 37-3](#) summarizes nine papers that reported a total of 49 pregnancies in 36

**TABLE 37-3** PREGNANCY OUTCOMES WITH TRANSPOSITION OF THE GREAT ARTERIES

|                          | N (%)    |

| Arrhythmia               | 8 (20%)  |

Data from references 23, 45-52.

women.<sup>23,44-51</sup> No maternal mortality was reported, and neonatal outcomes were generally good. Two women entered pregnancy with disability due to their heart disease (NYHA classes III and IV), and one delivered at 26 weeks as a result of preterm labor; the other developed severe CHF near term and died 19 months postpartum. CHF was frequently associated with uncontrolled tachyarrhythmias.

Zentner and colleagues<sup>52</sup> compared long-term outcomes after atrial repair in 19 women who completed 42 pregnancies with 15 women who never became pregnant. The group without pregnancies had greater numbers of women with *complex TGA*, defined as the presence of a VSD with or without pulmonary stenosis: 74% of pregnancies resulted in full-term infants (median gestational age, 39 [37.2 to 40] weeks; median birthweight, 3.0 [2.4 to 3.5] kg), and 26% of the infants were born premature (median gestational age 35 [31 to 40] weeks; median birthweight, 2.3 [1.3 to 2.4] kg). Within 12 months of pregnancy, three women had hospital admissions for heart failure, two had clinically significant arrhythmias, and one experienced sudden cardiac death. After a median follow-up of 5 (2 to 15) years, more women in the pregnancy group experienced a decline in their RV systolic function that necessitated medications (13 vs. 3), and two women required implantable cardioverter-defibrillator (ICD) placement. Canobbio and coworkers<sup>53</sup> reported a series derived from a registry. Of significance, this report is based on diverse practices rather than from centers with considerable experience managing CHD. Forty women carried 54 pregnancies that resulted in live births: 36 had Mustard repairs, and four had Senning repairs. In six pregnancies, heart failure developed in the second or third trimesters. In five, heart failure developed postpartum. One woman required transplantation postpartum, one died of heart failure 1 month after delivery, and another died 4 years later. This report clearly documents the potential for adverse outcome.

Tobler and associates<sup>54</sup> reported on 17 pregnancies in nine women with arterial repairs. One developed nonsustained ventricular tachycardia, and one developed a valve thrombosis.

Congenitally corrected TGA (ventricular inversion) is characterized by the passage of systemic venous blood into the right atrium, directly into the morphologic LV, and out through the transposed pulmonary artery. Pulmonary venous return passes directly from the left atrium into the morphologic RV and out through the aorta. The RV again serves as the systemic ventricle. Congenitally corrected TGA may be an isolated anomaly but may also be associated with other anomalies that result in cyanosis. See Table 37-4 for a summary of three series

**TABLE 37-4** PREGNANCY OUTCOMES WITH CONGENITALLY CORRECTED TRANSPOSITION OF THE GREAT ARTERIES

|                           | N (%)    |
|---------------------------|----------|
| Women                     | 54       |
| Cyanotic                  | 4 (10%)  |
| Pregnancies               | 125      |
| Cyanotic                  | 13 (12%) |
| Live births               | 96 (77%) |
| Miscarriages*             | 23       |
| Terminations              | 6        |
| Fetal deaths              | 1        |
| Premature birth (<35 wk*) | 9 (9%)   |
| Congenital heart disease  | 1 (1%)   |
| Congestive heart failure  | 6 (6%)   |
| Arrhythmia                | 2 (2%)   |
| Cerebrovascular accident  | 1 (1%)   |

Outcome of pregnancy in patients with congenitally corrected transposition of the great arteries. *Am J Cardiol.* 1999;84:820; Connolly H, Grogan M, Warnes C. Pregnancy among women with congenitally corrected transposition of great arteries. *J Am Coll Cardiol.* 1999;33:1692; Kowalik E, Klisiewicz A, Biernacka E, et al. Pregnancy and long-term cardiovascular outcomes in women with congenitally corrected transposition of the great arteries. *Int J Gynaecol Obstet.* 2014;125:154-157.

\*Miscarriages and premature births were concentrated among cyanotic mothers.

of pregnancies with congenitally corrected TGA.<sup>55-57</sup> Again, maternal and neonatal outcomes are good and are consistent with outcomes associated with other acyanotic forms of CHD. Miscarriage and premature birth are concentrated among those with cyanotic lesions.

**Young women with surgically or congenitally corrected TGA can successfully complete pregnancy. Nevertheless, they require aggressive management by an experienced team.** Women who are functionally impaired or who are cyanotic before pregnancy can expect more adverse outcomes and may deteriorate postpartum. Evaluation before pregnancy should include assessment of functional status, evaluation of right systemic heart function, and confirmation of normal oxygenation. When the right side of the heart is the systemic heart, pharmacologic afterload reduction should be maintained until pregnancy is confirmed. ACE inhibitors should be discontinued early in the first trimester. Postpartum, the systemic RV should be considered “at risk” to fail and should be managed with rate control ( $\beta$ -blocker), afterload reduction (ACE inhibitor), and appropriate management of preload (diuresis; see Tables 37-3 and 37-4).

The reported experience with TGA is to date the most extensive for any complex defect. The conclusions drawn from this experience are probably applicable to other, less common conditions with a systemic RV. **Functional status and cyanosis are the most reliable predictors of complicated pregnancies.** Arrhythmia is common and is frequently the cause of cardiac decompensation.

### Fontan Procedure

The Fontan procedure was initially performed to achieve a physiologic palliation of tricuspid atresia by connecting the right atrium directly to the pulmonary artery. **The Fontan procedure and subsequent modifications are currently used to correct a variety of complex congenital heart conditions characterized by a single functional ventricle.** The operation achieves a non-cyanotic state, with passive flow of systemic venous return

**TABLE 37-5** PREGNANCY OUTCOMES AFTER FONTAN PALLIATION

|                          | N (%)    |
|--------------------------|----------|
| Women                    | 27       |
| Pregnancies              | 43       |
| Live births              | 19 (44%) |
| Miscarriages             | 19       |
| Terminations             | 6        |
| Fetal deaths             | 0        |
| Premature birth (<35 wk) | 3 (15%)  |
| Congenital heart disease | 1 (5%)   |
| Congestive heart failure | 3 (15%)  |
| Arrhythmia               | 3 (16%)  |

Data from Canobbio M, Mair D, Van der Velde M, et al. Pregnancy outcomes after the Fontan repair. *J Am Coll Cardiol*. 1996;28:763; and Drenthen W, Pieper PG, Roos-Hesselink JW, et al, on behalf of the ZAHARA investigators. Pregnancy and delivery in women after Fontan palliation. *Heart*. 2006;92:1290.

through the lungs and a functionally systemic ventricle. Without a pulmonary pump, the cardiac price for this result is intolerance of increased intrathoracic pressure and elevated central venous pressure (CVP).

Experience with pregnancy in women after Fontan palliation is limited. In a survey of 76 women of reproductive age, Canobbio and associates<sup>58</sup> reported that 66% were counseled not to become pregnant despite a stable surgical outcome and a strong desire to have children. The remaining 34% were not counseled regarding pregnancy. Despite counseling against pregnancy, contraceptive use was inconsistent. Although the miscarriage rate was higher than in the general population, the preterm birth rate was low. Maternal complications were limited to arrhythmia, usually atrial, and CHF in the postpartum period. Although not reported in these small series, sluggish flow through the pulmonary circulation may increase the risk for thrombosis. The incidence of pulmonary emboli in nonpregnant patients with Fontan circulation may be as high as 17%. Another series reported 10 pregnancies in 6 women.<sup>59</sup> Of the 10 pregnancies, 5 ended in miscarriage before 12 weeks, and 1 was ectopic. Of the 4 completed pregnancies, 1 woman had a decline of NYHA class with both of her pregnancies, and the second pregnancy was complicated by atrial flutter. The other two women did not have maternal complications. These series remain small, and thus the ability to extrapolate to the individual with Fontan physiology is difficult, **but the uniqueness of the Fontan physiology warrants care in institutions with expertise in adult CHD.** Table 37-5 summarizes the outcomes with Fontan palliation of 43 pregnancies from 27 women reported by these groups.<sup>58,59</sup>

### Eisenmenger Syndrome

Eisenmenger syndrome describes pulmonary-systemic shunting associated with cyanosis and increased pulmonary pressures secondary to pulmonary vascular disease. **Eisenmenger syndrome may develop from any intracardiac shunt that results in blood from the high-pressure systemic circulation being directed into the pulmonary circulation.** Systemic pressure and excessive flow lead to microvascular injury, obliteration of pulmonary arterioles and capillaries, and in the end, elevated PVR. The time to onset of shunt reversal is variable, but most patients who have a large VSD or large PDA develop shunt reversal in infancy. Shunt reversal in those with an ASD is delayed until early adulthood. Survival at 10 years from diagnosis is 80%; at 25 years, it is 42%.<sup>60</sup>

Patients with Eisenmenger syndrome are at risk for CHF, hemoptysis due to pulmonary hemorrhage, sudden death due to arrhythmia, cerebrovascular accident (CVA), and hyperviscosity syndrome. The diagnosis should be considered in any cyanotic patient and is confirmed by echocardiography with the demonstration of increased pulmonary pressure and an intracardiac shunt. If the shunt is due to an ASD or a PDA, cardiac MRI may be necessary to establish the diagnosis. Treatment is nonspecific and includes supportive care and avoidance of destabilizing events such as surgery and unnecessary medications. Symptomatic hyperviscosity syndrome due to an elevated hematocrit can be treated with hydration and, if necessary, phlebotomy. Iron deficiency, preexisting or secondary to phlebotomy, can exacerbate hyperviscosity; microcytic cells are less deformable and are therefore more prone to occlude the microcirculation. Definitive therapy can be achieved only with heart-lung or lung transplantation. However, the 4-year survival with lung transplantation is less than 50%, a less favorable prognosis than that for many patients with Eisenmenger syndrome.

VSD, ASD, and PDA are responsible for 89% of reported cases of Eisenmenger syndrome in pregnancy.<sup>61</sup> Each lesion is initially associated with shunting from the systemic circulation to the pulmonary circulation. As PVR and pulmonary pressures increase over time and approach systemic pressures, the characteristic murmurs of a VSD or PDA may diminish. **Reversal of flow from the pulmonary to the systemic circulation and the development of hypoxemia with increasing hematocrit herald the development of Eisenmenger syndrome. The fall in SVR associated with pregnancy may initiate right-to-left shunting in a patient not previously cyanotic.**

In 1979, Gleicher and colleagues<sup>62</sup> reviewed published cases of Eisenmenger syndrome in pregnancy. Seventy pregnancies from 44 women were evaluated; 52% of the women died during pregnancy, and 30% of the pregnancies resulted in maternal death. The risks for death associated with first, second, and third pregnancies were 36%, 27%, and 33%, respectively. A first successful pregnancy did not confirm the safety of subsequent pregnancies. Most deaths (70%) occurred at the time of delivery or within 1 week postpartum. Excessive blood loss was associated with 35% of deaths, whereas thromboembolic conditions were responsible for 44%. Maternal mortality associated with cesarean delivery (80%) exceeded that associated with vaginal delivery (34%). Maternal death was not reported with first-trimester termination of pregnancy. Only 26% of pregnancies resulted in a term birth. Fifty-five percent of newborns were delivered preterm, and 32% were small for gestational age.

**A more modern review<sup>63</sup> of cases in the United Kingdom between 1991 and 1995 confirms the poor prognosis for pregnant women with Eisenmenger syndrome despite considerable advancement in the management of cardiac disease in pregnancy.** Mortality remains extremely high: 40% of the women died, and most deaths (96%) occurred within the first 35 days postpartum. Late diagnosis (relative risk [RR], 5.4) and delayed hospitalization significantly increased maternal mortality.

Although the risks associated with Eisenmenger syndrome in pregnancy are clear, appropriate management is controversial. Decreased activity, hospitalization, and oxygen supplementation are usually used. Reduction of pulmonary pressures and improved systemic oxygen saturation after oxygen supplementation indicate that PVR is not fixed and suggest a better

prognosis. Intercurrent antepartum events such as pneumonia or a urinary tract infection are poorly tolerated. Preventing microcytosis with iron supplementation may decrease the risk for microvascular slugging.

**Cesarean delivery is reserved for obstetric indications and is avoided whenever possible.** Hemodynamic stability must be maintained during labor and postpartum. When PVR is not fixed, oxygen supplementation may decrease pulmonary pressures. Systemic hypotension from hemorrhage or sympathectomy from epidural analgesia results in increased right-to-left shunting, increased hypoxemia, increased PVR, and worsening of the shunt. Volume overload or excessive systemic resistance, particularly postpartum, may further tax the failing right side of the heart. A pulmonary artery catheter and a peripheral arterial catheter are usually used to guide hemodynamic management. Narcotic-based regional analgesia provides adequate pain relief without excessive hemodynamic instability. Anticoagulation remains controversial. If patients are anticoagulated, caution should be exercised to avoid excessive treatment and associated hemorrhage.

Although use of a selective pulmonary vasodilator, inhaled nitric oxide (NO), has been reported to reduce pulmonary pressures, increase CO, and improve systemic oxygenation, maternal death was not averted. Use of sildenafil and L-arginine has been reported with apparent hemodynamic benefit and the survival of a single patient. Other case reports used pulmonary vasodilators with improved pregnancy outcomes, but nonetheless, maternal risk remains high. **Unlike many cardiac conditions in pregnancy, meticulous care frequently fails to prevent maternal death.**

### Coarctation of the Aorta

**Coarctation of the aorta results from a constriction of the aorta at or about the level of the ductus arteriosus or left subclavian artery.** Patients have a characteristic discrepancy in blood pressure between their right arm and lower extremities. Complications include dissection at the site of coarctation, rupture of associated cranial berry aneurysms, heart failure, and ischemic heart disease associated with cephalic hypertension.

Modern reports of uncorrected coarctation in pregnancy are limited. Historically, pregnancy was associated with a maternal mortality rate of 9% owing to aortic rupture, CHF, CVAs, and endocarditis.  $\beta$ -Blockade may serve to protect against dissection and may promote diastolic flow through the aortic narrowing.

Pediatric screening identifies most significant coarctations, which leads to repair. After repair, systemic hypertension may persist and may require treatment. In two reports of 216 pregnancies in 104 women, 41 were complicated by hypertension and one suffered a lethal dissection at 36 weeks.<sup>64,65</sup>

### SUMMARY

An increasing cohort of young women with corrected CHD will be presenting to their obstetricians pregnant and desiring to bear children. Some basic conclusions can be drawn from our experience with CHD to date. **First, Eisenmenger syndrome and pregnancy remain a lethal combination. New, effective strategies for therapy are not anticipated. Second, cyanotic heart disease in the absence of pulmonary hypertension is associated with increased rates of miscarriage and preterm birth. Third, mothers with cardiac disability (NYHA classes III and IV) or with evidence of right heart dilation have**

**a more complicated course in pregnancy. Fourth, arrhythmias may become worse in pregnancy and may precipitate cardiac decompensation.** Aggressive pharmacologic treatment is appropriate. Finally, many young women who are initially without cardiac disability and are acyanotic can have successful pregnancies.

### CARDIOMYOPATHY

**Dilated cardiomyopathy is characterized by the development of pulmonary edema in the context of LV dysfunction and dilation.** Patients usually present with signs and symptoms of pulmonary edema: dyspnea, cough, orthopnea, tachycardia, and occasionally, hemoptysis. Although characteristic of heart failure, these symptoms of pulmonary edema may also be due to previously undiagnosed congenital or rheumatic heart disease, pre-eclampsia, embolic disease, intrinsic pulmonary disease, or sepsis or from tocolysis. The diagnosis of cardiomyopathy is made in the clinical circumstances of characteristic signs and symptoms and findings of LV dysfunction and dilation on echocardiographic examination. The finding of an elevated B-type natriuretic peptide (BNP) can be used to help discriminate patients who need more definitive testing such as an echocardiogram. An elevated level may also be found with women with diastolic dysfunction or other conditions in which cardiac volume loading and stretch are increased. Ventricular dysfunction may be due to conditions extrinsic to the heart, such as thyrotoxicosis or hypertension, or to intrinsic myocardial dysfunction. Accurate diagnosis directs appropriate therapy and permits assessment of long-term prognosis.

**Peripartum cardiomyopathy is a rare syndrome of heart failure that presents in late pregnancy or postpartum.** The diagnosis is made after excluding other causes of pulmonary edema and heart failure. Failure to adhere to a rigorous definition of disease in the literature confounds conclusions regarding etiology and prognosis. A definition based on criteria for idiopathic dilated cardiomyopathy has been suggested (Box 37-3).<sup>66</sup> The incidence is estimated to be between 1 in 1300 and 1 in 15,000.<sup>67</sup> Although some of the variability in reported incidence is due to regional and ethnic differences, much is due to the imprecise definition of the disease. The cause of peripartum cardiomyopathy is unknown. Nutritional and immunologic mechanisms have been proposed. The prevalence of antibodies to echovirus and Coxsackie virus is not higher among women with cardiomyopathy compared with controls.

**The mortality rate for peripartum cardiomyopathy (PPCM) is reported to be 25% to 50%.** Death is usually due to progressive CHF, arrhythmia, or thromboembolism. Within 6 months, half of patients demonstrate resolution of LV dilation;

#### BOX 37-3 DIAGNOSTIC CRITERIA FOR PERIPARTUM CARDIOMYOPATHY

1. Heart failure within the last month of pregnancy or within 5 months postpartum
2. Absence of prior heart disease
3. No determinable cause
4. Echocardiographic indication of left ventricle dysfunction
  - Ejection fraction of <45% or fractional shortening of <30%
  - Left ventricle end-diastolic dimension of >2.7 cm/m<sup>2</sup>

their prognosis is very good. Of those who do not show resolution, an 85% mortality rate can be expected within the next 4 to 5 years.<sup>68</sup> The magnitude of risk for subsequent pregnancies after PPCM is unclear. A recent survey of 67 pregnancies in 63 women suggests a mortality rate of 8% when LV dysfunction has not resolved and 2% in patients with normal function.<sup>69</sup>

Women with established dilated cardiomyopathy who enter pregnancy with known disease are reported to have less severe outcomes. As might be expected, moderate to severe LV dysfunction and NYHA class III and IV symptoms are associated with worse outcomes. In a series of 36 pregnancies in 32 women, no deaths were reported. Three women developed pulmonary edema, and arrhythmia complicated six pregnancies. Pregnant women were much less likely to be treated with diuretics and  $\beta$ -blockers than were nonpregnant women.<sup>70</sup>

**Women with a diagnosis of PPCM in a previous pregnancy are at risk for heart failure in a subsequent pregnancy.** If LV ejection fraction (LVEF) has not normalized, the mortality rate may be as high as 19%.<sup>71</sup> In those in whom LVEF has normalized, a worsening of function and an increased incidence of symptoms of heart failure can be expected. Aggressive, appropriate pharmacologic management is frequently required.

Acute treatment of cardiomyopathy is directed at improving cardiac function and treating the inciting event. Diuretics are used to decrease preload and relieve pulmonary congestion, and digoxin may improve myocardial contractility and facilitate rate control when AF is present. Afterload reduction is achieved with ACE inhibitors postpartum or hydralazine before delivery.  $\beta$ -Blockade in stable, euvoletic patients has been clearly demonstrated to improve cardiac function and survival outside of pregnancy and should not be withheld from pregnant women. Significantly dilated and hypokinetic cardiac chambers pose a risk for clot formation and systemic embolization. Anticoagulation with heparin antepartum or warfarin postpartum should be considered. Implanted defibrillators have been used in pregnancy without significant complications. Arrhythmia is a common cause of death associated with cardiomyopathy outside pregnancy. Hemodynamic management during labor and delivery is frequently directed by a pulmonary artery catheter. Pain control decreases cardiac work and reduces tachycardia. A carefully dosed epidural is appropriate. Cesarean delivery is reserved for obstetric indications.

**The postpartum period represents a time of particular risk. Women have received exogenous volume loading from IV fluids during labor; blood volume is centralized with uterine contractions, extravascular fluid is mobilized, tachycardia persists, and SVR increases. Each physiologic change will work toward LV decompensation, therefore preemptive HR control, diuresis, and afterload reduction should be used.**

## MYOCARDIAL INFARCTION

Myocardial infarction is a rare event among women of reproductive age. Recent studies suggest a rate between 2.8 and 6.2 per 100,000 deliveries.<sup>71,72</sup> **An increased risk for MI in pregnancy is consistently associated with maternal age greater than 40 years, chronic hypertension, diabetes, smoking, migraine headache, transfusion, and postpartum infection.**<sup>72</sup>

Owing to the rarity of the event, information regarding MI in pregnancy is derived from case reports and is therefore subject to considerable reporting bias. Elkayam and associates<sup>73</sup> summarized 150 cases between 2006 and 2011 (Table 37-6).

**TABLE 37-6 MYOCARDIAL INFARCTION IN PREGNANCY**

|                      | N (%)         |
|----------------------|---------------|
| Pregnancies          | 150           |
| Mean age $\pm$ SD    | 34 $\pm$ 6 yr |
| Age range            | 17 to 52 yr   |
| Anterior infarction  | 69%           |
| Multiparous          | 47%           |
| Hypertension         | 15%           |
| Diabetes mellitus    | 9%            |
| Smoking              | 25%           |
| Family history of MI | 9%            |
| Hyperlipidemia       | 20%           |
| Preeclampsia         | 7%            |
| CHF after MI         | 38%           |
| Coronary anatomy     |               |
| Stenosis             | 27%           |
| Thrombus             | 17%           |
| Dissection           | 43%           |
| Spasm                | 2%            |
| Normal               | 9%            |
| Death                |               |
| Maternal             | 7%            |
| Infant               | 5%            |

Data from Elkayam U, Jalnapurkar S, Barakkat MN, et al. Pregnancy-associated acute myocardial infarction: a review of contemporary experience in 150 cases between 2006 and 2011. *Circulation*. 2014;129:1695-1702.

CHF, congestive heart failure; MI, myocardial infarction; SD, standard deviation.

**Coronary dissection and normal coronary arteries are observed in almost 50% of cases.** Delivery within 2 weeks of infarction may be associated with a maternal mortality rate as high as 50%. MI has been reported in association with cigarette smoking, hyperlipidemia, hypertension, diabetes mellitus, and family history of coronary artery disease as well as pheochromocytoma, Ehlers-Danlos type IV, antiphospholipid syndrome, multiple gestation, and sickle cell anemia. Medications such as ergot alkaloids given for bleeding, bromocriptine for lactation suppression, ritodrine and nifedipine for tocolysis, and prostaglandin E<sub>2</sub> in conjunction with severe hypertension have also been associated with MI (see Table 37-6).

The diagnosis of MI in pregnancy is often delayed because of the rarity of the event and common symptoms of pregnancy. During normal pregnancy, most women experience some increase in exercise intolerance and dyspnea. Chest pain due to reflux is common. **However, ST-segment elevation is not a normal finding, and in the context of ongoing chest pain, it should markedly increase the suspicion of acute MI.** The MB fraction of creatine kinase isoenzymes may be elevated at cesarean delivery as well. Troponin I levels are not elevated during labor and delivery. If confusion regarding the appropriate diagnosis exists in the context of a constellation of findings suggestive of MI, an echocardiogram can be used to confirm abnormal wall motion in the ischemic region.

**Acute therapy is based on rapid coronary reperfusion.** Coronary angioplasty and stenting have been reported in pregnancy and should not be withheld when appropriate for the mother's condition. Thrombolytic therapy has also been used in pregnancy.<sup>73</sup> Although effective, there may be a small but real incidence of associated maternal bleeding, preterm delivery, or fetal loss. Furthermore, thrombolytic drugs are contraindicated in patients with coronary dissection,<sup>74</sup> and given the high incidence of coronary dissection in pregnant patients with acute MI, the use of thrombolytic drugs likely should be avoided. Surgery

after thrombolytic therapy is associated with significant risk for hemorrhage.

Medications commonly used in the management of MI—such as morphine, organic nitrates, lidocaine,  $\beta$ -blockers, aspirin, magnesium sulfate, and calcium antagonists—may be used in appropriate doses in pregnancy. Clopidogrel should be strictly reserved for use after stenting procedures, whereas other glycoprotein IIb/IIIa inhibitors (bivalirudin, prasugrel, and ticagrelor) should be avoided. Use of clopidogrel at the time of cesarean delivery or other surgical procedures can lead to significant bleeding complications. Care should be taken to avoid the supine position and maternal hypotension during procedures, and a viable fetus should be monitored.

**Elective delivery within 2 weeks of infarction should be avoided because it is associated with an increased risk for maternal death.** Cesarean delivery is reserved for obstetric indications. Labor and delivery are managed with standard cardiac care, and pain is controlled, usually with carefully administered regional analgesia; tachycardia is prevented with pain control and is treated with  $\beta$ -blockers as needed. Hemodynamic stability is maintained, frequently using information from pulmonary and peripheral arterial catheters. Maternal pushing is avoided, and the second stage of labor is shortened with low forceps or vacuum. Diuresis is gently initiated postpartum with diuretics.

**The experience with pregnancy after a remote MI is limited. Of 33 reported cases, recurrent infarction and significant complications have not been reported.**<sup>75</sup>

## MARFAN SYNDROME

**Marfan syndrome is an autosomal-dominant genetic disorder caused by an abnormal gene for fibrillin on chromosome 15.** Disease prevalence is estimated to be four to six per 10,000. Sporadic cases represent 15% of those diagnosed. The production of abnormal connective tissue results in the characteristic feature of the disease: aortic root dilation, dislocation of the optic lens, deformity of the anterior thorax, scoliosis, long limbs, joint laxity, and arachnodactyly. Diagnosis is usually based on family history and physical examination that includes ocular, cardiovascular, and skeletal features.

When Marfan syndrome is untreated, life expectancy is reduced by one third, and most deaths are due to aortic dissection and rupture. Elective aortic repair is associated with a low mortality rate (1.5%), whereas emergent repair results in a much higher mortality rate (11.7%). Therefore elective repair has been recommended when the aortic root diameter measures 5.0 cm.<sup>76</sup> Using an absolute aortic diameter (AD) as an indication for surgery ignores relevant differences in aortic size associated with patients of different stature. These considerations are particularly important when caring for young women. An aortic ratio between measured and predicted AD can be calculated. A ratio of less than 1.3 with a dilation rate of less than 5% per year suggests a low risk for a cardiovascular event. The predicted diameter for young adults can be calculated as follows:

$$AD_{\text{predicted}} = 1.02 + (0.98 \times \text{body surface area})$$

The risk for aortic dissection is associated with the rate of change of blood pressure in the aorta over time in systole. Although simple reduction in blood pressure does not reduce the risk for dissection,  $\beta$ -blockade lowers the risk for reaching a critical cardiac end point at 10 years, from about 20% to 10%.

**TABLE 37-7 MARFAN SYNDROME IN PREGNANCY**

|                   | N (%)     |
|-------------------|-----------|
| Women             | 113       |
| Pregnancies       | 291       |
| Live births       | 234 (80%) |
| Miscarriages      | 15 (5%)   |
| Terminations      | 10 (3%)   |
| Fetal deaths      | 1 (0.3%)  |
| Aortic events     | 6 (2%)    |
| Dissection        | 3 (1%)    |
| Rapid dilation    | 2 (0.7%)  |
| Valve dysfunction | 1 (0.3%)  |
| Death             | 0         |

Data from Meijboom LJ, Vos FE, Timmermans J, Boers GH, Zwiderman AH, Mulder BJ. Pregnancy and aortic root growth in the Marfan syndrome: a prospective study. *Eur Heart J*. 2005;26:914-920; Donnelly RT, Pinto NM, Kocolas I, Yetman AT. The immediate and long-term impact of pregnancy on aortic growth rate and mortality in women with Marfan syndrome. *J Am Coll Cardiol*. 2012;60:224-229; and Rossiter J, Repke J, Morales A, et al. A prospective longitudinal evaluation of pregnancy in the Marfan syndrome. *Am J Obstet Gynecol*. 1995;173:1599.

**Literature surveys<sup>77</sup> of case reports suggest a maternal mortality rate associated with Marfan syndrome in pregnancy in excess of 50%.** These case reports likely represent a bias of reporting more severely affected pregnancies. Three prospective population-based studies<sup>78-80</sup> are summarized in Table 37-7. Aortic events—dissection, rapid dilation, or aortic valve dysfunction—occurred in 2% of cases ( $n = 6$ ). Of the three patients who experienced aortic dissection, two had prior dissections and the remaining had a prepregnancy AD of 4.2 cm. Two patients experienced rapid progressive dilation of the aorta, defined as greater than 5 mm from baseline. The final patient with a 4.9 cm aortic root had progression of aortic insufficiency from mild to severe by 38 weeks of gestation.

These studies suggest that women with mild disease, defined as an AD less than 4 cm, can attempt pregnancy with only modest risk. The risk associated with more advanced disease is certainly greater. **Given the data available, a precise risk for death from aortic dissection or rupture cannot be quantified, although patients with a prior aortic dissection or an AD greater than 4.5 cm likely are at higher risk. For women with ADs greater than 4 cm, prophylactic aortic graft and valve replacement is recommended before pregnancy.**<sup>76</sup> They will then assume the risk associated with an artificial valve and the risk associated with the remaining aorta. These risks may be significant; however, adequate data do not exist to quantify the risks. Fifty percent of the offspring of women with Marfan syndrome can be expected to have the disease.

**Management of pregnancies affected by Marfan syndrome should begin with an accurate assessment of the aortic root.** An absolute diameter, or preferably an aortic ratio, can be used to assess specific risk. The aortic root should be protected from hemodynamic forces with  $\beta$ -blockade. A resting HR of about 70 beats/min can usually be achieved. Although  $\beta$ -blockade may potentially contribute to impaired fetal growth, this risk is outweighed by the maternal risk without such treatment.

Labor and delivery are managed with standard cardiac care, with particular emphasis on the prevention of tachycardia. Patients with aortic roots less than 4 cm can be delivered vaginally, reserving cesarean delivery for obstetric indications. Some authors have recommended cesarean delivery for women with larger roots based on concerns about increased pressure in the aorta during labor, although data do not exist to make this a firm recommendation.

## PULMONARY HYPERTENSION

Although pulmonary hypertension is fundamentally a pulmonary disease, the major pathologic impact is on the right side of the heart. The incidence of primary pulmonary hypertension is 1 to 2 per 1 million, and women are affected more commonly than men. Secondary pulmonary hypertension may develop as a complication of cardiac disease such as mitral stenosis or secondary to intrinsic pulmonary disease. Drugs such as cocaine or appetite suppressants may also be associated with pulmonary hypertension. If left untreated, the median survival after diagnosis is 2.5 years.<sup>81</sup> More recently, survival has been reported to be 68% to 77% at 1 year, 40% to 56% at 3 years, and 22% to 38% at 5 years.<sup>82</sup> As might be expected, right heart failure and NYHA class III and IV symptoms predict adverse outcome. General therapy may include limitation of extreme exercise, supplemental oxygen, diuresis, and in some cases, anticoagulation.

Pulmonary vasodilator therapy generally improves symptoms, and lifestyle changes may improve survival. About 10% of patients will respond to high-dose calcium channel blockers. Of those who initially respond to nifedipine, the 5-year survival rate is 95%. IV prostacyclin is associated with a higher response rate but is also associated with side effects such as headache, jaw pain, diarrhea, flushing, and leg pain. A long-term IV line is required, and the dose must be increased on a regular basis. The 5-year survival rate for those who require treatment with prostacyclin is 54%. Subcutaneous, oral, and inhaled prostacyclin are also available, although each has limitations because of the route and timing of delivery.

Sildenafil, a cyclic guanosine monophosphate phosphodiesterase inhibitor, increases the endogenous production of nitric oxide and therefore operates as a potent vasodilator. Treatment with sildenafil improves functional status and hemodynamic profile, and ease of administration is a significant advantage.

**The maternal mortality with severe pulmonary hypertension is reported to be as high as 50%.<sup>83</sup>** Although a review of reported cases suggests an improvement in mortality from 30% between 1978 and 1996 to 17% between 1997 and 2007, the risk remains high. The improvement may be associated with the advent of vasodilator therapy, which highlights the value of a team with considerable experience in pharmacologic management of pulmonary hypertension. **Sudden, irreversible deterioration in the postpartum period is common, and as many as 75% of deaths will occur postpartum.<sup>84</sup>**

The symptoms of pulmonary hypertension are nonspecific. Increasing fatigue and shortness of breath are associated with progressive right-sided heart failure but are also ubiquitous in pregnancy. They can easily be attributed to a presumed upper respiratory infection. Hoarseness may be a result of impingement on the laryngeal nerve by an enlarged pulmonary artery. Patients may exhibit disproportionate lower extremity edema or oxygen desaturation out of proportion for a presumed illness. The diagnosis can be confirmed with echocardiography, in which the velocity of the regurgitant jet across the tricuspid valve can estimate pulmonary systolic pressure. A dilated, hypokinetic RV with displacement of the intraventricular septum into the LV suggests right-sided heart failure.

**Pulmonary hypertension with RV dysfunction is poorly tolerated in pregnancy.** A mortality rate between 17% and 30% should be expected. Antepartum management often requires hospitalization, and oxygen therapy may reduce PVR and may improve RV performance. Pharmacologic treatment

with pulmonary vasodilators may also be effective,<sup>82,85</sup> and anticoagulation with heparin should be considered. Worsening disease will usually be manifest by falling CO rather than rising RV pressure. Labor and delivery should be managed with standard cardiac care, with particular attention to RV filling as assessed by measurement of CVP. **Although the RV requires adequate filling to generate forward flow against an elevated PVR, modest elevations in CVP may precipitate increasing RV dysfunction.** Given fluid mobilization postpartum and the potential need to treat volume loss associated with delivery, appropriate filling may be difficult to achieve; in these cases, aggressive diuresis may be required. Modest underloading or overloading of the RV can result in rapid decompensation and death.

**Women with pulmonary hypertension and RV dysfunction should be strongly discouraged from becoming pregnant.** Because pulmonary artery pressures fall as the RV fails, the condition of the RV may be a more important consideration than an absolute systolic pulmonary pressure. Some women may consider pregnancy after a favorable response to treatment with pulmonary vasodilators. In a small series, two women whose pulmonary pressures and RV function had normalized carried three pregnancies successfully while being treated with nifedipine or prostacyclin. Neither experienced deterioration in their condition during the first year postpartum.

## OTHER CONDITIONS

Young women may experience **malignant ventricular arrhythmias** due to idiopathic ventricular fibrillation, cardiomyopathy, long-QT syndrome, CHD, or hypertrophic cardiomyopathy. An ICD can effectively protect these patients from sudden death. In a report of 44 pregnancies, no women experienced generator erosion or lead fractures due to the expanding pregnancy. Twenty-five percent experienced electrical discharges during pregnancy without complication.<sup>86</sup>

**Hypertrophic cardiomyopathy** is a genetic condition usually inherited in an autosomal-dominant pattern with variable penetrance. Although the condition can be subclassified, the physiologic impact of different forms is similar. Patients are at risk for malignant arrhythmia, diastolic dysfunction, and outflow tract obstruction. A risk for sudden death is suggested by a family history of sudden death, extreme hypertrophy (LV wall  $\geq 30$  mm), a history of syncope, nonsustained ventricular tachycardia, and hypotension with exercise. Arrhythmia risk is managed with an ICD and  $\beta$ -blockade. Volume loading during pregnancy in the face of diastolic dysfunction may result in pulmonary edema. Serum BNP can be used to direct volume management with diuretics. LV outflow tract obstruction is uncommon in young women. Reduced ventricular filling associated with blood loss, dehydration, or tachycardia will increase the functional obstruction. Management of hypertrophic cardiomyopathy has been recently reviewed.<sup>87</sup>

Reviews of case reports suggest a maternal mortality rate of 1% to 2% in these cases.<sup>88-90</sup> Given the biases associated with case report-derived data, this estimate probably sets an upper limit of expected mortality. Thaman and colleagues<sup>90</sup> reported 271 pregnancies in 127 women with hypertrophic cardiomyopathy, complicated by only two cases of pulmonary edema postpartum that resolved with appropriate therapy. In pregnancy, increased blood volume and LV dimension will tend to benefit the patient. Increased heart rate will not benefit the patient;

therefore  $\beta$ -blockers are generally used to manage tachycardia and some arrhythmias, and ICDs may also be used. Labor and delivery are managed with standard cardiac care with particular emphasis given to ensuring generous LV filling. **Excessive volume loading may reveal a stiff ventricle and diastolic dysfunction. In some patients, a relatively small increase in vascular volume results in a substantial increase in pulmonary pressure, pulmonary congestion, and desaturation.** Although diastolic dysfunction may be difficult to diagnose by echocardiography, careful attention to an  $O_2$  saturation monitor during labor and postpartum can reveal the need for augmented diuresis. Supine hypotension must be carefully avoided, and obstetric bleeding should be treated early and aggressively with volume replacement.

### CRITICAL CARE: HEMODYNAMIC MONITORING AND MANAGEMENT

Diseases unique to pregnancy, the physiologic stresses of pregnancy, and the special conditions that surround labor and delivery operate to create circumstances in which intensive care may be necessary more frequently than would be required among young nonpregnant individuals. Specialists in intensive care may not be familiar with the physiology of pregnancy and associated unique conditions such as preeclampsia or amniotic fluid embolus. They may also be unfamiliar with maternal-fetal physiologic relationships and decision making that must balance the needs of the mother and the fetus. **Therefore obstetricians must be familiar with basic principles and techniques of critical care medicine in order to primarily manage critically ill pregnant women or to serve as valuable consultants to a critical care team.**

Acute indications for invasive hemodynamic monitoring can be broadly categorized based on questions of physiology (Box 37-4). Severe preeclampsia, sepsis, acute respiratory distress

syndrome (ARDS), pneumonia, previously undiagnosed heart disease, and fluid management after resuscitation from obstetric hemorrhage are the most common conditions that require hemodynamic monitoring. Certain conditions, particularly maternal heart disease as discussed earlier, require a planned prospective decision for invasive monitoring. In these cases, the therapeutic window for hemodynamic management is narrow, and knowledge of the patient's baseline compensated hemodynamic status can serve as a goal for intrapartum management.

In many cases, initial therapy can and should be based empirically on an understanding of the patient's pathophysiology. If subsequent interventions are needed, specific data obtained from hemodynamic monitoring may be required. Physicians with abundant experience treating a particular disease may rely less on invasive monitoring because an improved understanding makes the clinical course more predictable. In contrast, physicians with less experience may have a lower threshold for using invasive hemodynamic monitoring. Therefore understanding principles of management is particularly important for obstetricians who do not necessarily anticipate critically ill patients in their practice.

### Hemodynamic Monitoring

**The objective of hemodynamic monitoring is to provide continuous assessment of systemic and intracardiac pressures and to provide the means to determine CO and therefore to calculate systemic and pulmonary resistances.** An arterial catheter is usually placed in the radial artery to measure systemic pressure, and the diastolic pressure obtained usually correlates well with noninvasive measurements. Systolic pressure may be significantly higher than noninvasive measurements because of a very brief peak in pressure in early systole. The spike in pressure contributes little to MAP. The noninvasive measurement is usually more clinically relevant to the patient's condition. The arterial catheter permits easy access to arterial blood sampling and relieves the patient from the discomfort of frequent blood draws.

Measurement of intracardiac pressures and CO are obtained through the insertion of a catheter into the central venous circulation and advancement into and through the right side of the heart. Venous access is most commonly obtained through the right internal jugular vein; a subclavian approach may also be used. Traditionally, insertion is guided by using the sternocleidomastoid muscle and the clavicle as landmarks. The higher-frequency ultrasound transducer found on a vaginal probe can also be used to facilitate insertion under direct visualization. Once central venous access has been obtained and confirmed, a pulmonary artery catheter can be "floated" into the right side of the heart and pulmonary artery. Figure 37-7 demonstrates the waveforms and normal pressure values found as the catheter passes through the heart. Success in floating the catheter is initially confirmed by observation of characteristic waveforms in the RV, pulmonary artery, and wedged position and subsequently with a radiograph. In experienced hands, complications from pulmonary artery catheterization are uncommon and include pneumothorax (<0.1%), pulmonary infarction (0 to 1.3%), pulmonary artery rupture (<0.1%), and septicemia (0.5% to 2.0%). Arrhythmias are usually transient and are associated with passage of the catheter through the RV. If the patient has significant pulmonary hypertension, difficulty may be encountered maintaining placement in the pulmonary artery.

Once the catheter has been successfully placed, continuous readings of CVP and pulmonary artery pressures can be

#### BOX 37-4 INDICATIONS FOR HEMODYNAMIC MONITORING

1. Why is the patient hypoxic?
  - Are pulmonary capillary pressures high because of relative volume overload (e.g., mitral stenosis postpartum)?
  - Are pulmonary capillary pressures high because of depressed cardiac function (e.g., cardiomyopathy)?
  - Is capillary membrane integrity intact (e.g., acute respiratory distress syndrome, pneumonia)?
2. Why is the patient persistently hypertensive?
  - Is vascular resistance elevated?
  - Is cardiac output elevated?
3. Why is the patient hypotensive?
  - Is left ventricle filling pressure low (e.g., after hemorrhage)?
  - Is vascular resistance low (e.g., as with septic shock)?
4. Why is the patient's urine output low?
  - Is left ventricle filling pressure low, resulting in low cardiac output?
5. Is the patient expected to be unstable in labor?
  - Is the window of left ventricle filling narrow (e.g., aortic stenosis)?
  - Will normal physiologic changes associated with delivery be tolerated poorly (e.g., volume loading postpartum, mitral stenosis, pulmonary hypertension)?

**FIG 37-7** Hemodynamic waveforms and normal pressure values associated with catheter positions during advancement of a pulmonary artery catheter.

obtained. By inflating the balloon at the catheter tip, the catheter can be wedged in the pulmonary artery to obtain a PAWP, which reflects the filling pressure—preload—in the left ventricle. CVP measured in the right atrium is a measure of RV filling pressure. In pregnant women, CVP cannot be assumed to accurately reflect LV filling. Right atrial pressures and systolic pulmonary pressures can be measured noninvasively by echocardiography.

CO is measured by thermodilution. A bolus of cold fluid is injected into the right atrium, and a curve of temperature change over time is recorded as the bolus passes through the pulmonary artery. From the shape of the curve, CO can be calculated; when the CO is higher, the dilutional curve is shorter in time and greater in maximal temperature change. More recently, catheters have been equipped with a heating element in the right atrial segment so that continuous measurement of CO can be performed. CO can be measured noninvasively with Doppler and impedance techniques. Doppler technique has been validated under a wide range of clinical circumstances.<sup>91-94</sup> The impedance technique tends to underestimate CO in pregnancy but accurately reflects changes in hemodynamics in many conditions. In conditions of pathologically high flow, impedance may significantly underestimate CO.<sup>95-97</sup> Cardiac index can be derived from CO in order to adjust for maternal size and equals CO divided by body surface area (BSA). However, BSA does not seem to be related to CO in pregnancy, therefore CO is usually preferred.<sup>94</sup> When CO is measured noninvasively and CVP is not available, resistance is expressed as total peripheral resistance (TPR) rather than SVR. In most clinical conditions, the differences between the two are not important.

Table 37-8 summarizes the formulae used to calculate hemodynamic parameters not directly measured. Normal values for

**TABLE 37-8**    CALCULATED HEMODYNAMIC VARIABLES

|                                     | <b>CALCULATION</b>                | <b>UNITS</b>                  |
|-------------------------------------|-----------------------------------|-------------------------------|
| Mean arterial pressure (MAP)        | $\frac{sBP + 2(dBP)}{3}$          | mm Hg                         |
| Stroke volume (SV)                  | $\frac{CO \cdot 1000}{HR}$        | mL                            |
| Systemic vascular resistance (SVR)  | $\frac{(MAP - CVO) \cdot 80}{CO}$ | dyne · sec · cm <sup>-5</sup> |
| Total peripheral resistance (TPR)   | $\frac{MAP \cdot 80}{CO}$         | dyne · sec · cm <sup>-5</sup> |
| Pulmonary vascular resistance (PVR) | $\frac{80(mPAP - PAWP)}{CO}$      | dyne · sec · cm <sup>-5</sup> |

CO, cardiac output; CVO, central venous oxygen; dBP, diastolic blood pressure; mPAP, mean pulmonary artery pressure; PAWP, pulmonary artery wedge pressure; sBP, systolic blood pressure.

CO, MAP, HR, SV, and TPR are summarized in Figure 37-1. In a study of 10 normal pregnant women at term, Clark and coworkers<sup>98</sup> determined that CVP, pulmonary artery pressure, PAWP, and LV work index were not different from nonpregnant measurements made about 3 months postpartum. The relationship between PAWP and LV work index fell within the normal range for nonpregnant individuals, suggesting normal contractility in pregnancy. PVR was 34% lower, and colloid osmotic pressure was reduced by 14%.

### Hemodynamic Management

Strategies of hemodynamic therapy that may be applicable to a variety of clinical circumstances are discussed in this section. As

outlined earlier, the use of hemodynamic monitoring should be directed at answering specific questions of maternal pathophysiology. To achieve a particular goal, a number of physiologic interventions are possible. Each of these interventions will precipitate a secondary or compensatory response. The secondary response, if excessive, may adversely affect the patient. The choice of intervention from available options will often be determined by the potential for and magnitude of adverse effect. **Hemodynamic monitoring permits the physician to choose an intervention and subsequently assess the positive and negative effects.**

Disruption of alveolar capillary fluid dynamics is frequently associated with acute oxygen desaturation due to excess alveolar fluid. Pulmonary edema is usually due to excess hydrostatic capillary pressure (e.g., cardiomyopathy, mitral stenosis) or to a disruption of alveolar capillary membrane integrity (e.g., pneumonia, ARDS). **Although a reduction in serum oncotic pressure is rarely a primary cause of pulmonary edema, the reduced serum albumin level in normal pregnancy can act in synergy with other forces and result in earlier or more severe pulmonary edema than would normally occur.**

The use of pulse oximetry facilitates the early detection of maternal desaturation. Oxygen supplementation improves maternal saturation but does not correct the underlying cause. If desaturation is progressive, further intervention will be required. In the normal heart, diuresis to reduce preload works to decrease alveolar water in patients with elevated PAWP and in patients with capillary leak. A reduction in capillary pressure from high normal to low normal will reduce the egress of water across damaged membranes. In many circumstances, these interventions are made empirically based on a diagnosis and an understanding of maternal physiology. For example, tocolysis with  $\beta$ -mimetic agents can induce pulmonary edema. Timely diagnosis, discontinuation of the offending agent, oxygen supplementation, and a single diuretic dose will usually be sufficient therapy. When initial interventions do not achieve an adequate effect, invasive monitoring may be required to direct subsequent care. Maternal diuresis to improve oxygen saturation, when excessive, may lead to a reduction in CO. **Fetal decompensation is usually encountered before a significant reduction in maternal perfusion and hypotension.** The maternal PAWP and CO can be used to direct maternal diuresis. If desaturation continues despite hemodynamic management, intubation may be required. Positive end-expiratory pressure (PEEP) can be used to increase intraalveolar pressure to impede the forces that drive water into alveolar spaces. PEEP may impede venous return and decrease CO as a result of the effects of the associated increase in extracardiac intrathoracic pressure. A PAWP in excess of PEEP is required for adequate ventricular filling. Only in the sickest of pregnant women will PEEP have a clinically significant impact on CO.

Disorders of blood pressure and perfusion can be managed with the knowledge of maternal hemodynamics. Figure 37-8 describes the relationships between MAP, CO, and vascular resistance. CO and MAP are represented on the x-axis and y-axis, respectively. Resistance is represented by diagonal isometric lines. Vasodilators or vasopressors that act on resistance produce vectors of change that run perpendicular to lines of resistance. Interventions that decrease ( $\beta$ -blockers, diuresis) or increase (dopamine, volume) CO produce vectors of change that run roughly parallel to lines of resistance. The region labeled “normal” represents the goal of therapy. Plotting patient data on

**FIG 37-8** Hemodynamic flow chart. Cardiac output and mean arterial pressure are plotted on the x-axis and y-axis, respectively. Diagonal lines are isometric lines of vascular resistance. Anticipated vectors of change can be used to predict patient response to intervention. TPR, total peripheral resistance.

the chart allows the clinician to visually determine the vector or combination of vectors that could return hemodynamics to normal.

Patient A represents a patient who is hypotensive with a low CO, as might be expected after hemorrhage or in heart failure. Given a low PAWP associated with hemorrhage, volume administration would be expected to create a vector that would return hemodynamics to normal. Alternatively, the patient could have a normal or high PAWP associated with heart failure and would need an inotropic agent such as dopamine. Patient B has a normal blood pressure but a high vascular resistance and low CO such as might be expected with a cardiomyopathy. Afterload reduction with a medication such as hydralazine will produce a vector of vasodilation and will return hemodynamics to normal. Patient C is hypertensive with a mixed hemodynamic pattern. She will need a combination of vectors to approach normal hemodynamics (e.g., hydralazine and  $\beta$ -blocker). Patient D is hypotensive and hyperdynamic with a low vascular resistance, hemodynamics that might be found in a patient with early sepsis. Treatment with volume could increase pressure but at the expense of high filling pressures and a potentially negative impact on developing ARDS. Alternatively, a small dose of an  $\alpha$ -adrenergic agent such as phenylephrine would create a vector perpendicular to lines of resistance and would return hemodynamics to normal.

#### KEY POINTS

- ◆ Hemodynamic changes in pregnancy may adversely affect maternal cardiac performance.
- ◆ Intercurrent events such as infection during pregnancy are usually the cause of decompensation.
- ◆ Women with heart disease in pregnancy frequently have unique psychosocial needs.
- ◆ Labor, delivery, and postpartum are periods of hemodynamic instability.

- ◆ The postpartum period can be characterized as a “perfect storm” of volume loading, tachycardia, and increased afterload; each of these may contribute to the destabilization of a pregnant woman with heart disease.
- ◆ Invasive hemodynamic monitoring should be used to address specific clinical questions.
- ◆ Many maternal heart conditions can be medically managed during pregnancy.
- ◆ Management of anticoagulation in women with mechanical valves requires an experienced team and careful consideration of the balance between maternal and fetal risk followed by appropriate counseling. Very aggressive therapeutic monitoring is required.
- ◆ Mothers with cyanotic heart disease are at particular risk for adverse fetal and neonatal outcomes.
- ◆ Eisenmenger syndrome, Marfan syndrome with a dilated aorta, and pulmonary hypertension with right heart dysfunction are associated with a very high risk for maternal mortality.
- ◆ Many women with congenital heart disease can successfully complete a pregnancy.
- ◆ Preconceptual counseling is based on achieving a balance between medical information and the patient’s value system.

Pulmonary diseases are among the most common medical complications of pregnancy. The occurrence of pulmonary disease during gestation may result in increased morbidity or mortality for both the mother and her fetus. Pregnancy may have an adverse or positive impact on the pulmonary function of the gravida depending on the particular complication that is being encountered. The cardiorespiratory changes that occur in pregnancy are reviewed in [Chapter 3](#), and the obstetrician and medical consultants should have a thorough understanding of these changes and their potential effects on the respiratory disease in question. It is also extremely important to realize that most diagnostic tests used to evaluate pulmonary function are not harmful to the fetus and, if indicated, should be performed during gestation. In this section, we discuss some of the respiratory complications that may be encountered during gestation,

the impact of pregnancy on the disease, and the potential impact of the disease on pregnancy.

## PNEUMONIA IN PREGNANCY

Pneumonia is an uncommon complication of pregnancy, observed in 0.78 to 2.7 per 1000 deliveries.<sup>1,2</sup> However, **pneumonia contributes to considerable maternal mortality and is reportedly the most common nonobstetric infection to cause maternal mortality in the peripartum period.**<sup>3</sup> Before the introduction of antibiotic therapy, maternal mortality was as high as 24%.<sup>2</sup> However, **with modern management and antibiotic therapy, the maternal mortality rate currently ranges from 0% to 4%.**<sup>1,3,4</sup> **Preterm delivery is a significant complication of pneumonia; even with antibiotic therapy and**

**modern management, it continues to occur in 4% to 43% of affected pregnancies.**<sup>1,3,4</sup>

The incidence of pneumonia in pregnancy may be increasing primarily as a reflection of the declining health status of certain segments of the childbearing population.<sup>1</sup> In addition, the epidemic of human immunodeficiency virus (HIV) infection has increased the number of potential mothers at risk for opportunistic lung infections. HIV infection further predisposes the pregnant woman to the infectious complications of the acquired immunodeficiency syndrome (AIDS).<sup>5</sup> Reported incidence rates range from 97 to 290 cases per 1000 HIV-infected people per year.<sup>6</sup> **HIV-infected people are 7.8 times more likely to develop pneumonia** than non-HIV-infected individuals with similar risk factors.<sup>6</sup> Women with medical conditions that increase the risk for pulmonary infection, such as cystic fibrosis, are now living to childbearing age more often than in the past. This disorder also contributes to the increased incidence of pneumonia in pregnancy.

**Pneumonia can complicate pregnancy at any time during gestation and may be associated with preterm birth, poor fetal growth, and perinatal loss.** Benedetti and colleagues<sup>3</sup> described 39 cases of pneumonia in pregnancy. Sixteen gravidas presented before 24 weeks' gestation, 15 between 25 and 36 weeks' gestation, and eight presented after 36 weeks' gestation. Twenty-seven patients in this series were followed to completion of pregnancy, and only two required delivery during the acute phase of pneumonia. Of these 27 patients, three suffered a fetal loss, and 24 delivered live fetuses; one neonatal death was due to prematurity.<sup>1</sup> Madinger and associates<sup>4</sup> reported 25 cases of pneumonia that occurred among 32,179 deliveries and observed that fetal and obstetric complications were much more common than in earlier studies. **Preterm labor occurred in 11 of 21 patients who had complete follow-up data, and pneumonia was present at the time of delivery in 11 patients. Preterm labor was more likely in those women who experienced bacteremia, required mechanical ventilation, or had a serious underlying maternal disease.** In addition to the complication of preterm labor, three perinatal deaths occurred in this series. In Berkowitz and La Sala's report<sup>1</sup> of 25 patients with pneumonia that complicated pregnancy, full-term delivery of normally grown infants occurred in 14 women, one delivered preterm, three had a voluntary termination of pregnancy, three had term deliveries of growth-restricted babies, and four were lost to follow-up. Birthweight was significantly lower in the study group ( $2770 \pm 224$  g vs.  $3173 \pm 99$  g in the control group;  $P < .01$ ). In this series, pneumonia complicated 1 in 367 deliveries, and the authors attributed the increase in the incidence of pneumonia in this population to a decline in general health status that included anemia and a significant incidence of cocaine use in the study group (52% vs. 10% in the general population) as well as HIV positivity in the study group (24% vs. 2% in controls). **Madinger and associates<sup>4</sup> reported preterm labor in 44% of cases with antepartum pneumonia, with a preterm birth rate of 36%. Maternal complications of pneumonia include respiratory failure and mechanical ventilation in 10% to 20%, bacteremia in 16%, and empyema in 8%.<sup>1,4</sup>** Respiratory failure due to pneumonia accounts for 12% of intubations during pregnancy.<sup>7</sup> A recent report by Chen and colleagues<sup>8</sup> documents that women with pneumonia during pregnancy have a significantly higher risk of low-birthweight (LBW) infants, preterm birth, small-for-gestational-age (SGA) infants, infants with low Apgar scores,

cesarean delivery, and preeclampsia/eclampsia compared with unaffected women.

## BACTERIOLOGY

Most series that have described pneumonia complicating pregnancy have used incomplete methodologies to diagnose the etiologic pathogens involved, relying primarily on cultures of blood and sputum. In most cases, no identifiable pathogen is reported; however, ***Streptococcus pneumoniae* and *Haemophilus influenzae* remain the most common identifiable causes of pneumonia in pregnancy.**<sup>1,3</sup> Because comprehensive serologic testing has rarely been undertaken, the true incidence of viral pneumonia, *Legionella*, and *Mycoplasma pneumoniae* in pregnancy is difficult to estimate. In Berkowitz and LaSala's series,<sup>1</sup> one patient had *Legionella* species. **Several unusual pathogens have been reported to cause pneumonia in pregnancy, including mumps, infectious mononucleosis, swine flu, influenza A, varicella, coccidioidomycosis, and other fungi.<sup>9</sup>** Varicella pneumonia complicates primary varicella infections in 9% of infections in pregnancy, compared with 0.3% to 1.8% in the nonpregnant population.<sup>10</sup> Influenza A has a higher mortality in pregnant than in nonpregnant patients. **The increase in virulence of viral infections reported in pregnancy may be secondary to the alterations in maternal immune status that characterize pregnancy, including reduced lymphocyte proliferative response, reduced cell-mediated cytotoxicity, and a decrease in the number of helper T lymphocytes (see Chapter 4).**<sup>11,12</sup> Viral pneumoniae can also be complicated by superimposed bacterial infection, particularly with pneumococcus (*S. pneumoniae*). **Recent reports have been made of community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) causing necrotizing pneumonia in pregnancy and postpartum.**<sup>11-13</sup>

Chemical pneumonitis results after the aspiration of gastric contents, and it can be superinfected with pathogens present in the oropharynx and gastric juices, primarily anaerobes and gram-negative bacteria.<sup>9</sup>

Heterosexual transmission of HIV has become an increasingly important mode of transmission. Many women infected with HIV are of childbearing age, and they are at risk for developing *Pneumocystis jiroveci* pneumonia (PJP) during pregnancy. The reported maternal mortality rate from PJP is as high as 50%.<sup>14</sup> Although the risk for maternal mortality is high with PJP infection, most HIV-infected pregnant women in the United States today receive PJP prophylaxis. This practice may actually lead to a decrease in the incidence and mortality from PJP pneumonia in pregnancy.

## BACTERIAL PNEUMONIA

***Streptococcus pneumoniae* (pneumococcus) is the most common bacterial pathogen to cause pneumonia in pregnancy, and *H. influenzae* is the next most common.** These pneumoniae typically present as acute illness accompanied by fever, chills, purulent productive cough, and a lobar pattern on chest radiograph (Fig. 38-1). **Streptococcal pneumonia produces a "rusty" sputum, and gram-positive diplococci appear on Gram stain with asymmetric consolidation and air bronchograms on chest radiograph. *H. influenzae* is a gram-negative coccobacillus that produces consolidation and air bronchograms, often in the upper lobes. Less frequent**

FIG 38-1 Right lower lobe pneumonia.

bacterial pathogens include *Klebsiella pneumoniae*, a gram-negative rod that causes extensive tissue destruction with air bronchograms, pleural effusion, and cavitation noted on chest radiograph. Patients with *Staphylococcus aureus* pneumonia present with pleuritis, chest pain, purulent sputum, and consolidation without air bronchograms noted on chest radiograph. Community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) can present with a viral-like prodrome that progresses to severe pneumonia with high fever, hypotension, and hemoptysis followed by septic shock and need for ventilator support.<sup>11</sup> Severe cases of CA-MRSA have been reported during influenza seasons or associated with a preceding influenza illness in 33% to 71% patients.<sup>11</sup> Leukopenia can be observed and has been found to be a predictor of poor outcome.<sup>11</sup> Patients can present with multilobar infiltrates and cavitation. Mortality from CA-MRSA pneumonia in the United States and Europe is reportedly greater than 50%.

Patients with atypical pneumonia pathogens—such as *M. pneumoniae*, *L. pneumophila*, and *Chlamydia pneumoniae* (Taiwan acute respiratory [TWAR] agent)—present with gradual onset and a lower fever, appear less ill, and have a mucoid sputum and a patchy or interstitial infiltrate on chest radiograph. The severity of the findings on chest radiograph is usually out of proportion to the mild clinical symptoms. *M. pneumoniae* is the most common organism responsible for atypical pneumonia and is best detected by the presence of cold agglutinins, which are present in 70% of cases.

The normal physiologic changes in the respiratory system associated with pregnancy result in a loss of ventilatory reserve. This, coupled with the relative immunosuppression that accompanies pregnancy, puts the mother and fetus at great risk from respiratory infection. **Therefore any gravida suspected of having pneumonia should be managed aggressively. Hospital admission is generally recommended,** and an investigation should be undertaken to determine the pathologic etiology. In a study of 133 women admitted with pneumonia during

pregnancy and managed using protocols based on the British and American Thoracic Societies' admission guidelines for management in nonpregnant individuals,<sup>15</sup> the authors reported that if the American Thoracic Society (ATS) guidelines had been used, 25% of the pregnant women with pneumonia could have avoided admission.<sup>15,16</sup> None of the gravidae who would have been managed as outpatients using the American criteria had any complications.<sup>17</sup> If the British Thoracic Society guidelines had been used, 66% of the pregnant women in this group would have been assigned to outpatient therapy. However, of those, 14% would have required readmission for complications. Of note, most of the 133 women who were hospitalized with pneumonia in this study did not receive a chest radiograph for confirmation of diagnosis. This limits the value of the study for use in guiding admission criteria for pneumonia in pregnancy. **Therefore until additional information is available, admission for all pregnant women with pneumonia is prudent.**

**Workup should include physical examination, arterial blood gases, chest radiograph, sputum for Gram stain and culture, and blood cultures.** Several recently published studies have called into question the use of cultures to identify the microbiology of community-acquired pneumonia. **The successful identification of the bacterial etiology with cultures has been found to range from 2.1% to about 50%.<sup>18,19</sup>** Review of available clinical data reflects an overall reliance on clinical judgment and the patient response to treatment to guide therapy. Other tests are available to identify the etiology of pneumonia that do not require culture and are more sensitive and specific. **An assay approved by the U.S. Food and Drug Administration (FDA) for pneumococcal urinary antigen has been assessed in several studies.<sup>20</sup>** The sensitivity for identifying pneumococcal disease in adults is reportedly 60% to 90% with specificity close to 100%.<sup>20</sup> In one study, the pneumococcal antigen was detected in 26% of patients in whom no pathogen had been identified.<sup>21</sup> This suggests that cases undiagnosed by standard testing can be identified with the assay. In this study, 10% of samples from patients with pneumonia caused by other agents were positive for the pneumococcal assay, which indicates a potential problem with specificity.<sup>21</sup> **Therefore if the response to therapy directed at pneumococcus (*Streptococcus pneumoniae*) is inadequate, coverage for other potential pathogens should be added. A test is available for *Legionella* urinary antigen as well, with a sensitivity of 70% and specificity of 90% for serogroup 1.<sup>22</sup>** This is especially useful in the United States and Europe because about 85% of *Legionella* isolates are serogroup 1.<sup>22</sup> *Legionella* is a common cause of severe community-acquired pneumonia; therefore the urinary antigen for serogroup 1 should be considered for any patient who requires admission to an intensive care unit (ICU) for pneumonia.<sup>22</sup>

Percutaneous transthoracic needle aspiration (PTNA) has been advocated as a valuable and safe method to increase the chance of establishing a causative agent in pneumonia.<sup>23</sup> This test should be reserved for use in compromised individuals, when tuberculosis (TB) is suspected in the absence of a productive cough, and in selected cases of chronic pneumonia, pneumonia associated with neoplasm or foreign body, suspected PJP pneumonia, and suspected conditions that necessitate lung biopsy.<sup>17</sup>

When admission for pneumonia is required, evidence suggests that inpatient and 30-day mortality have been reduced

when antibiotics are administered within 8 hours. Therefore current U.S. federal standards require that the first dose of antibiotics be administered within 4 hours of arrival to the hospital.<sup>24</sup> Empiric antibiotic coverage should be started, usually with a macrolide for mild illness with addition of a  $\beta$ -lactam for severe illness. Yost and colleagues<sup>15</sup> demonstrated that monotherapy with erythromycin was adequate in 118 of 119 women with pneumonia in pregnancy. A macrolide combined with a  $\beta$ -lactam is safe and will provide adequate coverage for most community-acquired bacterial pneumoniae, including *Legionella*. Dual coverage has been demonstrated to improve response to therapy even for abbreviated macrolide regimens.<sup>17</sup> This is theoretically because of an added antiinflammatory effect of the macrolides.<sup>19</sup> Azithromycin administration has been shown to be an independent predictor of positive outcome and reduced length of hospital stay in mild to moderate community-acquired pneumonia.<sup>17</sup> However, the use of macrolides to treat community-acquired pneumonia should be limited when possible because their use has also been associated with increased penicillin resistance among patients with *S. pneumoniae*.<sup>25</sup>

Once the results of the antigen, sputum culture, blood cultures, Gram stain, and serum studies are obtained and a pathogen has been identified, antibiotic therapy should be directed toward the identifiable pathogen. The quinolones as a class should be avoided in pregnancy because they may damage developing fetal cartilage. However, with the emergence of highly resistant bacterial pneumonia, their use may be life-saving and therefore justified in specific circumstances. The respiratory quinolones are not only effective against highly penicillin-resistant *S. pneumoniae* strains, their use reportedly does not increase resistance.<sup>25-27</sup> The respiratory quinolones include levofloxacin, gatifloxacin, and moxifloxacin. These are ideal agents for community-acquired pneumonia because they are highly active against penicillin-resistant strains of *S. pneumoniae*. They are also active against *Legionella* and the other atypical pulmonary pathogens. Another advantage is a favorable pharmacokinetic profile such that blood/lung levels are the same whether the drug is administered orally or intravenously.<sup>28</sup> Arguments against more extensive respiratory quinolone use are based on concerns about the potential for developing resistance, the variable incidence of *Legionella*, and cost. An additional caveat is that the respiratory quinolones are partially effective against mycobacterial TB. Therefore evaluation for this infection should be done when considering the use of quinolones for pneumonia. If CA-MRSA pneumonia is suspected, vancomycin or linezolid should be added to empiric therapy.<sup>11</sup> Additional therapy with clindamycin can be considered in difficult-to-treat cases because it has been shown to reduce production of staphylococcal exotoxins.<sup>26</sup> CA-MRSA is susceptible to fluoroquinolones and trimethoprim-sulfamethoxazole and often are only resistant to  $\beta$ -lactams.<sup>11</sup>

In addition to antibiotic therapy, oxygen supplementation should be given, and frequent arterial blood gas measurements should be obtained. Arterial saturation should be monitored with pulse oximetry with a goal of maintaining the  $PO_2$  at 70 mm Hg, a level necessary to ensure adequate fetal oxygenation. When the gravida is afebrile for 48 hours and has signs of clinical improvement, an oral cephalosporin or macrolide, or both, can be initiated and intravenous (IV) therapy discontinued. A total of 10 to 14 days of treatment should be completed.

**Pneumococcal polysaccharide vaccination prevents pneumococcal pneumonia in otherwise healthy populations with an efficacy of 65% to 84%.<sup>17</sup> The vaccine is safe in pregnancy and should be administered to high-risk gravidae. Those at high risk include individuals with sickle cell disease secondary to autosplenectomy, patients who have had a surgical splenectomy, and individuals who are immunosuppressed. An additional advantage to maternal immunization with the pneumococcal vaccine is that several studies have demonstrated a significant transplacental transmission of vaccine-specific antibodies.<sup>27</sup> After in utero exposure to the vaccine, significantly high concentrations of pneumococcal antibodies are present in infants at birth and at 2 months of age.<sup>27</sup> In addition, colostrum and breast milk antibodies are significantly increased in women who have received the pneumococcal vaccine.<sup>28</sup>**

Pneumonia in pregnancy can be complicated by respiratory failure that requires mechanical ventilation. In such cases, team management should include the obstetrician, a maternal-fetal medicine specialist, and an intensivist. In addition to meticulous management of the gravida's respiratory status, maintenance of the left lateral recumbent position is advocated to improve uteroplacental perfusion. **The potentially viable fetus should be monitored with continuous fetal monitoring. Serial ultrasound examinations for amniotic fluid index (AFI) and growth will help to guide clinical management. If positive end-expiratory pressure (PEEP) greater than 10 cm H<sub>2</sub>O is required to maintain oxygenation, central venous monitoring should be instituted to adequately monitor volume status and maintain maternal and uteroplacental perfusion. No evidence suggests that elective delivery results in an overall improvement in respiratory function<sup>29</sup>; therefore elective delivery should be undertaken with caution. However, if clear evidence of fetal compromise or profound maternal compromise and impending demise is apparent, delivery should be accomplished.**

## VIRAL PNEUMONIA

### Influenza Virus

Every year in the United States, an estimated 4 million cases of pneumonia occur that complicate influenza; this represents the sixth leading cause of death in this country.<sup>30</sup> Although three types of influenza virus—types A, B, and C—can cause human disease, most epidemic infections are due to influenza A,<sup>9</sup> which typically has an acute onset after a 1- to 4-day incubation period and first manifests as high fever, coryza, headache, malaise, and cough. In uncomplicated cases, the chest examination and chest radiograph remain clear.<sup>9</sup> If symptoms persist longer than 5 days, especially in a pregnancy, complications should be suspected. Pneumonia may complicate influenza as the result of either secondary bacterial infection or primary viral infection of the lung parenchyma. In the epidemic of 1957, autopsies demonstrated that pregnant women most commonly died of fulminant viral pneumonia, whereas nonpregnant patients died most often of secondary bacterial infection.<sup>31</sup> A large nested case-control study evaluated the rate of influenza-related complications over 17 influenza seasons in women enrolled in the Tennessee Medicaid system.<sup>32</sup> This study demonstrated a high risk for hospitalization for influenza-related reasons in low-risk pregnant women during the last trimester of pregnancy. The authors predicted that 25 of 10,000 women in the third trimester during the influenza season

will be hospitalized with influenza-related complications.<sup>32</sup> A more recent matched cohort study using the administrative database of pregnant women enrolled in the Tennessee Medicaid population examined pregnant women aged 25 to 44 years with respiratory hospitalization during influenza seasons in 1985 to 1993.<sup>33</sup> In this population of pregnant women, those with asthma accounted for half of all respiratory hospitalizations during influenza season. Of pregnant women with the diagnosis of asthma, 6% required respiratory hospitalization during the influenza season (odds ratio [OR], 10.63; 95% confidence interval [CI], 8.61 to 13.83) compared with women without a medical comorbidity. This study detected no significant increases in adverse perinatal outcome associated with respiratory hospitalization during flu season.<sup>33</sup>

**Early data on pandemic 2009 influenza A (H1N1) suggest pregnant women had an increased risk for hospitalization and death.** Siston and associates<sup>34</sup> identified 788 pregnant women in the United States with H1N1. Thirty died (5% of all reported H1N1 deaths in this period). Among 509 hospitalized women, 115 (22.5%) were admitted to an ICU. **Pregnant women who began treatment more than 4 days after symptom onset were more likely to be admitted to an ICU** (56.9% vs. 9.4%; relative risk [RR], 6.0; 95% CI, 3.5 to 10.6) **than those treated within 2 days after symptom onset.**<sup>34</sup>

Primary influenza pneumonia is characterized by rapid progression from a unilateral infiltrate to diffuse bilateral disease. The gravida may develop fulminant respiratory failure that requires mechanical ventilation and PEEP. **When pneumonia complicates influenza in pregnancy, antibiotics should be started, directed at the likely pathogens that can cause secondary infection: *Staphylococcus aureus*, *Streptococcus pneumoniae* (pneumococcus), *H. influenzae*, and certain enteric gram-negative bacteria.** Antiviral agents, such as amantadine and ribavirin, can be considered. It has been recommended that the influenza vaccine be given routinely to gravidae during the flu season (October to March) regardless of the trimester to prevent the occurrence of influenza and to prevent the development of secondary pneumonia. In addition to maternal protection, **prospective studies have demonstrated higher cord blood antibody levels to influenza in babies born to mothers immunized during pregnancy.** Disease onset is delayed and severity of the influenza is decreased in infants who have higher antibody levels.<sup>35</sup>

### Varicella Virus

Varicella zoster is a DNA virus that usually causes a benign self-limited illness in children but may infect up to 2% of all adults.<sup>36</sup> **Varicella infection occurs in 0.7 of every 1000 pregnancies.**<sup>37</sup> Pregnancy may increase the likelihood of varicella pneumonia complicating the primary infection.<sup>37,38</sup> **Varicella pneumonia occurs most often in the third trimester, and the infection is likely to be severe.**<sup>37,38</sup> The maternal mortality from varicella pneumonia is reportedly as high as 35% to 40%, compared with 11% to 17% in nonpregnant individuals. With modern management, mortality has decreased dramatically. One review reported three deaths in 28 women with varicella pneumonia.<sup>37</sup> Another described 347 pregnant women with Varicella zoster infection. Of these, 18 (5.2%) had pneumonia treated with acyclovir. None died. The authors noted that women with varicella pneumonia were significantly more likely to be current smokers (OR, 5.1; 95% CI, 1.6 to 16) and to have 100 or more skin lesions.<sup>39</sup> A more recent study

**FIG 38-2** This chest radiograph demonstrates bilateral nodular and interstitial pneumonia characteristic of varicella pneumonia. The patient—a 27-year-old gravida 6, para 2, abortus 3—was exposed to varicella infection in her two children. Characteristic skin vesicles of varicella occurred several days before the development of pulmonary symptoms. She required endotracheal intubation and mechanical ventilation for 6 days and was treated with intravenous acyclovir and ceftazidime for possible superimposed infection. The patient recovered fully and delivered a healthy infant at term.

by Zhang and colleagues<sup>38</sup> reported 935 cases of varicella pneumonia in pregnancy in the United States and no maternal deaths.

Varicella pneumonia usually presents 2 to 5 days after the onset of fever, rash, and malaise and is heralded by the onset of pulmonary symptoms that include cough, dyspnea, pruritic chest pain, and hemoptysis. The severity of the illness may vary from asymptomatic radiographic abnormalities to fulminant pneumonitis and respiratory failure (Fig. 38-2). **All gravidae with varicella pneumonia should be aggressively treated with antiviral therapy and admitted to the ICU for close observation.** Acyclovir, a DNA polymerase inhibitor, should be started. **The early use of acyclovir has been associated with an improved hospital course after the fifth day and a lower mean temperature, lower respiratory rate, and improved oxygenation and survival.**<sup>40</sup> **Treatment with acyclovir is safe in pregnancy.** Among 312 exposed pregnancies, no increase was seen in the number of birth defects, and no consistent pattern of congenital abnormalities was apparent.<sup>41</sup> **A dose of 7.5 mg/kg intravenously every 8 hours has been recommended.** The use of varicella immune globulin to prevent infection in individuals exposed to varicella is not possible because it is no longer available in the United States.

**Varicella vaccine is a live attenuated vaccine,** and it is the first vaccine against the herpesvirus. Extensive prelicensure studies have demonstrated that the **vaccine is safe and efficacious against varicella; therefore varicella vaccine was added to the universal childhood immunization schedule in the United States in 1995.** The program of universal childhood

vaccination against varicella in the United States has resulted in a sharp decline in the rate of death from varicella.<sup>42</sup> This vaccine is not recommended for use in pregnancy. However, the overall decline in the incidence of varicella secondary to vaccination will likely result in a decreased incidence of varicella infection and varicella pneumonia in pregnancy.

A recent study assessed the risk for congenital varicella syndrome and other birth defects in offspring of women who inadvertently received the varicella vaccine during pregnancy or within 3 months of conception.<sup>43</sup> Fifty-eight women received their first dose of varicella vaccine during the first or second trimester, and no cases of congenital varicella syndrome were identified among 56 live births (rate, 0%; 95% CI, 0 to 15.6). Among the prospective reports of live births, five congenital anomalies were reported. No specific pattern of anomalies was identified in either the susceptible cohort or the sample population as a whole. Although the numbers in the study are small, the results should provide some reassurance to health care providers and women with inadvertent exposure before or during pregnancy.<sup>43</sup>

### ***Pneumocystis jiroveci* Pneumonia**

*Pneumocystis jiroveci* (PJP), formerly *Pneumocystis carinii* pneumonia (PCP) remains the most prevalent opportunistic infection in patients infected with HIV.<sup>44</sup> It is an AIDS-defining illness that occurs more frequently when the helper T-cell count ( $CD4^+$ ) is less than 200 cells/mm<sup>3</sup>.<sup>44</sup> When AIDS is complicated by PJP, the mortality rate is 10% to 20% during the initial infection, but this rate can increase substantially with the need for mechanical ventilation. The transmission of *Pneumocystis* is not fully understood, although some evidence suggests person-to-person transmission as the most likely mode; however, acquisition from environmental sources may also occur.<sup>44</sup>

The symptoms of PJP are nonspecific; therefore it may be difficult to diagnose. Typical radiographic features of PJP are bilateral perihilar interstitial infiltrates that become increasingly homogeneous and diffuse as the disease progresses (Fig. 38-3). The diagnosis of PJP requires microscopic examination to identify *Pneumocystis* from a clinical source such as sputum, bronchoalveolar fluid, or lung tissue (Fig. 38-4). *Pneumocystis* cannot be propagated in culture. The fungus has trophic forms as well as a cyst state, which can be detected with a modified Papanicolaou, Wright-Giemsa, or Gram-Weigert stain.<sup>44</sup> Monoclonal antibodies are useful for detecting *Pneumocystis* as well. The application of polymerase chain reaction (PCR) to detect *Pneumocystis* has been an area of active research and may be valuable for detection in sputum and bronchoalveolar lavage fluid.<sup>45</sup> Trimethoprim-sulfamethoxazole is the preferred treatment for PJP. Thus far, resistance to this therapeutic agent has not been identified.<sup>44</sup>

A significant number of new infections with HIV are occurring in women of childbearing age. As of 1995, more than 80% of women with AIDS were of reproductive age. PJP pneumonia is the most common cause of AIDS-related death in the United States. Literature on PJP in pregnancy is scarce, but one report describes five cases of PJP in pregnancy and also reviews the literature.<sup>45</sup> In this series of 22 pregnant women with PJP, 11 patients (50%) died of pneumonia. The incidence of respiratory failure in this series was 59%. In individuals who required mechanical ventilation, the survival rate was 31%. The average gestational age was 25 weeks, with a range

**FIG 38-3** *Pneumocystis jiroveci* (formerly *P. carinii*) pneumonia with mixed interstitial and alveolar opacities, a ground-glass appearance.

**FIG 38-4** Wright-Giemsa stain of *Pneumocystis jiroveci* (formerly *P. carinii*) pneumonia.

of 6 weeks' gestation up to 1 week postpartum. Fifteen of the 22 patients had  $CD4^+$  counts performed, and the mean was 93 cells/mm<sup>3</sup>. The patients in this series were treated with a variety of regimens, including trimethoprim-sulfamethoxazole alone, trimethoprim-sulfamethoxazole and steroids, and pentamidine

isethionate. Six patients received trimethoprim-sulfamethoxazole alone, and six were given trimethoprim-sulfamethoxazole and steroids; four patients (66%) survived in each group. Only 12 babies survived; five stillbirths were reported, and four neonates died shortly after birth. In this series, **PJP pneumonia complicating pregnancy in the third trimester had a better maternal and fetal outcome compared with disease in the first or second trimester. Evidence also suggested that treatment with trimethoprim-sulfamethoxazole with or without steroids was associated with an increased survival rate.**<sup>45</sup>

The high mortality rate in this series may be skewed by the fact that this is a retrospective review, and severe cases are more likely to be reported than mild ones. In addition, all the women in this series were unaware of their HIV infection until the diagnosis of PJP was made; therefore none had received PJP prophylaxis.<sup>45</sup>

In summary, PJP pneumonia remains a dreaded complication of HIV infection and an AIDS-defining illness. The maternal and fetal mortality rate is very high when PJP complicates pregnancy. **Primary prophylaxis against PJP with trimethoprim-sulfamethoxazole in HIV-infected adults, including pregnant women and patients receiving highly active antiretroviral therapy (HAART), should begin when the CD4<sup>+</sup> count is less than 200 cells/mm<sup>3</sup> or when the patient has a history of oropharyngeal candidiasis** (see Chapter 53).<sup>46</sup> Prophylaxis should be discontinued when the CD4<sup>+</sup> cell count increases to more than 200 cells/mm<sup>3</sup> for a period of 3 months.<sup>44</sup> The use of HAART, as well as prophylaxis with trimethoprim-sulfamethoxazole, may decrease the incidence of PJP pneumonia in developed countries. However, many countries worldwide do not have the resources for HAART and therefore remain a reservoir for infection with PJP.

## TUBERCULOSIS IN PREGNANCY

The incidence of TB in the United States began to decline in the early part of the twentieth century and fell steadily until 1953, when the introduction of isoniazid led to a dramatic decrease, from 84,000 cases in 1953 to 22,255 cases in 1984.<sup>47</sup> However, since 1984, there have been significant changes in TB morbidity trends. **From 1985 through 1991, reported cases of TB increased by 18%, representing about 39,000 more cases than expected had the previous downward trend continued. This increase is due to many factors, including the HIV epidemic, deterioration in the health care infrastructure, and significantly more cases among immigrants.**<sup>47</sup> The emergence of drug-resistant TB has also become a serious concern. In New York City, in 1991, 33% of TB cases were resistant to at least one drug, and 19% were resistant to both isoniazid (INH) and rifampin (RIF).<sup>48</sup> Between 1985 and 1992, the number of TB cases in women of childbearing age increased by 40%.<sup>49</sup> One report noted TB-complicated pregnancies in 94.8 cases per 100,000 deliveries between 1991 and 1992.<sup>49,50</sup>

### Diagnosis

Most gravidæ diagnosed with TB in pregnancy are asymptomatic. The ATS and the Centers for Disease Control and Prevention (CDC) issued a statement on targeted tuberculin testing for latent tuberculosis infection (LTBI).<sup>51,52</sup> This is a strategic component of TB control that identifies people at high risk for developing TB who would benefit from treatment of LTBI if detected. **Those at risk include people who have had recent**

### BOX 38-1 HIGH-RISK FACTORS FOR TUBERCULOSIS

- Close contact with people known or suspected to have tuberculosis
- Medical risk factors known to increase risk for disease if infected
- Birth in a country with a high tuberculosis prevalence
- Medically underserved status
- Low income
- Alcohol addiction
- Intravenous drug use
- Residency in a long-term care facility (e.g., correctional institution, mental institution, nursing home or facility)
- Health professionals working in high-risk health care facilities

### BOX 38-2 CLINICAL RISK FACTORS FOR DEVELOPING ACTIVE TUBERCULOSIS

- Human immunodeficiency virus infection
- Recent tuberculosis infection
- Injection drug use
- Silicosis
- Solid organ transplantation
- Chronic renal failure
- Jejunioileal bypass
- Diabetes mellitus
- Carcinoma of the head or neck
- Underweight by >15%

infection with TB and those who have clinical conditions associated with an increased risk for progression of LTBI to active TB (Boxes 38-1 and 38-2).

**All gravidæ at high risk for TB should be screened with tuberculin skin testing (TST)** This is usually done with subcutaneous administration of intermediate-strength purified protein derivative (PPD).<sup>51</sup> If anergy is suspected, control antigens such as *Candida*, mumps, or tetanus toxoids should also be placed. **The sensitivity of the PPD is 90% to 99% for exposure to TB. The tine test is not recommended for screening because of its low sensitivity.**

The PPD remains the most commonly used screening test for TB. Three cut-off levels have been recommended for defining a positive tuberculin reaction: greater than 5 mm, greater than 10 mm, and 15 mm or more induration (Fig. 38-5). Induration of greater than 5 mm is a positive reaction in individuals with highest risk for conversion to active TB (see Box 38-2). Interferon- $\gamma$  release assays (IGRAs), an alternative diagnostic tool for LTBI, have specificity of greater than 95% for diagnosis of latent TB infection.<sup>53</sup> The sensitivity for T-SPOT.TB (Oxford Immunotec) appears to be higher than that of the QuantiFERON TB Gold in-Tube (QFT-GIT) test (Cellestis Ltd., Melbourne, Australia) or TST, approximately 90%, 80%, and 80%, respectively. CDC 2012 guidelines indicate that IGRAs can be used in place of, but not in addition to, TST in all situations—including pregnancy—in which the CDC recommends TST as an aid in diagnosing *Mycobacterium tuberculosis* infection. IGRA results can be available in 24 to 48 hours, and no follow-up visit is required for diagnosis. Because IGRAs are not affected by Bacille

**FIG 38-5** Positive purified protein derivative: induration >10 mm.

Calmette-Guérin (BCG) vaccination status, they are useful for evaluation of LTBI in BCG-vaccinated individuals.

Immigrants from areas where TB is endemic may have received the BCG vaccine. Such individuals likely have a positive response to the PPD.<sup>54</sup> However, this reactivity should wane over time. Therefore the PPD can be used to screen these patients for TB unless their skin tests are known to be positive. If the BCG vaccine was given 10 years earlier and the PPD is positive with a skin test reaction of 10 mm or more, that individual should be considered infected with TB and should be managed accordingly.<sup>54</sup>

Women with a positive PPD skin test must be evaluated for active TB with a thorough physical examination for extrapulmonary disease and a chest radiograph once they are beyond the first trimester. Symptoms of active TB include cough (74%), weight loss (41%), fever (30%), malaise and fatigue (30%), and hemoptysis (19%).<sup>55</sup> Individuals with active pulmonary TB may have radiographic findings that include adenopathy, multinodular infiltrates, cavitation, loss of volume in the upper lobes, and upper medial retraction of hilar markings (Fig. 38-6). The finding of acid-fast bacilli in early-morning sputum specimens confirms the diagnosis of pulmonary TB. Two direct amplification tests (DATs) have been approved by the FDA, the *Mycobacterium tuberculosis* Direct test (MTD; Gen-Probe, San Diego, CA) and the Amplicor *Mycobacterium tuberculosis* (Amplicor MTB) test (Roche Diagnostic Systems, Branchburg, NJ).<sup>56,57</sup> Both tests amplify and detect *M. tuberculosis* 16S ribosomal DNA. When testing acid-fast stain smear-negative respiratory specimens, the specificity remains greater than 95%, but the sensitivity ranges from 40% to 77%.<sup>56,57</sup> To date, these tests are FDA approved only for

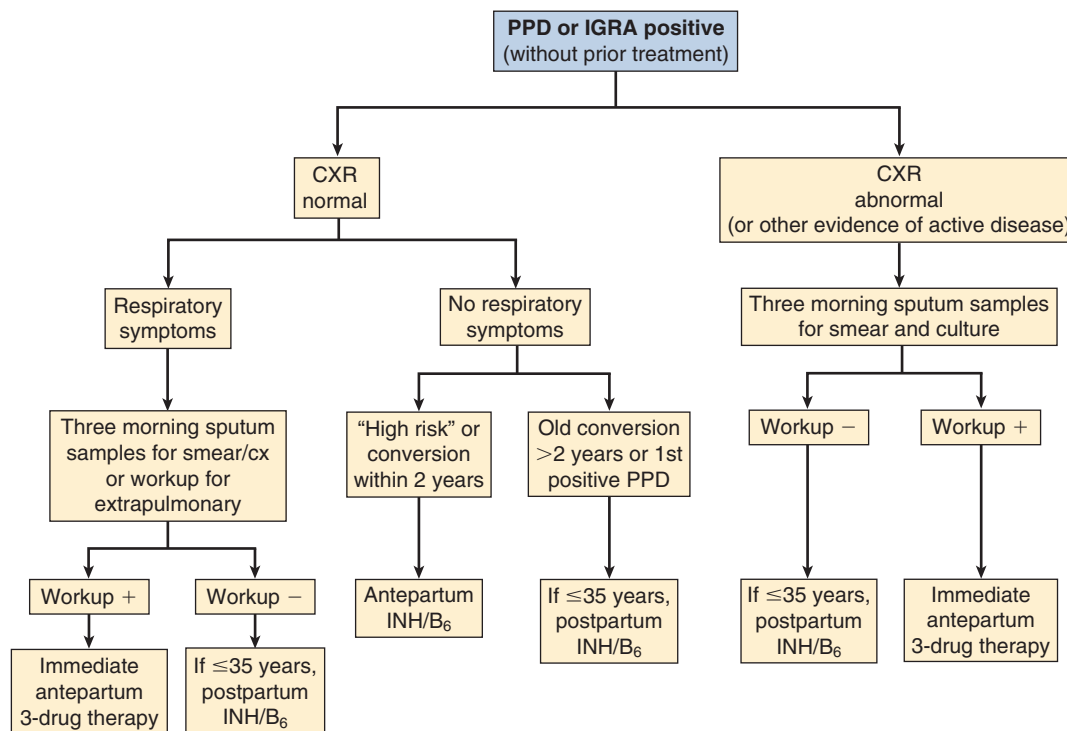

**FIG 38-6** Pulmonary tuberculosis.

testing acid-fast stain smear-positive respiratory specimens obtained from untreated patients or those who have received no more than 7 days of anti-TB therapy.

Extrapulmonary TB occurs in up to 16% of cases in the United States; however, in patients with AIDS, the pattern may occur in 60% to 70%.<sup>58</sup> Extrapulmonary sites include lymph nodes, bone, kidneys, and breasts. Extrapulmonary TB appears to be rare in pregnancy. Extrapulmonary TB that is confined to the lymph nodes has no effect on obstetric outcome, but TB at other extrapulmonary sites does adversely affect the outcome of pregnancy.<sup>59</sup> Rarely, mycobacteria invade the uteroplacental circulation, and congenital TB results.<sup>49</sup> The diagnosis of congenital TB is based on one of the following factors: (1) demonstration of primary hepatic complex or cavitating hepatic granuloma by percutaneous liver biopsy at birth; (2) infection of the maternal genital tract or placenta; (3) lesions noted in the first week of life; or (4) exclusion of the possibility of postnatal transmission by a thorough investigation of all contacts, including attendants.<sup>49</sup>

## Prevention

Most gravidæ with a positive PPD in pregnancy are asymptomatic with no evidence of active disease and are therefore classified as having LTBI. The risk for progression to active disease is highest in the first 2 years of conversion. It is important to prevent the onset of active disease while minimizing maternal and fetal risk. An algorithm for management of the positive PPD is presented in Figure 38-7. In women with a known recent conversion (2 years) to a positive PPD and no evidence of active disease, the recommended prophylaxis is INH, 300 mg/day, starting after the first trimester and continuing for 6 to 9 months. INH should be accompanied by pyridoxine (vitamin B<sub>6</sub>) supplementation, 50 mg/day, to prevent the peripheral neuropathy associated with INH treatment. Women with an unknown or prolonged duration of PPD positivity (>2 years) should receive INH, 300 mg/day, for 6 to 9 months after delivery. INH prophylaxis is not recommended for women older than 35 years who have an unknown or prolonged PPD positivity in the absence of active disease.

**FIG 38-7** Algorithm for the management of positive purified protein derivative (PPD). CX, culture; CXR, chest x-ray; IGRA, interferon- $\gamma$  release assay; INH, isoniazid.

The use of INH is discouraged in this group because of an **increased risk for hepatotoxicity**. INH is associated with hepatitis in both pregnant and nonpregnant adults. The risk for liver inflammation in pregnancy from INH use is rare, and therefore this therapy should be instituted when the risk for conversion to active disease is high.<sup>54</sup> Monthly monitoring of liver function tests may prevent this adverse outcome. Among individuals receiving INH, 10% to 20% develop mildly elevated liver function tests. These changes resolve once the drug is discontinued.

### Treatment

The gravida with active TB should be treated initially with INH, 300 mg/day, combined with RIF, 600 mg/day (Table 38-1).<sup>60</sup> Resistant disease results from initial infection with resistant strains (33%), or it can develop during therapy. If resistance to INH is identified or anticipated, ethambutol should be added, 2.5 g/day, and the treatment period should be extended to 18 months.<sup>60</sup> Ethambutol is teratogenic in animals; however, this has not been demonstrated in humans. The most common side effect of ethambutol therapy is optic neuritis. Streptomycin should be avoided during pregnancy because it is associated with eighth nerve damage in neonates.<sup>61</sup> Antituberculous agents not recommended for use in pregnancy include ethionamide, streptomycin, capreomycin, kanamycin, cycloserine, and pyrazinamide. However, recent case reports that document use of the above-mentioned antituberculous agents in pregnancy have revealed no adverse fetal or neonatal effects. No congenital abnormalities were reported, and pregnancy outcome in the individuals treated was good.<sup>60,61</sup> Untreated TB has been associated with higher morbidity and mortality among pregnant women; therefore the management of the gravida with multidrug-resistant TB should

be individualized. The patient should be counseled about the small risk for teratogenicity and the increased risk for maternal and fetal morbidity and mortality from progression of disease when treatment is delayed. **The risk for postpartum transmission of TB to the baby may be higher among infants born to mothers with drug-resistant TB.**<sup>62,63</sup> Therefore in patients with active disease at the time of delivery, separation of the mother and newborn should be accomplished to prevent infection of the newborn.

Women who are being treated with antituberculous drugs may breastfeed. Only 0.75% to 2.3% of INH and 0.05% of RIF is excreted into breast milk. Ethambutol excretion into breast milk is also minimal. However, if the infant is concurrently taking oral antituberculous therapy, excessive drug levels may be reached in the neonate, and breastfeeding should be avoided. **Breastfed infants of women receiving INH therapy should receive a multivitamin supplement that includes pyridoxine.**<sup>52</sup> Neonates of women on antituberculous therapy should have a PPD skin test at birth and again at 3 months of age. Infants born to women with active TB at the time of delivery should receive INH prophylaxis (10 mg/kg/day) until maternal disease has been inactive for 3 months as evidenced by negative maternal sputum cultures. Active TB in the neonate should be treated appropriately with INH and RIF immediately upon diagnosis or with multiagent therapy should drug-resistant organisms be identified. **Infants and children at high risk for intimate and prolonged exposure to untreated or ineffectively treated individuals should receive the BCG vaccine.**

### Summary

In summary, high-risk gravidae should be screened for TB and treated appropriately with INH prophylaxis for infection

**TABLE 38-1** ANTITUBERCULOSIS DRUGS

| DRUG  | FORM     | DAILY DOSE               | WEEKLY DOSE              | MAJOR ADVERSE REACTIONS   |
|---|----------|--------------------------|--------------------------|---|
| <b>First-Line Drugs (for Initial Treatment)</b> |          |                          |                          |   |
| Isoniazid                                       | PO or IM | 10 mg/kg up to 300 mg    | 15 mg/kg up to 900 mg    | Hepatic enzyme elevation, peripheral neuropathy hepatitis, hypersensitivity                                 |
| Rifampin  | PO       | 10 mg/kg up to 600 mg    | 10 mg/kg up to 600 mg    | Orange discoloration of secretions and urine, nausea, vomiting, hepatitis, febrile reaction, purpura (rare) |
| Pyrazinamide                                    | PO       | 15 to 30 mg/kg up to 2 g | 50 to 70 mg/kg           | Hepatotoxicity, hyperuricemia, arthralgias, skin rash, GI upset   |
| Ethambutol                                      | PO       | 15 mg/kg up to 2.5 g     | 50 mg/kg                 | Optic neuritis (decreased red-green color discrimination, decreased visual acuity), skin rash               |
| Streptomycin                                    | IM       | 15 mg/kg up to 1 g       | 25 to 30 mg/kg up to 1 g | Ototoxicity, nephrotoxicity   |
| <b>Second-Line Drugs (Daily Therapy)</b>        |          |                          |                          |   |
| Capreomycin                                     | IM       | 15 to 30 mg/kg up to 1 g |                          | Auditory, vestibular, and renal toxicity  |
| Kanamycin                                       | IM       | 15 to 30 mg/kg up to 1 g |                          | Auditory and renal toxicity, rare vestibular toxicity   |
| Ethionamide                                     | PO       | 15 to 20 mg/kg up to 1 g |                          | GI disturbance, hepatotoxicity, hypersensitivity  |
| Para-aminosalicylic acid                        | PO       | 150 mg/kg up to 1 g      |                          | GI disturbance, hypersensitivity, hepatotoxicity, sodium load   |
| Cycloserine                                     | PO       | 15 to 20 mg/kg up to 1 g |                          | Psychosis, convulsions, rash  |

GI, gastrointestinal; IM, intramuscular; PO, by mouth.

without overt disease and with dual antituberculous therapy for active disease, and the newborn should also be screened for evidence of TB. Proper screening and therapy will result in a good outcome for mother and fetus in most cases.

## ASTHMA IN PREGNANCY

Up to 8% of pregnancies are complicated by asthma, which may be the most common potentially serious medical condition to complicate pregnancy.<sup>64</sup> In general, the prevalence of and morbidity from asthma are increasing; however, asthma mortality has decreased in recent years. Asthma is characterized by chronic airway inflammation with increased airway responsiveness to a variety of stimuli and airway obstruction that is partially or completely reversible. Insight into the pathogenesis of asthma has changed with the recognition that airway inflammation is present in nearly all cases. **Current medical management for asthma emphasizes treatment of airway inflammation to decrease airway responsiveness and prevent asthma symptoms. The National Asthma Education and Prevention Program (NAEPP) Working Group has found that “it is safer for pregnant women with asthma to be treated with asthma medications than it is for them to have asthma symptoms and exacerbations.”**<sup>64</sup>

## Diagnosis

The enlarging uterus elevates the diaphragm about 4 cm with a reduction of the functional residual capacity (FRC). However, no clinically significant alterations occur in forced vital capacity (FVC), peak expiratory flow rate (PEFR), or forced expiratory volume in 1 second (FEV<sub>1</sub>) in normal pregnancy.

**Diagnosis of asthma in pregnancy is no different than for a nonpregnant patient. Asthma typically includes characteristic symptoms** (wheezing, chest cough, shortness of breath, chest tightness), **temporal relationships** (fluctuating intensity, worse at night), **and triggers** (e.g., allergens, exercise, infections). Wheezing on auscultation would support the diagnosis, but its absence does not rule it out. Ideally, such a diagnosis would be confirmed by demonstrating airway obstruction on spirometry that is at least partially reversible and greater than a 12% increase in FEV<sub>1</sub> after inhalation of albuterol.<sup>65,66</sup> However, reversible airway obstruction may not be demonstrable in some patients with asthma. In patients with a clinical picture

consistent with asthma in whom reversible airway obstruction cannot be demonstrated, a trial of asthma therapy is reasonable. In such patients, a positive response to asthma therapy can establish the presumptive diagnosis during pregnancy. If methacholine testing is deemed necessary to confirm asthma, it should be delayed until postpartum.<sup>64</sup>

In patients who present with new respiratory symptoms during pregnancy, the most common differential diagnosis would be dyspnea (breathlessness) of pregnancy, which can usually be differentiated from asthma by its lack of cough, wheezing, chest tightness, or airway obstruction. Other differential diagnosis considerations include gastroesophageal reflux, chronic cough from postnasal drip, and bronchitis.

**The NAEPP defined *mild intermittent*, *mild persistent*, *moderate persistent*, and *severe persistent asthma* according to daytime and nighttime symptoms—wheezing, cough, or dyspnea—and objective tests of pulmonary function.**<sup>64</sup>

The most commonly used pulmonary function parameters are the PEFR and FEV<sub>1</sub>. Current NAEPP guidelines suggest classifying degree of asthma *severity* in patients not on controller medication and degree of asthma *control* in patients on controller medication (Table 38-2).<sup>65,66</sup> In another study,<sup>67</sup> pregnant patients who had mild asthma by symptoms and pulmonary function but who required regular medications to control their asthma were found to be similar to those with moderate asthma with respect to asthma exacerbations; those who required regular systemic corticosteroids to control asthma symptoms were similar to patients with severe asthma with respect to exacerbations. Using the Juniper Quality of Life Questionnaire, asthma-specific quality of life in early pregnancy was found to be related to subsequent asthma morbidity but not to perinatal outcomes.<sup>68</sup>

## Effects of Pregnancy on Asthma

**Asthma during pregnancy has been associated with considerable maternal morbidity.** In a large prospective study, the effects of pregnancy on asthma were found to be variable: 23% improved and 30% become worse during pregnancy.<sup>67</sup> Women with *mild asthma* had an exacerbation rate of 12.6% and a hospitalization rate of 2.3%; those with *moderate asthma* had an exacerbation rate of 25.7% and a hospitalization rate of 6.8%; and those with *severe asthma* had an exacerbation rate of 51.9% and a hospitalization rate of 26.9%.<sup>67</sup>

**TABLE 38-2** CLASSIFICATION OF ASTHMA SEVERITY AND CONTROL IN PREGNANT PATIENTS

| ASTHMA CONTROL*   | WELL CONTROLLED   | NOT WELL CONTROLLED        |                     | VERY POORLY CONTROLLED |
|---|-------------------|----------------------------|---------------------|------------------------|
| Asthma severity <sup>†</sup>                              | Mild intermittent | Mild persistent            | Moderate persistent | Severe persistent      |
| Symptom frequency, albuterol use                          | ≤2 days/week      | >2 days/week but not daily | Daily symptoms      | Throughout the day     |
| Nighttime awakening                                       | ≤2 times/month    | >2 times/month             | >1 time/week        | ≥4 times/week          |

\*Assess in patients on long-term-control medications to determine whether step-up, step-down, or no change in therapy is indicated.

†Assess severity in patients who are not on long-term-control medications; see Table 38-5 to determine starting controller therapy based on severity.

FEV<sub>1</sub>, forced expiratory volume in 1 second.

## Effects of Asthma on Pregnancy

**Compared with women without a history of asthma, women with asthma have been reported to have higher risks for complications of pregnancy even after adjustment for potential confounders.**<sup>69</sup>

In a 2013 retrospective cohort study based on medical record data from 12 clinical centers in the United States from 2002 to 2008, Mendola and colleagues<sup>70</sup> found that the 17,404 gravidæ with asthma had increased risks for nearly all outcomes studied. Women with asthma had significantly higher adjusted odds ratios for preeclampsia (1.14; 95% CI, 1.06 to 1.22), superimposed preeclampsia (1.34; CI, 1.15 to 1.56), gestational diabetes (1.11; CI, 1.03 to 1.19), placental abruption (1.22; CI, 1.09 to 1.36), placenta previa (1.30; CI, 1.08 to 1.56), and maternal seizures (1.79; CI, 1.21 to 2.63). Asthmatic women had higher odds of preterm birth (1.17; CI, 1.12 to 1.23), preterm premature rupture of the membranes (PPROM; OR, 1.18; CI, 1.07 to 1.30), medically indicated preterm delivery (1.14; CI, 1.01 to 1.29), breech presentation (1.13; CI, 1.05 to 1.22), hemorrhage (1.09; CI, 1.03 to 1.16), pulmonary embolism (1.71; CI, 1.05 to 2.79), and maternal ICU admission (1.34; CI, 1.04 to 1.72). Patients with asthma were less likely to have spontaneous labor (0.87; CI, 0.84 to 0.90) and vaginal delivery (0.84; CI, 0.80 to 0.87).

A significant increase in congenital malformations (adjusted OR, 1.48; CI, 1.04 to 2.09) has also been associated with exacerbations during the first trimester.<sup>71</sup> Although residual confounding or common pathogenic factors may explain some of these associations, observational data that show strong associations between poor asthma control (based on symptoms, pulmonary function, or exacerbations) and these increased risks suggest potential benefits of active asthma management in pregnancy in terms of improved pregnancy outcomes.<sup>69,72,73</sup> **Prospective studies that actively managed asthma during pregnancy have generally had excellent perinatal outcomes.**<sup>73-79</sup> Significantly increased adverse outcomes included preterm birth before 37 weeks' gestation among those who had severe disease or required oral corticosteroids, increased preeclampsia and growth restriction among those with daily symptoms, and an increased rate of cesarean delivery among those with moderate or severe asthma.<sup>73,78</sup> Although these studies show that the gravida with mild or moderate asthma can have excellent maternal and perinatal outcomes, important caveats apply when interpreting them. Prospective studies have tended to find fewer significant adverse associations, possibly because of better asthma surveillance and treatment. In addition, women who enroll in research studies tend to be more compliant and better motivated than

the general public. The lack of finding more adverse outcomes among women with severe persistent asthma may also be a function of the relatively small numbers and the resulting lack of statistical power. Nonetheless, these prospective studies are reassuring in their consensus of good pregnancy outcomes, and they do not contradict that suboptimal control of asthma during pregnancy is associated with increased risk to the mother and baby.<sup>65,78</sup> In fact, a significant relationship has been reported between lower FEV<sub>1</sub> during pregnancy and increased risk for low birthweight and prematurity.<sup>80</sup>

## Asthma Management

The ultimate goal of asthma therapy during pregnancy is to maintain adequate oxygenation of the fetus by prevention of hypoxic episodes in the mother. Other goals include achievement of minimal or no maternal symptoms day or night, minimal or no exacerbations, no limitations of activities, maintenance of normal or near-normal pulmonary function, minimal use of albuterol, and minimal or no adverse effects from medications. Consultation or comanagement with an asthma specialist may aid in the evaluation of the role of allergy and irritants, completion pulmonary function tests, or reevaluation of the medication plan should difficulties arise in achieving the goals of therapy or if the patient has severe asthma. **Effective management of asthma during pregnancy relies on four integral components: (1) objective measures for assessment and monitoring, (2) patient education, (3) avoidance or control of asthma triggers, and (4) pharmacologic therapy.**

## Objective Measures for Assessment and Monitoring

Subjective measures of lung function by either the patient or physician can be an insensitive and inaccurate assessment of airway hyperresponsiveness, airway obstruction, and asthma severity. **The FEV<sub>1</sub> is the single best measure of pulmonary function.** When adjusted for confounders, a mean FEV<sub>1</sub> lower than 80% predicted has been found to be significantly associated with increased preterm delivery before 32 weeks and before 37 weeks and birthweight less than 2500 g.<sup>80</sup> However, measurement of FEV<sub>1</sub> requires a spirometer. **The PEF correlates well with the FEV<sub>1</sub> and has the advantage that it can be measured reliably with inexpensive, disposable, portable peak flowmeters.** Self-monitoring of PEF provides valuable insight into the course of asthma and helps detect early signs of deterioration so that timely therapy can be instituted. Because many pregnant women have increased symptoms, even those with mild or well-controlled disease need to be monitored with PEF and FEV<sub>1</sub>

testing as well as by observing their symptoms during pregnancy.<sup>65</sup> The typical PEFR in pregnancy is 380 to 550 L/min. The patient should establish her “personal best” PEFR then calculate her individualized PEFR zones: green greater than 80%, yellow 50% to 80%, and red zone less than 50% of personal best PEFR.

### Patient Education

The patient should be made aware that controlling asthma during pregnancy is especially important for the well-being of the fetus. She should have a basic understanding of the medical management of asthma during pregnancy, including self-monitoring of PEFRs and the correct use of inhalers. She should be instructed on proper PEFR technique: make the measurement while standing, take a maximal inspiration, and note the reading on the peak flowmeter. Women who smoke should be encouraged to quit. Active smoking, but not passive smoking, has been associated with increased asthma symptoms and fetal growth abnormalities.<sup>81</sup> Women should also be instructed to avoid and control other asthma triggers.

All patients should be educated regarding the relationship between asthma and pregnancy: instruction about self-treatment should include inhaler techniques, the importance of adherence to medication, and control of potential environmental triggers. The patient should know that discontinuation of medications during pregnancy is associated with more severe asthma for all categories of asthma severity.<sup>82</sup> Caregivers should discuss self-reported adherence to treatment with controller medication, and they should address any barriers to optimal adherence (e.g., cost, convenience, concern about side effects). **The importance of adherence to treatment should be stressed.** Advice on environmental control measures for reducing exposure to allergens can be provided on the basis of the results of allergy testing.

Patients should be provided with a schedule for maintenance medications and doses of rescue therapy for increased symptoms. It is important to explain when and how to increase controller medications, when and how to use prednisone, how to recognize a severe exacerbation, and when and how to seek urgent or emergency care. A written asthma action plan is optimal, an example of which is available at [http://www.nhlbi.nih.gov/files/docs/public/lung/asthma\\_actplan.pdf](http://www.nhlbi.nih.gov/files/docs/public/lung/asthma_actplan.pdf).

### Avoidance or Control of Asthma Triggers

**Limiting adverse environmental exposures during pregnancy is important for controlling asthma. Irritants and allergens that provoke acute symptoms also increase airway inflammation and hyperresponsiveness. Avoiding or controlling such triggers can reduce asthma symptoms, airway hyperresponsiveness, and the need for medical therapy.**<sup>66</sup> Association of asthma with allergies is common; 75% to 85% of patients with asthma have positive skin tests to common allergens that include animal dander, house dust mites, cockroach antigens, pollens, and molds. Other common nonimmunologic triggers include tobacco smoke, strong odors, air pollutants, food additives such as sulfites, and certain drugs including aspirin and  $\beta$ -blockers. Another trigger can be strenuous physical activity. For some patients, exercise-induced asthma can be avoided with inhalation of albuterol 10 to 30 minutes before exercise.

Specific measures for avoiding asthma triggers include using allergen-impermeable mattress and pillow covers, removing carpeting, weekly washing of bedding in hot water, avoiding tobacco smoke, inhibiting mite and mold growth by reducing

**TABLE 38-3** STEP THERAPY MEDICAL MANAGEMENT OF ASTHMA DURING PREGNANCY

| STEP  | ASTHMA SEVERITY     |
|---|---------------------|
| 1. No daily medications; albuterol as needed  | Mild intermittent   |
| 2. Low-dose inhaled corticosteroid (alternatives: LTRA or theophylline*)  | Mild persistent     |
| 3. Medium-dose inhaled corticosteroid <sup>†</sup> (alternatives: low-dose inhaled corticosteroid and LABA, LTRA, or theophylline*) | Moderate persistent |
| 4. Medium-dose inhaled corticosteroid and LABA (alternatives: medium-dose inhaled corticosteroid plus LTRA or theophylline*)        | Moderate persistent |
| 5. High-dose inhaled corticosteroid and LABA  | Severe persistent   |
| 6. High-dose inhaled corticosteroid and LABA and oral prednisone  | Severe persistent   |

\*Theophylline (serum level, 5-12  $\mu$ g/mL).

<sup>†</sup>We have modified step 3 to reflect the choice of a medium-dose inhaled corticosteroid over a low-dose inhaled corticosteroid plus a LABA because of the lack of safety data on the use of a LABA during pregnancy.

LABA, long-acting  $\beta$ -agonist; LTRA, leukotriene-receptor agonist.

humidity, and leaving the house when it is vacuumed. Stuffed animals in the bed can also be a trigger. Ideal animal dander control involves removing the pet from the home; allergic women should at least keep furry pets out of the bedroom. Cockroaches can be controlled by poison baits or traps and eliminating exposed food or garbage.

The use of allergen immunotherapy, or “allergy shots,” has been shown to be effective in improving asthma in allergic patients.<sup>66</sup> However, anaphylaxis is a risk for allergy injections—especially early in the course of immunotherapy, when the dose is being escalated—and anaphylaxis during pregnancy has been associated with fetal and maternal death. In a patient who is receiving a maintenance or near-maintenance dose, not experiencing adverse reactions to the injections, and apparently deriving clinical benefit, continuation of immunotherapy is recommended.<sup>69</sup> In such patients, a dose reduction may be considered to further decrease the chance of anaphylaxis. Risk-benefit considerations do not usually favor *beginning* allergy shots during pregnancy.

### Pharmacologic Therapy

Medications for asthma are divided into *long-term controllers* that prevent asthma manifestations—inhaled corticosteroids, long-acting  $\beta$ -agonists, leukotriene modifiers, and theophylline—and *rescue therapy*, such as with albuterol, to provide quick relief of symptoms.

Women who have previously been prescribed asthma medications should be asked about their use to classify their current level of therapy according to a step-care approach (Table 38-3) and to assess potential adherence problems and barriers. **Asthma medication has been reported to significantly decline in the first trimester according to the number of prescriptions filled; a 23% decrease in inhaled corticosteroids, a 13% decrease in  $\beta$ -agonist, and a 54% decrease in rescue corticosteroids was noted.**<sup>83</sup> Moreover, a substantial proportion of asthma exacerbations during pregnancy have been associated with nonadherence to inhaled corticosteroids. In addition to

assessing adherence, asking about past medications and their effectiveness and any side effects can help guide subsequent management decisions.

**It is safer for pregnant women with asthma to be treated with asthma medications than it is for them to have asthma symptoms and exacerbations.**<sup>64</sup> Typical dosages of commonly used asthma medications are listed in Table 38-4. Low, medium, and high doses of inhaled corticosteroid are presented in Table 38-5. The step-care therapeutic approach uses the least amount of drug intervention necessary to control a patient's severity of asthma.

Step Therapy

**The step-care therapeutic approach increases the number and frequency of medications with increasing asthma severity.**<sup>64,66</sup> Based on clinical trials in patients with varying degrees of disease severity, medications (see Table 38-3) are considered to be “preferred” or “alternative” at each step of therapy. Patients who do not respond optimally to treatment should be stepped up to more intensive medical therapy. Patients with poorly controlled asthma should generally be stepped up one step, and those with very poorly controlled asthma (see Table 38-2) should be increased by two steps.<sup>69</sup> Once control is achieved and sustained for several months, a step-down approach can be considered but should be undertaken cautiously and gradually to avoid compromising the stability of the asthma control. For some patients, it may be prudent to postpone attempts to reduce therapy that is effectively controlling the

patient's asthma until after delivery.<sup>64</sup> In the case of a patient who had a favorable response to an alternative drug before becoming pregnant, it would be appropriate to maintain the therapy that successfully controlled the patient's asthma before pregnancy. However, when initiating new treatment for asthma during pregnancy, preferred medications should be considered first rather than alternative treatment options.<sup>64</sup>

Inhaled Corticosteroids

**Inhaled corticosteroids are the preferred treatment for the management of all levels of persistent asthma during pregnancy.**<sup>64</sup> Airway inflammation is present in nearly all cases; therefore inhaled corticosteroids have been advocated as first-line therapy even for patients with mild persistent asthma. In a prospective observational study of 504 pregnant women, those who were not initially treated with inhaled budesonide or beclomethasone had a 17% acute exacerbation rate, compared with only a 4% rate among those treated with inhaled corticosteroids from the start of pregnancy.<sup>77</sup> Randomized controlled trials with pregnant patients have shown that inhaled beclomethasone is more effective than theophylline in improving pulmonary function<sup>79</sup> and that prescribing inhaled beclomethasone in addition to oral corticosteroids and inhaled  $\beta$ -agonists at the time of discharge after hospitalization for asthma reduces subsequent asthma readmissions compared with oral corticosteroids and inhaled  $\beta$ -agonists alone.<sup>84</sup>

**No consistent evidence links inhaled corticosteroid use to increases in congenital malformations or adverse perinatal outcomes.**<sup>64,85</sup> Because more data are available on budesonide use during pregnancy, it is the preferred inhaled corticosteroid,<sup>86</sup> and it is the only inhaled corticosteroid with an FDA pregnancy category B rating. However, if asthma is well controlled by a different inhaled corticosteroid, it may be continued during pregnancy. No human pregnancy data are available for the glucocorticoid ciclesonide.<sup>85</sup>

Inhaled  $\beta_2$ -Agonists

**As-needed use of inhaled  $\beta_2$ -agonists is currently recommended for all levels of asthma during pregnancy.**<sup>64</sup> Albuterol has a rapid onset of effect in the relief of acute bronchospasm through smooth muscle relaxation and is an excellent broncho-protective agent for pretreatment before exercise; however,  $\beta_2$ -agonists are associated with tremor, tachycardia, and palpitations. They do not block the development of airway hyperresponsiveness. **An increased frequency of bronchodilator use could be an indicator of the need for additional antiinflammatory therapy.** Appropriate  $\beta_2$ -agonist use appears to be safe during pregnancy.<sup>64,87</sup>

TABLE 38-4 TYPICAL DOSAGES OF ASTHMA MEDICATIONS

|  |   |
|--|---|
| Albuterol MDI                              | 2 to 4 puffs every 4-6 hours as needed  |
| Salmeterol DPI                             | 1 blister 2 times/day   |
| Formoterol                                 | 1 capsule 2 times/day   |

TABLE 38-5 COMPARATIVE DAILY DOSES FOR INHALED CORTICOSTEROIDS

|                    | DAILY DOSE*                        | LOW DOSE           | MEDIUM DOSE         | HIGH DOSE     |
|--------------------|------------------------------------|--------------------|---------------------|---------------|
| Beclomethasone MDI | 40 to 80 $\mu$ g/puff              | 80 to 240 $\mu$ g  | 240 to 480 $\mu$ g  | >480 $\mu$ g  |
| Budesonide DPI     | 90 or 180 $\mu$ g/inhalation       | 180 to 540 $\mu$ g | 540 to 1080 $\mu$ g | >1080 $\mu$ g |
| Flunisolide MDI    | 80 $\mu$ g/puff                    | 320 $\mu$ g        | 320 to 640 $\mu$ g  | >640 $\mu$ g  |
| Fluticasone MDI    | 44, 110, or 220 $\mu$ g/puff       | 88 to 264 $\mu$ g  | 264 to 440 $\mu$ g  | >440 $\mu$ g  |
| Fluticasone DPI    | 50, 100, or 250 $\mu$ g/inhalation | 100 to 300 $\mu$ g | 300 to 500 $\mu$ g  | >500 $\mu$ g  |
| Mometasone DPI     | 110 or 220 $\mu$ g/inhalation      | 110 to 220 $\mu$ g | 220 to 440 $\mu$ g  | >440 $\mu$ g  |
| Ciclesonide MDI    | 80 or 160 $\mu$ g/puff             | 160 to 320 $\mu$ g | 320 to 640 $\mu$ g  | >640 $\mu$ g  |

Modified from Asthma Care Quick Reference 2012. National Institutes of Health publication No. 12-5075. Available at [http://www.nhlbi.nih.gov/files/docs/guidelines/asthma\\_qrg.pdf](http://www.nhlbi.nih.gov/files/docs/guidelines/asthma_qrg.pdf).  
\*Note that total daily puffs are usually divided as a twice-a-day regimen.  
DPI, dry-powder inhaler; MDI, metered-dose inhaler.

Salmeterol and formoterol are long-acting  $\beta$ -agonist (LABA) preparations. Although human data are limited, the safety of LABAs during human pregnancy is considered likely based on the inhalational route and the generally reassuring data for short-acting  $\beta$ -agonists in addition to animal data.<sup>64,85</sup> LABAs should only be used in combination with inhaled corticosteroids during pregnancy, and they have been shown to be more effective than leukotriene-receptor antagonists (LTRAs) and theophylline as add-on therapy to inhaled corticosteroids.<sup>66</sup> The efficacy of these drugs during pregnancy is largely extrapolated from studies performed in nonpregnant patients.

### Omalizumab

Omalizumab is a humanized monoclonal antibody to immunoglobulin (Ig) E and is an FDA category B drug. An observational registry (the Xolair Pregnancy Registry [EXPECT]) to evaluate exposure to omalizumab had 128 outcomes as of July of 2011. The number of miscarriages (8), fetal deaths (1), preterm deliveries (19), and major birth defects (5) were not inconsistent with expectations for women with moderate to severe asthma.<sup>88</sup> Because of the paucity of safety data and the potential risk of anaphylaxis, omalizumab should not be initiated during pregnancy; a possible exception may be the patient who has allergies and remains uncontrolled despite medical management presented in Table 38-3. However, it would seem reasonable to continue omalizumab among women with severe asthma who become pregnant.

### Theophylline

Theophylline is an alternative treatment for mild and moderate persistent asthma during pregnancy (see Table 38-3).<sup>64</sup> Subjective symptoms of adverse theophylline effects include insomnia, heartburn, palpitations, and nausea; high doses have been observed to cause jitteriness, tachycardia, and vomiting in neonates. **Dosing guidelines have recommended that serum theophylline concentrations be maintained at 5 to 12  $\mu\text{g/mL}$  during pregnancy.**<sup>64</sup> Treatment with cimetidine, erythromycin, or azithromycin can decrease clearance with resultant toxicity; in such cases it may be appropriate to decrease the dosage of theophylline by half.<sup>79</sup> Theophylline is only indicated for chronic therapy and is not effective for the treatment of acute exacerbations during pregnancy.

Theophylline has not been shown to be associated with congenital anomalies.<sup>64,85</sup> In one randomized controlled trial, no differences were found in asthma exacerbations or perinatal outcomes in a cohort that received theophylline compared with the cohort that received inhaled beclomethasone.<sup>79</sup> However, the theophylline cohort had significantly more reported side effects and discontinuation of study medication, and they had an increased proportion of those with an FEV<sub>1</sub> lower than 80% predicted.

### Leukotriene Moderators

Leukotrienes are arachidonic acid metabolites that have been implicated in causing bronchospasm, mucous secretion, and increased vascular permeability. Bronchoconstriction associated with aspirin ingestion can be blocked by LTRAs. Montelukast and zafirlukast are both designated pregnancy category B. Although human data are limited for LTRA use in pregnancy, their use has not been associated with an increase in congenital anomalies.<sup>85,89</sup> **Leukotriene modifiers are less effective as single agents than inhaled corticosteroids and are less effective than LABAs as add-on therapy.**<sup>66</sup>

### Oral Corticosteroids

Prednisone is indicated for the maintenance therapy of severe persistent asthma (see Tables 38-3 and 38-4). For outpatient treatment of acute exacerbations, prednisone may be given 40 to 60 mg per day in one or two divided doses for 3 to 10 days.<sup>64</sup> In a retrospective study, pregnant asthmatic women were found to be undertreated with systemic corticosteroids when compared with nonpregnant patients in an emergency department (ED); they were also nearly 4 times more likely to return to the same ED within 2 weeks for asthma symptoms.<sup>90</sup>

Oral corticosteroid use during the first trimester of pregnancy was associated with a threefold increased risk for isolated cleft lip (background incidence is about 0.1%) with or without cleft palate.<sup>64,85</sup> Oral corticosteroid use has also been associated with an increased incidence of preeclampsia, preterm delivery, and low birthweight.<sup>73,75,85,87</sup> However, it is difficult to separate the effects of the oral corticosteroids on these outcomes from the effects of severe or uncontrolled asthma. Because of the uncertainties in these data and the definite risks of severe uncontrolled asthma to the mother and fetus, **the NAEPP recommends the use of oral corticosteroids when indicated for the long-term management of severe persistent asthma or for exacerbations during pregnancy.**<sup>64</sup>

### Management of Allergic Rhinitis and Gastroesophageal Reflux

**Rhinitis, sinusitis, and gastroesophageal reflux may exacerbate asthma symptoms, and their management should be considered an integral aspect of asthma care.** Intranasal corticosteroids are the most effective medications for control of allergic rhinitis. Loratadine and cetirizine are recommended second-generation antihistamines. Oral decongestant ingestion during the first trimester has been associated with gastroschisis; therefore short-term ( $\leq 3$  days) intranasal decongestants or intranasal corticosteroids should be considered before use of oral decongestants.<sup>64</sup> Controlling gastroesophageal reflux with acid reducers may improve asthma control.

### Antenatal Asthma Management

In general, data are lacking to guide the optimal obstetric management of the woman with asthma, and recommendations are based on extrapolation of data from other clinical settings and expert opinion.<sup>69</sup> Women with asthma should be offered influenza vaccination as appropriate. Patients with persistent asthma should be considered to be at risk for pregnancy complications. Adverse outcomes can be increased by underestimation of asthma severity and undertreatment of asthma. The first prenatal visit should include a detailed medical history with attention to coexisting medical conditions that could complicate the management of asthma, including rhinitis, sinusitis, reflux, or depression. The patient should be questioned about smoking history and the presence and severity of symptoms, episodes of nocturnal asthma, the number of days of work missed, and emergency care visits associated with asthma. Asthma severity or control should be determined (see Table 38-2). The type and amount of asthma medications, including the number of puffs of albuterol used per week, should be noted.

Those with moderate or severe asthma should have scheduling of prenatal visits based on clinical judgment. In addition to routine care, monthly or more frequent evaluations of asthma history (emergency visits, hospital admissions, symptom frequency, symptom interference with sleep or activity, medications,

dosages, and compliance) and pulmonary function (FEV<sub>1</sub> or PEFR) are recommended. Patients should be instructed on proper dosing and administration of their asthma medications.

Daily PEFR monitoring should be considered for patients with moderate or severe asthma and especially for patients who have difficulty perceiving signs of worsening asthma. It may be helpful to maintain an asthma diary that contains daily assessment of asthma status and includes PEFR measurements, symptoms and activity limitations, doctor visits, and a record of regular and as-needed medications taken. Identifying and avoiding asthma triggers, especially smoking, can lead to improved maternal well-being with less need for medications. Specific recommendations can be made for appropriate environmental controls based on the patient's history of exposure and, when available, results of blood or skin testing for IgE-mediated sensitivity to inhalant allergen asthma triggers.

**Women with asthma that is not well controlled, or those who have an exacerbation, may benefit from additional fetal surveillance in the form of ultrasound examinations and antenatal fetal testing.**<sup>64</sup> Because asthma has been associated with intrauterine growth restriction (IUGR) and preterm birth, it is useful to establish pregnancy dating accurately by first-trimester ultrasound. The intensity of antenatal surveillance of fetal well-being should be considered on the basis of the severity of the asthma as well as any other high-risk features of the pregnancy that may be present.

### Home Management of Asthma Exacerbations

An asthma exacerbation that causes minimal problems for the mother may have severe sequelae for the fetus. Patients should be instructed on rescue management and should be educated to recognize signs and symptoms of early asthma exacerbations such as coughing, chest tightness, dyspnea, or wheezing or by a 20% decrease in their PEFR. This is important so that prompt home rescue treatment may be instituted to avoid maternal and fetal hypoxia. In general, patients should use inhaled albuterol, 2 to 4 puffs every 20 minutes for up to 1 hour (Box 38-3). The

**response is considered good if symptoms are resolved or if they become subjectively mild, normal activities can be resumed, and the PEFR is more than 80% of the personal best.** For asthma exacerbations that can be managed at home, a course of oral prednisone is recommended, 40 to 60 mg per day in a single dose or in two divided doses for 3 to 10 days.<sup>64</sup> The patient should seek further medical attention if the response is incomplete or if fetal activity is decreased.

### Hospital and Emergency Department Management of Asthma Exacerbations

**The principal goal should be the prevention of hypoxia.** Measurement of oxygenation through pulse oximetry is essential, and arterial blood gases may be obtained if oxygen saturation remains less than 95%. Chest radiographs are not commonly needed. **Continuous electronic fetal monitoring should be initiated if gestation has advanced to the point of potential fetal viability.** Albuterol (2.5 to 5 mg every 20 minutes for three doses, then 2.5 to 10 mg every 1 to 4 hours as needed, or 10 to 15 mg/hour continuously) **should be delivered by a nebulizer driven with oxygen.**<sup>64</sup> Occasionally, nebulized treatment is not effective because the patient is moving air poorly; in such cases, 0.25 mg terbutaline can be administered subcutaneously every 20 minutes for three doses. Guidelines for the management of asthma exacerbations are presented in Box 38-4.

Systemic glucocorticoids are indicated for those with a poor response to treatment after 1 hour or as initial therapy for those who were taking prednisone. Methylprednisolone, prednisolone, or prednisone should be given 40 to 80 mg/day in a single or divided dose until peak flow reaches 70% of predicted or personal best, and then the dosage is tapered as the patient improves.<sup>64</sup> For patients who have a severe exacerbation, a higher initial dose of 120 to 180 mg/day given over 3 to 4 divided doses should be continued for 48 hours and then tapered as above.<sup>64,66</sup> In severe exacerbations if the patient is unresponsive to the initial regimen, consider treatment with magnesium sulfate, a bronchodilator.

#### BOX 38-3 HOME MANAGEMENT OF ACUTE ASTHMA EXACERBATIONS

Use albuterol MDI 2 to 4 puffs and measure PEFR.

##### Poor response:

- If PEFR is <50% predicted and severe wheezing and shortness of breath occur or decreased fetal movement is apparent, repeat albuterol 2 to 4 puffs by MDI and seek emergency care.

##### Incomplete response:

- If PEFR is 50% to 80% predicted or if persistent wheezing and shortness of breath occur, repeat albuterol treatment 2 to 4 puffs by MDI at 20-minute intervals up to two more times. If repeat PEFR is 50% to 80% predicted or if decreased fetal movement is noted, contact caregiver or seek emergency care.

##### Good response:

- If PEFR is >80% predicted, no wheezing or shortness of breath occur, and the fetus is moving normally, the patient can continue inhaled albuterol, 2 to 4 puffs by MDI, every 3 to 4 hours as needed.

Modified from Quick Reference NAEPP Expert Panel Report: Managing asthma during pregnancy: Recommendations for pharmacologic treatment—2004 update. *J Allergy Clin Immunol.* 2005;115:34-36. MDI, metered-dose inhaler; PEFR, peak expiratory flow rate.

### Labor and Delivery Management of Asthma

**Asthma medications should not be discontinued during labor and delivery.** Although asthma is usually quiescent during labor, consideration should be given to assessing PEFR. The patient should be kept hydrated and should receive adequate analgesia to decrease the risk for bronchospasm. It is commonly recommended that women who are currently taking systemic corticosteroids or who have received several short courses of systemic corticosteroids during pregnancy receive IV corticosteroids (e.g., hydrocortisone at a dose of 100 mg every 8 hours) during labor and for 24 hours after delivery to prevent adrenal crisis.<sup>69</sup> An elective delivery should be postponed if the patient is having an exacerbation. It is rarely necessary to perform a cesarean delivery for an acute asthma exacerbation; maternal and fetal compromise usually respond to aggressive medical management.

Prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) or PGE<sub>1</sub> can be used for cervical ripening, management of spontaneous or induced abortions, or postpartum hemorrhage, although the patient's respiratory status should be monitored.<sup>65</sup> **Methylergonovine and especially carboprost (15-methyl PGF<sub>2α</sub>) can cause bronchospasm.**<sup>65</sup> If tocolysis is needed, magnesium sulfate and terbutaline are preferable because they are bronchodilators; in contrast,

**BOX 38-4 EMERGENCY DEPARTMENT AND HOSPITAL-BASED MANAGEMENT OF ASTHMA EXACERBATION****Initial Assessment and Treatment**

History and examination (auscultation, use of accessory muscles, heart rate, respiratory rate), PEFR or FEV<sub>1</sub>, oxygen saturation, and other tests as indicated:

- If severe exacerbation (FEV<sub>1</sub> or PEFR is <50% with severe symptoms at rest), high-dose albuterol by nebulization every 20 minutes or continuously for 1 hour, inhaled ipratropium bromide, and systemic corticosteroids
- Initiate fetal assessment (consider fetal monitoring and/or BPP if fetus is potentially viable)
- Albuterol by MDI or nebulizer, up to three doses in the first hour
- Oral corticosteroid if no immediate response is seen or if the patient was recently treated with a systemic corticosteroid
- Oxygen to maintain pulse oximetry saturation >95%
- Repeat assessment: symptoms, physical examination, PEFR, oxygen saturation
- Continue albuterol every 60 minutes for 1 to 3 hours provided improvement is evident

**Repeat Assessment**

- Symptoms, physical examination, PEFR, oxygen saturation, other tests as needed
- Continue fetal assessment

**Good Response**

- FEV<sub>1</sub> or PEFR ≥70%
- Response sustained 60 minutes after last treatment
- No distress
- Physical examination: normal
- Reassuring fetal status
- Discharge home

**Incomplete Response**

- FEV<sub>1</sub> or PEFR ≥50% but <70%
- Mild or moderate symptoms
- Continue fetal assessment until patient has stabilized

- Monitor FEV<sub>1</sub> or PEFR, oxygen saturation, pulse
- Continue inhaled albuterol and oxygen
- Inhaled ipratropium bromide
- Systemic (oral or intravenous) corticosteroid
- Individualize decision for hospitalization

**Poor Response**

- FEV<sub>1</sub> or PEFR <50%
- PCO<sub>2</sub> >42 mm Hg
- Physical examination: symptoms severe, drowsiness, confusion
- Continue fetal assessment
- Admit to ICU

**Impending or Actual Respiratory Arrest**

- Admit to ICU
- Intubation and mechanical ventilation with 100% oxygen
- Nebulized albuterol plus inhaled ipratropium bromide
- Intravenous corticosteroid

**Intensive Care Unit**

- Inhaled albuterol hourly or continuously plus inhaled ipratropium bromide
- Intravenous corticosteroid
- Oxygen
- Possible intubation and mechanical ventilation
- Continue fetal assessment until patient has stabilized

**Discharge Home**

- Continue treatment with albuterol
- Oral systemic corticosteroid if indicated
- Initiate or continue inhaled corticosteroid until review at medical follow-up
- Patient education:
  - Review medicine use
  - Review/initiate action plan
  - Recommend close medical follow-up

Modified from Quick Reference NAEPP Expert Panel Report: Managing asthma during pregnancy: Recommendations for pharmacologic treatment—2004 update. *J Allergy Clin Immunol.* 2005;115:34-36.

BPP, biophysical profile; FEV<sub>1</sub>, forced expiratory volume in 1 second; ICU, intensive care unit; MDI, Metered-dose inhaler; PCO<sub>2</sub>, partial pressure of carbon dioxide; PEFR, peak expiratory flow rate.

indomethacin might induce bronchospasm in the aspirin-sensitive patient.<sup>65</sup> Use of calcium channel blockers for tocolysis among patients with asthma has not been reported, although an association with bronchospasm has not been observed with wide clinical use. Nonselective  $\beta$ -blockers may trigger bronchospasm.

Lumbar anesthesia has the benefit of reducing oxygen consumption and minute ventilation during labor. Fentanyl or butorphanol may be safer than morphine or meperidine, which can cause histamine release, but evidence of bronchospasm during labor is lacking. Communication among the obstetric, anesthetic, and pediatric caregivers is important for optimal care.

**Breastfeeding**

In general, only small amounts of asthma medications enter breast milk. Prednisone, theophylline, antihistamines, inhaled corticosteroids, LTRAs, and  $\beta_2$ -agonists are not considered to be contraindications for breastfeeding.<sup>64,65</sup> However, among sensitive neonates, theophylline may cause vomiting, feeding difficulties, jitteriness, and cardiac arrhythmias.

**Summary**

Asthma is an increasingly common problem during pregnancy. Mild and moderate asthma can be associated with excellent maternal and perinatal pregnancy outcomes, especially if patients are managed according to contemporary NAEPP recommendations. Severe and poorly controlled asthma may be associated with increased prematurity, preeclampsia, growth restriction, and a need for cesarean delivery. Severe asthma exacerbations can result in maternal morbidity and mortality and can have commensurate adverse pregnancy outcomes. The management of asthma during pregnancy should be based on objective assessment, trigger avoidance, patient education, and step therapy. Asthma medications should be continued during pregnancy and while breastfeeding.

**RESTRICTIVE LUNG DISEASE**

**Restrictive ventilatory defects occur when lung expansion is limited because of alterations in the lung parenchyma or**

**because of abnormalities in the pleura, chest wall, or the neuromuscular apparatus.** These conditions are characterized by a reduction in lung volumes and an increase in the ratio of FEV<sub>1</sub> to FVC.<sup>91</sup> The interstitial lung diseases include idiopathic pulmonary fibrosis, sarcoidosis, hypersensitivity pneumonitis, pneumoconiosis, drug-induced lung disease, and connective tissue disease. **Additional conditions that cause a restrictive ventilatory defect include pleural and chest wall diseases and extrathoracic conditions such as obesity, peritonitis, and ascites.**<sup>91</sup> Restrictive lung disease in pregnancy has not been well studied. Consequently, little is known about the effects of restrictive lung disease on the outcome of pregnancy or the effects of pregnancy on the disease process itself. Boggess and colleagues<sup>92</sup> presented data on nine pregnant women with interstitial and restrictive lung disease who were prospectively managed. Diagnoses included idiopathic pulmonary fibrosis, hypersensitivity pneumonitis, sarcoidosis, kyphoscoliosis, and multiple pulmonary emboli. Three of the gravidae described in this paper had severe disease characterized by a vital capacity of 1.5 L or less (50% predicted) or a diffusing capacity less than or equal to 50% predicted. Five of the patients had exercise-induced oxygen desaturation, and four patients required supplemental oxygen. One patient in the group had an adverse outcome and was delivered at 31 weeks; she subsequently required mechanical ventilation for 72 hours. All other patients were delivered at or beyond 36 weeks with no adverse intrapartum or postpartum complications. All infants were at or above the 30th percentile for growth. The authors concluded that restrictive lung disease was well tolerated in pregnancy. However, exercise intolerance was common; therefore early oxygen supplementation may be required.

### Sarcoidosis

**Sarcoidosis is a systemic granulomatosis disease of undetermined etiology that often affects young adults. Pregnancy outcome for most women with sarcoidosis is good.**<sup>93,94</sup> In a study of 35 pregnancies in 18 patients with sarcoidosis, disease activity remained stable in nine patients. During pregnancy, improvement was demonstrated in six patients, and in three, a worsening of the disease was reported.<sup>93</sup> During the postpartum period, 15 patients remained stable; however, in three women, a progression of the disease continued. Another retrospective study presented 15 pregnancies complicated by maternal sarcoidosis over a 10-year period.<sup>94</sup> **Eleven of these patients remained stable, two experienced disease progression, and two died as a result of severe complications of severe sarcoidosis.** In this group, factors indicative of a poor prognosis reportedly included parenchymal lesions on chest radiograph, advanced radiographic staging, advanced maternal age, low inflammatory activity, requirement for drugs other than steroids, and the presence of extrapulmonary sarcoidosis.<sup>94</sup> Both of the patients who succumbed during gestation had severe disease at the onset of pregnancy. The overall cesarean delivery rate was 40%; in addition, 27% of infants (4 of 15) weighed less than 2500 g. None of the patients developed preeclampsia. One possible explanation for the commonly observed improvement in sarcoidosis may be the increased concentration of cortisol during pregnancy. However, because sarcoidosis improves spontaneously in many nonpregnant patients, the improvement may be coincident with, but not due to, pregnancy.

One study examined 17 pregnancies in 10 patients and concluded that pregnancy had no consistent effect on the course of the disease.<sup>95</sup> Scadding<sup>96</sup> separated patients into three categories based on characteristic patterns of their chest radiographs. When the chest radiograph had resolved before pregnancy, the normal radiograph persisted throughout gestation. In women with resolving radiographic changes before pregnancy, resolution continued throughout the prenatal period. Patients with inactive fibrotic residual disease had stable chest radiographs, and those with active disease tended to have partial or complete resolution of those changes during pregnancy. Most patients in this latter group, however, experienced exacerbation of the disease within 3 to 6 months after delivery.<sup>96</sup>

**Patients with pulmonary hypertension complicating restrictive lung disease may suffer a mortality rate as high as 50% during gestation. These patients need close monitoring during labor and delivery and postpartum.** Invasive monitoring with a pulmonary artery catheter may be indicated to optimize cardiorespiratory function. **Gravidae with restrictive lung disease, including pulmonary sarcoidosis, may benefit from early institution of steroid therapy for evidence of worsening pulmonary status.** Individuals with evidence of severe disease need close monitoring and may require supplemental oxygen therapy during gestation.

**During labor, consideration should be given to early use of epidural anesthesia, if it is not contraindicated.** The proactive institution of pain management in this population will minimize pain, decrease sympathetic response, and therefore decrease oxygen consumption during labor and delivery. **The use of general anesthesia should be avoided, if possible,** because these patients may develop pulmonary complications after general anesthesia, including pneumonia and difficulty weaning from the ventilator. **In addition, close fetal surveillance throughout gestation is warranted because impaired oxygenation may compromise fetal growth.**

An additional consideration is the need to counsel all women with restrictive lung disease about the potential for continued impairment of their respiratory status during pregnancy, particularly if their respiratory disease is deteriorating at the time of conception. The individual with clinical signs consistent with pulmonary hypertension or severe restrictive disease should be cautioned about the possibility of maternal mortality due to worsening pulmonary function during gestation.

**In summary, although the literature on restrictive lung disease in pregnancy is limited, it supports the conclusion that most patients with restrictive lung disease complicating pregnancy—which includes those with pulmonary sarcoidosis—will have a favorable pregnancy outcome.** However, the clinician should keep in mind that a subgroup of women with restrictive lung disease can have significant worsening of their clinical condition during gestation.

### Cystic Fibrosis

Cystic fibrosis (CF) involves the exocrine glands and epithelial tissues of the pancreas, sweat glands, and mucous glands in the respiratory, digestive, and reproductive tracts. **Chronic obstructive pulmonary disease (COPD), pancreatic exocrine insufficiency, and elevated sweat electrolytes are present in most patients with CF.** The disease is **genetically transmitted with an autosomal-recessive pattern of inheritance.** The CF gene was identified and cloned in 1989; the gene is localized to

chromosome 7, and the molecular defect that accounts for the majority of cases has been identified. **In the United States, about 4% of the white population are heterozygous carriers of the CF gene, and the disease occurs in 1 in 3000 live white births.** Morbidity and mortality in CF is usually secondary to progressive chronic bronchial pulmonary disease. Pregnancy and the attendant physiologic changes can stress the pulmonary, cardiovascular, and nutritional status of women with CF. The purpose of this section is to familiarize the obstetrician with the physiologic effects of this complex disease and the impact of the disease on pregnancy and the impact of pregnancy on the disease. Additional factors that need to be addressed are the genetics of this disorder (see Chapter 10) and the implications for the newborn, as well as social issues, including who will raise the child should the mother succumb to her disease.

**Survival for patients with CF has increased dramatically since 1940. According to the Cystic Fibrosis Foundation's patient registry, mean survival in 2008 had increased to 39.6 years.** Women had a slightly lower median age of survival (27.3 years) compared with men (29.6 years). The reasons for sex differences in mortality are unclear. **Today, more than 45% of individuals with CF in the United States are older than 18 years.** This increase in survival of patients with CF is likely secondary to earlier diagnosis and intervention and to advances in antibiotic therapy and nutritional support. **Therefore, more women with CF are now entering reproductive age. In contrast to men with CF, who for the most part are infertile, women with CF are more often fertile. Infertility in women with CF may occasionally be due to anovulatory cycles and secondary amenorrhea, which result from significant malnutrition associated with advanced disease. A more common reason for infertility appears to result from alteration in the physiologic properties of cervical mucus.**

The first case of CF complicating pregnancy was reported in 1960. The annual number of CF pregnancies reported to the Cystic Fibrosis Foundation's patient registry doubled between 1986 and 1990, with 52 pregnancies reported in 1986 and 111 pregnancies reported in 1990. This same registry more recently reported on a total of 680 pregnancies in 8136 women between 1985 and 1997. This documents a dramatic increase in pregnancy complicated by CF, and increasing numbers are reported in other countries as well. **Because the number of women with CF who achieve pregnancy is steadily increasing, it is important that the obstetrician be familiar with the disease. Liberal consultation with a CF specialist should be obtained because a team effort will increase the chance for an improved pregnancy outcome.**

### Effect of Pregnancy on Cystic Fibrosis

The physiologic changes associated with pregnancy (see Chapter 3) are well tolerated by healthy gravidas; however, those with CF may adapt poorly. During pregnancy, an increase in resting minute ventilation at term may approach 150% of control values due to the increased oxygen consumption and increased carbon dioxide burden that occur during pregnancy. In addition, increased levels of circulating progesterone stimulates the respiratory drive. Enlargement of the abdominal contents and upward displacement of the diaphragm lead to a decrease in functional residual volume and a decrease in residual volume. Pregnancy is also accompanied by subtle alterations in gas exchange with widening of the alveolar-arterial oxygen gradient

that is most pronounced in the supine position. These alterations in pulmonary function are of little consequence to the normal pregnant woman. However, in the gravida with CF, these changes may contribute to respiratory decompensation that can lead to an increase in morbidity and mortality for the mother and the fetus.

During normal pregnancy, blood volume increases by an average of 50%. Cardiac output increases as well and reaches a plateau in midpregnancy. During labor, blood volume rises acutely, in large part because of the release of blood from the contracting uterus, and it is additionally increased after delivery secondary to augmented venous return with the release of caval obstruction.

**Women with CF and advanced lung disease may suffer from pulmonary hypertension with high pulmonary artery pressures. Regardless of the etiology, pulmonary hypertension is associated with unacceptable maternal risk during pregnancy and is considered to be a contraindication to pregnancy.** Women with significant pulmonary hypertension may develop cardiovascular collapse at the time of labor and delivery, with a maternal mortality rate that exceeds 25%. Additionally, **women with pulmonary hypertension may not be able to adequately increase cardiac output during pregnancy; therefore they suffer uteroplacental insufficiency that leads to intrauterine growth restriction and stillbirth.**

Nutritional requirements are increased during pregnancy, and about 300 kcal/day in additional fuel is needed to meet the requirements of mother and fetus. **Most patients with CF have pancreatic exocrine insufficiency. As a result, digestive enzymes and bicarbonate ions are diminished, which results in maldigestion, malabsorption, and malnutrition.**

Several reports suggest that **patients who have mild CF, good prepregnancy nutritional status, and less impairment of lung function tolerate pregnancy well. However, those with poor clinical status, malnutrition, hepatic dysfunction, or advanced lung disease are at increased risk from pregnancy.**<sup>97,98</sup> Kent and Farquharson<sup>98</sup> reviewed the literature and reported 217 pregnancies. In this series, the frequency of preterm delivery was 24.3%, and the perinatal death rate was 7.9%. **Poor outcomes were associated with a maternal weight gain of less than 4.5 kg and an FVC of less than 50% of predicted. A series of pregnancies in women with CF described by Edenborough and colleagues<sup>99</sup> reported 18 live births (81.8%), one third of which were preterm deliveries, and 18.2% of patients had abortions. Four maternal deaths occurred within 3.2 years after delivery.** In this series, lung function was available before delivery, immediately after delivery, and after pregnancy. Although the patients demonstrated a decline of 13% in FEV<sub>1</sub> and 11% in FVC during pregnancy, most returned to baseline pulmonary function after pregnancy. Although most of the women tolerated pregnancy well, **those with moderate to severe lung disease—an FEV<sub>1</sub> less than 60% of predicted—more often had preterm infants and had increased loss of lung function compared with those with milder disease.**<sup>99</sup> **In two series, prepregnancy FEV<sub>1</sub> was found to be the most useful predictor of outcome in pregnant women with CF.**<sup>99,100</sup> **In addition, a positive correlation was found between prepregnancy FEV<sub>1</sub> and maternal survival.**

Another report examined survival in 8136 women enrolled in the U.S. Cystic Fibrosis Foundation National Patient Registry from 1985 to 1997,<sup>101</sup> and 680 of these became pregnant. The

authors matched the 680 women in an index year to 3327 control women with CF. Women who reported a pregnancy were more likely to have had a higher percentage of predicted FEV<sub>1</sub> (67.5% predicted vs. 67.1% predicted, respectively;  $P > .001$ ) and a higher weight (52.9 vs. 46.4 kg, respectively;  $P > .001$ ). The 10-year survival rate in pregnant women (77%; 95% CI, 71% to 82%) was higher than in those women who did not become pregnant. A separate analysis that matched the pregnant patient's FEV<sub>1</sub> percent of predicted, age, *Pseudomonas aeruginosa* colonization, and pancreatic function obtained similar results. In this cohort, pregnancy was not harmful in any subgroup, which included patients with an FEV<sub>1</sub> 40% of predicted or diabetes mellitus.<sup>101</sup> **The authors concluded that women with CF who became pregnant were initially healthier and had better 10-year survival rates than women with CF who did not become pregnant.**

A 2014 report by Patel and colleagues<sup>102</sup> describes 1119 deliveries in women with CF in the United States, compared with 12,627,627 women without the disease, and documents an increased risk of death, mechanical ventilation, pneumonia, acute renal failure, preterm labor, diabetes, asthma, and an adverse composite CF outcome; however, the absolute risks were low.

**Pulmonary involvement in CF includes chronic infection of the airways and bronchiectasis. Selective infection with certain microorganisms occurs, such as *S. aureus*, *H. influenzae*, *P. aeruginosa*, and *Burkholderia cepacia*, although *P. aeruginosa* is the most frequent pathogen.** Parenteral antibiotics are the mainstays of treatment for these acute infections. However, pregnancy- and CF-associated alterations in pharmacokinetics can have grave consequences for these patients. It is well known that pregnant subjects have lower serum levels and higher urine levels of antibiotics than nonpregnant subjects. The lower levels in plasma are attributed to the increase in volume of distribution and an increase in glomerular filtration and renal clearance of the drugs, therefore monitoring drug levels is indicated when therapeutic response is less than optimal.

### Counseling Patients with Cystic Fibrosis in Pregnancy

Several factors must be considered when counseling a woman with CF who is considering pregnancy, including the possibility that her fetus will have CF (see Chapter 10). **When the mother has CF and the proposed father is a white individual of unknown genotype, the risk for the fetus having CF is 1 in 50, compared with 1 in 3000 in the general white population. If the prospective father is a known carrier of a CF mutation, the risk to the fetus increases to 1 in 2.** If, however, DNA testing does not identify a CF mutation in the prospective father, it is still possible that the father is a carrier of an unidentified CF mutation, making the risk for CF to the offspring 1 in 492.<sup>103</sup>

It is important that the woman with CF be advised about the potential adverse effects of pregnancy on maternal health status. Factors that may predict poor outcome include pre-pregnancy evidence of poor nutritional status, significant pulmonary disease with hypoxemia, and pulmonary hypertension. Liver disease and diabetes mellitus are also poor prognostic factors. **Gravidae with poor nutritional status, pulmonary hypertension (cor pulmonale), and deteriorating pulmonary function early in gestation should consider therapeutic abortion because the risk for maternal mortality may be unacceptably high.**

**The woman with CF who is considering pregnancy should also give consideration to the need for strong psychosocial and physical support after delivery.** The rigors of child rearing may add to the risk for maternal deterioration during this period. Family members should also be willing to provide physical and emotional support and should be aware of the potential for deterioration in the mother's health and the potential for maternal mortality. **In addition, the need for care of a potentially preterm growth-restricted neonate with all of its attendant morbidities and potential mortality should be discussed.** Over the long term, the woman and her family should also consider the fact that her life expectancy may be shortened by CF. **Overall, 20% of mothers with CF succumb to the disease before the child's tenth birthday, and this number increases to 40% if the FEV<sub>1</sub> is less than 40% of predicted.**<sup>104</sup> Plans should be made for rearing of the child in the event of maternal death.

### Management of the Pregnancy Complicated by Cystic Fibrosis

**Care of the gravida with CF should be a coordinated team effort. Physicians familiar with CF, its complications, and management should be included as well as a maternal-fetal medicine specialist and neonatal team.** The gravida should be assessed for potential risk factors such as severe lung disease, pulmonary hypertension, poor nutritional status, pancreatic failure, and liver disease—preferably before attempting gestation, but certainly during the early months of pregnancy. **Gravidae should be advised to be 90% of ideal body weight before conception if possible. A weight gain in pregnancy of 11 to 12 kg is recommended.**<sup>105</sup> **Frequent monitoring of weight, blood glucose, hemoglobin, total protein, serum albumin, prothrombin time, and fat-soluble vitamins A and E is suggested.**<sup>105</sup> At each visit, the history of caloric intake and symptoms of maldigestion and malabsorption should be taken, and pancreatic enzymes should be adjusted if needed. **Patients who are unable to achieve adequate weight gain through oral nutritional supplements may be given nocturnal enteral nasogastric tube feedings.** In this situation, the risk for aspiration should be considered, especially in patients with a history of gastroesophageal reflux, which is common in CF. **If malnutrition is severe, parenteral hyperalimentation may be necessary for successful completion of the pregnancy.** Baseline pulmonary function should be assessed, preferably before conception. Assessment should include FVC, FEV<sub>1</sub>, lung volumes, pulse oximetry, and arterial blood gases, if indicated. These values should be serially monitored during gestation, and deterioration in pulmonary function should be addressed immediately. An echocardiogram can assess the patient for pulmonary hypertension and cor pulmonale, and if this is diagnosed, the gravida should be advised of the high maternal risk.

**Early recognition and prompt treatment of pulmonary infections are important** in the management of the pregnant woman with CF. **Treatment includes IV antibiotics in the appropriate dose, keeping in mind the increased clearance of these drugs secondary to pregnancy and CF.** Plasma levels of aminoglycosides should be monitored and adjusted as indicated. Chest physical therapy and bronchial drainage are also important components of the management of pulmonary infections in CF. Because *P. aeruginosa* is the most frequently isolated bacterium associated with chronic endobronchitis

and bronchiectasis, antibiotic regimens should include coverage for this organism.

If the patient with CF has pancreatic insufficiency and diabetes mellitus, careful monitoring of blood glucose and insulin therapy are indicated. As previously mentioned, pancreatic enzymes may need to be replaced to optimize the patient's nutritional status. **Because of malabsorption of fats and frequent use of antibiotics, the patient with CF is prone to vitamin K deficiency; therefore prothrombin time should be checked regularly, and parenteral vitamin K should be administered if the prothrombin time is elevated.**

When managing pregnancy in a woman with CF, it is imperative to recognize that the fetus is at risk for uteroplacental insufficiency and IUGR. The maternal nutritional status and weight gain during pregnancy will likewise affect fetal growth; therefore **fundal height should be measured routinely, and serial ultrasound evaluations of fetal growth and amniotic fluid volume should be made.** Fetal kick counts may be useful for monitoring fetal status starting at 28 weeks. **If fetal compromise is evident, nonstress testing should be started at 32 weeks or sooner;** if fetal compromise is severe—such as no interval fetal growth, persistent decelerations, or poor biophysical profile scoring—delivery should be accomplished. Likewise, **evidence of profound maternal deterioration such as a marked and sustained decline in pulmonary function, development of right-sided heart failure, refractory hypoxemia, and progressive hypercapnia and respiratory acidosis may be indications for early delivery.** If the fetus is potentially viable, the administration of betamethasone may be beneficial. Vaginal delivery should be attempted when possible.

Labor, delivery, and the postpartum period can be particularly dangerous for the patient with CF. The augmentation in cardiac output stresses the cardiovascular system and can lead to cardiopulmonary failure in the patient with pulmonary hypertension and cor pulmonale. These patients are also more likely to develop right-sided heart failure. **Heart failure should be treated with aggressive diuresis and supplemental oxygen, and management can be optimized by insertion of a pulmonary artery catheter to monitor right- and left-sided filling pressures. Pain control will reduce the sympathetic response to labor and tachycardia. This will benefit the patient who demonstrates pulmonary or cardiac compromise.** In the patient with a normal partial thromboplastin time, insertion of an epidural catheter for continuous epidural analgesia may be beneficial. This is also useful in the event a cesarean delivery is indicated because general anesthesia and its possible effects on pulmonary function can be avoided. **If general anesthesia is needed, preoperative anticholinergic agents should be avoided because they tend to promote drying and inspissation of airway secretions.** Close fetal surveillance is also extremely important because the fetus who may have been suffering from uteroplacental insufficiency during gestation is more prone to develop evidence of fetal compromise during labor. **Cesarean delivery should be reserved for the usual obstetric indications.**

In summary, more women with CF are living to childbearing age and are capable of conceiving. Clinical experience thus far has demonstrated that **pregnancy in women with CF and mild disease is well tolerated, but women with severe disease have an associated increase in maternal and fetal morbidity and mortality.** The potential risk to any individual with CF desirous of pregnancy should be assessed and discussed with the patient and her family in detail.

## KEY POINTS

- ◆ Pneumonia is the most common nonobstetric infection that causes maternal mortality, and preterm delivery complicates pneumonia in up to 43% of cases. *Streptococcus pneumoniae* is the most common bacterial pathogen to cause pneumonia.
- ◆ To treat pneumonia, empiric antibiotic coverage should be started that includes a third-generation cephalosporin and a macrolide, such as azithromycin, to cover atypical pathogens. If CA-MRSA is suspected, add vancomycin or linezolid.
- ◆ The HIV-infected gravida with a CD4+ count of less than 200 cells per cubic millimeter should receive prophylaxis with trimethoprim-sulfamethoxazole, as well as HAART, to prevent PJP pneumonia.
- ◆ High-risk gravidae should be screened for TB and treated appropriately with isoniazid prophylaxis for infection without overt disease and with dual anti-TB therapy for active disease. If resistant TB is identified, ethambutol, 2.5 g/day, should be added to therapy, and the treatment period should be extended to 18 months.
- ◆ IGRAs can be used for screening for TB and are helpful in cases where BCG vaccine has been given.
- ◆ Inhaled corticosteroids are the preferred treatment for persistent asthma in pregnancy.
- ◆ It is safer for pregnant women with asthma to be treated with asthma medications than it is for them to have asthma symptoms and exacerbations.
- ◆ Inhaled albuterol is recommended for rescue therapy during pregnancy.
- ◆ Step-care therapy uses the principle of tailoring medical therapy according to asthma severity.
- ◆ The interstitial lung diseases include idiopathic pulmonary fibrosis, sarcoidosis, hypersensitivity pneumonitis, drug-induced lung disease, and connective tissue disease. Restrictive lung disease is generally well tolerated in pregnancy; however, exercise intolerance and need for oxygen supplementation may develop.
- ◆ Gravidae with pulmonary hypertension complicating restrictive lung disease may suffer a high mortality rate.
- ◆ An increasing number of women with cystic fibrosis are surviving to the reproductive years and usually maintain their fertility with meticulous management of pulmonary function, including pulmonary toilet and aggressive surveillance for signs of pulmonary infection and treatment with antibiotics in adequate doses. Close attention to nutrition is required secondary to maldigestion, malabsorption, and malnutrition, which can complicate cystic fibrosis. Gravidae with reassuring pulmonary function studies, good nutritional status, near-normal chest radiographs, and only mild obstructive lung disease will tolerate pregnancy well. Fetal growth should be monitored closely.

## OVERVIEW

Prior to just decades ago, women with preexisting renal disease were strongly discouraged from attempting pregnancy because of the expectation of poor perinatal outcome and the likelihood of renal disease progression. Currently, through better understanding of the prognosis and treatment of kidney disease during pregnancy, women with most renal conditions are no longer discouraged from attempting conception. This even holds true for women who have undergone renal transplantation.

This chapter first reviews the normal changes in the kidney and urinary collecting system in pregnancy and then it follows with the basic evaluation of maternal renal status, acute and chronic renal disorders in pregnancy, and the treatment of the post-renal transplant patient.

## ALTERED RENAL PHYSIOLOGY IN PREGNANCY

Pregnancy is associated with significant anatomic changes in the kidney and its collecting system (see [Chapter 3](#)). These changes begin to occur shortly after conception and may persist for several months postpartum.<sup>1,2</sup> The kidney is noted to increase in size and weight during the course of a pregnancy. **Of more clinical significance is the marked dilation of the collecting system, including both the renal pelvis and ureters. This dilation is most pronounced on the right side and is most likely due to hormonal changes** (i.e., from progesterone, endothelin, relaxin) **and mechanical obstruction by the gravid uterus** ([Fig. 39-1](#)).<sup>3-5</sup>

**Renal plasma flow increases greatly during pregnancy.**<sup>6</sup> It peaks by the end of the first trimester, and although it decreases near term, it remains higher than in the nonpregnant woman. This change is due in part to increased cardiac output and decreased renal vascular resistance. **The glomerular filtration rate (GFR) increases by 50% during a normal gestation.**<sup>7</sup> It rises early in pregnancy and remains elevated throughout gestation, and the percentage increase in GFR is greater than the percentage increase in renal plasma flow. This leads to an elevation of the filtration fraction, which results in a fall in serum blood urea nitrogen (BUN) and serum creatinine values.

Because GFR increases to such a great degree, electrolytes, glucose, and other filtered substances reach the renal tubules in greater amounts. The kidney handles sodium efficiently, reabsorbing most of the filtered load in the proximal convoluted tubule. Glucose reabsorption, however, does not increase proportionately during pregnancy. The average renal threshold for

**FIG 39-1** **A**, An intravenous pyelogram of a gravid patient in the late second trimester with flank pain. The image was taken in the anteroposterior view 15 minutes after the instillation of contrast dye. Note the dilation of the renal pelvises bilaterally, with the right side more dilated than the left. The fetus is seen in the vertex position. **B**, The same patient in the right lateral view.

glucose is reduced to 155 mg/dL from 194 mg/dL in the non-pregnant individual.<sup>8</sup> Therefore **glycosuria can be a feature of normal pregnancy**.  
Urate is handled by filtration and secretion. Its clearance increases early in pregnancy and leads to lower serum levels of uric acid. In late pregnancy, urate clearance and serum urate levels return to their prepregnancy values. **Serum urate levels are elevated in women with preeclampsia**. Whether this is due to decreased renal plasma flow, hemoconcentration, renal tubular dysfunction, or other renal circulatory changes remains unclear. A summary of the renal changes in normal pregnancy is shown in Table 39-1.

**ASYMPTOMATIC BACTERIURIA**

The prevalence of asymptomatic bacteriuria (ASB) in sexually active women has been reported to be as high as 5% to 6%.<sup>9,10</sup> The diagnosis of ASB is based on a clean-catch voided urine specimen. **To secure a diagnosis, the urine culture should reveal greater than 100,000 colonies/mL of a single organism.**<sup>11</sup> Some investigators have suggested that two consecutively voided specimens should contain the same organism prior to establishing the diagnosis of bacteriuria.<sup>12,13</sup> Bacteriuria occurs in 2% to 7% of pregnancies, particularly in multiparous women, a similar prevalence as seen in nonpregnant women. The pathogenic organisms are also similar in species and virulence factors to those observed in nonpregnant women (see Chapter 53); thus the basic mechanism of entry of bacteria into the urinary tract is likely to be the same for both groups. Bacteriuria often develops in the first month of pregnancy and is frequently associated with a reduction in urine concentrating ability, which suggests involvement of the kidney.<sup>7</sup> **The smooth muscle relaxation and subsequent ureteral dilation that accompany pregnancy are believed to facilitate the ascent of bacteria from the bladder to the kidney. As a result, untreated bacteriuria during**

**TABLE 39-1** SUMMARY OF RENAL CHANGES IN NORMAL PREGNANCY

| ALTERATION                               | MANIFESTATION   | CLINICAL RELEVANCE   |
|--|---|--|
| Increased renal size                     | Renal length is about 1 cm greater on radiographs.  | Postpartum decreases in size should not be mistaken for parenchymal loss.  |
| Dilation of pelvis, calyces, and ureters | Dilation resembles hydronephrosis on ultrasound or IVP and is usually more prominent on the right side. | Should not be mistaken for obstructive uropathy. Upper urinary tract infections can be more virulent.  |
| Changes in acid-base metabolism          | The renal bicarbonate reabsorption threshold decreases.   | Serum bicarbonate is 4 to 5 mM/L lower in pregnancy. PCO <sub>2</sub> is 10 mm Hg lower in normal pregnancy. PCO <sub>2</sub> of 40 mm Hg represents retention in pregnancy. |
| Renal water osmoregulation               | The osmotic threshold for AVP release decreases.  | Serum osmolality is decreased by approximately 10 mOsm/L.  |

**pregnancy has a greater propensity to progress to pyelonephritis (up to 40%) than in nonpregnant women.**<sup>14</sup> If a urine culture is negative for bacteria at the first prenatal visit, the risk of developing acute cystitis is less than 1%.<sup>10,15</sup>  
It is important to diagnose and treat ASB in pregnancy. If left untreated, a symptomatic urinary tract infection (UTI) will

**BOX 39-1 ANTIMICROBIAL TREATMENT REGIMENS FOR PREGNANT WOMEN WITH BACTERIURIA\***

- Amoxicillin 500 mg 3 times a day
- Ampicillin 500 mg 4 times a day
- Cephalexin 500 mg 4 times a day
- Nitrofurantoin 100 mg 4 times a day
- Sustained release nitrofurantoin 100 mg 2 times a day
- Trimethoprim 160 mg with sulfamethoxazole 800 mg 2 times a day

\*The agent of choice should be given for a 7-day course. A repeat urine culture is recommended 2 weeks after the treatment has been completed.

develop in up to 40% of these patients.<sup>6,10,16</sup> **Recognition and therapy for ASB can eliminate 70% of acute UTIs in pregnancy.** Nonetheless, 2% of pregnant women with negative first-trimester urine cultures develop symptomatic cystitis or pyelonephritis. This group accounts for 30% of the cases of acute UTI that develop during gestation. **The American College of Obstetricians and Gynecologists (ACOG) recommends routine screening of all women for ASB at their first prenatal visit.**<sup>17</sup> Some debate has surrounded whether the patient should collect a first void sample or simply a clean-catch sample. In pregnant women, the contamination rate of mid-stream samples is comparable for morning and clean-catch samples.<sup>18</sup> Other than progression to more serious infection, however, little evidence suggests that ASB has an effect on pregnancy outcome.<sup>9,19</sup>

***Escherichia coli* is the organism responsible for most cases of ASB and UTI during pregnancy.** Women can therefore be safely treated with nitrofurantoin, ampicillin, cephalosporins, and short-acting sulfa drugs (Box 39-1). Sulfa compounds should be avoided near term because they compete for bilirubin-binding sites on albumin in the fetus and newborn and therefore pose a risk for kernicterus. Nitrofurantoin should not be used in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency because of the risk for hemolytic crisis; if the fetus has a G6PD deficiency, it may also experience hemolysis. **Therapy for ASB is recommended for 7 days, and a follow-up culture should be performed 1 to 2 weeks after discontinuing therapy.** Approximately 15% of women will experience a reinfection or will not respond to initial therapy. Therapy in these cases should be reinstituted after careful microbial sensitivity testing. Women with a recurrent UTI during pregnancy and those with a history of pyelonephritis should eventually undergo imaging of the upper urinary tract. This procedure may be delayed until 3 months postpartum so that the anatomic changes of pregnancy can regress.

Occasionally it can be difficult to distinguish severe cystitis from pyelonephritis, although the presence of fever suggests upper tract infection. Although the drugs used for treatment are similar, pyelonephritis during pregnancy generally requires intravenous (IV) antibiotics. Sandberg and coinvestigators<sup>20</sup> studied symptomatic UTI in 174 women and found that C-reactive protein was elevated in 91% of pregnant women with acute pyelonephritis and in only 5% of women with cystitis. They also noted that the urine-concentrating ability was lower in women with acute pyelonephritis. Because the erythrocyte sedimentation rate is normally elevated in pregnancy, they found that this was not a useful parameter for distinguishing pyelonephritis from cystitis.

**PYELONEPHRITIS**

Pyelonephritis complicates 1% to 2% of all pregnancies and can result in significant maternal morbidity, and it is among the most common nonobstetric causes for hospitalization during pregnancy.<sup>21</sup> A recent 18-year retrospective analysis showed “the incidence of acute antepartum pyelonephritis during pregnancy was 0.5% (2894/543,430). Women with pyelonephritis in pregnancy were more likely to be black or Hispanic, young, less educated, and nulliparous; they initiate prenatal care late in gestation and use tobacco during pregnancy. Pregnancies of women with pyelonephritis, compared with those without, were more likely to be complicated by anemia (26.3% vs. 11.4%; odds ratio [OR], 2.6; 95% confidence interval [CI], 2.4 to 2.9), septicemia (1.9% vs. 0.03%; OR, 56.5; 95% CI, 41.3 to 77.4), acute pulmonary insufficiency (0.5% vs. 0.04%; OR, 12.5; 95% CI, 7.2 to 21.6), acute renal dysfunction (0.4% vs. 0.03%; OR, 16.5; 95% CI, 8.8 to 30.7), and spontaneous preterm birth (10.3% vs. 7.9%; OR, 1.3; 95% CI, 1.2 to 1.5). Most of the preterm births in this series occurred between 33 and 36 weeks.<sup>22</sup> **Recurrent pyelonephritis** has been implicated as a cause of fetal death and intrauterine growth restriction (IUGR). As noted above, an association between acute pyelonephritis and preterm labor is apparent.<sup>23,24</sup> Fan and coworkers,<sup>25</sup> however, have shown that if pyelonephritis is aggressively treated, it does not increase the likelihood of premature delivery or low birthweight. Hill and colleagues<sup>26</sup> reported 440 cases of acute pyelonephritis over a 2-year period and noted the disease to be more common in younger primigravid women without racial predilection. The majority of cases (53%) presented during the second trimester. The most common pathogen was *E. coli*, which accounted for 83% of cases; gram-positive organisms accounted for another 11.6%.<sup>26</sup>

**Acute pyelonephritis during pregnancy is most often treated on an inpatient basis with IV antibiotics. Empiric therapy should be begun as soon as the presumptive diagnosis is established.** Therapy can be tailored to the specific organism after antibiotic sensitivities have been determined, and because septicemia may occasionally result from pyelonephritis, blood cultures should be obtained if patients do not respond rapidly to initial antibiotic therapy. **Generally, a broad-spectrum first-generation cephalosporin is the initial therapy of choice.** Fan and coinvestigators<sup>25</sup> reviewed 107 cases of pyelonephritis and noted that 33% of the cases were resistant to ampicillin and 13% were resistant to first-generation cephalosporins; current rates of resistance to ampicillin and first-generation cephalosporins are likely higher. If resistance to more common therapies is encountered, a later-generation cephalosporin or an aminoglycoside can be safely administered. Peak and trough aminoglycoside levels should be measured whenever these are used, and serum creatinine and BUN level should be followed as well. During the febrile period, acetaminophen treatment is advised to keep the maternal temperature below 38° C.

**IV antibiotic therapy should be continued for 24 to 48 hours after the patient becomes afebrile and costovertebral angle tenderness subsides. After the cessation of IV therapy, treatment with appropriate oral antibiotics is recommended for 10 to 14 days.** Upon termination of therapy, urine cultures should be obtained each trimester for the remainder of gestation. **After an episode of acute pyelonephritis, antibiotic suppression should also be implemented and should be continued for the remainder of the pregnancy.** Nitrofurantoin 100 mg

once or twice daily is an acceptable regimen for suppression. In a study by Van Dorsten and colleagues,<sup>27</sup> nitrofurantoin suppression reduced the rate of subsequent positive cultures from 38% to 8%. However, nitrofurantoin did not lower the rate of positive cultures if inpatient antibiotic selection was inappropriate or if the urine culture was positive at the time of discharge.

The most common maternal complications associated with pyelonephritis are anemia, septicemia, transient renal dysfunction, and pulmonary insufficiency.<sup>26</sup> **Pulmonary injury that resembles adult respiratory distress syndrome (ARDS) can occur in pregnant women with acute pyelonephritis.**<sup>26</sup> **Clinical manifestations of this complication usually occur 24 to 48 hours after the patient is admitted for pyelonephritis.**<sup>28,29</sup> **Some of these women will require intubation, mechanical ventilation,<sup>6</sup> and positive end-expiratory pressure (PEEP). ARDS is believed to result from endotoxin-induced alveolar capillary membrane injury.** Towers and colleagues<sup>30</sup> found evidence of pulmonary injury in 11 of 130 patients with pyelonephritis. A fever of greater than 39.4°C, a maternal heart rate above 110 beats/min, and gestation beyond 20 weeks were factors associated with increased risk for pulmonary injury. The most predictive factors were fluid overload and tocolytic therapy.

Women with prior urinary tract surgery are at increased risk for pyelonephritis. Austenfeld and Snow<sup>31</sup> reported 64 pregnancies in 30 women who had previously undergone ureteral reimplantation for vesicoureteral reflux. During pregnancy, 57% of these women experienced one or more UTIs, and 17% had more than one UTI or an episode of pyelonephritis.<sup>31</sup> More frequent urine cultures and aggressive therapy during pregnancy are recommended for this group of high-risk parturients.

## ACUTE RENAL DISEASE IN PREGNANCY

### Urolithiasis

**Urolithiasis affects 0.03% of all pregnancies, a frequency similar to that of the general population.**<sup>32</sup> Colicky abdominal pain, recurrent UTI, and hematuria suggest urolithiasis.<sup>33</sup> If the diagnosis is suspected, IV pyelogram (IVP) should be considered, which limits this study to the minimum number of exposures necessary to make the diagnosis. Ultrasound can also be used to establish the diagnosis without radiation exposure. However, ultrasound alone may be limited in securing a diagnosis of urolithiasis. In a recent multicenter, longitudinal study the authors noted, "Of the group treated surgically after imaging with ultrasound alone, 23% had no evidence of a ureteral stone, resulting in the lowest positive predictive value of the modalities used. Alternative imaging techniques, particularly low-dose computerized tomography, offer improved diagnostic information that can optimize management and avoid unnecessary intervention."<sup>34</sup> Newer ultrasound flow studies can actually follow flow from the ureter to the bladder, and they can detect obstruction without the use of ionizing radiation. If transabdominal ultrasound is limited, transvaginal ultrasound can also be used to visualize the distal ureter.<sup>35</sup> Urine microscopy may detect crystals and can help distinguish the type of stone before it is passed. Serum calcium, phosphorous, and urate levels should be assayed for any woman with renal calculi to assist in the evaluation for possible hyperparathyroidism and gout.

**Because of the physiologic hydroureter of pregnancy, 75% to 85% of women with symptomatic urolithiasis will spontaneously pass their stones.**<sup>33</sup> Treatment should therefore be

**conservative and should consist of hydration and narcotic analgesia.**<sup>36</sup> Epidural anesthesia has been advocated to establish a segmental block from T11 to L2, although it is unknown whether this promotes passage of the stone. **Ureteral stenting to relieve obstruction is an option for managing pregnant women with renal stones. For refractory cases, nephrostomy tubes can also be used.** It should be noted that pregnancy increases the risk of stent encrustation, which requires frequent stent exchange every 4 to 6 weeks until delivery.<sup>37</sup> **Lithotripsy is contraindicated during pregnancy.**<sup>38</sup>

Recurrent UTI with urease-containing organisms causes precipitation of calcium phosphate in the kidney that may lead to the development of staghorn calculi. Surgery is rarely indicated in women with this condition during gestation. Individuals with staghorn calculi should have frequent urine cultures, and bacteriuria should be treated aggressively. Recurrent infections pose a risk for chronic pyelonephritis with resultant loss of kidney function.

### Glomerular Disease

**Acute glomerulonephritis is an uncommon complication of pregnancy, with a reported incidence of 1 per 40,000 pregnancies.**<sup>39</sup> Poststreptococcal glomerulonephritis is rarely observed in the adult population. In this disorder, renal function tends to deteriorate during the acute phase of the disease but usually recovers in time.<sup>40</sup> **Acute glomerulonephritis can be difficult to distinguish from preeclampsia. Periorbital edema, a striking clinical feature of acute glomerulonephritis, is often seen in preeclampsia. However, hematuria, red blood cell (RBC) casts in the urine sediment, and depressed serum complement levels support the diagnosis of glomerulonephritis.** A rise in antistreptolysin O titers may secure the diagnosis of poststreptococcal glomerulonephritis.

**Treatment of acute glomerulonephritis in pregnancy is similar to that for the nonpregnant individual.** Blood pressure control is essential, and careful attention to fluid balance is advised. Sodium intake should be restricted to 500 mg/day during the acute disease, and serum potassium levels must also be carefully monitored.

Packham and coworkers<sup>41</sup> extensively reviewed 395 pregnancies in 238 women with primary glomerulonephritis. Remarkably, only 51% of the infants were born after 36 weeks' gestation. Excluding therapeutic abortion, the fetal loss rate was 20%, with 15% occurring after 20 weeks' gestation. IUGR was noted in 15% of the cases, and maternal renal function deteriorated in 15% of pregnancies and failed to resolve following delivery in 5% of the study population. Hypertension was recorded in 52% of the pregnancies and developed prior to 32 weeks' gestation in 26%. In most cases, this blood pressure elevation was not an exacerbation of chronic hypertension. Eighteen percent of the women who developed de novo hypertension in pregnancy remained hypertensive postpartum, and increased proteinuria was recorded in 59% of these pregnancies and was irreversible in 15%. **The highest incidence of fetal and maternal complications in women with glomerular disease occurred in those with primary focal and segmental hyalinosis and sclerosis, whereas the lowest incidence was observed in non-immunoglobulin A (IgA) diffuse mesangial proliferative glomerulonephritis.**<sup>41</sup> The presence of severe vessel lesions on renal biopsy was associated with a significantly higher rate of fetal loss after 20 weeks' gestation. Packham and coworkers<sup>42</sup> also studied 33 pregnancies in 24 patients with biopsy-proven membranous

glomerulonephritis. Fetal loss occurred in 24% of pregnancies, preterm delivery was reported in 43%, and a term liveborn infant was delivered in only 33% of patients. Hypertension was noted in 46% of these pregnant women, and 30% had proteinuria in the nephrotic range during the first trimester. The presence of significant proteinuria during the first trimester correlated with poor fetal and maternal outcome.

Jungers and associates<sup>43</sup> described 69 pregnancies in 34 patients with IgA glomerulonephritis. The fetal loss rate in this group was 15%. Preexisting hypertension was statistically associated with poor fetal outcome. Hypertension at the time of conception also correlated with a deterioration of maternal renal function during pregnancy. Hypertension in the first pregnancy was highly predictive of recurrence of hypertension in a subsequent pregnancy. Kincaid-Smith and Fairley<sup>44</sup> analyzed 102 pregnancies in 65 women with IgA glomerulonephritis and noted that hypertension occurred in 63% of pregnancies, and it was severe in 18%. In this subset of women, a decline in renal function was observed in 22%. Abe<sup>45</sup> reported 240 pregnancies in 166 women with preexisting glomerular disease and found that 8% of the pregnancies resulted in a spontaneous abortion, 6% in a stillbirth, and 86% in a liveborn infant. Most losses occurred in women with a GFR less than 70 mL/min and preexisting hypertension. Even though the majority of women with significant renal insufficiency had good pregnancy outcomes, the long-term prognosis for these cases was worse if the GFR was less than 50 mL/min and the serum creatinine was more than 1.5 mg/dL.<sup>45</sup> The histopathogenic diagnosis of membranoproliferative glomerulonephritis seemed to carry the worst prognosis: 29% developed hypertension and 33% demonstrated a long-term decrease in renal function.

Imbasciati and Ponticelli<sup>46</sup> summarized six studies that comprised a total of 906 pregnancies in 558 women with preexisting glomerular disease. The overall perinatal mortality was 13%. Hypertension, azotemia, and nephrotic-range proteinuria were the strongest predictive factors for a poor pregnancy outcome. In this report, the histologic type of glomerulonephritis had little correlation with pregnancy outcome. Hypertension persisted in 3% to 12% of patients who developed hypertension for the first time during pregnancy. In 25% of patients, hypertension worsened during pregnancy and normalized postpartum.<sup>46</sup> Some of these cases represented superimposed preeclampsia. However, this diagnosis can be difficult to establish in women with baseline hypertension and proteinuria. Remarkably, only 3% of these 166 women experienced an acceleration of their glomerular disease after pregnancy.

### Acute Renal Failure in Pregnancy

**Acute renal failure (ARF) is defined as a urine output of less than 400 mL in 24 hours.** To establish the diagnosis, ureteral and urethral obstruction must be excluded. The incidence of ARF during pregnancy is approximately 1 per 10,000. It is most frequently observed following sepsis or in cases of sudden severe volume depletion as a result of hemorrhage.<sup>47</sup> ARF may also be observed with marked volume contraction associated with severe preeclampsia,<sup>48,49</sup> dehydration from hyperemesis gravidarum, and with acute fatty liver of pregnancy.<sup>48,51</sup>

The incidence of ARF in pregnancy has decreased over the years. Stratta and colleagues<sup>52</sup> reported 81 cases of pregnancy-related ARF between 1958 and 1987, which accounted for 9% of the total number of ARF cases that required dialysis during that time. In three successive 10-year periods (1958–1967,

1968–1977, and 1978–1987), the incidence of pregnancy-related ARF fell from 43% to 2.8% of the total number of cases of ARF. The incidence declined from 1 in 3000 to 1 in 15,000 pregnancies over the study period.<sup>52</sup> In these 81 cases of ARF, 11.6% experienced irreversible renal damage, the majority of which occurred in the setting of severe preeclampsia-eclampsia.<sup>52</sup>

**Renal ischemia is a common phenomenon in cases of ARF. With mild ischemia, quickly reversible prerenal failure results; with more prolonged ischemia, acute tubular necrosis occurs. This process is also reversible because glomeruli are not affected. Severe ischemia, however, may produce acute cortical necrosis.** This pathology is irreversible, although on occasion, a small amount of renal function is preserved.<sup>53</sup> Stratta and colleagues<sup>54</sup> have reported 17 cases of ARF complicating pregnancies over 15 years, and all were observed in the setting of preeclampsia-eclampsia; cortical necrosis occurred in 29.5% of the cases, and progression of ARF to cortical necrosis did not appear to be related to maternal age, parity, gestational age, duration of preeclampsia prior to delivery, or eclamptic seizures. **The only significant risk factor associated with cortical necrosis was placental abruption.** In another study, Turney and coworkers<sup>16</sup> demonstrated that acute cortical necrosis, which occurred in 12.7% of their patients with ARF, was associated with a 100% mortality within 6 years.

Sibai and colleagues<sup>55</sup> studied the remote prognosis in 31 consecutive cases of ARF in patients with hypertensive disorders of pregnancy. Eighteen of the 31 patients had “pure” preeclampsia, whereas 13 pregnancies had other hypertensive disorders and renal disease; of the 18 patients with pure preeclampsia, 5% required dialysis during hospitalization, and all 18 patients had acute tubular necrosis. Of the other 13 women, 42% required dialysis, and three patients had bilateral cortical necrosis. **The majority of pregnancies in both groups were complicated by placental abruption and hemorrhage.**<sup>55</sup> All 16 surviving patients in the pure preeclampsia group recovered normal renal function on long-term follow-up. Conversely, 9 of the 11 surviving patients in the nonpreeclamptic group required long-term dialysis, and four ultimately died of end-stage renal disease.<sup>55</sup> In a follow-up study, Turney and colleagues<sup>16</sup> found that maternal survival was adversely affected by increasing age. Their 1-year maternal survival rate was 78.6%, and follow-up of survivors showed normal renal function up to 31 years after ARF.

**Individuals with reversible ARF experience a period of oliguria of variable duration followed by polyuria, or a high-output phase. It is important to recognize that BUN and serum creatinine levels continue to rise early in the polyuric phase.** During the recovery phase, urine output approaches normal. In these patients, it is important to monitor electrolytes frequently and to carefully treat any imbalance. The urine to plasma osmolality ratio should be determined early in the course of the disease. If the ratio is 1.5 or greater, prerenal pathology is likely, and the disorder tends to be of shorter duration and of less severity. A ratio near 1.0 suggests acute tubular necrosis.

The main goal of treatment is the elimination of the underlying cause. Volume and electrolyte balance must be evaluated frequently. To assess volume requirements, invasive hemodynamic monitoring may be useful. This is especially true during the polyuric phase. Central hyperalimentation may also be required if renal failure is prolonged.

Acidosis frequently occurs in cases of ARF. Therefore, arterial blood gases should be followed regularly. **Acidosis must be**

treated promptly because it can exacerbate hyperkalemia, which can be fatal. If hyperkalemia develops, potassium restriction should be instituted immediately. Sodium bicarbonate, used to treat acidosis, may overload the patient with sodium and water. In such cases, peritoneal dialysis or hemodialysis may be necessary. **The main indications for dialysis in ARF of pregnancy are hypernatremia, hyperkalemia, severe acidosis, volume overload, and worsening uremia.**

### Hemolytic Uremic Syndrome

**The hemolytic uremic syndrome (HUS) is a rare idiopathic disorder that must be considered when a patient exhibits signs of hemolysis and decreasing renal function, particularly during the third trimester and in the postpartum period.** This idiopathic syndrome may occur as early as the first trimester and as late as 2 months postpartum, and it is part of a spectrum of disease that may also include thrombotic thrombocytopenic purpura (TTP; see Chapter 44).<sup>16,56-59</sup> Most individuals have no predisposing factors. Prodromal symptoms include vomiting, diarrhea, and a flulike illness. A review of 49 cases documented a 61% mortality rate, although with improved intensive care monitoring and treatment, the prognosis is now much improved.

**Disseminated intravascular coagulation (DIC) with hemolysis usually accompanies HUS. However, DIC is not the cause of the syndrome. Microscopically, the kidney shows thrombotic microangiopathy. The glomerular capillary wall is thick, and biopsy specimens taken later in the course of the disease show severe nephrosclerosis and deposition of the third component of complement (C<sub>3</sub>).**

Some investigators believe that this syndrome is due to decreased renal production of prostacyclin,<sup>60,61</sup> infusions of which have been used to treat these patients, although such therapy remains experimental. One observer noted a decrease in antithrombin III in a woman with postpartum HUS. This patient was successfully treated with an infusion of antithrombin III concentrate.<sup>62</sup>

Coratelli and coworkers<sup>56</sup> reported a case of HUS diagnosed at 13 weeks' gestation and confirmed by renal biopsy. Circulating endotoxin was detected and was progressively reduced by hemodialysis performed daily from the third to the ninth day of the disease. Complete normalization of renal function occurred by day 34. These investigators propose that initiation of early dialysis may play an important role in supporting patients through the disease process. They also propose that endotoxins are key pathogenic factors in the disorder.<sup>56</sup> In contrast, Li and coworkers<sup>63</sup> failed to measure any endotoxin in a patient's serum who developed HUS after an uncomplicated cesarean delivery; this patient eventually underwent dialysis and recovered. **Plasma exchange in cases of ARF caused by postpartum HUS can be vital to the treatment of this condition.**<sup>61</sup>

### Polycystic Kidney Disease

Adult polycystic kidney disease is an autosomal-dominant disorder that usually begins to manifest during the fifth decade of life. Reproductive-age women may occasionally display symptoms, and hypertension is a key component of this disorder. If a woman with adult polycystic kidney disease becomes pregnant, hypertension may be greatly exacerbated and may not improve following delivery.<sup>46</sup> However, the overall prognosis for the disorder does not appear to worsen with an increasing number of pregnancies.

### Vesicoureteral Reflux

Although vesicoureteral reflux may be exacerbated with pregnancy, it usually does not result in morbidity unless reflux becomes severe. If reflux is significant enough to warrant surgery, this should ideally be undertaken prior to pregnancy. Even with surgical correction, women with ureterovesical reflux remain at increased risk for pyelonephritis and should have urine cultures performed frequently.<sup>46</sup> If indicated prior to pregnancy, antibiotic suppression should be continued.

Brandes and Fritsche<sup>64</sup> have reported a case of ARF that resulted from ureteral obstruction by a gravid uterus. This case was complicated by a twin gestation with polyhydramnios at 34 weeks' gestation. The serum creatinine level peaked at 12.2 mg/dL but resolved immediately after amniotomy.<sup>64</sup> In cases remote from term, ureteral stenting or dialysis may be necessary if significant obstruction and/or reflux is present.

### Renal Artery Stenosis

Renal artery stenosis is rarely discovered during pregnancy.<sup>65</sup> This disorder may present as chronic hypertension with superimposed preeclampsia or as recurrent isolated preeclampsia. Although Doppler flow studies may be suggestive, renal angiography is the most specific and sensitive diagnostic test. Percutaneous transluminal angioplasty can be carried out at the time of angiography.<sup>65</sup>

### Nephrotic Syndrome

**The nephrotic syndrome was initially described as a 24-hour urine protein excretion equal to or in excess of 3.5 g, reduced serum albumin, edema, and hyperlipidemia.**<sup>66</sup> **Currently, the syndrome is defined by proteinuria alone, which is often the result of glomerular damage.**<sup>66</sup> The most common etiology of nephrotic syndrome in pregnancy, especially in the third trimester, is preeclampsia. Other etiologies include membranous and membranoproliferative glomerulopathy, minimal change glomerulopathy, lupus nephropathy, hereditary nephritis, diabetic nephropathy, renal vein thrombosis, and amyloidosis.<sup>67</sup>

Women with a newly diagnosed or persistent nephrotic syndrome need close monitoring during pregnancy. Whenever possible, the etiology of the proteinuria should be determined. In some cases, steroid therapy may be used to treat this condition; however, depending on the etiology, its use can actually aggravate the underlying disease process.<sup>67</sup> One common complication of nephrotic syndrome in pregnancy is profound edema secondary to protein excretion, which is further complicated by the normal decline in serum albumin associated with pregnancy.<sup>67</sup> Another complication is the development of a hypercoagulable state precipitated by urinary losses of antithrombin III, reduced levels of proteins C and S, hyperfibrinogenemia, and enhanced platelet aggregation.<sup>68</sup> For this reason, prophylactic anticoagulation may be considered for affected pregnant women.

## CHRONIC RENAL DISEASE IN PREGNANCY

**Chronic renal disease can be silent until its advanced stages. Because obstetricians routinely test women's urine for the presence of protein, glucose, and ketones, they may be the first to detect chronic renal disease.**

Any gravida with more than trace proteinuria should collect a 24-hour urine specimen for creatinine clearance and total protein excretion. Prior to pregnancy, 24-hour urinary protein

excretion should not exceed 0.2 g. During gestation, quantities up to 0.3 g per day may be considered normal (see [Chapter 3](#)). Moderate proteinuria (<2 g/day) is often seen with glomerular disease.

**Microscopic examination of the urine can reveal much about renal status.** If renal disease is suspected, a catheterized specimen should be obtained. More RBCs than one to two per high-power field (hpf) or RBC casts are indicative of glomerular disease. Less frequently, they suggest trauma or malignant hypertension. Increased numbers of white blood cells (WBCs)—that is, more than one to two per high-power field—or the appearance of WBC casts is usually indicative of acute or chronic infection. Cellular casts are found in the presence of renal tubular dysfunction, and hyaline casts are associated with significant proteinuria.

**The obstetrician can easily be misled when relying solely on BUN and serum creatinine levels to assess renal function.** A 70% decline in creatinine clearance, an indirect measure of GFR, can be seen before a significant rise in serum BUN or serum creatinine occurs. Little change in serum creatinine or in the BUN may be observed until the creatinine clearance falls below 50 mL/min. Below that level, small decrements in creatinine clearance can lead to marked azotemia as reflected by significant increases in serum BUN and creatinine. **A single creatinine clearance value less than 100 mL/min is therefore not diagnostic of renal disease. An incomplete 24-hour urine collection is the most frequent cause of this finding. An abnormal clearance rate should prompt a repeat assay.**

Serum urate is an often overlooked but helpful parameter in detecting renal dysfunction. **Excretion of uric acid is dependent not only on glomerular filtration but also on tubular secretion.** Therefore an elevated serum urate in the presence of a normal BUN and serum creatinine may implicate tubular disease, and a solitary increase in uric acid may also signify impending or early preeclampsia.

### Effect of Pregnancy on Renal Function

**Although baseline creatinine clearance is decreased in women with chronic renal insufficiency, a physiologic rise will often occur in pregnancy. A moderate fall in creatinine clearance may then be observed during late gestation in patients with renal disease. This decline is typically more severe in women with diffuse glomerular disease and typically reverses after delivery.**

**The long-term effect of pregnancy on renal disease remains controversial. If the serum creatinine is less than 1.5 mg/dL, pregnancy appears to have little effect on the long-term prognosis.** However, pregnancy is associated with an increased incidence of pyelonephritis in patients with chronic renal disease. Few data are available concerning the long-term effect of pregnancy on renal disease in women with significant azotemia. **Occasionally, some women with a baseline serum creatinine of more than 1.5 mg/dL will experience a significant decrease in renal function during gestation that does not improve during the postpartum period.**<sup>46,69</sup> This deterioration occurs more frequently in women with diffuse glomerulonephritis; however, it is not possible to predict which women with renal insufficiency will have a permanent decline in renal function. Moreover, if renal function significantly deteriorates during gestation, termination of pregnancy may not reverse the process. Therefore termination cannot be routinely recommended for

patients who become pregnant and whose baseline serum creatinine level exceeds 1.5 mg/dL solely based on the consideration of preserving maternal renal function. Ideally, women with chronic renal disease should be counseled prior to conception about the potential decline in renal function.

**Severe hypertension remains the greatest threat to a pregnant patient with chronic renal disease.** Left uncontrolled, hypertension can lead to cerebral hemorrhage and deteriorating renal function. Most pregnant women with chronic renal dysfunction also have preexisting hypertension.<sup>11,70</sup> Approximately 50% of these women will have worsening hypertension as pregnancy progresses, and diastolic blood pressures of 110 mm Hg or greater will develop in about 20% of cases.<sup>71</sup> Those women with diffuse proliferative glomerulonephritis and nephrosclerosis appear to be at the greatest risk for the development of severe hypertension.

**Worsening proteinuria is common during pregnancy complicated by chronic renal disease and often reaches the nephrotic range.**<sup>71</sup> In general, massive proteinuria alone does not carry an increased risk for mother or fetus.<sup>72</sup> Low serum albumin, however, has been correlated with low birthweight.<sup>73</sup> The development of massive proteinuria is not necessarily a harbinger of preeclampsia, although women with proteinuria are clearly at increased risk for this complication. **In late pregnancy, it can be particularly difficult to differentiate preeclampsia from worsening chronic renal disease. For this reason, an evaluation in the first trimester to establish a baseline for creatinine clearance and total protein is essential.**

### Effect of Chronic Renal Disease on Pregnancy

**More than 85% of women with chronic renal disease will have a surviving infant if renal function is well preserved.** Earlier reports were more pessimistic and cited a 6% incidence of stillbirth, a 5% incidence of neonatal death, and an increased risk for second-trimester loss.<sup>71</sup> If hypertension is uncontrolled and if renal function deteriorates, the likelihood of pregnancy loss is still high.<sup>41</sup> Antepartum fetal surveillance and advances in neonatal care have contributed to an improved perinatal outcome in these patients. One study reported a total fetal loss rate of 14% that included miscarriage, stillbirths, and neonatal deaths.<sup>70</sup>

**The outlook for pregnancies complicated by severe renal insufficiency with a baseline serum creatinine level more than 1.5 mg/dL is less certain. This is due in part to the limited number of pregnancies reported in these women.** One study reported no surviving infants when the maternal BUN was greater than 60 mg/dL.<sup>72</sup> Other investigations, however, have found that about 80% of such pregnancies resulted in surviving infants.<sup>70,74</sup> **Preterm birth and IUGR remain important complications, with the reported incidence of preterm birth ranging from 20% to 50%.**<sup>71,75</sup>

Imbasciati and Ponticelli<sup>46</sup> summarized three studies that comprised 81 pregnancies in 78 women with serum creatinine concentrations greater than 1.4 mg/dL. The perinatal loss rate was only 9%. However, 33% of the infants were growth restricted, and 50% were born preterm secondary to either maternal or fetal indications. Of concern, 33% of the women showed acceleration of their renal disease after delivery. Some individuals believe that growth restriction may be due to the lack of normal plasma volume increase as the pregnancy progresses. Cunningham and colleagues<sup>76</sup> demonstrated that women with moderate renal dysfunction exhibit increased creatinine

clearance and plasma volume expansion during gestation, whereas women with severe renal dysfunction generally do not.<sup>76</sup>

### Management of Chronic Renal Disease in Pregnancy

A 24-hour urine collection for creatinine clearance and total protein excretion should be obtained in women with known renal disease as soon as the pregnancy is confirmed. These parameters should be monitored periodically. A general guideline is to see patients every 2 weeks until 32 weeks' gestation and weekly thereafter.

Control of hypertension is critical in managing patients with chronic renal disease. Home blood pressure monitoring is advised for women with underlying hypertension, and  $\beta$ -blockers, calcium channel blockers, and hydralazine can be used to treat blood pressure effectively as long as the dosages are monitored carefully. Clonidine is occasionally useful in refractory patients. Doxazosin and prazosin may also be used if necessary. Angiotensin-converting enzyme (ACE) inhibitors are contraindicated because these drugs have been associated with fetal and neonatal oliguria/anuria<sup>77,78</sup> as well as anomalies.<sup>79</sup> In one study, 1 of 19 exposed infants had anuria and required dialysis.<sup>77,76</sup> Congenital anomalies, including microcephaly and encephalocele,<sup>77</sup> have been associated with the use of ACE inhibitors (see Chapter 8).<sup>75</sup>

The use of diuretics in pregnancy is controversial.<sup>80,81</sup> For massive debilitating edema, a short course of diuretics can be helpful, although electrolytes must be monitored carefully. Salt restriction does not appear to be beneficial once edema has developed; however, it should be instituted without hesitation in pregnant women with true renal insufficiency.

Fetal growth should be assessed with serial ultrasonography, because growth restriction is common in women with chronic renal disease. Antepartum fetal heart rate testing is often initiated at 28 to 32 weeks' gestation.<sup>11</sup>

If the patient manifests anemia in the presence of chronic renal disease, use of erythropoietin (EPO) may be considered. Because of the molecule's large size, recombinant EPO does not appear to cross the placenta. No cases of fetal morbidity or mortality were noted in a literature review<sup>82</sup> that spanned from 2002 through 2012. Use of EPO may be especially important for women who decline blood products.<sup>82</sup> One area of concern when using EPO in these patients is the possible exacerbation of hypertension.<sup>83,84</sup>

The timing of delivery should be individualized. Maternal indications for delivery include uncontrollable hypertension, the development of superimposed preeclampsia, and decreasing renal function after fetal viability has been reached. Fetal indications are dictated by assessment of fetal growth and biophysical testing.

Renal biopsy is rarely indicated during pregnancy, and it is not advised after 34 weeks' gestation, when delivery of the fetus and subsequent biopsy would prove a safer alternative. Excessive bleeding secondary to the greatly increased renal blood flow has been reported by some but not all observers.<sup>80,85</sup> If coagulation indices are normal and blood pressure is well controlled, morbidity should be no greater than that observed in the nonpregnant individual.<sup>86</sup> Packham and Fairley<sup>87</sup> reported a series of 111 renal biopsies performed in 104 pregnant women over 20 years. The complication rate was 4.5%. The most likely clinical dilemma necessitating renal biopsy in a pregnant woman would be the development of nephrotic syndrome and

increasing hypertension between 22 and 32 weeks' gestation. In this case, renal biopsy can distinguish chronic renal disease from preeclampsia and could significantly impact management.

### Hemodialysis in Pregnancy

Women with chronic hemodialysis can have successful pregnancies.<sup>88-94</sup> However, many women with chronic renal failure experience oligomenorrhea, and their fertility is often impaired.<sup>95</sup> These women commonly fail to use contraception; therefore it is important that testing be undertaken if a pregnancy is suspected.

As in all patients with impaired renal function, the most important aspect of care is meticulous control of blood pressure. During dialysis, wide fluctuations in blood pressure can occur.<sup>96</sup> Sudden volume shifts should be avoided because they may compromise fetal well-being.<sup>91,92</sup> In late pregnancy, continuous fetal heart rate monitoring should be carried out during dialysis.<sup>97</sup> If possible, positioning on the left side with uterine displacement away from the vena cava is preferred. During dialysis, careful attention to electrolyte balance is advised. Because pregnant women are in a state of chronic compensated respiratory alkalosis, a large reduction in serum bicarbonate should be avoided. Dialysates that contain glucose and bicarbonate are preferred, and those containing citrates should be avoided.<sup>94</sup>

Women should be counseled that a successful pregnancy will often require longer and more frequent periods of dialysis,<sup>89,94,96,98</sup> and a dose response to dialysis and pregnancy outcome is apparent. A recent study that compared outcomes in patients with end-stage renal disease (ESRD) found "a dose response between dialysis intensity and pregnancy outcomes emerged, with live birth rates of 48% in women dialyzed  $\leq 20$  hours per week and 85% in women dialyzed  $> 36$  hours per week ( $P = .02$ ), with a longer gestational age and greater infant birthweight for women dialyzed more intensively. Pregnancy complications were few and manageable. We conclude that pregnancy may be safe and feasible in women with ESRD receiving intensive hemodialysis."<sup>99</sup> A diet that includes at least 70 g of protein and 1.5 g of calcium daily is recommended. Weight gain should be limited to 0.5 kg between dialysis sessions. Chronic anemia is often a problem in patients on hemodialysis. The hematocrit should be kept above 25%, and transfusion with packed RBCs or EPO therapy may be necessary to accomplish this objective.<sup>89</sup>

Criteria for initiating hemodialysis during pregnancy is controversial.<sup>100</sup> Some investigators believe that beginning regular hemodialysis in patients with moderate renal insufficiency may improve pregnancy outcome.<sup>91</sup> Redrow and coworkers<sup>92</sup> reported 14 pregnancies in 13 women undergoing dialysis, 10 of which were successful. Five of eight pregnancies managed with chronic ambulatory peritoneal dialysis or chronic cycling peritoneal dialysis utilizing an automatic cycler for short exchanges were successful. The investigators hypothesize several advantages for peritoneal dialysis that include a more constant chemical and extracellular environment for the fetus, higher hematocrit levels, infrequent episodes of hypotension, and no need for heparin. They also postulate that intraperitoneal insulin facilitates the management of blood glucose in patients with diabetes and that intraperitoneal magnesium used in the dialysate reduces the likelihood of preterm labor.

Preterm birth occurs more frequently in women undergoing dialysis.<sup>101</sup> Progesterone is removed during dialysis, and at least one group has advocated that parenteral progesterone

therapy should be administered to the patient undergoing dialysis.<sup>102</sup> In their review, Yasin and Bey Doun<sup>94</sup> report a 40.7% incidence of premature labor.

## Renal Transplant

**Pregnancy following renal transplantation has become increasingly common.**<sup>103</sup> Many previously anovulatory patients begin ovulating postoperatively and regain fertility as renal function normalizes.<sup>104</sup> As with women who receive hemodialysis, many transplant recipients do not recognize that they are pregnant until well into the second trimester. A recent report of all women in the United Kingdom who became pregnant after a renal transplant included 105 pregnancies identified in 101 recipients. The median prepregnancy creatinine was 1.3 mg/dL. Preeclampsia developed in 24% compared with 4% of the comparison group. Median gestation at delivery was 36 weeks, and 52% of these women delivered before 37 weeks. Twenty-four infants (24%) were small for gestational age (SGA; <10th centile). Two cases of acute rejection were reported (2%). Potential predictive factors for poor pregnancy outcome included more than one previous kidney transplant ( $P = .03$ ), first-trimester serum creatinine greater than 1.4 mg/dL ( $P = .001$ ), and diastolic blood pressure over 90 mm Hg in the second ( $P = .002$ ) and third trimesters ( $P = .05$ ).<sup>105</sup> Similar studies have provided consistent results and have demonstrated an overall lower rate of morbidity and adverse pregnancy complications when compared with patients with ESRD on dialysis.<sup>106</sup> These outcomes hold true even for women who received a renal transplant during childhood. Wyld and colleagues<sup>107</sup> found that pregnancy outcomes for these women are similar to those for more recent transplant recipients, with no difference in the rates of live births, SGA infants, or gestational age at delivery.

**Many transplant recipients will discontinue all medications after discovering they are pregnant. The importance of continuing immunosuppressive therapy cannot be emphasized strongly enough to renal allograft recipients.** Glucocorticoids, especially prednisone, are metabolized in the placenta by 11 $\beta$ -hydroxysteroid dehydrogenase type 1 (11 $\beta$ -HSD1), and only limited amounts reach the fetus.<sup>108</sup> Azathioprine cannot be activated in the fetus because of its lack of inosinate pyrophosphorylase.<sup>109</sup> Azathioprine has been shown to cause decreased levels of IgG and IgM as well as a smaller thymic shadow on chest x-ray in these neonates.<sup>110</sup> Chromosomal aberrations, which cleared within 20 to 32 months, have also been demonstrated in lymphocytes of infants exposed to azathioprine in utero.<sup>111</sup> The long-term implications of this treatment are not yet known, and IUGR has also been reported in infants born to mothers receiving this medication.<sup>112</sup> These risks are clearly outweighed by the benefits, including reducing the risk of allograft rejection that may occur if medication is discontinued. Of note, a single report describes a successful kidney transplant during pregnancy in the first trimester. The patient received a kidney from her father at approximately 13 weeks' gestation, and she went on to experience a successful pregnancy.<sup>113</sup>

**Cyclosporine A appears to be relatively safe for use during gestation but does hold some risks. Women may develop arterial hypertension secondary to its interference with the normal hemodynamic adaptation to pregnancy.**<sup>114</sup> Cyclosporine metabolism appears to be increased during pregnancy and, as such, the dose may need to be increased to maintain therapeutic levels.<sup>115</sup> Cyclosporine crosses the placenta, and although no evidence of teratogenesis exists, its safety in pregnancy has

not been established.<sup>116,117</sup> In the absence of maternal hypertension, IUGR has been reported with use of cyclosporine A.<sup>118</sup> However, most women who receive cyclosporine have had no complications attributable to the drug, and the risk of allograft rejection certainly outweighs the risk to the fetus from the medication.

**Mycophenolate mofetil (MMF) has been shown to cause adverse effects on fetal development and is associated with first-trimester loss and congenital defects.** These anomalies include cleft lip and palate, limb anomalies, heart defects, and renal anomalies.<sup>119</sup> **This drug is contraindicated in pregnancy.**

**Sirolimus is also contraindicated in pregnancy. This medication has been shown to be embryotoxic and is associated with increased fetal mortality.**<sup>119</sup> It is recommended that women who wish to conceive be switched from this medication prior to becoming pregnant.<sup>119</sup>

**Tacrolimus has been poorly studied in pregnancy.** In 100 pregnancies in patients who were taking tacrolimus, 68 live births were reported, 60% of which were premature. Four infants had malformations, but no consistent pattern of anomalies was reported.<sup>120</sup> Patients taking tacrolimus require frequent monitoring of renal function and their drug levels.

**Davison<sup>121</sup> reviewed 1569 renal transplants in 1009 women and found that 22% of the women elected to abort their pregnancies, 16% had a spontaneous abortion, and 8% experienced perinatal deaths. Furthermore, he observed that 45% of the surviving pregnancies were delivered preterm, and 22% were complicated by IUGR. In addition, 3% of the infants were born with major malformations, a rate no different from that expected in the background population. Preeclampsia complicated 30% of the pregnancies, but as previously noted, the diagnosis is difficult to make in a patient who may already have hypertension and proteinuria. The allograft rejection rate in these women was 9%, a rate no different from that expected in a nonpregnant population.<sup>121</sup> The long-term rejection rate was also the same as for women who had not experienced a pregnancy.**

During pregnancy, renal allograft recipients must be carefully watched for signs of rejection. As previously mentioned, significant episodes of rejection may occur in as many as 9% of transplant recipients during gestation. Unfortunately, **the clinical hallmarks of rejection—fever, oliguria, tenderness, and decreasing renal function—are not always exhibited by the pregnant patient. Occasionally, rejection may mimic pyelonephritis or preeclampsia, which occurs in approximately one-third of renal transplant patients.** In these cases, renal biopsy is indicated to distinguish rejection from preeclampsia. Rejection has been known to occur during the puerperium, when maternal immune competence returns to its prepregnancy level.<sup>122</sup> Therefore it may be advisable to increase the dose of immunosuppressive medications in the immediate postpartum period.

**Infection can be disastrous for the renal allograft; therefore urine cultures should be obtained at least monthly during pregnancy, and any bacteriuria should be aggressively treated. It is crucial to recognize that the allograft is denervated, and pain may not accompany pyelonephritis; the only symptoms may be fever and nausea.**

Renal function, as determined by 24-hour creatinine clearance and protein excretion, should be assessed monthly. Approximately 15% of transplant recipients will exhibit a significant

**BOX 39-2 GUIDELINES FOR RENAL ALLOGRAFT RECIPIENTS CONSIDERING PREGNANCY**

- Wait 2 years after cadaver transplant or 1 year after a graft from a living donor.
- Immunosuppression should be at maintenance levels.
- Plasma creatinine should be <1.5 mg/dL.
- Hypertension should be absent or easily controlled.
- Minimal to no proteinuria should be present.
- Active graft rejection should not be evident.
- No pelvic/cecal distension should be apparent on a recent ultrasound or intravenous pyelogram.
- Prednisone dose should be 15 mg/day.
- Azathioprine dose should be 2 mg/kg/day.
- Cyclosporine A dose should be 2-4 mg/kg (available data on the use of this drug in pregnancy includes <150 patients).

Modified from Lindheimer M, Katz A. Pregnancy in the renal transplant patient. *Am J Kidney Dis.* 2000;19:173.

decrease in renal function in late pregnancy.<sup>67</sup> This condition usually, but not always, reverses after pregnancy. Proteinuria develops in about 40% of patients near term but most often disappears soon after delivery unless significant hypertension is present.

**Similar to women with chronic renal disease, serial ultrasonography should be used to assess fetal growth, and antepartum fetal heart rate testing should be considered at 28 to 32 weeks' gestation. Approximately 50% of renal allograft recipients will deliver preterm.** Preterm labor, preterm rupture of membranes, and IUGR are commonly observed. Cesarean delivery is reserved for obstetric indications. Allograft recipients may have an increased frequency of cephalopelvic disproportion from pelvic osteodystrophy as a result of prolonged renal disease with hypercalcemia or extended steroid use.<sup>123</sup> The transplanted kidney, however, rarely obstructs vaginal delivery despite its pelvic location.

Although many successful pregnancies have been reported in renal allograft recipients, no consensus has been reached as to when it is safe to attempt pregnancy after transplantation. Lindheimer and Katz<sup>124</sup> have suggested some guidelines, which are summarized in Box 39-2.

**KEY POINTS**

- ◆ Asymptomatic bacteriuria complicates 5% to 7% of pregnancies. If left untreated, it will result in symptomatic urinary tract infections in 40% of women.
- ◆ Pyelonephritis complicates 1% to 2% of pregnancies and generally requires inpatient treatment.
- ◆ Women with glomerular disease can have successful pregnancies, but pregnancy loss rates increase greatly if the patient has preexisting hypertension.
- ◆ Creatinine clearance can decline 70% before significant increases are seen in the BUN or serum creatinine level. Therefore a 24-hour urine specimen for creatinine clearance should be collected from any pregnant woman with underlying renal disease.
- ◆ The chance of a successful pregnancy outcome is reduced if the creatinine clearance is less than 50 mL/min or if the serum creatinine level is more than 1.5 mg/dL.

- ◆ Severe hypertension poses the greatest threat to the pregnant woman with chronic renal disease.
- ◆ Growth restriction and preeclampsia are common complications in women with chronic renal disease. Frequent sonograms and antepartum fetal surveillance at 28 weeks' gestation are recommended in affected pregnancies.
- ◆ Women with chronic renal disease are often anovulatory. Following transplantation, ovulation may resume, which can result in an unplanned pregnancy.
- ◆ Women should wait 2 years after receiving a cadaver renal allograft and 1 year after receiving a living allograft before attempting conception. Furthermore, no signs of allograft rejection should be apparent.
- ◆ Renal transplant patients may remain on cyclosporine or azathioprine throughout gestation, although levels may need to be adjusted during pregnancy. Other immunosuppressive medications such as mycophenolate mofetil and sirolimus are contraindicated.
- ◆ Renal function may decline as a result of pregnancy among patients with renal disease. An increased risk for this decline is observed in women with an elevated serum creatinine level (above 1.5mg/dL) and hypertension.

**FIG 40-1** Perinatal mortality rate in pregnancy complicated by insulin-dependent diabetes mellitus.

Insulin therapy was introduced nearly 100 years ago and remains perhaps the most important landmark in the care of pregnancy for the diabetic woman. Before insulin became available, pregnancy was not advised because it was likely to be accompanied by fetal mortality and also came with a substantial risk for maternal death. Over the past 30 years, however, management techniques have been developed that can prevent many complications associated with the diabetic pregnancy. These advances, based on our understanding of the pathophysiology, have resulted in perinatal mortality rates in optimally managed cases that approach those of the normal population. This dramatic improvement in perinatal outcome can be largely attributed to clinical efforts to establish improved maternal glycemic control both before conception and during gestation (Fig. 40-1). Excluding major congenital malformations, which continue to plague pregnancies in women with preexisting (type 1 and type 2) diabetes mellitus (DM), perinatal loss for the woman with diabetes has fortunately become an uncommon event.

Although the benefit of careful regulation of maternal glucose levels is well accepted, failure to establish optimal glycemic control—as well as other factors—continues to result in significant perinatal morbidity. Clinical experience has also resulted in recognition of the impact that vascular complications can have on pregnancy and the manner in which pregnancy can affect these disease processes. With current management techniques and a skilled, organized team approach, successful pregnancies have become the norm even for women with significant complications of DM.

Gestational diabetes mellitus (GDM), the most common type of diabetes found in pregnancy, is increasing in frequency worldwide. GDM continues to represent a significant challenge for both clinicians and investigators. After nearly 60 years since the concept of GDM was introduced, and as a recent result of large-scale observational studies and treatment trials, the clinical significance of this disorder is now accepted. However, controversy still remains concerning screening techniques, diagnostic criteria, thresholds for insulin initiation, and whether oral hypoglycemic agents are a suitable treatment.

Before considering these clinical issues, it is important to review the metabolic effects of pregnancy in relation to the pathophysiology of DM.

## **PATHOPHYSIOLOGY**

### **Normal Glucose Tolerance**

Significant alterations occur in maternal metabolism during pregnancy, which provide for adequate maternal nutritional

stores in early gestation to meet the increased maternal and fetal metabolic demands of late gestation and lactation. Although we are apt to think of DM as a disorder exclusively of maternal glucose metabolism, in fact **DM affects all aspects of nutrient metabolism**. In this section we consider maternal glucose metabolism as it relates to pancreatic  $\beta$ -cell production of insulin and insulin clearance, endogenous (i.e., primarily hepatic) glucose production, and suppression with insulin and peripheral glucose insulin sensitivity. We also address maternal protein and lipid insulin metabolism. Lastly, the effects of these alternations on maternal metabolism are examined as they relate to maternal energy expenditure and fetal growth.

### **Glucose Metabolism**

Normal pregnancy has been characterized as a “diabetogenic state” because of the progressive increase in postprandial glucose levels and increased insulin response in late gestation. **However, early gestation can be viewed as an anabolic state because of the increases in maternal fat stores and decreases in free fatty acid (FFA) concentration, particularly in normal weight and obese women.** Garcia-Patterson and colleagues<sup>1</sup> have described significant decreases in maternal insulin requirements in early gestation in women with type 1 diabetes (Fig. 40-2). The mechanism for the decrease in insulin requirements has been ascribed to various factors that include increased insulin sensitivity and decreased substrate availability secondary to factors such as nausea, the fetus acting as a glucose sink, and enhanced maternal insulin secretion; however, the exact mechanism is not known. Longitudinal studies in women with normal glucose tolerance have shown significant alterations in all aspects of glucose metabolism as early as the end of the first trimester.<sup>2</sup>

Progressive increases are seen in insulin secretion in response to an intravenous (IV) glucose challenge with advancing gestation (Fig. 40-3). The increases in insulin concentration are more pronounced in lean women, compared with obese women, most probably as a response to the greater decreases in insulin sensitivity in lean women, as will be described later. Data regarding insulin clearance in pregnancy are limited. In separate studies, Bellman, Lind, and colleagues and Burt and Davidson reported no difference in insulin disappearance rate when insulin was infused intravenously in late gestation compared with nongravid subjects. In contrast, using a radiolabeled insulin, Goodner and Freinkel described a 25% increase in insulin turnover in a pregnant compared with a nonpregnant rat model. Using the euglycemic clamp, Catalano and associates<sup>3</sup> reported a 20% increase in insulin clearance in lean women and a 30% increase in insulin clearance in obese women by late pregnancy (Fig. 40-4). Although the placenta is rich in insulinase, the exact mechanism for the increased insulin clearance in pregnancy remains speculative.

Although there is a progressive decrease in fasting glucose with advancing gestation, this decrease is most probably a result of the increase in plasma volume in early gestation and the increase in fetoplacental glucose utilization in late gestation. Using various stable isotope methodologies in cross-sectional study designs, Kalhan and Cowett were the first to describe increased fasting hepatic glucose production in late pregnancy. Additionally, using a stable isotope of glucose in a prospective longitudinal study design, Catalano and coworkers<sup>4</sup> reported a **30% increase in maternal fasting hepatic glucose production with advancing gestation** (Fig. 40-5), which remained significant even after adjusting for maternal weight gain. Tissue

**FIG 40-4** Longitudinal increases in metabolic clearance rate of insulin (mL/m²/min) in lean and obese women with normal glucose tolerance: pregravid and early and late pregnancy.

sensitivity to insulin involves both liver and peripheral tissues, primarily skeletal muscle. The increase in fasting maternal hepatic glucose production occurs despite a significant increase in fasting insulin concentration, which indicates a decrease in maternal hepatic glucose sensitivity in women with normal glucose tolerance in late pregnancy. In obese women, a further decrease of insulin to suppress hepatic glucose production was seen in late gestation, thereby indicating a further decrease in hepatic insulin sensitivity in obese women.

Estimates of peripheral insulin sensitivity in pregnancy have included measurements of insulin response to a fixed oral or IV glucose challenge or the ratio of insulin to glucose under a variety of experimental conditions. Methodologies such as the minimal model and the euglycemic-hyperinsulinemic clamp have improved our ability to quantify peripheral insulin sensitivity. In lean women in early gestation, Catalano and colleagues<sup>5</sup> reported a 40% decrease in maternal peripheral insulin sensitivity using the euglycemic-hyperinsulinemic clamp. However, when adjusted for changes in insulin concentrations during the

**FIG 40-5** Longitudinal increase in basal endogenous (primarily hepatic) glucose production (mg/min) in lean and obese women with normal glucose tolerance: pregravid and early and late pregnancy.

**FIG 40-6** Longitudinal changes in the insulin sensitivity index (glucose infusion rate adjusted for residual endogenous glucose production and insulin concentrations achieved during the glucose clamp) in lean and obese women with normal glucose tolerance: pregravid and early and late gestation.

clamp and residual hepatic glucose production (i.e., the insulin sensitivity index), insulin sensitivity *decreased* only 10% (Fig. 40-6). In contrast, a 15% *increase* was seen in the insulin sensitivity index in obese women in early pregnancy compared with pregravid estimates.<sup>6</sup> Hence, the decrease in insulin requirements in early gestation observed in some women may be a consequence of an increase in insulin sensitivity, particularly in women with decreased insulin sensitivity before conception.

Compared with the varied metabolic alterations in early pregnancy, consensus has been reached regarding the decrease in peripheral insulin sensitivity in late gestation. Spellacy and Goetz were among the first investigators to report an increase in insulin response to a glucose challenge in late gestation. Additionally, Burt demonstrated that pregnant women experienced

less hypoglycemia in response to exogenous insulin in comparison with nonpregnant subjects. **Later research by Fisher and associates (using a high-dose glucose infusion test), by Buchanan and colleagues (using the Bergman minimal model), and by Ryan and coworkers<sup>7</sup> and Catalano and associates<sup>2</sup> (using the euglycemic-hyperinsulinemic clamp) all demonstrated a decrease in insulin sensitivity ranging from 33% to 78% in late gestation.** However, all these quantitative estimates of insulin sensitivity are overestimates because of non-insulin-mediated glucose disposal by the fetus and placenta. Hay and colleagues reported that in the pregnant ewe model, about one third of maternal glucose use was accounted for by uterine, placental, and fetal tissue. Additionally, Marconi and coworkers reported that based on human fetal blood sampling, fetal glucose concentration was a function of fetal size and gestational age in addition to maternal glucose concentration.

The decrease in insulin sensitivity during pregnancy has been ascribed to an increased production of various placental and maternal hormones, such as human placental lactogen (hPL), progesterone, estrogen, cortisol, and prolactin. However, recent evidence has focused on the role of several new mediators of insulin resistance such as leptin, tumor necrosis factor alpha (TNF- $\alpha$ ), and resistin. Kirwan and coworkers<sup>8</sup> reported that TNF- $\alpha$  was inversely correlated with the changes in insulin sensitivity from the time before conception through late gestation. In combination with other placental hormones, multivariate stepwise regression analysis revealed that **TNF- $\alpha$  was the strongest independent predictor of insulin sensitivity in pregnancy, accounting for about half of the variance in the decrease in insulin sensitivity during gestation.**

Pregnancy has been characterized as a chronic low-grade inflammatory condition because of the increase in activation of circulating blood leukocytes.<sup>9</sup> The inflammation of pregnancy is further enhanced by maternal prepregnancy obesity. This increase in low-grade inflammation, particularly observed in obese women, has been related to increases in macrophage infiltration in both maternal white adipose tissue and the placenta. The increase in inflammation has been associated with increased circulating C-reactive protein (CRP) and interleukin-6 (IL-6). Both of these factors may exacerbate the increased insulin resistance previously noted in obese women with normal glucose tolerance because of effects on the postreceptor insulin-signaling cascade. These inflammatory cytokines may then relate to increased substrate availability for the developing fetus and resultant macrosomia.

Placental glucose transport is a process that takes place through facilitated diffusion. Glucose transport is dependent on a family of glucose transporters referred to as the *GLUT glucose transporter family*. **The principal glucose transporter in the placenta is GLUT1, which is located in the syncytiotrophoblast.**<sup>10</sup> GLUT1 is located on both the microvilli and basal membranes. Basal membrane GLUT1 may be the rate-limiting step in placental glucose transport. A twofold to threefold increase is seen in the expression of syncytiotrophoblast glucose transporters with advancing gestation. Although GLUT3 and GLUT4 expression have been identified in placental endothelial cells and intervillous nontrophoblastic cells, respectively, the role they may play in placental glucose transport remains speculative.

Debate has been ongoing regarding the location and/or function of insulin receptors in the placenta. In early pregnancy, insulin receptors are abundant on the syncytiotrophoblast, the

cellular layer in contact with maternal blood. In late gestation, insulin receptors are increased on the placental vascular endothelium (i.e., in contact with fetal blood). Maternal insulin response in early pregnancy, as is often seen in women who are obese or who have diabetes, was strongly related to placental weight at birth.<sup>11</sup> Placental weight at birth has the strongest correlation with birthweight, that is, fat and lean body mass.<sup>11</sup> The implication of these data is that early maternal pregnancy metabolism, insulin resistance and response, may affect placental growth and gene expression, which only becomes clinically manifest as fetal overgrowth in late gestation.

## DIABETES MELLITUS

Diabetes mellitus is a chronic metabolic disorder characterized by either absolute or relative insulin deficiency that results in increased glucose concentrations. Although glucose intolerance is the common outcome of DM, the pathophysiology remains heterogeneous. The two major classifications of DM are *type 1*, formerly referred to as *insulin-dependent* or *juvenile-onset diabetes*, and *type 2*, formerly referred to as *non-insulin-dependent* or *adult-onset diabetes*. During pregnancy, classification of women with diabetes has often relied on the White classification,<sup>12</sup> first proposed in the 1940s. This classification is based on factors such as the age of onset of diabetes and duration as well as end-organ involvement, primarily retinal and renal (Table 40-1).

All forms of diabetes can occur during pregnancy. However, in addition to types 1 and 2 diabetes, genetic causes of diabetes exist, the most common of which is maturity-onset diabetes of youth (MODY), characterized by  $\beta$ -cell dysfunction; it has an autosomal-dominant mode of inheritance and usually becomes manifest in young adulthood. Mutations in the glucokinase gene are a frequent cause of MODY. Various mutations have been described, and each mutation is associated with varying degrees of disease severity. The most common of these mutations, MODY2, occurs in the European population and involves the glucokinase gene. Because the age of onset of diabetes in women with MODY coincides with the reproductive years, it may be difficult to distinguish between type 1 DM and MODY. The glucokinase gene acts as a sensor in the  $\beta$ -cell, which leads to a secretory defect in insulin response. **Ellard and colleagues reported that 2.5% of women with GDM in the United Kingdom have the glucokinase mutation,** whereas Stoffel, in a small population in the United States, reported that 5% of patients had a glucokinase in mutation. In another U.S. population, Sewell and colleagues<sup>13</sup> reported no cases in 72 pregnant women with GDM or recently diagnosed pregestational

diabetes. The implication if the mother has the mutation is an increased risk for fetal macrosomia, whereas if the mutation is inherited from the father, the implication for the fetus is a significant decrease in growth secondary to relative insulinopenia.

## Type 1 Diabetes Mellitus

Type 1 diabetes mellitus is usually characterized by an abrupt onset at a young age and absolute insulinopenia with lifelong requirements for insulin replacement. Although depending on the population, the onset of type 1 diabetes may occur in individuals in their third or fourth decades of life. Although the phenotype of the individual with type 1 diabetes has often been conceptualized as being thin, in an 18-year follow-up study, the prevalence of overweight increased by 47%, and the prevalence of obesity increased sevenfold. Patients with DM may have a genetic predisposition for antibodies directed against their pancreatic islet cells. The degree of concordance for the development of type 1 diabetes in monozygotic twins is 33%, suggesting that the events subsequent to the development of autoantibodies and appearance of glucose intolerance are also related to environmental factors. Because of the complete dependence on exogenous insulin, pregnant women with type 1 diabetes are at increased risk for the development of diabetic ketoacidosis (DKA). Additionally, because intensive insulin therapy is used in women with type 1 diabetes to decrease the risk for spontaneous abortion and congenital anomalies in early gestation, these women are at increased risk for hypoglycemic reactions. Studies by Diamond and Rosenn have shown that women with type 1 diabetes are more likely to experience hypoglycemic reactions during pregnancy because of diminished counterregulatory epinephrine and glucagon response to hypoglycemia. The deficiency in this counterregulatory response may be in part due to an independent effect of pregnancy.

The alterations in glucose metabolism in women with type 1 diabetes are not well characterized. Because of maternal insulinopenia, insulin response during gestation can only be estimated relative to pregravid requirements. Estimates of the change in insulin requirements are complicated by the degree of preconceptional glucose control and potential presence of insulin antibodies. Garcia-Patterson<sup>1</sup> reported on the change in insulin requirements in women with type 1 diabetes and strict glucose control prior to conception. In early pregnancy, both insulin requirements and total insulin peak at 9 weeks' gestation and reach a nadir at 16 weeks to baseline prepregnancy levels. After 16 weeks, insulin requirements gradually increase through 37 weeks. This represents a total increase in insulin requirements of 5.19% per week and about a twofold increase relative to

prepregnancy requirements. A 5% decrease in insulin requirements after 36 weeks' gestation was also noted by McManus and Ryan. The decrease in insulin requirements was associated with a longer duration of DM but not with adverse perinatal outcome. The fall in insulin requirements in early pregnancy in women with type 1 diabetes may be a reflection of increased insulin sensitivity as was previously described.

Schmitz and associates have evaluated the longitudinal changes in insulin sensitivity in women with type 1 diabetes in early and late pregnancy, as well as postpartum, in comparison with nonpregnant women with type 1 diabetes. **In the pregnant women with type 1 diabetes, a 50% decrease in insulin sensitivity was observed only in late gestation.** No significant difference was found in insulin sensitivity in pregnant women with type 1 diabetes in early pregnancy or within 1 week of delivery compared with nonpregnant women with type 1 diabetes. Therefore based on the available data, women with type 1 diabetes appear to have a similar decrease in insulin sensitivity compared with women with normal glucose tolerance. Relative to the issue of placental transporters (GLUT1), a report by Jansson and Powell describes an increase in both basal GLUT1 expression and glucose transport activity from placental tissue in women with White class D pregnancies.

## Type 2 Diabetes and Gestational Diabetes

The pathophysiology of type 2 diabetes involves abnormalities of both insulin-sensitive tissue (i.e., both a decrease in skeletal muscle and hepatic sensitivity to insulin) and  $\beta$ -cell response as manifested by an inadequate insulin response for a given degree of glycemia. Initially in the course of the development of type 2 diabetes, the insulin response to a glucose challenge may be increased relative to that of individuals with normal glucose tolerance but is inadequate to maintain normoglycemia. Whether decreased insulin sensitivity precedes  $\beta$ -cell dysfunction in the development of type 2 diabetes continues to be debated. Arguments and experimental data support both hypotheses.

Despite the limitations of any classification system, certain generalizations can be made regarding women with type 2 diabetes or GDM. These individuals are typically older and more often are heavier compared with individuals with normal glucose tolerance. The onset of the disorder is usually insidious, with few patients complaining of the classic triad of polydipsia, polyphagia, and polyuria. Individuals with type 2 diabetes are often initially recommended to lose weight, increase their activity (i.e., exercise), and follow a diet low in saturated fats and high in complex carbohydrates. Oral agents are often used to increase insulin response, enhance insulin sensitivity, or increase renal excretion of glucose. Individuals with type 2 diabetes may eventually require insulin therapy to maintain euglycemia but are at significantly less risk for DKA. **Data from monozygotic twin studies have reported a lifetime risk for both twins developing type 2 diabetes that ranges between 58% and almost 100%, suggesting that the disorder has a strong genetic component.**

Type 2 pregestational diabetes is usually classified as class B diabetes according to the White classification system. Women who develop GDM—that is, glucose intolerance first recognized during pregnancy—share many of the metabolic characteristics of women with type 2 diabetes. Although earlier studies reported a 10% to 35% incidence of islet cell antibodies in women with GDM as measured by immunofluorescence techniques, research using specific monoclonal antibodies has described a much

lower incidence, on the order of 1% to 2%,<sup>14</sup> which suggests a low risk for type 1 diabetes in women with GDM. Furthermore, postpartum studies of women with GDM have demonstrated defects in insulin secretory response and decreased insulin sensitivity, indicating that typical type 2 abnormalities in glucose metabolism are present in women with GDM. The alterations in insulin secretory response and insulin resistance in women with a previous history of GDM compared with a weight-matched control group may differ depending on whether the women with previous GDM are lean or obese.<sup>15</sup> Thus in women with GDM, the hormonal events of pregnancy may represent an unmasking of a genetic susceptibility to type 2 diabetes.

Significant alterations in glucose metabolism are found in women who develop GDM relative to women with normal glucose tolerance. Decreased insulin response to a glucose challenge has been demonstrated by Yen, Fisher, and Buchanan and their colleagues in women with GDM in late gestation. In prospective longitudinal studies of both lean and obese women with GDM, Catalano and associates<sup>5</sup> also showed a progressive decrease in first-phase insulin response in late gestation in lean women who develop GDM compared with a weight-matched control group (Fig. 40-7). In contrast, in obese women who develop GDM, no difference in first-phase insulin response was reported, but rather a significant increase was seen in second-phase insulin response to an IV glucose challenge compared with that of a weight-matched control group (see Fig. 40-7). These differences in insulin response may be related to the ethnicity of the various study groups. Although the metabolic clearance rate of insulin is increased with advancing gestation, no evidence suggests that a significant difference exists between women with normal glucose tolerance and those with GDM.<sup>6</sup>

Fasting glucose concentrations decrease with advancing gestation in women who develop mild GDM. In late pregnancy, however, hepatic glucose production increases in women with GDM in comparison with a matched control group.<sup>5,6</sup> In late gestation, women with GDM have increased fasting insulin concentrations (Fig. 40-8) and less suppression of hepatic glucose production during insulin infusion, thereby indicating decreased hepatic glucose insulin sensitivity in women with GDM compared with a weight-matched control group.<sup>5,6,16</sup> In the studies of Xiang and associates,<sup>16</sup> a significant correlation was found between fasting FFA concentrations and hepatic glucose production, which suggests that increased FFA concentrations may contribute to hepatic insulin resistance.

Women with GDM have decreased insulin sensitivity in comparison with weight-matched control groups. Ryan and colleagues<sup>7</sup> were the first to report a 40% decrease in insulin sensitivity in women with GDM compared with a pregnant control group in late pregnancy using a hyperinsulinemic-euglycemic clamp. Xiang and associates<sup>16</sup> found that women with GDM who had normal glucose tolerance within 6 months of delivery had significantly decreased insulin sensitivity as estimated by the glucose clearance rate during a hyperinsulinemic-euglycemic clamp compared with that of a matched control group. Using similar techniques, Catalano and coworkers<sup>5,6</sup> described the longitudinal changes in insulin sensitivity in both lean and obese women who developed GDM in comparison with a matched control group. Women who developed GDM had decreased insulin sensitivity compared with that of the matched control group (Fig. 40-9). The differences in insulin sensitivity were greatest before and during early gestation; by late gestation, the differences in insulin sensitivity between the

**FIG 40-7** Longitudinal increase in insulin response to an intravenous glucose challenge in lean and obese women with normal glucose tolerance and gestational diabetes mellitus (GDM): pregravid and early and late pregnancy. **A**, First phase: area under the curve from 0 to 5 minutes. **B**, Second phase: area under the curve from 5 to 60 minutes.

groups were less pronounced but still significant. Of interest, an increase in insulin sensitivity was noted from the time before conception through early pregnancy (12 to 14 weeks), particularly in those women with the greatest decreases in insulin sensitivity before conception. **The changes in insulin sensitivity from the time before conception through early pregnancy were significantly correlated with changes in maternal weight gain and energy expenditure.** The relationship between these alterations in maternal glucose insulin sensitivity and weight gain and energy expenditure may help explain the decrease in maternal weight gain and insulin requirements in women with diabetes in early gestation.<sup>1</sup> In summary, the various degrees of decreased insulin sensitivity observed in late pregnancy in women with normal glucose tolerance or gestational diabetes are but a reflection of their individual prepregnancy insulin sensitivity. Unless unforeseen severe metabolic events occur during pregnancy, relatively uniform decreases are apparent in insulin sensitivity with advancing gestation in all women.

The interactions of  $\beta$ -cell response and insulin sensitivity are hallmarks of the metabolic adaptations of pregnancy. As

**FIG 40-8** Longitudinal increase in basal or fasting insulin ( $\mu$ g/mL) in lean and obese women with normal glucose tolerance and gestational diabetes mellitus (GDM): pregravid and early and late pregnancy.

**FIG 40-9** Longitudinal changes in the insulin sensitivity index (glucose infusion rate adjusted for residual endogenous glucose production and insulin concentrations achieved during the glucose clamp) in lean and obese women with normal glucose tolerance and gestational diabetes mellitus (GDM): pregravid and early and late pregnancy.

described by Bergman, the relationship between insulin response and insulin resistance is fixed in nonpregnant individuals and follows a hyperbolic curve (i.e., the disposition index [DI]; Fig. 40-10). Buchanan described a similar relationship between insulin response and insulin action during pregnancy. Indeed, when the DI has been compared between women with normal glucose tolerance and GDM both during and after pregnancy, the failure of the  $\beta$ -cell to compensate for insulin resistance in GDM has been similar to the hyperbolic changes in the control group (see Fig. 40-10). This relationship between insulin sensitivity and insulin resistance, however, may not hold in early pregnancy, when both an increase in insulin sensitivity and insulin response may be evident.

Studies in human skeletal muscle and adipose tissue have demonstrated that postreceptor defects in the insulin-signaling cascade are related to decreased insulin sensitivity in pregnancy.

Garvey and colleagues were the first to demonstrate that there were no significant differences in the glucose transporter (GLUT4) responsible for insulin action and skeletal muscle in pregnant compared with nonpregnant women. Based on the studies of Friedman and colleagues<sup>17</sup> in pregnant women with normal glucose tolerance and GDM, as well as in weight-matched nonpregnant control subjects, defects were apparent in the insulin-signaling cascade relating to pregnancy and to what may be additional abnormalities in women with gestational diabetes. **All pregnant women appeared to have a decrease in expression of insulin receptor substrate 1 (IRS1).** The down-regulation of the IRS1 protein closely parallels the decreased ability of insulin to induce additional steps in the insulin-signaling cascade, which results in movement of the GLUT4 to the cell surface membrane to facilitate glucose transport into the cell. The downregulation of IRS1 protein closely parallels the ability of insulin to stimulate 2-deoxyglucose uptake in vitro. In addition to the previous mechanisms, **women with GDM demonstrate a distinct decrease in the ability of insulin**

**FIG 40-10** Insulin sensitivity index. GDM, gestational diabetes mellitus.

**receptor- $\beta$ , that component of the insulin receptor not on the cell surface, to undergo tyrosine phosphorylation. The additional defect in the insulin-signaling cascade results in a 25% lower glucose transport activity (Fig. 40-11).**

### Amino Acid Metabolism

Although glucose is the primary source of energy for the fetus and placenta, no appreciable amounts of glucose are stored as glycogen in the fetus or placenta. However, accretion of protein is essential for growth of fetoplacental tissue. Nitrogen retention is increased in pregnancy in both maternal and fetal compartments, and this increase results in about 0.9 kg of maternal fat-free mass by 27 weeks.<sup>18</sup> A significant decrease is apparent in most basal maternal amino acid concentrations in early pregnancy before the accretion of significant maternal or fetal tissue. These anticipatory changes in amino acid metabolism occur after a shorter period of fasting in comparison with nonpregnant women and may be another example of the accelerated starvation of pregnancy described by Freinkel and coworkers.<sup>19</sup> Furthermore, amino acid concentrations, such as of serine, correlate significantly with fetal growth in both early and late gestation.<sup>20</sup> Maternal amino acid concentrations were significantly decreased in mothers of small-for-gestational-age (SGA) neonates in comparison with maternal amino acid concentrations in appropriately grown neonates.

Based on a review of various studies, Duggleby and Jackson have estimated that during pregnancy, protein synthesis is similar to that in nonpregnant women in the first trimester. **However, a 15% increase in protein synthesis occurs during the second trimester, and a further increase is seen in the third trimester, by about 25%.** Additionally, interindividual differences at each time point are marked, and these differences have a strong relationship with fetal growth: mothers who had increased protein turnover in midpregnancy had babies who had increased lean body mass after adjustment for important covariables.

Amino acids can be used for protein accrual or they can be oxidized as an energy source. Estimation of urea synthesis using stable isotopes has been performed in a number of studies. In general, a modest shift in oxidation occurs in early pregnancy with an accrual of amino acids for protein synthesis in late

**FIG 40-11** Schematic model of insulin-signaling cascade in skeletal muscle. GLUT, glucose transporter; IR, insulin receptor; IRS, insulin receptor substrate.

gestation. Kalhan and colleagues reported significant pregnancy-related adaptations in maternal protein metabolism early in gestation before any significant increase in fetal protein accretion. Catalano and associates have also reported decreased amino acid insulin sensitivity based on a decreased suppression of leucine turnover during insulin infusion in late gestation. Some evidence suggests an increase in basal leucine turnover in women with GDM compared with that of a matched control group. Whether these decreases in amino acid insulin sensitivity are related to decreased whole-body and liver protein synthesis or increased breakdown are not known at this time.

Cetin and associates reported that placental amino acid exchange is altered in pregnancies complicated by GDM. Ornithine concentrations were significantly increased in women with GDM compared with controls, and in the cord blood of infants of women with GDM, significant increases were observed in multiple amino acids, including phenylalanine and leucine, but decreases in glutamate were also found. The investigators speculate that in infants of women with GDM, the altered in utero fetal milieu affects fetal growth through multiple mechanisms that affect various nutrient compartments.

Amino acids are actively transported across the placenta from mother to fetus through energy-requiring amino acid transporters. These transporters are highly stereospecific, but they have low substrate specificity. Additionally, they may vary in location between the microvillus and basal membranes. Decreased amino acid concentrations have been reported in growth-restricted neonates in comparison with appropriately grown neonates, and decreased amino acid transporter activity has been implicated as a possible mechanism. However, the potential role, if any, of placental amino acid transporters in the development of fetal macrosomia in women with diabetes is currently unknown.

### Lipid Metabolism

Although ample literature supports the changes in glucose metabolism during gestation, the data regarding the alterations in lipid metabolism are meager by comparison. Darmady and Postle<sup>21</sup> measured serum cholesterol and triglyceride before, during, and after pregnancy in 34 normal women and observed a decrease in both cholesterol and triglyceride at about 7 weeks' gestation. Both of the levels increased progressively until term, and then a decrease was seen in serum triglyceride postpartum. The decrease was more rapid in women who breastfed compared with those women who bottle-fed their infants.<sup>21</sup> Additionally, Knopp and coworkers<sup>22</sup> have reported that a twofold to fourfold increase occurs in total triglyceride concentration and a 25% to 50% increase is seen in total cholesterol concentration during gestation. A 50% increase in low-density lipoprotein (LDL) cholesterol and a 30% increase in high-density lipoprotein (HDL) cholesterol is seen by midgestation, but these decrease slightly in the third trimester. Maternal triglyceride and very-low-density lipoprotein (VLDL) triglyceride levels in late gestation are positively correlated with maternal estradiol and insulin concentrations.

A study by Vahratian and associates examined the changes in lipid levels during pregnancy in normal-weight compared with overweight and obese women from 6 to 10 through 32 to 36 weeks' gestation. The levels of total cholesterol, triglycerides, and LDL and HDL cholesterol increased throughout gestation. Although the concentrations in the overweight and obese women were generally higher in early pregnancy, the rate of

change of LDL cholesterol and total cholesterol was lower in later gestation.

FFAs have been associated with fetal overgrowth, particularly of fetal adipose tissue. A significant difference in the arteriovenous FFA concentration is seen at birth, much the same as with arteriovenous glucose concentration. Multiple clinical studies suggest the contribution of maternal lipids to fetal growth and in particular to adiposity. Knopp and coworkers<sup>22</sup> reported that neonatal birthweight was positively correlated with triglyceride and FFA concentrations in late pregnancy. Similar conclusions were reached by Ogburn and colleagues, who showed that insulin concentrations decrease FFA concentrations, inhibit lipolysis, and result in increased fat deposition. Kleigman reported that infants of obese women had an increased birthweight and skinfold thickness and higher FFA levels compared with infants of lean women. DiCianni and associates<sup>23</sup> reported that in women with a positive glucose screen but normal glucose tolerance, their serum triglycerides and prepregnancy body mass index (BMI) had a significant correlation with birthweight at term. In Australia, Nolan and coworkers showed that nonfasting maternal triglycerides measured at 9 to 12 weeks' gestation were significantly correlated with neonatal birthweight ratio at term. Finally, in a well-controlled German GDM population, Schaeffer-Graf and colleagues<sup>24</sup> reported that **maternal FFA concentrations correlated with ultrasound estimates of neonatal abdominal circumference and anthropometric estimates of neonatal fat mass at delivery**. Maternal FFA concentrations were positively correlated with cord FFA. Although FFA concentrations were higher in cord blood of large-for-gestational-age (LGA) neonates compared with either appropriately grown or SGA neonates, a paradoxical negative correlation of cord triglycerides and birthweight was reported. The authors speculated that SGA newborns have a lower lipoprotein lipase activity and hence were unable to hydrolyze triglycerides. In contrast, the LGA neonates have lower cord triglyceride concentrations because of enhanced lipoprotein lipase activity resulting from their increased number of fat cells. Similar findings were noted by Merzouk and coworkers in growth-restricted infants. Lastly, the placentae of women with GDM have increased expression of genes related to inflammation and lipid metabolism in comparison with those of a BMI-matched control group.

In summary, in women with evidence of decreased insulin sensitivity (obesity and/or GDM) in addition to glucose, maternal lipid metabolism accounts for a significant proportion of fetal growth, particularly adiposity. These data support the original work by Freinkel,<sup>25</sup> **which proposed that fetal growth or overgrowth is a function of multiple nutritional factors in addition to glucose**.

Lipid metabolism in women with diabetes mellitus is influenced by whether the woman has type 1 or type 2 diabetes. This also applies when these women become pregnant. In women with type 2 diabetes and gestational diabetes, Knopp and coworkers<sup>22</sup> reported an increase in triglyceride and a decrease in HDL concentration. However, Montelongo and colleagues observed little change in FFA concentrations through all three trimesters after a 12-hour fast. Koukkou and coworkers noted an increase in total triglyceride but lower LDL cholesterol in women with GDM. Increased triglyceride concentrations during pregnancy have also been reported to be related to the development of GDM and preeclampsia in women with normal pregravid glucose tolerance, both of which are related to increased

insulin resistance. In women with type 1 diabetes, no change was observed in total triglycerides, but a lower cholesterol concentration was reported secondary to a decrease in HDL. This is of interest because HDL acts as a plasma antioxidant, and thus a lower HDL level may be related to the increase in congenital malformations in women with type 1 diabetes. Oxidative stress has been implicated as a potential factor in the incidence of anomalies in women with type 1 diabetes.

Hyperinsulinemic-euglycemic clamp studies in pregnant women with normal glucose tolerance and GDM revealed a decreased ability of insulin to suppress plasma FFAs with advancing gestation. Insulin's ability to suppress plasma FFAs was lower in women with GDM compared with women with normal glucose tolerance.

Taken together, these studies demonstrate decreased nutrient insulin sensitivity in all women with advancing gestation. These decreases in insulin sensitivity are further exacerbated by the presence of decreased pregravid maternal insulin sensitivity, which manifests in later pregnancy as GDM and results in greater nutrient availability and higher ambient insulin concentrations for the developing fetoplacental unit, which may eventually result in fetal overgrowth.

### Maternal Weight Gain and Energy Expenditure

**Estimates of the energy cost of pregnancy range from a cost of 80,000 kcal to a net savings of up to 10,000 kcal.**<sup>26</sup> As a result, the recommendations for nutritional intake in pregnancy differ and depend on the population being evaluated. Furthermore, recommendations for individuals within a population may be more diverse than previously believed, making general guidelines for nutritional intake difficult.

The theoretic energy cost of pregnancy was originally estimated by Hytten and Leitch<sup>18</sup> using a factorial method. The additional cost of pregnancy consisted of (1) the additional maternal and fetoplacental tissue accrued during pregnancy and (2) the additional "running cost" of pregnancy (e.g., the work of increased cardiac output). In Hytten's model, the greatest increases in maternal energy expenditure occur between 10 and 30 weeks' gestation, primarily because of maternal accretion of adipose tissue. However, the mean increases in maternal adipose tissue vary considerably among various ethnic groups. Forsum and associates reported a mean increase of more than 5 kg of adipose tissue in Swedish women, whereas Lawrence and colleagues found no increase in adipose tissue stores in women from the Gambia.

Basal metabolic rate accounts for 60% to 70% of total energy expenditure in individuals not engaged in competitive physical activity, and this correlates well with total energy expenditure. As with the changes in maternal accretion of adipose tissue, wide variations are seen in the change in maternal basal metabolic rate during gestation, not only in different populations but again within relatively homogeneous groups. The cumulative energy changes in basal metabolic rate range from a high of 52,000 kcal in Swedish women to a net savings of 10,700 kcal in women from the Gambia without nutritional supplementation. **The mean increase in basal metabolic rate in Western women relative to a nonpregnant, nonlactating control group averages about 20% to 25%.** However, the coefficient of variation of basal metabolic rate ranges from 93% in women in the United Kingdom to more than 200% in Swedish women.<sup>27</sup> When assessing energy intake in relation to energy expenditure,

however, estimated energy intake remains lower than the estimates of total energy expenditure. These discrepancies have usually been explained by factors such as increased metabolic efficiency during gestation, decreased maternal activity, and unreliable assessment of food intake.<sup>26</sup>

Data in nonpregnant subjects may help explain some of the wide variations in metabolic parameters during human gestation, even with homogeneous populations. Swinburn and colleagues reported that in the Pima Indian population, subjects with decreased insulin sensitivity gained less weight compared with more insulin-sensitive subjects (3.1 vs. 7.6 kg) over a period of 4 years. Furthermore, the percentage weight change per year was highly correlated with glucose disposal as estimated from clamp studies. Catalano and coworkers<sup>28</sup> evaluated the changes in maternal accretion of body fat and basal metabolic rate in lean and obese women with normal GDM. Women who developed GDM had decreased insulin sensitivity in early gestation compared with a matched control group and had significantly smaller increases in body fat than women with normal glucose tolerance. A significant inverse correlation was found between the changes in fat accretion and insulin sensitivity (i.e., women with decreased pregravid insulin sensitivity had less accretion of body fat compared with women with increased pregravid insulin sensitivity).

In the basal state, lean women increase the use of carbohydrate as a metabolic fuel, whereas in obese women, there is an increased use of lipids for oxidative needs. However, with the decrease in insulin sensitivity in late gestation, all women have an increase in fat oxidation and decrease in nonoxidative glucose metabolism (storage). These increases in lipid oxidation are positively correlated with the increases in maternal leptin concentrations, possibly accounting for a role of leptin in human pregnancy. The result of these studies emphasize that an inverse relationship exists between the changes in maternal insulin sensitivity and accretion of adipose tissue in early gestation. The ability of women with decreased pregravid glucose insulin sensitivity (obese women and women with GDM) to conserve energy, not significantly increase body fat, and make sufficient nutrients available to produce a healthy fetus supports the hypothesis that decreased maternal insulin sensitivity may have a reproductive metabolic advantage in women when food availability is marginal (i.e., the thrifty gene hypothesis). In contrast, decreased maternal insulin sensitivity before conception in areas where food is plentiful and a sedentary lifestyle is more common and may manifest as GDM, and this increases the long-term risk for both diabetes and obesity in the woman and her offspring.<sup>28</sup>

## PERINATAL MORBIDITY AND MORTALITY

### Fetal Death

In the past, sudden and unexplained stillbirth occurred in 10% to 30% of pregnancies complicated by type 1 DM, also called *insulin-dependent diabetes mellitus* (IDDM). Although relatively uncommon today, such losses still plague the pregnancies of patients who do not receive optimal care. Mathiesen and colleagues<sup>29</sup> reported 25 stillbirths among 1361 singleton births of women with type 1 diabetes. In this series, the offspring of women with type 1 or type 2 diabetes were five times more likely to be stillborn compared with those of mothers without diabetes. Stillbirths have been observed most often after the 36th week of pregnancy in patients with poor glycemic control, hydramnios,

fetal macrosomia, vascular disease, or preeclampsia. Women with vascular complications may develop fetal growth restriction (FGR) and intrauterine fetal demise (IUID) as early as the second trimester.

**Excessive stillbirth rates in pregnancies complicated by diabetes have been linked to chronic intrauterine hypoxia.**<sup>30</sup> Extramedullary hematopoiesis, frequently observed in stillborn infants of diabetic mothers (IDMs), supports chronic intrauterine hypoxia as a likely cause of these intrauterine fetal deaths. Studies of fetal umbilical cord blood samples in pregnant women with type 1 diabetes have demonstrated relative fetal erythremia and lactic acidemia. Maternal diabetes may also produce alterations in red blood cell (RBC) oxygen release and placental blood flow. Reduced uterine blood flow is thought to contribute to the increased incidence of intrauterine growth restriction (IUGR) observed in pregnancies complicated by diabetic vasculopathy. Ketoacidosis and preeclampsia, two factors known to be associated with an increased incidence of intrauterine deaths, may further decrease uterine blood flow.

Alterations in fetal carbohydrate metabolism also may contribute to intrauterine asphyxia. Considerable evidence links hyperinsulinemia and fetal hypoxia. Hyperinsulinemia induced in fetal lambs by an infusion of exogenous insulin produces an increase in oxygen consumption and a decrease in arterial oxygen content.<sup>30</sup> Persistent maternal-fetal hyperglycemia occurs independent of maternal uterine blood flow, which may not be increased enough to allow for enhanced oxygen delivery in the face of increased metabolic demands. Thus hyperinsulinemia in the fetus of the diabetic mother appears to increase the metabolic rate and oxygen requirement in the fetus. Other factors such as hyperglycemia, ketoacidosis, preeclampsia, and maternal vasculopathy can also reduce placental blood flow and fetal oxygenation.

**Congenital Malformations**

**Congenital malformations are the most important cause of perinatal loss in pregnancies complicated by type 1 and type 2 DM.** In the past, these anomalies were responsible for only 10% of all perinatal deaths. Malformations now account for 30% to 50% of perinatal mortality. Neonatal deaths exceed stillbirths in pregnancies complicated by pregestational DM, and fatal congenital malformations are responsible for this pattern.

Most studies have documented a two to sixfold increase in major malformations in infants of type 1 and type 2 diabetic mothers. A large population-based cohort study of Canadian women revealed a 23% decline in congenital malformations in diabetic pregnancies from 1996 through 2010; however, the relative risk (RR) for malformations remained elevated in women with preexisting diabetes (RR, 2.33; 95% confidence interval [CI], 1.59 to 3.43). In a prospective analysis, Simpson and associates observed an 8.5% incidence of major anomalies in the diabetic population, whereas the malformation rate in a small group of concurrently gathered control subjects was 2.4%. Similar figures were obtained in the Diabetes in Early Pregnancy Study in the United States. The incidence of major anomalies was 2.1% in 389 control patients and 9% in 279 diabetic women. A recent case-control study of 13,030 infants with congenital anomalies and 4895 controls revealed a prevalence in type 1 diabetes of 2.2% versus 0.5% and in type 2 diabetes of 5.1% versus 3.7% in controls. In general, the incidence of major malformations in worldwide

**FIG 40-12** Infant of a diabetic mother with sacral agenesis and hypoplastic lower extremities.

studies of offspring of diabetic women has ranged from 7.5% to 10% (Table 40-2).

**The insult that causes malformations in IDMs affects most organ systems and must act before the seventh week of gestation.** Central nervous system malformations—particularly anencephaly, open spina bifida, and holoprosencephaly—are increased tenfold. Cardiac anomalies are the most common malformations seen in IDMs, with ventricular septal defects and complex lesions such as transposition of the great vessels increased fivefold. The congenital defect thought to be most characteristic of diabetic embryopathy is sacral agenesis or caudal dysplasia, an anomaly found 200 to 400 times more often in offspring of diabetic women (Fig. 40-12). However, this defect is not pathognomonic for diabetes because it also occurs in nondiabetic pregnancies.

**Impaired glycemic control and associated derangements in maternal metabolism appear to contribute to abnormal embryogenesis.** Maternal hyperglycemia has been proposed by most investigators as the primary teratogenic factor, but hyperketonemia, hypoglycemia, somatomedin inhibitor excess, and excess free oxygen radicals have also been suggested (Box 40-1). The profile of a woman most likely to produce an anomalous infant would include a patient with poor periconceptual glucose control, long-standing diabetes, and vascular disease.

### BOX 40-1 PROPOSED FACTORS ASSOCIATED WITH TERATOGENESIS IN PREGNANCY COMPLICATED BY DIABETES MELLITUS

- Hyperglycemia
- Ketone body excess
- Somatomedin inhibition
- Arachidonic acid deficiency
- Free oxygen radical excess

Genetic susceptibility to the teratogenic influence of diabetes may also be a factor.

Several mechanisms have been proposed by which the previously mentioned teratogenic factors produce malformations. Freinkel and colleagues first suggested that anomalies might arise from inhibition of glycolysis, the key energy-producing process during embryogenesis. They found that the addition of D-mannose to the culture medium of rat embryos inhibited glycolysis and produced growth restriction and derangement of neural tube closure. Freinkel and colleagues stressed the sensitivity of normal embryogenesis to alterations in these key energy-producing pathways, a process he labeled “fuel-mediated” teratogenesis. Goldman and Baker suggested that the mechanism responsible for the increased incidence of neural tube defects (NTDs) in embryos cultured in a hyperglycemic medium may involve a functional deficiency of arachidonic acid, because supplementation with arachidonic acid or myoinositol will reduce the frequency of NTDs in this experimental model. Pinter and Reece, along with Pinter and associates, confirmed these studies and demonstrated that hyperglycemia-induced alterations in neural tube closure include disordered cells, decreased mitoses, and changes indicative of premature maturation. Pinter and colleagues further demonstrated that hyperglycemia during organogenesis has a primary deleterious effect on yolk sac function with resultant embryopathy.

Altered oxidative metabolism from maternal diabetes may cause increased production of free oxygen radicals in the developing embryo, which are likely teratogenic. Supplementation of oxygen radical-scavenging enzymes, such as superoxide dismutase, to the culture medium of rat embryos protects against growth delay and excess malformations. It has been suggested that excess free oxygen radicals may have a direct effect on embryonic prostaglandin biosynthesis. Free oxygen radical excess may enhance lipid peroxidation, and in turn, generated hydroperoxides might stimulate thromboxane biosynthesis and might inhibit prostacyclin production, an imbalance that could have profound effects on embryonic development. Finally, oxidative stress in diabetic rats is associated with the accumulation of glycation products and altered vascular endothelial growth factor (VEGF) expression in cardiovascular regions of the developing heart associated with endocardial cushion defects.

### Fetal Macrosomia

**Macrosomia** has been variously defined as birthweight greater than 4000 to 4500 g, as well as LGA, in which birthweight is above the 90th percentile for population and sex-specific growth curves. Fetal macrosomia complicates as many as 50% of pregnancies in women with GDM and 40% of pregnancies complicated by type 1 and type 2 diabetes, which includes some women treated with intensive glycemic control (Fig. 40-13). Delivery of an infant weighing greater than 4500 g occurs 10 times more often in women with diabetes

**FIG 40-13** Two extremes of growth abnormalities in pregnancies complicated by diabetes mellitus. On the left is a severely growth-restricted infant, and on the right is a macrosomic infant.

compared with a population of women with normal glucose tolerance.

According to the Pedersen hypothesis, maternal hyperglycemia results in fetal hyperglycemia and hyperinsulinemia, which results in excessive fetal growth. Increased fetal  $\beta$ -cell mass may be identified as early as the second trimester. Evidence in support of the Pedersen hypothesis has come from the studies of amniotic fluid and cord blood insulin and C-peptide concentrations. Both are increased in the amniotic fluid of insulin-treated women with diabetes at term and correlate with neonatal fat mass. Lipids and amino acids, which are elevated in pregnancies complicated by GDM, may also play a role in excessive fetal growth by either stimulating the release of insulin and other growth factors from the fetal pancreatic  $\beta$ -cells and placenta or by providing the necessary nutrients for excessive fetal growth.

**Infants of mothers with GDM have an increase in fat mass, compared with fat-free mass, in comparison with infants of women with normal glucose tolerance. Additionally, the growth is disproportionate, with chest-to-head and shoulder-to-head ratios larger than those of infants of women with normal glucose tolerance.** These anthropometric differences may contribute to the higher rate of shoulder dystocia and birth trauma observed in these infants.

The results of several clinical series have validated the Pedersen hypothesis inasmuch as tight maternal glycemic control has been associated with a reduction in macrosomia and, in particular, with a reduction in fat mass. Using daily capillary glucose values obtained during the second and third trimesters in women who required insulin, Landon and colleagues reported a rate of 9% for macrosomia when mean values were below 110 mg/dL compared with 34% when less optimal control was achieved. Jovanovic and associates have suggested that 1-hour postprandial glucose measurements correlate best with the frequency of macrosomia. After controlling for other factors, these authors noted that the strongest prediction for birthweight was third-trimester nonfasting glucose measurements.

In a series of metabolic studies, Catalano and associates<sup>31</sup> estimated body composition in 186 neonates using anthropometry. Fat-free mass, which represented 86% of mean birthweight, accounted for 83% of the variance in birthweight; and fat mass, which made up only 14% of birthweight, accounted for 46% of the variance in birthweight. In addition, significantly greater

fat-free mass was observed in male compared with female infants. Using independent variables such as maternal height, pregravid weight, weight gain during pregnancy, parity, paternal height and weight, neonatal sex, and gestational age, the authors accounted for 29% of the variance in birthweight, 30% of the variance in fat-free mass, and 17% of the variance in fat mass. Including estimates of maternal insulin sensitivity in 16 additional subjects, they were able to explain 48% of the variance in birthweight, 53% of the variance in fat-free mass, and 46% of the variance in fat mass. Studies by Caruso and colleagues have corroborated these findings, reporting that women with unexplained FGR had greater insulin sensitivity compared with a control group of women whose infants were an appropriate weight for their gestational age. The potential mechanisms for this relate to the possibility that maternal circulating nutrients for glucose, FFAs, and amino acids available for placental transport to the fetus are decreased because of the relative increase in maternal insulin sensitivity. A positive correlation between birthweight and weight gain has been observed in women with normal glucose tolerance. The correlation was strongest in women who were lean before conception, and it became progressively weaker as pregravid weight for height increased. In women with GDM, no significant correlations were found between maternal weight gain and birthweight irrespective of pregravid weight for height. Although these studies emphasize the role of the maternal metabolic environment and fetal growth, Kim and colleagues<sup>32</sup> have reported that GDM actually contributed the least (2.0% to 8.0%) to the development of LGA infants in a general obstetric population, whereas excessive gestational weight gain contributed the most (33.3% to 37.7%).

Normalization of birthweight in infants of women with GDM, however, may in itself not help those infants achieve optimal growth. In a study of approximately 400 infants of women with normal glucose tolerance and GDM, Catalano and coworkers<sup>31</sup> showed that the infants of women with GDM had increased fat mass, but not lean body mass or weight, compared with a control group even after adjustment for potential confounding variables (Table 40-3). Similarly, when only infants who were an appropriate size for their gestational age (i.e., between the 10th and 90th percentiles) were examined, the infants of the women with GDM had significantly greater fat mass and percentage of body fat but had less lean mass compared with the control group, and no difference was observed in birthweight. Of note, in the infants of the women with GDM, the strongest correlations with fat mass were fasting glucose and gestational age; this accounted for 17% of the variance in infant fat mass.

## Hypoglycemia

**Neonatal hypoglycemia, a blood glucose level less than 35 to 40 mg/dL during the first 12 hours of life, results from a**

**rapid drop in plasma glucose concentrations following clamping of the umbilical cord. Hypoglycemia, a byproduct of hyperinsulinemia, is particularly common in macrosomic newborns, in whom rates exceed 50%.** We have observed an overall rate of 27% in offspring of diabetic women delivered at our institution. The degree of hypoglycemia may be influenced by at least two factors: maternal glucose control during the latter half of pregnancy during labor and delivery. Prior poor maternal glucose control can result in fetal  $\beta$ -cell hyperplasia, which leads to exaggerated insulin release following delivery. IDMs who exhibit hypoglycemia have elevated cord C-peptide and free insulin levels at birth and show an exaggerated pancreatic response to glucose loading. The hyperinsulinemia and resultant hypoglycemia typically lasts for several days following birth.

## Respiratory Distress Syndrome

Experimental animal studies have provided evidence that hyperglycemia and hyperinsulinemia can affect pulmonary surfactant biosynthesis, and in vitro studies have documented that insulin can interfere with substrate availability for surfactant biosynthesis. Insulin excess may interfere with the normal timing of glucocorticoid-induced pulmonary maturation in the fetus. Cortisol apparently acts on pulmonary fibroblasts to induce synthesis of fibroblast-pneumocyte factor, which then acts on type II cells to stimulate phospholipid synthesis. Carlson and coworkers demonstrated that insulin blocks cortisol action at the level of the fibroblast by reducing the production of fibroblast-pneumocyte factor.

Clinical studies to investigate the effect of maternal diabetes on fetal lung maturation have produced conflicting data. The role of amniocentesis in determining fetal lung maturity is discussed with timing and mode of delivery. **Several studies suggest that in women with well-controlled diabetes whose fetus is delivered at 38 to 39 weeks' gestation, the risk for respiratory distress syndrome (RDS) is no higher than that observed in the general population.** Kjos and Walther<sup>33</sup> studied the outcome of 526 diabetic gestations delivered within 5 days of amniotic fluid fetal lung maturation testing and reported hyaline membrane disease (HMD) in five neonates (0.95%), all of whom were delivered before 34 weeks' gestation. Mimouni and associates compared outcomes of 127 IDMs with matched controls and concluded that well-controlled diabetes in pregnancy is not a direct risk factor for the development of RDS. Yet cesarean delivery not preceded by labor and prematurity, both of which are increased in diabetic pregnancies, clearly increases the likelihood of neonatal respiratory disease. With cesarean delivery, many of these cases represent retained lung fluid or transient tachypnea of the newborn, which usually resolves within the first days of life.

## Calcium and Magnesium Metabolism

Neonatal hypocalcemia, with serum levels below 7 mg/dL or an ionized level less than 4 mg/dL, occurs at an increased rate in IDMs when controlling for predisposing factors such as prematurity and birth asphyxia. With modern management, the frequency of neonatal hypocalcemia is less than 5% in IDMs. Hypocalcemia in IDMs has been associated with a failure to increase parathyroid hormone synthesis following birth. Decreased serum magnesium levels have also been documented in pregnant diabetic women as well as in their infants. Mimouni and associates described reduced amniotic fluid magnesium

**TABLE 40-3 NEONATAL BODY COMPOSITION**

|              | <b>GDM (N = 195)</b> | <b>NGT (N = 220)</b> | <b>P VALUE</b> |
|--------------|----------------------|----------------------|----------------|
| Weight (g)   | 3398 $\pm$ 550       | 3337 $\pm$ 549       | .26            |
| FFM (g)      | 2962 $\pm$ 405       | 2975 $\pm$ 408       | .74            |
| Fat mass (g) | 436 $\pm$ 206        | 362 $\pm$ 198        | .0002          |
| Body fat     | 12.4 $\pm$ 4.6       | 10.4 $\pm$ 4.6       | .0001          |

FFM, fat-free mass; GDM, gestational diabetes mellitus; NGT, normal glucose tolerance.

concentrations in women with type 1 DM. These findings may be explained by a drop in fetal urinary magnesium excretion, which would accompany a relative magnesium-deficient state. Paradoxically, magnesium deficiency may then inhibit fetal parathyroid hormone secretion.

### Hyperbilirubinemia and Polycythemia

Hyperbilirubinemia is frequently observed in the IDM. Neonatal jaundice has been reported in as many as 25% to 53% of pregnancies complicated by pregestational DM and 38% of pregnancies in women with GDM. Jaundice observed in IDMs can be attributed largely to prematurity. However, jaundice is also increased in macrosomic IDMs.

Although severe hyperbilirubinemia may be observed independent of polycythemia, a common pathway for these complications most likely involves increased RBC production, which is stimulated by increased erythropoietin (EPO) in the IDM. Presumably, the major stimulus for red cell production is a state of relative hypoxia in utero. Cord EPO levels generally are normal in IDMs whose mothers demonstrate good glycemic control during gestation; however, hemoglobin A1c (HbA1c) values in late pregnancy are significantly elevated in mothers of hyperbilirubinemic infants.

### Cardiomyopathy

A transient form of cardiomyopathy may occur in IDMs. Among symptomatic infants, septal hypertrophy may cause left ventricular outflow obstruction. Although most infants are asymptomatic, respiratory distress or signs of cardiac failure may arise. Cardiac hypertrophy likely results from fetal hyperinsulinemia, which leads to fat and glycogen deposition in the myocardium. Thus cardiomyopathy generally occurs in pregnancies complicated by macrosomia in which glucose levels are poorly controlled. Elevated levels of B-type natriuretic peptide (BNP) produced during cardiac stress have been reported in umbilical blood of IDMs and have been correlated with maternal glycemic control. In most cases, symptoms of cardiomyopathy improve over several weeks with supportive care, and echocardiographic changes resolve as well.

## MATERNAL CLASSIFICATION AND RISK ASSESSMENT

Priscilla White first noted that the patient's age at onset of diabetes, the duration of the disease, and the presence of vasculopathy significantly influenced perinatal outcome. Her classification system has been widely applied to pregnant women with diabetes, and a modification of this scheme is presented in Table 40-1. Counseling a patient and formulating a plan of management requires assessment of both maternal and fetal risk. The White classification may facilitate this evaluation, yet consideration of glycemic control in early pregnancy is also vital to risk assessment.

**Class A<sub>1</sub> DM includes those women who have demonstrated carbohydrate intolerance during an oral glucose tolerance test (GTT); however, their fasting and postprandial glucose levels are maintained within physiologic range by dietary regulation alone. Class A<sub>2</sub> includes women with GDM who require medical management that consists of insulin or oral hypoglycemic therapy** in response to repetitive elevations of fasting or postpartum glucose levels following dietary intervention.

Two international workshop conferences on gestational diabetes sponsored by the American Diabetes Association (ADA) in cooperation with the American College of Obstetricians and Gynecologists (ACOG) recommended that the term *gestational diabetes*, rather than *class A diabetes*, be used to describe women with carbohydrate intolerance of variable severity with onset or recognition during the present pregnancy. The definition applies whether insulin or only diet modification is used for treatment and whether the condition persists after pregnancy. It does not exclude the possibility that unrecognized glucose intolerance may have antedated the pregnancy or may have begun with pregnancy. **The increasing frequency of type 2 diabetes has drawn attention to the need to distinguish diabetes first identified in early pregnancy as most likely representing cases of "overt diabetes."** The term *gestational diabetes* fails to specify whether the patient requires dietary adjustment alone or treatment with diet and insulin. This distinction is important because those women who are normoglycemic while fasting appear to have a significantly lower perinatal mortality rate. Women with GDM who require medical management are at greater risk for a poor perinatal outcome than those whose diabetes is controlled by diet alone.

Women who require insulin are designated by the letters B, C, D, R, F, and T. Class B patients are those whose onset of disease occurs after age 20 years. They have had diabetes for less than 10 years and have no vascular complications. Included in this subgroup of patients are those who have been previously treated with oral hypoglycemic agents.

Class C diabetes includes patients whose onset of disease was between the ages of 10 and 19 years and those who have had the disease for 10 to 19 years. Vascular disease is not present.

Class D represents women whose disease is of 20 years' duration or more, those whose disease onset occurred before the age of 10 years, and those who have benign retinopathy. The latter includes microaneurysms, exudates, and venous dilation.

### Nephropathy

Renal disease develops in 25% to 30% of women with IDDM, with a peak incidence after 16 years of diabetes. **Overt diabetic nephropathy is diagnosed in women with type 1 or type 2 DM when persistent proteinuria exists in the absence of infection or other urinary tract disease. Damm and colleagues<sup>34</sup> have reported the prevalence of diabetic nephropathy during pregnancy to be 2.3% (5/220) in women with type 2 diabetes and 2.5% (11/445) in women with type 1 diabetes.** The criteria for diagnosis in the nonpregnant state includes a total urinary protein excretion (TPE) of greater than 500 mg in 24 hours or greater than 300 mg in 24 hours of urinary albumin excretion (UAE).

Before the development of overt diabetic nephropathy, some individuals develop incipient diabetic nephropathy defined by repetitive increases in UAE known as *microalbuminuria*. The diagnosis is established from a 24-hour urine collection exhibiting UAE of 20 to 199 µg/min or 30 to 299 mg in 24 hours. It is important to note that women who exhibit microalbuminuria in early pregnancy have a 35% to 60% risk for superimposed preeclampsia.<sup>35</sup> Without specific interventions, about 80% of individuals with type 1 diabetes who develop sustained microalbuminuria experience an increase in UAE of 10% to 20% per year, leading to overt nephropathy. In the nonpregnant individual, improvement of glycemic and blood pressure control has been demonstrated to reduce the risk for, or slow the progression

of, diabetic nephropathy. Renoprotective or antihypertensive therapy consisting of either angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers (ARBs) is indicated in nonpregnant women with diabetes who exhibit microalbuminuria or overt nephropathy. **In contrast, both ACE inhibitors and ARBs are contraindicated during pregnancy because they may result in fetal proximal tubal dysgenesis and oligohydramnios.** A population-based study by Cooper and colleagues<sup>36</sup> has indicated potential teratogenesis in women who received ACE inhibitors in early pregnancy and thus calls into question whether such agents are advised in women attempting conception. These researchers studied a cohort of 29,507 infants enrolled in Tennessee Medicaid born between 1985 and 2000 for whom there was no evidence of maternal diabetes. A total of 209 infants with exposure to ACE inhibitors during the first trimester alone were compared with 202 infants exposed to other antihypertensives during the first trimester and with 29,096 infants with no exposure to any antihypertensive agents during pregnancy. Major congenital malformations were identified from linked vital records and hospitalization claims during the first year of life. Infants with only first-trimester exposure to ACE inhibitors had an increased risk for major congenital malformations (RR, 2.71; 95% CI, 1.72 to 4.27) compared with infants who had no fetal exposure to other antihypertensive medications during only the first trimester. The increased risk conferred by ACE inhibitor exposure manifested as primarily anomalies of the cardiovascular and central nervous systems. Clearly, given this information, the risk and benefits of use of ACE inhibitors in diabetic women planning pregnancy must be considered.

Women with diabetic nephropathy have a significantly reduced life expectancy. Disease progression is characterized by hypertension, declining glomerular filtration rate (GFR), and eventual end-stage renal disease (ESRD) that requires dialysis or transplantation. In women with overt nephropathy, ESRD occurs in 50% by 10 years and in greater than 75% by 20 years.

**Class F describes pregnant women with underlying renal disease. This includes those with reduced creatinine clearance or proteinuria of at least 500 mg in 24 hours measured during the first 20 weeks of gestation.** Two factors present before 20 weeks' gestation appear to be predictive of adverse perinatal outcome in these women (e.g., preterm delivery, low birthweight, or preeclampsia): proteinuria greater than 3 g per 24 hours and serum creatinine greater than 1.5 mg/dL.

In a series of 45 class F women, 12 women had such risk factors.<sup>37</sup> Preeclampsia developed in 92%, with a mean

gestational age at delivery of 34 weeks, compared with an incidence of preeclampsia of 36% in 33 women without these risk factors who reached an average gestational age of 36 weeks. Remarkably, perinatal survival was 100% in this series, and no deliveries occurred before 30 weeks' gestation. Comparable series' detailing perinatal outcomes in class F patients are presented in Table 40-4.

The management of the diabetic woman with nephropathy requires great expertise. Limitation of dietary protein, which may reduce protein excretion in nonpregnant patients, has not been adequately studied during pregnancy. Although controversial, some nephrologists recommend a modified reduction in protein intake for pregnant women with nephropathy. **Control of hypertension in pregnant women with diabetic nephropathy is crucial to prevent further deterioration of kidney function and to optimize pregnancy outcome.** Suboptimal control of blood pressure has been associated with a significantly increased risk for preterm delivery in this population. **Thus in contrast to higher suggested thresholds for treatment in nondiabetic individuals, some have recommended instituting antihypertensive therapy to maintain blood pressure less than 135/85 mm Hg in pregnant women with nephropathy.**<sup>38</sup> Prospective studies to evaluate blood pressure targets in pregnant women with diabetic nephropathy have not been conducted. Because calcium channel blockers have renoprotective effects similar to those of ACE inhibitors and do not appear to be teratogenic, these agents are our first choice for treatment of hypertension in pregnant women with diabetic nephropathy. Whether such agents benefit normotensive pregnant women with microalbuminuria or nephropathy has not been determined. Other options for treatment include labetalol or hydralazine.

Studies are limited and conflict as to whether a permanent worsening of diabetic renal disease in women with mild to moderate renal insufficiency occurs as a result of pregnancy. Several small studies of women with serum creatinine greater than 1.5 mg/dL suggest that pregnancy may be associated with a more rapid decline in postpartum renal function. The increased risk of ESRD in nondiabetic women with previous preeclampsia also raises the question as to whether preeclampsia has an independent effect on the incidence and progression of diabetic nephropathy. **In summary, no deleterious effect on the progression of diabetic nephropathy is apparent provided that serum creatinine is in the normal range and significant proteinuria is absent in early pregnancy.**<sup>39</sup> In a review of 35 pregnancies complicated by diabetic nephropathy,

proteinuria increased in 69%, and hypertension developed in 73%. After delivery, proteinuria declined in 65% of cases. In only two patients did protein excretion increase after gestation. In Gordon's series, 26 women (58%) had more than a 1-g increase in proteinuria, and by the third trimester, 25 (56%) excreted more than 3 g in 24 hours. In most cases, protein excretion returned to baseline levels after gestation.

Normal pregnancy is marked by an approximate 50% increase in GFR, and thus a rise in creatinine clearance, accompanied by a modest decline in serum creatinine. Most women with diabetic nephropathy, however, do not exhibit a rise in creatinine clearance during gestation. In a study of 46 class F pregnancies, Gordon and colleagues reported a mean decrease in creatinine clearance of 7.9%. When evaluated according to initial creatinine clearance, no difference in the degree of change was noted when subjects were classified according to first-trimester renal function. Whereas few patients exhibited a rise in creatinine clearance, other smaller studies have demonstrated an increase in creatinine clearance in about one third of women. Given the importance of blood pressure control in reducing cardiovascular and renal complications in the nonpregnant state, Carr and colleagues<sup>40</sup> studied the effect of poorly controlled hypertension in early pregnancy on renal function in 43 women with type 1 diabetes with nephropathy. Those women with mean arterial pressure in excess of 100 mm Hg demonstrated higher serum creatinine levels (1.23 vs. 0.895 mg/dL) compared with women with controlled hypertension.

With overt diabetic nephropathy, both albumin and total protein excretion may rise significantly during gestation. Importantly, a rise in total protein excretion to levels exceeding 300 mg in 24 hours may also be observed in women both with and without microalbuminuria in early pregnancy. Biesenbach and Zazgornik reported an average increase by the third trimester in total protein excretion to 478 mg in 24 hours in seven women with microalbuminuria in early pregnancy. This observation underscores the importance of obtaining baseline 24-hour urine measurements for total protein in all diabetic women because confusion arises as to the significance when new-onset macroalbuminuria or proteinuria is detected during the third trimester. Despite this recommendation, it may be challenging to distinguish preeclampsia from the natural progression of diabetic nephropathy, which often manifests as progressive proteinuria during pregnancy.

Gordon and colleagues<sup>37</sup> have detailed the progressive rise in proteinuria during pregnancy in 46 class F pregnancies. The mean increase in proteinuria between initial values and third-trimester values was 3.08 ( $\pm 4$  g) in 24 hours. Twenty-six women (58%) had more than a 1-g increase in proteinuria, and by the third trimester, 25 (56%) excreted more than 3 g in 24 hours, including three women who exceeded 10 g in 24 hours. The mean change in proteinuria was not correlated with alterations in creatinine clearance, and a similar increase in proteinuria was observed during pregnancy regardless of the initial level present.

**In summary, changes in creatinine clearance are variable during pregnancy in women with diabetic nephropathy. Most women with nephropathy will not exhibit a normal rise in creatinine clearance. Protein excretion will frequently rise during gestation to levels that can reach the nephrotic range.**

With improved survival of diabetic patients after renal transplantation, a growing number of kidney recipients have now achieved pregnancy (class T). Attempting pregnancy is not advised until 2 years after transplantation. Mycophenolate is

contraindicated during pregnancy, and a decision as to whether to discontinue this drug prior to conception should be individualized. Most diabetic renal transplant patients have underlying hypertension, although in one series of 28 women, preeclampsia was diagnosed in only 17% of cases. Allograft rejection occurred in one case. Overall, despite an increase in deliveries before 37 weeks, perinatal survival was 100%. These excellent results have come from improvements in both perinatal management and newer immunosuppressive regimens.

Many transplantation centers strive to perform combined kidney-pancreas transplantations in diabetic individuals with ESRD. Gilbert-Hayn and McGrory reviewed pregnancy outcomes in 43 pancreas-kidney recipients, of whom 66% developed hypertension and 77% had pregnancies that resulted in preterm birth. In this series, 6% of women experienced a rejection episode during pregnancy.

## Retinopathy

**Class R diabetes designates women with proliferative retinopathy, which represents neovascularization or growth of new retinal capillaries. These vessels may cause vitreous hemorrhage with scarring and retinal detachment, which results in vision loss.** As with nephropathy, prevalence of retinal disease is highly related to the duration of diabetes. At 20 years, nearly 80% of diabetic individuals have some element of diabetic retinopathy. Background changes are generally apparent, whereas proliferative diabetic retinopathy fortunately complicates only 3% of pregnancies. Excellent glycemic control prevents retinopathy and may slow its progression. Parity is not associated with a risk for subsequent retinopathy; however, pregnancy does convey more than a twofold independent risk for progression of existing retinopathy. **Progression of diabetic retinopathy during pregnancy is associated with (1) retinal status at inception, (2) duration and early onset of diabetes, (3) elevated first-trimester HbA1c and persistent poor glycemic control or rapid normalization of blood glucose, and (4) hypertension.**<sup>41</sup> Retinopathy may worsen significantly during pregnancy despite the major advances that have been made in diagnosis and treatment of existing retinopathy. Ideally, women planning a pregnancy should have a comprehensive eye examination and treatment before conception. For those discovered to have proliferative changes during pregnancy, laser photocoagulation therapy with careful follow-up has helped maintain many pregnancies to a gestational age at which neonatal survival is likely.

In a large series of 172 patients, including 40 cases with background retinopathy and 11 with proliferative changes, only one patient developed new-onset proliferative retinopathy during pregnancy. A review of the literature by Kitzmiller and colleagues<sup>42</sup> confirms the observation that progression to proliferative retinopathy during pregnancy rarely occurs in women with background retinopathy or in those without any eye-ground changes. Of the 561 women in these two categories, only 17 (3%) developed neovascularization during gestation. In contrast, 23 of 26 (88.5%) with untreated proliferative disease experienced worsening retinopathy during pregnancy.

Pregnancy may increase the prevalence of some background retinal changes. Characteristic streak-blob hemorrhages and soft exudates have been noted, and such retinopathy may progress despite strict metabolic control. At least two studies have related worsening retinal disease to plasma glucose at the first prenatal visit as well as the magnitude of improvement in glycemia during early pregnancy. In a subset of 140 women without

proliferative retinopathy at baseline followed in the Diabetes in Early Pregnancy Study, progression of retinopathy was seen in 10.3%, 21.1%, 18.8%, and 54.8% of patients with no retinopathy, microaneurysms only, mild nonproliferative retinopathy, and moderate to severe nonproliferative retinopathy at baseline, respectively. Elevated glycosylated hemoglobin at baseline and the magnitude of improvement of glucose control through week 14 were associated with a higher risk for progression of retinopathy. Women with an initial glycohemoglobin greater than 6 standard deviations (SDs) above the control mean were nearly three times as likely to experience worsening retinopathy compared with those within 2 SDs of the mean. Whether improving control or simply suboptimal control contributes to a deterioration of background retinopathy remains uncertain. Hypertension may also be a significant risk factor for the progression of retinopathy during pregnancy. **For women with proliferative changes, laser photocoagulation is indicated, and most will respond to this therapy. However, women who demonstrate severe florid disc neovascularization that is unresponsive to laser therapy during early pregnancy may be at great risk for deterioration of their vision.** Termination of pregnancy may need to be considered in this group of patients.

In labor, women with proliferative retinopathy are generally advised to avoid the Valsalva maneuver to reduce the risk for retinal hemorrhage. Shortening of the second stage of labor or cesarean delivery has been advocated; however, studies are lacking that address this issue.

In addition to background and proliferative eye disease, vaso-occlusive lesions associated with the development of macular edema have been described during pregnancy. Cystic macular edema is most often found in patients with proteinuric nephropathy and hypertensive disease, leading to retinal edema; macular capillary permeability is a feature of this process, and the degree of macular edema is directly related to the fall in plasma oncotic pressure present in these women. In one series, seven women with minimal or no retinopathy before becoming pregnant developed severe macular edema associated with preproliferative or proliferative retinopathy during the course of their pregnancies. Although proliferation was controlled with photocoagulation, the macular edema worsened until delivery in all cases and was often aggravated by photocoagulation. Although both macular edema and retinopathy regressed after delivery in some patients, in others, these pathologic processes persisted and resulted in significant visual loss.

### Coronary Artery Disease

**Class H diabetes refers to the presence of diabetes of any duration associated with ischemic myocardial disease.** Symptomatic coronary artery disease is rare in type 1 diabetic women who are younger than 35 years. It is unknown whether the small number of women who have coronary artery disease are at an increased risk for infarction during gestation. The maternal mortality rate exceeded 50% for cases of infarction during pregnancy reported before 1980; however, all but 1 of 23 cases reported from 1980 to 2005 survived. A high index of suspicion for ischemic heart disease should be maintained in women with long-standing diabetes because anginal symptoms may be minimal in women, and infarction may present as congestive heart failure. Although more than a dozen reports have described successful pregnancies following myocardial infarction (MI) in diabetic women, cardiac status should be carefully assessed early in gestation or, preferably, before pregnancy. If

electrocardiographic (ECG) abnormalities are encountered, echocardiography may be used to assess ventricular function, or modified stress testing may be performed. The decision to undertake a pregnancy in a woman with type 1 or type 2 DM and coronary artery disease needs to be made only after serious consideration. The potential for morbidity and mortality must be thoroughly reviewed with the patient and her family. The management of MI during pregnancy is discussed in [Chapter 37](#).

### EARLY SCREENING FOR OVERT DIABETES AND DETECTION OF GESTATIONAL DIABETES MELLITUS

**The frequency of diabetes complicating pregnancy has generally been estimated to be as high as 6% to 7% with approximately 90% of these cases representing women with GDM.**<sup>43</sup> Utilizing a pregnancy risk-assessment monitoring system between 2007 and 2010, DeSisto and colleagues<sup>43</sup> confirmed that the prevalence of GDM is rising in the United States and may now be as high as 9.2%. The increasing frequency of GDM can be attributed to the worldwide obesity epidemic as well the introduction of less stringent criteria for the diagnosis now being adapted by some institutions. An increased prevalence of GDM is found in women of ethnic groups that have high frequencies of type 2 diabetes. These include women of Hispanic, African, Native American, Asian, and Pacific Island ancestry. Women with GDM represent a group with significant risk for developing glucose intolerance later in life. O'Sullivan projected that 50% of women with GDM would become diabetic in follow-up at 22 to 28 years. Kjos and colleagues reported that 60% of Latina women will develop type 2 diabetes, and this level of risk may actually be manifest by 5 years after the GDM index pregnancy. The likelihood for subsequent diabetes increases when GDM is diagnosed in early pregnancy and when maternal fasting glucose levels are elevated. Presumably, some of these women with impaired  $\beta$ -cell function may represent cases of unidentified preexisting type 2 diabetes.

As noted earlier, GDM is a state restricted to pregnant women whose impaired glucose tolerance (IGT) is discovered during pregnancy. Because in most cases, patients with GDM have normal fasting glucose levels, some challenge of glucose tolerance must be undertaken. Traditionally, obstetricians relied on historic and clinical risk factors to select those patients most likely to develop GDM. This group included patients with a family history of diabetes and those whose past pregnancies were marked by an unexplained stillbirth or the delivery of a malformed or macrosomic infant. Obesity, hypertension, glycosuria, and maternal age older than 25 years were other indications for screening. Although multiple risk factors may increase the likelihood of GDM, more than half of all women who exhibit an abnormal GTT lack any of these risk factors.

The ACOG suggests that all pregnant women be screened for GDM, whether by the patient's medical history, clinical risk factors, or laboratory screening tests to determine blood glucose levels ([Box 40-2](#)). Screening is generally performed at 24 to 28 weeks' gestation, when the "diabetogenic state" of pregnancy has been established. ACOG also recommends early pregnancy screening for undiagnosed type 2 diabetes in women with a previous history of GDM, a history of impaired glucose metabolism, or those who are obese. Studies validating various approaches to early pregnancy screening for both type 2 diabetes and GDM

**BOX 40-2 SCREENING STRATEGY FOR DETECTING GDM**

GDM risk assessment should be ascertained at the first prenatal visit.

- Low risk: Blood glucose testing is not routinely required if *all* of the following characteristics are present:
  - Member of an ethnic group with a low prevalence of GDM
  - No known diabetes in first-degree relatives
  - Age <25 years
  - Weight normal before pregnancy
  - No history of abnormal glucose metabolism
  - No history of poor obstetric outcome
- Average risk: Perform blood glucose testing at 24 to 28 weeks by one of the following methods:
  - Two-step procedure: A 50-g GCT followed by a diagnostic oral GTT in those who meet the threshold value in the GCT
  - One-step procedure: Diagnostic oral GTT performed on all subjects
- High risk: Perform blood glucose testing as soon as feasible using the procedures described above if one or more of these are present:
  - Severe obesity
  - Strong family history of type 2 diabetes
  - Previous history of GDM, impaired glucose metabolism, or glucosuria

If GDM is not diagnosed, blood glucose testing should be repeated at 24 to 28 weeks or anytime a patient has symptoms or signs suggestive of hyperglycemia.

From Metzger BE, Buchanan TA, Coustan DR, et al. Summary and recommendations of the Fifth International Workshop Conference on Gestational Diabetes Mellitus. *Diabetes Care*. 2010;30:3154. GCT, glucose challenge test; GDM, gestational diabetes mellitus; GTT, glucose tolerance test.

are, however, lacking. A simple approach to early screening for diabetes is to obtain an HbA1c level in women believed to be at greatest risk. A diagnosis of overt diabetes is made if the level is greater than or equal to 6.5%. If the level is between 5.7% and 6.4%, suggesting impaired glucose tolerance, a diagnostic oral GTT is performed. For those women with normal results or those with an HbA1c level less than 5.7%, screening for GDM is then undertaken at 24 to 28 weeks. Recently, Hughes and colleagues<sup>44</sup> suggested that an early HbA1c level greater than or equal to 5.9% is optimal for detecting overt diabetes in women at less than 20 weeks' gestation and also identifies women at increased risk of adverse pregnancy outcomes.

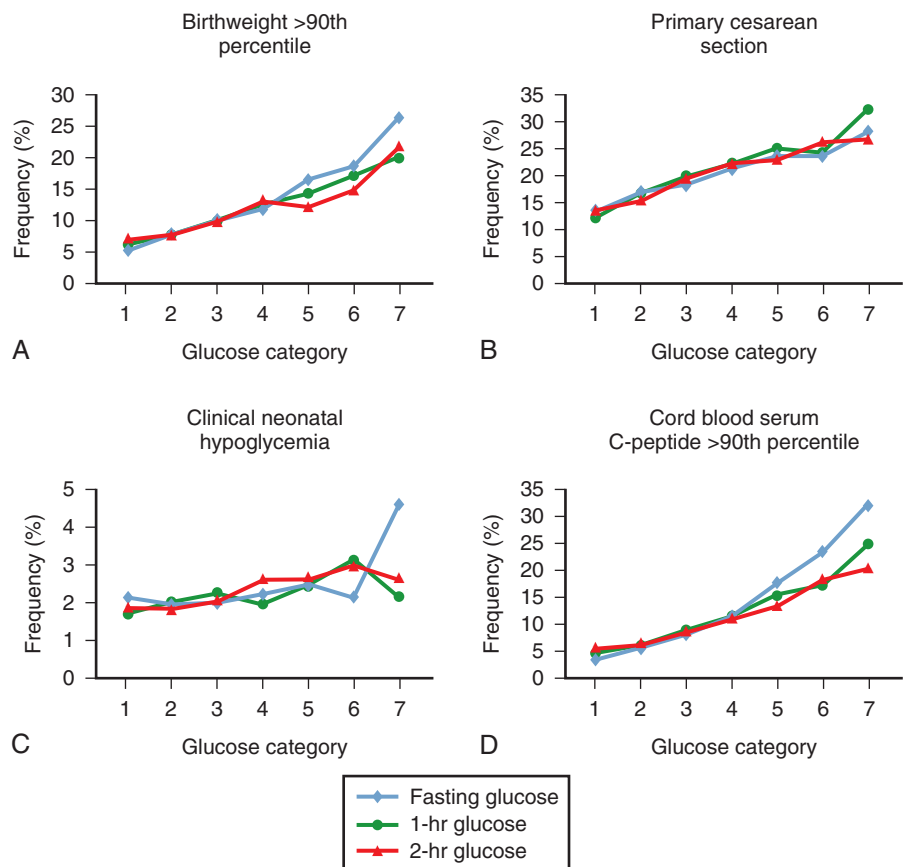

Despite the widespread acceptance of screening for and treating GDM in the United States, expert panels have only recently recognized the benefit of GDM screening programs altogether.<sup>45,46</sup> The criteria for the diagnosis of GDM originally designated a population at increased risk for the development of type 2 diabetes in later life. The fact that O'Sullivan's original work that established the criteria used for the diagnosis of GDM failed to evaluate an association between mild carbohydrate tolerance and perinatal outcome led many to question the overall significance of this diagnosis.

**The Hyperglycemia and Adverse Pregnancy Outcome (HAPO) study was designed to aid in the development of internationally agreed-upon diagnostic criteria for GDM based on their predictive value for pregnancy outcome.**<sup>47</sup> This landmark multicenter international study allowed for analysis of blinded, 75-g, 2-hour oral GTT data in more than 25,000

gravidas without pregestational diabetes. Glycemia was evaluated in relation to various perinatal and maternal outcomes. **Increases in each of the three values on the 75-g, 2-hour oral GTT were associated with graded increases in the likelihood of outcomes such as an LGA infant, cesarean delivery, fetal C-peptide levels, and neonatal adiposity (Fig. 40-14).** The HAPO study investigators did not offer specific recommendations for the diagnostic criteria of GDM. Because a continuous association was found between glucose values and perinatal outcome, it was apparent that any new recommended diagnostic criteria would need to be arrived at by consensus. To meet this challenge, the International Association of Diabetes and Pregnancy Study Groups (IADPSG) convened a workshop conference in 2008.<sup>48</sup> An odds ratio of 1.75 greater than the mean was selected for the outcomes of increased neonatal body fat, LGA, and cord serum C-peptide greater than the 90th percentile, which yielded the recommended diagnostic criteria for GDM (Table 40-5).

Importantly, the IADPSG task force recommended that a 75-g, 2-hour oral GTT be performed universally during pregnancy and that the diagnosis of GDM be made when any single value on the oral GTT was met or exceeded.<sup>48</sup> Using the proposed criteria, 17.8% of the HAPO study population would be identified as having GDM. A recent retrospective cohort study confirmed a greater than twofold increased risk of LGA infants among the offspring of untreated women who met only the IADPSG criteria for diagnosis of GDM (and not the ACOG accepted Carpenter and Coustan criteria) when compared with a control population.<sup>46</sup> There are, however, no data from randomized treatment trials regarding therapeutic interventions for the expanded group of women identified as having GDM using IADPSG criteria for the diagnosis. This important consideration was paramount to the conclusions of the 2013 Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD) Consensus Development Conference on diagnosing GDM.<sup>49</sup> The conferees recommended that health care providers continue to use a two-step approach to the screening and diagnosis of GDM because no evidence suggests that using the 2-hour oral GTT criteria to diagnose GDM would lead to clinically significant improvements in maternal or newborn outcomes and that a significant increase in health care costs would accompany adoption of the IADPSG criteria. Another major concern with the IADPSG approach is the reliance on a single oral GTT value to confer the diagnosis of GDM.<sup>49</sup> Theoretic cost-benefit analyses have suggested a benefit to using the IADPSG criteria; however, one such study recognized the benefit to hinge on follow-up and potential prevention of type 2 diabetes in the additional group of women identified as having GDM using IADPSG criteria. Proponents of the IADPSG approach to diagnosis cite (1) the fact that the two-step approach may miss approximately 25% of GDM in those who pass the 50-g screen yet demonstrate an abnormal oral GTT, and (2) the rate of prediabetes in women in the United States is approximately 26%, and this figure is not very different from the rate of GDM using the IADPSG criteria. A recent systematic review of diagnostic thresholds for GDM concluded that a pragmatic approach to the diagnosis of GDM utilizing a HAPO study odds ratio (OR) of 2.0 as a threshold, in contrast to the IADPSG criteria (OR, 1.75), warrants further consideration, until additional analysis of the data comparing mutually exclusive groups of women is provided and large randomized controlled trials (RCTs) to investigate different diagnostic thresholds

**FIG 40-14** Frequency of perinatal and maternal outcomes in relation to maternal glycemia. (Modified from Metzger BE, Lowe LP, Dyer AR, for the HAPO Study Cooperative Research Group: Hyperglycemia and adverse pregnancy outcomes. *N Engl J Med*. 2008;358:1991.)

**TABLE 40-5** INTERNATIONAL ASSOCIATION OF DIABETES AND PREGNANCY STUDY GROUPS’ DEFINITION OF GDM\*

| GLUCOSE         |           |       | FREQUENCY OF GDM (%)    |
|-----------------|-----------|-------|-------------------------|
| Fasting glucose | 92 mg/dL  | Alone | 8.3                     |
| 1-hr glucose    | 180 mg/dL | Plus  | 5.7 = 14                |
| 2-hr glucose    | 153 mg/dL | Plus  | 2.1 = 16.1 <sup>†</sup> |

From Metzger BE, Gabbe SG, Persson B, for the International Association of Diabetes and Pregnancy Study Groups Consensus Panel. Recommendations on the diagnosis and classification of hyperglycemia in pregnancy. *Diabetes Care*. 2010;33:676.  
\*Based on a universal, 75-g, 2-hr glucose tolerance test. Diagnosis of GDM is made if one value is met or exceeded.  
<sup>†</sup>Approximately 1.7% of the HAPO study population were unblinded because of fasting glucose  $\geq 105$  mg/dL and/or at 2 hr,  $\geq 200$  mg/dL. As a result, the frequency of GDM in this population would be 17.8%.  
GDM, gestational diabetes mellitus.

are completed.<sup>50,51</sup> Utilizing an OR of 2.0 with HAPO-derived data would result in a frequency of GDM of approximately 10%, in contrast to the 18% when using the proposed IADPSG thresholds.<sup>52</sup> To date, two observational and one cross-sectional study have confirmed a markedly increased frequency of GDM utilizing the IADPSG criteria for diagnosis without a reduction in LGA infants.<sup>53,54</sup> The ADA recently summarized the dilemma concerning the two strategies—the IADPSG one-step approach using a 2-hour, 75-g oral GTT versus the traditional two-step method using a diagnostic 3-hour oral GTT—with the following key points:

1. Data are insufficient to strongly demonstrate the superiority of one strategy over the other.
2. The decision of which strategy to implement must therefore be made based on relative values placed on currently unmeasured factors (e.g., cost-benefit estimation; willingness to change practice based on correlation studies, rather than on clinical intervention trial results; relative role of cost considerations; and available infrastructure).
3. Further research is needed to resolve these uncertainties.

**At the present time, most practitioners in the United States continue to perform glucose-challenge screening followed by a diagnostic 100-g oral GTT (two-step approach).** The 50-g glucose challenge may be performed in the fasting or fed state. Sensitivity is improved if the test is performed in the fasting state. **A plasma value between 130 and 140 mg/dL is commonly used as a threshold for performing a 3-hour oral GTT (Table 40-6).** Coustan and coworkers have demonstrated that 10% of women with GDM have screening test values between 130 and 139 mg/dL. This study indicated that the sensitivity of screening would be increased from 90% to nearly 100% if universal screening were used with a threshold of 130 mg/dL. The prevalence of positive screening tests that require further diagnostic testing increases from 14% (140 mg/dL) to 23% (130 mg/dL), which is accompanied by about a 12% increase in the overall cost to diagnose each case of GDM.

Using the plasma cutoff of 135 to 140 mg/dL, approximately 15% to 20% of patients with an abnormal screening value can be expected to have an abnormal 3-hour oral GTT. Patients

| 3-hr glucose                   | 145                     | 110                 |

\*Diagnosis of gestational diabetes is made when any two values are met or exceeded in a 100-g, 3-hour test.

GDM, gestational diabetes mellitus; GTT, glucose tolerance test; NDDG, National Diabetes Data Group.

whose 1-hour screening value exceeds 190 mg/dL (10.5 mmol/L) will exhibit an abnormal oral GTT in 90% of cases. In women with a screening value between 190 and 215 mg/dL, it is preferable to check a fasting blood glucose level before administering a 100-g carbohydrate load. If the fasting glucose is greater than 95 mg/dL, the patient is treated for GDM.

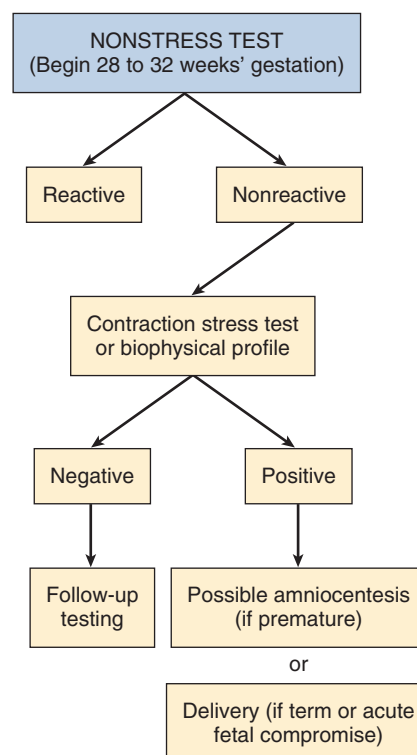

The criteria for establishing the diagnosis of gestational diabetes based on a 100-g, 3-hour oral GTT are listed in Table 40-6. Both sets of diagnostic criteria are endorsed by ACOG. The U.S. National Diabetes Data Group (NDDG) criteria represent a theoretic conversion of O'Sullivan's thresholds in whole blood. Carpenter and Coustan prefer to use another modification of these data, which is supported by a comparison of the old Somogyi-Nelson method and current plasma glucose oxidase assays. Several studies have confirmed that patients diagnosed using the less stringent Carpenter and Coustan criteria experience as much perinatal morbidity (macrosomia and cesarean delivery) as subjects diagnosed by the NDDG criteria. In one study of 26,000 women that compared the two sets of criteria using cross-sectional data, the diagnosis of GDM increased approximately 50% utilizing the Carpenter-Coustan criteria. A recent secondary analysis of the NICHD Maternal-Fetal Medicine Units (MFMU) Network RCT for mild GDM demonstrated that the beneficial treatment effect was seen in subjects diagnosed by both NDDG and Carpenter-Coustan criteria. Using either of the two 100-g, 3-hour oral GTT criteria, the patient must have at least two abnormal glucose determinations to be diagnosed with GDM.

## TREATMENT OF THE PATIENT WITH TYPE 1 OR TYPE 2 DIABETES MELLITUS

Clinical efforts aimed at optimizing maternal control are considered the key component responsible for the decline in perinatal deaths in pregnancies complicated by DM over the past few decades. Self-monitoring of blood glucose, combined with intensive insulin therapy, has resulted in improved glycemia for many pregnant diabetic women. Women with pregestational diabetes should monitor their glucose control six to eight times daily using glucose-oxidase-impregnated reagent strips and a glucose reflectance meter. Target glucose levels for control of diabetes during pregnancy have been established largely based on expert opinion (Table 40-7). A recent review of twelve studies concerning patterns of glycemia in normal pregnancy suggested that glucose concentrations are significantly lower than suggested normal therapeutic targets (Fig. 40-16).<sup>55</sup>

**TABLE 40-7** TARGET PLASMA GLUCOSE LEVELS IN PREGNANCY

| TIME                                | GLUCOSE LEVEL (mg/dL) |
|-------------------------------------|-----------------------|
| Before breakfast                    | 60-90                 |
| Before lunch, supper, bedtime snack | 60-105                |
| One hour after meals                | ≤140                  |
| Two hours after meals               | ≤120                  |
| 2 AM to 6 AM                        | >60                   |

**FIG 40-15** Algorithm for antepartum fetal testing.

The technology of continuous glucose monitoring (CGM) has been studied in pregnant diabetic women. By providing a total of 288 measurements daily, compared with six to eight blood glucose measurements using self-monitoring of blood glucose, CGM can provide a more complete glycemic profile and can presumably detect unrecognized postprandial hyperglycemia as well as symptomatic hypoglycemia. A randomized trial of 71 women with pregestational diabetes confirmed a lower third-trimester HbA1c level and reduced birthweight and macrosomia in women who underwent CGM.

Insulin therapy is recommended by the ADA as the primary medication to achieve optimal glycemic control in pregnant women with both type 1 and type 2 diabetes. Women with type 2 diabetes may present in early pregnancy on an oral agent for treatment of their diabetes. Our approach is to continue metformin therapy in well-controlled type 2 diabetic women, whereas those receiving other agents are generally switched to insulin therapy. Many type 2 diabetic women who enter pregnancy with their disease controlled with metformin will eventually require the addition of insulin to their regimen. To achieve the best glycemic control possible for each patient, conventional insulin therapy is abandoned during pregnancy in favor of intensive therapy. Insulin regimens have classically included multiple injections of

**FIG 40-16** Patterns of glycemia in normal pregnancy. BG, blood glucose; FBG, fasting blood glucose; PP, postpartum; SD, standard deviation. (From Hernandez TL, Friedman JE, Van Pelt RE, Barbour LA. Patterns of glycemia in normal pregnancy: should the current therapeutic targets be challenged? *Diabetes Care*. 2011;34:1660.)

insulin—usually before breakfast, lunch, the evening meal, and often at bedtime—complemented by self-monitoring of blood glucose and adjustment of insulin dose according to glucose profiles. Patients are instructed on dietary composition, insulin action, recognition and treatment of hypoglycemia, adjusting insulin dosage for exercise and sick days, as well as monitoring for hyperglycemia and potential ketosis. **These principles form the foundation for intensive insulin therapy in which an attempt is made to simulate physiologic insulin requirements. Insulin administration is provided for both basal needs and meals, and rapid adjustments are made in response to glucose measurements. The treatment regimen generally involves three to four daily injections or the use of continuous subcutaneous insulin infusion (CSII) devices.** With either approach, frequent self-monitoring of blood glucose is fundamental to achieve the therapeutic objective of physiologic glucose control. Glucose determinations are made in the fasting state and before lunch, dinner, and at bedtime. Postprandial and nocturnal values are also advised. Patients are instructed on an insulin dose for each meal and at bedtime, if necessary. Mealtime insulin needs are determined by the composition of the meal, the premeal glucose measurement, and the level of activity anticipated following the meal. Basal or intermediate-acting insulin

requirements are determined by periodic 2:00 AM to 4:00 AM glucose measurements, as well as late afternoon values, which reflect morning intermediate-acting insulin action.

In patients whose diabetes is not well controlled, a brief period of hospitalization may be necessary for the initiation of therapy. Patients are encouraged to contact their physician at any time if questions should arise concerning the management of their diabetes. **During pregnancy, we advise women to report their glucose values by telephone, fax, or e-mail on at least a weekly basis.**

Insulin therapy must be individualized with dosage determinations tailored to diet and exercise. Insulin requirements during pregnancy have been reported to average 0.7 U/kg in the first trimester, increasing to 1.1 U/kg by term, although the variation in requirements is considerable. Garcia-Patterson and colleagues have noted a steady increase in insulin requirements from 16 to 37 weeks, and unstable requirements are common before 16 weeks. **Semisynthetic human insulin preparations and newer insulin analogues (Table 40-8) are preferred for use during pregnancy. Insulin lispro and insulin aspart are rapid-acting insulin preparations that have replaced regular insulin.** Insulin lispro features reversal of proline and lysine at positions B28 and B29, and because it remains in monomeric form, it is

rapidly absorbed. Its duration of action is shorter than that of regular insulin, so unexpected hypoglycemia hours after injection is avoided. Insulin lispro appears to be safe for use during pregnancy and is a category B drug. Insulin aspart has also been compared with human insulin in women with type 1 diabetes during pregnancy, and comparable fetal outcomes have been observed among both groups; however, limited information exists concerning glycemia in treated women (see Table 40-8).

The long-acting insulin analogues glargine and detemir have been designed to more accurately mimic basal insulin secretion. Observational data would suggest that use of insulin glargine is safe during pregnancy; it has a flat profile, compared with neutral protamine Hagedorn (NPH), so that when administered with rapid-acting insulin, unpredictable spikes in insulin levels and resultant hypoglycemia appear to be less common. **However, the flat profile of glargine may be undesirable during pregnancy when variation in basal insulin needs are likely. For this reason, we frequently suggest that women who receive glargine change to a twice-daily regimen of NPH insulin. A multicenter trial that compared insulin detemir with NPH insulin in 310 type 1 diabetic pregnant women demonstrated equivalent efficacy of insulin detemir with respect to hypoglycemic episodes and HbA1c levels.<sup>56</sup> The U.S. Food and Drug Administration (FDA) has now designated insulin detemir as a class B medication. Our approach is to maintain patients on insulin detemir if their blood glucose is well controlled.**

Insulin is generally administered in three to five injections. We prefer a four-injection regimen, although most patients present taking a combination of intermediate-acting (NPH) and short-acting (lispro or aspart) insulin before dinner and breakfast. As a general rule, the amount of intermediate-acting insulin will exceed the short-acting component by a 2:1 ratio. Patients usually receive two thirds of their total dose with breakfast and the remaining third in the evening as a combined dose at dinner or split into components with short-acting or rapid-acting insulin at dinner and intermediate-acting insulin at bedtime in an effort to minimize periods of nocturnal hypoglycemia. These episodes frequently occur when the mother is in a relative fasting state, whereas placental and fetal glucose consumption continue. Finally, some women may require a small dose of short-acting insulin before lunch, thus constituting a four-injection regimen.

Open-loop CSII pump therapy is preferred by many women with type 1 diabetes during pregnancy. The pump is a battery-powered unit that may be worn like a beeper during most daily activities. These systems provide continuous short-acting insulin therapy through a subcutaneous infusion. The basal infusion rate and bolus doses to cover meals are determined by frequent self-monitoring of blood glucose.

Pregnant women may need to be hospitalized before initiation of pump therapy. Women must be educated regarding the strategy of continuous infusion and should have their glucose stabilized over several days. This requires that multiple blood glucose determinations be made for the prevention of periods of hyperglycemia and hypoglycemia. Most recently, pump therapy has been linked with a CGM system to provide this information. Glucose values may become normalized with minimal amplitude of daily excursions in most patients.

Episodes of hypoglycemia are often reduced with pump therapy. When they do occur, they are usually secondary to errors in dose selection or failure to adhere to the required diet. The risk for nocturnal hypoglycemia, which is increased in the

pregnant state, necessitates that great care be undertaken in selecting patients for CSII. Patients using the pump who fail to exhibit normal counterregulatory responses to hypoglycemia should probably check their glucose values at 2:00 AM to 3:00 AM to detect nocturnal hypoglycemia.

The mechanics of the CSII systems are relatively simple. A fine-gauge infusion cannula is attached by connecting tubing to the pump. This cannula is reimplanted every 2 to 3 days at a different site, usually in the anterior abdominal wall. Rapid-acting insulin (usually insulin lispro) is stored in the pump syringe. Infusion occurs at a basal rate, which can be fixed or altered for a specific time of day by a computer program. For example, the basal rate can be programmed for a lower dose at night. Preprandial boluses can be adjusted manually before each meal and snack. Half of the total daily insulin is usually given as the basal rate with the remainder given as boluses infused before each meal. The largest bolus (30% to 35%) is administered with breakfast, followed by 25% before dinner and 15% to 20% before snacks.

Patients without any pancreatic reserve may have rapid elevations of blood glucose if the pump fails or if intercurrent infection is present. Since the advent of buffered insulin, insulin aggregation leading to occlusion of the Silastic infusion tubing is uncommon. Failure of the pump is associated with a steady rise in ketonemia in the nonpregnant patient.

It is unclear whether CSII is superior to multiple-injection regimens. Coustan and colleagues randomized 22 patients to intensive conventional therapy with multiple injections versus pump therapy. No differences were found between the two treatment groups with respect to outpatient mean glucose levels, glycosylated hemoglobin levels, or glycemic excursions. Gabbe and colleagues reported a large retrospective cohort study of women who began pump therapy during gestation compared with a group treated with multiple-injection regimens. Women using pumps, most with insulin lispro, had fewer hypoglycemic reactions and comparable glucose control and pregnancy outcomes. Notably, **a systematic review that compared randomized trials of CSII versus multiple-injection regimens revealed no difference in measures of glycemic control or pregnancy outcome.<sup>57</sup>**

**Diet therapy is critical to successful regulation of maternal diabetes. A program that consists of three meals and several snacks is used for most patients.** Dietary composition should be 40% to 60% complex high-fiber carbohydrates, 20% protein, and 30% to 40% fat with less than 10% saturated fats, up to 10% polyunsaturated fatty acids, and the remainder derived from monosaturated sources. Caloric intake is established based on prepregnancy weight and weight gain during gestation. Weight reduction is not advised. Patients with a BMI of 22 to 27 should consume about 35 kcal/kg ideal body weight. Obese women (BMI > 30) may be managed with an intake as low as 15 kcal/kg actual weight. Any further caloric restriction that results in ketonuria requires an increase in caloric consumption. In general, caloric distribution is as follows: 10% to 20% with breakfast, 20% to 30% with lunch, 30% to 40% percent with dinner, and up to 30% as snacks. Snacks may be necessary to minimize episodes of hypoglycemia, especially at bedtime (Box 40-3).

**The presence of maternal vasculopathy should be thoroughly assessed early in pregnancy by an ophthalmologist familiar with diabetic retinopathy. Ophthalmologic examinations are performed during each trimester and are repeated**

**BOX 40-3 DIETARY RECOMMENDATIONS**

- Three meals, three snacks
- Diet: 30-35 kcal/kg normal body weight, 2000 to 2400 kcal/day
- Composition: carbohydrate 40%-50% complex, high fiber; protein 20%; fat 30%-40% (<10% saturated)
- Weight gain: per Institute of Medicine guidelines

**BOX 40-4 LESSONS LEARNED**

- Remember that the patient is more than her blood glucose.
- Do not underestimate the patient's insight; ask for her input in determining what changes to make in order to improve glucose control.
- Keep the insulin program simple and make changes based on patterns.
- Enlist the support of the patient's family.
- Avoid hypoglycemic reactions.
- Work closely with the health care team, including the nurse educator, nutritionist, and social worker.
- When glucose control is poor, it is often the diet.
- Weekends are not our "friends," especially three- and four-day weekends; they change the patient's daily routine, and glucose control may worsen.
- When changing the insulin regimen, try to change just one insulin and one dose at a time.
- Insulin analogues are valuable.
- Respond aggressively to nausea, vomiting, and fever.

From Gabbe SG, Carpenter LB, Garrison EA. New strategies for glucose control in patients with type 1 and type 2 diabetes mellitus in pregnancy. *Clin Obstet Gynecol*. 2007;50:1014.

**more often if retinopathy is detected.** Baseline renal function is established by assaying a 24-hour urine collection for creatinine clearance and protein. An ECG and urine culture are also obtained.

Most patients with type 1 and type 2 DM are followed with outpatient visits at 1- to 2-week intervals. At each visit, control is assessed and adjustments in insulin dosage are made; however, patients should be instructed to call at any time if periods of hypoglycemia (<60 mg/dL) or hyperglycemia (>200 mg/dL) occur. Ketone testing is advised for persistent glucose levels that exceed 200 mg/dL. **The increased risk for hypoglycemia in pregnant individuals may be related to defective glucose counterregulatory hormone mechanisms, and both epinephrine and glucagon appear to be suppressed in pregnant diabetic women during hypoglycemia.** For these reasons, patients should test glucose levels frequently, and family members should be instructed on the technique of glucagon injection for the treatment of severe reactions. [Box 40-4](#) provides some important lessons we have learned over the years in caring for our patients.

**Ketoacidosis**

**With the implementation of antenatal care programs that stress strict metabolic control of blood glucose levels for women who require insulin, diabetic ketoacidosis (DKA) has fortunately become a less common occurrence. DKA has been reported to complicate between 0.5% and 3.0% of diabetic pregnancies.**<sup>58</sup> Kilvert and colleagues reported 11 cases of ketoacidosis in 635 insulin-treated pregnancies over a 20-year

period. One fetal loss and one spontaneous miscarriage complicated the affected pregnancies.

**DKA can occur in the newly diagnosed diabetic patient, and the hormonal milieu of pregnancy may become the background for this phenomenon.** Because pregnancy is a state of insulin resistance marked by enhanced lipolysis and ketogenesis, DKA may develop in a pregnant woman with glucose levels that barely exceed 200 mg/dL (11.1 mmol/L). **This phenomenon has been referred to as euglycemic ketoacidosis.** DKA occurs in a background of impaired insulin action with an increase in counterregulatory hormones such as glucagon, cortisol, and catecholamines. Thus, because of the contrainsulin state of pregnancy with a predisposition to lipolysis, DKA may be diagnosed during pregnancy with minimal hyperglycemia accompanied by a fall in plasma bicarbonate (anion gap acidosis), a pH value less than 7.30, and ketonemia.

Early recognition of signs and symptoms of DKA improves both maternal and fetal outcome. As in the nonpregnant state, clinical signs of volume depletion follow the symptoms of hyperglycemia, which include polydipsia and polyuria. Malaise, headache, nausea, and vomiting are common complaints. **A pregnant diabetic woman with poor fluid intake and persistent vomiting over 8 to 12 hours should be evaluated for potential DKA.** A low serum bicarbonate level prompts an arterial blood gas determination to rule out this diagnosis. Occasionally, DKA presents in a woman with undiagnosed diabetes who receives  $\beta$ -mimetic agents such as terbutaline to arrest preterm labor.

Once the diagnosis of DKA is established and the patient is stabilized, she should be transported to a facility where tertiary care in both perinatology and neonatology is available. Therapy hinges on the meticulous correction of metabolic and fluid abnormalities. An attempt at treatment of any underlying cause for DKA, such as infection, should be initiated as well. The general management of DKA in pregnancy is outlined in [Box 40-5](#). **Fluid resuscitation and insulin infusion should be maintained even in the face of normoglycemia until bicarbonate levels return to normal, indicating that acidemia has cleared.** DKA does represent a substantial risk for fetal compromise, and the combined effects of maternal acidosis, hyperglycemia-induced hyperinsulinemia, dehydration, and electrolyte abnormalities may result in stillbirth. Not surprisingly, fetal heart rate monitoring may reveal late decelerations ([Fig. 40-17](#)). Fortunately, **successful fetal resuscitation often accompanies correction of maternal acidosis.** However, this process may take several hours. Therefore every effort should be made to correct and stabilize the mother's condition before intervening and delivering a preterm infant.

**ANTEPARTUM FETAL EVALUATION**

Maternal diabetes can result in fetal hyperglycemia and hyperinsulinemia and can thereby increase the risk for fetal hypoxia. Thus protocols for antepartum fetal assessment in pregnancies complicated by DM have been incorporated into the care plan for outpatient monitoring. A program of fetal surveillance is initiated during the third trimester, when the risk for sudden intrauterine death increases ([Tables 40-9 and 40-10](#)). To date, no randomized trials of fetal monitoring have been done in pregnancies complicated by diabetes to provide clinical evidence, so decisions regarding the timing of initiation of testing, as well as the frequency, often follow local custom. **Because improvement in maternal glucose control has played a major**

**BOX 40-5 MANAGEMENT OF DIABETIC KETOACIDOSIS DURING PREGNANCY****Intravenous Fluids**

Isotonic sodium chloride is used, with total replacement of 4-6 L in the first 12 hr.

- Insert intravenous catheters: Maintain hourly flow sheet for fluids and electrolytes, potassium, insulin, and laboratory results.
- Administer normal saline (0.9% NaCl) at 1-2 L/hr for the first hour.
- Infuse normal saline at 250 to 500 mL/hr depending on hydration state (8 hr). If serum sodium is elevated, use half-normal saline (0.45% NaCl).
- When plasma or serum glucose reaches 200 mg/dL, change to 5% dextrose with 0.45% NaCl at 150-250 mL/hr.
- After 8 hr, use half-normal saline at 125 mL/hr.

**Potassium**

Establish adequate renal function (urine output ~50 mL/hr).

- If serum potassium is <3.3 mEq/L, hold insulin and give 20-30 mEq K<sup>+</sup>/hr until K<sup>+</sup> is >3.3 mEq/L or is being corrected.
- If serum K<sup>+</sup> is >3.3 mEq/L but <5.3 mEq/L, give 20-30 mEq K<sup>+</sup> in each liter of IV fluid to keep serum K<sup>+</sup> between 4 and 5 mEq/L.
- If serum K<sup>+</sup> is >5.3 mEq/L, do not give K<sup>+</sup> but check serum K<sup>+</sup> every 2 hr.

**Insulin**

Use regular insulin intravenously.

- Consider a loading dose of 0.1-0.2 U/kg as an IV bolus depending on plasma glucose.
- Begin continuous insulin infusion at 0.1 U/kg/hr.
- If plasma or serum glucose does not fall by 50-70 mg/dL in the first hour, double the insulin infusion every hour until a steady glucose decline is achieved.
- When plasma or serum glucose reaches 200 mg/dL, reduce insulin infusion to 0.05-0.1 U/kg/hr.
- Keep plasma or serum glucose between 100 and 150 mg/dL until resolution of diabetic ketoacidosis.

**Bicarbonate**

Assess need, and provide based on pH.

- pH >7.0: No HCO<sub>3</sub><sup>-</sup> is needed.
- pH is 6.9-7.0: Dilute NaHCO<sub>3</sub> (50 mmol) in 200 mL H<sub>2</sub>O with 10 mEq KCl and infuse over 1 hr. Repeat NaHCO<sub>3</sub> administration every 2 hr until pH is 7.0. Monitor serum K<sup>+</sup>.
- pH <6.9-7.0: Dilute NaHCO<sub>3</sub> (100 mmol) in 400 mL H<sub>2</sub>O with 20 mEq KCl and infuse for 2 hr. Repeat NaHCO<sub>3</sub> administration every 2 hr until pH is 7.0. Monitor serum K<sup>+</sup>.

role in reducing perinatal mortality in diabetic pregnancies, antepartum fetal monitoring tests are now used primarily to reassure the obstetrician and to avoid unnecessary premature intervention. These techniques have few false-negative results, and in a woman with well-controlled diabetes and no vasculopathy or significant hypertension, reassuring antepartum testing allows the fetus to benefit from further maturation in utero. A subset of women who had diabetes prior to gestation will have falling insulin requirements in late pregnancy, which in limited cohort studies have not been associated with adverse outcomes. However, in a recent retrospective review of 139 pregnancies of

women with preexisting diabetes, 25% of women had greater than a 15% fall in insulin requirements, which was associated with an increased risk of preeclampsia and SGA infants.<sup>59</sup> Prospective studies are needed to confirm these findings in order to guide clinical management when insulin requirements decline in late pregnancy.

Maternal assessment of fetal activity serves as a simple screening technique in a program of fetal surveillance. During the third trimester, women are instructed to perform daily fetal movement counts. Women with a variety of high-risk antepartum conditions, including diabetes, appear to have an increased incidence of alarming fetal activity patterns. Although the false-negative rate with maternal monitoring of fetal activity is low (~1%), the false-positive rate may be as high as 60%. Although generally believed to be associated with decreased fetal movement, maternal hypoglycemia may actually stimulate fetal activity.

The nonstress test (NST) remains the preferred primary method to assess antepartum fetal well-being in the patient with DM. If the NST is nonreactive, a biophysical profile (BPP) or contraction stress test (CST) is then performed (see Fig. 40-15). We generally begin heart rate monitoring by 32 weeks' gestation. Two studies have also demonstrated an increased fetal death rate within 1 week of a reactive NST in pregnancies complicated by IDDM compared with other high-risk gestations. **If the NST is to be used as the primary method of antepartum heart rate testing, we prefer that it be done at least twice weekly after the patient reaches 32 weeks' gestation. In some centers, twice-weekly testing includes an NST followed several days later by a BPP. In patients with vascular disease, poor glucose control, or suspected FGR in whom the incidence of abnormal tests and intrauterine deaths is greater, testing is often initiated between 28 and 32 weeks' gestation.**

Doppler umbilical artery velocimetry has been proposed as a clinical tool for antepartum fetal surveillance in pregnancies at risk for placental vascular disease (see Chapter 33). Because Doppler studies of the umbilical artery may be predictive of fetal

**FIG 40-17** Fetal heart rate monitoring during an acute episode of diabetic ketoacidosis. **A**, Recurrent late decelerations are observed. **B**, Following hydration and correction of acidosis, the tracing improves. **C**, Fetal tracing in a patient with acute diabetic ketoacidosis at 34 weeks' gestation demonstrating repetitive late decelerations (solid arrows) and minimal variability. An emergency cesarean delivery was performed. The arterial cord pH was 6.85. (From Sibai B. Diabetic ketoacidosis in pregnancy. *Obstet Gynecol.* 2014;123:167.)

outcome in diabetic pregnancies complicated by vascular disease, we reserve the use of screening Doppler measurements for women with nephropathy or hypertensive disease. Elevated placental resistance, as evidenced by an increased systolic-to-diastolic ratio, is associated with FGR and preeclampsia in these high-risk patients. In contrast, patients with well-controlled diabetes without vascular disease rarely demonstrate abnormal fetal umbilical artery waveforms.

**It is important not only to include the results of antepartum fetal testing but also to weigh all of the clinical features that involve the mother and fetus before deciding to intervene for suspected fetal compromise, especially if this decision may result in a preterm delivery** (see [Tables 40-9](#) and [40-10](#)). Our review of studies that comprised 993 diabetic women revealed that in 5% of cases, an abnormal test of fetal condition led to delivery. It appears that outpatient testing pro-

ocols work well in diabetic patients who require insulin. Abnormal fetal testing is more common in women whose diabetes is poorly controlled and in those who have hypertension or significant vasculopathy that may be associated with FGR. It follows that these subgroups probably benefit most from a program of antepartum fetal surveillance.

Ultrasound can be a valuable tool in evaluating fetal growth, estimating fetal weight, and detecting hydramnios and malformations. Maternal serum alpha-fetoprotein (MSAFP) determination at 16 weeks' gestation is often used in association with a detailed ultrasound study during the midtrimester in an attempt to detect NTDs and other anomalies (see [Chapter 10](#)). Levels of MSAFP, unconjugated estriol (uE<sub>3</sub>), and inhibin A in diabetic women are lower than those in the nondiabetic population. A lower threshold for the upper limit of normal (ULN) for MSAFP, 1.5 multiples of the median (MoM), may thus be preferable in

pregnancies complicated by DM in order to help detect spina bifida and other major malformations that are increased in this population. **A comprehensive ultrasound examination at 18 to 20 weeks, as well as fetal echocardiography performed at 20 to 22 weeks, is undertaken to diagnose fetal anomalies. Whereas the risk for defects, including cardiac anomalies, is increased with markedly elevated maternal HbA1c levels, the frequency in women with moderate control remains elevated compared with that of nondiabetic pregnancies. Thus we prefer to utilize fetal echocardiography as a screening tool in all type 1 and type 2 diabetic pregnancies.** Greene and Benacerraf performed detailed sonography in the midtrimester and detected 18 of 32 malformations in a series of 432 diabetic pregnancies. The specificity was in excess of 99%, and the negative predictive value was 97%. Spina bifida was identified in all cases; however, ventricular septal defects, limb abnormalities, and facial clefts were missed. A review of the prenatal diagnosis experience in 289 women with IDDM in the Ohio State University Diabetes in Pregnancy Program revealed 29 anomalies, of which 12 were cardiac, 14 were noncardiac, and 3 were combined. Twelve of 15 cardiac (80%) and 10 of 17 noncardiac lesions (59%) were identified prenatally. When considering cardiac defects alone, we could not identify a glycosylated hemoglobin cutoff for these anomalies. Starikov and colleagues<sup>60</sup> identified 30 fetal cardiac defects in a series of 535 diabetic women and noted the risk to be 8.3% in women with an HbA1c greater than 8.5%, compared with 3.9% in those below this cutoff.

Ultrasound examinations should be performed during the third trimester to assess fetal growth. The detection of fetal macrosomia, the leading risk factor for shoulder dystocia, is important in the selection of patients who are best delivered by cesarean section. **An increased rate of cephalopelvic disproportion and shoulder dystocia, accompanied by significant risk for traumatic birth injury and asphyxia, has been consistently associated with vaginal delivery of large infants. The risk for such complications rises exponentially when birthweight exceeds 4 kg, and it is greater for the fetus of a diabetic mother when compared with a fetus with similar weight whose mother does not have diabetes (Fig. 40-18).**<sup>61</sup>

**FIG 40-18** Frequency of shoulder dystocia for increasing birthweight by maternal diabetes status and method of vaginal delivery, spontaneous or assisted. (Modified from Nesbitt TS, Gilbert WM, Herrchen B. Shoulder dystocia and associated risk factors with macrosomic infants born in California. *Am J Obstet Gynecol.* 1998;17:476.)

Sonographic measurements of the fetal abdominal circumference have proved most helpful in predicting fetal macrosomia. The abdomen is likely to be large because of increased subcutaneous fat deposition. However, it is critical to recognize that a single ultrasound examination may have limited accuracy in predicting macrosomia at term in women with diabetes. Using serial sonographic examinations, accelerated abdominal growth may be identified between 28 and 32 weeks' gestation in pregnancies complicated by diabetes.<sup>62</sup>

## TIMING AND MODE OF DELIVERY

**Delivery should be delayed until fetal maturation has taken place, provided diabetes is well controlled and antepartum surveillance remains normal.** The ACOG suggests delivery be delayed until 39 weeks in women without vascular disease whose diabetes is well controlled. In our practice, induction of labor is often planned at 39 to 40 weeks' gestation in such patients. For diabetic women with vascular disease, it has been suggested that delivery may be undertaken at 37 to 39 weeks. Women with vascular disease are delivered prior to 37 weeks only if hypertension worsens, if significant FGR is present, or if biophysical testing mandates early delivery. Depending on clinical circumstances, antenatal corticosteroids may be administered to accelerate fetal lung maturity. This must be done with caution because significant maternal hyperglycemia may be observed for several days after antenatal corticosteroids are given. In women with poor glycemic control, an individualized approach to the timing of delivery is recommended. Options may include late preterm or early term delivery or amniocentesis to assess lung maturity prior to delivery. **Tests of fetal lung maturity appear to have the same predictive value in diabetic pregnancies as in the normal population.**

The presence of the acidic phospholipid phosphatidylglycerol (PG) is the final marker of fetal pulmonary maturation. Several authors have suggested that fetal hyperinsulinemia may be associated with delayed appearance of PG and an increased incidence of RDS. Landon and coworkers have correlated the appearance of PG in amniotic fluid with maternal glycemic control during gestation. RDS may occur in the IDM with a mature lecithin-to-sphingomyelin (L/S) ratio or fetal lung maturity index but absent PG. Moore<sup>63</sup> compared PG production in amniotic fluid specimens from 295 diabetic women and 590 matched controls and reported that the onset of PG production was delayed in GDM from  $35.9 \pm 1.1$  weeks to  $37.3 \pm 1$  weeks and to  $38.7 \pm 0.9$  weeks in pregestational diabetic pregnancies. In this study, delayed appearance of PG was not associated with the level of glycemic control. In addition, the lamellar body count may be used to assess amniotic fluid for lung maturity; cut-off values in diabetic patients are similar to those in the nondiabetic population (see Chapter 11).

**When antepartum testing suggests fetal compromise, delivery must be considered. If amniotic fluid analysis yields a test result that indicates lung maturity, delivery should be accomplished promptly. In the presence of presumed lung immaturity, the decision to proceed with delivery should be based on confirmation of deteriorating fetal condition by several tests that show abnormal values.** For example, if the NST and the BPP indicate fetal compromise, delivery is indicated. Finally, several maternal indications exist for delivery that include significant preeclampsia, worsening renal function, and deteriorating vision secondary to proliferative retinopathy.

**Choosing the route of delivery for the diabetic patient remains controversial.** Cesarean delivery rates as high as 50% are common in series of pregestational diabetic women. This figure is likely to represent the practice trends of most obstetricians and perinatologists in the United States. A trial of labor following previous cesarean delivery may be undertaken in select cases and has a reported success rate of 64%.

**The increased rate of shoulder dystocia and brachial plexus injury in the offspring of diabetic women has prompted adoption of early induction strategies, as well as selection of patients for cesarean delivery, based on ultrasound estimation of fetal size. Such approaches are limited by the relative inaccuracy of ultrasound prediction of birthweight.** Despite the limitations, Kjos and colleagues demonstrated that induction at 38 weeks in a population of women with GDM was associated with a lower frequency of LGA infants and shoulder dystocia without an increased rate of cesarean delivery. This is in contrast to studies of induction in nondiabetic women, in which suspected macrosomia is apparently associated with an increased rate of cesarean delivery. In a decision tree analysis of cost-effectiveness, Rouse and colleagues found that whereas elective cesarean delivery for macrosomia to prevent permanent brachial plexus injury was prohibitively expensive in the nondiabetic woman, at a cost of several million dollars per permanent brachial plexus injury prevented, 489 cesarean deliveries—at a cost per avoided birth injury of \$880,000 per case—for those diabetic pregnancies with an estimated fetal size greater than 4000 g seemed to be at least tenable.

The overall risk for shoulder dystocia in the macrosomic fetus of an IDM is greater than in large infants of normal pregnancy. The risk for shoulder dystocia with a fetal weight greater than 4000 g in diabetic gravidas is about 30%. Somewhat less impressive yet significantly greater frequencies of shoulder dystocia for delivery of a macrosomic fetus of IDMs, compared with non-IDMs, have been reported by Nesbitt and colleagues (see Fig. 40-18).<sup>61</sup> At present, the ACOG recommends consideration of cesarean delivery in diabetic women when estimated fetal weight exceeds 4500 g. Our approach continues to be to consider cesarean delivery when the estimated weight is 4000 to 4500 g after evaluating obstetric history and clinical pelvimetry. Despite attempts to select patients with obvious fetal macrosomia for elective cesarean delivery, arrest of dilation or descent despite adequate labor should alert the physician to the possibility of cephalopelvic disproportion. Approximately 25% of deliveries of macrosomic infants (>4000 g) following a prolonged second stage are complicated by shoulder dystocia; therefore it follows that cesarean delivery should be considered in a diabetic woman who demonstrates significant protracted labor or failure of descent.

## GLUCOREGULATION DURING LABOR AND DELIVERY

**Because neonatal hypoglycemia is in part related to maternal glucose levels during labor, it is important to maintain maternal plasma glucose levels within the physiologic normal range.** The patient is given nothing by mouth after midnight of the evening before induction or elective cesarean delivery. The usual bedtime dose of insulin is administered, or for women receiving pump therapy, the infusion is continued overnight. Upon arrival to labor and delivery, early in the morning, the patient's capillary glucose level is assessed with a bedside

### BOX 40-6 INSULIN MANAGEMENT DURING LABOR AND DELIVERY

- Usual dose of intermediate-acting insulin is given at bedtime.
- Morning dose of insulin is withheld.
- Intravenous infusion of normal saline is begun.
- Once active labor begins or glucose levels fall to <70 mg/dL, the infusion is changed from saline to 5% dextrose and is delivered at a rate of 2.5 mg/kg/min.
- Glucose levels are checked hourly using a portable reflectance meter allowing for adjustment in the infusion rate.
- Regular (short-acting) insulin is administered by intravenous infusion if glucose levels exceed 140 mg/dL.

From Jovanovic L, Peterson CM. Management of the pregnant, insulin-dependent diabetic woman. *Diabetes Care*. 1980;3:63.

reflectance meter. In women who use continuous insulin infusion pumps, this therapy may be used during the latent phase of labor or early in the induction process. Basal infusion rates are generally reduced, and boluses may be given based on carbohydrate consumption and to correct hyperglycemia. Once active labor begins, IV infusion of both insulin and glucose is then begun based on maternal glucose levels (Box 40-6). Also, 10 U of short-acting insulin may be added to 1000 mL of solution containing 5% dextrose. An infusion rate of 100 to 125 mL/hr (1 U/hr) will result in good glucose control in most cases. Insulin may also be infused from a syringe pump at a dose of 0.25 to 2 U/hr and adjusted to maintain normal glucose values. Glucose levels are recorded hourly during the active phase of labor, and the infusion rate is adjusted accordingly. Patients with well-controlled diabetes are often euglycemic once active labor begins and then require increased glucose infusion at a rate of 2.5 mg/kg/min, which mimics strenuous exercise requirements. During the second stage of labor, in response to hyperglycemia associated with increased catecholamine secretion, it may be necessary to increase the insulin infusion.

When cesarean delivery is to be performed, it should be scheduled for early morning. This simplifies intrapartum glucose control and allows the neonatal team to prepare for the care of the newborn. The patient is given nothing by mouth, and her usual morning insulin dose is withheld. If her surgery is not performed early in the day, one third to one half of the patient's intermediate-acting dose of insulin may be administered. Regional anesthesia allows detection of maternal hypoglycemia. Following surgery, glucose levels are monitored every 2 hours, and an IV solution of 5% dextrose is administered.

Postpartum insulin requirements are usually significantly lower than during pregnancy. The antepartum objective of tight glucose control is relaxed for the first 24 to 48 hours after delivery. Patients delivered vaginally who are able to eat a regular diet are given one third to one half of their end-of-pregnancy dose of NPH insulin and rapid-acting insulin the morning of the first postpartum day. Many patients with type 2 diabetes will not require insulin for 24 to 48 hours postpartum, and these women can be managed with insulin or oral agents as preferred; frequent glucose determinations are used to guide insulin dosage. Most patients are stabilized on this regimen within a few days after delivery.

Whether they receive insulin or oral agents, women with diabetes are encouraged to breastfeed. The additional 500 kcal required daily are given as approximately 100 g of carbohydrate and 20 g of protein. The insulin dose may be somewhat lower in lactating diabetic women. Hypoglycemia appears to be common in the first week after delivery and immediately after nursing.

## MANAGEMENT OF THE WOMAN WITH GESTATIONAL DIABETES

### Is There a Benefit to the Treatment of Gestational Diabetes Mellitus?

**The frequency of GDM has increased worldwide, and up to 14% of pregnancies are affected.**<sup>64</sup> With both an increased incidence and the proposed lowering of the threshold for diagnosis, the health care costs of GDM can be expected to rise proportionately. It follows that whether a benefit exists to the treatment of GDM has assumed even greater importance now than in the past.

The 2013 guidelines of the U.S. Preventive Services Task Force (USPSTF)<sup>45</sup> acknowledged a treatment benefit for GDM for the first time. Their systematic review and meta-analysis concluded that treatment of GDM results in less preeclampsia, shoulder dystocia, and macrosomia.

### Randomized Treatment Trials for Gestational Diabetes Mellitus

Two important RCTs conducted over the last decade have provided high-level evidence that treatment of GDM confers both maternal and perinatal benefits. The Australian Carbohydrate Intolerance Study in Pregnant Women (ACHOIS) was a multicenter, 10-year randomized treatment trial of 1000 women conducted at 14 sites in Australia.<sup>65</sup>

Treatment was associated with a significant reduction in the rate of the primary outcome, a composite of serious perinatal complications (perinatal death, shoulder dystocia, birth trauma that included fracture or nerve palsy; adjusted RR, 0.33; 95% CI, 0.14 to 0.75). Overall, seven infants in the treatment group had a serious complication (all shoulder dystocia) compared with 23 infants in the untreated group, of whom five experienced perinatal death, four had birth trauma, and 16 had shoulder dystocia.

Among secondary neonatal outcomes, no significant differences were found in the rates of neonatal hypoglycemia that required IV therapy, jaundice that required phototherapy, or respiratory disease that required supplemental oxygen. Neonatal intensive care unit (NICU) admissions were remarkably high in both groups: 71% in treated versus 61% in untreated patients ( $P = .01$ ). Importantly, treatment did reduce the frequency of LGA infants from 22% to 13% and birthweight greater than 4000 g from 21% to 10%. Among maternal outcomes, preeclampsia was significantly reduced with treatment (12% vs. 18%).

The ACHOIS study was followed by the NICHD MFMU Network RCT of 958 cases of mild GDM.<sup>66</sup> In this study, mild GDM was defined as a fasting glucose less than 95 mg/dL with two of the three postglucose values exceeding established thresholds.

These investigators found no significant difference in the frequency of the primary composite perinatal outcome—perinatal death, neonatal hypoglycemia, elevated cord C-peptide level, or

TABLE 40-11

RESULTS OF RANDOMIZED CONTROLLED TRIALS FOR TREATMENT OF GESTATIONAL DIABETES MELLITUS

|                   | LANDON ET AL <sup>66</sup> (2009) | CROWTHER ET AL <sup>65</sup> (2005) |
|-------------------|-----------------------------------|-------------------------------------|
| Preeclampsia      | ↓                                 | ↓                                   |
| Weight gain       | ↓                                 | ↓                                   |
| LGA infant        | ↓                                 | ↓                                   |
| Neonatal fat mass | ↓                                 | —                                   |
| Shoulder dystocia | ↓                                 | Not studied                         |

LGA, large for gestational age.

birth trauma—in the treatment group (32.4%) compared with the usual care group (37%;  $P = .14$ ). Several key differences in secondary outcomes, however, were observed with treatment, including a lower frequency of LGA infants with birthweight exceeding 4000 g and decreased neonatal fat mass.

Among maternal outcomes, rates of labor induction were similar between groups; however, cesarean delivery was performed less often in treated women (26.9% vs. 33.8). This rate remained lower after excluding cases of abnormal presentation, prior cesarean delivery, placenta previa, and oligohydramnios (13% vs. 19.7%;  $P = .011$ ). A lower rate of shoulder dystocia (1.5% vs. 4%) and preeclampsia or gestational hypertension (8.6% vs. 13.6%) was also found in the treatment group.

**In summary, the NICHD MFMU trial demonstrated that although treatment of mild GDM did not reduce the frequency of several neonatal morbidities characteristic of diabetic pregnancy, it did lower the risk for fetal overgrowth, neonatal fat mass, shoulder dystocia, cesarean delivery, and hypertensive disorders of pregnancy.**<sup>66</sup> These findings, along with those reported in the ACHOIS study, have confirmed a benefit to treatment of even mild carbohydrate intolerance of pregnancy (Table 40-11).

### Treatment of the Woman with Gestational Diabetes Mellitus

**The mainstay of treatment of GDM remains nutritional counseling and dietary intervention. The optimal diet should provide caloric and nutrient needs to sustain pregnancy without resulting in significant postprandial hyperglycemia.** Women with GDM generally do not need hospitalization for dietary instruction and management. Once the diagnosis is established, women are begun on a dietary program of 2000 to 2500 kcal daily. This represents approximately 35 kcal/kg of present pregnancy weight. For women who are overweight and obese, a reduction in caloric intake to 25 kcal/kg/day and 15 kcal/kg/day (present pregnancy weight), respectively, may be advised. Jovanovic-Peterson and Peterson have noted that the usually prescribed diet composed of 50% to 60% carbohydrate will cause excessive weight gain and postprandial hyperglycemia and will require insulin therapy in 50% of patients. For this reason, these authors have suggested limiting carbohydrates to 33% to 40% of calories. Barbour<sup>67</sup> has noted that with carbohydrate restriction, many women will substitute fat and thereby potentially transfer excess FFAs, which are associated with fetal fat accretion.

Complex carbohydrates are preferred to simple carbohydrates because they are less likely to produce significant postprandial hyperglycemia. A randomized crossover study found that liberalizing complex carbohydrate intake in GDM women resulted in

achievement of glycemia below current targets and also lowered postprandial FFA concentrations.<sup>68</sup> In spite of the widespread prevalence of GDM, Hernandez and colleagues<sup>69</sup> have noted that only six RCTs of 250 women have provided the evidence that a diet higher in complex carbohydrate and lower in simple sugar and saturated fat may be effective in blunting postprandial hyperglycemia and thereby preventing worsened insulin resistance and promoting excess fetal growth. Clearly, additional clinical trials are needed to help define the optimal diet for women with GDM. In light of the 2009 Institute of Medicine (IOM) recommendations concerning weight gain during pregnancy, the question arises as to their applicability to women with GDM. These guidelines did not specify recommendations for women with diabetes, yet limited weight gain may be advisable in obese diabetic women. The IOM recommends a weight gain of 11 to 20 lb for obese women (BMI 30 or greater). A specified carbohydrate-limited diet in obese women with GDM both improves glycemic control and reduces weight gain. An independent effect of maternal obesity, weight gain, and diabetes on birthweight is also apparent.

**Once the patient with GDM is placed on an appropriate diet, surveillance of blood glucose levels is necessary to be certain that glycemic control has been established.** We prefer to have patients perform daily self-monitoring of blood glucose that consists of a fasting glucose level and three postprandial determinations. We provide women with GDM with a reflectance meter and carefully review values following the initial week of diet intervention. In women with good control on diet therapy alone, the frequency of testing can be reduced and tailored accordingly. We do not use CGM in women with GDM, although reports exist of improved glycemic control and pregnancy outcomes in women with GDM utilizing this technology.<sup>70</sup>

Glycemic target thresholds of fasting glucose less than 95 mg/dL, 1-hour postprandial glucose less than 140 mg/dL, and 2-hour postprandial glucose less than 120 mg/dL have been suggested by the Fifth International Workshop Conference on GDM. If a patient repetitively exceeds established thresholds, pharmacologic therapy is recommended. In our experience, if the majority of values at a particular time point are elevated, pharmacologic therapy should be initiated. Approximately 25% to 50% of women with GDM require insulin or oral agents. Some cases are managed with a single dose of bedtime NPH insulin to treat isolated fasting hyperglycemia, whereas others require treatment of postprandial hyperglycemia with insulin lispro or aspart at appropriate mealtimes. Up to four injections daily may be necessary to achieve adequate control. Whereas some have recommended calculating starting insulin dosage based on body weight, we have typically prescribed 15 to 20 U of NPH insulin in the morning and at bedtime (if fasting glucose is elevated) along with 5 to 10 U of rapid-acting insulin to cover specific mealtime elevations. Continued monitoring of glucose levels with feedback allows the practitioner to make frequent adjustments in the insulin regimen. It is important to recognize that use of the previously mentioned cutoffs for initiating insulin are based on data regarding increased perinatal morbidity when such values are exceeded in women with preexisting diabetes. Data have yet to be gathered from controlled trials to identify ideal glycemic targets for prevention of fetal morbidity associated with GDM.

An observational study conducted by Langer and colleagues found that women with a fasting glucose between 96 and

105 mg/dL have a greater incidence of LGA infants (28.6%) when receiving diet therapy alone compared with those receiving both diet therapy and insulin. In women with an initial fasting glucose between 95 and 104 mg/dL, 70% required insulin therapy to achieve optimal control.

**During the past 15 years, oral hypoglycemic therapy has become a suitable alternative to insulin treatment in women with GDM.** At present, glyburide is the most commonly prescribed medication in the United States for the treatment of GDM.<sup>71</sup> Nicholson and colleagues<sup>72</sup> performed a systematic review of the evidence from randomized trials and observational studies and concluded that glycemia was equivalent in women who received oral hypoglycemic agents compared with those who received insulin. Moreover, no evidence suggested increased adverse neonatal outcomes with the use of oral hypoglycemic agents. ACOG recognizes that either insulin or oral agents may be appropriate first-line therapy for GDM. At present, data are insufficient to recommend treatment with any oral agent other than glyburide or metformin. In a landmark study, Langer and colleagues<sup>73</sup> reported results from a randomized trial of 404 women who received insulin versus glyburide and noted similar improvement in glycemia with both regimens. The frequency of macrosomia and neonatal hypoglycemia was similar in the two study groups. Only 4% of women failed glyburide therapy and required a change to insulin. Cord blood analysis revealed no detectable glyburide in exposed pregnancies. Subsequently, Hebert and colleagues reported that glyburide appears to cross the placenta in significant amounts; this observation has raised concerns regarding the safety of this agent. Importantly, clinical studies have revealed increased rates of neonatal hypoglycemia with glyburide use in GDM. It is, however, unknown whether glyburide can affect progression to type 2 diabetes in treated women or whether glucose homeostasis is altered later in life in their offspring.

Following Langer's randomized trial, several smaller studies reported success in achieving good glycemic control with glyburide but with slightly higher failure rates (15% to 20%). Jacobson and colleagues recently reported on the implementation of glyburide as an alternative to insulin in a large managed-care organization. These authors noted a similar frequency of LGA infants and macrosomia among 268 women treated with insulin compared with 236 who received glyburide. In this nonrandomized study, more women in the glyburide group achieved lower mean fasting and postprandial glucose levels compared with insulin-treated subjects. Importantly, the authors noted an increased rate of preeclampsia, need for neonatal phototherapy, and birth injury in the glyburide group, all of which point to the need for further study concerning safety.

Lain and colleagues performed a randomized trial of 99 women with GDM that compared glyburide with insulin treatment. These authors reported no increase in neonatal fat mass, BMI, ponderal index, or anthropometric measures in glyburide-treated offspring, although a significantly greater rate of infant birthweights higher than 4000 g was observed in the glyburide-treated group (22% vs. 2.4%). Similar to insulin therapy, glyburide action must be carefully balanced with meals and snacks to prevent maternal hyperglycemia. **Observational data suggest that glyburide may be less successful in obese women and in those with marked hyperglycemia discovered early in gestation.** In our experience, most women with fasting glucose levels of 115 mg/dL or higher will fail to achieve adequate glucose control with glyburide and will require insulin therapy

**BOX 40-7 SUMMARY OF GLYBURIDE VERSUS INSULIN TREATMENT IN GESTATIONAL DIABETES MELLITUS**

- Maternal fasting and postprandial glycemia comparable to that with insulin treatment
- Glyburide failure rate of 15%-20%
- Glyburide failures associated with earlier diagnosis of gestational diabetes and fasting glucose levels >110-115 mg/dL
- Comparable neonatal outcomes
- Significant cost savings

(Box 40-7). The usual dose of glyburide is 2.5 to 20 mg daily in divided doses, usually before breakfast and dinner, although pharmacokinetic studies during pregnancy indicate that a daily dose as great as 30 mg may be necessary to achieve adequate control. Caritis and Hebert have suggested that glyburide is optimally administered 30 to 60 minutes prior to a meal.

**Metformin has also been used for treatment of GDM. Although metformin clearly crosses the placenta, it does not appear to be teratogenic.** Rowan and colleagues<sup>74</sup> randomized 761 women with GDM at 20 to 33 weeks to metformin and insulin as needed versus insulin therapy alone. No differences in perinatal outcomes were reported, and a composite of perinatal morbidity—neonatal hypoglycemia, respiratory distress, birth trauma, prematurity, and need for phototherapy in the infant—was observed in about one third of women in each group. Metformin use was well tolerated, and treated women gained less weight than those who received insulin; however, 46% of these women required supplemental insulin to achieve glycemic control. A 2-year follow-up study of the offspring from this trial reported no significant difference in total body fat or central adiposity between infants of metformin-treated mothers versus those of insulin-treated mothers; however, an increase in subcutaneous adiposity was reported. Carlsen and colleagues<sup>75</sup> reported that in offspring of women who were continued on with metformin treatment for polycystic ovary syndrome, no difference was reported at birth in infant weight or length; however, at 1 year of age, the offspring of the women who used metformin in pregnancy were heavier than in the placebo group ( $10.2 \pm 1.2$  vs.  $9.7 \pm 1.1$  kg,  $P = .003$ ). Further follow-up of these children is necessary to determine the significance of this finding. Another, smaller follow-up study<sup>76</sup> at 18 months of children exposed to metformin in utero found these offspring to be taller and heavier than insulin-exposed children. Body composition did not differ between the two groups.

**It appears that glyburide may be superior to metformin in achieving satisfactory glucose control in women with GDM.** A randomized trial<sup>77</sup> of 149 women compared metformin with glyburide for the treatment of GDM and found that 35% of women randomized to metformin, compared with 16% who received glyburide, required insulin to achieve adequate control.

Exercise may serve as a useful adjunctive treatment for women with GDM. Physical exercise may improve glycemic control because increased insulin sensitivity accompanies cardiovascular conditioning. A randomized study of 41 women with GDM who manifested elevated fasting glucose levels and would normally require insulin therapy utilized a supervised bicycle ergometry training program. No statistical differences were observed in weekly blood glucose determinations between the study groups. Another study that used arm ergometry three

times per week resulted in a significant reduction in mean fasting glucose in the exercise group as well as a reduction in glucose concentration following a 1-hour, 50-g challenge. Because the total number of women with GDM studied in randomized trials is limited, the role of exercise as a primary therapy in GDM remains unknown. Nonetheless, a program of moderate exercise has been advocated by the ADA as part of the treatment of GDM.

**Women with GDM that is well controlled are at low risk for an IUFD. For this reason, we do not routinely institute antepartum fetal heart rate testing in uncomplicated diet-controlled GDM. Women with a hypertensive disorder, a history of a prior stillbirth, or suspected macrosomia do undergo fetal testing.**<sup>78</sup> Additionally, those who require insulin or oral agents for treatment of GDM undergo twice-weekly heart rate testing at 32 weeks' gestation. Using such a protocol at the Ohio State University Hospital Diabetes in Pregnancy Program, we observed only six intrauterine deaths in more than 3500 women with uncomplicated GDM in the past 25 years. Thus it appears that the third-trimester stillbirth rate in these patients is no higher than that of the general obstetric population. A study of 389 women with GDM documented an antepartum stillbirth rate of 7.7 per 10,000, which was not significantly different from the rate of 4.8 per 1000 observed in nondiabetic low-risk patients. In this study, because only 7% of fetuses were delivered on the basis of a low BPP score, the benefit of testing all GDM pregnancies remains in question. At present, without prospective studies to compare outcomes in monitored and unmonitored women with GDM without other risk factors, it is not possible to determine whether any benefits exist to antepartum fetal surveillance in this population.

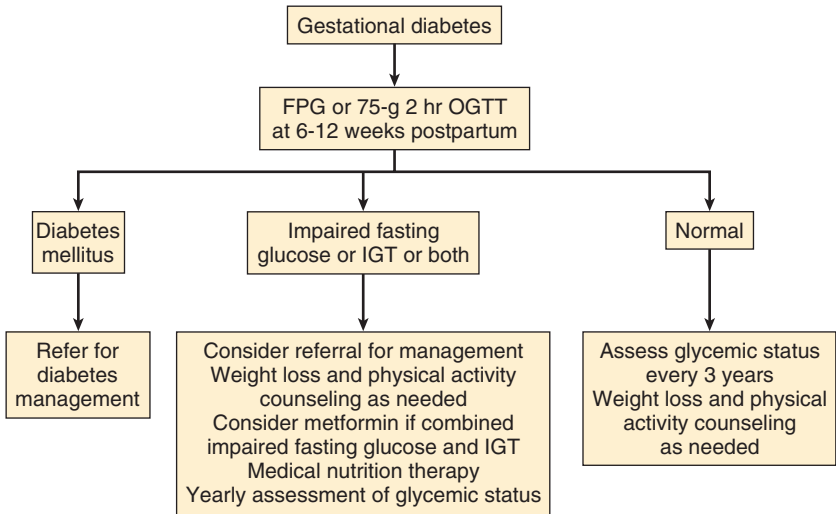

Because many obstetricians have extrapolated the increased risk for stillbirth in women with type 1 or type 2 diabetes to those with GDM, a remarkable number of GDM pregnancies are subject to scheduled delivery at term. At present, the ACOG suggests that if GDM is well controlled on diet or medication, delivery should not be undertaken prior to 39 weeks' gestation. If glycemic control is suboptimum, ACOG recommends that the decision to schedule late-preterm or early-term birth in such cases should be individualized. As with antepartum fetal testing, in the otherwise uncomplicated group, should scheduled induction be the standard approach for these pregnancies complicated by GDM? Available observational and retrospective data do not permit an evidence-based recommendation. Rosenstein and colleagues<sup>78</sup> have recommended that women with class A2 GDM routinely undergo induction at 39 weeks based on a large retrospective cohort that indicated that infant mortality at 39 weeks (8.7/1000) was statistically lower than the risk of stillbirth plus infant mortality with expectant management over an additional week (15.2/1000). A secondary analysis<sup>79</sup> of the MFMU trial of treatment of mild GDM revealed that induction of labor prior to 40 weeks' gestation does not increase the rate of cesarean delivery.

Kjos and colleagues conducted a prospective randomized trial of active induction of labor at 38 weeks' gestation versus expectant management in a series that included 187 women with GDM who required insulin. The cesarean delivery rate was not significantly different in the expectant-management group (31%) compared with the active-induction group (25%); however, an increased prevalence of LGA infants (23% vs. 10%) was observed in the expectant-management group. Moreover, the frequency of shoulder dystocia was 3% in this group, with

**FIG 40-19** Management of postpartum glucose screening results. FPG, fasting plasma glucose; IGT, impaired glucose tolerance; OGTT, oral glucose tolerance test. (Modified from American College of Obstetricians and Gynecologists Committee Opinion No. 435, June 2009.)

no cases reported in those undergoing induction at 38 weeks' gestation. These data led the authors to conclude that scheduled elective induction should be considered in insulin-requiring patients with GDM because it does not increase the risk for cesarean delivery and it lowers the risk for shoulder dystocia. In women managed expectantly, monitoring of fetal growth should be considered because of an apparent increasing risk for macrosomia with advancing gestational age. As with women with preexisting diabetes, scheduled cesarean delivery to prevent birth trauma is offered to women with suspected macrosomia or a history of prior shoulder dystocia. A range of 58 to 588 cesarean deliveries with an estimated fetal weight of 4500 g and 148 to 962 cesarean deliveries with an estimated fetal weight of 4000 g have been suggested as needed to prevent a single case of permanent brachial plexus injury.<sup>80</sup> We use the same estimated weight cutoffs in considering the mode of delivery in pregnancies complicated by GDM as previously discussed with regard to pregnancies complicated by preexisting diabetes.

**POSTPARTUM FOLLOW-UP OF WOMEN WITH GESTATIONAL DIABETES MELLITUS**

**Women with GDM have a sevenfold increased risk for developing type 2 diabetes compared with women who do not have diabetes during pregnancy.**<sup>81</sup> Follow-up studies for up to 28 years of O'Sullivan's original cohort of women indicated a prevalence of diabetes in 50% to 60% of women with previous GDM. A follow-up study of up to 10 years in 11,270 women with GDM compared with 174,146 women without GDM revealed a 15.7% frequency of diabetes in patients with a history

of GDM compared with 1% in the non-GDM population.<sup>82</sup> Findings of abnormal carbohydrate intolerance may manifest early in the postpartum period depending on the population studied and its risk factors. As many as one third of women with GDM will have overt diabetes, impaired fasting glucose, or IGT identified during postpartum testing conducted within 6 to 12 weeks of delivery (Table 40-12). Thus both the ADA and the ACOG (Fig. 40-19) recommend postpartum glucose testing following a diagnosis of GDM. Nevertheless, the prevalence of postpartum glucose screening with either a fasting plasma glucose or a 2-hour oral GTT has ranged from only 23% to 58% in seven reported studies.<sup>82</sup> Most recently, a retrospective cohort study of 2016 GDM women in the United Kingdom found that only 18.5% underwent follow-up screening at 6 months and that annual screening remained constant at approximately 20%. A report of 11,825 women with GDM from a large health maintenance organization indicated that postpartum testing was performed in only 50% (*n* = 5939) of eligible women. In this series, of 5857 women with test results, 16.3% (*n* = 956) had impaired fasting glucose or IGT, whereas 1.1% (*n* = 66) were found to have overt diabetes. After adjustment for demographic and clinical factors, abnormal postpartum test results were associated with having required insulin or oral agents during pregnancy and with a longer period from delivery to postpartum testing.

Some debate surrounds whether postpartum glucose testing can be limited to fasting glucose versus a 75-g 2-hour oral GTT. Whereas some have reported sufficiently high sensitivity using a fasting glucose alone (cutoff of 6 mmol/L or 108 mg/dL) to detect diabetes in women with prior GDM, more recent reports

indicate the need for a complete 75-g 2-hour oral GTT to achieve satisfactory sensitivity. McClean and colleagues reported 272 abnormal postpartum oral GTTs (27.6%), with 109 women identified as having frank diabetes. Eleven of these (10%) had fasting plasma glucose less than or equal to 6 mmol/L ( $\leq 108$  mg/dL), as did 62% of 114 cases of IGT. These authors concluded that a postpartum fasting plasma glucose is not sensitive enough in a high-risk population to classify glucose tolerance status accurately. However, only 5 of 109 women with overt diabetes did not require insulin during pregnancy, and of these, three had a postpartum fasting plasma glucose of less than or equal to 6 mmol/L. **Currently, the ACOG recommends using either a fasting plasma glucose or a 75-g 2-hour oral GTT at 6 to 12 weeks' postpartum (see Fig. 40-19). The optimal frequency of subsequent testing has not been established; however, the ADA recommends repeat testing at least every 3 years for women with prior GDM and normal results of postpartum screening.**

Given the high risk for subsequent diabetes in women with prior GDM, this population is ideally suited for preventive strategies to lower their risk for deteriorating carbohydrate tolerance.<sup>84-86</sup> Ample evidence shows that breastfeeding improves immediate postpartum glucose tolerance, yet much less is known about whether lactation prevents progression to type 2 diabetes. However, substantial evidence shows that both lifestyle changes and pharmacotherapy can prevent or delay the progression of IGT to type 2 diabetes following GDM.<sup>84,85</sup> In the Diabetes Prevention Program, which compared lifestyle changes to metformin therapy, intensive lifestyle changes of diet and exercise resulted in an average weight loss of 15 lb, most of which was sustained throughout the study. Fewer individuals randomized to lifestyle intervention developed diabetes (14%) compared with the metformin group (22%) and placebo-treated subjects (29%). When women with a history of GDM in this population were studied, Ratner and colleagues<sup>86</sup> found that metformin and lifestyle intervention were similarly effective in reducing the incidence of diabetes in women with a history of GDM. In women with a history of GDM and IGT, the incidence of subsequent diabetes was reduced by 50% and 53% in subjects who received metformin and lifestyle intervention, respectively, compared with placebo. It follows that women with GDM found to have IGT on postpartum glucose tolerance testing should be referred for preventive therapy.

**Women with GDM are at high risk for recurrence in future pregnancies. Gethum and colleagues found a 41.3% incidence in second pregnancies in this group.** These authors also documented that the risk for GDM is significantly increased in the third pregnancy if the first pregnancy was complicated with GDM compared with a first affected pregnancy followed by an unaffected pregnancy. **Because of the high recurrence risk with previous GDM, we recommend early pregnancy screening or testing, followed by screening at 24 to 28 weeks, or testing in those not found to have GDM earlier in pregnancy.**

### Long-Term Effects of Glucose Intolerance on Mother and Fetus

The metabolic syndrome encompasses a myriad metabolic disturbances that include core metabolic problems such as obesity, insulin resistance, and hyperinsulinemia. Related metabolic dysfunctions include hyperlipidemia, hypertension, inflammation, and atherosclerotic vascular disease. The metabolic alterations in

pregnancy provide a useful paradigm for the long-term risks of both mother and fetus relative to metabolic dysfunction.

Based on the original work of O'Sullivan and colleagues, GDM is a significant risk factor for the later development of type 2 diabetes. These findings have been replicated in a number of studies. **In a review of the incidence of type 2 diabetes in women with a previous history of GDM, Kim and associates<sup>87</sup> reported that the cumulative incidence of type 2 diabetes increased markedly in the first 5 years after delivery and plateaued after 10 years to about 50%. Elevated fasting glucose during pregnancy was the most common risk factor.**

During pregnancy, women with GDM have an increased risk for hypertensive disorders such as preeclampsia. Carr and coworkers reported that women with a family history of type 2 diabetes and a history of prior GDM are at a threefold higher risk for developing the metabolic syndrome. Additionally, such women were at increased risk for cardiovascular dysfunction such as coronary artery disease and stroke. Hence, not only is the diagnosis of GDM in pregnancy a harbinger of chronic metabolic disease, it also offers an opportunity to initiate efforts to prevent cardiovascular disease in this at-risk population.

The developmental origins of health and disease (DOHAD), or a perinatal programming concept, has recently gained wider acceptance because of the increase in childhood and adult obesity. However, the effect of a hyperglycemic environment on long-term fetal development has been recognized for decades. On the basis of the Pima Indian studies of Pettitt and associates,<sup>88</sup> children of Pima women are at increased risk for both diabetes and obesity. This risk persisted when the offspring of the women with diabetes were compared with that of their siblings born before the mother developed glucose intolerance. These studies were later confirmed and expanded on by Dabelea and colleagues,<sup>89</sup> also in a Pima Indian population. **In fact, the strongest risk factor for diabetes in Pima Indian children is being exposed to maternal diabetes while in utero, independent of maternal obesity and birthweight.** In a white population, Boney reported not only that the LGA children of the women with GDM had an increased risk for diabetes and obesity but also that 50% had evidence of the metabolic syndrome; however, this risk was no longer significant after adjustment for maternal obesity. In a recent multiethnic study, Hillier and coworkers observed that increasing levels of hyperglycemia, particularly fasting hyperglycemia less than the level diagnostic for GDM, were associated with an increased risk for childhood obesity. More recently, Clausen and associates reported that **the risk for being overweight was twofold greater in the young adults of mothers with GDM or type 1 diabetes. The risk for the metabolic syndrome was also increased fourfold in comparison with a matched cohort from the same background population.**<sup>90</sup> In contrast to these findings, two systematic reviews and meta-analyses have concluded that childhood obesity associations with GDM may be attenuated with adjustment for maternal obesity or BMI. In summary, observations are inconsistent with respect to the risk for childhood obesity in the offspring of GDM women. The potential improvement in long-term childhood outcomes with treatment of GDM has been addressed in follow-up studies of the two large randomized treatment trials for GDM.<sup>91,92</sup> In a 4- to 5-year follow-up of children from the ACHOIS study, Gillman and colleagues<sup>91</sup> reported that treatment did not result in a change in offspring BMI. Similarly, Landon and colleagues<sup>92</sup> followed

500 children at ages 5 to 10 years from the MFMU study of mild GDM and found no overall reduction in childhood obesity or metabolic dysfunction in the offspring of treated women. These authors did note an association between neonatal and childhood obesity with a treatment effect suggested in female offspring with the highest neonatal fat mass. Importantly, both the ACHOIS and MFMU RCTs included women with mild GDM, and thus it remains open to question whether fetal programming of metabolic function in GDM can have an intergenerational effect that may be modified by treatment.

## PREPREGNANCY COUNSELING OF WOMEN WITH PREEXISTING DIABETES MELLITUS

**Anomalies of the cardiac, renal, and central nervous systems arise during the first 7 weeks of gestation, a time when it is most unusual for patients to seek prenatal care. Therefore the management and counseling of women with diabetes in the reproductive age group should begin before conception.** Additionally, preconception care for women with diabetes can reduce the occurrence of other adverse birth outcomes. A cost-benefit analysis that estimated a frequency of 2.2% of U.S. births annually to women with preexisting diabetes suggested that universal preconception care might avert 8397 preterm deliveries, 3725 birth defects, and 1872 perinatal deaths with discounted lifetime costs averted as high as \$4.3 billion for the affected cohort of children.<sup>93</sup> In the United Kingdom, about 50% of diabetic women receive preconception counseling, whereas estimates as low as 20% have been reported in the United States. Prepregnancy counseling includes an assessment of vascular status and glycemic control. Physicians who care for young women with diabetes must be aware of the importance of such counseling. At this time, the nonpregnant patient can learn techniques for self-monitoring of blood glucose as well as the need for proper dietary management. Folic acid dietary supplementation at a dose of at least 0.4 mg daily should be prescribed to reduce the frequency of NTDs, although it has not specifically been studied in the diabetic population. During counseling, questions may be answered regarding risk factors for complications and the plan for general management of diabetes in pregnancy. Planning for pregnancy should optimally be accomplished over several months, and glycosylated hemoglobin measurements are performed to aid in the timing of conception (Box 40-8).

A reduced rate of major congenital malformations in patients optimally managed before conception has been consistently observed with special diabetes clinics. Mills and associates reported that diabetic women registered before pregnancy had fewer infants with anomalies compared with late registrants (4.9% vs. 9%). Although the incidence of 4.9% remains higher than that in a normal control population (2%), normalization of glycemia was not established in the early-entry group. Kitzmiller and colleagues studied 84 women with pregestational DM who were recruited for preconception education and management during a 7-year period. A group of 110 pregnancies in women with IDDM who presented in the first trimester without preconceptional counseling served as controls in this study. One anomaly (1.2%) occurred in the preconception group compared with 12 malformations (10.9%) in the control population.

**Glycosylated hemoglobin levels obtained during the first trimester may be used to counsel diabetic women regarding**

### BOX 40-8 PREPREGNANCY CARE FOR DIABETIC WOMEN

- Multidisciplinary care team: Obstetrician, endocrinologist, diabetes educator, nutritionist
- Evaluation for vascular complications
  - Retinal examination
  - Assess renal function: Serum creatinine and evaluation for proteinuria
- Evaluation for cardiovascular status
  - Hypertension
  - Ischemic cardiac disease: Electrocardiogram if longstanding diabetes, hypertension, or symptoms
- Review medications
  - Angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers, and statins are best avoided if planning conception.
  - Folate supplementation is recommended.
- Assessment of glycemic control
  - Measure HbA1c every 2 months.
  - Target HbA1c should be  $\leq 7.0\%$ .
  - Contraception is not advised until glucose is well controlled.
- Promote healthy lifestyle
  - Regular exercise
  - Nutrition counseling and weight loss for obese women
  - Smoking cessation

**the risk for an anomalous infant.** Miller and colleagues first observed that elevated HbA1c concentrations early in pregnancy correlated with an increased incidence of malformations. In a series of 58 patients with elevated glycosylated hemoglobin levels, 13 malformed infants (22%) were noted. This is in contrast to a 3.4% incidence of major malformations in 58 women whose glycosylated hemoglobin levels were in the normal range. Overall, the risk for a major fetal anomaly may be as high as 25% when the glycosylated hemoglobin level is several percent above normal values. Greene reported that 14 of 35 pregnancies with a glycosylated hemoglobin that exceeded 12.8% were complicated by major malformations. In his series from the Joslin Diabetes Clinic, the risk for major anomalies did not become evident until glycosylated hemoglobin values exceeded 6 SD above the mean. The risk for spontaneous abortion also appears to be increased with marked elevations in glycosylated hemoglobin. However, for diabetic women with good glucose control, there appears to be no greater likelihood of miscarriage. In summary, women with type 1 or type 2 DM should be advised to achieve an HbA1c level close to the upper limit of the normal range before conceiving in order to reduce the risk for a major fetal malformation or miscarriage.

## CONTRACEPTION

No evidence suggests that DM impairs fertility; thus family planning is an important consideration for the diabetic woman. A careful history and complete gynecologic examination and counseling are required before selecting a method of contraception. Barrier methods of birth control continue to be safe and inexpensive. When used correctly with a spermicide, the diaphragm has a failure rate of less than 10%. **Because no risks are inherent to the diaphragm and other barrier methods, and because these methods do not affect carbohydrate**

**metabolism, they have become the preferred interim method of contraception for women with DM.** The intrauterine device (IUD) may also be used by diabetic women without concerns about an increased risk for infection.

Combined oral contraceptives (OCs) are the most effective reversible method of contraception with failure rates generally less than 1%. The low-dose preparations are not associated with an increased risk of developing diabetes in women with prior GDM; however, controversy continues in regard to their use in women with overt diabetes. **The serious side effects of OC use, including thromboembolic disease and MI, may be increased in diabetic women who use combined OCs.**<sup>95</sup> A retrospective study of 136 diabetic women found five cardiovascular complications in those who primarily used low-dose pills. Three patients had cerebrovascular accidents, one had an MI, and one had an axillary vein thrombosis. Despite diabetes increasing the risk for cerebral thromboembolism fivefold compared with controls, this risk was not enhanced by use of combined OCs in a retrospective case-control study.

In one report, several diabetic women exhibited rapid progression of retinopathy with OC use. Klein and colleagues<sup>95</sup> studied the impact of OCs in a cross-sectional study of 384 insulin-dependent women and reported no association between OCs and progression of vascular complications. For physicians who prescribe low-dose OCs to diabetic women, their use should probably be restricted to patients without serious vascular complications or additional risk factors such as a strong family history of myocardial disease or smoking. In these women, a monophasic preparation (progestin only) may be considered. In women taking OCs, the lowest dose of estrogen and progesterone should be used. Patients should have blood pressure monitoring after the first cycle and quarterly, with baseline and follow-up lipid levels obtained as well.

Women who use OCs may demonstrate increased resistance to insulin as a result of a diminished concentration of insulin receptors. Despite the fact that carbohydrate metabolism may be affected by the progestin component of the pill, disturbances in diabetic control are actually uncommon with its use. Triphasic OCs may also be used safely in women with a history of GDM without other risk factors. Kjos and colleagues<sup>96</sup> performed a prospective randomized study of 230 women with recent GDM. OC users were randomized to low-dose norethindrone or levonorgestrel preparations in combination with ethinyl estradiol. The rate of subsequent diabetes in OC users was 15% to 20% after 1 year of follow-up. This rate was not significantly different from that in non-OC users (17%). Importantly, no adverse effects on total cholesterol, low-density lipoprotein (LDL), high-density lipoprotein (HDL), or triglycerides were found with OC use. In a separate study, Kjos and colleagues found that progestin-only preparations were associated with an increased risk for diabetes during breastfeeding.

**At present, little information is available concerning long-acting progestins in women with diabetes or previous GDM.**

A statistically significant yet clinically limited deterioration in carbohydrate tolerance has been reported in healthy depot medroxyprogesterone acetate (DMPA) users. As observed with other progestins, DMPA may lower serum triglyceride and HDL cholesterol levels but not LDL or total cholesterol. For this reason, DMPA is not recommended as a first-line method of contraception for women with diabetes. The progestin-only OC would be preferred because it does not produce significant metabolic effects in diabetic women.

## KEY POINTS

- ◆ Pregnancy has been characterized as a diabetogenic state because of increased postprandial glucose levels in late gestation.
- ◆ Both hepatic and peripheral (tissue) insulin sensitivity are reduced in normal pregnancy. As a result, a progressive increase in insulin secretion follows a glucose challenge.
- ◆ In women with GDM, the hormonal milieu of pregnancy may represent an unmasking of a susceptibility to the development of type 2 DM.
- ◆ According to the Pedersen hypothesis, maternal hyperglycemia results in fetal hyperglycemia and hyperinsulinemia, which results in excessive fetal growth and perinatal morbidities. Tight maternal glycemic control is associated with a reduced risk for fetal macrosomia.
- ◆ Congenital malformations occur with a twofold to sixfold increased rate in offspring of women with pregestational diabetes compared with that of the normal population. Impaired glycemic control and associated derangement in maternal metabolism appear to contribute to abnormal embryogenesis.
- ◆ Women with class F (nephropathic) diabetes have an increased risk for preeclampsia and preterm delivery that correlates with their degree of renal impairment.
- ◆ Diabetic retinopathy may worsen during pregnancy, yet for women optimally treated with laser photocoagulation *before* pregnancy, significant deterioration of vision is uncommon.
- ◆ Screening for GDM is generally performed between 24 and 28 weeks' gestation. A two-step method that consists of a 50-g screen and a diagnostic 100-g oral glucose tolerance test is commonly performed in the United States.
- ◆ Treatment of women with type 1 and type 2 DM during pregnancy requires intensive therapy that consists of frequent self-monitoring of blood glucose and aggressive insulin dosing by multiple injections or continuous subcutaneous insulin infusion (insulin pump).
- ◆ The cornerstone of treatment for GDM is dietary therapy. Insulin and oral agents are reserved for individuals who manifest significant fasting hyperglycemia or postprandial glucose elevations despite dietary intervention.
- ◆ Antepartum fetal assessment for women with both pregestational diabetes or GDM is based on the degree of risk believed to be present in each case. Glycemic control, prior obstetric history, and the presence of vascular disease or hypertension are important considerations.
- ◆ Delivery should generally be delayed in patients whose glucose is well controlled until 39 weeks' gestation. The mode of delivery for the suspected large fetus remains controversial. In cases of suspected macrosomia, cesarean delivery has been recommended to prevent a traumatic birth.
- ◆ Women with type 1 and type 2 DM should seek pre-pregnancy consultation. Efforts to improve glycemic control before conception have been associated with a significant reduction in the rate of congenital malformations in the offspring of such women.

## OVERVIEW

Obesity in women is such a common problem that the implications relative to pregnancy often are overlooked, or possibly ignored, because of the lack of specific treatments. For example, medical treatment of hypertension or diabetes mellitus involves medications that have relatively rapid onset, and the effects of treatment can be quantitatively monitored. In contrast, the management of obesity—in addition to medical and surgical treatments—requires long-term approaches that include public health and economic initiatives, nutrition, and behavioral modifications. Therefore an understanding of the management of obesity during pregnancy begins prior to conception and continues through the postpartum period; that is, it must be seen from a life-course perspective. Although the care of the obese women during pregnancy requires the involvement of the obstetrician/gynecologist, depending on the comfort level of the provider, other health care professionals can offer specific expertise relative to management.

## PREVALENCE OF OBESITY IN WOMEN OF REPRODUCTIVE AGE

Obesity is commonly classified by the body mass index (BMI), which is weight in kilograms divided by height in meters squared ( $\text{kg}/\text{m}^2$ ) using the World Health Organization (WHO) criteria. Underweight is less than 18.5, normal weight is 18.5 to 24.9, overweight is 25.0 to 29.9; obese class I, is 30.0 to 34.9, obese class II is 35.0 to 39.9, and obese class III is 40 or more.<sup>1</sup> Based on the 2011 to 2012 National Health and Nutrition Examination Survey (NHANES), the prevalence of obesity in women of reproductive age (20 to 39 years) in the United States was 31.8% (95% confidence interval [CI], 28.5 to 35.5), whereas overweight plus obesity was 58.5% (95% CI, 51.4 to 65.2) of that population.<sup>2</sup> The prevalence of overweight and obesity is higher in non-Hispanic black and Mexican women in the United States (Table 41-1). BMI is often used as a measure that correlates with fat mass. In non-pregnant women of reproductive age, BMI explains about 50%

**TABLE 41-1** PREVALENCE OF OBESITY AND OVERWEIGHT IN WOMEN OF REPRODUCTIVE AGE\*

| ALL RACE/<br>ETHNICITY GROUPS | NON-HISPANIC<br>WHITE | NON-HISPANIC<br>BLACK | HISPANIC         | MEXICAN AMERICAN |
|-------------------------------|-----------------------|-----------------------|------------------|------------------|
| 31.9 (28.6-35.5)              | 26.9 (23.0-31.3)      | 56.2 (44.3-67.5)      | 34.4 (30.9-38.2) | 37.8 (33.2-42.7) |
| 55.8 (49.6-61.9)              | 50.7 (43.1-58.2)      | 74.2 (65.9-81.1)      | 65.4 (59.9-70.5) | 68.8 (62.1-74.8) |

Data from National Health and Nutrition Examination Survey 2009–2010. Values are mean ± standard deviation.  
\*Reproductive age is 20 to 39 years old.

to 70% of the variance in fat mass. However, because of the increase in total body water that occurs with advancing gestation, the correlation becomes progressively less robust.<sup>3</sup> Because of racial differences in body composition, the WHO has discussed different cutoff criteria for the classification of obesity in Asian women.<sup>4</sup>

Based on Centers for Disease Control and Prevention (CDC) data, no significant change occurred in the prevalence of obesity in women of reproductive age from 2003 through 2004 to 2011 through 2012.<sup>5</sup> From 1999 through 2010, however, obesity (BMI ≥30) in women aged 20 to 39 years appeared to increase, from 28.4% (95% CI, 24.4 to 32.4) to 34.0% (95% CI, 29.0 to 39.1), again with a higher prevalence in non-Hispanic black and Mexican American women.<sup>5</sup> Of greater concern is the increasing prevalence of grade II obesity (17.2%; 95% CI, 14.2 to 20.7) and grade III obesity (7.5%; 95% CI, 5.8 to 9.7) in women aged 20 to 39 years from 2009 through 2010.<sup>6</sup>

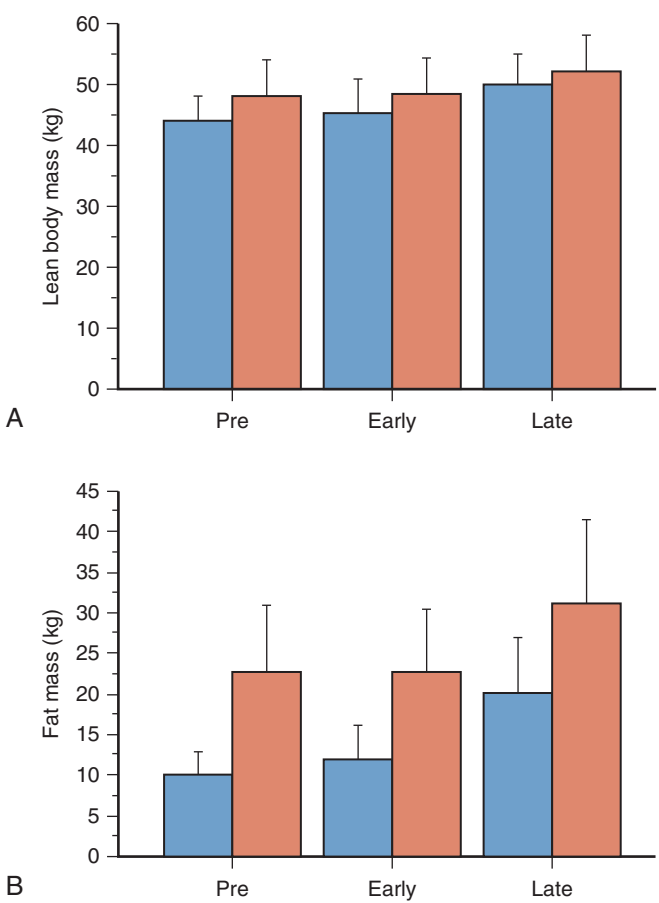

Multiple social, environmental, behavioral, and biologic determinants lead to the development of obesity. Major single-gene defects (homozygosity for recessive alleles) account for about 5% of early-onset severe obesity.<sup>7,8</sup> About 60 single nucleotide polymorphisms (SNPs) have been associated with obesity based on genome-wide significance levels.<sup>7,9</sup> Although when taken individually, each of these factors may only account for a small proportion of the variance in obesity, when taken together, their combination and interactions explain a far greater proportion of the variance.<sup>7</sup>

Multiple commonly held beliefs are associated with the development of obesity, and many more are associated with prescriptions to achieve weight loss.<sup>10</sup> In the simplest terms, weight loss or gain is related to the balance between energy intake and energy expenditure, although the relationships are not linear. For example, if a person increases energy expenditure by walking an extra mile per day and maintains caloric intake constant, the weight loss over time will be only approximately 20% of expected.<sup>11</sup> This is because the physiologic compensation for changes in energy expenditure or requirements to maintain the decreased weight are less than would be expected if the relationships were linear.<sup>12</sup>

As obstetrician/gynecologists, we encourage our patients to breastfeed. Although many maternal and neonatal benefits accompany breastfeeding, the concept that infants who are breastfed are less likely to be obese in later life did not hold true in a randomized controlled trial (RCT) of more than 13,000 children followed for more than 6 years.<sup>13</sup> The previous reports may have been affected by confounding and selection bias.

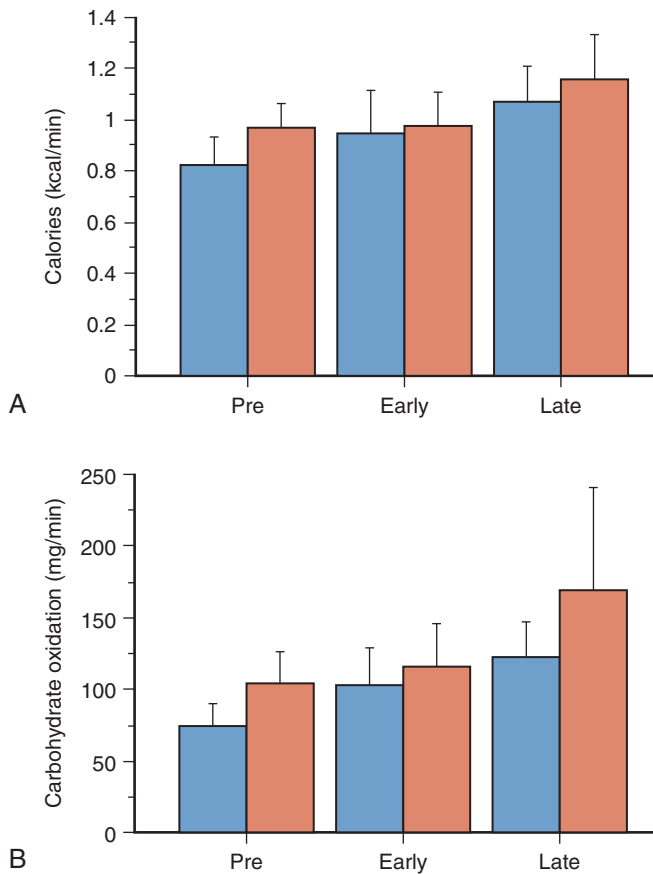

METABOLISM IN OBESE PREGNANT WOMEN

Large epidemiologic studies have reported that obese women gain less weight during pregnancy compared with nonobese women.<sup>14</sup> Based on small longitudinal metabolic studies in healthy lean and obese women before and during early and late

**FIG 41-1** **A**, Longitudinal changes (mean ± standard deviation [SD]) in lean body mass in lean (blue bars, *n* = 5) and obese women (red bars, *n* = 6) before pregnancy (Pre) and in early (12–14 weeks) and late pregnancy (34–36 weeks). Change over time, *P* = .0001, and group, *P* = .34. **B**, Longitudinal changes (mean ± SD) in fat mass in lean (blue bars, *n* = 5) and obese women (red bars, *n* = 6) before pregnancy and in early (12–14 weeks) and late pregnancy (34–36 weeks). Change over time, *P* = .0001 and group, *P* = .02. (From Catalano P, Resi V, Presley L, Hauguel-deMouzon. Changes in maternal lipid metabolism in lean and obese pregnancy are related to fetal adiposity. *Reproductive Sciences* 22, number 1 [supplement], March 25–28, 2015, 62nd Annual Meeting, San Francisco CA. Abstract F-137.)

gestation, significant changes were observed over time and between groups. **A significant increase in lean and fat mass was reported in both lean and obese women, but a greater increase in fat mass was seen in lean women (Fig. 41-1).** A significant 23% increase in resting energy expenditure over time was not different between groups (Fig. 41-2, *A*). Basal carbohydrate oxidation increased 68% over time and was greater in obese women (see Fig. 41-2, *B*). A 40% decrease in insulin sensitivity was reported as estimated by the glucose infusion rate during the hyperinsulinemic-euglycemic clamp divided by the

**FIG 41-2** **A**, Longitudinal changes (mean  $\pm$  standard deviation [SD]) in resting metabolic rate in lean (blue bars,  $n = 5$ ) and obese women (red bars,  $n = 6$ ) before pregnancy (Pre) and in early (12-14 weeks) and late pregnancy (34-36 weeks). Change over time,  $P = .0002$ , and group,  $P = .22$ . **B**, Longitudinal changes (mean  $\pm$  SD) in carbohydrate oxidation in lean (blue bars,  $n = 5$ ) and obese women (red bars,  $n = 6$ ) before pregnancy and in early (12-14 weeks) and late pregnancy (34-36 weeks). Change over time,  $P = .008$ , and group,  $P = .04$ . (From Catalano P, Resi V, Presley L, Hauguel-deMouzon. Changes in maternal lipid metabolism in lean and obese pregnancy are related to fetal adiposity. *Reproductive Sciences* 22, number 1 [supplement], March 25-28, 2015, 62nd Annual Meeting, San Francisco CA. Abstract F-137.)

mean insulin concentrations (i.e., the insulin sensitivity index [ISI]) in lean and obese women over time, with a trend ( $P = .07$ ) for a greater decrease in obese compared with lean women (Fig. 41-3). As a result of the significant decrease in insulin sensitivity, fat oxidation increased 220% during the clamp in both lean and obese women ( $P = .003$ ) because of the decreased ability to suppress lipolysis. Basal free fatty acids decreased 16% over time ( $P = .02$ ), and a 62% increase was seen in free fatty acids with insulin infusion during the clamp ( $P = .0004$ ), but no significant difference was noted between groups (Fig. 41-4). Although a 61% increase in fasting cholesterol and a 260% increase in triglycerides ( $P = .0001$ ) were observed over time, no significant difference was found between lean and obese women (Fig. 41-5). Others have reported that in late pregnancy, obese women have increases in circulating triglycerides, very-low-density lipoprotein (VLDL) cholesterol, and lower high-density lipoprotein (HDL) as compared with that of lean women.<sup>15-18</sup> In summary, **significant increases in many lipid components are seen during pregnancy, some of which are increased to a greater degree in obese, compared with lean, women.**

**FIG 41-3** Longitudinal changes in insulin sensitivity index (mean  $\pm$  standard deviation [SD]) as estimated by the hyperinsulinemic-euglycemic clamp (mg/kg/min) in lean (blue bars,  $n = 5$ ) and obese women (red bars,  $n = 6$ ) before pregnancy (Pre) and in early (12-14 weeks) and late pregnancy (34-36 weeks). Change over time,  $P = .0001$ , and group,  $P = .07$ . (From Catalano P, Resi V, Presley L, Hauguel-deMouzon. Changes in maternal lipid metabolism in lean and obese pregnancy are related to fetal adiposity. *Reproductive Sciences* 22, number 1 [supplement], March 25-28, 2015, 62nd Annual Meeting, San Francisco CA. Abstract F-137.)

### Recommendations for Gestational Weight Gain in Obese Women

Weight gain recommendations for pregnancy were first published by the Institute of Medicine (IOM) in 1990.<sup>19</sup> At that time, prior to the increased prevalence of obesity in the population, the purpose was to establish recommendations for a healthy gestational weight gain for both the mother and her fetus primarily because of concerns for low birthweight and nutritional status. The recommendation for weight gain for women who were *obese*—defined as a prepregnancy BMI greater than 29—was at least 15 lb. Since that time, a significant increase has been seen in the number of women of childbearing age who are overweight or obese. Women also are becoming pregnant at an older age and with an increasing number of chronic medical conditions such as hypertension and diabetes. Hence, in 2009, the IOM revised the gestational weight guidelines taking into account more recent literature and the increased proportion of overweight and obesity in women of reproductive age (Table 41-2).<sup>20</sup>

Although the 2009 IOM recommendations for gestational weight gain are not dramatically different from the 1990 guidelines except in regard to obese women, other substantive differences were apparent. These include using the WHO criteria for defining pregravid BMI<sup>1</sup> and eliminating specific recommendations for certain populations that included women of short stature, pregnant adolescents, and different racial or ethnic groups.<sup>20</sup> **Based on these more recent definitions, excessive gestational weight gain occurs in 38% of normal-weight women, 63% of overweight women, and 46% of obese women. Excessive gestational weight gain is a significant factor for postpartum weight retention and hence is a significant contributor to the obesity epidemic.**<sup>21</sup>

Some authors have suggested that weight gain for obese women less than that specified in the current IOM recommendations may improve some perinatal outcomes.<sup>22</sup> However, potential fetal risks relate to inadequate gestational weight gain in obese women.<sup>23</sup> Although the issue of gestational weight gain

**FIG 41-4 A,** Longitudinal changes in basal free fatty acid concentration (mean  $\pm$  standard deviation [SD]) in lean (blue bars,  $n = 5$ ) and obese women (red bars,  $n = 6$ ) before pregnancy (Pre) and in early (12-14 weeks) and late pregnancy (34-36 weeks). Change over time,  $P = .02$ , and group,  $P = .30$ . **B,** Longitudinal changes in free fatty acid concentration during the hyperinsulinemic-euglycemic clamp in lean (blue bars,  $n = 5$ ) and obese women (red bars,  $n = 6$ ) before pregnancy and in early (12-14 weeks) and late pregnancy (34-36 weeks). Change over time,  $P = .0004$ , and group,  $P = .82$ . (From Catalano P, Resi V, Presley L, Hauguel-deMouzon. Changes in maternal lipid metabolism in lean and obese pregnancy are related to fetal adiposity. *Reproductive Sciences* 22, number 1 [supplement], March 25-28, 2015, 62nd Annual Meeting, San Francisco CA. Abstract F-137.)

**FIG 41-5 A,** Longitudinal changes in basal triglyceride concentration in lean (blue bars,  $n = 5$ ) and obese women (red bars,  $n = 6$ ) before pregnancy (Pre) and in early (12-14 weeks) and late pregnancy (34-36 weeks). Change over time,  $P = .0001$ , and group,  $P = .22$ . **B,** Longitudinal changes in basal cholesterol concentrations in lean (blue bars,  $n = 5$ ) and obese women (red bars,  $n = 6$ ) before pregnancy and in early (12-14 weeks) and late pregnancy (34-36 weeks). Change over time,  $P = .0001$ , and group,  $P = .67$ . (From Catalano P, Resi V, Presley L, Hauguel-deMouzon. Changes in maternal lipid metabolism in lean and obese pregnancy are related to fetal adiposity. *Reproductive Sciences* 22, number 1 [supplement], March 25-28, 2015, 62nd Annual Meeting, San Francisco CA. Abstract F-137.)

**TABLE 41-2** RECOMMENDATIONS FOR TOTAL AND RATE OF WEIGHT GAIN DURING PREGNANCY BY PREPREGNANCY BMI

| PREPREGNANCY BMI             | BMI (kg/m <sup>2</sup> ) | TOTAL WEIGHT GAIN (RANGE) (lb) | RATES OF WEIGHT GAIN* IN TRIMESTERS 2 AND 3 (MEAN AND RANGE) (lb/wk) |
|------------------------------|--------------------------|--------------------------------|--|
| Underweight                  | <18.5                    | 28-40                          | 1 (1-1.3)  |
| Normal weight                | 18.5-24.9                | 25-35                          | 1 (0.8-1)  |
| Overweight                   | 25.0-29.9                | 15-25                          | 0.6 (0.5-0.7)  |
| Obese (includes all classes) | $\geq 30.0$              | 11-20                          | 0.5 (0.4-0.6)  |

From Rasmussin KM, Abrams B, Bodnar LM, et al. Weight gain during pregnancy: re-examining the guidelines. Institute of Medicine, 2009.  
\*Calculations assume a 0.5-2 kg (1.1-4.4 lb) weight gain in the first trimester.  
BMI, body mass index.

is much debated in the United States, it is noteworthy that recommendations in other countries are not uniform. The Society of Obstetricians and Gynecologists of Canada<sup>24</sup> have adopted the 2009 IOM recommendations,<sup>20</sup> whereas recommendations from Sweden<sup>25</sup> and China<sup>26</sup> are unique to their own populations. Finally, the Centre for Maternal and Child Enquiries (CMACE) and Royal College of Obstetricians and

Gynaecologists (RCOG) have no clinical recommendations or clinical guidelines for weight gain during pregnancy.<sup>27</sup>

**During pregnancy, medications for weight management are not recommended because of safety concerns and side effects.**<sup>28</sup> The classical anorexiant, such as phentermine, alter the release and reuptake of neurotransmitters that impact appetite. Other drugs such as orlistat reduce intestinal fat absorption

by inhibiting pancreatic lipase. Metformin, which decreases hepatic glucose production, has been associated with decreased gestational weight gain in some studies when used to treat mild gestational diabetes mellitus (GDM).<sup>29</sup> Metformin has not been used solely to manage gestational weight gain, and it crosses the placenta in significant amounts.<sup>29</sup>

The primary weight-management strategies during pregnancy are dietary control, exercise, and behavior modification. These strategies have been used either alone<sup>30,31</sup> or in combination<sup>32,33</sup> to avoid excessive gestational weight gain. None of these strategies is uniform. For example, with diet, some studies have examined the role of food having a low glycemic index,<sup>30</sup> whereas others have used probiotic interventions.<sup>34</sup> Unfortunately, the authors of a recent Cochrane review concluded that **there is not enough evidence to recommend any specific intervention for preventing excessive weight gain in pregnancy**, because studies have suffered from methodologic limitations, small sample sizes, and insufficient power to detect clinically meaningful effect size.<sup>35</sup> In general, **nutritional strategies, rather than exercise, appear to be more useful in avoiding excessive gestational weight gain in pregnancy.**<sup>36</sup>

## PREGNANCY COMPLICATIONS IN OBESE WOMEN

### Early Pregnancy

A number of pregnancy complications are associated with obesity. **The risk of spontaneous abortion** (odds ratio [OR], 1.2; 95% CI, 1.01 to 1.46) **and recurrent miscarriage** (OR, 3.5; 95% CI, 1.03 to 12.01) **is increased in obese women** as compared with age-matched controls.<sup>37</sup> **The risk of congenital anomalies is also increased in obese mothers, who are at increased risk for pregnancies affected by neural tube, cardiovascular, orofacial, and limb-reduction anomalies.**<sup>38</sup>

Based on the Northern Congenital Abnormality Survey, routine ultrasound detected 46.2% (1146 of 2483) of structural anomalies in fetuses with a normal karyotype.<sup>39</sup> Detection rates decreased significantly with increasing maternal BMI ( $P = .0007$ , test for trend), and the odds of detection of any anomaly were significantly lower in obese women than in those with a normal BMI (adjusted OR [aOR], 0.77; 95% CI, 0.60 to 0.99).<sup>39</sup> Factors associated with the decreased ability to detect congenital anomalies in obese women include the distance from the skin surface to the fetus, resolution/penetration of sonographic equipment, prolonged time to complete the examination, and the experience of the sonographer.<sup>40</sup> Potential means to optimize image quality in obese pregnant women include a vaginal approach in the first trimester, using the maternal umbilicus as an acoustic window, and tissue harmonic imaging.<sup>40</sup> Fetal magnetic resonance imaging (MRI) obviates many of these technical problems, but because its use is limited by cost and availability, the use of MRI for routine screening of anomalies is not recommended.<sup>41</sup>

In the First- And Second-Trimester Evaluation of Risk (FASTER) Research Consortium trial, the detection rate for cardiac anomalies among women with a BMI less than 25 was higher (21.6%) at a significantly lower false-positive rate (FPR, 78.4%; 95% CI, 77.3 to 79.5) compared with obese women (8.3% detection rate with an FPR of 91.7%; 95% CI, 90.1 to 92.2). In a logistic regression model, maternal obesity significantly decreased the likelihood of sonographic detection of common anomalies (aOR, 0.7; 95% CI, 0.6 to 0.9).<sup>42</sup>

Maternal obesity also affects measures of serum analytes because of the increased plasma volume in obese pregnant women. Although weight adjustment for analytes related to neural tube defects (NTDs) and trisomy 18 improves detection rates, this adjustment does not increase detection rates for trisomy 21.<sup>41</sup> In prenatal testing for trisomies 21 and 18 using cell-free DNA (cfDNA), the false-positive rates were significantly lower ( $P = .03$ ) than with standard screening (serum biochemical assays with or without nuchal translucency measurement). The positive predictive value for cfDNA was also better for trisomy 21 (45.5% vs. 4.2%) and trisomy 18 (40.0% vs. 8.3%). The median BMI in this study was 27.4 (range, 15.5 to 59).<sup>43</sup> It should be noted, however, that these test characteristics were for “positive” results and did not take into account results from women who were unable to have results obtained from the assay, an occurrence that is more common as BMI increases. Also, maternal obesity is associated with an increase in total, but not fetal, cfDNA. In a small study, total cfDNA increased 1.7% per BMI unit, and when adjusted for blood volume, it increased 3.2% per BMI unit. Therefore in the future, cfDNA values may need to be adjusted for maternal BMI for better interpretation of clinical data.<sup>44</sup>

### Mid to Late Pregnancy

**The risk of metabolic problems is increased, which includes GDM<sup>45</sup> and preeclampsia,<sup>46</sup> as is the risk of cardiac dysfunction, proteinuria, sleep apnea, and nonalcoholic fatty liver disease (NAFLD)<sup>47,48</sup> in obese as compared with normal-weight pregnant women.** Because of the increased insulin resistance often observed in obese women before pregnancy, preexisting subclinical metabolic dysfunction may become manifest as obstetric conditions such as preeclampsia, gestational diabetes, and obstructive sleep apnea (OSA)<sup>49</sup> and are associated with adverse pregnancy outcomes.<sup>50-52</sup> These disorders may have a higher prevalence in certain racial or ethnic groups including black Africans and Southern Asians.<sup>53</sup> In early gestation, hypertension, suspected glucose intolerance, or OSA should be screened for at the first antenatal visit with a history, physical examination, and laboratory and clinical studies as needed. Women with suspected OSA—those with symptoms of snoring, excessive daytime sleepiness, witnessed apneas, or unexplained hypoxia—should be referred to a sleep medicine specialist for evaluation and possible treatment.<sup>54</sup> Although universal screening for gestational diabetes is recommended at 24 to 28 weeks gestation, screening for glucose intolerance in early gestation (gestational diabetes or overt diabetes) should be based on risk factors that include maternal obesity, known impaired fasting or 2-hour glucose levels based on a 75-g glucose tolerance test, or previous gestational diabetes (see Chapter 40).<sup>55</sup> It has not been determined, however, whether universal testing early in pregnancy to detect overt diabetes is of clinical value or is cost-effective.<sup>56</sup> In addition, NAFLD—the most common liver disease in developed countries—usually presents with elevated liver function tests.<sup>57</sup> NAFLD is related to increased insulin resistance and is often confused with other disorders of liver function during pregnancy such as the hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome.

Is there any treatment to prevent metabolic complications such as gestational diabetes in obese women once they are pregnant? Lifestyle interventions in studies of small numbers of obese women to prevent the development of GDM have not been successful.<sup>58,59</sup> A Cochrane review reported that no

conclusive evidence for exercise in pregnancy to prevent GDM was available to guide practice.<sup>60</sup> Supplementation with a probiotic and myo-inositol in two European studies has been reported to reduce the frequency of gestational diabetes.<sup>61,62</sup> However, these trials were conducted in nonobese populations. Although prevention of preeclampsia with calcium supplementation and vitamin C and E have not been successful,<sup>63,64</sup> optimizing glucose control in women with GDM may decrease the rate of preeclampsia.<sup>65</sup> The administration of low-dose aspirin (60 to 80 mg/day) in the late first trimester is suggested in women with a medical history of early-onset preeclampsia and preterm delivery at less than 34<sup>0/7</sup> weeks or preeclampsia in more than one prior pregnancy.<sup>66</sup>

**Not only is the risk of indicated preterm deliveries increased<sup>67</sup> because of the aforementioned antepartum complications, the risk of idiopathic preterm birth is also increased<sup>68</sup> in overweight and obese pregnant women. The risk of stillbirth also increases** (test for trend,  $P < .01$ ) **with progressive degrees of maternal obesity:** BMI class I (adjusted hazard ratio [aHR], 1.3; 95% CI, 1.2 to 1.4), BMI class II (aHR, 1.4; 95% CI, 1.3 to 1.6), and extreme obesity (aHR, 1.9; 95% CI, 1.6 to 2.1). A further increased risk of stillbirth was seen in obese black, compared with obese white, mothers.<sup>69</sup> The underlying etiology for intrauterine fetal death in obese women is unknown, and as such, no specific recommendations exist regarding prevention other than optimizing general obstetric care relative to medical or obstetric conditions. **Although obese women are at increased risk for adverse perinatal outcomes, data are insufficient to recommend antenatal surveillance in this population without additional clinical indications.**<sup>70</sup> As a noninvasive option, fetal movement counts, such as kick counts, are suggested (see Chapter 11).

### Intrapartum Complications

**At delivery, obese women are at increased risk of cesarean delivery, endometritis, wound rupture/dehiscence, and venous thrombosis, and they have an almost twofold increased risk of composite maternal morbidity and a fivefold risk of neonatal injury.**<sup>71</sup> The unadjusted ORs of cesarean delivery are 1.46 (95% CI, 1.34 to 1.60), 2.05 (95% CI, 1.86 to 2.27), and 2.89 (95% CI, 2.28 to 3.79) for overweight, obese, and severely obese women, respectively, compared with normal-weight women.<sup>72</sup> Maternal obesity alone is not an indication for induction of labor.<sup>73</sup> However, obese women are at increased risk of a prolonged pregnancy and have an increased rate of induction of labor.<sup>74</sup> Although compared with spontaneous labor, induction of labor is associated with an increased risk of cesarean delivery in obese women,<sup>75</sup> no specific recommendations have been made to decrease the risk of primary cesarean delivery in this population.<sup>76</sup>

**The length of labor in nulliparous women is proportional to maternal BMI.**<sup>77</sup> In a study that adjusted for maternal height, labor induction, membrane rupture, oxytocin use, epidural anesthesia, net maternal weight gain, and fetal size, the median duration of labor from 0 to 10 cm was significantly longer in overweight and obese women. In overweight women, the prolongation was between 4 and 6 cm, and for obese women, labor was slower before 7 cm.<sup>78</sup> **In a mixed nulliparous and multiparous cohort, the second stage of labor was not significantly different among normal, overweight, and obese women.** The intrauterine pressure generated during a standardized Valsalva

maneuver also was not significantly different among the various weight groups.<sup>79</sup>

The rate of trial of labor after cesarean (TOLAC) has been decreasing since the mid-1990s and is now less than 10% (see Chapter 20).<sup>76</sup> TOLAC success rates are inversely related to BMI: for a BMI less than 19.8, the rate is 83.1%; when BMI is between 19.8 and 26, the rate is 79.9%; between 26.1 and 29, the rate is 69.3%; and when BMI exceeds 29, the rate is 68.2% ( $P < .001$ ). Similarly, gaining over 40 lb during pregnancy is associated with a decreased TOLAC success rate (66.8% vs. 79.1%,  $P < .001$ ).<sup>80</sup> Class III women undergoing a TOLAC had greater composite morbidity—which included prolonged hospital stay, endometritis, rupture/dehiscence, and neonatal injury (fractures, brachial plexus injuries, and lacerations)—compared with class III women having an elective cesarean delivery, although absolute morbidities were small.<sup>71</sup> The risk is increased significantly for postpartum atonic hemorrhage ( $>1000$  mL) for class III obese women after a vaginal delivery (5.2%) and instrumental delivery (13.6%), compared with normal-weight women (4.4%), but not after cesarean delivery.<sup>81</sup>

**Maternal obesity significantly increases the risk of anesthetic complications.** The CMACE/RCOG recommendations state that women with a pregravid BMI greater than 40 should have an antenatal consultation with an obstetric anesthesiologist to discuss and document anesthetic management plans for labor and delivery (see Chapter 16).<sup>27</sup> For all other obese women, early consultation with an obstetric anesthesiologist at the time of admission to labor and delivery should be considered to obtain proper equipment to monitor blood pressure, establish venous access, and screen for relevant comorbid conditions.<sup>82</sup> The risk of epidural failure is greater in obese women, compared with normal weight and overweight women<sup>83</sup>; therefore early labor epidural placement should be considered. This may mitigate increased time in the obese patient from decision for an emergency cesarean to delivery. Compared with normal-weight women, severely obese women at term have significantly greater hypotension and prolonged fetal heart rate decelerations after controlling for epidural bolus dose and hypertensive disorders.<sup>84</sup> The combination of spinal anesthesia and obesity significantly impairs respiratory function for up to 2 hours after the procedure.<sup>85</sup> General anesthesia also poses a risk for the obese pregnant women because of potential difficulties with endotracheal intubation (see Chapter 16).<sup>86</sup> However, general anesthesia is not a contraindication in obese women, but consideration should be given to the need for preoxygenation, proper positioning of the patient, and fiberoptic equipment intubation availability.<sup>87</sup>

**Broad-spectrum antimicrobial prophylaxis is recommended for all cesarean deliveries unless the patient is already receiving antibiotics for conditions such as chorioamnionitis.**<sup>88</sup> In a study of normal weight, overweight, and obese women, after 2-g dosing 30 to 60 minutes before skin incision, cefazolin concentrations in adipose tissue were inversely proportional to BMI. In obese and extremely obese patients, adipose tissue concentrations of cefazolin at the time of skin incision were less than the minimally inhibitory concentration for gram-negative rods ( $<4$   $\mu\text{g/g}$  of tissue) in 20% and 33% of obese and severely obese patients, respectively.<sup>89</sup> However, differences in clinical outcomes have not been established, and a proper dosing based on BMI has not been recommended.

**The optimal type of skin incision for primary cesarean delivery in order to decrease morbidity in obese class II and III patients has not been resolved.** Using data from a perinatal

**FIG 41-6** Frequency of surgical site infection (SSI) following cesarean delivery in women stratified by maternal body mass index (BMI). (From Wloch C, Wilson J, Lamagni T, et al. Risk factors for surgical site infection following cesarean section in England: results from a multicenter cohort study. *BJOG*. 2012;119:1324-1333.)

database, it was reported that a vertical skin incision was associated with a higher rate of wound complications than a transverse incision.<sup>90</sup> More recent data from a secondary analysis of the Maternal-Fetal Medicine Unit's (MFMU) cesarean registry, which used a composite of wound complications (infection, seroma, hematoma, wound evisceration, and fascial dehiscence) as the primary outcome, reported that in a univariate analysis, patients with a vertical skin incision had a significantly higher rate of wound complications; however, after adjustment for confounding factors, a vertical incision was associated with a significantly lower risk for wound complications.<sup>91</sup> The discrepancy was most likely explained by selection bias. Others have reported that in obese women with a voluminous panniculus, a supraumbilical incision was associated with favorable outcomes.<sup>92</sup>

Closure with suture of subcutaneous tissue greater than 2 cm in depth can significantly decrease the incidence of wound disruption.<sup>93</sup> The additional use of a subcutaneous drain with bulb suction in obese women with at least 4 cm of subcutaneous fat was not effective in preventing wound complications and may have potentiated postcesarean wound complications.<sup>94</sup> Compared with normal-weight women, the risk of surgical site infections (SSIs) is increased following a cesarean delivery in overweight women (OR, 1.6; 95% CI, 1.2 to 2.2), obese class I women (OR, 2.4; 95% CI, 1.7 to 3.4), and obese class II and III women (OR, 3.7; 95% CI, 2.6 to 5.2; Fig. 41-6).<sup>95</sup> Subcutaneous skin thickness greater than 3 cm is a significant risk factor (OR, 2.8; 95% CI, 1.3 to 5.9) for postcesarean wound infection after adjusting for maternal BMI.<sup>96</sup> Types of skin preparation, skin-closure techniques, and supplemental oxygen have not proved useful in decreasing the rate of postcesarean infectious morbidity.<sup>97-99</sup>

## POSTPARTUM CONSIDERATIONS

### Maternal

Obesity is a risk factor for venous thromboembolism (VTE) in the general population (see Chapter 45).<sup>100</sup> In a case-control study<sup>101</sup> of over 71,000 women in Denmark, the relative risk of VTE in obese women during pregnancy was 9.7 (95% CI, 3.1 to 30.8), and during the postpartum period, it was 2.8 (95% CI, 0.8 to 9.8) after adjustment for age, parity, clomiphene citrate stimulation, and diabetes. Obesity also was associated

with a higher risk of pulmonary embolism (aOR, 14.9; 95% CI, 3.0 to 74.8). However, these data are associated with very wide confidence intervals that limit confidence in the precision of the estimate. The Pregnancy and Thrombosis Working Group<sup>100</sup> in the United States recommends consideration of thromboprophylaxis only in selected patients and notes that data are insufficient to recommend routine pharmacologic prophylaxis in patients having a cesarean delivery.<sup>101</sup> **Because cesarean delivery increases the risk of VTE, placement of pneumatic compression devices has been recommended for all patients before and after cesarean delivery by the American College of Obstetricians and Gynecologists (ACOG).**<sup>102</sup> In contrast, the RCOG in the United Kingdom recommends obese women who have two or more additional risk factors such as smoking should be considered for prophylactic low-molecular-weight heparin (LMWH) as early in pregnancy as practical and should continue this therapy until 6 weeks postpartum. Additionally, the RCOG recommends that obese women who have one or more additional risk factors for VTE should be considered for LMWH for 7 days after delivery.<sup>27</sup>

Few randomized trials have addressed management of wound complications following cesarean delivery.<sup>103</sup> Risk factors for wound complications in addition to maternal obesity include diabetes, chorioamnionitis, corticosteroids, stress, and poor nutrition.<sup>104</sup> In a retrospective study of 2492 cesarean deliveries, the risk of postcesarean infection was 18.4%, and risk was highest among obese women (OR, 1.43; 95% CI, 1.09 to 1.88) after adjustment for diabetes and emergent/elective cesarean deliveries. Among women with diabetes, obesity increased the risk of postcesarean infection to an even greater extent (OR, 2.06; 95% CI, 1.13 to 3.75).<sup>105</sup> Management of the infected postcesarean wound includes antibiotics and evacuation of any hematoma/seroma. **An open wound can be managed in any of three ways: with secondary closure, closure by secondary intention with dressings, and closure by secondary intention using negative pressure wound therapy (NPWT).** Secondary closure and NPWT are associated with improved healing times compared with closure by secondary intention with dressings in nonpregnant patients.<sup>104</sup>

Excessive gestational weight gain is associated with short- and long-term postpartum weight retention.<sup>106</sup> In the Danish birth cohort ( $n = 60,892$ ), underweight women retained an average of 2.3 kg and obese women lost 1.7 kg by 6 months postpartum. However, the variation of weight loss was great in the overweight and obese women, and the crude risks for postpartum weight retention showed only moderate associations with pregravid BMI. The greatest contribution to retention of over 5 kg at 6 months postdelivery was the degree of excessive weight gain during pregnancy. For example, women who gained in excess of 20 kg had a risk of postpartum weight retention that was sixfold greater than women who gained 10 to 15 kg.<sup>107</sup> Similar findings were reported among Asian populations.<sup>108</sup>

In the Fit for Delivery study, although behavioral intervention did not result in a significant decrease in gestational weight gain in overweight/obese women, a significant increase was reported among those who received the intervention in the proportion of overweight/obese women (30.7% vs. 18.7%) who returned to or were below their pregravid weight by 6 months postpartum.<sup>109</sup> Traditional means to decrease postpartum weight reduction have used behavioral intervention that involves diet and physical activity.<sup>110</sup> In a small study, use of the Internet-based program from the United States Department of Agriculture

(USDA), MyPyramid Menu Planner for Moms—which computes energy needs to achieve a defined weight loss based on demographic, anthropometric, and lactation status—resulted in significantly increased weight loss compared with a control group.<sup>111</sup> In a larger study in breastfeeding women that compared a Mediterranean-style diet with the MyPyramid menu planner for pregnancy and breastfeeding, both groups achieved a similar degree of moderate weight loss ( $-2.3 \pm 3.4$  kg vs.  $-3.1 \pm 3.4$  kg, respectively) over 4 months.<sup>112</sup> In an RCT in which women were followed over 10 months, family-based behavioral intervention did not result in a significant increase in postpartum weight loss compared with a control group. In a multivariate analysis, only baseline energy intake, work status, and breastfeeding were significant predictors of weight change.<sup>113</sup> Finally, in a Cochrane analysis, diet alone or diet plus exercise, but not exercise alone, helped women lose weight postpartum. Pregravid obesity, but not gestational weight gain, has been associated with early termination of breastfeeding<sup>114</sup> and also with postpartum anemia.<sup>115</sup> For breastfeeding women, more evidence is required to discern whether diet or exercise or both are detrimental for either mother or infant.<sup>116</sup>

**The optimal treatment of obesity in pregnancy is prevention of obesity before pregnancy occurs.** As discussed previously, the obstetrician/gynecologist, either in conjunction with other health care providers or individually, may consider using prepregnancy behavioral modification such as motivational interviewing to achieve behavioral change in areas such as weight control.<sup>117</sup> **Although achieving a normal BMI is the ideal, based on the results of the Look Ahead trial, a weight loss of even 5% to 7% significantly improved metabolic health.**<sup>118</sup>

**Weight loss between pregnancies in obese women has been shown to decrease the risk of a large for gestational age (LGA) infant** (aOR, 0.61; 95% CI, 0.52 to 0.73), **whereas an interpregnancy weight gain was associated with an increased risk of delivering an LGA infant** (aOR, 1.37; 95% CI, 1.21 to 1.54). Risk of a small-for-gestational-age (SGA) infant was not increased unless there was a loss of more than 8 kg/m<sup>2</sup>.<sup>119</sup> The interpregnancy interval in women who lost weight in this study was longer than that seen in the women who gained weight between pregnancies, which underscores the importance of contraceptive counseling in this population.<sup>120</sup>

### Neonate/Child

**The infants of obese women are at increased risk for fetal macrosomia and, more specifically, for increased body fat compared with infants of normal-weight women.**<sup>121,122</sup> Long-term risks for the offspring include an increased risk of the metabolic syndrome<sup>123</sup> and childhood obesity.<sup>124</sup> The risk of childhood obesity in offspring of obese women persists even after adjustment for complications such as GDM.<sup>125</sup> In a large Scandinavian study, higher maternal BMI was associated with an increased risk of asthma.<sup>126</sup> Maternal obesity has also been linked to altered behavior in the offspring, including an increased risk of autism spectrum disorders, childhood developmental delay, and attention-deficit/hyperactivity disorder.<sup>127</sup> However, as compelling as these data may seem, it is impossible in these observational studies to separate other prenatal and postnatal influences from obesity on outcomes in the offspring. Socioeconomic issues, behavior, activity, and diet within families often are not adjusted for the analysis of metabolic outcomes in the offspring of obese women, and thus the potential for confounding remains.<sup>128</sup>

## OTHER CONSIDERATIONS

### Facilities

Several adaptations of the facility are needed for the obese patient in both inpatient and outpatient settings. **In the outpatient setting, common requirements include large chairs and examining tables capable of supporting weights up to 500 to 750 lb, large blood pressure cuffs capable of extending around 80% of the arm circumference, and large wheelchairs.**<sup>129</sup> An increase in equipment size necessitates increased storage space and more staff to safely assist patients.

In labor and delivery units, birthing beds must be capable of supporting vaginal delivery with appropriate monitoring equipment. **Because of the increased possibility of emergency cesarean delivery in obese women, doorways and hallways require enough space to accommodate large beds and additional staff moving patients safely.** In the operating room, motorized lifts to assist obese patient onto the operating table<sup>130</sup> and sufficient space to allow staff to move safely and efficiently are necessary.<sup>27</sup> **Operating tables need to be strong enough to safely support patients with weights up to 500 to 750 lb and should have attachments to increase the width of tables.** Although no consensus has been reached in regard to the optimal positioning of the obese patient at the time of cesarean delivery,<sup>131</sup> operating tables should be able to accommodate various positions to the satisfaction of anesthesia and obstetric staff. **Long instruments are also necessary to facilitate the surgeon's access to the proper tissue planes.** Finally, consideration should be given to practice drills for staff to safely prepare for emergency cesarean delivery of the obese patient, particularly for those with a BMI greater than 40.

### KEY POINTS

- ◆ Behavioral modification of diet or diet plus exercise can decrease excessive gestational weight gain in obese women.
- ◆ Weight gain in pregnancy should be based on pregravid BMI and should follow the IOM recommendations.
- ◆ Obese women should be counseled as to the limitation of ultrasound in identifying structural anomalies.
- ◆ At the first prenatal visit, obese women should be screened for glucose intolerance.
- ◆ Antenatal fetal surveillance is not recommended for obese women without other maternal or fetal indications.
- ◆ Obese women should be counseled about the increased risk of cesarean delivery for obese, compared with normal-weight, women.
- ◆ Closure of subcutaneous tissue greater than 2 cm, but not placement of subcutaneous drains, decreases the risk of postpartum cesarean wound complications.
- ◆ Excessive gestational weight gain is a significant risk factor for postpartum weight retention.
- ◆ Behavioral interventions that use diet and/or diet and exercise can improve postpartum weight reduction but not exercise alone.
- ◆ Because of the increase in plasma volume in obese women, consideration should be given to increase the bolus of preepidural intravenous fluid and dosage of prophylactic antibiotics for cesarean delivery.

Along with diabetes mellitus, thyroid diseases are the most frequent endocrine pathology seen in pregnancy; parathyroid diseases, on the other hand, are rare but may present a diagnostic and therapeutic challenge to the obstetrician. The obstetrician should be aware of the symptoms and signs of the particular disease, the effect of pregnancy on the interpretation of endocrine tests, and the transfer of hormones and medications across the placenta with potential complications for the fetus and neonate. It is imperative that a team approach be used in the management of these conditions; **the close cooperation of the obstetrician, endocrinologist, neonatologist, pediatric endocrinologist, and anesthesiologist well in advance of the delivery time will offer the patient the best maternal and perinatal outcomes.**

## PARATHYROID DISEASES

Although uncommon in pregnancy, parathyroid diseases may produce significant perinatal and maternal morbidity and mortality if not diagnosed and properly managed.

### Calcium Homeostasis During Pregnancy

Parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D ( $1,25[\text{OH}]_2\text{D}_3$ ) are responsible for maintaining calcium homeostasis. **About 50% of serum calcium is protein bound, mostly to albumin; 10% is complexed to anions; and 40% circulates free as ionized calcium. During pregnancy, active transfer of maternal calcium to the fetus occurs.** A full-term infant requires 25 to 30 g of calcium during the course of pregnancy for new bone mineralization, most of it in the third trimester.

Total serum calcium during gestation is 8% below postpartum levels.<sup>1</sup> **Ionized calcium levels, however, remain unchanged throughout gestation.** Serum phosphate and renal tubular reabsorption of phosphorus also remain normal throughout pregnancy. Maternal serum PTH levels are slightly decreased in the first half of pregnancy (about 20% of the mean nonpregnant values) but return to normal by midgestation.<sup>2</sup>

Blood levels of  $1,25(\text{OH})_2\text{D}_3$  (calcitriol), the active metabolite of vitamin D, increase early in gestation to twice the nonpregnancy level in the third trimester. This increase comes as a result of stimulation of maternal renal  $1\alpha$ -hydroxylase activity by estrogen, placental lactogen, and PTH as well as synthesis of calcitriol by the placenta. Also, 24-hour urinary calcium excretion increases with each trimester of gestation and decreases in the postpartum period,<sup>2</sup> which reflects the increased intestinal calcium absorption induced by higher levels of  $1,25$ -hydroxyvitamin D during gestation.

**Parathyroid hormone-related protein (PTHrP), a peptide responsible for the hypercalcemia found in many malignant tumors, increases in early pregnancy.** The source of maternal serum PTHrP is multiple, and both fetal and maternal sites have been postulated (placenta, myometrium, amnion, decidua, fetal parathyroid glands, breast, umbilical cord). PTHrP increases  $1\alpha$ -hydroxylase activity with an increase in  $1,25(\text{OH})_2\text{D}_3$ ; in addition, PTHrP plays a role in placental calcium transport and may also help protect the maternal skeleton during pregnancy.

Serum calcitonin levels are higher during pregnancy and in the postpartum period compared with nonpregnant controls.

Osteocalcin is a bone-specific protein released by osteoblasts into the circulation proportional to the rate of new bone formation. **Markers of bone resorption increase during pregnancy and reach values in the last trimester of pregnancy up to**

**twice the normal level.** These changes are consistent with the increase in bone turnover at the time of maximal transfer of maternal calcium to the fetus.

After delivery, urinary calcium excretion is reduced; ionized serum calcium remains within normal limits; and total calcium,  $1,25$ -hydroxyvitamin D, and serum PTH return to prepregnancy levels. Intestinal absorption of calcium decreases to the nonpregnant rate as a result of the previously mentioned return to normal levels of  $1,25(\text{OH})_2\text{D}_3$ .<sup>1</sup> Early concern for calcium loss in lactating mothers, with the development of osteopenia, has not been confirmed, and **extra calcium supplementation during breastfeeding appears to be unnecessary** because calcium supplementation above normal does not significantly reduce the amount of lost bone during gestation.<sup>5</sup> The alteration in calcium and bone metabolism that accompanies human lactation represents a physiologic response that is independent of calcium intake.

### Hyperparathyroidism

The prevalence of primary hyperparathyroidism (PHPT) is 0.5%. The incidence of the disease in pregnancy is unknown, but it is definitely rare, and most of the reported cases have been single ones complemented with a review of the literature. With the introduction of routine, automated techniques in clinical medicine and with early diagnosis, most patients with PHPT are symptom free, and their serum calcium elevation is mild. In nonpregnant PHPT patients, indications for surgery include (1) serum calcium greater than 1 mg/dL ( $>0.25$  mmol/L) above the upper limit of normal; (2) bone densitometry with a T score of  $-2.5$  or greater at the lumbar spine, total hip, femoral neck, or distal third of the radius; (3) vertebral fracture; (4) creatinine clearance below 60 mL/min; or (5) clinical signs and symptoms of a stone or visualization of a stone on imaging. It is estimated that 10% of PHPT patients have a mutation in one of 11 genes. They may occur as part of complex disorders, such as multiple endocrine neoplasia (MEN) syndromes 1 through 4; as a familial disorder, familial isolated primary hyperparathyroidism (FIHPT); in the syndrome of familial hypocalciuric hypercalcemia (FHH); and in the syndrome of neonatal severe primary hyperparathyroidism (NSPHPT). In practice, genetic testing is indicated in cases of primary hyperparathyroidism (1) in the presence of multigland disease, (2) in the very young (before pregnancy), (3) with parathyroid carcinoma or atypical adenoma, and (4) with a family history of hypercalcemia in first-degree relatives. Genetic testing is expensive; therefore patients should be referred to genetic counselors, and appropriate tests should be performed by accredited centers.

The first case of PHPT during pregnancy was reported in 1931. Shortly thereafter, the first case of neonatal hypocalcemia to cause tetany in a mother with undiagnosed hypercalcemia due to hyperparathyroidism was described by Friderichsen. **The most common cause of PHPT in pregnancy is a single parathyroid adenoma, which is present in about 80% of all cases.** Primary hyperplasia of the four parathyroid glands accounts for about 15% of the cases reported, 3% are due to multiple adenomas, and only a few cases due to parathyroid carcinoma have been reported in the English literature. In 1962, Ludwig reviewed the literature on the subject and described 21 women with 40 pregnancies: the incidence of fetal wastage was 27.5%; and neonatal tetany as a result of hypocalcemia, representing the first indication of maternal hyperparathyroidism, occurred in 19% of these cases. In contrast to the previous high neonatal morbidity and

mortality, reviewing the literature from 1976 to 1990, Kelly<sup>3</sup> found only two perinatal deaths (5%) among 37 infants born of hyperparathyroid mothers. Two additional cases of perinatal deaths were reported in mothers with hypercalcemic crisis.

**In the nonpregnant state, almost 70% of patients are symptom free, and the diagnosis is made through the routine use of biochemical screening. In pregnancy, because routine calcium determinations are not routinely performed, manifestations of the disease are present in almost 70% of the diagnosed patients.** In a review of 70 pregnant women, gastrointestinal symptoms such as nausea, vomiting, and anorexia were present in 36% of patients, whereas 34% presented with weakness and fatigue. In 26%, mental symptoms that included headaches, lethargy, agitation, emotional lability, confusion, and inappropriate behavior were reported. Nephrolithiasis was detected in 36%, bone disease in 19%, acute pancreatitis in 13%, and hypertension in 10%. Only 24% of these patients were symptom free.

Parathyroid cancer is a rare cause of hyperparathyroidism, with very few cases documented in pregnancy. Serum calcium levels are significantly higher than in other cases of PHPT, and perinatal mortality and morbidity are significant. Hypercalcemia with values above 13 mg/dL in the presence of a palpable neck mass should raise a strong suspicion of parathyroid carcinoma. On the contrary, in the presence of mild hypercalcemia and a neck mass, the most common cause of the neck lesion is a thyroid nodule. One other clinical feature of parathyroid carcinoma is poor response to the usual clinical therapeutic measures such as intensive hydration and loop diuretics. Surgery is the only effective therapy.

**Hyperparathyroidism should be considered in the differential diagnosis of acute pancreatitis during pregnancy,** which has been reported in 13% of women with primary hyperparathyroidism. The incidence of *acute pancreatitis* in nonpregnant hyperparathyroid women is about 1.5% and is less than 1% in normal pregnancy. It is mostly likely to occur during the last trimester of pregnancy or the postpartum period but has also been reported in the first trimester of pregnancy, mimicking hyperemesis gravidarum (HG). **Serum calcium should be obtained in any pregnant woman with persistent significant nausea, vomiting, and abdominal pain.**

Hyperparathyroid crisis, a serious complication of PHPT, has been reported during gestation and the postpartum period and is characterized by severe nausea and vomiting, generalized weakness, changes in mental status, and severe dehydration. Hypertension may be present and should be differentiated from preeclampsia. The serum calcium level is frequently higher than 14 mg/dL; hypokalemia and elevation in serum creatinine are routinely seen. If not recognized and treated promptly, hyperparathyroid crisis may progress to uremia, coma, and death. Of the 12 cases reported in the literature, four occurred in the postpartum period. Patients presented with severe nausea, vomiting, and elevation in serum creatinine due to dehydration. Serum calcium levels higher than 20 mg/dL were reported in three cases, and three patients died. In addition, six cases have been associated with pancreatitis, and four fetal deaths have also been reported.

**Bone disease in patients with PHPT is now unusual,** but in early series, it was a common complication. Radiologic evaluation of the bones showed diffuse demineralization, subperiosteal resorption of the phalanges, and in severe cases, single or multiple cystic lesions and generalized osteoporosis.

Shani and associates reported<sup>4</sup> five cases of excessive amniotic fluid in mothers with PHPT and serum calcium levels between 11.3 and 14 mg/dL. The authors suggested that the fetal polyuria was, similar to adult polyuria, a common finding in patients with hyperparathyroidism.

**The two most common causes of neonatal morbidity are prematurity and neonatal hypocalcemia, and the latter is related to levels of maternal hypercalcemia.** In early reports, it was often the only clue of maternal hyperparathyroidism. Neonatal hypocalcemia develops between the second and fourteenth day of life and lasts for a few days.

Preeclampsia has been reported in some cases of PHPT. Hultin and coworkers examined whether parathyroid adenoma, the main cause of hyperparathyroidism, diagnosed and treated before pregnancy is associated with preeclampsia. They reviewed the records of 52 women, between 1973 and 1997 with the diagnosis of parathyroid adenoma confirmed by surgery and compared them with 519 women without the disease, all of whom had a subsequent singleton pregnancy. They concluded that PHPT due to a single adenoma diagnosed and treated before delivery is significantly associated with preeclampsia (adjusted odds ratio [aOR], 6.89; 95% confidence interval [CI], 2.30 to 20.58;  $P < .0001$ ). Therefore treated PHPT should be considered a risk factor for preeclampsia in future pregnancies.

The clinical manifestations of PHPT and pregnancy complications—maternal, fetal, and neonatal—are directly related to the serum calcium level. Dochez and Ducarme reviewed 34 published articles in English and French on the characteristics of PHPT, clinical presentations, pregnancy complications, birth outcomes, and management of PHPT during pregnancy. They emphasized the need to rule out FHH and hereditary syndromes such as multiple endocrine neoplasia syndrome (MEN-1 or MEN-2) and familial parathyroid hyperplasia. Nephrolithiasis was the most common finding in symptomatic patients during pregnancy; other maternal complications include depression, constipation, bone fracture, maternal heart rhythm disorders, pancreatitis, parathyroid crisis, and HG. Maternal hypertension and preeclampsia were observed in 25% of these patients.

**The diagnosis of PHPT is based on persistent hypercalcemia in the presence of increased PTH or a PTH level inappropriate for the level of serum calcium.**<sup>5</sup> In pregnancy, because of the presence of hypoalbuminemia, a persistent total serum calcium value higher than 9.5 mg/dL is suspicious for hypercalcemia. A determination of 24-hour urinary calcium excretion is helpful in the diagnosis, because most women with PHPT have an increase in urinary calcium excretion above the usual hypercalciuria of normal pregnancy. Urinary calcium excretion is low or low normal in the syndrome of familial hypocalciuric hypercalcemia (FHH), another cause of hypercalcemia that must be included in the differential diagnosis. The serum alkaline phosphatase level may be increased in PHPT. However, it is also increased in normal pregnancy. **Ultrasonography of the neck is the current first-line investigation during pregnancy for localization of parathyroid diseases, with a sensitivity of 69% and a specificity of 94% in experienced hands. Parathyroid contrast imaging studies are contraindicated in pregnancy.**

## Hypercalcemia

### Differential Diagnosis

**Although most young women with hypercalcemia have PHPT, other unusual causes should be ruled out, mainly**

**BOX 42-1 CAUSES OF HYPERCALCEMIA IN PREGNANCY AND THE PUERPERIUM**

Hyperparathyroidism (most common)

Rare causes related to pregnancy

Familial hypocalciuric hypercalcemia\*

Postpartum hypercalcemia in hypoparathyroidism

Parathyroid hormone–related protein induced hypercalcemia

Other causes not related to pregnancy

Malignancy

Endocrine

- Thyrotoxicosis
- Adrenal insufficiency

Vitamin overdose

- Vitamin D

\*Different expression with significant neonatal manifestations.

**endocrine disorders, vitamin D or A overdose, the use of thiazide diuretics, or granulomatous diseases (Box 42-1).** A brief discussion of three uncommon syndromes associated with hypercalcemia during pregnancy follows.

FHH is an autosomal-dominant condition with a high penetrance for hypercalcemia. The disorder is associated with an inactivating mutation in the gene for the calcium-sensing receptor. Mild hypercalcemia, a slight elevation in serum PTH, mild hypermagnesemia, and low urinary calcium excretion are the typical findings. Infants born to mothers with FHH may present with different clinical manifestations: (1) asymptomatic hypercalcemia can develop in an affected offspring if the mother is a carrier for FHH, (2) severe neonatal hypocalcemia can return to normal a few weeks after delivery, or (3) severe neonatal hypercalcemia can occur in infants homozygous for the FHH gene defect.

Postpartum hypercalcemia can occur in women with treated hypoparathyroidism, and the mechanism for hypercalcemia is not well understood. Nausea and vomiting develop a few days after delivery; therefore patients with treated hypoparathyroidism should be followed postpartum with serum calcium determinations, and vitamin D should be discontinued if hypercalcemia occurs. In severe cases, intravenous fluids and glucocorticoid therapy are required (Fig. 42-1).

A few cases of hypercalcemia mediated by PTHrP during pregnancy and postpartum have been reported. In one case, hypercalcemia developed in two successive pregnancies. In the second pregnancy, serum PTHrP levels were elevated to three times normal, and the infant was born with mild hypercalcemia that returned to normal within 24 hours after delivery. In a second case, a 25-year-old woman had massive bilateral breast

**FIG 42-1** Serum calcium (triangles) and creatinine (squares) levels during pregnancy and 1 month after delivery in a woman with hypoparathyroidism who was treated with vitamin D and calcium. Normal range indicated by green shading.

enlargement at 24 weeks' gestation. Her serum calcium level was 14.3 mg/dL, but her serum PTH level was undetectable. She underwent bilateral mastectomy during pregnancy. The immunohistochemical studies demonstrated PTHrP antigenic activity in breast tissue.

### Therapy

**Surgery is the only effective treatment for PHPT**, and the procedure is safe when performed by a surgeon with extensive experience in neck surgery.<sup>6</sup> The cure rate is excellent, and complications due to surgery are low, particularly in the presence of a single lesion. Improvements in the outcome of surgery and avoidance of intraoperative and postoperative complications include (1) preoperative parathyroid adenoma localization by ultrasonography, (2) minimally invasive parathyroidectomy techniques, (3) intraoperative PHPT monitoring to confirm successful surgery, and (4) detection and management of postpartum hypocalcemia.

Although guidelines for the management of PHPT in non-pregnant individuals have been suggested, the proper medical management of PHPT in pregnancy has not been uniformly agreed on. For asymptomatic pregnant women in whom serum calcium is not greater than 1 mg above normal range, close follow-up with proper hydration and avoidance of medications that could elevate calcium, such as thiazide diuretics, is reasonable. Because most of the neonatal complications have been reported in patients with symptomatic disease, a surgical approach is indicated in such patients and in those with complications such as nephrolithiasis, bone disease, and persistent hypercalcemia (>1 mg above the normal range). **It is preferable to perform the surgery in the second trimester of pregnancy.**

In a series reported by Carella and Gossain, 38 women underwent parathyroidectomy during pregnancy, seven during the first trimester and 18 in the second trimester. In the total group of 25, there was only one fetal loss. In 12 women in whom surgery was performed during the third trimester of pregnancy, the incidence of perinatal complications was 58%. For women with PHP first diagnosed after 28 weeks' gestation, the optimal treatment strategy is unclear, and the decision in such a situation should be based on the general condition of the patient, severity of hypercalcemia, and other complicating circumstances. A significantly lower incidence of complications, both maternal and fetal, was reported in a review of 16 published cases of patients operated on after 27 weeks' gestation.

**Medical therapy is reserved for patients with significant hypercalcemia who are not surgical candidates.** Oral phosphate therapy of 1.5 to 2.5 g/day has been shown to be effective in controlling hypercalcemia. Good hydration, early treatment of urinary tract infections, and avoidance of supplements and medications known to cause elevations in serum calcium—such as vitamin D, vitamin A, aminophylline, and thiazide diuretics—are all important therapeutic measures. Serum calcium should be determined on a regular basis. A novel oral agent that acts directly on the calcium sensor, cinacalcet hydrochloride, has been used in isolated cases. It reduces serum calcium in combination with calcitonin.<sup>7</sup>

**In patients undergoing surgical treatment, hypocalcemia—albeit transient—may occur after surgery in some cases.** Therefore serum calcium should be checked every 6 hours, and if the patient develops hypocalcemic symptoms, intravenous (IV) calcium in the form of calcium gluconate (1 to 2 g of calcium-gluconate, equivalent to 90 to 180 mg elemental calcium, in 50 mL of 5% dextrose) can be infused over 10 to 20 minutes. Oral calcitriol 0.5 mg every 8 to 12 hours and oral calcium should be started when oral feeding is tolerated. In patients with bone disease, postsurgical hypocalcemia may be profound; therefore aggressive treatment is needed. These patients may benefit from vitamin D supplementation in the form of calcitriol, 0.25 to 0.5 µg/day, for a few days before operative intervention.

## Hypoparathyroidism

**The most common etiology of hypoparathyroidism is damage to or removal of the parathyroid glands in the course of surgery for thyroid gland pathology.** The incidence of permanent hypoparathyroidism after thyroid surgery has been estimated to be between 0.2% and 3.5%. In many cases, hypocalcemia in the immediate postoperative period is only transitory. Idiopathic hypoparathyroidism is much less common and is frequently associated with other autoimmune endocrinopathies as part of the polyglandular autoimmune syndrome type 1.

The requirement for calcium supplementation and vitamin D may decrease in some women with hypoparathyroidism during the second half of pregnancy and lactation. In a few cases, hypocalcemic symptoms ameliorate with progression of pregnancy. The explanation for these findings is not clear but may be related to the increased intestinal absorption of calcium and/or the production of vitamin D by the placenta.

Clinical clues for the diagnosis of hypoparathyroidism include a previous history of thyroid surgery and clinical, radiologic, and laboratory information. **Typical symptoms of hypocalcemia are numbness and tingling of the fingers and toes and around the lips.** Patients may complain of carpal spasm, laryngeal

stridor, and dyspnea. Convulsions may be a manifestation of severe hypocalcemia. On physical examination, patients with idiopathic hypoparathyroidism demonstrate changes in the teeth, skin, nails, and hair as well as papilledema and cataracts. Chvostek sign, a twitch of the facial muscles—notably those of the upper lip—when a sharp tap is given over the facial nerve, is seen in many patients with hypocalcemia. Chvostek sign has also been described in 10% of normal adults. Trousseau sign is another manifestation of hypocalcemia. It is the induction of spasm of the hand and forearm by reducing the circulation in the arm with a blood pressure cuff. The constriction should be maintained above the systolic blood pressure for 2 minutes before the test is considered negative.

**The diagnosis of hypoparathyroidism is confirmed by the presence of persistent low serum calcium and high serum phosphate levels.** Serum PTH is low in primary hypoparathyroidism. The differential diagnosis of hypocalcemia includes rickets and osteomalacia.

**Radiologic bone changes characterized by generalized skeletal demineralization, subperiosteal bone resorption, bowing of the long bones, osteitis fibrosa cystica, and rib and limb deformities may be present in the newborn as a consequence of intrauterine hyperparathyroidism.** Loughhead and colleagues<sup>8</sup> described 16 infants of hypoparathyroid mothers, and secondary hyperparathyroidism in the infants resolved by 1 month of age.

**Treatment of hypoparathyroidism in pregnancy does not differ from that in the nonpregnant state, including a normal high-calcium diet and vitamin D supplementation.** Normal calcium supplementation during pregnancy is about 1.2 g/day. Calcitriol, 1 to 3 µg/day, is used almost routinely in most patients affected with hypoparathyroidism. Calcitriol must be given in divided doses because its half-life is much shorter than that of vitamin D. If vitamin D is used, the dose is in the range of 50,000 to 150,000 IU/wk. Vitamin D requirements may decrease in some patients by the second half of gestation. The importance of compliance with medications should be strongly emphasized, particularly when calcitriol is prescribed, in view of its short half-life. The major problem in the treatment of hypoparathyroidism is the recurrence of hypercalcemia and hypocalcemia; therefore serum calcium determinations should be performed at regular intervals.

Lactation in mothers taking vitamin D may be contraindicated because a metabolite of vitamin D, 25-hydroxyvitamin D, has been detected in breast milk in high concentration in a mother taking 50,000 IU of vitamin D daily. Regardless of the form of vitamin D prescribed, serum calcium determinations should be done in the postpartum period, particularly in breast-feeding mothers.

## Pseudohypoparathyroidism

Pseudohypoparathyroidism encompasses several different disorders, having as a common feature varying degrees of target-organ resistance to PTH. In some forms of the syndrome, somatic changes are present that include short stature, obesity, a round face, brachydactyly, and mental retardation with brain calcifications. This variant is known as *Albright syndrome type 1a*. Most patients suffer from hypocalcemia due to a derangement of renal 1α-hydroxylase and production of calcitriol, and a few cases have been reported during pregnancy. Infants are at risk for intrauterine fetal hyperparathyroidism, perhaps because of the relative maternal hypocalcemia during pregnancy.

### Vitamin D Deficiency

Classically, vitamin D deficiency was related to the development of rickets, with its subsequent impact on obstetric care. Deformities of weight-bearing bones, including the pelvis, prevented vaginal delivery in mothers affected by the disease.<sup>9</sup> In recent years, however, conflicting results have been published on the potential deleterious effect of vitamin D deficiency in a variety of medical problems from autoimmune disease to cancer. Several reviews on obstetric, fetal, and neonatal outcomes have been reported.<sup>9</sup> The normal reference range values for serum vitamin D (25[OH]D), the active metabolite of vitamin D, are controversial, with values varying between 20 and 40 ng/mL, equivalent to 50 to 100 nmol/L.

Many studies in the past few years had linked low maternal 25(OH)D levels with maternal, fetal, and neonatal complications. In a report from Amsterdam, mothers with singleton pregnancies and serum 25(OH)D levels below 29.9 nmol/L (12 ng/mL) had infants with a lower birthweight and a higher incidence of growth restriction than mothers with values of over 50 nmol/L (20 ng/mL). Hart and colleagues examined the relationship between maternal vitamin D deficiency at 18 weeks' gestation and long-term health outcomes in 901 mother-offspring pairs in Perth, Western Australia. The incidence of serum 25(OH)D deficiency (<50 nmol/L [ $<20$  ng/mL]) was present in 36% of the pregnant women. After adjusting for relevant covariates, women with vitamin D deficiency had children with impaired lung development at age 6, neurocognitive deficiencies at age 10, increased risk of eating disorders in adolescence, and lower peak bone mass at age 20.

Recent systemic reviews and meta-analyses of observational studies and randomized controlled trials (RCTs) have failed to corroborate earlier observations. Theodoratou and colleagues<sup>10</sup> concluded that despite a few hundred systematic reviews and meta-analyses, highly convincing evidence for a clear role of vitamin D does not exist for any outcome, but associations with a selection of outcomes are probable. De-Regil and colleagues<sup>11</sup> reviewed six small trials with a total of 1023 women and compared five studies with vitamin D supplementation versus no treatment or placebo. The authors concluded that the use of vitamin D supplements during pregnancy improves vitamin concentrations as measured by 25-hydroxyvitamin D at term. However, the clinical significance of this finding has yet to be determined because quality evidence related to the clinical benefits of vitamin supplementation during pregnancy is insufficient. It is apparent that more studies are needed, preferably an RCT to understand the interrelationship with other factors such as age, ethnicity, seasonal variation, BMI, medical diseases, gestational age, and so on. Further studies on serum PTH and its relationship to serum vitamin D may be warranted. In the meantime, the practicing obstetrician will have to decide for each individual patient whether determination of 25(OH)D levels is indicated, what the normal values for pregnancy are, whether they are trimester specific, what the proper treatment should be, and how often the test needs to be repeated in pregnancy; this must be done also taking into consideration the cost of the tests and the possible implications for the fetus and newborn.

In 2010, the Institute of Medicine (IOM)<sup>12</sup> reviewed nearly 1000 published studies that included reports of protection from cancer, autoimmune disease, heart disease, and diabetes with vitamin D supplementation. In brief, they recommended that the lower normal limit for serum 25(OH)D should be "about"

20 ng/mL or 50 nmol/L. **For women who are not pregnant, the authors of the report recommend a daily vitamin D dietary allowance of 600 IU with an upper limit intake of 4000 IU; for calcium, they recommended a 1000-mg dietary allowance and an upper limit intake of 2500 mg a day. In the presence of vitamin D insufficiency/deficiency, it is reasonable to normalize serum levels as early as possible, preferably starting early in pregnancy. Detection of women at risk for vitamin D deficiency by proper history seems reasonable until the results of an RCT become available.** Recent evidence suggests that vitamin D deficiency is common during pregnancy, especially among high-risk groups that include vegetarians, women with limited sun exposure (e.g., those who live in cold climates, reside in northern latitudes, or wear sun and winter protective clothing), and ethnic minorities, especially those with darker skin. For pregnant women thought to be at increased risk of vitamin D deficiency, maternal serum 25(OH)D levels can be considered and should be interpreted in the context of the individual clinical circumstance.

**The American College of Obstetricians and Gynecologists (ACOG) has stated, "At this time there is insufficient evidence to support a recommendation for screening all pregnant women for vitamin D deficiency. For pregnant women thought to be at increased risk of vitamin D deficiency, maternal serum 25(OH)D levels can be considered and should be interpreted in the context of the individual clinical circumstance. When vitamin D deficiency is identified during pregnancy, most experts agree that 1000 to 2000 IU/day of vitamin D is safe."**

### Osteoporosis

The condition of idiopathic osteoporosis related to pregnancy, *pregnancy and lactation-associated osteoporosis* (PLO), was recognized in the 1950s. In the past few years, interest has increased in several clinical aspects of osteoporosis in pregnancy and lactation.<sup>13</sup> Although the prevalence is unknown, approximately 120 cases have been reported. Another form of rare pregnancy-associated osteoporosis is called *transient osteoporosis of pregnancy*. It usually presents in the third trimester of pregnancy—sometimes with very severe pain while walking or standing, usually localized in the hip—and it sometimes leads to hip fracture, with complete recovery a few months postpartum. Preexisting secondary causes of osteoporosis such as vitamin D deficiency, celiac disease, anorexia nervosa, mastocytosis, and hyperparathyroidism or hyperthyroidism should always be considered. Severe PLO may prompt screening for an underlying monogenetic bone disorder when associated with one of the following three features: (1) severely reduced bone density; (2) family history of osteoporosis or multiple fractures, joint hypermobility, blue sclerae, congenital blindness, or severely reduced vision; or (3) a history of fractures before pregnancy.

Although osteoporosis has been diagnosed during pregnancy, pregnancy unmasks low bone mass, it does not cause it. Postural changes during pregnancy, including increased lordosis, when superimposed on a small and transient decrease in bone mass may lead to pain and even fractures. In a study of 24 women with symptoms of bone pain for many years, 18 complained of back pain, 5 complained of hip pain, and 1 complained of ankle pain in late pregnancy and up to 8 months after delivery; radiologic examination of the spine showed vertebral deformities in 17, bone mass was measured in 21, evidence of osteoporosis was found in 7, and 13 were osteopenic. The authors concluded that

bone mass was probably low before pregnancy and that a transient and slight decrease in bone mass during pregnancy could have weakened the bone further.

A recent study identified 78 cases with exposure to bisphosphonates before conception or during pregnancy. Although it did not demonstrate serious adverse effects, cases of increased spontaneous abortions, shortened gestational age, low neonatal birthweight, and transient hypocalcemia of the newborn were reported. Etidronate appears to be the agent to use in women with severe disease who are planning pregnancy, although the drug should be stopped a few months before conception.

The impact of lactation on the progression of osteoporosis is controversial. It has been suggested that lactation by itself is not a determinant of bone mineral density. Although one investigation reported that lactation for more than 8 months was associated with greater bone mineral density at both the femoral neck and shaft, another study found that nursing for longer than 9 months produced a greater decrease in bone mass than observed during the first 6- to 9-month period of nursing. Given this controversy, the health care provider must decide whether cessation of lactation is advisable in the management of osteoporosis. Bolzetta and colleagues studied 752 women (mean age,  $64.5 \pm 9.3$  years) of whom 23% reported vertebral osteoporotic fractures. The women with vertebral fractures had breastfed their infants for longer periods ( $11.8 \pm 12.9$  vs.  $9.3 \pm 11.2$  months,  $P = .03$ ) and had more pregnancies ( $2.6 \pm 2.2$  vs.  $2.2 \pm 1.3$ ,  $P = .002$ ). Breastfeeding for more than 18 months was associated with a twofold risk of developing vertebral fractures (OR, 2.12; 95% CI, 1.14 to 5.38;  $P = .04$ ), particularly in those without current or past use of drugs that positively affect bone. The authors concluded that an association exists between long periods of breastfeeding and vertebral fractures, which supports a role for lengthy lactation as a risk factor for osteoporotic fractures after menopause.

Heparin-associated osteoporosis has been reported during pregnancy that may be related to the total dose of heparin.<sup>14</sup> **The authors concluded that heparin adversely affected bone density in about one third of exposed patients.**

## THYROID DISEASES

**Thyroid disorders in pregnancy present a unique opportunity for health care professionals to use a similar “team approach” that has successfully improved the care of women with diabetes mellitus.** Because of changes in thyroid economy that occur early in pregnancy, it is imperative to advise women with chronic thyroid diseases to plan their pregnancies and contact their health care professionals before or as soon as the diagnosis of pregnancy is confirmed. Autoimmune thyroid disease occurs five to eight times more often in women than in men, and its course could be affected by the immunologic changes that occur in pregnancy and in the postpartum period.<sup>15,16</sup>

In early pregnancy, the maternal thyroid gland is challenged with an increased demand for thyroid hormone secretion, due mainly to (1) the increase in thyroxine-binding globulin (TBG) secondary to the effect of estrogens on the liver; (2) the stimulatory effect of human chorionic gonadotropin (hCG) on the thyroid-stimulating hormone (TSH) receptor; (3) high concentrations of type 3 iodothyronine deiodinase (D3), which degrades thyroxine and triiodothyronine to inactive compounds; and (4) the supply of iodine available to the thyroid gland. In the United States, the iodine content in the diet—although decreased

in past decades—appears to be insufficient in only about 10% of pregnancies. **The suggested total daily iodine ingestion for pregnant women is 229  $\mu\text{g}/\text{day}$ , and for lactating women, it is 289  $\mu\text{g}/\text{day}$ ; prenatal vitamins should contain 150  $\mu\text{g}$  of iodine in the form of potassium iodine.**<sup>17</sup>

**The normal thyroid gland is able to compensate for the increase in thyroid hormone demands by increasing its secretion of thyroid hormones and maintaining them within normal limits throughout gestation.** However, in those situations in which there is a subtle pathologic abnormality of the thyroid gland, such as chronic autoimmune thyroiditis, or in women on thyroid hormone replacement therapy, the normal increase in the production of thyroid hormones is not met. As a consequence, the pregnant woman could develop biochemical markers of hypothyroidism (i.e., an elevation in serum TSH).

**Active secretion of thyroid hormones by the fetal thyroid gland commences at about 18 weeks’ gestation, although iodine uptake by the fetal gland occurs between 10 and 14 weeks.**<sup>18</sup> **Transfer of thyroxine ( $T_4$ ) from mother to embryo occurs from early pregnancy.** Maternal  $T_4$  has been demonstrated in coelomic fluid at 6 weeks and in the fetal brain at 9 weeks. Maternal transfer continues until delivery but only in significant amounts in the presence of fetal hypothyroidism. Thyroid hormone receptor gene expression has been shown in human fetal brain by 8 weeks’ gestation, which supports the important role of maternal thyroid hormone during the first trimester of human pregnancy in fetal brain development.

The levels of maternal thyroid hormone concentrations, both total thyroxine ( $TT_4$ ) and total triiodothyronine ( $TT_3$ ), increase from early pregnancy as the result of an elevation in TBG and a reduced peripheral TBG degradation rate. TBG reaches a plateau by 20 weeks’ gestation and remains unchanged until delivery. Despite these acute changes in total hormone concentration, **the serum free fractions of both  $T_4$  and  $T_3$  remain within normal limits**, unless supply of iodine to the mother is decreased or abnormalities of the thyroid gland are present.

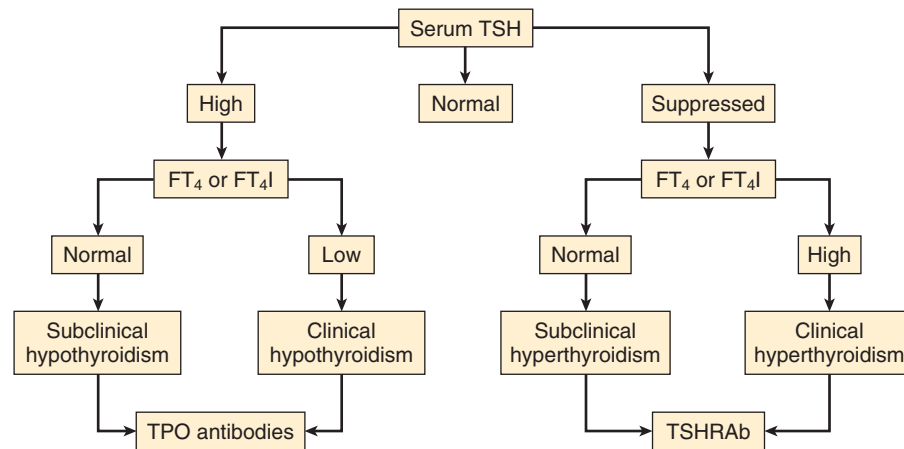

Human chorionic gonadotropin (hCG) is a weak thyroid stimulator that acts on the maternal thyroid gland TSH receptor; peak hCG values are reached by 9 to 12 weeks’ gestation. In situations in which there is a high production of hCG—such as in cases of multiple pregnancies, hydatidiform mole, and HG—serum free  $T_4$  ( $FT_4$ ) concentrations rise to levels seen in thyrotoxicosis, with a transient suppression in serum TSH values.

Goiter is commonly seen in pregnancy in areas of iodine deficiency. However, in the United States and other areas of the world with sufficient iodine intake, the thyroid gland does not clinically increase in size during pregnancy. **Therefore the detection of a goiter in pregnancy is an abnormal finding that needs careful evaluation.** The most common cause of diffuse goiter is chronic autoimmune thyroiditis or Hashimoto thyroiditis. Most patients are euthyroid, and the diagnosis is made by the determination of thyroid antibodies, mainly thyroid peroxidase (TPO). Antibody concentration decreases during pregnancy and increases in the postpartum period. High values in the first trimester of pregnancy are predictors of the syndrome of postpartum thyroid dysfunction.

## Thyroid Function Tests

Measurement of serum TSH is the most practical, simple, and economic screening test for thyroid dysfunction.<sup>19</sup> Normal TSH concentrations, as well as serum  $FT_4$  and  $TT_4$  determinations,

**FIG 42-2** Algorithm for the interpretation of thyroid function tests in pregnancy. Serum thyroid-stimulating hormone (TSH) upper limit of normal in the first trimester of pregnancy is 2.5 mIU/L; in the second and third trimesters, it is 3 mIU/L. The serum TSH lower limit of normal in the first trimester of pregnancy may be as low as 0.1 mIU/L or may even be undetectable. Subclinical hyperthyroidism in the absence of TSH receptor antibodies (TSHRabs) is a normal first-trimester physiologic finding. Presence of serum thyroid peroxidase (TPO) antibodies is consistent with a diagnosis of chronic thyroiditis. Presence of TSHRab is consistent with the diagnosis of Graves disease. FT<sub>4</sub>, free thyroxine; FT<sub>4</sub>I, free thyroxine index.

are trimester specific and depend on iodine intake in a given population, ethnicity, and assay performance; serum TSH is lower in the first trimester compared with prepregnancy values and with the second and third trimester of pregnancy. An elevated serum TSH value is consistent with the diagnosis of primary hypothyroidism, whereas a low one, with few exceptions, is a normal finding in the first trimester (Fig. 42-2) secondary to the stimulatory effect of hCG on the thyroid gland TSH receptor. Significant clinical data<sup>19</sup> support a serum TSH below 2.5 mIU/L in the first trimester, and less than 3.0 mIU/L in the second and third trimesters, as the upper limit of normal.<sup>20</sup> However, studies from China, the United Kingdom, and India that have used a specific reference range for their populations reported TSH reference ranges in the first trimester up to 4.5 mIU/L.<sup>21-23</sup> Guidelines from the American Thyroid Association (ATA) and the Endocrine Society (ES) recommend the use of trimester-specific reference ranges for serum TSH and FT<sub>4</sub> in a given population, and when not available, they recommend a serum TSH upper limit of normal of 2.5 mIU/L in the first trimester and up to 3.0 mIU/L in the second and third trimesters, as noted above. **Because most pregnant women present for their first obstetric visit after 6 weeks gestation, the upper serum TSH limit of 2.5 mIU/L is reasonable for detection of hypothyroidism.**

A word of caution is required regarding the determination of FT<sub>4</sub> levels in the different trimesters of pregnancy. A significant inconsistency is found in FT<sub>4</sub> values in the second half of pregnancy among the different immunoassays, as reported by commercial laboratories, because of both the methodology used and the variation in dietary iodine intake among the different populations studied. FT<sub>4</sub> values in the lower limits of normal, and even in the hypothyroid range, are not uncommonly seen in daily clinical practice, particularly in the third trimester of pregnancy. Lee and colleagues<sup>24</sup> compared the diagnostic performances of two different immunoassays to traditional approaches for estimating FT<sub>4</sub> (total T<sub>4</sub> and FT<sub>4</sub> index [FT<sub>4</sub>I]) relative to the physiologic TSH changes known to occur throughout pregnancy. They studied euthyroid women who were negative for TPO antibody in the first, second, and third trimesters of gestation. Control women were premenopausal nonpregnant women

matched for ethnicity. Serum TT<sub>4</sub>, as expected, was elevated in all three trimesters, and serum FT<sub>4</sub>I was elevated in the first trimester compared with controls ( $P < .05$ ) and returned to the nonpregnant range in the second and third trimesters. In contrast, FT<sub>4</sub> values were either comparable or lower than controls as measured by two different immunoassays, and by the second and third trimesters, they were about 65% of controls. The authors concluded that TT<sub>4</sub> and FT<sub>4</sub>I retained an appropriate inverse relationship with serum TSH throughout pregnancy and appeared to provide a more reliable FT<sub>4</sub> estimate than the FT<sub>4</sub> test. Because the determination of FT<sub>4</sub> by the dialysis method—the gold standard for FT<sub>4</sub> assessment—or the use of tandem mass spectrometry are not routinely available, the determination of TT<sub>4</sub> adjusted by a factor of 1.5 for pregnant patients has been suggested.<sup>24</sup> Therefore it is imperative for the practicing physician to be familiar with the interpretation and significance of the thyroid tests as reported by a given commercial laboratory.

A suppressed serum TSH value and high concentrations of FT<sub>4</sub> or FT<sub>4</sub>I is diagnostic of hyperthyroidism. However, in rare situations, hyperthyroidism may be diagnosed in the presence of suppressed TSH and normal concentrations of FT<sub>4</sub>, such as in the case of an autonomous thyroid nodule. In such cases, a serum TT<sub>3</sub> or free triiodothyronine index (FT<sub>3</sub>I) determination should be obtained.

### Thyroid-Stimulating Hormone Receptor Antibodies

Graves disease is caused by direct stimulation of the thyroid epithelial cells by TSH receptor-stimulating antibodies (TSHRabs, or TRAbs). Highly sensitive and specific assays for detection of TRAbs are now commercially available that are very valuable in assessing fetal and neonatal risk in pregnancy, not only in women with active disease but also in those with a previous history of Graves hyperthyroidism, both in spontaneous remission and after ablation therapy. TRAbs are also used in the differential diagnosis of hyperthyroidism, when the etiology is not clinically evident. Two methods are used for measuring TRAbs, *competition-based assays* (thyroid-binding inhibitor [TBI]–thyroid-binding inhibitor immunoglobulin [TBII] assays) or *bioassays* that detect cyclic adenosine monophosphate (cAMP) production (thyroid-stimulating immunoglobulin [TSI] assays).

The specificity of TBI-TBII methods is lower because positive tests may be obtained in patients with chronic autoimmune (Hashimoto) thyroiditis who may have TRAbs with TSH receptor (TSHR)-blocking activity. Like all immunoglobulin G (IgG) molecules, TRAb crosses the placenta during pregnancy, and in significant titers—that is, over three times the reference range—it can stimulate the fetal thyroid gland and produce hyperthyroidism (TRAbs with stimulating function) or, rarely, hypothyroidism (TRAbs with blocking activity). Recently, predictable levels for the development of fetal/neonatal hyperthyroidism using second-generation TBI-TBII methods have been reported. This topic is discussed in the section on fetal and neonatal hyperthyroidism in this chapter.

### Prepregnancy Counseling

The physician may be faced with different clinical situations when counseling a woman suffering from thyroid disease who is contemplating pregnancy:

1. **Hyperthyroidism diagnosed “de novo” or under antithyroid drug (ATD) treatment.** A choice of the three classic therapeutic options for hyperthyroidism treatment should be given: (1) long-term ATD therapy, (2) radioactive iodine-131 (<sup>131</sup>I) ablation, or (3) near-total thyroidectomy. Potential side effects of ATDs on the fetus should be discussed with the future parents. <sup>131</sup>I ablation therapy should be avoided in patients with positive TRAb titers because serum levels increase following <sup>131</sup>I therapy, and the effect persists for several years; fetuses whose mothers have titers above three times the normal level in the second half of pregnancy are at risk of fetal and neonatal hyperthyroidism. Surgery is another option selected by some physicians and patients concerned about the potential side effects of ATDs or radioactive treatment. **Regardless of the form of therapy chosen, it is important for the patient to be euthyroid at the time of conception.** In a large series of untreated hyperthyroid pregnant women, a doubling in the incidence of congenital malformations was reported in the first trimester compared with euthyroid women.
2. **Previous treatment with <sup>131</sup>I for thyroid carcinoma.** It is reasonable for patients treated with ablative doses of <sup>131</sup>I to wait 6 months to 1 year after completion of treatment before conception. Data obtained from 2673 pregnancies in patients treated for thyroid carcinoma but without significant external radiation to the ovaries were analyzed by Garsi and colleagues, who found no evidence that exposure to radioiodine affects the outcome of subsequent pregnancies and offspring.
3. **Treated hypothyroidism. Women under treatment with thyroid hormone usually require an increase in L-thyroxine dose soon after conception.**<sup>25,26</sup> The increase in requirements is observed as early as the first 6 to 8 weeks after the last menstrual period. As soon as the diagnosis of pregnancy is made, thyroid function tests should be performed, and thyroid doses should be adjusted accordingly. It has been recommended to add two extra doses of L-thyroxine per week to the customary doses as soon as the diagnosis of pregnancy is confirmed until the results of thyroid function tests become available.<sup>26</sup> Recently it was reported that in hypothyroid women (excluding those who underwent thyroidectomy because of thyroid cancer) on L-thyroxine replacement therapy, if the serum TSH was below 1.3 mIU/L before conception, only 17% of women needed an increase in L-thyroxine in the first trimester of pregnancy compared with

58% of those with a serum TSH above 1.3 mIU/L.<sup>81</sup> After delivery, the dose should be reduced to prepregnancy levels in most women. Common medications may affect the absorption of L-thyroxine, such as ferrous sulfate and calcium, among others. Patients should take L-thyroxine at least 2 hours apart from other medications and 1 hour before or after food intake, ideally early in the morning on awakening and 1 hour before food ingestion. However, during pregnancy, in those women affected by nausea or vomiting, the dose may be taken at bedtime on an empty stomach.

4. **Euthyroid chronic thyroiditis.** Patients with Hashimoto thyroiditis are at a greater risk for developing hypothyroidism de novo early in pregnancy, spontaneous abortions, prematurity, and postpartum thyroiditis.<sup>27</sup>

### Maternal-Placental-Fetal Interactions

Studies over the past few decades have shown an important role of maternal thyroid hormones in embryogenesis.<sup>18,28</sup> Maternal T<sub>4</sub> crosses the placenta in the first half of pregnancy at a time when the fetal thyroid gland is not functional, and maternal TSH does not cross the placenta. Thyrotropin-releasing hormone (TRH) does cross the placental barrier, but its physiologic significance is unknown.

Methimazole (MMI), propylthiouracil (PTU), and carbimazole (CMZ)—a drug that is metabolized to methimazole—do cross the placenta, may induce congenital malformations if given early in pregnancy, and if given in inappropriately high doses may produce fetal goiter and hypothyroidism. Preparations that contain iodine given in large doses or for prolonged periods are contraindicated in pregnancy because accumulation by the fetal thyroid may induce goiter and hypothyroidism.

As mentioned above, TRAb crosses the placenta, and serum concentrations decrease with progression of pregnancy. However, its titers increase significantly in Graves hyperthyroidism after therapy with <sup>131</sup>I.

### Hyperthyroidism

Autoimmune hyperthyroidism affects pregnancy in about 0.1% to 0.4% of patients.<sup>29</sup> Classically, it has been stated that Graves disease is the most common cause of hyperthyroxinemia in pregnancy; other etiologies are uncommon (Box 42-2). As will be discussed subsequently, hyperthyroidism due to inappropriate secretion or action of hCG is recognized as the most common cause of transient hyperthyroidism in pregnancy.<sup>30</sup> In our experience, single toxic adenoma and multinodular toxic goiter are found in less than 10% of cases. Subacute thyroiditis is rarely seen during gestation.

### Gestational Hyperthyroidism

Also known as *gestational thyrotoxicosis*, *transient hyperthyroidism of hyperemesis gravidarum*, and *transient nonautoimmune hyperthyroidism of early pregnancy*, this condition is defined as transient hyperthyroidism in the first trimester of pregnancy due, with few exceptions, to high titers of hCG secretion that stimulate the TSH receptor. The most common causes of gestational hyperthyroidism are HG, multiple gestation, and hydatidiform mole. Other isolated reports included hyperplacentalism.

### Transient Hyperthyroidism of Hyperemesis Gravidarum

Hyperemesis gravidarum (HG) is characterized by severe nausea and vomiting with onset between 4 and 8 weeks' gestation that

requires frequent visits to the emergency department and sometimes repeated hospitalizations for IV hydration.<sup>31</sup> Weight loss of at least 5 kg, ketonuria, abnormal liver function tests, and hypokalemia are common findings, depending on the severity of vomiting and dehydration.  $FT_4$  and  $TT_4$  levels are elevated, sometimes up to four to six times the normal values, whereas  $TT_3$  and  $FT_3$  values are elevated in up to 40% of affected

women, although  $FT_3$  values are not as high as those of serum  $FT_4$ .<sup>30</sup> The  $TT_3/TT_4$  ratio is less than 20, compared with Graves hyperthyroidism, in which the ratio is more than 20. Serum TSH measured by a sensitive assay is consistently undetected or suppressed. **Despite the significant biochemical hyperthyroidism, signs and symptoms of hypermetabolism are mild or absent.** Patients may complain of mild palpitations and heat intolerance, but perspiration, proximal muscle weakness, and frequent bowel movements are rare. On physical examination, ophthalmopathy and goiter are absent, a mild tremor of the outstretched fingers is occasionally seen, and tachycardia may be present due in part to dehydration. Significant in the medical history is the lack of hyperthyroid symptoms before conception because most patients with Graves disease diagnosed for the first time during gestation give a history of hypermetabolic symptoms that antedate conception. Spontaneous normalization of hyperthyroxinemia parallels the improvement in vomiting and weight gain, and most cases resolve spontaneously between 14 and 20 weeks' gestation, although persistence of hyperthyroidism beyond 20 weeks' gestation has been reported in 15% to 25% of cases. Suppressed serum TSH may lag for a few more weeks after normalization of free thyroid hormone levels (Fig. 42-3). **Antithyroid medications are not needed.** In one series in which antithyroid medication was used, pregnancy outcome was not significantly different from that of a similar group of patients who received no therapy. Occasionally, severe vomiting and hyperthyroidism may require parenteral nutrition.

The degree of thyroid abnormalities is directly related to the severity of vomiting and weight loss. In 67 patients studied by Goodwin and colleagues,<sup>30</sup> liver and electrolyte abnormalities were routinely found in women with worse symptoms, including severe vomiting, weight loss of at least 5 kg, and significant dehydration. They also presented with more significant elevations in  $FT_4$  levels and suppression of serum TSH values; indeed, in 30% of their patients, serum TSH was undetectable ( $<0.04$  mIU/L). Those with a lesser degree of hyperemesis had a less severe disorder of thyroid function.

**FIG 42-3** A representative example of transient hyperthyroidism of hyperemesis gravidarum. By week 6, vomiting begins; it becomes severe by week 10. Serum free thyroxine index ( $FT_4I$ ) is elevated, and thyrotropin is suppressed. By weeks 16 to 18, vomiting subsides with marked improvement of the  $FT_4I$  value. During this period, the patient loses 3.6 kg. By week 18, the serum  $FT_4I$  returns to normal, but the serum thyrotropin remains suppressed until week 26. The patient improves and gains weight and delivers a healthy infant at term. The orange band indicates the reference range. LNMP, last normal menstrual period; TSH, thyroid-stimulating hormone.

**TABLE 42-1** DIAGNOSIS OF GRAVES HYPERTHYROIDISM VERSUS GESTATIONAL THYROTOXICOSIS

|                             | GRAVES HYPERTHYROIDISM | GESTATIONAL THYROTOXICOSIS |

—, None; +, mild; ++, severe.

**Transient hyperthyroidism due to HG should be suspected in women who present in the first few weeks after conception with sudden onset of severe nausea and vomiting and thyroid tests in the hyperthyroid range.** These patients do not complain of hypermetabolic symptoms that antedate pregnancy, goiter is not detected by palpation, and symptoms or signs of tissue thyrotoxicosis are mild or absent. In addition, screens for thyroid anti-TPO antibodies and TRAbs, markers of autoimmune thyroid disease, are negative. The differential diagnosis may also be difficult because vomiting can also be a presenting symptom of the hyperthyroidism of Graves disease (Table 42-1).

The cause of the elevations of thyroid hormones in patients with HG is the endocrine effect of hCG.<sup>32</sup> Most likely, high levels of hCG—a known stimulator of the TSH receptor—play an important role, as does the prolongation in its biologic activity seen in twin pregnancies. A significant, albeit weak, correlation has been found between the degree of thyroid stimulation and total hCG levels in normal women and in those with hyperemesis.<sup>32</sup> Titers of more than 200,000 mIU/mL of hCG consistently bring serum TSH to undetectable values. A case has been reported in a mother and daughter with recurrent hyperemesis, in whom hCG levels were not elevated. Both were heterozygous for a missense mutation in the extracellular domain of the thyrotropin receptor. The mutant receptor was more sensitive than the wild-type receptor to hCG, which accounted for the occurrence of hyperthyroidism despite the presence of normal hCG levels.

As noted previously, the diagnosis of transient hyperthyroidism of HG should be considered in women with severe vomiting, no clinical manifestations of Graves disease, biochemical evidence of hyperthyroidism in early pregnancy, suppressed or undetectable serum TSH values, and elevated serum FT<sub>4</sub>. Normal serum TSH in early pregnancy may be as low as 0.01 mIU/L; therefore the presence of elevated serum FT<sub>4</sub> is required for the diagnosis. Vomiting should be persistent and severe with a significant weight loss because most women with morning sickness of pregnancy have normal thyroid function tests. The syndrome may repeat in future pregnancies.

HG may also occur in women with Graves hyperthyroidism. It may occur during remission of the disease, explained by the additional action of hCG early in gestation; **the differential diagnosis between the two entities may be difficult, but the presence of TRAb favors the diagnosis of Graves hyperthyroidism.**<sup>33</sup>

**Obstetric outcome is not affected by gestational hyperthyroidism. Birthweight may be slightly lower, but not significantly different, compared with fetuses of control mothers and is related to maternal weight loss.**

Gestational trophoblastic diseases, partial and complete hydatidiform moles, and choriocarcinoma are other causes of hyperthyroidism early in pregnancy.

### BOX 42-3 POTENTIAL MATERNAL AND FETAL COMPLICATIONS OF GRAVES HYPERTHYROIDISM

| MATERNAL                       | FETAL                             |
|--------------------------------|-----------------------------------|

### Graves Disease

**The natural course of hyperthyroidism due to Graves disease in pregnancy is characterized by an exacerbation of symptoms in the first trimester and during the postpartum period and an amelioration of symptoms in the second half of pregnancy.** Stimulation of the thyroid gland by hCG in the first trimester and an elevation in TRAb values have been suggested as the cause of the exacerbation. Immunologic responses caused by changes in lymphocyte subsets could explain spontaneous improvement in the second half of pregnancy and recurrences in the postpartum period. In a study that compared Graves disease in pregnant and nonpregnant women, Kung and Jones postulated that the amelioration of symptoms seen with progression of pregnancy was due to a decrease in the titers of TRAbs with stimulating activity and an increase in TRAbs with thyroid-blocking activity. The reverse was true in the postpartum period, when aggravation of Graves hyperthyroidism usually occurs. In another study, it was suggested that the amelioration of Graves disease in the last half of pregnancy is induced by a decrease of thyroid receptor antibodies (TRAbs, TSIs) but not by the appearance of thyroid stimulation-blocking antibodies (TSBAs).

When hyperthyroidism is properly managed throughout pregnancy, the outcome for mother and fetus is good; however, maternal and neonatal complications for mothers with untreated or poorly controlled hyperthyroidism are significantly increased (Box 42-3).<sup>34</sup>

In most patients in whom the diagnosis is made for the first time during pregnancy, hyperthyroid symptoms antedate conception. The clinical diagnosis of thyrotoxicosis may present

difficulties during gestation because many symptoms and signs are commonly seen in normal pregnancy, such as mild palpitations, heart rate between 90 and 100 beats/min, mild heat intolerance, shortness of breath on exercise, and warm skin. However, some clinical clues increase the likelihood of the diagnosis of hyperthyroidism: presence of goiter, ophthalmopathy, proximal muscle weakness, tachycardia with a pulse rate of more than 100 beats/min, and weight loss or inability to gain weight despite a good appetite. Occasionally, the patient may be seen for the first time in congestive heart failure, and the etiologic diagnosis is difficult because many of the physical findings are suggestive of cardiac valvular disease, particularly mitral insufficiency or stenosis. Hyperthyroidism under poor control is frequently complicated by preeclampsia, small-for-gestational-age (SGA) infants, and preterm delivery. The physician should suspect hyperthyroidism in the presence of systolic hypertension with an inappropriately low diastolic blood pressure and a wide pulse pressure, which is also seen in other conditions such as aortic insufficiency.

Classic symptoms of hyperthyroidism include nervousness, increased sweating, increased appetite, heat intolerance, insomnia, proximal muscle weakness, irritability, changes in personality, frequent bowel movements, decreased tolerance to exercise (sometimes manifested as shortness of breath), eye irritation, frequent lacrimation, pruritus, and weight loss. Not all symptoms are present in a given patient; therefore the physician should be aware of subtle complaints, particularly in the presence of weight loss or inability to gain weight. As mentioned previously, in the first trimester of pregnancy, differentiating the diagnosis from transient hyperthyroidism of HG presents a real challenge for the health care professional.

**On physical examination, the thyroid gland is enlarged in almost every pregnant woman with Graves disease.** Indeed, the absence of a goiter makes the diagnosis unlikely in young people. The gland is diffusely enlarged, between two and six times the normal size, and varies from soft to firm; sometimes it is irregular to palpation, with one lobe being more prominent than the other. A thrill may be felt or a bruit may be heard, indications of a hyperdynamic circulation. Examination of the eyes may reveal obvious ophthalmopathy, but in most cases, exophthalmos is absent or mild, with one eye slightly more prominent than the other with retraction of the upper lid. Extraocular movements may be impaired on careful eye examination. Stare is common, as is injection or edema of the conjunctiva. Severe ophthalmopathy is rare in pregnancy; glucocorticoid therapy and surgical orbital wall decompression may be required to restore visual acuity. Pretibial myxedema is rare, seen in less than 10% of women. A hyperdynamic heart with a loud systolic murmur is a common finding. Proximal muscle weakness, fine tremor of the outstretched fingers, and hyperkinetic symptoms are seen frequently. The skin is warm and moist, and palmar erythema is accentuated.

As discussed previously (see [Thyroid Function Tests](#)), almost every patient with Graves disease will have an elevated FT<sub>4</sub> concentration. **An undetected TSH value in the presence of a high FT<sub>4</sub>, or FT<sub>4</sub>I or TT<sub>4</sub> adjusted for pregnancy confirms the diagnosis of hyperthyroidism.**<sup>29</sup> In some unusual situations, the serum FT<sub>4</sub> may be at the upper limit of normal or slightly elevated, in which case the determination of TT<sub>3</sub> or adjusted TT<sub>3</sub> will confirm the diagnosis of hyperthyroidism. Thyroid peroxidase antibodies (TPOAbs) or thyroid antimicrobial antibodies, markers of thyroid autoimmune disease, are

elevated in most patients with Graves disease, although it is of no clinical relevance for the diagnosis; the titers of TRAb, both TBII and TSI, are elevated, which confirms the clinical diagnosis of Graves hyperthyroidism, and their actual titers have a prognostic importance for fetal and neonatal hyperthyroidism (see later discussion).

Significant maternal and perinatal morbidity and mortality were reported in early studies of pregnancies complicated by hyperthyroidism. In the past 25 years, however, there has been a significant decrease in the incidence of maternal and fetal complications directly related to improved control of maternal hyperthyroidism (see [Box 42-3](#)).<sup>34-36</sup> In patients whose hyperthyroidism is poorly controlled, one of the most common maternal complications is pregnancy-induced hypertension (PIH). In women with uncontrolled hyperthyroidism, the risk for severe preeclampsia was five times greater than that in patients with controlled disease.<sup>34</sup> Other complications include preterm delivery, placental abruption, birthweight less than 2500 g, stillbirth, and miscarriage. Congestive heart failure may occur in women untreated or treated for a short period in the presence of PIH or operative delivery. Left ventricular dysfunction is usually detected by echocardiography in women with cardiovascular manifestations. Although these changes are reversible, they may persist for several weeks or months after achieving a euthyroid state. In one study, reduction in peripheral vascular resistance and higher cardiac output were still present despite normalization of T<sub>4</sub> levels. This is an important finding with significant clinical implications. **Left ventricular decompensation in hyperthyroid pregnant women may develop in the presence of superimposed preeclampsia, at the time of delivery, or with undercurrent complications such as anemia or infection.** We have seen congestive heart failure in the first half of pregnancy in women with long-standing hyperthyroidism. It is likely that the aggravation of hyperthyroidism seen in the first part of pregnancy played an important role in the development of this complication. Careful monitoring of fluid administration is imperative in these situations. Thyroid storm has been observed in pregnancy and was reported 2 weeks postpartum in a woman whose hyperthyroidism was uncontrolled during pregnancy in association with multiorgan failure.

**Fetal and neonatal complications are also related to maternal control of hyperthyroidism.** Intrauterine growth restriction (IUGR), prematurity, stillbirth, and neonatal morbidity are the most common complications. Millar and coworkers<sup>34</sup> demonstrated that uncontrolled hyperthyroidism during the entire gestation was associated with a ninefold greater incidence of low-birthweight (LBW) infants compared with the control population. The incidence of LBW infants was almost 2.5 times greater in those whose hyperthyroidism was treated during pregnancy but who became euthyroid at some time during gestation. In mothers who achieved a euthyroid state before or early in pregnancy, the incidence of LBW infants was no different from that in the control population. Delivery of an SGA infant is correlated with the presence of maternal thyrotoxicosis lasting more than 30 weeks of pregnancy, a duration of Graves disease of approximately 10 years, and the onset of Graves disease before age 20 years. The reported incidences of spontaneous abortions (25.7%) and premature delivery (14.9%) in mothers who were hyperthyroid at the time of conception are higher than those in euthyroid mothers, 12.8% and 9.5%, respectively. Neonatal central hypothyroidism has been reported in infants whose mothers remained hyperthyroid throughout their pregnancies.

**FIG 42-4** A representative example of management of hyperthyroidism in pregnancy. The patient is hyperthyroid at time of conception on methimazole (MMI) 10 mg daily. When pregnancy is diagnosed, MMI is discontinued, and propylthiouracil (PTU) is added at a dosage of 150 mg three times daily. By the end of the first trimester, PTU is discontinued and MMI is given at a dosage of 20 mg daily. By week 20, the free thyroxine index (FT<sub>4</sub>I) is almost normal, and the MMI dosage is reduced to 10 mg. By week 26, the FT<sub>4</sub>I is in the upper reference range and thyrotropin remains suppressed; the MMI dosage is reduced to 5 mg daily. The FT<sub>4</sub>I remains in the upper reference range, and by week 34 MMI is discontinued (D/C), and the patient remains euthyroid until delivery. The orange band indicates the reference range. LNMP, last normal menstrual period; TSH, thyroid-stimulating hormone.

Many of these infants recovered normal thyroid function in a few weeks, whereas another group had long-standing hypopituitary dysfunction.<sup>37</sup>

The use of ultrasonography for monitoring the size of the fetal thyroid gland as an indicator of thyroid dysfunction and possible need for therapeutic intervention was evaluated by Luton and associates in France.<sup>38</sup> In a group of hyperthyroid women considered to be at high risk (presence of TRAbs) and on antithyroid therapy, fetal goiter was detected in 11 of 41 patients. Four fetuses were hyperthyroid, and seven were hypothyroid secondary to high doses of maternal antithyroid drug treatment; all of them benefited from adjusting drug therapy. The authors concluded that ultrasonography of the fetal thyroid gland by an experienced ultrasonographer is an excellent diagnostic tool, in conjunction with close teamwork, to ensure normal fetal thyroid function.

Treatment of hyperthyroidism is essential to prevent maternal, fetal, and neonatal complications (Fig. 42-4). **The goal of treatment is normalization of thyroid tests as soon as possible and maintenance of euthyroidism with the minimal amount of antithyroid medication.** Excessive amounts of ATDs crossing the placenta may affect the fetal thyroid, with the development of fetal hypothyroidism with or without goiter. Patients should be monitored at regular intervals, and the dose of their medications should be adjusted to keep the FT<sub>4</sub> or FT<sub>4</sub>I or TT<sub>4</sub> very close to the upper limit of the reference range for pregnancy, or just above it. Momotani and associates<sup>35</sup> showed that fetal serum TSH was elevated even in mothers with FT<sub>4</sub> within the normal range; furthermore, they demonstrated that normalization of maternal serum TT<sub>3</sub> is a risk factor for the development of fetal hypothyroidism, which supports the recommendations that serum TT<sub>3</sub> determination should rarely be used to assess maternal thyroid function during gestation.

To achieve a euthyroid state, and with the aim to keep the FT<sub>4</sub> in the upper limit of the nonpregnant reference range and even slightly above normal, thyroid tests should be performed

every 2 weeks at the beginning of treatment and every 2 to 4 weeks when euthyroidism is achieved. Because of the immunologic changes that occur with the progression of pregnancy, the requirement for antithyroid medications decreases after the second half of gestation. Some women with small goiters, a short duration of symptoms, low serum TRAb titers, and taking minimal amounts of antithyroid medication are able to discontinue ATDs by 34 weeks' gestation or beyond. It is estimated that 30% to 40% are able to remain euthyroid without antithyroid therapy in the last few weeks of pregnancy.<sup>34,36</sup>

In a study of 44 women in 46 pregnancies, the correlation among TRAb activity, the dose of antithyroid therapy, and neonatal outcome was studied.<sup>36</sup> Medication was discontinued in 30 pregnancies 3 to 18 weeks before delivery. Neonatal thyrotoxicosis was seen in four infants whose mothers' TBII levels exceeded 70% (normal, <15%). Interestingly, of the infants born with elevated serum TSH, maternal TBII was less than 30% in most, suggesting that in Graves disease-associated hyperthyroid pregnancies, a low TBII titer is an indication to use the minimal amount of antithyroid therapy to avoid the development of fetal hypothyroidism with or without goiter.

In the United States, the two available ATDs are PTU and MMI. Both drugs are effective in controlling symptoms. Recently, the risk for hepatic toxicity with PTU was revisited. An alarming number of deaths and cases requiring liver transplantation were noted (Box 42-4). MMI can also induce liver toxicity, but these effects are milder, confined to cholestasis, not associated with liver failure, and seen more frequently in patients older than 61 years. It is estimated that about 4000 pregnant women per year in the United States would be expected to be treated with ATDs, most of them with PTU, as recommended per previous practice guidelines. Taylor and Vaidya<sup>40</sup> found six reported cases of PTU-induced liver failure; it has been estimated that four women per year will have severe PTU-related hepatic complications.<sup>39</sup> **Although the incidence of both liver toxicity with PTU and embryopathy from MMI are very low,**

From Patil-Sisodia K, Mestman JH. Graves hyperthyroidism and pregnancy: a clinical update. *Endocr Pract.* 2010;16:118-129.

a panel convened by the U.S. Food and Drug Administration (FDA) and the ATA recommended the use of PTU only in the first trimester of pregnancy with a change to MMI in the second trimester (see Fig. 42-4).<sup>41</sup> Other indications for the preferential use of PTU over MMI are drug allergy to MMI and in thyroid storm, because of the ability of PTU to inhibit peripheral conversion of T<sub>4</sub> to T<sub>3</sub>.

To our knowledge, no studies have shown PTU to be superior to MMI in the management of hyperthyroidism in pregnancy; both drugs have similar placental transfer kinetics. Furthermore, when the efficacies of both drugs were compared, euthyroidism was achieved equally with equivalent amounts of drugs and at the same weeks of treatment. Neonatal outcomes were no different in both groups.

Aplasia cutis congenita, a localized lesion in the parietal area of the scalp characterized by congenital absence of the skin and a punched-out ulcer-like lesion, has occurred in a small group of infants born to mothers on MMI therapy. Only one case has been reported with the use of PTU. However, the incidence in the general population is 0.03% of newborns.

Several studies have described a specific embryopathy in infants born to mothers treated with MMI in the first trimester of pregnancy.<sup>42</sup> This has been named *methimazole embryopathy*, and it includes choanal atresia (failure of the nasal passages to develop), tracheoesophageal fistula, esophageal atresia, omphalocele, hypothelia and athelia (failure of the nipples to develop), minor dysmorphic features, and developmental delay. Very few cases have been described, and none with the use of PTU. The prevalence of these malformations in the general population is 1 in 2500 for esophageal atresia and 1 in 1000 for choanal atresia. The doses of MMI were 5 to 50 mg/day in one study; in the second study, both affected mothers took more than 20 mg/day. In an epidemiologic report, Barbero and associates<sup>42</sup> described an OR of 18 (95% CI, 3 to 121) for choanal atresia among infants whose mothers received MMI in the first trimester compared with the general population; however, the authors could not exclude the possibility that hyperthyroidism itself may be associated with this and other abnormalities. Recently, congenital heart defects were reported in children whose mothers

were exposed to MMI with carbimazole (MMI-CMZ) early in pregnancy. In one study, echocardiography was performed in 60 of the 68 neonates born of mothers with Graves disease, and four cases of congenital heart defects were diagnosed (two atrial septal defects, one ventricular septal defect, and one tetralogy of Fallot).<sup>43</sup> In the Danish Civil Registration System study,<sup>44-46</sup> 1097 children exposed to MMI-CMZ and 564 children exposed to PTU in early pregnancy were followed after birth for a median of 8.3 years and were compared with 881,730 unexposed children. They reported a series of congenital malformations in neonates exposed to PTU in early pregnancy; they tended to be less severe than the ones observed with MMI and affected mainly the face and neck area and the urinary system. Some of these malformations were detected within 2 years after birth and needed surgery. The adjusted risk for face and neck region defects (preauricular and branchial sinus fistula/cyst) was 4.92, and for the urinary system (single cyst of the kidney and hydronephrosis) it was 2.73. Previous studies did not show PTU-associated congenital malformations of any statistical significance. Yoshihara and colleagues in Japan studied the pregnancy outcomes of 6744 women with 5967 live births that included 1426 women treated with MMI and 1578 with PTU. The overall rate of major anomalies in the MMI group was 4.1% (most of them part of the MMI embryopathy syndrome), a rate significantly higher than the 2.1% in the control group. The incidence of congenital malformations in the PTU group was not different from that of the control group. The contrast between the PTU anomalies in the Danish and Japanese studies could be due to the follow-up of the newborns in the Danish study 2 years after birth.

The reports of congenital malformations in children exposed to PTU opens a new dilemma in the management of hyperthyroidism in women planning pregnancy, and in all women of reproductive age, because unplanned pregnancy is reported to be over 50% in our population. The ATA and ES both recommend either prescribing PTU in women with active hyperthyroidism who are planning a pregnancy or switching from MMI to PTU as soon as the diagnosis of pregnancy is confirmed. Laurberg and Andersen reviewed the literature on the association between the periods of exposure in early pregnancy and the development of birth defects. They concluded that high risk was confined to gestational weeks 6 through 10, the major period of organogenesis. PTU-associated defects might occur if PTU is given later than gestational week 5, which suggests that the risk of birth defects could be minimized if pregnant women stop ATD intake before gestational week 6. Their recommendation for fertile women on drug therapy is to receive written instructions (1) to perform a pregnancy test within a few days after a missed menstrual period; (2) if the test is positive, to contact their physician; (3) if feasible, to discontinue ATD therapy and follow thyroid tests weekly for the remaining of the first trimester; and (4) if drug therapy is needed, PTU should be used because birth defects seem to be less severe with PTU.

The initial recommended dose of PTU is 100 to 450 mg/day, given every 8 hours, and for MMI, 10 to 20 mg/day given in a single daily dose; very seldom is a larger initial dose required. MMI is given once or twice daily, which allows for improvement in patient compliance. Because of its shorter half-life, PTU should be given every 8 hours. **In our experience, 20 mg/day of MMI or 100 to 150 mg of PTU three times a day is an effective initial dose in most patients.** Drug side effects are related to the ATD dose. Those with large goiters and longer

duration of the disease may need higher doses at the initiation of therapy. In patients with minimal symptoms, an initial dose of 10 mg of MMI daily or PTU 50 mg two or three times a day may be initiated. In the majority of patients, clinical improvement is seen in 2 to 6 weeks, and improvement in thyroid tests occurs within the first 2 weeks of therapy, with normalization to chemical euthyroidism in 3 to 7 weeks. Resistance to drug therapy is unusual, most likely a result of poor patient compliance. **Once clinical improvement occurs, mainly weight gain and reduction in tachycardia, the dose of antithyroid medication may be reduced by half of the initial dose.** The daily dose is adjusted every few weeks according to the clinical response and the results of thyroid tests, and serum TSH remains suppressed despite the normalization of thyroid hormone levels; normalization of serum TSH is an indicator to reduce the dose of medication. If an exacerbation of symptoms or worsening of the thyroid tests occurs, the amount of antithyroid medication is doubled.

**The main concerns of maternal drug therapy are the potential side effects in the fetus, mainly goiter and hypothyroidism, as well as birth defects—hence the importance of using the minimal drug dose to keep FT<sub>4</sub> in the upper limit of the reference range or just above the normal nonpregnant range.** However, small elevations in serum TSH in the neonate have been reported even with lower doses of antithyroid medication. Furthermore, in one study, cord blood FT<sub>4</sub> values were not correlated with the antithyroid medication dose at term. As mentioned previously,<sup>36</sup> in the presence of maternal TBII values less than 30%, the dose of MMI required to control hyperthyroidism may be lower than in women with elevated TBII titers, and such a dose may protect the fetus from hypothyroidism. **We do not recommend adding T<sub>4</sub> to ATD therapy (block-replace regimen) in the management of Graves disease in pregnancy. It is difficult to interpret the serum T<sub>4</sub> level, and this may lead to more unnecessary antithyroid medications.**

In addition to PTU-induced liver failure, side effects of ATDs occur in 3% to 5% of treated patients (see Box 42-4). **The most common complications of both drugs are pruritus and skin rash,** which usually resolve after switching to the other antithyroid medication. However, allergies to both antithyroid medications have been reported in a pregnant woman with type 1 diabetes mellitus. In general, the rash occurs 2 to 6 weeks after initiation of therapy. Because pruritus may be an initial symptom of hyperthyroidism, it is customary to ask the patient during the first visit whether she is bothered by this. Other complications that are much less common are migratory polyarthritis, a lupus-like syndrome, and cholestatic jaundice. Agranulocytosis, a serious but unusual complication, has been reported in 1 in 300 patients receiving PTU or MMI. It manifests as fever, malaise, gingivitis, and sore throat. Agranulocytosis occurs in the first 12 weeks of therapy and appears to be related to the dose of medication. Patients should be made aware of the potential adverse effects of these drugs at the time the prescription is given and should be advised to discontinue the medication at once if these effects appear. In this setting, a leukocyte count should be obtained immediately. Although some have recommended routine white blood cell counts in patients on antithyroid therapy, such testing is not indicated because granulocytopenia or agranulocytosis may appear without warning symptoms.

**β-Adrenergic blocking agents** (propranolol 20 to 40 mg every 6 hours or atenolol 25 to 50 mg/day) **are very effective in controlling hyperdynamic symptoms and are indicated for**

**the first few weeks in patients who have symptoms.** One situation in which β-adrenergic blocking agents may be very effective is in the treatment of severe hyperthyroidism during labor. In a case reported in which both mother and fetus were affected, labetalol was infused at a rate of 2 mg/min and controlled maternal and fetal tachycardia within 45 minutes.

Subtotal thyroidectomy in pregnancy is effective in managing severe hyperthyroidism. However, indications for surgical treatment are few and include allergy to ATDs, requirements of large doses of medication, patient preference, and the exceptional case of resistance to drug therapy. Two issues are significant when advising surgical therapy: first, the mother should be prepared with β-adrenergic blocking agents to render her hemodynamically stable and with Lugol's solution for at least 10 days to reduce thyroid gland vascularity (use of potassium iodide for a short time is not contraindicated); and second, a determination of TRAb is of the utmost importance because a value three times greater than normal places the fetus at risk for fetal hyperthyroidism.<sup>47</sup>

**<sup>131</sup>I therapy is contraindicated in pregnancy because when given after 12 weeks' gestation, it could produce fetal hypothyroidism.<sup>48</sup> A pregnancy test is mandatory in any woman of childbearing age before a therapeutic or diagnostic dose of <sup>131</sup>I is administered.**

Iodine crosses the placenta. If given in large amounts and for prolonged periods, it may produce a fetal goiter and hypothyroidism. Therefore its therapeutic use is not recommended in pregnancy. However, iodine was used in small amounts (6 to 40 mg/day) in a group of pregnant Japanese women with mild hyperthyroidism. Elevation in serum TSH was observed in 2 of 35 newborns, and the mothers were slightly hyperthyroid at the time of delivery. Despite this observation, iodine therapy is not routinely indicated in the treatment of hyperthyroidism in pregnancy.

**Breastfeeding should be permitted if the daily dose of PTU or MMI is less than 300 mg/day or 20 mg/day, respectively.** It is prudent to give the total dose in divided doses after each feeding. Occasionally, thyroid function tests may be done in the baby.<sup>49</sup> In a very provocative study, PTU was given to lactating hyperthyroid mothers whose infants were born with elevated serum TSH levels. Infant TSH levels normalized even with continuation of PTU therapy by the mothers. In another study, thyroid tests were done at regular intervals in breast-fed infants of mothers taking up to 20 mg of MM daily and showed no evidence of hypothyroidism. The authors followed the children up to 74 months of age and found no evidence of physical or intellectual developmental deficits compared with 176 controls.

Fetal surveillance with serial ultrasounds, nonstress tests (NSTs), and biophysical profiles (BPPs) is indicated for patients with uncontrolled hyperthyroidism, in the presence of fetal tachycardia or IUGR, in pregnancies complicated by preeclampsia, or when indicated for other obstetric or medical complications.

## Treatment of Thyroid Storm

Thyroid storm is a clinical diagnosis based on severe signs of thyrotoxicosis with significant hyperpyrexia (>103° F) and neuropsychiatric symptoms essential for the clinical diagnosis. Tachycardia with a pulse rate that exceeds 140 beats/min is not uncommon, and congestive heart failure is a frequent complication. Gastrointestinal symptoms such as nausea and vomiting

accompanied by liver compromise have been reported. Burch and Wartofsky have derived a scoring system based on clinical symptoms to predict the likelihood of thyroid storm. Laboratory tests show the classic hyperthyroid changes, although the actual elevation in FT<sub>4</sub> values does not help in the diagnosis.

Management includes the following:

1. Admission to the intensive care unit is initiated for supportive therapy such as fluids and correction of electrolyte abnormalities, oxygen therapy as needed, and control of hyperpyrexia. Acetaminophen is the drug of choice because aspirin may increase free thyroid hormones.
2. Management of congestive heart failure is undertaken, which may require large doses of digoxin.
3. Proper antibiotic therapy is instituted in case of infection.
4. To control hyperadrenergic symptoms,  $\beta$ -adrenergic blocker therapy can be used, such as propranolol 60 to 80 mg every 4 hours orally or 1 mg/min intravenously. Esmolol, a short-acting  $\beta$ -acting antagonist, can be given intravenously with a loading dose of 250 to 500  $\mu$ g/kg of body weight followed by continuous infusion at 50 to 100  $\mu$ g/kg/min.
5. MMI 30 mg or PTU 300 mg every 6 hours can also be used. If the patient is unable to take oral medications, a nasogastric tube may be needed; thioamides block the synthesis of thyroid hormones in a few hours.
6. One hour after the administration of thioamides, iodine is administered in the form of Lugol's solution, 10 drops three times a day, or sodium iodide is given intravenously 1 g every 12 hours.
7. Glucocorticoids are also helpful because they reduce the peripheral conversion of serum T<sub>4</sub> to T<sub>3</sub>. They are administered in the form of hydrocortisone every 8 hours or equivalent amounts of other glucocorticoids.

**In summary, thyroid storm is a life-threatening condition with a mortality rate of 20% to 30%,<sup>50</sup> and it requires early recognition and aggressive therapy in an intensive unit care setting.**

### Fetal Hyperthyroidism

In mothers with hyperthyroidism due to Graves disease, either active or past, high concentrations of TRAb that cross the placental barrier stimulate fetal production of thyroid hormones and may cause fetal hyperthyroidism. However, in mothers with active disease who are under drug treatment, the hyperactive fetal thyroid is controlled by maternal therapy, and the fetus remains euthyroid during fetal life. Within a few days after birth, when the beneficial effect of antithyroid therapy ceases, the neonate may develop neonatal hyperthyroidism (see the section, “[Neonatal Hyperthyroidism](#)”). **Women at risk for an infant with fetal hyperthyroidism are those with a history of Graves disease previously treated with ablation therapy, either by surgery or with <sup>131</sup>I, with elevated TRAb titers despite maternal euthyroidism.** The fetuses of women with Graves disease–associated hyperthyroidism who undergo therapeutic thyroidectomy in the second trimester of pregnancy are also at risk for hyperthyroidism if the mother carries high titers of TRAb.<sup>47</sup> The fetal thyroid TSH receptor starts responding to TSI stimulation during the second trimester, and the placental transfer of IgG from mother to fetus increases by the end of the second trimester, reaching a level in the fetus similar to that of the mother at about 30 weeks' gestation.

**Fetal hyperthyroidism is diagnosed in the presence of persistent fetal tachycardia (>160 beats/min), IUGR,**

**oligohydramnios, hydrops, and occasionally a goiter identified on ultrasonography, sometimes manifested as hyperextension of the fetal neck.**<sup>51</sup> The diagnosis may be confirmed by measuring thyroid hormone levels in cord blood obtained by cordocentesis. Serial cordocentesis for monitoring drug therapy has been proposed, but its value has been questioned.<sup>52,53</sup> A fetal heart monitor tracing that demonstrated a sustained baseline of 170 to 180 beats/min with moderate variability that exhibited accelerations without decelerations was present in two fetuses of hyperthyroid mothers. The authors stated that “this pattern is unique to fetal thyrotoxicosis.” Heckel and associates reviewed nine cases of fetal hyperthyroidism treated with antithyroid medications. Fetal tachycardia was the most frequent sign, whereas oligohydramnios and IUGR were reported in only two cases. Fetal goiter was detected by ultrasonography in three cases. Treatment consisted of antithyroid medication given to the mother (MMI, 10 to 20 mg/day),<sup>54</sup> and the dose is guided by the improvement and resolution of fetal tachycardia, a decrease in the goiter size, and normalization of fetal growth—all are indicators of good therapeutic response.

Luton and associates performed clinical fetal evaluation in 72 mothers with a past or present history of Graves hyperthyroidism. The main tools were the determination of maternal TRAb and fetal ultrasonography; cordocentesis was rarely indicated. In 31 mothers, TRAb titers were undetectable, and none of the patients received antithyroid medications. All infants were born euthyroid. Of 30 women positive for TRAb and on antithyroid drug therapy, neonatal function was normal. Eleven fetuses were diagnosed with goiter by ultrasonography, and seven of them were hypothyroid at birth. Their mothers had low TRAb titers and had received antithyroid therapy, probably in higher doses than needed. In the four hyperthyroid newborns, maternal TRAb titers were very high, and their mothers may not have received enough medication. The authors recommended monthly fetal ultrasonography after 20 weeks' gestation with determination of TRAb early in gestation and again by 24 to 28 weeks' gestation.

In summary, the diagnosis of fetal hyperthyroidism should be suspected in the presence of fetal tachycardia, IUGR, oligohydramnios or polyhydramnios, and accelerated bone maturation (the presence of the distal femoral ossification center before 31 weeks' gestation) with or without fetal goiter in mothers with active hyperthyroidism or in women with a history of Graves disease treated previously by ablation therapy in the presence of high titers of serum TRAb. The indications for ordering a determination of TRAbs are described in [Box 42-5](#). This should

be done in patients at risk between 22 and 28 weeks' gestation, although some investigators recommended this test early in pregnancy and late in the second trimester.<sup>51</sup> The diagnosis may be confirmed by the determination of fetal thyroid hormones by cordocentesis in those centers with expertise in this technique.

### Neonatal Hyperthyroidism

Neonatal hyperthyroidism is infrequent, with an incidence of 1% to 5% of infants born to mothers with Graves disease; therefore it affects 1 in 50,000 neonates. **In most cases, the disease is caused by the transfer of maternal immunoglobulin antibodies with stimulating activity to the fetus.** When present in high concentrations in maternal serum, these TSH receptor antibodies with stimulating activity (TRAbs) cross the placental barrier, stimulate the TSH receptor of the fetal thyroid gland, and may produce fetal or neonatal hyperthyroidism. Thyroid-stimulating receptor (TSHR) responsiveness to TSH develops early in the second trimester. When the mother is treated with antithyroid medications, the fetus benefits from maternal therapy and remains euthyroid during pregnancy despite the high circulating antibody titer. However, the protective effect of the ATD is lost after delivery, and neonatal hyperthyroidism may develop within a few days after birth. High titers of TRAb, a threefold increase over baseline, in the third trimester of pregnancy are a predictor of neonatal hyperthyroidism. If neonatal hyperthyroidism is not recognized and treated properly, neonatal mortality could be as high as 30%. Because the half-life of the antibodies is only a few weeks, complete resolution of neonatal hyperthyroidism is the rule.

Sporadic cases of neonatal hyperthyroidism without evidence of the presence of circulating TSI in the mother or infant have been published. Activation of mutations in the TSH receptor molecule is the cause of this entity. It is inherited as an autosomal-dominant trait and, in contrast to Graves neonatal hyperthyroidism, the condition persists indefinitely. Treatment with antithyroid medications followed by thyroid ablation therapy will eventually be needed.

As described previously, two methods are currently available for the determination of TRAb: receptor assays that measure thyroid-binding inhibitory immunoglobulins (TBII) and bioassays that measure the ability of TRAb to stimulate the production of cAMP (TSI). Abeillon-du Payrat and colleagues reported their experience with a second-generation TBII assay in 47 neonates born to 42 mothers with history of Graves disease. The assay result was considered positive above a cutoff value of 1.5 IU/L. A value over 5 IU/L measured in the second trimester indicated a risk of neonatal hyperthyroidism (sensitivity 100%, specificity 43%). Nine infants were born with hyperthyroidism: four who were asymptomatic resolved spontaneously within 3 to 45 days; in the other five infants, ATD treatment was needed, and two infants were admitted to the neonatal intensive care unit. The TBII value normalized after a median of 3 months. Interestingly, four of the nine mothers were on thyroid replacement therapy following thyroid ablation therapy, three with surgery and one with <sup>131</sup>I. No mother with a TSI (bioassay) below 400% gave birth to a hyperthyroid neonate. Besançon and associates evaluated the course of thyroid function and clinical outcome during the first postnatal month in babies born to mothers with Graves disease. Of the 68 babies, 33 of their mothers were on drug therapy during pregnancy, and their TRAb assay was positive. They recommend measuring TRAb in

cord blood because a positive value indicates a high risk of neonatal hyperthyroidism. Of note, serum FT<sub>4</sub> should be repeated in the neonate between 3 and 5 days because a rapid FT<sub>4</sub> elevation during the first postnatal week is predictive of hyperthyroidism. Levy-Shraga and colleagues retrospectively studied the outcome of 96 neonates of mothers with Graves disease. Four infants were diagnosed with overt neonatal hyperthyroidism. In a subgroup of 77 newborns with subclinical hyperthyroidism, serum FT<sub>4</sub> levels peaked at day 5 and returned to normal by day 14 postpartum. Elevated FT<sub>4</sub> was associated with poor weight gain in the first 2 weeks of life. Serum TSH may remain suppressed for up to 3 months. These authors also advised thyroid tests between days 3 and 5 after birth to ensure early detection of neonatal hyperthyroidism.

### Neonatal Central Hypothyroidism

Infants of untreated hyperthyroid mothers may be born with transient central hypothyroidism of pituitary or hypothalamic origin. High levels of T<sub>4</sub> cross the placental barrier and feed back to the fetal pituitary with suppression of fetal pituitary TSH. The diagnosis is made in the presence of a low FT<sub>4</sub> and a normal or low TSH level in cord blood. This complication should be avoidable with proper management of maternal hyperthyroidism.<sup>37</sup> Prolonged suppression of pituitary TSH production in some infants may produce a chronic state of hypothalamic-pituitary-thyroid axis dysfunction.

### Resistance to Thyroid Hormone Syndrome

Described by Weiss and Refetoff and colleagues, resistance to thyroid hormone (RTH) is a syndrome of reduced end-organ responsiveness to thyroid hormone caused primarily by mutations in the thyroid hormone receptor  $\beta$ -gene, characterized by elevated free thyroid hormones with nonsuppressed TSH and with signs of hyperthyroidism in some tissues and hypothyroidism in others. The clinical manifestations include goiter and tachycardia, and the prevalence is about 1/40,000 live births. Unaffected fetuses of mothers with RTH syndrome and affected fetuses from normal mothers are at risk for poor obstetric outcome. Anselmo and associates reported 36 couples with 9 mothers and 9 fathers affected by the disease and with 18 unaffected relatives. The rates of miscarriage were 23.7% when the mother was affected, 6.7% when the father was affected, and 8.8% with unaffected first-degree relatives, with a rate of 8.1% in the general population. The birthweights of unaffected infants born to affected mothers were lower than those of affected newborns, who in addition had a lower serum TSH at birth. This finding suggests that high maternal thyroid hormone levels produced fetal thyrotoxicosis and had a direct toxic effect on the fetus. The approach to a pregnant patient with the RTH syndrome would depend on the genotype of the fetus. This requires obtaining the genotype of the fetus from DNA through amniocentesis or chorionic villus sampling, a history of the course and outcome of previous pregnancies, and information about other family members with RTH syndrome.

### Hypothyroidism

Until 1980, few cases of pregnancy in women with myxedema were published because it was believed that most hypothyroid women were infertile. Soon after the determination of serum TSH became commercially available to confirm the diagnosis of primary hypothyroidism, a few series of hypothyroidism in pregnancy were described.<sup>55,56</sup> The incidence of hypothyroidism,

defined at the time of these original publications as an elevation in serum TSH above 5 mIU/L, was reported to be between 2% and 4%.<sup>57,58</sup>

### Etiology and Classification of Hypothyroidism

The two most common etiologies of primary hypothyroidism in countries with sufficient dietary iodine supply are autoimmune (Hashimoto) thyroiditis and post-thyroid ablation therapy, either surgical or <sup>131</sup>I induced. Others include congenital disease (about 1 in 3000 births in the United States), drug-induced hypothyroidism (with lithium, amiodarone, iodine excess, and ATDs), and prior head and neck radiation for nonthyroid malignant disease. Earlier studies in women with “hypothyroxinemia,” diagnosed as a low serum protein-bound iodine (serum TSH was not available for the diagnosis of hypothyroidism), reported a high incidence of congenital malformations, perinatal mortality, and impaired mental and somatic development in infants of hypothyroid women. In contrast, recent reports have shown no increase in the incidence of congenital malformations. Secondary hypothyroidism includes diseases of the pituitary gland or hypothalamus. Autoimmune hypophysitis as a cause of secondary hypothyroidism is of interest to the obstetrician for its relationship to Sheehan syndrome.<sup>59</sup>

Regardless of the etiology, primary hypothyroidism is classified as either *subclinical hypothyroidism* (normal serum FT<sub>4</sub> and elevated serum TSH) or *overt clinical hypothyroidism* (low serum T<sub>4</sub> and elevated TSH or normal FT<sub>4</sub> with serum TSH values >10 mIU/L). The spectrum of pregnant women diagnosed with hypothyroidism includes (1) women with subclinical and overt hypothyroidism diagnosed for the first time during pregnancy; (2) hypothyroid women who are not consistent in taking their medication or those who discontinue thyroid therapy before or at the time of conception because of poor medical advice or because of the misconception that thyroid medications may affect the fetus; (3) women on thyroid replacement therapy who require larger doses in pregnancy (30% to 40% on pre-pregnancy levothyroxine therapy); (4) hyperthyroid patients on excessive amounts of ATD therapy; (5) rarely in the United States, those with severe iodine deficiency; and (6) some patients on lithium or amiodarone therapy.

### SUBCLINICAL HYPOTHYROIDISM

**Subclinical hypothyroidism (SCH) diagnosed in the first trimester of pregnancy has been associated with maternal, fetal, and neonatal complications in some but not all studies.** The most commonly reported complications are miscarriage, preterm delivery, and preeclampsia.<sup>57-62</sup> Others include gestational diabetes, gestational hypertension, placental abruption, and low birthweight. Lower intelligence quotients (IQs) in these infants and other neurocognitive deficits have been described in the past,<sup>63,64</sup> but this has not been confirmed recently.

Most patients with subclinical hypothyroidism do not have overt clinical symptoms. Thyroid tests may be requested by the physician because of vague symptoms that resemble hypothyroidism, a patient or family history of thyroid disease, or findings in the physical examination such as the presence of a goiter. As will be discussed later (in the section on screening), in women who present for preconception counseling or at the time of the first obstetric visit, a selective list of potential risk factors should be evaluated, and if any are positive, thyroid tests should be obtained. **One laboratory test diagnostic of subclinical**

**hypothyroidism is an elevated serum TSH in the presence of normal trimester-specific FT<sub>4</sub> levels.** A determination of TPOAbs is helpful to determine the etiology of hypothyroidism because they are present in 70% to 80% of hypothyroid patients of childbearing age. As mentioned earlier in the section “[Thyroid Function Tests](#),” the recommended serum TSH upper limit of normal, if gestation-specific reference ranges are not available, is 2.5 mIU/L in the first trimester and up to 3 mIU/L in the second and third trimesters.<sup>65,66</sup> A significant number of women on thyroid replacement therapy have become hypothyroid, most of them subclinical, by the time of the first obstetric visit because of the physiologic increase in the need for thyroid hormones in the first trimester of pregnancy.<sup>25,26</sup> Taylor and colleagues reported that in the United Kingdom, 46% of levothyroxine-treated women aged 18 to 45 years had a serum TSH level greater than 2.5 mIU/L; among pregnant women who had their TSH measured in the first trimester, 62.8% had a TSH level greater than 2.5 mIU/L, with 7.4% greater than 10 mIU/L.

Casey and associates<sup>61</sup> undertook a prospective thyroid screening study to evaluate pregnancy outcomes in women with subclinical hypothyroidism diagnosed before 20 weeks’ gestation. Compared with euthyroid women, pregnancies of women with subclinical hypothyroidism were three times more likely to be complicated by placental abruption, a very preterm birth (before 34 weeks’ gestation), and admission of their newborns to the neonatal intensive care nursery. Respiratory distress syndrome was twice as likely. In contrast, Cleary-Goldman and colleagues<sup>62</sup> reported no adverse outcomes in a group of 247 women with subclinical hypothyroidism diagnosed on the basis of a serum TSH more than the 97.5th percentile (TSH >4.29 mIU/L) and FT<sub>4</sub> between the 2.5th and 97.5th percentiles (0.3 and 0.71 ng/dL).

In a randomized study by Negro and colleagues<sup>67</sup> in southern Italy, 4657 women were screened for serum TSH and TPOAbs within the first 11 weeks of gestation. Of this group, 642 women presented with a serum TSH between 2.5 and 5 mIU/L and negative TPOAbs. The pregnancy loss (miscarriage) rate was 6.1%, compared with 3.6% in women with a serum TSH below 2.5 mIU/L ( $P = .006$ ). Liu and associates performed thyroid function tests in 3315 women at low risk for thyroid dysfunction at 4 to 8 weeks’ gestation from iodine-sufficient areas of China. The pregnancy-specific reference range for TSH in their population was 0.29 to 5.22 mIU/L. They also determined thyroid antibodies, TPOAb and antithyroglobulin antibody (TgAb). The risk of miscarriage was not significantly increased in women with serum TSH greater than 2.5 and less than 5.22 mIU/L, compared with women with TSH less than 2.5 mIU/L (3.5% vs. 2.2%) with exception of those women with positive thyroid antibodies (10.0% vs. 3.5%). In a prospective study from Australia of 152 women in the first trimester, Schnerer and associates<sup>68</sup> reported a significant increase in miscarriages in those women with a serum TSH greater than 2.9 mIU/L. In a review of five studies that evaluated SCH and miscarriages, only two of them showed a significant association of SCH and miscarriage. Taylor and colleagues<sup>69</sup> found no increased in miscarriage in first-trimester women on levothyroxine replacement therapy with serum TSH greater than 2.5 and less than 4.5 mIU/L compared with those with a serum TSH below 2.51 mIU/L. Of interest, the adjusted odds of miscarriage in women with serum TSH greater than 10 mIU/L was 3.95 versus 1.0 in women with a serum TSH between 0.2 and 2.5 mIU/L. The above studies emphasize the

importance of the serum TSH—specific reference range for different populations, which may be affected by ethnicity, geographic region, and iodine intake.

#### NEUROLOGIC DEVELOPMENT AND SUBCLINICAL HYPOTHYROIDISM

In 1999, a retrospective study reported neuropsychological development in young children of mothers diagnosed early in pregnancy with hypothyroidism, a group of them with slight elevations in serum TSH. In a recent study from the United Kingdom, Lazarus and colleagues conducted a randomized trial of pregnant women at a median gestational age of 12.3 weeks. A serum TSH above the 97.5th percentile, FT<sub>4</sub> levels below 2.5th percentile, or both were considered diagnostic of thyroid deficiency. Two groups of patients were studied: 390 in the screening group and 404 in the control group; 150 µg of levothyroxine were prescribed to women in the screening group at a median of 13.3 weeks. The dose was adjusted to achieve serum TSH values of 0.1 to 1.0 mIU/L, and the primary outcome was the infant's IQ at 3 years of age. **The authors concluded that no benefit was found with routine screening for maternal hypothyroidism at about 12 to 13 weeks' gestation in the prevention of impaired childhood cognitive function.** In contrast, two recent studies suggested that normalization of thyroid function in hypothyroid women by midgestation avoids neurodevelopmental defects in the children.<sup>70,71</sup> A recently completed study organized by the National Institute of Child Health and Human Development (NICHD)<sup>71a,71b</sup> included a total of 97,226 pregnant women from 14 institutions in the United States. In this randomized trial, women with subclinical hypothyroidism or hypothyroxinemia received L-thyroxine or placebo. The obstetric outcomes and the neurocognitive function of the offspring at 5 years were not significantly different.

#### CLINICAL HYPOTHYROIDISM

**The diagnosis of clinical or overt hypothyroidism in pregnancy is confirmed by the presence of an elevated serum TSH and an FT<sub>4</sub> below the trimester-specific reference range or a serum TSH greater than 10 mIU/L irrespective of the serum thyroxine level.** Patients with overt hypothyroidism may complain of tiredness, cold intolerance, fatigue, muscle cramps, constipation, irregular menstrual periods, infertility, and deepening of the voice. On physical examination, the skin may be dry and cold, deep tendon reflexes may be delayed, and bradycardia may be detected as well as periorbital edema. A goiter is present in almost 80% of patients in whom the etiology is chronic thyroiditis. In the other 20% of women with chronic thyroiditis, no goiter is found; this is called *atrophic thyroiditis*, also known as *primary myxedema* or *chronic thyroiditis without goiter*. Of course, a well-healed scar in the neck suggests that the patient has had a prior surgical thyroidectomy. The degree of severity of the clinical symptoms varies with the thyroid abnormalities on testing, although correlation is not always good between clinical and chemical parameters. It is important to emphasize that many patients with frank hypothyroidism by laboratory tests offer no specific complaints. Spontaneous pregnancies have been reported in newly diagnosed women with a serum TSH higher than 150 mIU/L at the time of the first obstetric visit.<sup>56</sup> The mean TSH value at the time of diagnosis of overt hypothyroidism was  $89.7 \pm 86.2$  mIU/mL (normal, 0.4 to 5.0) with a mean FT<sub>4</sub>I of  $2.1 \pm 1.5$  (normal, 4.5 to 12).<sup>57</sup> **Serum thyroid antibodies—TPOAbs, also known as**

**antimicrosomal antibodies—are elevated in almost 95% of patients with autoimmune hypothyroidism.**

As in the case of hyperthyroidism, untreated overt hypothyroidism is associated with adverse neonatal outcomes that include premature birth, SGA infants, and in one study, an increased prevalence of fetal death. **One of the most common obstetric complications is preeclampsia, with an incidence of 21% in a combined study of 60 patients with overt hypothyroidism.**<sup>56,57</sup> Preeclampsia has not been reported in all series, although some of them were retrospective analyses. Low birth-weight was detected in 16.6% of births, mostly related to preterm delivery. Hirsh and coworkers retrospectively compared outcomes of 101 pregnant women with serum TSH greater than 20 mIU/L at diagnosis of pregnancy with a control group of 205 euthyroid pregnant women identified from the 2009–2010 computerized database of a health maintenance organization in Israel. The mean duration of clinical hypothyroidism during pregnancy was  $21.2 \pm 13.2$  weeks, and in 36 cases (34.9%), all TSH levels during pregnancy remained elevated. The incidence of severe hypothyroidism (TSH >20 mIU/L) was 1.1% of all hypothyroid mothers. Surprisingly, the incidence of miscarriages, prematurity, and other pregnancy complications was not different between the control and study groups. The authors speculated that the low incidence of complications could be due to the normal median FT<sub>4</sub> level at the time of maximal serum TSH measurement and intensive levothyroxine therapy in addition to the thorough obstetric management provided in their country.

#### ISOLATED HYPOTHYROXINEMIA

The term *isolated hypothyroxinemia* is reserved for those patients in areas of sufficient dietary iodine intake with values less than the trimester-specific FT<sub>4</sub> reference range in the presence of normal serum TSH values. Although the pathophysiologic explanation for such an entity is not clear, maternal hypothyroxinemia is extremely frequent in endemic areas of iodine deficiency and is associated with increased perinatal morbidity and mortality and an increased incidence of hypothyroidism in neonates.<sup>72</sup> Recently, a study from China found that isolated hypothyroxinemia was associated with iron deficiency, both before pregnancy and in the first trimester.

Two reports from iodine-sufficient countries confirmed previous reports of the adverse role of maternal hypothyroxinemia in the neuropsychological development of children. Li and colleagues collected serum from 1268 women at 16 to 20 weeks' gestation at Shenyang Maternal and Neonatal Health Clinic in an area described as "iodine sufficient." Intellectual and motor development scores were evaluated in the children at 25 to 30 months of age using the Bayley Scales of Infant Development. Eighteen women (1.8%) were diagnosed as having subclinical hypothyroidism; 19 women were hypothyroxinemic (1.5%); and 34 (2.6%) were euthyroid with an elevated level of TPOAbs. The authors concluded that maternal subclinical hypothyroidism, hypothyroxinemia, and euthyroidism with elevated serum TPOAb titers are all statistically significant predictors of lower motor and intellectual development at 25 to 30 months. In a population-based cohort study in the Netherlands, Henrichs and colleagues<sup>64</sup> observed that mild and severe hypothyroxinemia were associated with a higher risk for expressive language delay across all ages, categorized as either mild (OR, 1.44; 95% CI, 1.09 to 1.91;  $P = .010$ ) or severe (OR, 1.8; 95% CI, 1.24 to 2.61;  $P = .002$ ).

**BOX 42-6 INDICATIONS FOR THYROID TESTING IN PREGNANCY**

History of thyroid dysfunction or prior thyroid surgery  
 Age greater than 30 years  
 Symptoms of thyroid dysfunction or the presence of goiter  
 Thyroid peroxidase antibody positive  
 Type 1 diabetes or other autoimmune disorders  
 History of head/neck radiation  
 Family history of thyroid dysfunction  
 Morbid obesity (body mass index  $\geq 40$  kg/m<sup>2</sup>)  
 Use of amiodarone or lithium or recent administration of iodinated radiologic contrast  
 Unexplained infertility  
 Residing in an area of known moderate to severe iodine sufficiency

From Stagnaro-Green A et al. Guidelines of the American Thyroid Association for the Diagnosis and Management of Thyroid Disease During Pregnancy and Postpartum. *Thyroid*. 2011;21:1081.

No adverse obstetric outcomes were reported by Casey and associates<sup>73</sup> in evaluating 17,289 women before 20 weeks' gestation: the prevalence of hypothyroxinemia was 1%, subclinical hypothyroidism was 3%. A study by Lazarus and colleagues<sup>74</sup> included patients with hypothyroxinemia along with women with hypothyroidism who were treated with levothyroxine, and no difference was found in the IQs of children of treated mothers compared with the children of untreated mothers.

It is important to recognize that the assay technique used to determine FT<sub>4</sub>, particularly in the second half of pregnancy, may be more difficult to perform.<sup>24</sup>

**Universal Versus Selective Screening for Thyroid Disease**

Despite the potential obstetric and pediatric complications from maternal thyroid dysfunction reported in the past 50 years, the consistency of reports on the incidence of maternal subclinical and clinical hypothyroidism in the first trimester, and our recognized difficulty in diagnosing the disease both by medical history and physical examination, **when and how to screen for thyroid disease in pregnant and nonpregnant individuals remains a very controversial issue, and different positions have been adopted by several medical organizations.** A consensus development conference on subclinical thyroid disease was sponsored by the American Association of Clinical Endocrinologists (AACE), the ATA, and the ES. Their recommendation was based on an extensive review of the published literature available at that time, and it limited thyroid tests to women at high risk for thyroid disease.<sup>75</sup> In 2007, the Committee on Obstetric Practice of the American College of Obstetricians and Gynecologists (ACOG) stated, "Without evidence that identification and treatment of pregnant women with subclinical hypothyroidism improves maternal or infant outcomes, routine screening for subclinical hypothyroidism currently is not recommended." **It is reasonable to perform a determination of serum TSH at the first obstetric visit in those women at higher risk for thyroid dysfunction (Box 42-6).** In the second version of the ES guidelines and the ATA Clinical Guidelines for Thyroid and Pregnancy,<sup>76</sup> universal screening is not recommended, but it is strongly suggested that health care professionals personally ask during preconception counseling or in the first obstetric visit about risk factors for thyroid disease. **The main**

**barrier to universal screening is the lack of RCTs that demonstrate a reversal of both obstetric and intellectual abnormalities in the offspring after normalization of thyroid deficiency by maternal L-thyroxine replacement therapy.**

Several studies have consistently demonstrated the failure to recognize women at risk for thyroid dysfunction when using a case-finding strategy, based on actual thyroid dysfunction symptoms, a personal or family history of thyroid disease, and obstetric history.

Vaidya and coworkers<sup>77</sup> offered thyroid function tests early in pregnancy to 1560 women to evaluate the effectiveness of universal screening versus case finding. They showed that targeted screening would still have missed about one third of all pregnant women with an elevated serum TSH. They divided women early in pregnancy into two groups, a low-risk group that included 75% of the women and a high-risk group that comprised the remaining 25%. The high-risk group included those with a personal and family history of thyroid disorders or other autoimmune disease and current and past treatment with ATDs, L-thyroxine, radioiodine, or thyroid surgery. Forty women, 2.6% of the total group, had an elevated serum TSH, and 70% of them were in the high-risk group.

Similar conclusions have been reported in other studies. Wang and coworkers performed thyroid tests in the first trimester of pregnancy and classified 367 women (12.7%) out of 2899 as high risk, following the recommendations of the ES guidelines.<sup>20</sup> Of the 2899, 294 had thyroid dysfunction: hypothyroidism was reported in 7.5%, most of which was subclinical hypothyroidism; 1% had hyperthyroidism; and 0.9% had hypothyroxinemia. Positive antibodies were detected in 279 (9.6%), and 196 of them were euthyroid. The prevalence of thyroid dysfunction in the high-risk group was higher than in the low-risk group (15% vs. 9.4%;  $P = .001$ ). However, of the 217 women with an elevated serum TSH, 171 (78.8%) belonged to the low-risk group. The authors concluded that a case-finding strategy for screening thyroid function in the high-risk group would miss about 81.6% of women with an elevated serum TSH and 80.4% women with hyperthyroidism. In a study from the Czech Republic, Horacek and colleagues concluded that more than 55% of pregnant women at risk would be missed if only those with high-risk criteria were examined. The authors stated that a more extensive screening of thyroid autoimmunity and dysfunction seems warranted.

Ong and colleagues performed thyroid tests and evaluated levels of  $\beta$ -hCG and pregnancy-associated plasma protein A (PAPP-A) in 2411 women, mostly white, in Western Australia between 9 and 14 weeks' gestation. Their objective was to determine whether thyroid function tests performed with first-trimester screening predicts adverse pregnancy outcomes. One hundred thirty-three women (5.5%) had serum TSH greater than 2.15 mIU/L (above the 97.5th percentile for the first trimester), five of whom (0.2%) had a serum TSH greater than 10 mIU/L. On multivariate analysis, neither maternal serum TSH greater than 2.15 mIU/L nor TSH as a continuous variable predicted primary or secondary outcomes. **Their conclusions were that testing TSH as part of first-trimester screening does not predict adverse pregnancy outcomes.** The authors questioned whether screening is justified to detect these cases.

Negro and colleagues<sup>78</sup> reported on a prospective randomized study of 4562 women in southern Italy. Thyroid tests were done very early in pregnancy. Their conclusion was that universal screening did not affect the rate of adverse events in comparison

to targeted high-risk case finding, implying a negative outcome. As discussed in the section on subclinical hypothyroidism, in the same article by Negro and associates, a subgroup of low-risk patients detected to be hypothyroid were treated with L-thyroxine and were compared with a nontreated group. The rate of pregnancy-related adverse events was reduced by nearly 40% after detection and treatment.

A cost-effectiveness approach to compare universal screening with case finding was reported in two studies, and both concluded that universal screening is cost-effective compared with a case-finding strategy.<sup>79</sup> However, Thung and colleagues added in their conclusions that a wide range of circumstances should be considered before universal screening is adopted. The same position was voiced by Stagnaro-Green and Schwartz.

**A number of barriers must be considered before universal routine thyroid function screening can be recommended in pregnancy.**<sup>80</sup> They include the selection of thyroid tests to be used (TSH, FT<sub>4</sub>, TPOAb), the threshold applied to characterize an abnormality, weeks of gestation, appropriate intervention, and monitoring. **The second issue still in dispute is the management of hypothyroid women in the preconceptional period.** It is accepted that most of these women will need an increase in the L-thyroxine dose soon after conception.<sup>25,26</sup> It could be argued whether the target of serum TSH between 0.3 and 2.5 mIU/L before pregnancy is reasonable in anticipation of the increase in T<sub>4</sub> requirements. Abalovich and associates<sup>81</sup> reported that when the serum TSH is below 1.3 mIU/L before conception, only 17% of women need an increase in L-thyroxine in the first trimester. It has also been recommended that women on L-thyroxine therapy be advised at the time of confirmation of pregnancy to increase their dose empirically by two doses a week until the results of the thyroid tests are available.<sup>26</sup>

The Controlled Antenatal Thyroid Screening trial<sup>74</sup> failed to show any benefit of levothyroxine therapy on the cognitive function of children of mothers with hypothyroidism or hypothyroxinemia. An argument about the study is that mothers did not receive thyroxine therapy until a median gestational age of 13.4 weeks. As mentioned above, a small number of children whose hypothyroid mothers started levothyroxine therapy after the first trimester of pregnancy had no neurocognitive deficits when evaluated after 5 years of age.<sup>70,71</sup> As previously mentioned, the NICHD Maternal-Fetal Medicine Units Network study of universal screening and L-thyroxine treatment for women with subclinical hypothyroidism or euthyroid chronic thyroiditis diagnosed during pregnancy showed no differences in the obstetric outcomes or neurocognitive development of the offspring at 5 years of age. **The practicing physician should consider this new information when deciding whether universal screening versus case finding is warranted and which women may benefit from thyroxine therapy.**

### Euthyroid Chronic or Hashimoto Thyroiditis

Chronic or Hashimoto thyroiditis<sup>83</sup> is a benign inflammatory disorder of the thyroid gland with a prevalence in women of childbearing age of 5% to 20%. **Chronic autoimmune thyroid disease is more common in women with other autoimmune diseases, particularly type 1 diabetes.**

In the United States, the incidence is greater in the white than in the black population. The classic clinical picture is characterized by the presence of a goiter with a firm, rubbery consistency that moves freely on swallowing. Absence of a goiter (atrophic thyroiditis) may be present in 20% to 30% of patients.

On presentation, patients have no symptoms of thyroid dysfunction. A goiter is discovered on routine physical examination, by neck ultrasonography, or by the patient or a family member or acquaintance. The diagnosis may be suggested by a hyperechoic pattern on an ultrasound of the thyroid gland, and **diagnosis is confirmed by the presence of thyroid autoantibodies (TPOAb or TgAb).** The actual antibody titer is not correlated with the size of the goiter, symptoms, or severity of the disease. From a practical point of view, determination of TgAb is unnecessary if TPOAbs are positive. It is estimated that 5% of women with chronic thyroiditis have an isolated positive TgAb and a significantly higher serum TSH compared with women who do not have autoimmune thyroiditis. Patients with euthyroid chronic thyroiditis may develop hypothyroidism over time. The odds ratio was 8 over 20 years in those women with a normal serum TSH and positive antibodies.<sup>27</sup>

**The importance of diagnosing chronic thyroiditis in women of childbearing age relates to the potential consequences in pregnancy and in the postpartum period.** Women with chronic thyroiditis who are known to be euthyroid should be evaluated early in pregnancy because they are at risk for developing hypothyroidism de novo, with an increased risk of miscarriages, prematurity (according to some studies), and breech presentation.<sup>84</sup>

In rare situations, women with chronic thyroiditis—particularly those without a goiter, the atrophic form—may have high titers of serum TRAb-blocking antibodies compared with the stimulating antibodies present in women with Graves hyperthyroidism. These antibodies cross the placenta, and at high titers, they block the fetal TSH receptor and cause transient congenital hypothyroidism.<sup>85</sup> The neonatal disease resolves spontaneously over 3 to 6 months, but these infants should receive levothyroxine and should be closely followed for several years. **Therefore in mothers who have given birth to infants with congenital hypothyroidism, TRAb should be determined.**

In 1990, Stagnaro-Green and colleagues<sup>84</sup> reported a twofold to threefold increased risk for spontaneous abortion in euthyroid women with positive thyroid autoantibodies, studies confirmed by later publications. Preterm delivery was associated with the presence of thyroid antibodies in three out of four reports from Belgium, Italy, Japan, and Pakistan. A significant increase in preterm premature rupture of the membranes in TPOAb-positive euthyroid mothers was also reported.

Regarding the therapeutic use of L-thyroxine in women with euthyroid chronic thyroiditis (normal serum TSH and positive TPO antibodies), there is only one published study.<sup>86</sup> The authors performed thyroid tests that included TPOAbs in a group of 984 women early in pregnancy; 113 (11.7%) of them were TPOAb positive, with normal serum TSH values (reference range, 0.27 to 4.2 mIU/L). Their first obstetric visit was at 10.3 ± 3.1 weeks. Fifty-seven TPOAb-positive women were treated with L-thyroxine, with a dose between 0.5 and 1 µg/kg per day according to TSH values and TPOAb titers. They were compared with 58 untreated TPOAb-positive women and a control group of TPOAb-negative women. Two end points were evaluated: the incidences of miscarriage and preterm delivery. **The L-thyroxine-treated group had an incidence of complications similar to that of the control group, whereas the untreated chronic thyroiditis group had a threefold increase in miscarriages and preterm deliveries and in addition developed impaired thyroid function in the second half of pregnancy.**

A higher incidence of thyroid autoimmunity has been reported in women with polycystic ovary syndrome (PCOS) and idiopathic infertility. Of 992 women who attended a fertility clinic in Belgium, 16% had evidence of thyroid autoimmunity. Both antibodies were present in 74, only TPOAb was present in 41, and 48 had isolated TgAb detected.<sup>87</sup> In a Dutch study, in a selected group of women between 25 and 30 years of age, the prevalence of TgAb and TPOAb was 14% and 12%, respectively. Based on these and other studies, **it appears reasonable, in an infertility workup, to determine serum TgAb in the presence of a negative serum TPOAb.**

Infertile women seeking treatment should have serum TSH measured before treatment is started and every 2 weeks after the initiation of treatment because the risk of developing hypothyroidism is significant. Furthermore, the early diagnosis of hypothyroidism and prompt levothyroxine therapy may improve pregnancy outcome.

**There is also agreement in the literature that the presence of TPOAb in the first trimester of pregnancy is a risk factor for the development of postpartum thyroiditis** (see the later section, “Postpartum Thyroid Dysfunction”).

### Treatment of Hypothyroidism

L-Thyroxine is the drug of choice for the treatment of hypothyroidism. **In view of the complications mentioned previously, it is important to normalize thyroid tests as early as possible before conception or soon after the diagnosis of pregnancy.** In women on L-thyroxine replacement therapy, how much the dose will need to be increased from prepregnancy levels depends on the etiology of the hypothyroidism.<sup>88</sup> Loh and colleagues reported an increase in L-thyroxine dose of 16% by the second trimester in patients with primary hypothyroidism and reported a 51% increase following ablation therapy for Graves disease by surgery or <sup>131</sup>I therapy. For patients with a history of thyroid cancer, the increase was 21% by the second trimester, depending on the level of TSH suppression recommended for cancer patients. In newly diagnosed pregnant women, the levothyroxine dose may be calculated according to body weight (2 to 2.4 µg/kg/day), a dose higher than recommended in nonpregnant patients (1.7 to 2 µg/kg/day). In patients with severe hypothyroidism, the normalization of serum TSH is delayed, but normal serum FT<sub>4</sub> or FT<sub>4</sub>I values are achieved in the first 2 weeks of therapy if sufficient L-thyroxine is administered. Abalovich and colleagues retrospectively analyzed seventy-seven patients with newly diagnosed hypothyroidism in pregnancy. The objective was to normalize the serum TSH to a value less than 2.5 mIU/L in the first trimester and less than 3.0 mIU/L in the second and third trimesters. The authors suggested that if the serum TSH is less than 4.2 mIU/L, the levothyroxine starting dose should be 1.2 µg/kg/day; with TSH greater than 4.2 and less than 10 mIU/L, 1.42 µg/kg/day is appropriate; and for women with overt hypothyroidism, 2.33 µg/kg/day is required. Only 11% and 23% of SCH and chronic hypothyroidism, respectively, required dose adjustment. The time at which a euthyroid state was achieved was 6.06 ± 3.3 days in SCH and 5.3 ± 1.8 days in overt hypothyroidism.

**Women planning their pregnancies should have a serum TSH below 2.5 mIU/L, ideally closer to 1 mIU/L, given the greater requirements expected early in gestation.** The serum TSH should be repeated every 2 to 6 weeks during the first 20 weeks' gestation and at 24 to 28 weeks and at 32 to 34 weeks. The aim is to keep serum TSH, as well as serum FT<sub>4</sub> or FT<sub>4</sub>I,

within normal trimester-specific reference ranges. The T<sub>4</sub> dose should be adjusted. Increased thyroid requirements are seen in about 20% to 30% of patients in the second half of pregnancy. Immediately after delivery, patients should return to their prepregnancy dose. Interference in the absorption of T<sub>4</sub> was discussed previously.<sup>20</sup>

Hypothyroid treated women who require in vitro fertilization (IVF) should have their thyroid tests measured before the initiation of controlled ovarian hyperstimulation. In a group of 72 selected hypothyroid women on replacement therapy and with a serum TSH below 2.5 mIU/L, determination of serum TSH was obtained at three points: (1) before treatment, (2) at the time of hCG administration, and (3) at 16 days after hCG administration. Serum TSH levels were 1.7 ± 0.7 at baseline, 2.9 ± 1.3 at the time of hCG administration, and 3.2 ± 1.7 mIU/L after 16 days. Serum TSH exceeded 2.5 mIU/L in 46 women (63.8%) and in 49 (68%) 16 days after hCG administration. The authors suggested strictly monitoring serum TSH in hypothyroid-treated women during IVF cycles, adjusting therapy if necessary. Karmon and colleagues<sup>89</sup> evaluated differences in intrauterine insemination (IUI) outcomes among euthyroid women with preconceptional serum TSH values in the normal (0.4 to 2.4 mIU/L) and high-normal (2.5 to 4.9 mIU/L) ranges. No autoimmunity tests were available. Data were obtained from a single family center and comprised a total of 1477 women who underwent 4064 IUI cycles. No difference in adverse outcomes was reported between the groups. The above studies<sup>89,90</sup> should remind us that as health professionals who take care of women planning a pregnancy, the lack of uniformity in the results of well-planned medical protocols and discrepancies in their observations complicate our ability to counsel these patients.

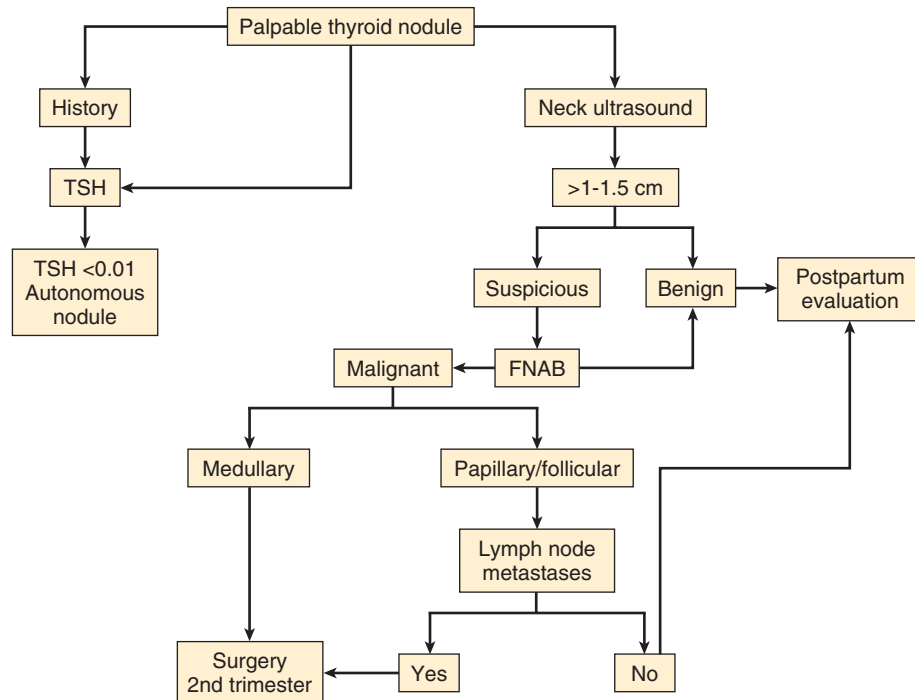

### Single Nodule of the Thyroid Gland

The incidence of thyroid nodularity in pregnancy has been studied by several groups using ultrasonography. The three studies were done in Belgium, Germany, and China—areas of mild iodine deficiency, where the incidence of thyroid nodules is increased. They examined the frequency of nodules, the effect of progression of pregnancy on nodule size, and new nodule formation. Together they showed a prevalence of 3% to 23%, the incidence being higher with increasing parity.

**It is estimated that nodular thyroid disease is clinically detectable in 10% of pregnant women. The size of the thyroid nodule clinically detectable is 1.0 to 1.5 cm.** In most cases, it is discovered during the first routine clinical examination or is detected by the patient. The probability for a single or solitary thyroid nodule to be malignant is between 5% and 10%, depending on risk factors such as previous radiation therapy to the head, neck, or chest; rapid growth of a painless nodule; patient age; and family history of thyroid cancer. Papillary carcinoma accounts for almost 75% to 80% of malignant tumors, and follicular neoplasms account for 15% to 20%; a few percent are represented by medullary thyroid carcinoma. Undifferentiated thyroid carcinoma is extremely rare in patients younger than 50 years.

The incidence of thyroid carcinoma in the general population has risen significantly in recent decades, perhaps because of the increased detection of small papillary cancers, from 3.6 per 100,000 in 1973 to 8.7 per 100,000 in 2002—a 2.4-fold increase (95% CI, 2.2 to 2.6; *P* < .001 for trend). In part, this increase could be explained by the routine use of thyroid ultrasonography.

EVALUATION OF A PALPABLE THYROID NODULE  
IN PREGNANCY: THERAPEUTIC OPTIONS

**FIG 42-5** American Thyroid Association clinical guidelines for thyroid and pregnancy. FNAB, fine-needle aspiration biopsy; TSH, thyroid-stimulating hormone.

It is estimated that as many as 14 of every 100,000 pregnancies in the United States are complicated by a new diagnosis of thyroid cancer. In a retrospective study from the California Cancer Registry from 1991 to 1999, 129 cases of thyroid cancer were diagnosed during pregnancy; 3.3 per 100,000 were diagnosed before pregnancy; 0.3 per 100,000 were diagnosed at the time of delivery; and 10.8 per 100,000 were diagnosed within 1 year after delivery.

There is a paucity of information in the literature regarding the management and timing of the workup in the presence of thyroid nodularity. The ATA management guidelines for patients with thyroid nodules and differentiated thyroid carcinoma<sup>91</sup> recommended a similar evaluation of thyroid nodules in pregnancy as for the nonpregnant patient, with the exception, of course, that a radionuclide scan is contraindicated. In the presence of a thyroid nodule, they stressed the importance of a careful medical history, including a family history of malignant thyroid disease. If the family history is positive for familial medullary thyroid carcinoma or multiple endocrine neoplasia type 2, the evaluation of the nodule and management requires a more aggressive approach.

Careful examination of the neck enables the physician to define and characterize the thyroid lesion (Fig. 42-5). In addition to the size of the nodule, the consistency, tenderness, fixation to the skin, and presence of metastasis in the thyroid bed should be noted. A hard, painless nodule that measures more than 2 cm in diameter is suspicious of malignancy. Serum TSH and FT<sub>4</sub> need to be assessed. A suppressed or undetectable TSH value in the presence of a single or dominant thyroid nodule is consistent with an autonomous or "hot" thyroid nodule, in which case a fine-needle aspiration biopsy (FNAB) is not

indicated; these are rarely malignant. Interpretation of TSH values requires caution because a low or suppressed value may be present in a number of pregnancies in the first trimester. Serum calcitonin determination is reserved for patients with a family history of medullary thyroid carcinoma.<sup>91</sup> In expert hands, high-resolution real-time ultrasound is very helpful in defining the size of the lesion, characterizing the dominant nodule in a multinodular gland, and identifying characteristics of the lesion suspicious for malignancy: microcalcifications, a hypoechoic pattern, or irregular margins among other findings, such as whether the lesion is solid, cystic, or mixed. If FNAB of the nodule is indicated, pregnancy is not a contraindication, and FNAB may be performed at any time during gestation irrespective of gestational age. The importance of a competent cytopathologist in the interpretation and diagnosis of the specimens cannot be overemphasized.

In the presence of a single thyroid nodule detected on physical examination or a dominant nodule in a multinodular gland, the following approach is recommended by the ATA Clinical Guidelines for Thyroid and Pregnancy<sup>76</sup> (see Fig. 42-5):

1. In the presence of a solid lesion smaller than 1 to 1.5 cm, follow-up in the postpartum period is indicated.
2. Nodules larger than 1 to 1.5 cm should be considered for FNAB if ultrasound findings are suspicious.
3. In the presence of tracheal obstruction, immediate surgery is indicated.
4. If the FNAB is diagnostic of malignancy or it is a suspicious lesion, surgery may be postponed until after delivery except with lymph node metastases, if the diagnosis is a large primary lesion, or if extensive lymph node involvement is apparent in a medullary cancer.

5. Surgery can be postponed until after delivery during the last weeks of pregnancy, and FNAB could be safely postponed until after delivery.
6. A woman with a malignant lesion or a rapidly growing lesion should be offered surgery in the second trimester of gestation.
7. Women with follicular lesions or early-stage papillary carcinoma may postpone surgery until after delivery because these lesions are not expected to progress rapidly.

**When advising pregnant women on the evaluation of a thyroid nodule, it must be kept in mind that the incidence of malignancy is between 5% and 10%, and in most cases, the tumors are slow growing.**

It is generally agreed that elective surgery should be avoided in the first trimester and after 24 weeks' gestation because of the potential risks for spontaneous abortion and premature delivery, respectively. Based on clinical experience, the recommendations for total thyroidectomy in the second trimester are to avoid unnecessary exposure of the embryo to anesthetic drugs and to avoid potential prematurity due to surgery. However, no well-controlled study is available to support such recommendations.<sup>92</sup> One report showed a higher risk for complications from thyroid and parathyroid surgery during pregnancy. Thyroidectomy during pregnancy was associated with a complication rate of 21%, compared with 8%, for malignant lesions and 27%, compared with 14%, for benign lesions. This was a retrospective, cross-sectional analysis of hospital discharge data. Complications included suspected fetal compromise, abortion, and cesarean delivery and hysterectomy. A skilled surgeon with ample experience in thyroid surgery should perform the procedure.

In one retrospective study, a conservative approach to the management of a single thyroid nodule was recommended.<sup>93</sup> In this report, 61 women were pregnant at the time of the diagnosis of differentiated thyroid carcinoma. Fourteen women were operated on during pregnancy, whereas the other 47 women underwent surgical treatment 1 to 84 months after delivery. The authors concluded that both diagnostic studies and initial therapy might be delayed until after delivery in most patients. Yasmeen and associates reviewed cancer registry data and compared disease-related survival in 6505 women diagnosed with thyroid cancer during pregnancy or 1 year after delivery. No significant difference in outcome was apparent up to 11 years later compared with an age-matched nonpregnant cohort.

Recently, 15 women diagnosed with thyroid cancer during pregnancy or within 1 year postpartum were compared with 61 women matched for age whose cancer was treated before pregnancy. The authors reported that women diagnosed in pregnancy or in the first year postpartum were more likely to have persistent or recurrent disease and suggested that estrogen may play a role in these poorer outcomes.<sup>94</sup> Messuti and colleagues studied retrospectively 340 women younger than 45 years with differentiated thyroid cancer and compared persistence/recurrence of thyroid tumor in three groups: (1) those diagnosed at least 2 years after delivery, (2) those diagnosed during pregnancy and within 2 years after delivery, and (3) women who were nulliparous at the time of diagnosis. These researchers concluded that persistence/recurrence of disease was significantly higher in the group diagnosed during or within 2 years of delivery than in the control group ( $P = .023$ ), which is consistent with the study by Moosa and colleagues.<sup>94</sup> Further studies are needed before a firm recommendation can be offered to patients diagnosed with thyroid cancer in pregnancy or postpartum.

## Patients With Known Thyroid Cancer Before Pregnancy

**Pregnancy does not appear to be a risk factor for recurrences in women with a previous history of treated thyroid cancer and no evidence of residual disease.** Leboeuf and colleagues<sup>95</sup> published a retrospective analysis of 36 women who became pregnant a median of 4.3 years after initial therapy for differentiated thyroid carcinoma. They were evaluated a median of 4 months after delivery (0.1 to 1.7 years), and serum thyroglobulin values were available before and after pregnancy. Two women treated with thyroidectomy and radioactive iodine and one treated with thyroidectomy alone, whose serum thyroglobulin values were elevated before pregnancy, had new evidence of disease with an increase in thyroglobulin values and cervical nodes detected by ultrasonography. The authors concluded that pregnancy "is probably a mild stimulus to cancer growth as evidenced by minor disease progression in some patients with known structural disease before pregnancy."

Hirsch and associates<sup>96</sup> evaluated 63 consecutive women, for a total of 90 births, who were followed at their institution from 1992 to 2009 and who had given birth at least once after total thyroidectomy, and they evaluated 58 who received <sup>131</sup>I for papillary thyroid cancer. Serum thyroglobulin values and neck ultrasound were compared before and after pregnancy. In this study, levels of serum TSH during pregnancy were correlated with disease persistence before pregnancy and disease progression during pregnancy. They concluded that pregnancy does not cause thyroid cancer recurrence in survivors who have no structural or biochemical evidence of disease persistence at the time of conception. The conclusions from both studies indicate no progression of the disease in women free of disease before pregnancy. However, the possibility of progression exists in those patients who have evidence of residual cancer at the time of conception.

Women on suppressive T<sub>4</sub> therapy for thyroid cancer before pregnancy must continue with therapy, adjusting the levothyroxine dose to keep serum TSH at the same level as before pregnancy and serum TFT<sub>4</sub> within the normal reference range.<sup>97,98</sup> In women treated with <sup>131</sup>I therapy after thyroidectomy for thyroid cancer, a potential concern exists for future fertility and a risk for complications, mainly birth defects. Miscarriages, preterm delivery, stillbirth, and congenital abnormalities were not reported in a systemic review of the literature by Sawka and coworkers.<sup>99</sup> Irregular menses in the first year after treatment occurred in 27% of women following radioactive iodine treatment, and early menopause occurred in some women. Garsi and colleagues<sup>100</sup> described 483 patients exposed to <sup>131</sup>I treatment for thyroid carcinoma and concluded that **no evidence suggests that exposure to radioiodine affects the outcome of subsequent pregnancies and offspring.**

## Postpartum Thyroid Dysfunction

**Postpartum thyroiditis (PPT) is defined as transient thyroid dysfunction in the first year after delivery in women who were euthyroid before pregnancy on no thyroid therapy.**<sup>101,102</sup>

PPT also occurs following spontaneous or medically induced abortions.<sup>103</sup> **The etiology in most cases is autoimmune chronic (Hashimoto) thyroiditis, with a few cases due to hypothalamic or pituitary lesions (Box 42-7).**<sup>104</sup>

PPT, a variant of Hashimoto or chronic thyroiditis, is the most common cause of thyroid dysfunction in the postpartum period. Women with type 1 diabetes mellitus and other

autoimmune diseases are at higher risk for developing PPT.<sup>105</sup> The clinical diagnosis is not always obvious, and the clinician should be concerned about nonspecific symptoms such as tiredness, fatigue, depression, palpitations, and irritability in women following the birth of a child or after a miscarriage or abortion. Fatigue is the most common complaint.<sup>106</sup> Predictors for the development of PPT include high titers of TPOAb in the first trimester of gestation, family or personal history of thyroid disease, presence of goiter, and smoking. Patients at risk should be evaluated in the first year postpartum at 3, 6, and 12 months after delivery.

Postpartum thyroiditis may also develop in women with negative antibodies. In a study from the Netherlands, the authors suggested two forms of PPT: an autoimmune form, which is most common and eventually will develop into chronic hypothyroidism, and a nonautoimmune form without antibodies that appears to be transient without progressing to permanent hypothyroidism. This has recently been confirmed.<sup>102</sup> The incidence of PPT in women with negative TPOAb was 1.7%.

**The clinical course of PPT is not uniform** (Fig. 42-6). In about one third of cases, mild symptoms of hyperthyroidism may develop between 1 and 4 months postpartum. On physical

examination, a goiter is felt in most cases and is firm and non-tender to palpation. Tachycardia may be detected. Thyroid tests are in the hyperthyroid range, and thyroid antibodies (TPOAbs) are elevated in the vast majority of cases. Titers of TRAb, a marker of Graves disease, are negative. In one third of the patients, the hyperthyroid phase is followed by hypothyroidism (3 to 7 months) and return to a euthyroid state by 7 to 12 months after delivery. Antibody titers have a tendency to increase during this process, and a change in the size of the goiter is usually noted. In one third of patients, the course of PPT is different, characterized by an initial episode of hypothyroidism between 3 and 7 months postpartum without the initial hyperthyroid phase. The permanent incidence of hypothyroidism 12 months after delivery ranges from 2% to 21%. By 5 years after the diagnosis of PPT, most studies report an incidence of permanent hypothyroidism of 50%. In summary, presentation of PPT is characterized by (1) an episode of hyperthyroidism (1 to 3 months), followed by hypothyroidism (3 to 7 months) and reverting to euthyroidism (after the seventh month); (2) an episode of hyperthyroidism (1 to 4 months) reverting to euthyroidism; (3) an episode of hypothyroidism (3 to 7 months) reverting to a euthyroid state; and (4) permanent hypothyroidism after the hypothyroid phase (see Fig. 42-6). **It is recommended that a diagnosis of PPT be considered for any thyroid abnormality that occurs within 1 year after a delivery or miscarriage.**

Graves hyperthyroidism may recur after delivery with an exacerbation in the first 3 months or between 6 and 12 months postpartum. The symptoms of hyperthyroidism are more severe than those in patients with PPT, and patients with Graves disease benefit from antithyroid medications. On physical examination, women with Graves hyperthyroidism may present with ophthalmopathy, a visible goiter, and in many situations a bruit. Titers of TRAb are positive. If not contraindicated, as in breastfeeding mothers, a 4- or 24-hour thyroid radioactive iodine uptake (RAIU) is helpful in establishing the etiology. It will be very low in patients with PPT, whereas it is high normal or elevated in patients with recurrent hyperthyroidism due to Graves disease. Ide and colleagues studied 42 women with newly developed hyperthyroidism after delivery. Eighteen patients had Graves disease and 24 had thyroiditis. Twelve of 14 patients who developed thyrotoxicosis in the first 3 months postpartum had postpartum thyroiditis; all patients who developed thyrotoxicosis after 6.5 months postpartum had Graves disease. TRAbs were positive in all women with Graves hyperthyroidism and were negative in those with PPT. **The late postpartum period (8 to 12 months) is associated with the risk of developing Graves disease de novo.** Whether hyperthyroidism is due to a recurrence or new onset of Graves disease, treatment with antithyroid medications is indicated, or the physician may advise ablation therapy.

Although most patients with PPT recover spontaneously, treatment is indicated for symptomatic patients. In the presence of hyperthyroid symptoms,  $\beta$ -adrenergic blocking drugs (propranolol 10 to 40 mg every 6 hr or atenolol 25 to 50 mg every 24 hr) are effective in controlling the symptoms. Anti-thyroid medications are not effective because the hyperthyroxinemia is secondary to the release of thyroid hormones due to the acute injury to the gland (destructive hyperthyroidism). For hypothyroid symptoms, small amounts of L-thyroxine (50  $\mu$ g/day) will control symptoms and allow for spontaneous recovery of thyroid function after discontinuation of the drug. However,

in women who desire future pregnancies, it has been recommended that L-thyroxine therapy be continued because these patients are at high risk for developing hypothyroidism in a future pregnancy.<sup>107</sup>

Preventing PPT with the administration of selenium during pregnancy in women with chronic thyroiditis was evaluated by Negro and associates. They studied two groups of pregnant women: 77 received 200 µg/day of selenium during pregnancy and postpartum, and 74 were given a placebo. A significant reduction was seen in the incidence of PPT between both groups: 28.6% of women receiving selenium developed PPT compared with 48.6% of those taking placebo ( $P < .01$ ). Future studies will be needed to confirm these findings.

### KEY POINTS

- ◆ Hyperthyroidism due to Graves disease needs to be differentiated in the first trimester of pregnancy from the syndrome of gestational thyrotoxicosis.
- ◆ Recent reports indicate increased risk for liver failure with the use of propylthiouracil (PTU); it is recommended that PTU be used in the first trimester of pregnancy and methimazole (MMI) after 13 weeks' gestation. MMI is not indicated in the first trimester because of the potential risk for the syndrome of MMI embryopathy. PTU may also be teratogenic, but the risk is much less than that associated with MMI.
- ◆ Women with Graves disease planning a pregnancy should be informed of the teratogenicity of antithyroid drugs.
- ◆ The dose of antithyroid medications should be adjusted frequently, aiming to use the minimal amount of drug that will keep the FT<sub>4</sub> at the upper limit of normal.
- ◆ Breastfeeding is not contraindicated in women on antithyroid therapy, provided that the maximal daily dose is 300 mg of PTU and 20 mg of MMI.
- ◆ Hypothyroid women on thyroid replacement therapy should have their thyroid tests checked at the time of planning their pregnancy, and they should have their serum TSH adjusted to close to 1 mIU/L.
- ◆ Women on suppressive T<sub>4</sub> therapy for thyroid cancer before pregnancy must continue with therapy. The levothyroxine dose should be adjusted to keep serum TSH at the same level before pregnancy and to keep FT<sub>4</sub> within the normal reference range.
- ◆ In hypothyroid women, thyroid tests should be performed at the time pregnancy is diagnosed and should be checked every 2 to 4 weeks in the first trimester. An increase in levothyroxine dose is needed in more than 50% of patients on thyroid replacement therapy.
- ◆ Women with risk factors for thyroid disease—such as a family history of thyroid disease, the presence of a goiter, or a history of PPT—should be studied before or early in pregnancy. Determinations of serum TSH and TPOAb are recommended in these women.
- ◆ Postpartum thyroiditis affects up to 16.7% of all women in the postpartum period. Women with chronic thyroiditis are at higher risk for developing the syndrome. Long-term follow-up is strongly advised because up to 50% of these patients will develop permanent hypothyroidism in 5 to 10 years.
