## ANTERIOR PITUITARY

### Anterior Pituitary Hormone Changes in Pregnancy

During pregnancy, the normal pituitary gland enlarges considerably as a result of estrogen-stimulated lactotroph hyperplasia.<sup>1,2</sup> Prolactin (PRL) levels rise gradually throughout gestation to prepare the breast for lactation.<sup>3</sup> Beginning in the second half of pregnancy, circulating levels of a growth hormone (GH) variant made by the syncytiotrophoblastic epithelium of the placenta increase, and pituitary GH secretion decreases as a result of the negative feedback effects of insulin-like growth factor I (IGF-1).<sup>4,5</sup> Pregnant patients with acromegaly have autonomous GH secretion; both forms of GH therefore persist in the blood.<sup>6</sup>

**Cortisol levels rise progressively over the course of a normal gestation and result in a twofold to threefold increase by term due both to the estrogen-induced increase in corticosteroid-binding globulin (CBG) levels and an increase in cortisol production, so that the bioactive “free” fraction, urinary free cortisol levels, and salivary cortisol levels are also increased.**<sup>7,8</sup>

## Pituitary Tumors

Pituitary adenomas cause problems because of hormone hypersecretion and by causing hypopituitarism, and pregnancy-induced alterations in hormone secretion complicate the evaluation of patients with pituitary neoplasms. The influence of various types of therapy on the developing fetus also affects therapeutic decision making.

### Prolactinoma

Hyperprolactinemia commonly causes symptoms of galactorrhea, amenorrhea, and infertility.<sup>9</sup> The differential diagnosis of hyperprolactinemia is extensive,<sup>9</sup> but this discussion will focus on the patient with prolactinoma. The choice of therapy has important consequences for decisions regarding pregnancy. **Transsphenoidal surgery for microadenomas is curative in 50% to 60% of prolactinomas after accounting for recurrences, and it rarely causes hypopituitarism when it is performed by experienced neurosurgeons on women with tumors less than 10 mm in diameter.**<sup>10</sup> For patients with *macroadenomas*, tumors 10 mm in diameter or larger, surgical cure rates are lower, and the risk of causing hypopituitarism is considerably greater.<sup>10</sup>

**The dopamine agonists bromocriptine and cabergoline are the primary mode of medical therapy, restoring ovulatory menses in about 80% and 90% of cases, respectively,<sup>9,10</sup> and reducing macroadenoma size.** A reduction in size of 50% or more occurs in 50% to 75% of patients with bromocriptine and in more than 90% of patients with cabergoline.<sup>10</sup>

The stimulatory effect of the hormonal milieu of pregnancy and the withdrawal of the dopamine agonist may result in significant prolactinoma enlargement (Fig. 43-1). Tumor enlargement that required intervention during pregnancy has been reported in 18 of 764 (2.4%) women with microadenomas, 50 of 238 (21%) with macroadenomas that had not undergone prior surgery or radiotherapy, and 7/148 (4.7%) with macroadenomas that had undergone prior surgery or radiotherapy.<sup>11-14</sup> In almost all cases, such enlargement was successfully treated with reinstitution of a dopamine agonist.<sup>14</sup> If the pregnancy is sufficiently advanced, another approach is to deliver the baby electively.<sup>14</sup> Surgical decompression is only resorted to if these other approaches fail.<sup>14</sup>

**FIG 43-1** Coronal and sagittal magnetic resonance imaging scans of an intrasellar prolactin-secreting macroadenoma in a woman before conception (**A** and **B**) and at 7 months of gestation (**C** and **D**). Note the marked tumor enlargement at the latter point, at which time the patient was complaining of headaches. (From Molitch ME. Medical treatment of prolactinomas. *Endocrinol Metab Clin North Am*. 1999;28:143-170.)

When a dopamine agonist is stopped once a woman has missed her menstrual period and pregnancy is diagnosed, no increase in spontaneous abortions, ectopic pregnancies, trophoblastic disease, multiple pregnancies, or malformations were found in over 6000 pregnancies in which bromocriptine was used and in 822 pregnancies in which cabergoline was used.<sup>11-15</sup> Although data on safety of continuous dopamine agonist therapy during pregnancy are limited, treatment is probably not harmful.<sup>14</sup>

Patients with large macroadenomas should be assessed monthly for symptoms of tumor enlargement, and visual fields should be tested each trimester. PRL levels may rise without tumor enlargement and may not rise with tumor enlargement; therefore such tests are often misleading<sup>16</sup> and should not be done. In some patients, postpartum PRL levels and tumor sizes are actually reduced compared with values before pregnancy.<sup>17</sup> Therefore many women may be ovulatory postpartum and would not need resumption of a dopamine agonist. Nursing does not cause an increase of PRL levels nor does it increase headaches or visual disturbances suggestive of tumor enlargement.<sup>18</sup>

### Acromegaly

Acromegaly is associated with infertility in about two thirds of cases because of associated hyperprolactinemia, hypopituitarism due to tumor mass effects, and even increased GH/IGF-1 levels (menses are restored with lowering of GH/IGF-1 levels); two or more of these causes occur in about one quarter of cases.<sup>19</sup> Most patients with acromegaly are treated with surgery as primary therapy; those not cured by surgery are usually treated medically with the somatostatin analogues octreotide and lanreotide.<sup>20</sup> Cabergoline may also be helpful in some cases.<sup>20</sup>

Conventional assays cannot distinguish between normal pituitary GH and the placental GH variant.<sup>4</sup> If it is critical to make a diagnosis of acromegaly during pregnancy, it may be possible by demonstrating GH pulsatility with frequent sampling, given that GH secretion in acromegaly is highly pulsatile but that of the placental variant is not.<sup>6,21</sup>

Only four patients with GH-secreting tumors have been reported to have enlargement of their tumors with a resultant visual field defect, in one case during pregnancy.<sup>22-25</sup> However, in one of these cases tumor enlargement was more likely due to octreotide withdrawal, and in another, it was due to hemorrhage into the tumor. Therefore as with prolactinomas, patients with acromegaly with macroadenomas should be monitored for symptoms of tumor enlargement and visual field testing.

Because of GH-induced insulin resistance, the risk of gestational diabetes is increased in acromegalic patients along with salt retention and gestational hypertension.<sup>26,27</sup> Cardiac disease has not proved to be an issue in pregnant women with acromegaly.<sup>26,27</sup>

The considerations regarding the use of bromocriptine and cabergoline in women with prolactinomas also apply to those with acromegaly. Fewer than 50 pregnant patients treated with somatostatin analogues have been reported, and no malformations were found in their children.<sup>26-28</sup> However, a decrease in uterine artery blood flow has been reported with short-acting octreotide,<sup>28</sup> and one fetus appeared to have intrauterine growth restriction (IUGR) that responded positively to a lower dose of long-acting release octreotide.<sup>25</sup> Octreotide binds to somatostatin receptors in the placenta and crosses the placenta,<sup>28</sup> and it can therefore affect developing fetal tissues in which somatostatin receptors are widespread. I recommend that octreotide and other somatostatin analogues be discontinued if pregnancy is

considered and that contraception be used when these drugs are administered, and most<sup>25,29</sup> but not all<sup>28</sup> others concur. A reasonable option could be to switch to short-acting somatostatin analogues so that these can be continued until pregnancy is diagnosed and then stopped; their short half-life would then prevent fetal exposure. On the other hand, these drugs can control tumor growth, and for enlarging tumors, their reintroduction during pregnancy may be warranted rather than operating. Pegvisomant, a GH receptor antagonist, has been given to a patient with acromegaly during pregnancy without harm,<sup>30</sup> but its safety has not been established.

**Thyrotropin-Secreting Tumors**

Only three cases of pregnancy occurring in women with thyrotropin (thyroid-stimulating hormone [TSH])-secreting tumors have been reported.<sup>31-33</sup> In one of these cases, octreotide was stopped but had to be reinstituted to control tumor size.<sup>31</sup> In a second, octreotide was continued during pregnancy for tumor size control.<sup>32</sup> The most pressing issue with such tumors is the need to control hyperthyroidism during pregnancy, which can usually be done with standard antithyroid drugs (Chapter 43).<sup>33</sup> However, with growing macroadenomas, octreotide may be necessary for tumor size control,<sup>31,32</sup> and it is possible that it may be necessary to control the hyperthyroidism if thionamides are ineffective.

**Clinically Nonfunctioning Adenomas**

**Pregnancy would not be expected to influence tumor size in patients with clinically nonfunctioning adenomas (CNFAs). Indeed, only two cases have been reported in which tumor enlargement during pregnancy resulted in a visual field defect.**<sup>22,34</sup> In the second case, the patient responded rapidly to bromocriptine treatment, probably due to shrinkage of the lactotroph hyperplasia with decompression of the chiasm and probably with little or no direct effect on the tumor itself.<sup>34</sup>

Most CNFAs are actually gonadotroph adenomas. Two patients have been reported who had gonadotroph adenomas that secreted intact follicle-stimulating hormone (FSH) with a resultant ovarian hyperstimulation syndrome<sup>35,36</sup>; both became pregnant, one after having the FSH hypersecretion controlled by bromocriptine<sup>35</sup> and the second following surgical removal of the tumor.<sup>36</sup>

**Hypopituitarism**

**Hypopituitarism** may be partial or complete, and loss of gonadotropin secretion is common. Induction of ovulation may be difficult, and a variety of techniques have been used by reproductive endocrinologists, including administration of hCG and FSH,<sup>37,38</sup> pulsatile gonadotropin-releasing hormone,<sup>37,38</sup> and in vitro fertilization.<sup>39,40</sup> The malformation rate is normal in such pregnancies, but there seems to be an increased frequency of cesarean deliveries, miscarriages, and small-for-gestational-age (SGA) babies.<sup>34,38,40</sup>

**Because of increased thyroxine turnover and volume of distribution in pregnancy, thyroxine (T<sub>4</sub>) levels usually fall and TSH levels rise with a fixed thyroxine dose over the course of gestation.**<sup>41</sup> The average increase in thyroxine needed in these patients is about 0.05 mg/day. Because patients with hypothalamic/pituitary dysfunction may not elevate their TSH levels normally in the face of the increased need for thyroxine, it is reasonable to increase the thyroxine supplementation by 0.025 mg after the first 4 to 6 weeks and by an

additional 0.025 mg after the second trimester, also following total T<sub>4</sub> levels.

**The dose of chronic glucocorticoid replacement does not usually need to be increased during pregnancy.**<sup>8</sup> Hydrocortisone is metabolized by the placental enzyme 11 $\beta$ -hydroxysteroid dehydrogenase 2 (11 $\beta$ -HSD2); thus the fetus is generally protected from any overdose of hydrocortisone. The usual dose is in the range of 12 to 15 mg/m<sup>2</sup> given in two or three divided doses; 10 mg in the morning and 5 mg in the afternoon is a common regimen.<sup>8</sup> Additional glucocorticoids are needed for the stress of labor and delivery, such as 75 mg of intravenous (IV) hydrocortisone every 8 hours with rapid tapering postpartum.<sup>8</sup> Prednisolone does not cross the placenta, and prednisone crosses only minimally.<sup>42</sup> Suppression of neonatal adrenal function in offspring of women taking prednisone during pregnancy is very uncommon,<sup>43</sup> and the amounts passed in breast milk are negligible.<sup>44</sup>

Few data are available on the use of GH during pregnancy in hypopituitary individuals, and in most series, GH therapy has been stopped at conception.<sup>45</sup> Because the GH variant, which is biologically active, is produced by the placenta in substantial amounts beginning in the second half of pregnancy, and it can access the maternal circulation (see above), then at most the mother would be GH deficient only in the first half of pregnancy. When Curran and colleagues<sup>45</sup> analyzed 25 pregnancies that occurred in 16 patients with GH deficiency during which GH therapy was not continued, they found no adverse outcome for either the fetus or the mother from omitting GH therapy and concluded that GH replacement therapy during pregnancy is not essential for GH-deficient women.

**Sheehan Syndrome**

**Sheehan syndrome consists of pituitary necrosis secondary to ischemia that occurs within hours of delivery,**<sup>46</sup> usually secondary to hypotension and shock from an obstetric hemorrhage. The degree of ischemia and necrosis dictates the subsequent patient course (Table 43-1). This syndrome rarely occurs in current obstetric practice.<sup>47</sup>

Acute necrosis is suspected in the setting of an obstetric hemorrhage in which hypotension and tachycardia persist following adequate replacement of blood products. Failure to lactate and hypoglycemia may also occur.<sup>46</sup> Investigation should include obtaining blood samples for adrenocorticotrophic hormone (ACTH), cortisol, prolactin, and free thyroxine. The ACTH stimulation test would be normal because the adrenal cortex would not be atrophied. Free thyroxine levels may prove normal initially because the hormone has a half-life of 7 days, and an additional sample should be sent after 1 week. Prolactin levels

**TABLE 43-1      SYMPTOMS AND SIGNS OF SHEEHAN SYNDROME**

| ACUTE FORM          | CHRONIC FORM          |
|---------------------|-----------------------|
| Hypotension         | Light headedness      |
| Tachycardia         | Fatigue               |
| Failure to lactate  | Failure to lactate    |
| Hypoglycemia        | Persistent amenorrhea |
| Extreme fatigue     | Decreased body hair   |
| Nausea and vomiting | Dry skin              |
|                     | Loss of libido        |
|                     | Nausea and vomiting   |
|                     | Cold intolerance      |

are usually low in this setting. Diabetes insipidus (DI) may also occur and would be revealed with dehydration testing.<sup>48</sup>

**If acute necrosis is suspected, treatment with saline and stress doses of corticosteroids should be instituted immediately after drawing the blood for testing.** If later free thyroxine levels become low, therapy with levothyroxine is indicated. Additional pituitary testing with subsequent therapy should be delayed until recovery.

When milder forms of infarction occur, diagnosis may be delayed for months or years.<sup>46</sup> These women generally have a history of amenorrhea, decreased libido, failure to lactate, breast atrophy, loss of pubic and axillary hair, fatigue, and symptoms of secondary adrenal insufficiency with nausea, vomiting, diarrhea, and abdominal pain.<sup>46</sup> Rarely, some women retain gonadotropin secretion and may have normal menses and fertility.<sup>43</sup>

### Lymphocytic Hypophysitis

**Lymphocytic hypophysitis is thought to be autoimmune, with infiltration and destruction of the parenchyma of the pituitary and infundibulum by lymphocytes and plasma cells.**<sup>49-51</sup> Generally occurring during pregnancy or in the postpartum period,<sup>49-51</sup> this condition is associated with symptoms of hypopituitarism or an enlarging mass lesion with headaches and visual field defects, and it is suspected based on its timing and lack of association with an obstetric hemorrhage or prior history of menstrual difficulties or infertility.<sup>49-51</sup> DI may also occur.<sup>49-51</sup> On magnetic resonance imaging (MRI) scans, diffuse enhancement is usually seen rather than a focal lesion that might indicate a tumor.<sup>49-51</sup> The clinical picture often allows a clinical diagnosis to be made without invasive procedures.

**Treatment of lymphocytic hypophysitis is generally conservative and involves identification and correction of any pituitary deficits, especially of ACTH secretion, which is particularly common in this condition.**<sup>49-51</sup> Data regarding the beneficial effects of high-dose corticosteroid treatment are inconclusive.<sup>50</sup> Surgery to debulk but not remove the gland is indicated in the presence of uncontrolled headaches, visual field defects, and progressive enlargement on scan. Spontaneous regression and resumption of partial or normal pituitary function may occur, although most patients progress to chronic panhypopituitarism.<sup>49-51</sup>

### POSTERIOR PITUITARY

**The set point for plasma osmolality at which arginine vasopressin (AVP) is secreted and thirst is stimulated is reduced approximately 5 to 10 mOsm/kg in pregnancy.**<sup>52</sup> The placenta produces vasopressinase, an enzyme that rapidly inactivates AVP, thereby greatly increasing its clearance.<sup>53,54</sup>

**Standard water deprivation tests, which require 5% weight loss, should be avoided during pregnancy because they can cause uterine irritability and can alter placental perfusion. Instead, desmopressin (dDAVP) is used to assess urinary concentrating ability.**<sup>53</sup> Urinary concentrating ability in the pregnant patient should be determined in the seated position, because the lateral recumbent position inhibits maximal urinary concentration.<sup>52</sup>

### Diabetes Insipidus

**Central DI may develop in pregnancy because of an enlarging pituitary lesion, lymphocytic hypophysitis, or**

**hypothalamic disease. Because of the increased clearance of AVP by placental vasopressinase, DI usually worsens during gestation, and subclinical DI may become manifest.**<sup>53-55</sup> Desmopressin is resistant to vasopressinase and provides satisfactory, safe treatment during gestation, although a higher dose may be required.<sup>56</sup> During monitoring of the clinical response, clinicians should remember that the normal sodium concentration is 5 mEq/L lower during pregnancy,<sup>52</sup> and dDAVP transfers minimally into breast milk.<sup>56</sup>

Transient AVP-resistant forms of DI secondary to placental production of vasopressinase may occur spontaneously in one pregnancy but not in a subsequent one.<sup>57</sup> Some of these patients may respond to dDAVP therapy. Another rare cause of transient DI of pregnancy is placental abruption, in which the abruption causes a rise in vasopressinase.<sup>58</sup>

Acute fatty liver of pregnancy and other disturbances of hepatic function such as hepatitis may be associated with late-onset transient DI of pregnancy in some patients.<sup>59</sup> In some cases, this has been associated with the hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome.<sup>60</sup> It is presumed the hepatic dysfunction is associated with reduced degradation of vasopressinase, which further increases vasopressinase levels and the clearance of AVP. Polyuria may develop either prior to delivery or postpartum.

DI that develops postpartum may be a result of Sheehan syndrome. Transient DI of unknown etiology has been described postpartum, lasting only days to weeks.<sup>61</sup>

Congenital nephrogenic DI is a rare X-linked disorder caused by a mutation in the vasopressin V2 receptor gene, which predominantly affects males.<sup>53</sup> Female carriers of this disease may have significant polyuria during pregnancy. Treatment is with thiazide diuretics,<sup>54</sup> which should be used with caution in pregnant women.

### ADRENALS

In addition to the changes during pregnancy in cortisol outlined previously, plasma renin activity, angiotensin II, and aldosterone increase threefold to sevenfold during pregnancy, and blood volume is also increased.<sup>62</sup>

### Cushing Syndrome

Fewer than 150 cases of Cushing syndrome in pregnancy have been reported.<sup>63-69</sup> Less than 50% of the pregnant patients described had pituitary adenomas, a similar number had adrenal adenomas, and more than 10% had adrenal carcinomas.<sup>63-68</sup> Pregnancies associated with the ectopic ACTH syndrome have been reported only rarely.<sup>65,67,68</sup> In many cases, the hypercortisolism first became apparent during pregnancy, with improvement and even remission after parturition.<sup>65,66,68</sup> Recently, cases have been reported of pregnancy-induced Cushing syndrome from human chorionic gonadotropin (hCG)-induced stimulation of ectopic luteinizing hormone (LH)/hCG receptors on the adrenal.<sup>69</sup>

Diagnosing Cushing syndrome during pregnancy may be difficult. Both conditions may be associated with weight gain in a central distribution, fatigue, edema, emotional upset, glucose intolerance, and hypertension. The striae associated with normal pregnancy are usually pale, but they are red or purple in Cushing syndrome. Hirsutism and acne may point to excessive androgen production, and proximal myopathy and bone fractures point to Cushing syndrome.

The laboratory evaluation is difficult. Elevated total and free serum cortisol and ACTH levels and urinary free cortisol excretion are compatible with that of normal pregnancy. The overnight dexamethasone test usually demonstrates inadequate suppression during normal pregnancy.<sup>8,67</sup> ACTH levels are normal to elevated even with adrenal adenomas,<sup>8,63-65</sup> perhaps because of the production of ACTH by the placenta or from the nonsuppressible stimulation of pituitary ACTH by placental corticotropin-releasing hormone (CRH).

**A persistent circadian variation in the elevated levels of total and free serum cortisol during normal pregnancy may be most helpful in distinguishing Cushing syndrome from the hypercortisolism of pregnancy, because this finding is characteristically absent in all forms of Cushing syndrome.**<sup>7,8</sup> Midnight levels of salivary cortisol during pregnancy have not yet been standardized.<sup>66</sup> In some cases, MRI scanning of the pituitary (without contrast) or ultrasound of the adrenal may be helpful, but the high frequencies of “incidentalomas” in both glands makes interpretation of imaging difficult.<sup>70,71</sup> Little experience has been reported with CRH stimulation testing or petrosal venous sinus sampling during pregnancy.<sup>65,67,68</sup>

**Cushing syndrome is associated with a pregnancy loss rate of 25% due to spontaneous abortion, stillbirth, and early neonatal death because of extreme prematurity.**<sup>63,66-68</sup> The passage of cortisol across the placenta may rarely result in suppression of the fetal adrenals.<sup>72</sup> Hypertension develops in most mothers with Cushing syndrome, and diabetes and myopathy are frequent. Postoperative wound infection and dehiscence are common after cesarean delivery.

In a review of 136 pregnancies collected from the literature, Lindsay and colleagues<sup>67</sup> found that the frequency of live births increased from 76% to 89% when active treatment was instituted by a gestational age of 20 weeks. Therefore treatment during pregnancy has been advocated.<sup>63,67,68</sup>

**Medical therapy for Cushing syndrome during pregnancy with metyrapone and ketoconazole is not very effective,**<sup>66-68</sup> and IUGR has been reported with ketoconazole.<sup>67</sup> **The FDA has issued a black-box warning for ketoconazole with respect to severe liver toxicity; therefore its use cannot be recommended.** Mitotane should be avoided because of fetal toxicity. Two new medications have recently been approved for the treatment of Cushing disease. Mifepristone, a cortisol receptor blocker, is highly effective, but because it is also a progesterone receptor blocker and an abortifacient, it cannot be used during pregnancy.<sup>73</sup> **Pasireotide is a new somatostatin analogue with modest efficacy in patients with Cushing disease.**<sup>74</sup> **It has the adverse effect of hyperglycemia, and there is no experience with its use during pregnancy.** However, the same cautions discussed above for somatostatin analogues should also hold true for the use of pasireotide in a patient with Cushing disease.

Transsphenoidal resection of a pituitary ACTH-secreting adenoma and laparoscopic resection of adrenal adenomas have been carried out successfully in several patients during the second trimester.<sup>66-68</sup> The live birth rate is approximately 87% after unilateral or bilateral adrenalectomy.<sup>67</sup> **Although any surgery poses risks for the mother and fetus,<sup>75</sup> it appears that with Cushing syndrome, the risks of not operating are considerably higher than those of proceeding with surgery.**

## Adrenal Insufficiency

In developed countries, the most common etiology for primary adrenal insufficiency is autoimmune adrenalitis.

Primary adrenal insufficiency from infections (**tuberculosis** or fungal), bilateral metastatic disease, hemorrhage, or infarctions is uncommon. Secondary adrenal insufficiency from pituitary neoplasms or glucocorticoid suppression of the hypothalamic-pituitary-adrenal axis may also occur.

Recognition of adrenal insufficiency may be difficult because many of the clinical features are found in normal pregnancies, including weakness, lightheadedness, syncope, nausea, vomiting, hyponatremia, and increased pigmentation. Addisonian hyperpigmentation may be distinguished from chloasma of pregnancy by its presence on the mucous membranes, on extensor surfaces, and on unexposed areas. Weight loss, hypoglycemia, salt craving, and excessive hyponatremia should prompt a clinical evaluation. **If unrecognized, maternal adrenal crisis may ensue at times of stress, such as a urinary tract infection or labor.**<sup>76-78</sup> **The fetoplacental unit largely controls its own steroid milieu, so maternal adrenal insufficiency generally causes no problems with fetal development.** Women with Addison disease are relatively infertile, and babies born to mothers with Addison disease have increased risks of preterm birth, low birthweight, and an increased rate of cesarean delivery.<sup>79</sup> Severe maternal hyponatremia or metabolic acidosis and poor maternal compliance with therapy may cause a poor fetal outcome.<sup>76-78</sup> Association with other autoimmune conditions such as anticardiolipin antibodies may lead to additional risks such as miscarriage.<sup>80</sup>

Adrenal insufficiency may be associated with laboratory findings of hyponatremia, hyperkalemia, hypoglycemia, eosinophilia, and lymphocytosis. Early morning plasma cortisol levels of 3.0 µg/dL (83 nmol/L) or less confirm adrenal insufficiency, whereas a cortisol level greater than 19 µg/dL (525 nmol/L) in the first or early second trimester excludes the diagnosis in a clinically stable patient.<sup>81</sup> However, plasma cortisol levels may fall in the normal “nonpregnant” range due to the increase in CBG concentrations in the second and third trimesters, but they will not be appropriately elevated for the stage of pregnancy.<sup>82</sup> Normal basal and cosyntropin (250 µg)-stimulated cortisol values have been established for pregnant women; for the first, second, and third trimesters, basal morning values (mean ± standard deviation [SD]) were 9.3 ± 2.2 µg/dL (257 ± 61 nmol/L), 14.5 ± 4.3 µg/dL (401 ± 119 nmol/L), and 16.6 ± 4.2 µg/dL (459 ± 116 nmol/L). Stimulated values were 29.5 ± 16.1 µg/dL (815 ± 445 nmol/L), 37.9 ± 9.0 µg/dL (1047 ± 249 nmol/L), and 34.7 ± 7.5 µg/dL (959 ± 207 nmol/L).<sup>83</sup> The 1-µg low-dose cosyntropin test has been reported to be accurate at 24 to 34 weeks’ gestation using a cutoff of 30 µg/dL (828 nmol/L).<sup>81</sup> With primary adrenal insufficiency, ACTH levels will be elevated, and a level above 100 pg/mL (22 pmol/L) is consistent with the diagnosis.<sup>84</sup> However, ACTH will not be low with secondary forms because of placental production of this hormone, albeit insufficient to maintain normal maternal adrenal function.

In the unstable patient, empiric glucocorticoid therapy of hydrocortisone 50 to 75 mg IV should be administered pending the results of diagnostic testing. Thereafter, doses of 50 to 75 mg every 6 to 8 hours should be given in the face of severe stress and during labor.<sup>78</sup> Despite the normal increase in plasma cortisol during pregnancy, baseline maternal replacement doses of corticosteroids usually are not different from those required in the nonpregnant state.<sup>78</sup> Mineralocorticoid replacement requirements usually do not change during gestation, although some clinicians have reduced doses of fludrocortisone in the third

trimester in an attempt to treat Addisonian patients who develop edema, exacerbation of hypertension, and preeclampsia.<sup>78</sup>

**Patients who have received glucocorticoids as antiinflammatory therapy are presumed to have adrenal axis suppression for at least 1 year following cessation of such therapy.<sup>85</sup> These patients should be treated with stress doses of glucocorticoids during labor and delivery.** They are at risk for postoperative wound infection and dehiscence, as are patients with endogenous Cushing syndrome, and their offspring are at risk for transient adrenal insufficiency.

### Primary Hyperaldosteronism

**Primary hyperaldosteronism rarely has been reported in pregnancy and is most often caused by an adrenal adenoma.<sup>86-89</sup>** Reports of glucocorticoid-remediable hyperaldosteronism in pregnancy are rare.<sup>90</sup> The elevated aldosterone levels found in affected patients during pregnancy are similar to those in normal pregnant women, but the plasma renin activity is suppressed.<sup>88</sup> Moderate to severe **hypertension** develops in 85%, proteinuria in 52%, and hypokalemia in 55% of patients; symptoms may include headache, malaise, and muscle cramps.<sup>86-89</sup> Placental abruption and preterm delivery are also risks.<sup>86,87</sup> Interestingly, the very high progesterone levels of pregnancy may have an antimineralocorticoid effect at the renal tubules, and thus the hypertension and hypokalemia may ameliorate during pregnancy in some women.<sup>89</sup>

**Spironolactone, the usual nonpregnant therapy for hyperaldosteronism, is contraindicated in pregnancy because it crosses the placenta and is a potent antiandrogen, which can cause ambiguous genitalia in a male fetus.<sup>86</sup>** Eplerenone, a more selective aldosterone receptor blocker without antiandrogen activity, has been used successfully in one case during pregnancy without any untoward consequences for the fetus.<sup>91</sup> Surgical therapy may be delayed until after delivery if hypertension can be controlled with agents safe in pregnancy, such as amiloride, methyldopa, labetalol, and calcium channel blockers.<sup>86,87</sup> On the other hand, laparoscopic removal of an aldosterone-producing adenoma during pregnancy has been reported.<sup>88</sup> Potassium supplementation may be required, but the hypokalemia may ameliorate in pregnancy because of the antikaliuretic effect of progesterone. Both hypertension and hypokalemia may exacerbate postpartum because of removal of the progesterone effect.<sup>89</sup>

### Pheochromocytoma

**Exacerbation of hypertension is the typical presentation of pheochromocytoma, which can often be mistaken for pregnancy-induced hypertension or preeclampsia.<sup>92-95</sup>** As the uterus enlarges and an actively moving fetus compresses the neoplasm, maternal complications such as severe hypertension, hemorrhage into the neoplasm, hemodynamic collapse, myocardial infarction, cardiac arrhythmias, congestive heart failure, and cerebral hemorrhage may occur. In 10% of patients, tumors may be outside of the adrenal, such as at the aortic bifurcation, and are particularly prone to hypertensive episodes with changes in position, uterine contractions, fetal movement, and Valsalva maneuvers.<sup>92-95</sup> Unrecognized pheochromocytoma has been associated with a maternal mortality rate of 50%.<sup>92-95</sup>

Placental transfer of catecholamines is minimal,<sup>96</sup> likely because of high placental concentrations of catechol O-methyltransferase and monoamine oxidase.<sup>96</sup> **Adverse**

**fetal effects such as hypoxia are a result of catecholamine-induced uteroplacental vasoconstriction and placental insufficiency<sup>92,93</sup> and of maternal hypertension, hypotension, or vascular collapse.** Placental abruption may also occur.<sup>92</sup>

Diagnosis requires a high index of suspicion. Preconception screening of families known to have multiple endocrine neoplasia (MEN) type 2, von Hippel-Lindau disease, and neurofibromatosis is important.<sup>97</sup> **The diagnosis should be considered in pregnant women with severe or paroxysmal hypertension, particularly in the first half of pregnancy or in association with orthostatic hypotension or episodic symptoms of pallor, anxiety, headaches, palpitations, chest pain, or diaphoresis.**

**Laboratory diagnosis of pheochromocytoma relies on measuring urine metanephrines and catecholamines and plasma metanephrines.<sup>92-95</sup>** This is unchanged from the nonpregnant state because catecholamine metabolism is not altered by pregnancy per se. If possible, methyldopa and labetalol should be discontinued because these agents may interfere with the quantification of the catecholamines.<sup>98</sup> Tumor localization with MRI, with high-intensity signals noted on T<sub>2</sub>-weighted images, provides the best sensitivity without fetal exposure to ionizing radiation.<sup>92,93</sup>

Differentiation from preeclampsia is generally simple. Edema, proteinuria, and hyperuricemia found in women with preeclampsia are absent in those with pheochromocytomas. Plasma and urinary catecholamines may be modestly elevated in severe preeclampsia and other serious pregnancy complications that require hospitalization, although they remain normal in mild preeclampsia or in pregnancy-induced hypertension.<sup>99</sup> Catecholamine levels are two to four times normal after an eclamptic seizure, however.<sup>100</sup>

**Initial medical management involves  $\alpha$ -blockade with phenoxybenzamine, phentolamine, prazosin, or labetalol.** All of these agents are well-tolerated by the fetus, but phenoxybenzamine is considered the preferred agent because it provides long-acting, stable, noncompetitive blockade.<sup>92-95</sup> Phenoxybenzamine is started at a dose of 10 mg twice daily, with titration until the hypertension is controlled. Placental transfer of phenoxybenzamine occurs<sup>101</sup> but is generally considered safe.<sup>92-95</sup> However, two neonates of mothers treated with phenoxybenzamine have been reported with respiratory distress and hypotension that required ventilatory and inotropic support.<sup>102</sup> **Beta-blockade is reserved for treating maternal tachycardia or arrhythmias that persist after full  $\alpha$ -blockade and volume repletion.<sup>92-95</sup>**  $\beta$ -Blockers may be associated with fetal bradycardia and with IUGR but are generally safe, with wide experience concerning their use.<sup>93</sup> All of these potential fetal risks are small compared with the risk of fetal wastage from unblocked high maternal levels of catecholamines. Hypertensive emergencies should be treated with phentolamine (1 to 5 mg) or nitroprusside, although the latter should be limited because of potential fetal cyanide toxicity.

Timing of surgical excision of the neoplasm is controversial and may depend on the success of the medical management and the location of the tumor. **Pressure from the uterus, motion of the fetus, and labor contractions are all stimuli that may cause an acute crisis.** In the first half of pregnancy, surgical excision may proceed once adequate  $\alpha$ -blockade is established, although the risk of fetal loss may be higher with first-trimester surgery. In the early second trimester, fetal loss is less likely with surgery compared with the first trimester, and the size of the uterus will not make excision difficult. If a pheochromocytoma

is not recognized until the second half of gestation, increasing uterine size makes surgical exploration challenging. Successful laparoscopic excision of pheochromocytomas has been described in the second trimester.<sup>92-95</sup> Other options include combined cesarean delivery and tumor resection or delivery followed by tumor resection at a later date.

Although successful vaginal delivery has been reported,<sup>103</sup> rates of maternal mortality have been higher than with cesarean delivery. Labor may result in uncontrolled release of catecholamines secondary to pain and uterine contractions. Severe maternal hypertension may lead to placental ischemia and fetal hypoxia. Cesarean delivery is most common, but in the well-blocked patient, vaginal delivery may be possible with pain management with epidural anesthesia and use of techniques of passive descent and instrumented delivery.

### KEY POINTS

- ◆ About 30% of prolactin-secreting macroadenomas enlarge significantly during pregnancy.
- ◆ Dopamine agonists can be used safely for the treatment of prolactinomas if stopped when pregnancy is diagnosed.
- ◆ In patients with acromegaly, the risks of gestational diabetes and hypertension are increased.
- ◆ Gonadotropins, gonadotropin-releasing hormone, and assisted reproductive technology have been used successfully to achieve pregnancy in women with hypopituitarism.
- ◆ Sheehan syndrome is very uncommon with modern obstetric practice but still must be thought of in the postpartum unstable patient following hemorrhage.
- ◆ Lymphocytic hypophysitis that occurs during pregnancy is often associated with ACTH deficiency and may be fatal.
- ◆ Subclinical diabetes insipidus may become manifest during pregnancy because of placental vasopressinase.
- ◆ Cushing syndrome is associated with adverse outcomes for mother and fetus and should be treated aggressively during pregnancy.
- ◆ Although maintenance glucocorticoid replacement does not need to be increased in pregnant women with either hypopituitarism or primary adrenal insufficiency, stress doses of hydrocortisone are needed during labor and delivery and other stressful situations.
- ◆ Pheochromocytomas must be treated aggressively and usually require surgical resection during the pregnancy.

## PREGNANCY-ASSOCIATED THROMBOCYTOPENIA

Affecting approximately 4% of pregnancies, thrombocytopenia is the most frequent hematologic complication of pregnancy that results in consultation. As gestation progresses, platelet counts generally fall slightly owing to hemodilution and increased destruction.<sup>1</sup> Commonly, platelet counts will reach a nadir of 120,000/mm<sup>3</sup> during pregnancy; however, they should not fall below the normal range. **In pregnancy, the vast majority of cases of mild to moderate thrombocytopenia are caused by gestational thrombocytopenia.**<sup>2</sup> This form of thrombocytopenia has little likelihood of causing maternal or neonatal complications.<sup>3</sup> The obstetrician, however, should rule out

other etiologies of thrombocytopenia that are associated with severe maternal or perinatal morbidity. The common and rare causes of thrombocytopenia in the gravida at term are shown in the [Box 44-1](#).

## Gestational Thrombocytopenia

Most patients with gestational thrombocytopenia generally have a platelet count of 120,000 to 149,000/mm<sup>3</sup>. However, about 1% of patients with gestational thrombocytopenia will have a platelet count of 50,000 to 99,000/mm<sup>3</sup>. **These patients require no therapy, and the fetus appears to be at negligible risk of being born with clinically significant thrombocytopenia or a bleeding diathesis.** This distinct entity was first suggested but not specifically defined in a study published in 1986 by Hart and colleagues.<sup>4</sup> In this report, 28 of 116 pregnant women (24%) who were evaluated prospectively during an 8-month period had platelet counts less than 150,000/mm<sup>3</sup> at least once during pregnancy. In all 17 patients who were followed after delivery, platelet counts returned to normal. These researchers were actually describing gestational thrombocytopenia before the condition had been recognized as a distinct entity. Samuels and colleagues<sup>5</sup> also investigated 74 mothers with gestational thrombocytopenia. Regardless of platelet antibody status, none of the infants born to these mothers demonstrated thrombocytopenia. Burrows and Kelton<sup>6</sup> have further shown that **there is little risk to the mother or neonate in cases of gestational thrombocytopenia.** In their study of 1357 healthy, pregnant women, 112 (8.3%) had platelet counts less than 150,000/mm<sup>3</sup>. The lowest platelet count was 97,000/mm<sup>3</sup>. The incidence of thrombocytopenia (platelet count < 150,000/mm<sup>3</sup>) in the infants of these 112 women was 4.3%, not statistically different from infants born to healthy pregnant women without thrombocytopenia (1.5%).<sup>5</sup> None of these infants had platelet counts less than 100,000/mm<sup>3</sup>. Indeed, the reports by Samuels and colleagues<sup>5</sup> and Burrows and Kelton<sup>6</sup> have convincingly demonstrated that gestational thrombocytopenia is a distinct and common entity that requires no treatment. However, **the obstetrician must use judgment in giving this diagnosis because no test exists**

**BOX 44-1 CAUSES OF THROMBOCYTOPENIA DURING PREGNANCY****Common Causes**

Gestational thrombocytopenia  
Severe preeclampsia  
Hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome  
Disseminated intravascular coagulation

**Uncommon Causes**

Immune thrombocytopenic purpura  
Antiphospholipid antibody syndrome  
Systemic lupus erythematosus  
Human immunodeficiency virus (HIV) infection

**Rare Causes**

Thrombotic thrombocytopenic purpura  
Hemolytic uremic syndrome  
Type 2b von Willebrand syndrome  
Hemoglobin SC crisis with splenic sequestration  
Folic acid deficiency  
Hematologic malignancies  
May-Hegglin anomaly (congenital thrombocytopenia)  
Wiskott-Aldrich syndrome

**for this disorder. If platelet counts continue to fall to levels below 50,000/mm<sup>3</sup>, other diagnoses should be entertained.**

The decrease in platelet count that occurs in gestational thrombocytopenia is not merely the result of dilution of platelets with increasing blood volume; it also appears to be due to an acceleration of the normal increase in platelet destruction that occurs during pregnancy. This is demonstrated by the fact that the mean platelet volume (MPV) is increased in patients with gestational thrombocytopenia. However, if the platelet counts fall below 20,000/mm<sup>3</sup> or if clinical bleeding is present, further investigation and intervention are warranted. This scenario, however, is rare, and it is difficult to determine whether these patients with profound thrombocytopenia have gestational thrombocytopenia or thrombocytopenia from another cause. Platelet antibody testing should only be utilized if suspicion is high for immune thrombocytopenic purpura (ITP). This would include a platelet count less than 50,000/mm<sup>3</sup>.

**Immune Thrombocytopenic Purpura**

Immune thrombocytopenic purpura affects 1 to 3 per 1000 pregnancies and rarely causes neonatal complications. Although rare cases of neonatal thrombocytopenia have been reported, fetal complications are almost nonexistent.<sup>5</sup> Therefore the focus should be on maternal disease and well-being.

In general, **pregnancy has not been determined to cause ITP or to change its severity**, but rare exceptions do exist. Harrington and associates<sup>7</sup> were the first to demonstrate that ITP was humorally mediated, and Shulman and colleagues<sup>8</sup> showed that the mediator of this disorder was immunoglobulin G (IgG). These findings were confirmed when Cines and Schreiber<sup>9</sup> developed the first platelet antiglobulin test, a radioimmunoassay, in 1979. Today, this test is usually performed using an enzyme-linked immunosorbent assay (ELISA) or flow cytometry. Newer assays have shown that these autoantibodies may be directed against specific platelet surface glycoproteins, including the IIb/IIIa and Ib/IX complexes.<sup>10</sup> In vivo, after the platelets are coated with antibody, they are removed from circulation by binding to

**BOX 44-2 PENTAD OF FINDINGS IN THROMBOTIC THROMBOCYTOPENIC PURPURA\***

Microangiopathic hemolytic anemia<sup>†</sup>  
Thrombocytopenia<sup>†</sup>  
Neurologic abnormalities<sup>†</sup> that include confusion, headache, paresis, visual hallucinations, seizures  
Fever  
Renal dysfunction

\*The classic pentad is found in only 40% of patients.

<sup>†</sup>These three findings are present in 74% of patients.

the Fc receptors of macrophages in the reticuloendothelial system, especially the spleen. **Approximately 90% of women with ITP have platelet-associated IgG.<sup>9</sup> Unfortunately, this is not specific for ITP, because studies have shown that these tests are also positive in women with gestational thrombocytopenia and preeclampsia.**

To make the issue more confusing, the pathogenesis of ITP in children and adults usually differs. Childhood ITP most often follows a viral infection and clinically presents with petechiae and bleeding. This form of ITP is generally self-limited and disappears over time. Conversely, adults have milder bleeding and easy bruisability and are often diagnosed after a prolonged period of subtle symptoms. Adult ITP usually runs a chronic course, and long-term therapy is often eventually needed. Many pregnancies occur in women in their late teens and early twenties. In these women with a history of ITP, it may be difficult to ascertain whether the patient has childhood ITP or adult ITP. The distinction is important for counseling concerning long-term prognosis.

**ITP has a predisposition for women aged 18 to 40 years, with an overall female-male ratio of 1.7.<sup>11</sup>** It is a diagnosis of exclusion. The patient must have isolated thrombocytopenia with an unremarkable peripheral smear. She must have only bleeding clinically consistent with a depressed platelet count, such as petechiae. She must not be taking any medication, herbal compound, or illicit drug that may cause thrombocytopenia. Finally, the patient must have no other disease process than can cause thrombocytopenia, such as those listed in the box earlier in this chapter.<sup>11,12</sup> The American Society of Hematology has published a review of ITP that details the diagnostic and therapeutic guidelines.<sup>13</sup>

**Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome**

These two conditions are characterized by microangiopathic hemolytic anemia and severe thrombocytopenia. Pregnancy does not predispose a patient to these conditions, but they should be considered when evaluating the gravida with severe thrombocytopenia. Thrombotic thrombocytopenic purpura (TTP) is characterized by a pentad of findings, which are shown in [Box 44-2](#).<sup>14,15</sup> **The complete pentad occurs only in approximately 40% of patients, but approximately 75% have a triad of microangiopathic hemolytic anemia, thrombocytopenia, and neurologic changes.<sup>16</sup>** Pathologically, these patients have thrombotic occlusions of arterioles and capillaries.<sup>14</sup> These occur in multiple organs, and no specific clinical manifestation for the disease is recognized. The clinical picture reflects the organs that are involved.

**TTP/hemolytic uremic syndrome (HUS) may mimic preeclampsia.** Because preeclampsia is much more common than this disorder, it should be considered first. However, **delay in diagnosing TTP/HUS can have fatal consequences.**

**To diagnose the hemolytic anemia associated with TTP, the indirect antiglobulin (Coombs) test must be negative.** This rules out an immune-mediated cause for the hemolytic anemia. Lactate dehydrogenase (LDH) should be elevated, the indirect bilirubin should be increased, and haptoglobin should be decreased, indicating ongoing hemolysis. Schistocytes are usually seen on the peripheral smear, if it is carefully reviewed. These tests all signify hemolysis, but specificities and sensitivities differ. For instance, LDH can be elevated in liver disease. Schistocytes are very specific but manifest themselves once the hemolysis is severe. The clinician should use the clinical picture, as well as some of these tests, to make the diagnosis of hemolysis. To be classified as TTP, the platelet count should be less than  $100,000/\text{mm}^3$ . In renal insufficiency associated with TTP, the urine sediment is usually normal with an occasional red blood cell (RBC). This finding helps distinguish this disorder from a lupus flare, which more often has associated hematuria and casts. The serum creatinine is usually greater than 2 mg/dL. This degree of renal dysfunction is unusual, but not rare, in preeclampsia. Proteinuria, more than a trace amount, is usually seen on urine dipstick.

**The neurologic findings in TTP are usually nonspecific. They include headache, confusion, and lethargy.** Infrequently, generalized tonic-clonic seizures occur. Terrell and coworkers<sup>17</sup> examined the epidemiology of TTP/HUS occurring in Oklahoma between 1996 and 2004. In 206 reported cases, they found that 37% were idiopathic. However, 13% were associated with an autoimmune disease, and 7% occurred in pregnancy and postpartum. These researchers were able to project that the annual incidence of suspected TTP/HUS is 11 cases per million population, whereas the annual incidence of proven cases is 4.5 cases per million.<sup>17</sup> **If this disease is so rare, why include it in a text on obstetrics? Because if untreated, TTP carries a 90% mortality rate, whereas treatment with plasma exchange decreases the mortality rate to 20%.** Therefore obstetricians must be aware of this disease process so it can be quickly and aggressively treated.

Tsai and colleagues<sup>18,19</sup> have found that a decrease of ADAMTS13 (the von Willebrand cleaving enzyme) activity is strongly associated with TTP. This metalloprotease, also known as *von Willebrand cleaving enzyme*, cleaves unusually large multimers of von Willebrand factor (ULVWF). Activity can be decreased from a decrease in the metalloprotease or antibodies against it. If a deficiency in the activity and/or concentration of ADAMTS13 is apparent, ULVWF circulates in increased amounts, leading to increased platelet aggregation and the initiation of TTP. ADAMTS13 can be readily assayed in clinical laboratories. Ferrari and colleagues<sup>20</sup> have shown that **all four immunoglobulin subclasses of anti-ADAMTS13 antibodies are associated with TTP, but the IgG4 subclass is most common.** Congenital TTP is usually associated with a mutation of *ADAMTS13* that leads to a profound decrease in its activity.<sup>21</sup> Moatti-Cohen and colleagues<sup>21</sup> queried the French registry of thrombotic microangiopathies and found that 24% of women who developed TTP during pregnancy had the congenital type (Upshaw-Schulman syndrome) compared with less than 5% of total adult cases. Weiner<sup>22</sup> has published the most extensive literature review concerning TTP.

In this series of 45 patients, **40 developed the disease antepartum, and 50% occurred before 24 weeks' gestation. The mean gestational age at onset of symptoms was 23.4 weeks.** This finding may be helpful when trying to distinguish TTP from other causes of thrombocytopenia and microangiopathic hemolytic anemia that occur during gestation. In Weiner's review, the fetal and maternal mortality rates were 84% and 44%, respectively. These mortality rates are overly pessimistic, because this series included many patients who contracted the disease before plasma infusion/exchange therapy was utilized to treat TTP.

However, TTP may be confused with rarely occurring early-onset severe preeclampsia. **In preeclampsia, antithrombin III levels are frequently low, and this is not the case with TTP. This test, therefore, may be a useful discriminator between these two disorders.**

Although HUS has many features in common with TTP, it usually has its onset in the postpartum period. Patients with HUS display a triad of microangiopathic hemolytic anemia, acute nephropathy, and thrombocytopenia. HUS is rare in adults, and the thrombocytopenia is usually milder than that seen in TTP, with only 50% of patients having a platelet count less than  $100,000/\text{mm}^3$  at the time of diagnosis. The thrombocytopenia worsens as the disease progresses. A major difference between TTP and HUS is that 15% to 25% of patients with HUS develop chronic renal disease. HUS often follows infections with verotoxin-producing enteric bacteria. Cyclosporine therapy, cytotoxic drugs, and oral contraceptives may predispose adults to develop HUS. **The majority of cases of HUS that occur in pregnancy develop at least 2 days after delivery.** In fact, in one series, only 9 of 62 cases (14.5%) of pregnancy-associated HUS occurred antepartum. Four of these nine patients developed symptoms on the day of delivery. The mean time from delivery to development of HUS in patients in this series was 26.6 days. The maternal mortality rate may exceed 50% in postpartum HUS; however, this mortality rate is based on historic data. With plasmapheresis and dialysis, the likelihood of maternal death is probably much less. **It is not important to make the distinction between TTP and HUS, because the initial therapy for both disorders is plasmapheresis.**

## EVALUATION OF THROMBOCYTOPENIA DURING PREGNANCY AND THE PUERPERIUM

Before deciding on a course to follow in treating the patient with thrombocytopenia, the obstetrician must evaluate the patient and attempt to ascertain the etiology of her low platelet count, realizing that gestational thrombocytopenia will be the most likely diagnosis. Important management decisions are dependent on arriving at an accurate diagnosis; therefore a complete medical history is critically important. It is essential to learn whether the patient has previously had a depressed platelet count or bleeding diathesis. It is also important to know whether these clinical conditions occur coincidentally with pregnancy. A complete medication history should be elicited, because certain medications—such as heparin, many antibiotics, and histamine-2 blockers—can result in profound maternal thrombocytopenia. The obstetric history should focus on whether any maternal or neonatal bleeding problems occurred in the past. **Excessive bleeding from an episiotomy site or cesarean delivery incision site or bleeding from intravenous (IV) sites during labor should alert the physician to the possibility of thrombocytopenia in the previous pregnancy.** The obstetrician should also

question whether the infant had any bleeding diathesis or any problem occurred following a circumcision. The obstetrician should also ask pertinent questions to determine whether severe preeclampsia or hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome is the cause of her thrombocytopenia. The treatment of preeclampsia and HELLP are discussed in [Chapter 31](#). All thrombocytopenic pregnant women should be carefully evaluated for the presence of risk factors for human immunodeficiency virus (HIV) infection, because this infection can cause an ITP-like syndrome. Also, a family history should be elicited because familial forms of thrombocytopenia exist.

An accurate assessment of gestational age should also be carried out. This is important not only in helping to determine the etiology of the thrombocytopenia but also in the timing of delivery. A thorough physical examination of the patient should be performed, and the physician should look for the presence of ecchymoses or petechiae. The conjunctivae and nail beds often reveal petechiae when they are not readily apparent elsewhere on the body. Blood pressure should be determined to ascertain whether the patient has impending preeclampsia. If the patient is developing HELLP syndrome, scleral icterus may be present, and an eye exam should be performed to look for evidence of arteriolar spasm or hemorrhage.

**It is imperative that a peripheral blood smear be examined by an experienced physician or technologist whenever a case of pregnancy-associated thrombocytopenia is diagnosed.** The presence or absence of evidence of microangiopathic hemolysis on the smear will help establish a diagnosis. This specialist can also rule out platelet clumping, which will result in a factitious thrombocytopenia. Platelet clumping in ethylenediaminetetraacetic acid (EDTA, a lavender-top tube) occurs in about 3 per 1000 individuals and may lead to a spurious diagnosis of thrombocytopenia. If platelet clumping is suspected, the physician should ask the laboratory to perform a platelet count on citrate-collected blood (a blue-top tube). If the count is normal, platelet clumping is likely, and the patient is not thrombocytopenic. Other laboratory evaluations should be performed as necessary to rule out preeclampsia and HELLP syndrome as well as disseminated intravascular coagulation (DIC). If a diagnosis of ITP is entertained, appropriate platelet antibody testing may aid in the diagnosis but is of limited utility during pregnancy.

After determining the etiology of thrombocytopenia, the physician can better determine whether imminent delivery is necessary, if the thrombocytopenia should be treated before initiating delivery, or if the low platelet count should be monitored during an ongoing pregnancy.

## THERAPY OF THROMBOCYTOPENIA DURING PREGNANCY

### Gestational Thrombocytopenia

**Gestational thrombocytopenia, the most common form of thrombocytopenia encountered in the third trimester, requires no special intervention or therapy.** The most important therapeutic issue is to refrain from treatment and testing that may lead to unnecessary intervention or iatrogenic preterm delivery. In patients with mild to moderate thrombocytopenia and no antenatal or antecedent history of thrombocytopenia, the patient should be treated as a normal pregnant patient. If the maternal platelet count drops below  $50,000/\text{mm}^3$ , the patient may still have gestational thrombocytopenia, but not enough data are available on mothers with counts this low to

determine whether any maternal or fetal risks exist. These patients, therefore, should be treated as if they have de novo ITP. Although approximately 4% of patients have gestational thrombocytopenia, less than 1% of alternate uncomplicated pregnant women will have gestational thrombocytopenia with platelet counts less than  $100,000/\text{mm}^3$ .<sup>6</sup>

### Immune Thrombocytopenic Purpura

Treatment of the gravida with ITP during pregnancy and the puerperium requires special attention to the mother, because platelet counts can drop to very low numbers during gestation. As in other cases of thrombocytopenia, maternal therapy needs to be instituted only if a bleeding diathesis is evident or to prevent a bleeding complication if surgery is anticipated. Usually no spontaneous bleeding is present unless the platelet count falls below  $20,000/\text{mm}^3$ .<sup>23</sup> In a meta-analysis of 17 studies, the risk of fatal hemorrhage in an individual younger than 40 years of age with a platelet count less than  $30,000/\text{mm}^3$  was 0.4%. The predicted 5-year mortality rate in this setting was 2.2%.<sup>23</sup> **Surgical bleeding does not usually occur until the platelet count is less than  $50,000/\text{mm}^3$ . The American Society of Hematology presently recommends that hospital admission is not necessary unless the platelet count falls to below  $20,000/\text{mm}^3$  or if clinical bleeding is present.**<sup>21</sup>

The conventional forms of raising the platelet count in the patient with ITP include glucocorticoid therapy, IV gamma globulins, platelet transfusions, and splenectomy. If the patient has clinical bleeding or if the platelet count is below  $20,000/\text{mm}^3$ , there is usually a need to raise the platelet count in a relatively short period of time. Although oral glucocorticoids can be used, IV glucocorticoids may work more rapidly. Any steroid with a glucocorticoid effect can be used. However, **hematologists have had the most experience with methylprednisolone. This medication can be given intravenously and has very little mineralocorticoid effect.** It is important to avoid steroids with strong mineralocorticoid effects because these agents can disturb electrolyte balance, cause fluid retention, and result in hypertension. The usual dose of methylprednisolone is 1.0 to 1.5 mg/kg of *total body weight* intravenously daily in divided doses. It usually takes approximately 2 days for a response, but it may take up to 10 days for a maximum response. Even though methylprednisolone has very little mineralocorticoid effect, some may be observed because of the large dose being administered. Therefore **it is important to follow the patient's electrolytes.** The likelihood is low that methylprednisolone will cause neonatal adrenal suppression because little crosses the placenta. It is metabolized by placental  $11\beta$ -dehydrogenase type 1 to an inactive 11-keto metabolite. Park-Wyllie and colleagues<sup>24</sup> performed a meta-analysis, which confirmed the general safety of glucocorticoids during pregnancy. They did, however, find a 3.4-fold increased risk of cleft lip and palate with first-trimester exposure. The risk/benefit ratio should be discussed with the patient before initiation of therapy (see [Chapter 8](#)).

After the platelet count has risen satisfactorily using IV methylprednisolone, the patient can be switched to oral prednisone. The usual dose is 60 to 100 mg/day. Prednisone can be given in a single dose, but less gastrointestinal upset occurs with divided doses. The physician can rapidly taper the dose to 30 to 40 mg/day and decrease it slowly thereafter. The dose should be titrated to keep the platelet count at approximately  $100,000/\text{mm}^3$ . If therapy is initiated with oral prednisone, the usual daily dose is 1 mg/kg total body weight.

The likelihood of a favorable response to glucocorticoids is about 70%. It is important to realize that **if the patient has been taking glucocorticoids for a period of at least 2 to 3 weeks, she may have adrenal suppression and should undergo increased doses of steroids during labor and delivery to avoid an adrenal crisis. Tapering should be done slowly thereafter.** Also, if the patient has been taking glucocorticoids for some time, she may experience significant side effects, including fluid retention, hirsutism, acne, striae, poor wound healing, and monilia vaginitis. In rare circumstances, patients on long-term steroids during gestation can develop osteopenia or cataract formation. The chance of any fetal or neonatal side effects from the glucocorticoids, however, is remote.

**Although glucocorticoids are the mainstays of treating maternal thrombocytopenia, up to 30% of patients do not respond to these medications. In such cases, IV immunoglobulin (IVIG) is used.** This agent probably works by binding to the IgG Fc receptors on reticuloendothelial cells and preventing destruction of platelets. It may also adhere to receptors on platelets and prevent antiplatelet antibodies from binding to these sites. The usual dose is 0.4 g/kg/day for 3 to 5 days. However, it may be necessary to use as much as 1 g/kg/day. The response usually begins in 2 to 3 days and peaks in 5 days. An alternative regimen is to give 1 g/kg once and observe the patient. Often this single dose will result in an adequate increase in platelets. The length of this response is variable, and the timing of the dose is extremely important. If the obstetrician wants a peak platelet count for delivery, therapy should be instituted about 5 to 8 days before the planned delivery. The most frequent adverse reaction is postinfusion headache, which may be lessened by slowing the infusion rate.

IVIG is a blood product from many pooled donors. Early in its use, concerns were raised about hepatitis C transmission. No recent cases of viral infection from IVIG use have been reported. This is due to careful donor screening as well as an intensive purification process. IVIG should be used before seriously contemplating splenectomy, because some patients experience long-term remission with IVIG, and others have a spontaneous increase in platelet counts postpartum. In severe life-threatening hemorrhage, recombinant factor VIIa can be used in conjunction with other therapies. This is a very expensive and complicated therapy that should only be undertaken with the assistance of a physician familiar with its use.

IV anti-D has been used in emergent settings in Rh-positive, direct antiglobulin–negative patients. In life-threatening situations, when other methods fail, this could be considered an option. The usual dose is 50 to 75  $\mu\text{g/kg}$ .<sup>25</sup> Anti-D binds to IgG Fc receptors different than those bound by IVIG.

The **American Society of Hematology (ASH)** has made specific recommendations for treating TTP in pregnancy.<sup>21</sup> They state that virtually no indication exists for cordocentesis to determine the fetal platelet count. This group recommends **no pharmacologic treatment in the first or second trimesters unless the platelet count is less than 30,000/mm<sup>3</sup> or if clinically significant bleeding is evident. If the count is between 10,000/mm<sup>3</sup> and 30,000/mm<sup>3</sup> in the second or third trimester, IVIG is recommended. The ASH does not recommend platelet transfusion unless the platelet count falls below 10,000/mm<sup>3</sup>.**

In the midtrimester, splenectomy can also be used to raise the maternal platelet count. This procedure is reserved for those who do not respond to medical management, with the platelet count

remaining below 20,000/mm<sup>3</sup> and with clinical bleeding. It can also be performed postpartum if the patient does not respond to medical management. In extremely emergent cases of life-threatening bleeding or unresponsiveness to other therapies, splenectomy can be performed at the time of cesarean delivery after extending a midline incision cephalad.

In an emergent situation, platelets can be transfused during cesarean delivery if significant clinical bleeding is evident. Platelets can be transfused before a vaginal delivery if the mother's platelet count is less than 10,000/mm<sup>3</sup> or at any count if clinically significant bleeding is present. **Each "pack" of platelets increases the platelet count by approximately 10,000/mm<sup>3</sup>. The half-life of these platelets is extremely short because the same antibodies and reticuloendothelial cell clearance rates that affect the mother's endogenous platelets also affect the transfused platelets. However, if platelets are transfused at the beginning of surgery, hemostasis adequate to carry out the surgical procedure should be provided.**

If the patient with profound thrombocytopenia undergoes cesarean delivery, certain surgical precautions should be taken. Needless to say, the key is adequate surgical hemostasis. The bladder flap may be left open to avoid hematoma formation. If the parietal peritoneum is closed, subfascial drains are helpful if hemostasis is imperfect. If the peritoneum is not closed, the peritoneal edges should be carefully inspected to make certain no bleeding vessels are present. Small "bleeders" may not be apparent if the patient is hypotensive; therefore the operator must watch for bleeding as the blood pressure rises toward the end of the surgical case. If severe, life-threatening hemorrhage occurs, recombinant factor VIIa and platelet transfusion can be used.

**In summary, the treatment of thrombocytopenia during gestation is dependent on its etiology.** The obstetrician need not act on the mother's platelet count unless it is below 30,000/mm<sup>3</sup>, if it is below 50,000/mm<sup>3</sup> with evidence of clinical bleeding, or if surgery is anticipated.<sup>9</sup> In these cases, the treatment depends on the diagnosis. Furthermore, whether delivery needs to be expedited or can be delayed is also dependent on the etiology of thrombocytopenia, the patient's physical health, fetal well-being, and gestational age.

## MANAGEMENT OF THROMBOTIC THROMBOCYTOPENIC PURPURA AND HEMOLYTIC UREMIC SYNDROME

Before the use of plasma exchange, maternal and fetal outcomes in pregnancies complicated by TTP were uniformly poor.<sup>17</sup> The first cases treated with plasma exchange for TTP during pregnancy were reported in 1984, and no large series of patients with TTP in pregnancy have been undertaken. A review of 11 patients described in case reports reveals that **the prognosis has improved greatly with plasma infusion and plasma exchange.**<sup>25</sup> These researchers also demonstrated that cyclosporin may increase the duration of remission. In one case report, TTP relapses were prevented by using prophylactic monthly plasma exchange throughout gestation.<sup>26</sup> If TTP is suspected, plasma exchange should be initiated immediately.

HUS has been more difficult to treat, and only a few case reports have appeared. **Supportive therapy remains the mainstay in cases of HUS,** although dialysis is often necessary with close attention to fluid management. Platelet function inhibitors were used in two cases during pregnancy. Plasma infusion and

plasma exchange can be attempted, but the results have not been as good as those observed in cases of TTP. Vincristine has been administered with some success in nonpregnant patients but has not been tried in pregnancy, and prostacyclin infusion has been effective in children but has not been used during pregnancy.

## FETAL/NEONATAL ALLOIMMUNE THROMBOCYTOPENIA

**In neonatal alloimmune thrombocytopenia, a rare disorder, the mother lacks a specific platelet antigen and develops antibodies to this antigen.** The disease is somewhat analogous to Rh isoimmunization but involves platelets. If the fetus inherits an antigen from its father and the mother lacks the antigen, maternal antibody can develop and can cross the placenta. This results in severe neonatal thrombocytopenia and possibly fetal intracranial hemorrhage. The mother, however, will have a normal platelet count. **The most common antibodies noted in these patients is anti-HPA-1a antibodies, although several other antibodies have been identified.** If this disorder is suspected, the mother's blood should be sent to a reference laboratory with experience in diagnosing neonatal alloimmune thrombocytopenia. **These patients should be managed in a tertiary care center with experience caring for mothers and infants with this rare disorder.** Transfusion of maternal platelets into the neonate has improved outcome in these cases. After birth or in utero, the child can be transfused with the mother's platelets (because she lacks the antigen) or with donor platelets known to lack the antigen. Bussel and colleagues<sup>27</sup> demonstrated that neonates who had an older sibling that was affected, especially with an antenatal intracranial hemorrhage, had lower platelet counts than the index pregnancy.<sup>28</sup> Pacheco and colleagues<sup>29</sup> have described an excellent algorithm based on risk stratification for evaluating mothers at risk of having a neonate with alloimmune thrombocytopenia. It describes all of the testing that should be performed. McQuilten and colleagues<sup>30</sup> reviewed the experience in Australia and showed that cordocentesis with transfusion, IVIG administration, and corticosteroids have all been used with good results. Kamphuis and Oepkes<sup>31</sup> reviewed the experience in the Netherlands and demonstrated that weekly IVIG alone can virtually prevent fetal/neonatal intracranial hemorrhage in neonatal alloimmune thrombocytopenia; therefore they believe that fetal blood sampling should be abandoned because of its risks. Rayment and coworkers<sup>32</sup> searched the Cochrane database and the Childbirth Group's trial register to ascertain whether they could discern the optimal management of alloimmune thrombocytopenia. They reviewed four trials that involved 206 patients. Because of incomplete data and differences in interventions, they could not conclude the best treatment plan for these patients.<sup>32</sup> They convincingly show that more randomized studies to look at medication doses and timing need to be performed.<sup>31</sup>

## IRON DEFICIENCY ANEMIA

During a singleton pregnancy, maternal plasma volume gradually expands by approximately 50% (1000 mL). The total RBC mass also increases but only by approximately 300 mg (25%), and this starts later in pregnancy. It is not surprising, therefore, that **hemoglobin and hematocrit levels usually fall during gestation. These changes are not necessarily pathologic but usually represent a physiologic alteration of pregnancy.** By 6

### BOX 44-3 CAUSES OF ANEMIA DURING PREGNANCY

#### Common Causes: 85% of Anemia

Physiologic anemia  
Iron deficiency

#### Uncommon Causes

Folic acid deficiency  
Vitamin B<sub>12</sub> deficiency  
Hemoglobinopathies
 

- Sickle cell disease
- Hemoglobin SC
- $\beta$ -Thalassemia minor

 Bariatric surgery  
Gastrointestinal bleeding

#### Rare Causes

Hemoglobinopathies
 

- $\beta$ -Thalassemia major
- $\alpha$ -Thalassemia

 Syndromes of chronic hemolysis
 

- Hereditary spherocytosis
- Paroxysmal nocturnal hemoglobinuria

 Hematologic malignancy

weeks postpartum, in the absence of excessive blood loss during the puerperium, hemoglobin and hematocrit levels have returned to normal if the mother has adequate iron stores.

**Most clinicians diagnose anemia when the hemoglobin concentration is less than 11 g/dL or the hematocrit is less than 32%.<sup>33</sup> Using these criteria, 50% of pregnant women are anemic.** Many women have hemoglobin concentrations as low as 10 gm/dL and recover. The incidence of anemia changes depending on the population studied. It is unfortunate that this problem is often ignored; in developing nations, iron deficiency is an overwhelming problem, and worldwide, many maternal deaths occur because of excessive blood loss in those who were already anemic. Causes of anemia are shown in Box 44-3.

**Approximately 75% of anemia that occurs during pregnancy is secondary to iron deficiency.** Ho and colleagues<sup>34</sup> performed elaborate hematologic evaluations of 221 gravidas at term in Taiwan. None of the studied patients received an added iron preparation during gestation. Of the previously nonanemic patients, 10.4% developed clinical anemia after a full-term delivery. Of these 23 patients, 11 (47.8%) developed florid iron deficiency anemia, and another 11 demonstrated moderate iron depletion. The other anemic patient in the group had folate deficiency. Of the 198 nonanemic gravidas at term, 46.5% showed evidence of iron depletion stores even though they had a normal hematocrit.<sup>34</sup>

To distinguish the normal physiologic changes of pregnancy from those of pathologic iron deficiency, the normal iron requirements of pregnancy (Table 44-1) and the proper use of hematologic laboratory parameters must be understood. In adult women, iron stores are located in the bone marrow, liver, and spleen in the form of ferritin, which constitutes approximately 25% (500 mg) of the 2 g of iron stores found in the normal woman. Approximately 65% of stored iron is located in the circulating RBCs. **If the dietary iron intake is poor, the interval between pregnancies is short, or the delivery is complicated by hemorrhage, iron deficiency anemia readily and rapidly develops.**

**TABLE 44-1** IRON REQUIREMENTS FOR PREGNANCY AND THE PUERPERIUM

| FUNCTION                      | REQUIREMENT |
|-------------------------------|-------------|
| Increased red blood cell mass | 450 mg      |
| Fetus and placenta            | 360 mg      |
| Vaginal delivery              | 190 mg      |
| Lactation                     | 1 mg/day    |

The first pathologic change to occur in iron deficiency anemia is the depletion of bone marrow, liver, and spleen iron stores. This may take a few weeks to a few months depending on the level of the woman's iron stores. Over a period of a few weeks, the serum iron level falls, as does the percentage saturation of transferrin. The total iron-binding capacity rises simultaneously with the fall of iron, because this is a reflection of unbound transferrin. A falling hemoglobin and hematocrit follow within 2 weeks. Microcytic hypochromic RBCs are released into the circulation. If this is a pure iron deficiency, a reticulocytosis will occur within 3 days of initiating therapy, and the hemoglobin concentration will increase within a week. However, it may take more than a month to completely replete iron stores. A patient who has a very low hemoglobin as a result of iron deficiency immediately postpartum should return to normal by her 6-week postpartum visit. If iron deficiency is combined with folate or vitamin B12 deficiency, normocytic and normochromic RBCs are observed on the peripheral blood smear.

**Care must be taken when using laboratory parameters to establish the diagnosis of iron deficiency anemia during gestation.** A serum iron concentration less than 60 mg/dL with a less than 16% saturation of transferrin is suggestive of iron deficiency. Conversely, a single normal serum iron concentration does not rule out iron deficiency. For example, a patient may take iron for several days, and this may result in a transiently normal serum iron concentration while iron stores are still negligible. An increase in iron-binding capacity is not reliable, however, because 15% of pregnant women without iron deficiency show an increase in this parameter.<sup>35</sup> If a patient has been iron deficient for an extended period of time, her serum iron level can rise before she has depleted her iron stores. **The ferritin level indicates the total status of her iron stores.** Serum ferritin levels normally decrease minimally during pregnancy. However, a significantly reduced ferritin concentration is indicative of iron deficiency anemia and is the best parameter to judge the degree of iron deficiency. However, ferritin levels are variable and can change 25% from one day to the next.<sup>36</sup> Tran and colleagues<sup>37</sup> have demonstrated that iron deficiency is the only possible diagnosis for a low ferritin. If a ferritin of 41 ng/mL is used as a cutoff, serum ferritin has 98% sensitivity and 98% specificity in diagnosing iron deficiency.<sup>38</sup> This is true if there is no concomitant infectious or inflammatory process.

Ahluwalia<sup>39</sup> compared iron status in normal and obese pregnant women and found by comparing ferritin that obese women had decreased iron stores. It was also found that obese pregnant women had higher concentrations of the inflammatory marker hepcidin, the concentration of which correlated directly with iron status; it was therefore surmised that chronic inflammation in obese pregnant women may impede their ability to absorb iron.

As part of a large study that included 1171 pregnant women between 1999 and 2006, Mei and colleagues,<sup>40</sup> working through the National Centers for Chronic Disease Prevention and Health

**TABLE 44-2** ELEMENTAL IRON AVAILABLE FROM COMMON GENERIC IRON PREPARATIONS

| PREPARATION              | ELEMENTAL IRON (mg) |
|--------------------------|---------------------|
| Ferrous gluconate 325 mg | 37-39               |
| Ferrous sulfate 325 mg   | 60-65               |
| Ferrous fumarate 325 mg  | 107                 |

Promotion, assessed total body iron using ferritin and soluble transferrin receptor concentrations. They found that iron deficiency increased during pregnancy from  $6.9\% \pm 2.2\%$  in the first trimester to  $29.5\% \pm 2.7\%$  in the third trimester. The prevalence of iron deficiency was highest in women with a parity of at least two. Iron deficiency was significantly higher in Mexican-American and non-Hispanic black women. Statistical analysis showed that this difference was not due to educational level or family income.<sup>40</sup>

Bone marrow aspiration is rarely necessary for the diagnosis of iron deficiency. It is reserved for persistent anemia with confusing hematologic parameters and can be safely performed during pregnancy.

Whether all women should receive prophylactic iron in addition to that contained in prenatal vitamins during pregnancy remains controversial. In reviewing the Cochrane database, Milman and colleagues<sup>41</sup> found that 20% of fertile women have iron stores greater than 500 mg, which is the required minimum for pregnancy. They also noted that 40% of women have iron stores between 100 and 500 mg, and 40% have virtually no iron stores. Based on these data, **most women do need some iron supplementation.** No consensus was reached, however, on how much iron supplementation may be needed in patients with iron deficiency.

In pregnancy, iron absorption from the duodenum increases, providing 1.3 to 2.6 mg of elemental iron daily. An acid environment in the duodenum helps this absorption; therefore the frequent ingestion of antacid medications commonly used by many patients decreases the absorption of iron. Chronic use of H<sub>2</sub> blockers and proton pump inhibitors also diminishes iron absorption. Vitamin C, in addition to the iron, may increase the acidic environment of the stomach and increase absorption. In patients who do not show clear signs of iron deficiency, it is uncertain whether prophylactic iron, in addition to what is in prenatal vitamins, leads to an increased hemoglobin concentration at term. Iron prophylaxis, however, is safe because only amounts that can be used are absorbed. With the exception of dyspepsia and constipation, side effects are few. **One 325 mg tablet of ferrous sulfate daily provides adequate prophylaxis. It contains 60 mg of elemental iron, 10% of which is absorbed.** If the iron is not needed, it will not be absorbed and will be excreted in the feces. The standard generic iron tablets and the amount of elemental iron they provide are listed in Table 44-2.

In iron-deficient patients, one iron tablet three times daily has been recommended, although the evidence-based source of this recommendation is difficult to ascertain. Most individuals can absorb as much iron as they need taking iron twice daily. Iron should be taken 30 minutes before meals to allow maximum absorption. However, when taken in this manner, dyspepsia and nausea are more common. Therapy, therefore, must be individualized to maximize patient compliance. Reveiz and colleagues<sup>33</sup> examined the Cochrane database to see whether an optimal

treatment for iron deficiency during pregnancy could be discerned. They identified 23 trials that comprised 3198 women. Many of the trials were from low-income countries, were generally small, and had poor methodology. Although oral iron supplementation led to a reduction in the incidence of anemia, it was not possible to assess the effects of treatment by severity of anemia. The authors concluded that despite a high incidence and significant ramifications of this disease, a paucity of good-quality trials exists. Whereas these trials could be relatively easy to design and would be relatively inexpensive compared with so many other investigations being carried out, a lack of interest among researchers and funding institutions in the United States is apparent.

Young and colleagues<sup>42</sup> studied the effectiveness of weekly iron supplementation and found it to be almost as effective as daily supplementation in raising the hemoglobin concentration in iron-deficient patients. This approach can be used in patients with less than optimal compliance. Yakoob and Bhutta<sup>43</sup> systematically reviewed 31 studies in the Cochrane database to determine whether routine iron supplementation affects the incidence of anemia in pregnancy. They included studies that used iron alone and iron with folic acid and found a 73% reduction in anemia with routine supplementation. However, no difference was found in rates of anemia at term with intermittent iron-folate when compared with daily supplementation (relative risk [RR], 1.61; 95% confidence interval [CI], 0.82 to 3.14).

**For those patients who are noncompliant or unable to take oral iron and are severely anemic, IV iron can be given.** Singh and colleagues<sup>44</sup> found that parenteral iron can be safely given and significantly raises the hematocrit in patients. It also raises the serum ferritin. Hallak and coworkers<sup>45</sup> examined the safety and efficacy of parenteral iron administration. Of 26 patients receiving parenteral iron, only one developed signs of mild allergy during the test dose and was excluded from the study. The remaining 21 pregnant patients completed the course of therapy and received a mean of 1000 mg of elemental iron. Their hemoglobin increased an average of 1.6 g/dL from the beginning to the end of therapy and rose another 0.8 g/dL during the following 2 weeks. Ferritin levels increased from 2.9 ng/mL at the beginning of therapy to 122.8 ng/dL by the end of treatment. Ferritin levels decreased to a mean of 109.4 ng/mL 2 weeks later, demonstrating that the iron was being utilized. Only mild transient side effects were noted; therefore the authors concluded that parenteral iron therapy can be used safely during pregnancy.

**Parenteral iron is indicated in those who cannot or will not take oral iron therapy and are not anemic enough to require transfusion.** In fact, by building iron stores in the patients before delivery, we may be able to prevent a need for transfusion postpartum in the severely anemic patient. Iron dextran comes in a concentration of 50 mg/mL. It can be given intramuscularly or intravenously, although intramuscular injection is very painful. **Iron dextran can result in anaphylaxis caused by dissociation of the iron and carbohydrate components.** The reaction may be immediate or delayed; therefore a 0.5 mL test dose should be given, and epinephrine should be readily available. Anaphylaxis usually occurs within several minutes but may take 2 days to develop. **In the past 3 years, our group has given iron dextran to 14 patients. Two developed a severe reaction within minutes of the test dose. Although neither patient developed shortness of breath, both exhibited severe bone pain and myalgias.** The dosage for iron

**TABLE 44-3    PARENTERAL IRON ADMINISTRATION**

| MEDICATION                      | DOSE  | PREPARATION                  |
|---------------------------------|---|------------------------------|
| Iron dextran                    | Total dose (mL) = 0.0442 (desired Hb – observed Hb) × LBW + (0.26 × LBW), 100 mg/dose maximum | 50 mg elemental iron/mL      |
| Iron sucrose                    | 100 mg/dose, usually 1 dose/day, usually 10 doses needed                                      | 20 mg elemental iron/mL      |
| Sodium ferric gluconate complex | 125 mg/dose, usually 1 dose/day, usually 8 doses needed                                       | 12.5 mg of elemental iron/mL |

Hb, hemoglobin; LBW, lean body weight.

dextran therapy is shown in Table 44-3. Although iron dextran is rarely used in the United States and Canada, in developing nations, this compound is the only parenteral iron readily available, and therefore its discussion is included in this chapter.

Today, two other agents with excellent safety records are available for parenteral iron therapy. Both of these compounds have the disadvantage of requiring multiple doses to accomplish what can be done with one dose of iron dextran; however, they have the advantage of less likelihood of a severe adverse reaction. Iron sucrose complex is given intravenously, usually daily, with a maximum dose of 100 mg. Patients generally require 10 doses (1 g) to obtain the desired rise in ferritin and subsequent rise in hemoglobin concentration. Sodium ferric gluconate complex can be used similarly, and the maximum dose is 125 mg. It is usually given daily, and eight doses (1 g) are most often required to obtain the desired results. Sodium ferric gluconate appears to have the least risk of adverse side effects. If the patient has concomitant renal insufficiency, subcutaneous erythropoietin can be given to help raise the hemoglobin concentration if iron stores have already been increased. These agents should be used only in patients with severe iron deficiency who cannot absorb iron or who will not or cannot take oral iron. A parenteral iron overdose can lead to hemosiderosis.

It is still uncertain whether anemia results in an increased risk for poor pregnancy outcome. In their literature review, Scholl and Hediger<sup>46</sup> concluded that anemia diagnosed in early pregnancy is associated with preterm delivery and low birthweight (LBW). In this study, women with iron deficiency anemia had twice the risk of preterm delivery and three times the risk of delivering an LBW infant. Preterm labor, however, is a multifactorial problem, and many other confounders were present in this study. Yip<sup>47</sup> reviewed the literature concerning pregnancy outcome with anemia and found through epidemiologic studies an association between moderate anemia and poor perinatal outcome, yet he was unable to determine whether this relationship was causal. Sifakis and Pharmakides<sup>48</sup> observed that hemoglobin concentrations below 6 g/dL are associated with preterm birth, spontaneous abortion, LBW, and fetal deaths. Nevertheless, a mild to moderate anemia did not appear to have any significant effect on fetal outcomes. Hemminki and Starfield<sup>49</sup> reviewed controlled trials and concluded that routine iron administration did not decrease preterm labor or raise birthweight. Conversely, Stephansson and colleagues<sup>50</sup> found an increased risk of stillbirth and growth-restricted infants in women with hemoglobin concentrations greater than 14.6 g/dL at their prenatal visit. Demmouche and colleagues<sup>51</sup> found that nearly 50% of 207 women were anemic, and 14.43% were

severely anemic with a hemoglobin less than 9 g/dL. No difference in birthweight was reported between anemic and nonanemic pregnant women.

In summary, iron deficiency is very prevalent in the general pregnant population. **In developing nations, severe anemia is alarmingly common and is a major cause of maternal morbidity and mortality.** Routine iron administration as formulated in prenatal vitamins should be used unless it is certain that the patient is iron replete. Iron prophylaxis can be taken as one iron tablet daily, or as one study showed, it can be given on a weekly basis. An association between adverse pregnancy outcome and maternal anemia, especially severe anemia, may exist; however, it is uncertain whether this is a causal relationship.

## MEGALOBlastic ANEMIA

Folic acid, a water-soluble vitamin, is found in strawberries, green vegetables, peanuts, and liver. Folate stores are located primarily in the liver and are usually sufficient for 6 weeks. After 3 weeks of a diet deficient in folate, the serum folate level falls. Two weeks later, hypersegmentation of neutrophils occurs. After 17 weeks without folic acid ingestion, RBC folate levels drop. In the next week, a megaloblastic bone marrow develops. **During pregnancy, folate deficiency is the most common cause of megaloblastic anemia. The daily folate requirement in the nonpregnant state is approximately 50 µg, but this rises at least fourfold during gestation. Fetal demands increase the requirement, as does the decrease in the gastrointestinal absorption of folate during pregnancy.**

**Clinical megaloblastic anemia seldom occurs before the third trimester of pregnancy.** If the patient is at risk for folate deficiency or has mild anemia, an attempt should be made to detect this disorder before megaloblastosis occurs. Serum folate and RBC folate levels are the best tests for folate deficiency. Whereas serum folate reflects recently ingested folate, **RBC folate levels give a better idea of folate status at the tissue level.**

Folate deficiency rarely occurs in the fetus and is not a cause of significant perinatal morbidity. However, some evidence shows that fetuses homozygous for the C677T variant of the gene that encodes for 5,10-methylene tetrahydrofolate reductase have a 20% lower folate level and may be at risk for a neural tube defect (NTD). Because infants born to mothers with type 1 and type 2 diabetes mellitus have an increased incidence of NTDs, Kaplan and colleagues<sup>52</sup> studied 31 pregnant women with diabetes and 54 controls to determine whether aberrations in folate metabolism are apparent in patients with diabetes. They found no differences in how ingested folate is processed in the pregnant patient with diabetes. **Prenatal vitamins that require physician prescription contain 1 mg of folic acid, and most nonprescription prenatal vitamins contain 0.8 mg of folic acid. These amounts are more than adequate to prevent and treat folate deficiency. Women with significant hemoglobinopathies, patients taking anticonvulsant medications, women carrying a multiple gestation, and women with frequent conception may require more than 1 mg of supplemental folate daily. Often, 4 mg of folic acid is recommended daily because this is the dose that has been shown to reduce the risk of recurrent NTDs.** However, no studies have demonstrated the optimal dose of folic acid in women with the conditions listed above. If the patient is folic acid deficient, her reticulocyte count will be depressed. Within 3 days after the administration of

sufficient folic acid, reticulocytosis usually occurs. In fact, **folic acid deficiency should be considered when a patient has unexplained thrombocytopenia.** The leukopenia and thrombocytopenia that accompany megaloblastosis are rapidly reversed, and **the hematocrit level may rise as much as 1% per day after 1 week of folate replacement.**

Vollsett and colleagues<sup>53</sup> performed a retrospective analysis of 14,492 pregnancies in 5883 women in Norway to determine whether elevated homocysteine levels are associated with pregnancy complications. An elevated homocysteine level is often found with depressed folate levels, so they compared those in the upper quartile of homocysteine levels with those in the lower quartile. They noted a 32% higher risk for preeclampsia (odds ratio [OR], 1.32), a 38% greater risk for prematurity (OR, 1.38), and a 10% increased risk for very low birthweight (OR, 2.01). All trends were statistically significant, but the limitations inherent in retrospective epidemiologic studies apply here.<sup>53</sup> Munger and associates<sup>54</sup> investigated serum folate, RBC folate, active pyridoxine, and homocysteine concentrations in 347 pregnancies complicated by facial clefting and in 469 controls. Low RBC and serum folate levels were significantly associated with an increased risk of clefting, whereas pyridoxine and homocysteine levels were not. Therefore homocysteine does not appear to have an etiologic role in clefting.

Iron deficiency is frequently observed in association with folic acid deficiency. If a patient with folate deficiency does not develop a significant reticulocytosis within 1 week after administration of sufficient replacement therapy, appropriate tests for iron deficiency should be performed.

Until recently, the prevalence of vitamin B<sub>12</sub> deficiency in pregnancy was unusual. However, bariatric surgery has become increasingly common. Individuals who were morbidly obese and not ovulating suddenly ovulate and become pregnant, and now **we regularly encounter individuals with vitamin B<sub>12</sub> deficiency following bariatric surgery.** Cobalamin is found only in animal products, and the daily minimum required intake is 6 to 9 µg. Total body stores are 2 to 5 mg, and one half of this is stored in the liver. For cobalamin to be absorbed, an individual needs (1) acid-pepsin in the stomach, (2) intrinsic factor secreted by parietal cells in the stomach, (3) pancreatic proteases, and (4) an intact ileum with receptors to bind the cobalamin–intrinsic factor complex. **Because of the abundant vitamin B<sub>12</sub> stores in the body, it takes several years for a clinical vitamin B<sub>12</sub> deficiency to develop.**<sup>55</sup> Prolonged vitamin B<sub>12</sub> deficiency can result in subacute combined degeneration, which involves the dorsal horns and lateral columns of the spinal cord. This can result in sensory and proprioception deficits, which can progress and cause serious disabilities. Fortunately, these changes are reversible when detected early.

**In addition to bariatric surgery, gastrointestinal diseases such as Crohn disease may lead to an inability to absorb vitamin B<sub>12</sub>.** Because of advances in medical care, more individuals with these chronic disorders are becoming pregnant. As primary care physicians for women, we must be prepared to diagnose and coordinate care in these complex patients. Furthermore, we are encountering more patients taking metformin, which is being prescribed for polycystic ovarian syndrome (PCOS) and other disorders in addition to type 2 diabetes mellitus and gestational diabetes. It is important to note that this medication can also result in vitamin B<sub>12</sub> deficiency, because approximately 10% to 30% of patients taking metformin may have depressed vitamin B<sub>12</sub> levels, which can be reversed with

increased calcium intake.<sup>56</sup> The major causes of vitamin B<sub>12</sub> deficiency are listed in [Box 44-4](#).

**Megaloblastic anemia usually leads to a suspicion of folate or vitamin B<sub>12</sub> deficiency. As noted earlier, if an associated iron deficiency is present, the RBC indices may portray a normocytic, normochromic picture.** Therefore it is important to look at more specific tests for vitamin B<sub>12</sub> and folate deficiencies. Vitamin B<sub>12</sub> levels may fall during pregnancy, but this finding may not represent a pathologic process. Also, serum vitamin B<sub>12</sub> levels may be normal in up to 5% of individuals with a true deficiency.<sup>57</sup>

**Evaluation of methylmalonate and homocysteine levels can be used to distinguish folate deficiency from vitamin B<sub>12</sub> deficiency.** Vitamin B<sub>12</sub> is a cofactor in the metabolism of both methylmalonic acid and homocysteine. A deficiency in vitamin B<sub>12</sub> will therefore lead to an increased concentration of both of these compounds. Folic acid is a cofactor in the metabolism of homocysteine, therefore a folate deficiency will lead to an elevated homocysteine level. Savage and colleagues<sup>57</sup> found elevated methylmalonic acid levels in 98% of individuals with a vitamin B<sub>12</sub> deficiency but in only 12% of individuals with a folate deficiency; he also found elevated homocysteine levels in 96% of individuals with a vitamin B<sub>12</sub> deficiency and in 91% of individuals with a folate deficiency. [Figure 44-1](#) schematically shows how to incorporate methylmalonic acid and homocysteine testing into the evaluation of megaloblastic anemia.

HEMOGLOBINOPATHIES

Hemoglobin is a tetrameric protein composed of two pairs of polypeptide chains with a heme group attached to each chain. The normal adult hemoglobin A1 (HbA1) comprises 95% of

hemoglobin. It consists of two α-chains and two β-chains. The remaining 5% of hemoglobin usually consists of HbA2, which contains two α- and two δ-chains, and HbF, with two α- and two γ-chains. In the fetus, HbF (fetal hemoglobin) declines during the third trimester of pregnancy, reaching its permanent nadir several months after birth. Hemoglobinopathies arise when a change occurs in the structure of a peptide chain or a defect compromises the ability to synthesize a specific polypeptide chain. The patterns of inheritance are often straightforward, and the prevalences of the most common hemoglobinopathies in black adults are listed in [Table 44-4](#).

Hemoglobin S

Hemoglobin S, a variant form of hemoglobin, is present in patients with sickle cell disease (HbSS) and sickle cell trait (HbAS). A single substitution of valine for glutamic acid at the sixth position in the β-polypeptide chain causes a significant change in the physical characteristics of this hemoglobin. At low oxygen tensions, RBCs that contain HbS assume a sickle shape. Sludging in small vessels occurs and results in microinfarction of the affected organs. Sick cells have a life span of 5 to 10 days, compared with 120 days for a normal RBC. Sickling is triggered by dehydration, hypoxia, or acidosis. Infants with sickle cell anemia show no signs of the disease until the concentration of HbF falls to adult levels. Some patients do not experience symptoms until adolescence.

Approximately 1 in 12 black adults in the United States is heterozygous for HbS and therefore has sickle cell trait (HbAS) and carries the affected gene. **These individuals generally have 35% to 45% HbS and are asymptomatic. The child of two individuals with sickle cell trait has a 50% probability of inheriting the trait and a 25% probability of actually having**

**BOX 44-4 CAUSES OF VITAMIN B<sub>12</sub> DEFICIENCY THAT MAY BE ENCOUNTERED IN PREGNANCY**

- Strict vegetarian diet
- Use of proton pump inhibitors
- Metformin
- Gastritis
- Gastrectomy
- Ileal bypass
- Crohn disease
- Sprue
- *Helicobacter pylori* infection

| TABLE 44-4 FREQUENCY OF COMMON HEMOGLOBINOPATHIES IN BLACK ADULTS IN THE UNITED STATES |           |
|--|-----------|
| HEMOGLOBIN TYPE  | FREQUENCY |
| Hemoglobin AS  | 1 in 12   |
| Hemoglobin SS  | 1 in 708  |
| Hemoglobin AC  | 1 in 41   |
| Hemoglobin CC  | 1 in 4790 |
| Hemoglobin SC  | 1 in 757  |
| Hemoglobin S/β-thalassemia   | 1 in 1672 |

Increased methylmalonate and folate levels indicate vitamin B<sub>12</sub> deficiency. Normal methylmalonate and increased homocysteine levels indicate folate deficiency.

**FIG 44-1** Use of methylmalonate and homocysteine levels in the workup of megaloblastic anemia.

**sickle cell disease.** One of every 625 black children born in the United States is homozygous for HbS, and the frequency of sickle cell disease among blacks is 1 in 708. **All at-risk patients should undergo hemoglobin electrophoresis.** Although it is more expensive, it will identify all patients with aberrant hemoglobin types.

The traditional teaching is that women with sickle cell trait are not at increased risk for maternal and perinatal morbidity. A report by Larrabee and Monga<sup>58</sup> questions this. In their study, 162 women with HbAS had a 24.7% incidence of preeclampsia compared with 10.3% of controls. Furthermore, the mean birthweight of infants born to women with HbAS was 3082 g compared with 3369 g for controls ( $P < .0001$ ). The rate of postpartum endometritis was 12.3% for sickle trait patients, compared with 5.1% for controls ( $P < .001$ ), despite similar rates of cesarean delivery. This study indicates that **we should increase our surveillance in patients with HbAS.**

**If a patient has HbAS, the spouse/partner should be tested, and if both are carriers of a hemoglobinopathy, prenatal diagnosis should be offered.** This can be done rapidly by DNA analysis with polymerase chain reaction (PCR) amplification of DNA fragments. Testing can be performed on amniocytes, and the diagnosis can also be made by chorionic villus sampling (CVS).

A study conducted on patients from Michigan highlights the possibility that adolescents with sickle cell disease may not receive adequate contraceptive counseling.<sup>59</sup> These researchers at Nationwide Children's Hospital found that of 250 women with sickle cell disease, only 20 had filled prescriptions for contraception. Among the 195 adolescents, 49 underwent 59 pregnancies during the study period. The authors suggest that significant gaps may exist in family planning care for young women with sickle cell disease.

**Painful vasoocclusive episodes that involve multiple organs are the clinical hallmark of sickle cell disease.** The most common sites for these episodes are the extremities, joints, and abdomen. Vasoocclusive episodes can also occur in the lung and can result in pulmonary infarction. **Analgesia, oxygen, and hydration are the clinical foundations for treating these painful crises, and physicians often underestimate the associated pain.** Patients have often received many narcotics and may have a tolerance to the usual dosage of these medications. **It is very important to treat this pain, no matter how much narcotic pain medication is needed. If the obstetrician is uncomfortable with these large doses, he or she should consult with a pain specialist with experience in this area.**

Sickle cell disease can affect virtually all organ systems. **Osteomyelitis** is common, and osteomyelitis caused by *Salmonella* is found almost exclusively in these patients. The risk of **pyelonephritis** is increased, especially during pregnancy. Sickling may also occur in the renal medulla, in which oxygen tension is reduced, resulting in papillary necrosis. These patients also exhibit renal tubular dysfunction and hyposthenuria. Because of chronic hemolysis and decreased RBC survival, patients with sickle cell anemia often demonstrate some degree of jaundice. Biliary stasis commonly occurs during crises, and **cholelithiasis** is seen in about 30% of cases. Because of chronic anemia, **high-output cardiac failure** can occur. Left ventricular hypertrophy and cardiomegaly are common.

**Pregnancies complicated by sickle cell disease are at risk for poor perinatal outcomes.** The rate of spontaneous abortion may be as high as 25%, and the perinatal mortality rate

**is approximately 15%.** Powars and coworkers<sup>60</sup> studied 156 pregnancies in 79 women with sickle cell anemia. In this group, the perinatal mortality rate was 52.7% before 1972 and 22.7% after that time. In a report by Seoud and coworkers,<sup>61</sup> the perinatal mortality rate was 10.5%. Much of this poor perinatal outcome is related to preterm birth. **Approximately 30% of infants born to mothers with sickle cell disease have birthweights less than 2500 g.** In the report by Seoud and coworkers,<sup>61</sup> the mean birthweight was 2443 g. In a multicenter study, Smith and colleagues<sup>62</sup> reported that 21% of infants born to mothers with sickle cell disease were small for gestational age (SGA). It has been hypothesized that sickling in the uterine vessels may lead to decreased fetal oxygenation and intrauterine growth restriction (IUGR).

Persistent HbF in the mother decreases episodes of painful crises during pregnancy and may also have a protective effect on the neonate. Morris and colleagues<sup>63</sup> studied 270 singleton pregnancies in 175 women with sickle cell disease and found an overall rate of fetal wastage of 32.2%. **Mothers with high HbF levels had a significantly lower perinatal mortality rate.** Hydroxyurea reduces the incidence of painful crises and increases HbF concentration and is especially useful in children, although its safety in pregnancy has not been established. If an individual becomes pregnant while using hydroxyurea, it should be discontinued, but pregnancy termination is not justified. Parvovirus B19 infection is usually asymptomatic in pregnant women but can cause fetal hydrops. In women with AS or SS hemoglobin, parvovirus B19 can result in an acute hemolytic anemia.<sup>64</sup>

**Stillbirth rates of 8% to 10% have been described in patients with sickle cell disease, although these rates include studies that took place many years ago.** Whereas the widespread use of antenatal fetal testing has reduced the number of stillbirths significantly, the rates of preterm delivery are higher. These fetal deaths happen not only during crises but also unexpectedly; therefore **careful antepartum fetal testing must be used that includes serial ultrasonography to assess fetal growth.** Anyaegbunam and coworkers<sup>65</sup> examined Doppler flow velocimetry in patients with hemoglobinopathies and showed abnormal systolic/diastolic ratios for the uterine or umbilical arteries in 88% of patients with HbSS compared with 7% with HbAS and 4% with HbAA. Howard and colleagues<sup>66</sup> observed that maternal exchange transfusions did not change uteroplacental Doppler blood flow velocimetry in these patients, which suggests that although maternal well-being may be improved, no change in uteroplacental pathology occurs.

**Although maternal mortality is rare in patients with sickle cell anemia, maternal morbidity is significant. Infections are common and occur in 50% to 67% of women with HbSS.** Most are urinary tract infections (UTIs), which can be detected by frequent urine cultures. Common infecting organisms for the bladder, kidneys, lungs, and other sites include *Streptococcus pneumoniae*, *Haemophilus influenzae* type B, *Escherichia coli*, *Salmonella*, and *Klebsiella*. Patients with HbAS are at greater risk for a UTI and should be screened. Pulmonary infection and infarction are also common, and **patients with sickle cell anemia should receive pneumococcal vaccine before pregnancy.** Maternal deaths have been reported in association with pulmonary complications in sickle cell disease. **Any infection demands prompt attention, because fever, dehydration, and acidosis results in further sickling and painful crises.** The incidence of **pregnancy-induced hypertension** is increased in

patients with sickle cell anemia and may complicate almost one third of pregnancies in these patients.<sup>62</sup> A study by Villers and colleagues<sup>67</sup> delineated maternal risks and pregnancy complications in 17,952 deliveries in women with sickle cell disease between 2000 and 2003. **They observed that cerebral vein thrombosis, pneumonia, pyelonephritis, deep venous thrombosis, transfusion, postpartum infections, sepsis, and systemic inflammatory response syndrome (SIRS) were statistically more common in women with sickle cell disease. Furthermore, they found that pregnancy-related complications including hypertensive disorders, antepartum bleeding, abruptio, preterm labor, growth restriction, and urinary tract infections were much more common in parturients with sickle cell disease.** Seaman and colleagues<sup>68</sup> reviewed the Pennsylvania Health Care Cost Containment Council database to investigate maternal morbidity in 212 women with HbSS. They found that thromboembolic phenomena were 1 to 1.5 times greater in these individuals than in the general population, especially in patients with sickle cell crisis and pneumonia.

**The care of the pregnant patient with sickle cell anemia must be individualized and meticulous.** These patients benefit from care in a medical center experienced in treating the multitude of problems that can complicate such pregnancies. From early gestation, good dietary habits should be promoted, and a folic acid supplement of at least 1 mg/day should be administered as soon as pregnancy is confirmed. This is because these patients are in a state of chronic hemolysis, and folic acid is needed for their increased hematopoiesis. Although hemoglobin and hematocrit levels are decreased, iron supplements should not be routinely given. Serum iron and ferritin levels should be checked monthly, and iron supplementation should be started only when these levels are diminished. Often, because of ongoing hemolysis, serum ferritin values are significantly higher in pregnant women with HbSS disease than in those with HbAA disease. Routine iron supplementation, even with prenatal vitamins, should not be given, because iron overload can lead to hemosiderosis and even hemochromatosis. Patients with sickle cell anemia may benefit from an echocardiogram in the first trimester because they are at increased risk for hypertensive and other cardiovascular complications during pregnancy.

**No role exists for prophylactic transfusions in these patients.** Although a few studies showed decreased maternal and neonatal morbidity with exchange transfusion,<sup>69,70</sup> Koshy and colleagues<sup>71</sup> followed 72 pregnant patients with sickle cell anemia: half received prophylactic transfusions and half received transfusions only for medical or obstetric emergencies. **No significant difference was seen in perinatal outcome between the offspring of mothers who received prophylactic transfusions and those who did not. Two risk factors were identified as harbingers of an unfavorable outcome: the occurrence of a perinatal death in a previous pregnancy and twins in the current pregnancy. Even though no difference in perinatal morbidity and mortality was reported, prophylactic transfusion did appear to decrease significantly the incidence of painful crises.**

Mahomed<sup>72</sup> reviewed the Cochrane database and found that evidence was insufficient to make any conclusions about the use of prophylactic RBC transfusion in patients with sickle cell disease. Many of the cited studies did not show evidence of benefit to the fetus from exchange transfusion. A review by Hassell<sup>73</sup> summarized the various small studies and concluded

that prophylactic transfusion does not improve fetal and neonatal outcome. He did not, however, attempt to quantify changes in maternal well-being.

In a study of 128 patients, Ngo and colleagues<sup>74</sup> attempted to delineate whether prophylactic partial exchange transfusion improved fetal/neonatal outcomes. Although their control group comprised patients with HbAA, they demonstrated significant perinatal/neonatal complications in patients with sickle cell disease who received prophylactic exchange transfusions. The study would have been much stronger had they used a control group of patients with HbSS who had not received exchange transfusions.

Transfusion should be reserved for the same indications that would be used if the patient were not pregnant. However, in the postpartum period, the obstetrician should realize that the patient with HbSS will not increase her hemoglobin/hematocrit as quickly as would the patient with HbAA.

**Vaginal delivery is preferred for patients with sickle cell disease, and cesarean delivery should be reserved for obstetric indications.** Patients should labor in the left lateral recumbent position and should receive supplemental oxygen. Although adequate hydration should be maintained, fluid overload must be avoided. Conduction anesthesia is recommended because it provides excellent pain relief and can be used for cesarean delivery if necessary. Winder and colleagues<sup>75</sup> reported a case in which epidural anesthesia was used antepartum to relieve a painful crisis, and the patient's hospital stay was significantly shortened. [Figure 44-2](#) provides a schematic presentation of the care of patients with sickle cell anemia. It can also be adapted to patients with other hemoglobinopathies.

## Hemoglobin SC Disease

Hemoglobin C is another  $\beta$ -chain variant. It results from a G to A point mutation in the first nucleotide of codon 6. The gene is present in 2% of blacks. Clinically significant HbSC disease occurs in 1 in 833 black adults in the United States. **Women with both S and C hemoglobin suffer less morbidity in pregnancy than do patients with only HbS.** As in sickle cell disease, however, the incidence of early spontaneous pregnancy loss and pregnancy-induced hypertension are increased. Because patients with SC disease can have only mild symptoms, this hemoglobinopathy may remain undiagnosed until a crisis occurs during pregnancy.

Whereas patients with HbSS often undergo "autosplenectomy" as a result of splenic infarction, patients with HbSC may have an enlarged, tender spleen. **Crises in patients with HbSC may be marked by sequestration of a large volume of RBCs in the spleen accompanied by a dramatic fall in hematocrit.**<sup>76</sup> **Because these patients have increased splenic activity, they may be mildly thrombocytopenic throughout pregnancy and may become profoundly thrombocytopenic during a crisis.** During gestation, patients with HbSC should receive the same program of prenatal care outlined for women with HbSS (see [Fig. 44-2](#)).

## Thalassemia

**Thalassemia is due to a defect in the rate of globin chain synthesis.** Any of the polypeptide chains can be affected. As a result, production and accumulation of abnormal globin subunits occurs and leads to ineffective erythropoiesis and a decreased life span of RBCs. The disease may range from minimal suppression of synthesis of the affected chain to its

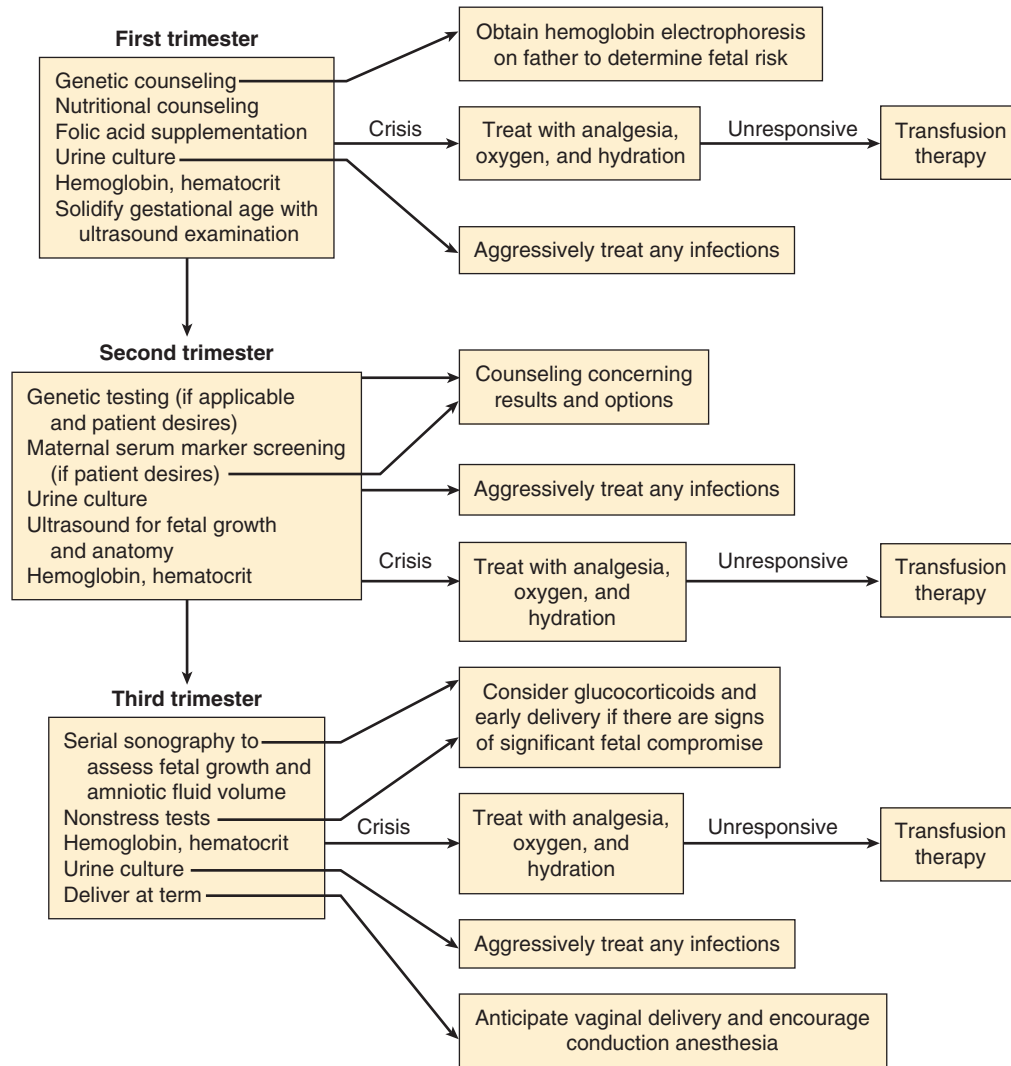

FIG 44-2 Schematic presentation of the care of patients with sickle cell anemia.

complete absence. Either  $\alpha$ - or  $\beta$ -thalassemia can occur, and heterozygous patients are often asymptomatic.

Thalassemia can be detected by prenatal diagnosis. Prenatal diagnosis of  $\beta$ -thalassemia can be accomplished by DNA from villi or amniocytes. Because there are many  $\beta$ -globin mutations, it is important to report the patient's ethnicity and the geographic region of the family when submitting specimens. The laboratory can then test for specific mutations based on this information and will be able to identify  $\beta$ -thalassemia in 90% of cases.  $\alpha$ -Thalassemia is also amenable to prenatal diagnosis using quantitative PCR or Southern blot analysis. **The American College of Obstetricians and Gynecologists (ACOG) recommends thalassemia screening for pregnant women with a low mean corpuscular volume (MCV) and no evidence of iron deficiency.**<sup>77</sup>

**Homozygous  $\alpha$ -thalassemia results in the formation of tetramers of  $\beta$ -chains known as hemoglobin Bart. This hemoglobinopathy can result in hydrops fetalis.** Ghosh and coinvestigators<sup>78</sup> reported their experience caring for 26 Chinese women who were at risk to deliver a fetus with homozygous  $\alpha$ -thalassemia. Six of the 26 fetuses were affected. In two of the six cases, progressive fetal ascites appeared before 24 weeks'

gestation. These pregnancies were terminated, and the diagnoses were confirmed. The remaining four patients had evidence of IUGR by 28 weeks' gestation. At later gestational ages, an increase in the transverse cardiac diameter was seen in the affected fetuses. Woo and colleagues<sup>79</sup> reported that umbilical artery velocimetry revealed **a hyperdynamic circulatory state in fetuses that were hydropic because of  $\alpha$ -thalassemia.** In a study from Taiwan, Hsieh and colleagues<sup>80</sup> demonstrated that umbilical vein blood flow measurements can help to distinguish hydrops fetalis caused by hemoglobin Bart from hydrops fetalis from other causes. The umbilical vein diameter, blood velocity, and blood flow in fetuses with hemoglobin Bart were usually higher than those in fetuses with hydrops fetalis due to other etiologies.

**$\beta$ -Thalassemia is the most common form of thalassemia,** although patients with the heterozygous state are usually asymptomatic; they are detected by an increase in their level of both HbA2 and HbF. HbE is another  $\beta$ -chain variant found generally in patients from Southeast Asia. The clinical course is variable and is similar to that described for  $\beta$ -thalassemia. In the homozygous state of  $\beta$ -thalassemia, synthesis of HbA1 may be completely suppressed. HbA2 levels of greater than 50% are found

in 40% of patients with  $\beta$ -thalassemia, and an elevated HbF level is observed in 50% of these patients. **The homozygous state of  $\beta$ -thalassemia is known as *thalassemia major*** (formerly known as *Cooley anemia*). Patients with this disorder are transfusion dependent and have marked hepatosplenomegaly and bone changes secondary to increased hematopoiesis. These individuals usually die of infectious or cardiovascular complications, have a decreased life expectancy, and **rarely become pregnant**. They also have a high rate of infertility, although successful full-term pregnancies have been reported. The few patients who do become pregnant generally exhibit severe anemia and congestive heart failure.<sup>81</sup> Prenatal care is dependent on transfusion therapy similar to that used in the care of the patient with sickle cell disease.

Heterozygous  $\beta$ -thalassemia has different forms of expression. Patients with *thalassemia minima* have microcytosis but are asymptomatic. Those with *thalassemia intermedia* exhibit splenomegaly and significant anemia and may become transfusion dependent during pregnancy. Their anemia can be significant enough to produce high-output cardiac failure. If these patients have not undergone splenectomy, they are at risk for a hypersplenic crisis as seen in HbSC disease. Also, extramedullary hematopoiesis may impinge on the spine, resulting in neurologic symptoms.

These patients should be managed with a treatment program similar to that followed for patients with sickle cell disease (see Fig. 44-2). **As in the case of sickle hemoglobinopathies, iron supplementation should be given only if necessary, because indiscriminate use of iron can lead to hemosiderosis and hemochromatosis.** White and coworkers<sup>82</sup> have shown that patients with a  $\beta$ -thalassemia usually have a much higher ferritin concentration than normal patients and those who are  $\alpha$ -thalassemia carriers. In  $\beta$ -thalassemia carriers, the incidence of iron deficiency anemia is four times less common than it is in  $\alpha$ -thalassemia carriers and in normal patients.<sup>82</sup> Although iron is not necessary, **folic acid supplementation appears important in  $\beta$ -thalassemia carriers.** Leung and coinvestigators<sup>83</sup> showed that the daily administration of folate significantly increased the predelivery hemoglobin concentration in both nulliparous and multiparous patients.

Patients who are transfusion dependent can develop iron overload, but few data are available on the safety of iron chelating agents during pregnancy. Ricchi and colleagues<sup>84</sup> report a case of successful pregnancy while using deferasirox in the first trimester. The pregnancy went to term, and no fetal malformations were reported. This therapy has not been reported in other pregnancies; therefore chelating agents should only be used in emergent situations.

**As in the case of sickle cell disease, antepartum fetal evaluation is essential in patients with thalassemia who are anemic.** Patients with clinically significant thalassemia should undergo serial ultrasonography to track fetal growth as well as nonstress testing to evaluate fetal well-being. Asymptomatic thalassemia carriers need no special testing.

Occasionally, individuals will inherit two hemoglobinopathies, such as sickle cell thalassemia (HbS thalassemia). The prevalence of this disorder among adult blacks in the United States is 1 in 1672.<sup>85</sup> The clinical course is variable: if minimal suppression of  $\beta$ -chains occurs, patients may be free of symptoms; however, with total suppression of  $\beta$ -chain synthesis, a clinical picture similar to that of sickle cell disease will develop. The course of these patients during pregnancy is quite variable,

and their therapy must be individualized. **In summary, Figure 44-3 presents a stepwise approach to the workup of anemia and the diagnosis of the conditions discussed in this chapter.**

## VON WILLEBRAND DISEASE

**The most common congenital bleeding disorder in humans is von Willebrand disease (vWD), and up to 1% of the population may have some form of the disorder.** Type 1 is an autosomal-dominant disorder, whereas type 3 and occasionally type 2 are autosomal recessive.<sup>86</sup> vWD is related to **quantitative or qualitative abnormalities of von Willebrand factor (vWF)**. This multimeric glycoprotein serves as carrier protein of factor VIII, prolonging its life span in plasma. It also promotes platelet adhesion to the damaged vessel and platelet aggregation. **Distinct abnormalities of vWF are responsible for the three types of vWD.** Types 1 and 3 are characterized by a quantitative defect of vWF, whereas type 2 comprises subtypes 2A, 2B, 2M, and 2N and refers to molecular variants with a qualitative defect of vWF. In these subtypes, there are various problems in binding of vWF to factor VII or platelet surface.<sup>87</sup> The knowledge of the structure of the vWF gene and the use of PCR have led to the identification of the molecular basis of vWD in a significant number of patients.<sup>88</sup> **In type 2B, the only clinical symptom in pregnancy may be thrombocytopenia.**<sup>89</sup> Therefore this diagnosis should be considered in the gravida with isolated thrombocytopenia during pregnancy who exhibits a significant bleeding diathesis.

**The clinical severity of vWD is variable. Menorrhagia, easy bruising, gingival bleeding, and epistaxis are common.** Menorrhagia is most severe in patients with types 2 and 3 vWD but is most common in patients with type 1 disease. In a compilation of two studies, 17% of women with severe menorrhagia had a form of vWD.<sup>90</sup> Some patients may be entirely asymptomatic until they have severe bleeding after surgery or trauma, and **von Willebrand disease does not appear to affect fetal growth or development.**

Classically, the bleeding time is prolonged in patients with vWD as a result of diminished platelet aggregation. Occasionally, the activated partial thromboplastin time (aPTT) is also abnormal. This is only seen when the factor VIII activity is extremely low.<sup>91</sup> **In pregnancy, clotting factors that include the factor VIII complex increase, and the patient's bleeding time may improve as gestation progresses.**<sup>90</sup> This is especially true for type 1A vWD. In type 1B, the patient may not correct her bleeding time.<sup>90</sup> In type 2B, the platelet count decreases, which may be exacerbated in pregnancy.<sup>91</sup> There will, however, be an improvement in the vWF multimeric pattern.<sup>92</sup>

Heavy bleeding may be encountered in patients with vWD undergoing elective or spontaneous first-trimester pregnancy loss because the levels of factor VIII have not yet risen.<sup>93</sup> **Most important, postpartum hemorrhage may be a serious problem. The concentration of factor VIII appears to determine the risk of hemorrhage.** If the level is greater than 50% of normal and the patient has a normal bleeding time, excessive bleeding should not occur at vaginal delivery.<sup>87</sup> In a study by Kadir and colleagues,<sup>93</sup> 18.5% of patients with vWD experienced a significant postpartum hemorrhage, and 6 of 31 patients required transfusion. The clinical course during labor is variable. In a study by Chediak and colleagues,<sup>94</sup> bleeding complications were seen in six of eight (75%) pregnancies. Five of the newborns had vWD, one of whom was born with a scalp hematoma.

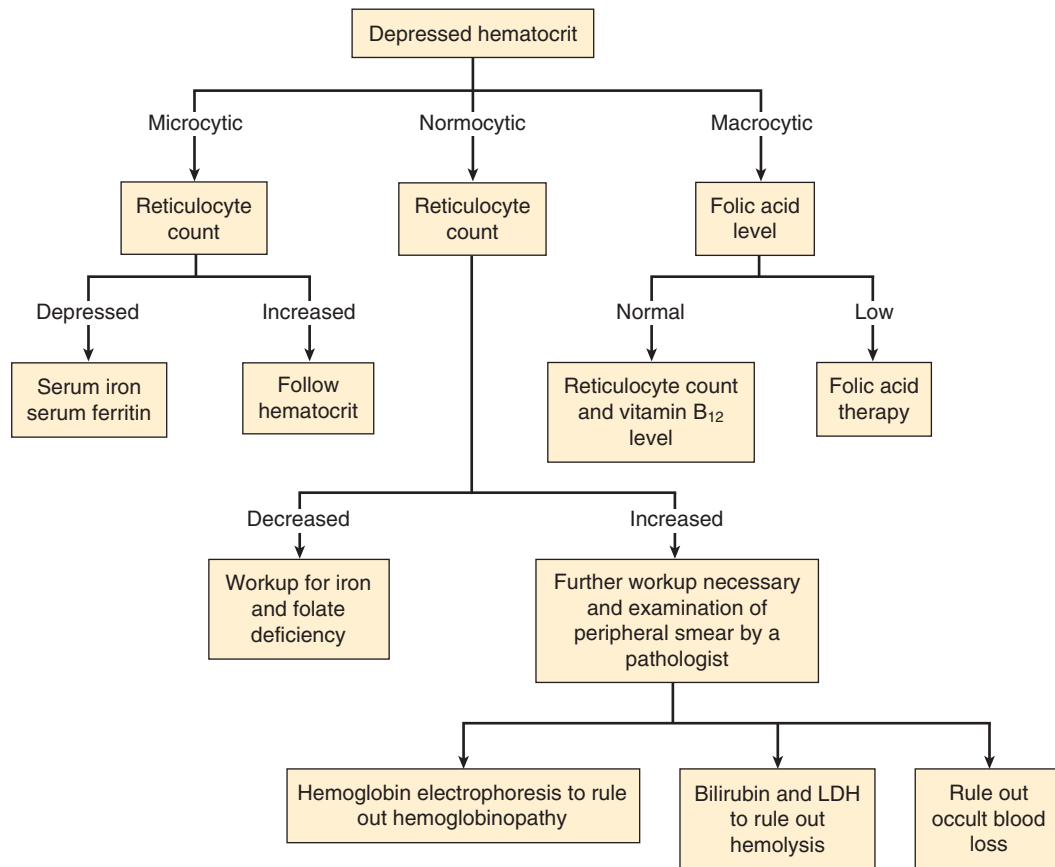

FIG 44-3 Evaluation of anemia. LDH, lactate dehydrogenase.

Conversely, Conti and associates<sup>95</sup> reported no bleeding complications during the puerperium in five women with vWD. Ieko and colleagues<sup>96</sup> demonstrated that factor VIII concentrate could raise the platelet levels in patients with type 2B vWD. Ito and coinvestigators<sup>55</sup> followed six women with type 1 vWD in 10 term pregnancies, three induced abortions, and one spontaneous abortion. Bleeding complications occurred within 1 week after term delivery and immediately after both spontaneous and induced abortions. Pacheco and coworkers<sup>97</sup> published a comprehensive review of vWD coexisting with pregnancy. This study confirmed that most type I patients do not need treatment as long as the factor VIII concentration is greater than 50%. They also stressed the need for close postpartum follow-up because levels of vWF can plummet a few days postpartum. It was recommended that pudendal anesthesia and operative vaginal delivery be avoided if possible.<sup>97</sup>

As noted earlier, **bleeding during pregnancy is rare because levels of factor VIII and vWF increase during pregnancy. However, shortly after delivery, they drop. If the factor VIII level is less than 50%, treatment during labor and delivery should be initiated. Hemorrhage can also occur several days postpartum.** Therefore factor VIII levels should be checked before the patient goes home after delivery.

Desmopressin is the treatment of choice for type 1 vWD.<sup>98</sup> It elicits the release of vWF from endothelial cells. Intranasal preparations of 300 µg are usually used, although the half-life of desmopressin is about 8 hours, so the dose should be repeated every 12 hours. In emergent or preoperative situations, 0.3 µg/kg of desmopressin can be given intravenously

over 30 minutes.<sup>97</sup> Desmopressin can rarely cause hyponatremia and fluid retention.<sup>98</sup> Patients can develop tachyphylaxis with desmopressin, so it should not be used for prolonged periods. Also, desmopressin can initiate uterine contractions and should be used with caution in patients in the second or early third trimesters of pregnancy.

For those women who do not respond to desmopressin or for those with vWD types other than 1A, Humate-P or Alphanate should be used. These commercially available concentrates of **antihemophilic factor** have been tested extensively in clinical studies. They contain two to three times more vWF than they do factor VIII concentrate.<sup>99</sup> The usual dose of Humate-P or Alphanate is 20 to 50 U/kg. During labor, this can be given every 12 hours. For labor and delivery, usually the lower end of the dosage range will suffice. If a cesarean delivery is needed, the upper end of the dosage range should be used. These compounds have been heated at high temperature and treated with solvents and detergents to inactivate blood-borne viruses. It is important to note that products that contain highly purified factor VIII obtained by recombinant DNA should not be used. They contain very little vWF and are ineffective in vWD. Therefore the infused factor VIII has a very short half-life because vWF is essential to prevent the degradation of factor VIII. **Bleeding during pregnancy is rare.** Patients with classic type 1 vWD usually need no treatment owing to the increase in factor VIII levels during pregnancy. Those with a history of postpartum hemorrhage should be given an IV dose of desmopressin immediately after delivery, and the dose should be repeated 24 hours later. For those with types 2 and 3 disease, factor VIII/vWF

concentrates are occasionally needed. Before a cesarean delivery, factor VIII activity should be measured. If it is less than 50% of expected, patients with type 1 vWD should be given desmopressin, and patients with vWD type 2 or type 3 should receive factor VIII/vWF concentrate.<sup>100</sup> **In an emergent situation, if the type of vWD is not known with certainty, factor VIII/vWF concentrate should be used.**

### KEY POINTS

- ◆ Four percent of pregnancies will be complicated by maternal platelet counts of less than 150,000/mm<sup>3</sup>. The vast majority of these patients have gestational thrombocytopenia with a benign course and need no intervention.
- ◆ Surgical bleeding occurs if the platelet count falls below 50,000/mm<sup>3</sup>, and spontaneous bleeding occurs if the platelet count falls below 20,000/mm<sup>3</sup>. Platelet counts below 30,000/mm<sup>3</sup> warrant therapy during pregnancy.
- ◆ In the second and third trimesters of pregnancy, intravenous immunoglobulin is an effective initial treatment, although glucocorticoids can also be utilized.
- ◆ Iron deficiency anemia is the most common cause of anemia in pregnancy, and serum ferritin is the single best test to diagnose it.
- ◆ If a patient with presumed iron deficiency does not increase her reticulocyte count with iron therapy, she may also have a concomitant folic acid deficiency.
- ◆ Patients pregnant with twins, those on anticonvulsant therapy, those with a hemoglobinopathy, and those who conceive frequently need supplemental folic acid during gestation.
- ◆ Most hereditary hemoglobinopathies can be detected in utero, and prenatal diagnosis should be offered to the patient early in pregnancy. Early testing can be done using DNA analysis from the chorionic villus sampling specimen.
- ◆ As in the nonpregnant patient, analgesia, hydration, and oxygen are the key factors in treating pregnant women with sickle cell crisis.
- ◆ Women with sickle cell disease are at high risk for maternal complications during the puerperium and should be closely monitored.
- ◆ Patients with sickle cell disease are at increased risk for a fetus with growth restriction and adverse fetal outcomes; therefore they warrant frequent sonography and antepartum fetal evaluation.
- ◆ Any woman with a low mean corpuscular volume without evidence of iron deficiency should be screened for thalassemia.
- ◆ In the pregnant patient with von Willebrand disease, the normal increase in the factor VIII clotting complex reduces the risk of bleeding, but levels can fall postpartum and can place the patient at risk for delayed postpartum hemorrhage.

## BACKGROUND AND HISTORIC NOTES

Pregnancy, childbirth, and the puerperium pose serious challenges to a woman's hemostatic system. Whereas implantation, placentation, and uterine spiral artery remodeling lead to the development of the high-volume, high-flow, low-resistance uteroplacental circulation required for human fetal development, they require enhanced hemostatic responsiveness to avoid potentially fatal hemorrhage. **The price paid for this essential hemostatic adaptation to human hemochorial placentation is an increased risk of superficial and deep venous thrombosis (DVT) and pulmonary embolus (PE).** Acquired or inherited thrombophilias, obesity, advanced maternal age, advanced parity, antepartum hospitalizations, surgery, and infection are major risk factors for DVT and PE in pregnancy and the puerperium. The expeditious identification and prompt treatment of thrombotic events is critical to avoiding death and serious post-phlebotic sequelae.

## DIAGNOSES AND DEFINITIONS

Thrombosis is the obstruction or occlusion of a vessel by a blood clot. Venous thromboembolism (VTE) includes venous thrombosis of the deep venous system of the lower (common) or upper (uncommon) extremity (DVT). Thrombosis or inflammation of the *superficial* venous system is generally not associated with morbidity, although in some cases it can develop into or be associated with DVT or PE. In fact, 10% to 20% of superficial thrombosis cases in nonpregnant patients are associated with DVT. **Pulmonary embolus is the obstruction of the pulmonary artery or one of its branches, arising from a clot from a DVT in approximately 90% of cases.** A majority of PE cases are due to deportment of thrombus from the lower extremities; for the purposes of this chapter, *pulmonary embolus* will refer to VTE of the pulmonary vasculature (rather than air, fat, or amniotic fluid embolism).

## Symptoms

### Deep Venous Thrombosis

Clinical findings typical of DVT include erythema, warmth, pain, edema, and tenderness localized to the area of the thrombosis. Occasionally, a palpable cord may be present that corresponds to a thrombosed vein. **Homans sign** is pain and tenderness elicited on compression of the calf muscles by squeezing the muscles or by dorsiflexion of the foot. These are rather nonspecific signs and symptoms that involve a broad differential diagnosis, including cellulitis, ruptured or strained muscle or tendon, trauma, ruptured popliteal (Baker) cyst, cutaneous vasculitis, superficial thrombophlebitis, and lymphedema. The specificity of these manifestations is less than 50%, and among patients with these signs and symptoms, the diagnosis of DVT is confirmed by objective testing in only approximately one third of the group.<sup>1,2</sup>

### Pulmonary Embolism

Tachypnea (>20 breaths/min) and tachycardia (>100 beats/min) are present in 90% of patients with acute PE, but these findings lack specificity and generate a broad differential diagnosis.<sup>3</sup> Presyncope and syncope are rarer symptoms and indicate a massive embolus.<sup>4</sup>

## EPIDEMIOLOGY AND INCIDENCE

Occurring in approximately in 1 in 1500 pregnancies, VTE is a relatively uncommon disorder but is a leading cause of mortality and serious morbidity in pregnant women.<sup>5-12</sup> This rate represents a nearly tenfold increase compared with non-pregnant women of comparable childbearing age. According to the most recent U.S. vital statistics, from 2006 through 2010, VTE was a leading cause of maternal mortality that contributed to 9% of pregnancy-related deaths.<sup>13</sup> Classic teaching viewed the postpartum period as the period of maximal thrombotic occurrence. However, management styles of prior eras that included prolonged puerperal bed rest and estrogen to suppress lactation likely inflated this risk.<sup>10</sup> More recent studies have shown that a majority of thromboembolic events happen in the antepartum period.<sup>5,7,14-16</sup> Given its shorter duration, and after adjusting for duration of exposure, the day-to-day relative risk of VTE is about threefold to eightfold higher in the puerperium.<sup>12</sup> New evidence suggests that the risk for a thrombotic event extends out to 12 weeks postpartum, although the absolute increase in risk is quite low after 6 weeks.<sup>17</sup>

## GENETICS

It is well known that inherited mutations in various components of the coagulation cascade, the so-called inherited thrombophilias, contribute to significant risk for thrombosis, especially in the presence of other risk factors such as pregnancy, surgery (e.g., cesarean delivery), trauma, infection, or immobility. **Factor V Leiden is the most common mutation and accounts for over 40% of inherited thrombophilias in most studies.** Most of these genetic mutations act in an autosomal-dominant manner, thus one mutation will incur an elevated risk for VTE; individuals with two mutations will have higher risks for thrombotic events than those with one. Patients with a strong family history of thrombotic events who have screened negative for the panel of known thrombophilia mutations likely have an as yet unrecognized gene defect in a specific component of the coagulation

cascade. The details of the known inherited thrombophilias are discussed later in this chapter.

## PHYSIOLOGY OF HEMOSTASIS

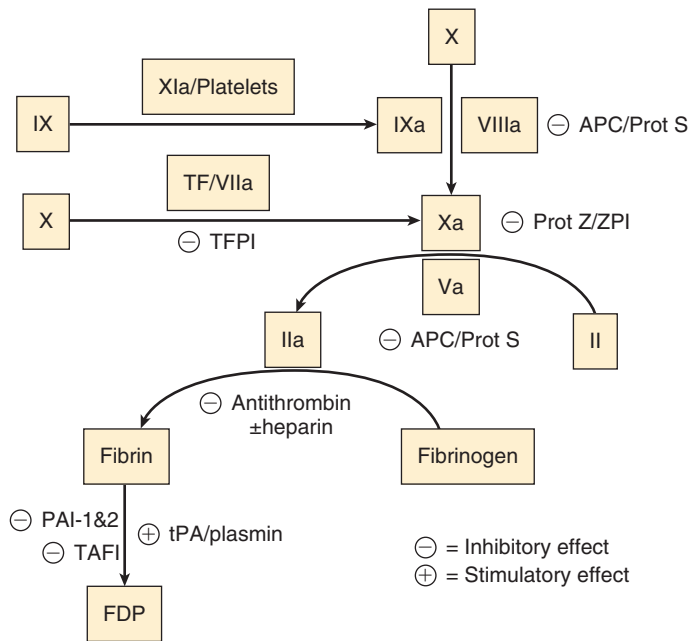

### Vasoconstriction and Platelet Action

Vasoconstriction and platelet activity play a primary initial role in limiting blood loss following vascular disruption and endothelial damage. Vasoconstriction limits blood flow and also limits the size of thrombus necessary to repair the defect. Platelet adherence to damaged vessels is mediated by the formation of von Willebrand factor (vWF) “bridges” anchored at one end to subendothelial collagen and at the other to the platelet glycoprotein Ib (GP Ib)/factor IX/V receptor.<sup>18</sup> Platelet adhesion stimulates release of  $\alpha$ -granules that contain vWF, thrombospondin, platelet factor 4, fibrinogen,  $\beta$ -thromboglobulin, and platelet-derived growth factor as well as dense granules that contain adenosine diphosphate (ADP) and serotonin. These latter molecules, when combined with the release of thromboxane A<sub>2</sub> (TXA<sub>2</sub>), contribute to further vasoconstriction and platelet activation. In addition, ADP causes a conformational change in the platelet GP IIb/IIIa receptor that promotes aggregation by forming interplatelet fibrinogen, fibronectin, and vitronectin bridges.<sup>19</sup>

### Coagulation Cascade

**Platelet action alone is insufficient to provide adequate hemostasis in the face of a substantial vascular insult; in this setting, the coagulation cascade—with resultant fibrin plug formation—is required to restore hemostasis.** Tissue factor (TF), a cell membrane-bound glycoprotein, is the primary initiator of the coagulation cascade.<sup>20</sup> It is expressed constitutively by epithelial, stromal, and perivascular cells throughout the body and in abundance by endometrial stromal cells and the pregnant uterine decidua.<sup>20,21</sup> TF is also present in low concentrations in blood, on activated platelets, and in high levels in amniotic fluid, which accounts for the coagulopathy seen in amniotic fluid embolism.<sup>22</sup> It is interesting to note that although intrauterine survival is possible in the absence of platelets or fibrinogen, it is not possible in the absence of TF.<sup>23</sup> Clotting is initiated by the binding of TF to factor VII, the only clotting factor with intrinsic coagulation activity in its zymogenic form (Fig. 45-1).

Following endothelial injury and in the presence of ionized calcium, perivascular cell- or platelet-bound TF comes into contact with factor VII on anionic cell membrane phospholipids. Factor VII has low intrinsic clotting activity but can be autoactivated after binding to TF, or it can be activated by thrombin or activated factors such as IXa, Xa, or XIIa.<sup>20,24</sup> The TF-activated factor VII (VIIa) complex initiates the elements of the coagulation cascade by activating both factors IX and X. Activated factor IX (IXa) complexes with its cofactor VIIIa to indirectly activate X. Once generated, Xa binds with its cofactor Va to convert prothrombin (factor II) to thrombin (factor IIa). Cofactors V and VIII can each be activated by either thrombin or Xa, and XIIa activates XI on the surface of activated platelets, which provides an alternative route to IX activation. Factor XII can be activated by kallikrein/kininogen as well as by plasmin. **The key event of hemostasis occurs when thrombin cleaves fibrinogen to produce fibrin.** Fibrin monomers self-polymerize and are cross-linked by thrombin-activated factor XIIIa. Although TF is the initiator of hemostasis, thrombin is the ultimate arbiter of clotting; it not only activates platelets

**FIG 45-1** Hemostatic, thrombotic, and fibrinolytic pathways. APC, activated protein C; FDP, fibrin degradation product; PAI, plasminogen activator inhibitor; PROT, protein; TAFI, thrombin-activatable fibrinolysis inhibitor; TFPI, tissue factor pathway inhibitor; tPA, tissue-type plasminogen activator; ZPI, protein Z-dependent protease inhibitor.

and generates fibrin, it also activates critical clotting factors and cofactors (V, VII, VIII, XI, and XIII). **Figure 45-1** provides a diagram of the interaction of the various components of the coagulation cascade.

### Anticoagulant System

The risk of thrombosis, the inappropriate and excessive activation of the clotting cascade, is restrained by the anticoagulant system (see **Fig. 45-1**). Evidence shows that the coagulation system “idles” like a car engine to quickly respond to vascular injury, and thus **the anticoagulant system performs the critical role of preventing inappropriate acceleration of clotting.**<sup>24</sup> Tissue factor pathway inhibitor (TFPI) binds to the prothrombinase complex (factor Xa/TF/factor VIIa) to stop TF-mediated clotting.<sup>25</sup> However, as noted, factor XIa generation can bypass this block. Moreover, in the 10 to 15 seconds before TFPI-mediated prothrombinase inhibition, sufficient quantities of factors Va, VIIIa, IXa, and Xa and thrombin are generated to sustain clotting for some time. As a result, additional physiologic anticoagulant molecules are required to maintain blood fluidity.

Paradoxically, thrombin also plays a pivotal role in the anticoagulant system by binding to thrombomodulin, which causes a conformation change that allows it to activate protein C. The activated protein C (APC) molecule binds to anionic endothelial cell membrane phospholipids on damaged vessels or to the endothelial cell protein-C receptor (EPCR) to inactivate factors Va and VIIIa.<sup>26</sup> Protein S is an important cofactor in this process because it enhances APC activity. Factor Va is also a cofactor in APC-mediated factor VIIIa inactivation.

Factor Xa can also be inhibited by the protein Z-dependent protease inhibitor (ZPI). When ZPI forms a complex with its cofactor, protein Z, its inhibitory activity is enhanced a thousandfold, although ZPI can also inhibit factor XIa independent

of protein Z.<sup>27</sup> Deficiencies of protein Z can promote both bleeding and thrombosis, although the latter predominates particularly in the presence of other thrombophilias.

**Thrombin activity is modulated by a number of serine protease inhibitors—such as heparin cofactor II,  $\alpha$ -2 macroglobulin, and antithrombin—which serve to inactivate thrombin and Xa.** The most active inhibitor within this group is antithrombin, which binds to either thrombin or factor Xa and then to heparin or other glycosaminoglycans, augmenting antithrombin’s rate of thrombin inactivation more than a thousandfold.<sup>28,29</sup> The other two inhibitors work in a similar fashion to inhibit thrombin.

### Clot Lysis and Fibrinolysis

Fibrinolysis is a further critical element in preventing overwhelming thrombosis (see **Fig. 45-1**). Tissue-type plasminogen activator (tPA), an endothelial enzyme metabolized by the liver, becomes embedded in fibrin and cleaves plasminogen to generate plasmin, which in turn cleaves fibrin into fibrin degradation products; the latter are indirect measures of fibrinolysis. These fibrin degradation products can also inhibit thrombin action, a favorable effect when production is limited, but a contributor to disseminated intravascular coagulation (DIC) when production is excessive. A second plasminogen activator, urokinase-type plasminogen activator (uPA), is produced by endothelial cells. A series of fibrinolysis inhibitors also prevent hemorrhage from premature clot lysis. The  $\alpha$ -2 plasmin inhibitor is bound to the fibrin clot, where it prevents premature fibrinolysis. Platelets and endothelial cells release type 1 plasminogen activator inhibitor (PAI-1), an inactivator of tPA. In pregnancy, the decidua is also a rich source of PAI-1,<sup>30</sup> whereas the placenta produces mostly type 2 (PAI-2). The thrombin-activatable fibrinolysis inhibitor (TAFI) is another fibrinolytic inhibitor that is also activated by the thrombin-thrombomodulin complex.<sup>31</sup> TAFI modifies fibrin and renders it resistant to inactivation by plasmin.

### PATHOPHYSIOLOGY OF THROMBOSIS IN PREGNANCY

Characteristic physiologic changes in decidual and systemic hemostatic systems occur in pregnancy in preparation for the hemostatic challenges of implantation, placentation, and childbirth. Decidual TF and PAI-1 expression are greatly increased in response to progesterone, and levels of placental-derived PAI-2, which are negligible prior to pregnancy, increase until term.<sup>30,31</sup> Pregnancy is associated with systemic changes that enhance hemostatic capability and promote thrombosis. For example, **a doubling occurs in circulating concentrations of fibrinogen, and 20% to 1000% increases are seen in factors VII, VIII, IX, X, and XII, all of which peak at term in preparation for delivery.**<sup>32</sup> Levels of vWF also increase up to 400% at term.<sup>32</sup> In contrast, levels of prothrombin and factor V remain unchanged, and levels of factor XIII and XI decline modestly. **Concomitantly, there is a 40% to 60% decrease in the levels of free protein S, conferring an overall resistance to activated protein C.**<sup>32,33</sup> Further reductions in free protein-S concentrations are caused by stress, cesarean delivery, and infection; this accounts for the high rate of PE following cesarean deliveries, particularly in association with prolonged labor and endomyometritis. **Coagulation parameters** may normalize as early as 3 weeks postpartum, but **they generally return to baseline at 6 to 12 weeks.**

The risk of thrombosis in pregnancy is also related to physical changes in the gravid woman. **Venous stasis in the lower extremities results from compression of the inferior vena cava (IVC) and pelvic veins by the enlarging uterus.**<sup>34,35</sup> Despite the presence of the sigmoid colon promoting uterine dextrorotation, ultrasound findings indicate lower flow velocities in the left leg veins throughout pregnancy.<sup>36</sup> This would explain why multiple studies have confirmed that **the incidence of thrombosis is far greater in the left leg than in the right.**<sup>5,15</sup> Hormone mediated increases in deep vein capacitance secondary to increased circulating levels of estrogen and local production of prostacyclin and nitric oxide also contribute to the increased risk of thrombosis.

### Antiphospholipid Syndrome

**Overall, antiphospholipid syndrome (APS) is responsible for approximately 14% of thromboembolic events in pregnancy.**<sup>37,38</sup> The diagnosis of APS requires the presence of prior or current vascular thrombosis or characteristic obstetric complications together with at least one laboratory criterion, such as anticardiolipin antibodies (immunoglobulin G [IgG] or IgM greater than 40 GPL [1 GPL unit is 1 µg of IgG antibody] or 40 MPL [1 MPL unit is 1 µg of IgM antibody] or greater than the 99th percentile), anti-β-2 glycoprotein-I (IgG or IgM greater than the 99th percentile), or lupus anticoagulant.<sup>39</sup> Refer to [Chapter 46](#) for details of diagnosis and treatment of APS.

The antiphospholipid antibodies (APAs) are a class of self-recognition immunoglobulins whose epitopes are proteins bound to negatively charged phospholipids. These antibodies must be present on two or more occasions at least 12 weeks apart for diagnosis<sup>39</sup> and are present in 2.2% of the general obstetric population, and most affected patients have uncomplicated pregnancies.<sup>40</sup> **Thus providers should use caution when ordering and interpreting tests in the absence of APS-qualifying clinical criteria.**

APS has been associated with both venous (DVT, PE) and arterial vascular events (stroke). A meta-analysis of 18 studies has shown elevated risk of DVT, PE, and recurrent VTE among patients with systemic lupus erythematosus (SLE) who test positive for APA. Overall, when compared with those SLE patients who do not test positive for either test, those with lupus anticoagulants and anticardiolipin antibodies have a respective sixfold and twofold increased risk of venous thrombosis.<sup>41</sup> These antibodies also pose a risk to patients without SLE. The lifetime prevalence of arterial or venous thrombosis in affected non-SLE patients is approximately 30%, with an event rate of 1% per year.<sup>42,43</sup> The risks of thromboembolic events are highly dependent on the presence of other predisposing factors that include pregnancy, estrogen exposure, immobility, surgery, and infection. As noted above, APS has also been associated with adverse pregnancy outcome and accounts for 14% of VTE in pregnancy.<sup>37,38</sup> In fact, the risk of a thrombotic event in pregnancy is 5% even with prophylaxis.<sup>44</sup> All patients who present with VTE in pregnancy or in the postpartum period should have an appropriate APS workup.

### Inherited Thrombophilias

The inherited thrombophilias are a heterogeneous group of genetic disorders associated with arterial and venous thrombosis as well as fetal loss. As with APAs, the occurrence of a thromboembolic event is highly dependent on other predisposing

factors such as pregnancy, exogenous estrogens, immobility, obesity, surgery, infection, trauma, and the presence of other thrombophilias. However, the most important risk modifier is a personal or family history of venous thrombosis.<sup>45</sup> [Table 45-1](#) presents the prevalence and risk of venous thrombosis among pregnant patients with and without a personal or family history of venous thrombosis. As noted, the thrombophilias are divided into high and low risk based on the overall risk of VTE. The screening for and management of inherited thrombophilias during and around the time of pregnancy has been recently addressed by American College of Obstetricians and Gynecologists (ACOG).<sup>46</sup> **All patients who present with VTE in pregnancy or postpartum should be considered for an appropriate workup for inherited thrombophilias.**

Recent prospective studies have suggested that lower-risk inherited thrombophilias may have an even weaker association with maternal thrombosis than that reported by the retrospective studies cited in [Table 45-1](#). For example, a prospective study of 4885 low-risk women screened in the first trimester of pregnancy noted that 134 (2.7%) carried the factor V Leiden mutation, but none had a thromboembolic event during pregnancy or the in puerperium (95% confidence interval [CI], 0% to 2.7%).<sup>47</sup> In two other prospective studies<sup>48,49</sup> that involved 584 Irish and 4250 British pregnant women again screened for factor V Leiden early in pregnancy, no thrombotic episodes were noted among carriers. Said and associates<sup>50</sup> tested 1707 Australian nulliparous women blindly for factor V Leiden, the prothrombin gene G20210A mutation, and a thrombomodulin polymorphism prior to 22 weeks and reported an expected prevalence of heterozygosity for the factor V Leiden and prothrombin G20210A gene mutations and homozygosity for the thrombomodulin polymorphism of 5.39%, 2.38%, and 3.51%, respectively; again, none of the patients developed VTEs. However, one prospective study<sup>51</sup> of 2480 women tested for activated protein-C resistance/factor V Leiden early in pregnancy observed that affected patients had an eightfold increase in VTE. Thus the true risk of thrombosis in patients with low-risk inherited thrombophilias is probably lower than that suggested by retrospective case-control and cohort studies and is also likely dependent on the presence of concomitant risk factors such as a strong family history, obesity, and surgery.

### Risk Factors and Associations

**Virchow triad—vascular stasis, hypercoagulability, and vascular trauma—describes the three classic antecedents to thrombosis, and many of the physiologic changes of pregnancy contribute to these criteria.** Other pregnancy-specific risk factors for thrombosis include increased parity, postpartum endomyometritis, operative vaginal delivery, and cesarean delivery. The latter is associated with a substantial ninefold increase in VTE risk compared with vaginal delivery.<sup>14</sup> Risk factors not unique to pregnancy include age greater than 35 years, obesity, trauma, immobility, infection, smoking, nephrotic syndrome, hyperviscosity syndromes, cancer, surgery (particularly orthopedic procedures), and a history of DVT or PE ([Table 45-2](#)). **Admission to the hospital in pregnancy may be associated with a seventeenfold increased risk for VTE compared with a nonhospitalized cohort, with this risk remaining high (sixfold) for the 28 days after admission.**<sup>52</sup> In vitro fertilization (IVF) has been shown to increase the risk for VTE in the first trimester in a cross-sectional study in Sweden, although the overall absolute risk is still rather low.<sup>53</sup>

## Complications

Thromboembolism is associated with serious complications that include arrhythmia, hypoxia, pulmonary hypertension, heart failure, and postthrombotic syndrome of the extremities. Thromboembolism is a major cause of death worldwide; thus prompt diagnosis and treatment is a priority. When confronted with the signs and symptoms suggestive of VTE, rapid initiation of the workup and treatment is essential to avoid complications. Complications of anticoagulation, such as bleeding or thrombocytopenia, are also a reality and should be avoided.

## Considerations in Management of Pregnant Women

Pregnancy and the postpartum period are considered a high-risk period for thromboembolism. Key considerations in the workup and management of pregnant women are the selection of appropriate diagnostic tools and anticoagulation regimens with special concern regarding pregnancy-related changes and fetal exposures.

## Diagnosis of Venous Thromboembolism

### DEEP VENOUS THROMBOSIS

#### CLINICAL SIGNS AND SYMPTOMS

The clinical findings typical of DVT include erythema, warmth, pain, edema, and tenderness localized to the area of the thrombosis. Occasionally, a palpable cord may correspond to a thrombosed vein. Homans sign is the pain and tenderness elicited on compression of the calf muscles by squeezing the muscles or by dorsiflexion of the foot. These are rather nonspecific signs and symptoms that involve a broad differential diagnosis that includes cellulitis, ruptured or strained muscle or tendon, trauma, ruptured popliteal (Baker) cyst, cutaneous vasculitis,

superficial thrombophlebitis, and lymphedema. In fact, as noted above, evidence suggests that the specificities of these manifestations are less than 50%, and among patients with these signs and symptoms, the diagnosis of DVT is confirmed by objective testing in only approximately one third of the group.<sup>1,2</sup>

#### RISK-SCORING SYSTEM

Work by Chan and colleagues<sup>54</sup> demonstrated that subjective assessment by “thrombosis experts” of clinical risk of DVT in symptomatic pregnant patients can categorize patients prior to diagnostic testing into two groups, one *low risk* (1.5% prevalence, 98.5% negative predictive value) and the other *non-low risk* (25% prevalence). **Three factors—symptoms in the left leg, a leg circumference discrepancy of 2 cm or more, or first-trimester presentation—were highly predictive of DVT.** Furthermore, this study and one additional validation study demonstrated that patients who lack all three criteria were at no risk for VTE.<sup>55</sup> Thus determination of prediagnostic study risk can be helpful before proceeding to the selection and interpretation of diagnostic tests.

#### IMAGING

Contrast venography, an invasive technique that involves the injection of dye into a vein distal to the site of suspected thrombosis, followed by radiographic imaging is now rarely used for diagnosis of DVT. The risks of radiation and contrast allergy, as well as its technical difficulty, particularly preclude its use in pregnancy.<sup>56</sup>

**The most common diagnostic modality used in the evaluation of patients with suspected DVT is venous ultrasonography (VUS) with or without color Doppler.** This modality has virtually replaced the cumbersome and less accurate impedance

TABLE 45-2    RISK FACTORS FOR  
VENOUS THROMBOEMBOLISM

| GENERAL   | PREGNANCY RELATED          |
|---|----------------------------|
| Age >35 years   | Increased parity           |
| Obesity   | Postpartum endomyometritis |
| Trauma  | Operative vaginal delivery |
| Immobility  | Cesarean delivery          |
| Infection   |                            |
| Smoking   |                            |
| Nephrotic syndrome                                      |                            |
| Hyperviscosity syndromes                                |                            |
| Cancer  |                            |
| Surgery, especially orthopedic                          |                            |
| Prior deep venous thromboembolism or pulmonary embolism |                            |
| Hospital admission                                      |                            |

plethysmography technique. The ultrasound transducer is placed over the common femoral vein beginning at the inguinal ligament and is then sequentially moved to image the greater saphenous vein, the superficial femoral vein, and the popliteal vein to its trifurcation with the deep veins of the calf. Compression VUS involves the application of pressure with the probe to determine whether the vein under investigation is compressible. **The most accurate ultrasonic criterion for diagnosing venous thrombosis is noncompressibility of the venous lumen in a transverse plane under gentle probe pressure using duplex and color flow Doppler imaging.**<sup>1</sup> The overall sensitivity and specificity of VUS has been reported at 90% to 100% for proximal vein thromboses, but traditionally it has been considered lower for the detection of calf vein thromboses.<sup>57</sup> This is confirmed by a more recent meta-analysis, which demonstrated that in nonpregnant patients, duplex ultrasound has a pooled sensitivity of 96.4% for proximal (knee or thigh) DVT and 75.2% for distal (calf) DVT, and total specificity is 94.3%.<sup>58</sup>

Magnetic resonance imaging (MRI) appears to have equivalent test performance characteristics to VUS. One meta-analysis demonstrated a sensitivity of 91.5% and specificity of 94.8% for diagnosis of DVT in nonpregnant patients with suspected DVT or PE.<sup>59</sup> Similar to VUS, sensitivity is also improved for distal, compared with proximal, thrombi (93.9% vs. 62.1%). The advantage of MRI may be in the ability to detect more centralized DVT, like those in the pelvic, iliac, or femoral veins.

D-DIMER ASSAYS

Laboratory evaluation of serum concentrations of D-dimer, a product of the degradation of fibrin by plasmin, has been increasingly advocated as a helpful test in the diagnosis of DVT in the nonpregnant population. Testing relies on the use of monoclonal antibodies to D-dimer fragments. The most accurate and reliable tests for D-dimer appears to be two rapid enzyme-linked immunosorbent assays (ELISAs; Instant-IA D-dimer [Stago] and Vidas DD [bioMérieux]) and a rapid whole blood assay (SimpliRED D-dimer [Agen Biomedical]). The test is limited by factors that may contribute to false-positive testing, including pregnancy, postpartum and postoperative periods, and superficial thrombophlebitis.<sup>60,61</sup> In particular, **normal pregnancy causes a physiologic increase in D-dimer, with levels that exceed the threshold for normal in 78% and 100% of patients in the second and third trimesters, respectively.**<sup>62</sup> The performance of the SimpliRED D-dimer test was evaluated by Chan and colleagues<sup>54</sup> in a prospective cohort of pregnant patients at risk for

DVT. In this population, who had a DVT prevalence of 8.7%, sensitivity of D-dimer testing was 100% and specificity was 60%. Utility in particular appeared to be stratified across gestation; false-positive rates were 0%, 24%, and 51% for the first, second, and third trimesters, respectively. The value of D-dimer testing in pregnancy may lie in its ability to rule out disease because this same study showed a negative predictive value of 100% with a 95% confidence interval of 95% to 100%. The value of D-dimer testing in the late second and third trimesters is likely to be lower than in the first half of pregnancy because patients in the late second and third trimester will likely have levels above the threshold. Thus at this time, although D-dimer appears useful as a test to rule out a DVT, its routine use in pregnancy cannot be endorsed.

WORKUP OF PATIENTS WITH SUSPECTED DEEP  
VENOUS THROMBOSIS

The diagnostic paradigm outlined in Figure 45-2 can be used to diagnose DVT in pregnant patients with maximal sensitivity and specificity. Risk may be stratified as in the section above (see “Risk-Scoring System”).

PULMONARY EMBOLUS

CLINICAL SIGNS AND SYMPTOMS

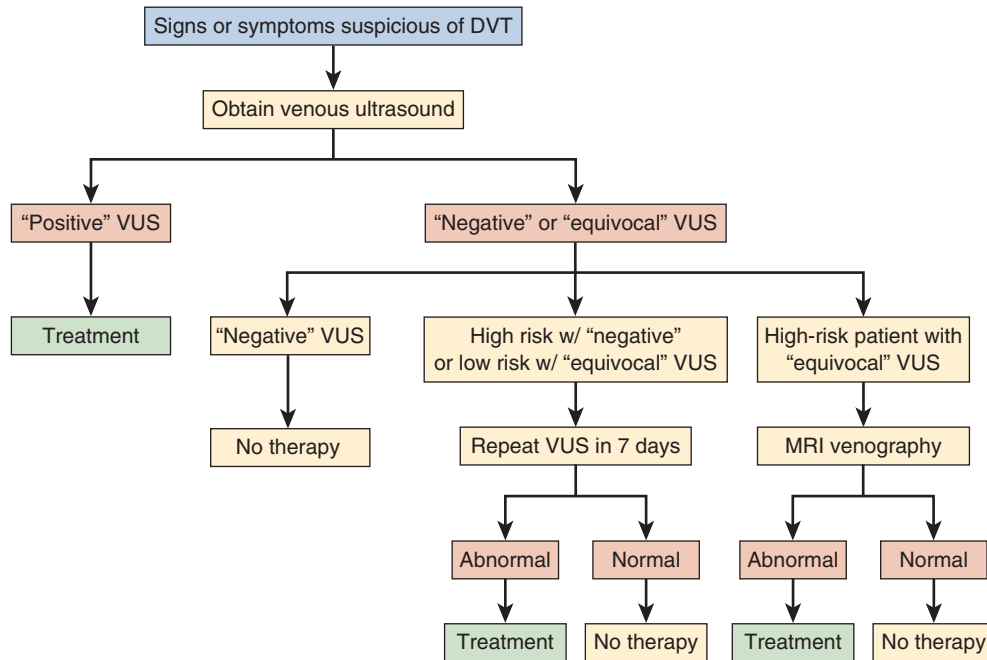

Tachypnea (>20 breaths/min) and tachycardia (>100 beats/min) are present in 90% of patients with acute PE, but these findings lack specificity and generate a broad differential diagnosis.<sup>3</sup> Presyncope and syncope are rarer symptoms and indicate a massive embolus.<sup>4</sup>

NONSPECIFIC STUDIES

The classic electrocardiography (ECG) changes associated with PE are the S1, Q3, and inverted T3. Other findings include nonspecific ST changes, right bundle branch block, or right axis deviation. These findings are usually associated with cor pulmonale and right-sided heart strain or overload, reflective of more serious cardiopulmonary compromise. About 26% to 32% of patients with massive PE had the above-mentioned ECG changes.<sup>63</sup> These findings are why the Royal College of Obstetricians and Gynaecologists (RCOG)<sup>64</sup> have recommended that an ECG be performed in women who present with signs and symptoms of an acute PE. **Arterial blood gases and oxygen saturation have limited value in the assessment of acute PE, particularly in a pregnant population.** Measurements of PO<sub>2</sub> are greater than 80 mm Hg in 29% of PE patients younger than 40 years of age.<sup>65</sup> In another study, up to 18% of patients with PE had PO<sub>2</sub> measurements of more than 85 mm Hg.

**The chest radiograph may be abnormal in up to 84% of affected patients.**<sup>3</sup> The common findings on radiography are pleural effusion, pulmonary infiltrates, atelectasis, and elevated hemidiaphragm. The eponymous findings of pulmonary infarction such as a wedge-shaped infiltrate (Hampton hump) or decreased vascularity (Westermarck sign) are rare.<sup>66</sup> Although a normal chest radiograph in the setting of dyspnea, tachypnea, and hypoxemia in a patient without known preexistent pulmonary or cardiovascular disease is suggestive of PE, a chest radiograph cannot be used to confirm the diagnosis.<sup>66</sup> It is useful, however, in the workup for PE as a tool for selecting the correct diagnostic modality (ventilation-perfusion [V/Q] scan vs. computed tomography [CT] scan; see below).

A large PE can create changes consistent with cor pulmonale and right-sided heart strain. Large emboli in the main

**FIG 45-2** Diagnostic algorithm for suspected deep venous thrombosis. MRI, magnetic resonance imaging; VUS, venous ultrasonography.

pulmonary artery and its primary branches can result in acute right-sided heart failure, which is the ultimate cause of death in most patients with PE. Between 30% and 80% of patients with PE display echocardiographic abnormalities in right ventricular size or function.<sup>67-69</sup> Typical findings include a dilated and hypokinetic right ventricle, tricuspid regurgitation, and absence of preexisting pulmonary arterial or left-sided heart pathology. Transesophageal echocardiography with or without contrast appears to improve the imaging of main or right pulmonary artery emboli and, occasionally, of left pulmonary artery clots.<sup>70</sup> For these reasons, **bedside echocardiography can be very useful for the unstable patient or the patient unable to travel for other imaging studies.**

**Ventilation-Perfusion Scanning.** Perfusion scanning uses intravenously injected radioisotope-labeled albumin macroaggregates that deposit in the pulmonary capillary bed. Ventilation scanning involves the inhalation of radiolabeled aerosols, whose distribution is evaluated by gamma camera. The comparison of these two images allows for interpretation of characteristic patterns that are then used to assign diagnostic probabilities (high, intermediate, or low). More than 90% of high-risk patients with high probability ventilation-perfusion (V/Q) scans have a PE, whereas less than 6% of low-risk patients with low-probability scans have a PE. **Given that most young, healthy women have little underlying lung pulmonary pathology, the diagnostic efficacy of V/Q scanning in pregnancy is substantially higher than that in older, nonpregnant patients.**

**Spiral Computed Tomographic Pulmonary Angiography.** Spiral CT scanning (computed tomographic pulmonary angiography [CTPA]) requires injection of intravenous (IV) contrast while simultaneously imaging the distribution of contrast in the pulmonary vasculature with a CT scanner.<sup>66</sup> Although this can be an effective judge of large, segmental, and central emboli, CT is of limited value with small subsegmental vessels and horizontally oriented vessels in the right middle lobe. One strength of CTPA is its utility in diagnosing nonembolic pulmonary phenomena such as pneumonia or pulmonary edema.

In nonpregnant patients, CTPA is often the modality of choice; however, this is not likely the case in pregnancy. Several studies have shown that **CTPA performs less well in pregnant compared with nonpregnant cohorts.** Andreou and associates<sup>71</sup> demonstrated in a small study of 32 patients with suspected PE that contrast enhancement of the pulmonary arteries is reduced in pregnant women compared with nonpregnant women, likely due to the increased cardiac output of pregnancy. Another reason may be the more frequent dilution or interruption of contrast by nonopacified blood from the lower vena cava in pregnancy.<sup>72</sup> Comparing CTPA imaging in 40 pregnant patients with that in 40 nonpregnant patients, U-King-Im and colleagues<sup>73</sup> also demonstrated a threefold higher rate of suboptimal studies in the pregnant population (27.5% vs. 7.5%).

**Ventilation-Perfusion Scanning Versus Computed Tomographic Pulmonary Angiography.** V/Q scanning and CTPA have been directly compared in pregnant patients by Cahill and colleagues,<sup>74</sup> who retrospectively evaluated a cohort of 304 pregnant or postpartum women evaluated for pulmonary embolism. CTPA was performed in 108 women, and a V/Q scan was done in 196. In women with a normal chest radiograph, CTPA yielded nondiagnostic results 5.4 times more often than V/Q scanning (30.0% vs. 5.4%). As would be expected, in those patients with an abnormal chest radiograph, V/Q scanning was more often nondiagnostic. Ridge and colleagues<sup>72</sup> evaluated these two techniques prospectively in a total of 50 patients. Again, they found that CTPA more often gave a nondiagnostic result (35.7% vs. 2.1%), and V/Q scanning was adequate for diagnosis more frequently (35.7% vs. 4%). For these reasons, as well as considerations of radiation exposure (see below), **V/Q scanning is the modality of choice for pregnant patients with suspected PE and a normal chest radiograph.**

**Magnetic Resonance Angiography.** Magnetic resonance angiography (MRA) may be performed using MRI during IV injection of gadolinium. Faster image-acquisition rates and improved image timing to respiratory and cardiac motion have allowed this technique to be utilized. Preliminary experience by Meaney

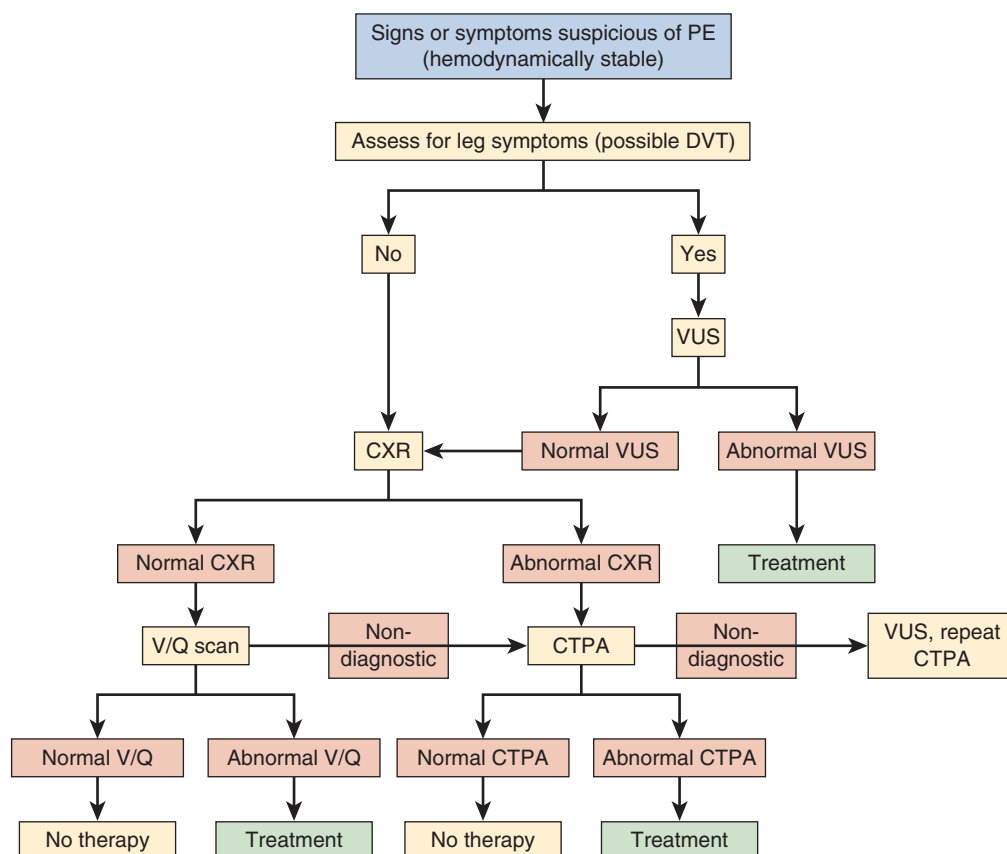

and colleagues<sup>75</sup> suggested a sensitivity of 100%, specificity of 95%, and positive and negative predictive values of 87% and 100%, respectively, for MRA in 30 patients also assessed by classic pulmonary angiography. Another prospective study that involved 141 patients showed an overall sensitivity of only 77% in comparison to pulmonary angiography, with the sensitivity broken down to 40%, 84%, and 100% for isolated subsegmental, segmental, and central pulmonary emboli, respectively.<sup>76</sup> Because MRA does not involve ionizing radiation, it is an appealing alternative to CT scanning and angiography for pregnancy, and further assessment in large trials are needed to prove its ultimate utility as a primary diagnostic modality. Gadolinium contrast crosses the placenta and enters the amniotic fluid through excretion by the fetal kidneys. A majority of animal studies suggest no teratogenic effects by gadolinium, and it is considered a category C agent by the U.S. Food and Drug Administration (FDA), although it should be used with caution.

**D-Dimer Assays.** The D-dimer assay appears to have much lower sensitivity in patients with PE and thus it is not helpful as a test for ruling out disease. Negative D-dimer testing has been observed in patients with confirmed PE.<sup>77</sup> Damodaram and associates<sup>78</sup> report a sensitivity and specificity of 73% and 15% for D-dimer in testing for suspected PE in pregnancy. The difference in D-dimer test performance for PE in pregnancy may be due to the smaller clot burden compared with DVT coupled with the increase in intravascular plasma volume of pregnancy. This unacceptably high false-negative rate indicated **no role for D-dimer testing in the workup of pregnant patients with suspected PE.**

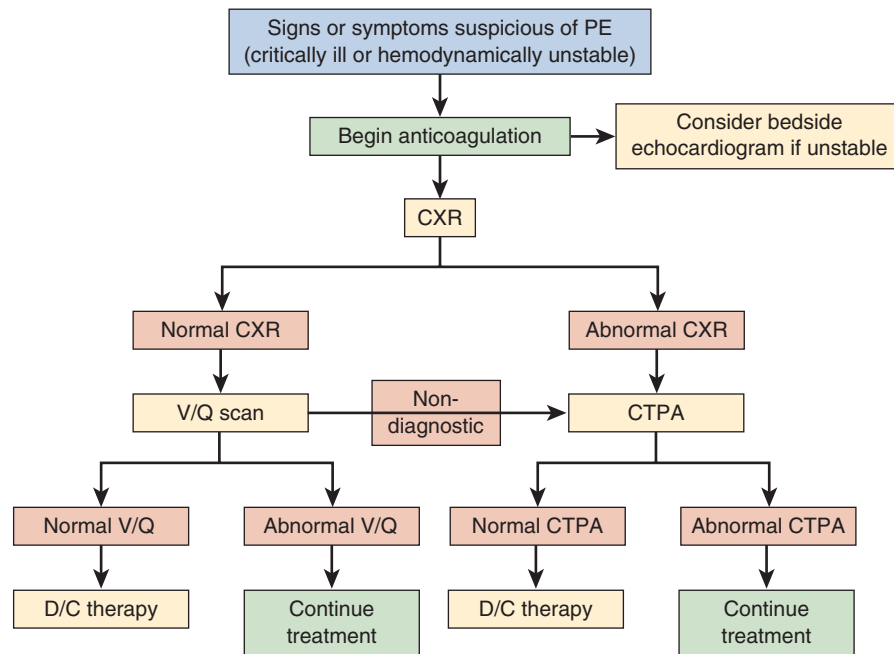

**Lower Extremity Evaluation.** Most PEs (90%) arise from lower extremity DVTs, and among patients with the diagnosis of PE, half will be found to harbor a lower extremity DVT; this includes up to 20% of PE patients without signs or symptoms of lower extremity DVT.<sup>79-81</sup> In patients who present with signs or symptoms of PE who also have left-sided lower extremity symptoms, it is reasonable to begin with lower extremity VUS to detect DVT because the need for therapeutic anticoagulation is similar. This avoids exposure to the ionizing radiation, as well as the burden of more complicated testing, associated with CTPA and V/Q scanning. Furthermore, in high-risk patients in whom CTPA or V/Q scanning is nondiagnostic or even negative, evaluation of the leg veins for DVT can be helpful to reinforce results. In such cases, however, a negative VUS study is still associated with a 25% risk of PE, which suggests further studies are generally needed.<sup>82</sup>

#### WORKUP OF PATIENTS WITH SUSPECTED PULMONARY EMBOLUS

Workup of patients with suspected PE should begin with evaluation of their cardiorespiratory status to determine whether they are critically ill; this would include an ECG and chest radiograph. Patients who are stable hemodynamically with favorable oxygenation status (oxygen saturation >80%) should be evaluated in a carefully ordered fashion, taking into account the possibility of lower extremity DVT and the results of the chest radiograph (Fig. 45-3), according to an algorithm advocated by a panel of experts from the American Thoracic Society, the Society of Thoracic Radiology, and ACOG.<sup>83</sup> If lower extremity

**FIG 45-3** Diagnostic algorithm for suspected pulmonary embolus (PE) in a hemodynamically stable patient. CTPA, computed tomographic pulmonary angiography; CXR, chest radiograph; DVT, deep venous thrombosis; V/Q, ventilation-perfusion; VUS, venous ultrasound.

**FIG 45-4** Diagnostic algorithm for suspected pulmonary embolism (PE) in a critically ill or hemodynamically unstable patient. CTPA, computed tomographic pulmonary angiography; CXR, chest radiograph; D/C, discontinue; V/Q, ventilation-perfusion.

symptoms are present, particularly if left sided, VUS can be performed; if results are positive, therapeutic anticoagulation should begin. **Chest radiography should definitely be performed when VUS is negative or when no lower extremity signs or symptoms are apparent. Although the chest radiograph is not typically used in the actual diagnosis, it allows for proper selection of the next diagnostic test.** V/Q scan is performed if the chest radiograph is normal. A positive (high or moderate probability) V/Q scan should prompt therapeutic anticoagulation. A negative test should exclude the diagnosis. A nondiagnostic result—such as intermediate probability/equivocal test in any patient and a low-probability result in a high-risk patient (one with prior VTE, known thrombophilia, family history of thrombosis in a first-degree relative under 50 years of age, or other clinical risk factors)—should trigger performance of CTPA.

For such patients, and for those with an abnormal chest radiograph, CTPA is the diagnostic modality of choice. Positive tests will prompt initiation of anticoagulation. In the patient with an abnormal chest radiograph who has a negative CTPA, the true etiology of the chest pathology is often seen on CT. Alternatively, if the CTPA is nondiagnostic, further testing is performed, such as MRA or serial lower extremity VUS studies.

**In the critically ill patient, anticoagulation should be started—in the absence of contraindications—and a similar protocol is followed (Fig. 45-4).** Very unstable patients who cannot be transported safely can be evaluated with a bedside echocardiogram, which may have more test accuracy in this setting.

### Radiation Exposure from Diagnostic Procedures FETAL EXPOSURE

The diagnosis of DVT and PE in pregnant patients poses unique challenges because of concerns in regard to fetal radiation exposure. ACOG advises that exposure to less than 5 rads has not been associated with increases in pregnancy loss or fetal

**TABLE 45-3** FETAL RADIATION EXPOSURE OF VARIOUS IONIZING MODALITIES

| RADIOLOGIC MODALITY           | FETAL RADIATION EXPOSURE (RADS) |
|-------------------------------|---------------------------------|
| Chest radiograph              | <0.01                           |
| Venography                    |                                 |
| Limited, shielded             | <0.05                           |
| Full (unilateral), unshielded | 0.31                            |
| Pulmonary angiography         |                                 |

Modified from Togliani M, Weg J. Venous thromboembolism during pregnancy. *N Engl J Med*. 1996;335(2):108-114.

anomalies.<sup>84</sup> Exposure to ionizing radiation doses above 1 rad, however, may create a marginally increased risk of childhood leukemia (from 1/3000 baseline to 1/2000).<sup>85,86</sup> Table 45-3 outlines the *fetal* radiation exposure of different radiation modalities. **A combination of chest x-ray, V/Q scan, and pulmonary angiography exposes the fetus to less than 0.5 rads.**<sup>10</sup> CTPA is associated with only slightly lower radiation levels for the fetus compared with V/Q scanning. Although the concern for possible adverse effects should not prevent a medically important test from being performed, judicious use and selection of tests is advised.

### MATERNAL EXPOSURE

Radiation exposure to the maternal breast is also an important consideration when choosing tests because the increased glandularity and proliferative state of the pregnant breast presumably make it more radiosensitive. This is an important concern with respect to cumulative radiation exposure and

cancer risk.<sup>87</sup> V/Q scanning results in substantially lower maternal breast radiation exposure. CTPA is estimated to expose maternal breast tissue to 150 times more ionizing radiation than V/Q scanning<sup>88</sup> with doses estimated at 2 to 6 rads.<sup>89,90</sup> This dose can be reduced approximately 50% to 60% with breast shielding, without significant reduction in image quality.<sup>91</sup>

MRI and ultrasonography have not been associated with any adverse fetal effects, and teratogenic effects have not been described after administration of gadolinium contrast media.<sup>92</sup> Concerns about fetal goiter following maternal radiographic contrast exposure suggest that fetal heart rate monitoring may be used to detect the reduced variability that can be seen with fetal hypothyroidism, and neonatal thyroid function should be tested during the first week of life.<sup>92</sup>

## Management of Venous Thromboembolism PREVENTION

### PERIOPERATIVE PREVENTION

Evidence is very limited regarding the value of perioperative thromboprophylaxis with cesarean delivery.<sup>93,94</sup> **Perioperative administration of low-dose unfractionated heparin may be appropriate in patients undergoing cesarean delivery with clear risk factors such as obesity, malignancy, immobility, or a high-risk chronic medical disease.** As noted, patients with low-risk thrombogenic thrombophilias require postoperative prophylaxis. Nonpharmacologic interventions aimed at preventing VTE include graduated elastic compression stockings and pneumatic compression devices. In pregnancy, a cohort study suggested that the use of graduated compression stockings reduced the prevalence of postpartum VTE from 4.3% to 0.9%.<sup>95</sup> **Because these stockings and pneumatic compression devices pose no hemorrhagic risk and do little harm, they should be strongly considered for thromboprophylaxis in all patients with risk factors, such as those patients who are hospitalized or immobilized, including pregnant or postoperative cesarean patients.** The left lateral decubitus position in the third trimester may also reduce the risk of VTE.

### PRECONCEPTION COUNSELING

Preconception counseling is particularly important for patients at high-risk for recurrent VTE in pregnancy and for patients with a recent VTE. Patients on long-term anticoagulation before pregnancy, for example, should be advised of the risks of pregnancy. In particular, patients on warfarin can be counseled that they would be advised to switch from warfarin to a heparin-based regimen upon finding out about pregnancy. In particular, it would be helpful for the woman to know that the risks of warfarin embryopathy are highest between the sixth and twelfth weeks of pregnancy, so vigilance on tracking the last menstrual period is important.

## THERAPY

### UNFRACTIONATED HEPARIN

Unfractionated heparin (UFH) affects anticoagulation by enhancing antithrombin activity, increasing factor Xa inhibitor activity, and inhibiting platelet aggregation.<sup>96</sup> UFH, an FDA category C agent, does not cross the placenta and is not teratogenic.<sup>97</sup> The chief side effects of heparin include hemorrhage, osteoporosis, and thrombocytopenia. The former is more common with treatment coinciding with surgery or liver disease or with concomitant aspirin use. Heparin-associated bone loss is usually reversible and correlates more with therapy that exceeds

15,000 U/day for more than 6 months and can be opposed by supplemental calcium use (1500 mg/day).<sup>98,99</sup> **Heparin-induced thrombocytopenia (HIT) occurs in 3% of patients,** and type 1HIT is the most common form; it occurs within days of exposure, is self-limited, and is not associated with a significant risk of hemorrhage or thrombosis. Immunoglobulin-mediated type 2 HIT, on the other hand, is rare and usually occurs 5 to 14 days following initiation of therapy; paradoxically, it increases the risk of thrombosis. Monitoring for HIT should include serial platelet counts every 2 to 3 days from day 4 until day 14 or until heparin is stopped, whichever occurs first.<sup>100</sup> A 50% decline in platelet count from its pretreatment maximum suggests immune-mediated HIT type 2 and should prompt cessation of all heparin exposure, including that in IV flushes. The diagnosis of HIT type 2 can be confirmed by serotonin release assays, heparin-induced platelet aggregation assays, flow cytometry, or solid-phase immunoassays.<sup>101</sup>

**Protamine sulfate reverses the effect of intravenously administered UFH.** It is given by slow IV infusion of less than 20 mg/min, with no more than 50 mg given over 10 minutes. The total dose of protamine required is calculated based on the residual amount of circulating heparin, with a ratio of 1 mg of protamine sulfate necessary for every 100 U of residual circulating heparin. Residual heparin is calculated by assuming a half-life of 30 to 60 minutes of IV heparin. However, repeated serial administrations of lower doses of protamine, coinciding with serial measurements of the activated partial thromboplastin time (aPTT), are required when the heparin is dosed subcutaneously.

### LOW-MOLECULAR-WEIGHT HEPARIN

The low-molecular-weight heparins (LMWHs)—dalteparin, enoxaparin, and tinzaparin—are reliable and safe alternatives to UFH and have fewer side effects. Enzymatic manipulation of standard heparin produces lower molecular weight molecules with equivalent anti-factor Xa but little or no antithrombin effects. The LMWHs have longer half-lives, and a closer correlation exists between anti-factor Xa activity and body weight than subcutaneously administered UFH. We suggest following anti-factor Xa levels in pregnant patients, although this is not universal practice, because the variability in binding, distribution, metabolism, and excretion is far greater. However, this approach may be justified in pregnancy because of an increased rate of subprophylactic levels in pregnancy in patients on standard 40-mg once-daily enoxaparin dosing, which may be due to enhanced renal clearance.<sup>102,103</sup> The LMWHs (pregnancy category B) do not cross the placenta and do not enter breast milk, and the risk of hemorrhage associated with LMWH is lower. **However, regional anesthesia is contraindicated within 18 to 24 hours of therapeutic LMWH administration.** Accordingly, we recommend switching to UFH at 36 weeks or earlier if preterm delivery is expected. Protamine is not as effective in fully reversing the anti-factor Xa activity of LMWH, although it may reduce bleeding. Dosing of 1 mg of protamine for every 100 antifactor Xa units of LMWH can normalize aPTT values, but antifactor Xa levels can only be reversed by 80%.<sup>104,105</sup> Whereas the risk of HIT type 2 is lower in patients who receive LMWH, platelet counts should still be checked every 2 to 3 days from day 4 to day 14.<sup>100,106,107</sup>

### FONDAPARINUX

Fondaparinux is a synthetic heparin pentasaccharide that complexes with the antithrombin binding site for heparin to permit

the selective inactivation of factor Xa but not thrombin. A major advantage of this medication is that there does not appear to be a risk of HIT type 2. It has comparable efficacy to both LMWH and UFH in nonpregnant patients.<sup>108,109</sup> Although fondaparinux has been used in a small number of pregnant patients without complication,<sup>110-113</sup> umbilical cord plasma concentrations at 10% of those of maternal plasma have been demonstrated, which suggests limited transplacental passage.<sup>114</sup> Use of fondaparinux should be limited to women without other therapeutic alternatives, such as those with a history of HIT type 2 or heparin allergies and those who have failed other anticoagulants.

### COUMARIN

The coumarins are vitamin K antagonists that block the vitamin K–dependent, function-enhancing posttranslational modifications of prothrombin and factors VII, IX, and X as well as the anticlotting agents protein C and S. Coumadin (warfarin) has been shown to be effective for both the primary and secondary prevention of VTE, stroke, myocardial infarction, and systemic embolism due to artificial valves and atrial fibrillation.<sup>115</sup> **Warfarin is a pregnancy category X medication because fetal exposure can cause nasal and midface hypoplasia, microphthalmia, mental retardation, and other ocular, skeletal, and central nervous system malformations** (see Chapter 8). Teratogenic potential is greatest between the 6th and 12th weeks of pregnancy, and the risk of warfarin also includes fetal hemorrhage. As a result, warfarin is rarely used during gestation, although the exceptional case of a patient requiring therapeutic anticoagulation who cannot be sufficiently treated with the heparins may require its use (e.g., certain patients with artificial heart valves). Warfarin is also favored in the postpartum period because it is safe to use during lactation.

Therapy is started at a dose of 5 to 10 mg for 2 days, with subsequent doses titrated to achieve an international normalized ratio (INR) of 2.0 to 3.0. Peak effects occur within 72 hours, and its half-life is from 36 to 42 hours.<sup>115</sup> **Warfarin metabolism is greatly affected by genetic polymorphisms, making the response to particular dosing regimens unpredictable.** A pharmacogenetic approach to warfarin dosing includes testing for particular variations in vitamin K and warfarin metabolic enzymes and using this information to formulate a dosing regimen that expeditiously achieves a proper maintenance dose.<sup>116</sup> A criticism of this approach is that pharmacogenetics only account for 30% to 50% of the variability in response because environment, diet, and comorbidities often have a significant influence as well. A nomogram for predicting warfarin dosing, based on patient-specific responses to warfarin doses as assessed by day 3 and day 5 INRs, has been proposed by Lazo-Langner and associates.<sup>117</sup> Avoiding the need for costly genetic testing, this protocol accounts for individual variation of warfarin metabolism.

Because of protein C's shorter half-life relative to the other vitamin K–dependent clotting factors, warfarin may initially create a prothrombotic state, particularly in pregnancy. Thus patients who are started on warfarin postpartum should be on therapeutic doses of UFH or LMWH for 5 days and until the INR is therapeutic for 48 hours. Coumadin effects can be reversed by vitamin K.<sup>118</sup> The INR generally normalizes within 6 hours of a 5 mg dose of vitamin K and within 4 days with cessation of warfarin therapy. Fresh-frozen plasma can be used to achieve immediate reversal of effects. RCOG recommends avoiding warfarin until at least the fifth postpartum day and

**TABLE 45-4** WEIGHT-BASED NOMOGRAM FOR UNFRACTIONATED HEPARIN

Give a bolus of 80 U/kg, followed by a maintenance dosage of 18 U/kg/hr following aPTT values every 6 hr and with the following adjustments for aPTT values obtained:

| aPTT VALUE                    | ADJUSTMENT   |
|-------------------------------|--|
| <35 sec (<1.2× control value) | Repeat full bolus (80 U/kg) then increase infusion rate by 4 U/kg/hr |
| 35–45 sec (1.2–1.5× control)  | Repeat half bolus (40 U/kg) then increase infusion rate by 2 U/kg/hr |
| 46–70 sec (1.6–2.3× control)  | No change in infusion rate   |
| 71–90 sec (2.4–3× control)    | Decrease infusion rate by 2 U/kg/hr                                  |
| >90 sec (>3× control)         | Stop infusion for 1 hour then decrease to 3 U/kg/hr                  |

aPTT, activated partial thromboplastin time.

even longer in patients at increased risk for postpartum hemorrhage.<sup>64</sup>

### TREATMENT OF ACUTE DEEP VEIN THROMBOSIS OR PULMONARY EMBOLUS

Women with new-onset VTE diagnosed during pregnancy should receive therapeutic anticoagulation, and this treatment should be continued for at least 20 weeks. If this period of time expires before the end of the postpartum period, prophylactic anticoagulation should be initiated in patients without highly thrombogenic thrombophilias and should be continued for 6 weeks to 6 months postpartum, depending on the severity of the thrombotic event and the underlying risk factors. During pregnancy, UFH and the LMWHs are the drugs of choice given their efficacy and safety profile. **Therapeutic doses of the LMWH enoxaparin may start at 1 mg/kg subcutaneously twice daily.** Dosing should be titrated to achieve anti-factor Xa levels of 0.6 to 1.0 U/mL when tested 4 hours after injection because of inconsistent efficacy of this weight-based regimen in pregnant patients.<sup>119</sup> UFH for acute DVT or PE is initially given intravenously and is titrated to keep the aPTT at 1.5 to 2.5 times control (checked every 4 to 6 hours during the titration period), usually according to weight-based protocols (Table 45-4).<sup>120</sup> IV heparin should be continued for 5 to 10 days or until clinical improvement is noted. This regimen can be changed to subcutaneous injections every 8 to 12 hours to keep the aPTT at 1.5 to 2.0 times control when tested 6 hours after injection.

**Prophylactic Anticoagulation Recommendations for Low-, Moderate-, and High-Risk Groups.** Risk stratification based on the likelihoods of recurrence, such as in Table 45-1, is the essential foundation of the recommendations for antepartum and postpartum anticoagulation in patients without recent or active VTE. This issue has recently been addressed by ACOG<sup>121</sup> and is summarized in Table 45-5. The first principle is that **the postpartum period represents a time of elevated risk, particularly in patients with risk factors.** For this reason, anticoagulation recommendations in the postpartum period are typically a maintenance of antepartum recommendations or an increase. The second principle is that **the various thrombophilias can be classified into high- and low-risk types, and anticoagulation recommendations for each type will be different depending on whether the patient has a personal history of VTE.** Third, **patients with recurrent VTE who have tested negative**

**TABLE 45-5** ANTICOAGULATION IN PREGNANCY: INDICATIONS, TYPES, AND TIMING

| INDICATION   | DESCRIPTION  | ANTEPARTUM   | POSTPARTUM  |
|--|--|--|---|
| VTE in current pregnancy   |  | Therapeutic LMWH/UFH to complete 20-week course, then therapeutic or prophylactic LMWH/UFH regimen as appropriate based on thrombophilia or risk factors | Therapeutic LMWH/UFH regimen to complete 20-week course, followed by prophylactic LMWH or postpartum warfarin               |
| High-risk thrombophilia  | History of one prior VTE                                 | Therapeutic or prophylactic LMWH/UFH   | Therapeutic or prophylactic LMWH regimen or postpartum warfarin; dosing/level to match antepartum regimen                   |
| <ul style="list-style-type: none"> <li>FVL homozygous</li> <li>Prothrombin G20210A mutation homozygous</li> <li>FVL/prothrombin G20210A mutation double heterozygous</li> <li>Antithrombin III deficiency</li> </ul> | No history of VTE  | Prophylactic LMWH/UFH  | Prophylactic LMWH or postpartum warfarin  |
| Low-risk thrombophilia   | History of one prior VTE                                 | Prophylactic LMWH/UFH or surveillance without anticoagulation  | Prophylactic LMWH/UFH or postpartum warfarin  |
| <ul style="list-style-type: none"> <li>FVL heterozygous</li> <li>Prothrombin G20210A mutation heterozygous</li> <li>Protein C deficiency</li> <li>Protein S deficiency</li> </ul>                                    | No history of VTE  | Surveillance without anticoagulation or prophylactic LMWH/UFH  | Surveillance without anticoagulation or prophylactic LMWH/UFH or postpartum warfarin if patient has additional risk factors |
| No thrombophilia   | History of one prior VTE (pregnancy or estrogen related) | Prophylactic LMWH/UFH or surveillance without anticoagulation  | Prophylactic LMWH or postpartum warfarin  |
|  | History of one prior VTE (idiopathic)                    | Prophylactic LMWH/UFH or surveillance without anticoagulation  | Prophylactic LMWH or postpartum warfarin  |
| Two or more prior VTE episodes (thrombophilia or no thrombophilia)   | On long-term anticoagulation                             | Therapeutic LMWH/UFH   | Resumption of long-term anticoagulation therapy   |
|  | Not on long-term anticoagulation                         | Therapeutic or prophylactic LMWH/UFH   | Therapeutic or prophylactic LMWH/UFH  |

Modified from American College of Obstetricians and Gynecologists. Practice Bulletin no. 123: Thromboembolism in pregnancy. *Obstet Gynecol.* 2011;118(3):718-729. FVL, factor V Leiden; LMWH, low-molecular-weight heparin; UFH, unfractionated heparin; VTE, venous thromboembolism.

for the known inherited thrombophilias likely have an underlying pathology (e.g., an undiagnosed genetic malformation in a step in the coagulation cascade) and should be cared for cautiously.

After this stratification, appropriate dosing is chosen (Table 45-6). Dosing regimens are categorized into prophylactic and therapeutic types. Prophylactic therapy is warranted in all patients with low to moderate risk during pregnancy and the postpartum period. **Typical prophylactic doses of the LMWH enoxaparin may start at 40 mg subcutaneously daily.** Weight-based dosing in pregnant patients may be unreliable, and some investigators, but not all, recommend titrating doses to achieve anti-factor Xa levels of 0.1 to 0.2 U/mL 4 hours after injection. UFH prophylaxis may range from 5000 to 10,000 units subcutaneously every 12 hours, with dosing adjusted by trimester and based on weight. Because of inconsistent efficacy in pregnant patients, and because the aPTT cannot be followed in prophylactic dosing, this dosing may be titrated to achieve heparin levels (by protamine titration assay) of 0.1 to 0.2 U/mL.<sup>122</sup> Therapeutic dosing of LMWH and UFH should be followed with anti-factor Xa levels or aPTT, respectively, as in Table 45-6. Postpartum anticoagulation is typically done with LMWH (prophylactic or therapeutic dosing), warfarin, or a newer agent if the patient is on long-term anticoagulation.

#### INFERIOR VENA CAVA FILTERS

The use of IVC filters is primarily restricted to patients with absolute contraindications to medical anticoagulation or those who have failed therapeutic anticoagulation. Pregnant patients in need of prophylaxis with a history of HIT type 2 or with true heparin or LMWH allergies are potential candidates for IVC filters. However, the introduction of fondaparinux may eliminate this need. The use of IVC filters is discouraged in younger patients, but newer retrievable filters may be appropriate.<sup>123</sup>

**TABLE 45-6** EXAMPLE ANTICOAGULATION REGIMENS

| TYPE                               | DRUG AND DOSING   | SURVEILLANCE  |
|------------------------------------|---|---|
| Prophylactic LMWH                  | Enoxaparin 40 mg SC once daily  | Consider target anti-Xa levels of 0.1-0.2 U/mL 4 hours after injection                  |
| Therapeutic LMWH                   | Enoxaparin 1 mg/kg/12 hr  | Target anti-Xa levels of 0.6-1.0 U/mL tested 4 hours after injection                    |
| Prophylactic UFH                   | First trimester: UFH 5000-7500 units SC/12 hr<br>Second trimester: UFH 7500-10,000 units SC/12 hr<br>Third trimester: UFH 10,000 units SC/12 hr | aPTT should be in the normal range<br>Consider target heparin levels of 0.1-0.2 U/mL    |
| Therapeutic UFH                    | UFH 10,000 U (or more)/12 hr  | Target aPTT in 1.5-2.5× control range tested 6 hours after injection                    |
| Warfarin (postpartum, therapeutic) | Begin 5-10 mg oral daily and titrate to INR target  | Overlap UFH or LMWH therapy until INR is >2.0 for more than 2 days; target INR, 2.0-3.0 |

#### DELIVERY AND ANESTHESIA CONCERNS

As noted earlier, the major concerns of therapeutic anticoagulation in pregnancy are regional anesthesia use and the risk of hemorrhage. Regional anesthesia is contraindicated within 18 to 24 hours of therapeutic LMWH use, thus LMWH should be converted to UFH at 36 weeks or earlier if clinically indicated.

Vaginal or cesarean delivery more than 24 hours after therapeutic LMWH dosing should not pose a risk of hemorrhage, although protamine sulfate may be necessary to partially reverse anticoagulation. Protamine sulfate may also be used to normalize completely an elevated aPTT in patients on therapeutic UFH near the time of delivery. Heparin anticoagulation may be restarted 3 to 6 hours after vaginal delivery and 6 to 8 hours after cesarean delivery. Coumadin anticoagulation may be started on the first postpartum or postoperative day, although it should be recognized that RCOG recommends waiting until at least the fifth day postpartum. As noted earlier, because of the paradoxical increase in APC resistance and factor VIII after starting coumadin, therapeutic doses of the heparins should be continued for 5 days and until the INR reaches therapeutic range (2.0 to 3.0) for 2 successive days.

The risk of hemorrhage or complication from regional anesthesia is minimal when administered more than 12 hours after a prophylactic dose of LMWH. Again, given the difficulty of timing administration with the onset of labor, we recommend converting from LMWH to UFH at 36 weeks or earlier as clinically indicated. As with therapeutic use, anticoagulation may be restarted 3 to 6 hours after vaginal delivery and 6 to 8 hours after cesarean delivery.

#### POSTPARTUM BREASTFEEDING

UFH does not cross into breast milk and is therefore considered safe during breastfeeding. Warfarin is also considered safe for breastfeeding because it does not accumulate in breast milk and has no effect on the coagulation of breastfeeding neonates. Long-term use of UFH is associated with bone loss, typically in doses higher than 15,000 U/day and for use longer than 6 months. Bone density typically recovers over time after discontinuing heparin.

#### KEY POINTS

- ◆ Pregnancy, childbirth, and the puerperium pose serious hemorrhagic challenges that are met by increased decidua and systemic clotting potential.
- ◆ VTE is a leading cause of mortality and serious morbidity in pregnant women, with a prevalence of 1 per 1000 to 1 per 2000 pregnancies; the greatest risk of fatal PE occurs following caesarean deliveries.
- ◆ Inherited and acquired thrombophilias account for most VTEs in pregnancy.
- ◆ VUS is the most common diagnostic modality used in the evaluation of patients with suspected DVT, with an overall sensitivity and specificity of 90% to 100% for proximal vein thromboses.
- ◆ In stable patients with suspected PE and leg signs or symptoms, VUS should be performed because it may avoid the risks of radiation exposure and may detect a DVT, the cause of the PE.
- ◆ Stable patients with suspected PE should have a chest radiograph to determine the diagnostic test to be used. A nondiagnostic chest radiograph should therefore prompt performance of a V/Q scan. A patient with abnormal chest radiography should be evaluated with spiral CTPA.
- ◆ Heparin remains the mainstay of therapy for VTE, with its most serious but rare complication being

immunoglobulin-mediated HIT type 2, which usually occurs 5 to 14 days following initiation of therapy and paradoxically increases the risk of thrombosis.

- ◆ Thromboprophylaxis is warranted in high- and moderate-risk groups based on a history of VTE and the presence of thrombophilia and should be selected according to overall risk for recurrence.
- ◆ Protamine sulfate can entirely reverse the anticoagulant effect of UFH and can partially (80%) reverse the effect of LMWH.
- ◆ Graduated elastic compression stockings and pneumatic compression devices appear to reduce the likelihood of VTE in pregnancy and, at a minimum, should be used in all high-risk patients and should be strongly considered for all patients undergoing cesarean delivery. (We follow this recommendation in our own practice).

## SYSTEMIC LUPUS ERYTHEMATOSUS

### Epidemiology and Etiology

Systemic lupus erythematosus (SLE) is a chronic inflammatory and autoimmune disorder that can affect multiple organ systems, including the skin, joints, kidneys, central nervous system, heart, lungs, and liver.

SLE is more prevalent among women than men, and most women who are affected by the disease manifest it at some

point during their reproductive years. Not infrequently, an initial diagnosis is made during the course of an evaluation for pregnancy complications or during pregnancy or the postpartum period. **Significant racial differences are apparent in disease prevalence: black women have a prevalence of 405 per 100,000 compared with a prevalence of 164 per 100,000 among white women.**<sup>1</sup>

Genetic predisposition appears to be an important contributing factor to the development of SLE in that 5% to 12%

of relatives of SLE patients also have the disease. The concordance for SLE is high (~25%) among monozygotic twins. Rare genetic factors such as deficiencies in complement components and mutations in the *TREX1* gene, which encodes a DNA-degrading enzyme—as well as more common single nucleotide polymorphisms (SNPs) in the major histocompatibility complex (MHC)—are associated with the development of SLE.<sup>2</sup> Although an individual may be genetically predisposed to develop SLE, the cause appears to be multifactorial. Studies have identified various exposures—such as to the Epstein-Barr virus, ultraviolet (UV) light, and silica dust—as having associations with SLE.<sup>3</sup> Emerging research suggests that such exposures may mediate the development of SLE through epigenetic changes that cause sustained alterations in gene expression.<sup>3</sup>

Consistent with the higher prevalence of SLE among women, **hormonal factors appear to play an important role. Early menarche, oral contraceptives, and postmenopausal hormone replacement have all been associated with an increased risk for SLE.**<sup>4</sup>

Clinical Manifestations

The clinical course of SLE is characterized by periods of disease “flares” interspersed with periods of remission. The most common presenting symptoms of SLE include arthralgias, fatigue, malaise, weight change, Raynaud phenomenon, fever, photosensitive rash, and alopecia. Constitutional symptoms will be present in nearly all women at some point in their disease course. **More than 90% of individuals with SLE will experience arthralgias,** which are typically migratory and most commonly involve the proximal interphalangeal and metacarpophalangeal joints, wrists, and knees. The arthralgias of SLE typically improve as the day progresses. **Most patients also have skin manifestations at some point in the course of the disease, and the classic presentation is a malar “butterfly” rash that worsens with sun exposure.** For women who present in the postpartum period, some SLE symptoms—such as fatigue and hair loss—may be easily overlooked. More severe but less common manifestations include discoid lupus (inflammatory skin lesions that result in scarring), lupus nephritis (LN), pleurisy, pericarditis, and seizures or psychosis.

Diagnosis

The American College of Rheumatology (ACR) has devised a set of diagnostic criteria for SLE. These criteria were most recently revised in 1997 (Table 46-1) and are highly sensitive and specific for SLE. To be diagnosed with SLE, **a patient must have at least four of the 11 clinical and laboratory criteria, either serially or simultaneously.** It should be emphasized, however, that some women with features of SLE might not meet the strict diagnostic criteria but can still be at risk for pregnancy complications. These women may benefit from increased surveillance and even treatment.

Because nearly all individuals with SLE will have a positive antinuclear antibody (ANA) titer, this is a reasonable initial screening test for women with suggestive symptoms. **If the ANA test is negative, a diagnosis of SLE is highly unlikely.** However, an elevated ANA titer is not specific for SLE because it can also be seen in other autoimmune conditions such as Sjögren syndrome, scleroderma, and rheumatoid arthritis (RA). **Anti-double-stranded DNA (anti-dsDNA) and anti-Smith (anti-Sm) antibodies are more highly specific for SLE, albeit less sensitive.** Anti-dsDNA titers are frequently elevated in

TABLE 46-1      REVISED AMERICAN COLLEGE OF RHEUMATOLOGY CRITERIA FOR CLASSIFICATION OF SYSTEMIC LUPUS ERYTHEMATOSUS (1982 AND 1997)

|                      |   |
|----------------------|---|
| Malar rash           | Fixed erythema, flat or raised, over the malar eminences that tends to spare the nasolabial folds   |
| Discoid rash         | Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions   |
| Oral ulcers          | Oral or nasopharyngeal ulceration, usually painless   |
| Arthritis            | Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion  |
| Serositis            | Pleuritis (convincing history of pleuritic pain, rubbing heard by a physician, or evidence of pleural effusion) Pericarditis documented by ECG or rub or evidence of effusion   |
| Renal                | Persistent proteinuria greater than 0.5 g/day or greater than 3+ if quantitation is not performed Cellular casts: Red cell, hemoglobin, granular, tubular, or mixed   |
| Neurologic           | Seizures in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance) Psychosis in the absence of drugs or metabolic derangements   |
| Hematologic          | Hemolytic anemia with reticulocytosis Leukopenia <4000/mm <sup>3</sup> on two or more occasions Lymphopenia <1500/mm <sup>3</sup> on two or more occasions Thrombocytopenia <100,000/mm <sup>3</sup> in the absence of drugs  |
| Immunologic          | Anti-DNA: Antibody to native DNA in abnormal titer Anti-Sm: Presence of antibody to Sm nuclear antigen Positive finding of antiphospholipid antibodies based on* (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (2) a positive test result for lupus anticoagulant using a standard method, or (3) a false-positive serologic test for syphilis for 6 months |
| Antinuclear antibody | An abnormal titer of ANA by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with drug-induced lupus syndrome  |

For the purposes of enrollment in clinical studies, a person is defined as having systemic lupus erythematosus (SLE) if four or more of the 11 criteria are present, serially or simultaneously.  
\*Testing for antiphospholipid antibodies should also include IgG and IgM anti-β2-glycoprotein I antibodies.  
ANA, antinuclear antibody; ECG, electrocardiograph; Ig, immunoglobulin.

the setting of a disease flare, whereas Anti-Sm antibodies are detected in 30% to 40% of individuals with SLE and are associated with LN. Antiribonucleoprotein (anti-RNP) antibodies are associated with myositis and Raynaud phenomenon. **Patients with either SLE or Sjögren syndrome may also have anti-Ro/SSA and anti-La/SSB antibodies, which are particularly relevant to the obstetric patient because of the association with neonatal lupus erythematosus (NLE) and congenital heart block (CHB).**

Lupus Flare in Pregnancy

Studies on the risk of SLE flare in pregnancy have yielded inconsistent results. In the 1960s and 1970s, studies suggested a significant risk for disease flare in pregnancy with accompanying high rates of adverse maternal and fetal/neonatal outcomes. However, more recent studies indicate that pregnancy may not significantly increase the risk of an SLE flare.<sup>5,6</sup> If flares do occur in pregnancy, they are generally not severe and are relatively easily treated.<sup>7</sup> **The best predictor of the course of SLE during**

gestation is the state of disease activity at the onset of pregnancy. In one study, approximately one third of women who were in remission for at least 6 months prior to pregnancy suffered an SLE flare compared with two thirds of women with active disease at the beginning of pregnancy.<sup>8</sup> Thus **women with SLE should be counseled to delay pregnancy until their disease has been in remission for at least 6 months.**

The detection of SLE flare in pregnancy requires frequent clinical assessment and astute clinical judgment. **Flares in pregnancy most commonly manifest as fatigue, joint pain, rash, and proteinuria. Assessing anti-dsDNA titers and complement (C3 and C4) levels may provide additional evidence of disease flares in women with clinical symptoms. The routine assessment of anti-dsDNA and complement levels in asymptomatic women is of doubtful clinical utility.**<sup>9</sup>

### Lupus Nephritis in Pregnancy

Renal manifestations are present in approximately half of all patients with SLE. Although LN may be suspected based on hematuria, proteinuria, and casts on urinalysis, confirmation of the diagnosis requires a renal biopsy. According to the International Society of Nephrology and the Renal Pathology Society, six classes of LN have been defined, with the most common and severe form being class IV, or diffuse LN.<sup>10</sup> All patients with active diffuse LN have proteinuria and hematuria, and a significant subset of patients will progress to nephrotic syndrome, hypertension, and renal insufficiency. **Women with LN, particularly active disease, are at especially increased risk for adverse pregnancy outcomes that include hypertensive disorders of pregnancy, disease flares, low birthweight infants, and indicated preterm delivery.**<sup>11</sup> Similar to SLE in general, the activity of LN during pregnancy is related to disease status at conception. In one study, an LN flare was seen in only 9% of cases in which the disease was in remission for at least 5 months prior to pregnancy, compared with 66% of cases in which disease was clinically active at conception.<sup>12</sup> Women with baseline renal insufficiency are at greatest risk. Ideally, assessment of baseline renal status—serum creatinine and urine protein excretion—is done prior to planning a pregnancy. If the patient is already pregnant, assessment as early as feasible in the pregnancy is recommended. **As a general rule, a serum creatinine of 1.4 to 1.9 mg/dL (estimated glomerular filtration rate [EGFR] ~30 to 59 mL/min/1.73 m<sup>2</sup>) is a relative contraindication to pregnancy given the substantial risk of midterm pregnancy complications that might require preterm delivery. Most experts consider a serum creatinine of 2.0 mg/dL or greater (EGFR ~15 to 29 mL/min/1.73 m<sup>2</sup>) to be an absolute contraindication to pregnancy, again because of the substantial risk of pregnancy complications requiring extreme preterm birth (PTB) and the threat to long-term renal function.** Women with moderate and especially severe baseline renal insufficiency should be counseled regarding the small (5% to 10%) but real risk of an irreversible decline in renal function during pregnancy.<sup>13</sup>

**Women with LN often have increasing proteinuria across gestation, related in part to increased glomerular filtration.** However, an isolated increase in proteinuria without new-onset or worsening hypertension or a significant rise in serum creatinine should not be an indication for preterm delivery. Furthermore, the American College of Obstetricians and Gynecologists (ACOG) no longer considers proteinuria a necessary diagnostic criterion for preeclampsia.

**Distinguishing between a flare in SLE (and LN) and preeclampsia can pose a clinical dilemma.** Both entities can present with hypertension and proteinuria. If the pregnancy is at or near term, delivery may be the most prudent strategy. Preeclampsia should resolve after delivery. However, if the pregnancy is still very preterm, distinguishing between a disease flare and preeclampsia is more critical. A SLE flare can usually be treated, such as with corticosteroids, to prolong the pregnancy and optimize neonatal outcomes. Because elevated anti-dsDNA titers and low complement levels are often seen in active SLE, assessing them may aid in distinguishing between a disease flare and preeclampsia. However, it should be emphasized that hypocomplementemia can also be seen in preeclampsia.<sup>14</sup> **Examination of the urine sediment** may also provide useful information because hematuria and cellular casts often accompany an LN flare but are not characteristic of preeclampsia. Renal biopsy may be considered in difficult cases but is usually avoided during pregnancy unless management of the pregnancy is incumbent upon the results.

**Women with severe LN are often treated with mycophenolate mofetil (MMF), a significant teratogen that is contraindicated in pregnancy.** MMF is typically replaced by azathioprine (AZA) when a pregnancy is planned or soon after conception in an unplanned pregnancy. In one study, preconceptional replacement of MMF with AZA among women with inactive disease did not lead to an increase in LN flares in the 3 to 6 months prior to a confirmed pregnancy.<sup>15</sup>

### Pregnancy Complications

**Women with SLE do not appear to be less fertile than women without SLE, but they are at increased risk for multiple adverse pregnancy outcomes that include pregnancy loss, PTB, preeclampsia, and intrauterine growth restriction (IUGR).**

#### Pregnancy Loss

Studies from the 1960s and 1970s reported pregnancy loss rates as high as 50% among women with SLE. Although rates of pregnancy loss appear to have declined over the decades, probably related to improved treatment and surveillance, women with SLE are still at greater risk for pregnancy loss compared with women who do not have SLE. One study found that even women with disease remission at the onset of pregnancy had a risk of miscarriage or fetal death of 17% compared with 5% for women without SLE.<sup>16</sup> A meta-analysis reported a spontaneous abortion rate of 16% and a stillbirth rate of 3.6% among women with SLE.<sup>11</sup> The National Institutes of Health (NIH) sponsored Predictors of Pregnancy Outcome: Biomarker In Antiphospholipid Antibody Syndrome and Systemic Lupus Erythematosus (PROMISSE), a study that followed a cohort of women with inactive or mild-to-moderate SLE activity at conception. Because patients were enrolled in the late first or early second trimesters, early pregnancy loss was not assessed. However, **the overall fetal death rate among these women was 4%, and the neonatal death rate was 1%.**<sup>17</sup>

**Active disease at the onset of pregnancy confers an increased risk for pregnancy loss.** Among a cohort of 267 pregnancies followed between 1987 and 2002, 77% resulted in a live birth among women with high-activity SLE compared with 88% among those with low-activity disease.<sup>18</sup> In addition to disease activity, LN, hypertension, and antiphospholipid antibodies (aPLs) are all associated with an increased risk for pregnancy loss (see Chapter 27).<sup>19</sup>

### Intrauterine Growth Restriction

The increased risk for stillbirth among women with SLE is likely related to higher rates of placental insufficiency and IUGR (see Chapter 33), particularly among pregnancies complicated by active disease, hypertension, LN, and/or antiphospholipid syndrome (APS). **Although the rate of IUGR among pregnancies complicated by SLE has been reported to be as high as 40%,<sup>20</sup> modern treatments and improved pregnancy surveillance have probably decreased this rate.** A study from the National Inpatient Sample analyzed over 16 million hospital admissions for childbirth and found that 5.6% of women with SLE carried a diagnosis of IUGR, compared with 1.5% among women without SLE (this difference was not statistically significant).<sup>21</sup> In the PROMISSE study, 8% of infants of women with mild to moderate SLE were small for gestational age (SGA).<sup>17</sup> **Chronic, high-dose glucocorticoid treatment is also a risk factor for IUGR.** Because of the increased risk for IUGR and stillbirth, it is standard practice to assess fetal growth intermittently with ultrasound after 20 weeks and to perform antenatal testing (non-stress tests or biophysical profiles) in the third trimester.

### Preterm Birth

**Women with SLE have an approximately threefold increased risk for PTB.<sup>22</sup>** In the PROMISSE study, 9% of pregnancies delivered before 36 weeks.<sup>17</sup> Most of these PTBs are not spontaneous but are rather iatrogenic, the result of fetal or maternal indications (IUGR, preeclampsia, disease flare, deteriorating renal function, etc.). Women with active disease, aPLs, LN, and hypertension are at particular risk for PTB. In one study, a full-term delivery was achieved in only 26% of women with high-activity SLE compared with 61% of women with low-activity disease or remission.<sup>23</sup> High-dose glucocorticoids have also been associated with an increased risk for preterm premature rupture of membranes.

### Hypertensive Disorders of Pregnancy

**Hypertensive disorders (gestational hypertension or preeclampsia) occur in 10% to 30% of pregnancies with SLE.<sup>5,21</sup>** The risk for preeclampsia is particularly increased in women with LN and/or chronic hypertension. Preeclampsia may develop in as many as two thirds of women with LN<sup>23</sup> and is a frequent indication for iatrogenic PTB. It appears that preeclampsia is also more likely to develop at an earlier gestational age among women with a history of LN compared with those without such a history (37.5 weeks vs. 34.5 weeks in one study<sup>24</sup>). **Daily low-dose aspirin (typically 81 mg in the United States) beginning early in pregnancy is recommended for women with SLE, particularly those with renal manifestations, because evidence suggests this may modestly decrease the risk of developing preeclampsia.<sup>25</sup>**

As mentioned previously, it may be difficult in some cases to distinguish between an SLE flare and preeclampsia, and astute clinical judgment is required. Hospitalization for maternal and fetal monitoring, administration of antenatal steroids, and thoughtful determination of the need for delivery is frequently indicated in these cases.

### Neonatal Lupus Erythematosus

Neonatal lupus erythematosus is an acquired autoimmune condition related to the transplacental transfer of anti-Ro/SSA and anti-La/SSB antibodies. NLE most commonly presents as an erythematous, scaling, plaquelike rash that begins in

the early neonatal period and may persist for 1 to 2 months. Less common manifestations of NLE include hematologic abnormalities (leukopenia, hemolytic anemia, thrombocytopenia) and hepatosplenomegaly. Fortunately, the incidence of NLE is low. **Among all pregnant women with SLE, the risk of NLE is less than 5%.** Of those women with SLE who test positive for anti-Ro/SSA and anti-La/SSB antibodies, at most 15% to 20% will have an affected newborn. Many mothers of newborns with NLE will not carry a current diagnosis of SLE. However, a significant number of these women will develop symptomatic autoimmune disease, often Sjögren syndrome, in the future. They should therefore be counseled to seek medical evaluation if symptoms of SLE or Sjögren syndrome develop.

**The most serious manifestation of NLE is complete heart block. It is most frequently diagnosed at a routine prenatal visit when a fixed fetal bradycardia of 50 to 80 beats/min is detected. CHB is most commonly diagnosed between 16 and 24 weeks' gestation, and it is rarely diagnosed in the third trimester.** It is caused by the binding of antibodies to antigens in fetal cardiac tissue with subsequent damage to the cardiac conduction system and, ultimately, complete atrioventricular (AV) dissociation. Some cases progress to endocardial fibroelastosis, which can result in cardiac failure that leads to fetal hydrops and fetal death. Among women with anti-Ro/SSA and anti-La/SSB antibodies, the risk for CHB in the fetus is only 1% to 2%. However, women with a prior affected child have a recurrence risk for CHB of 15% to 20% in subsequent pregnancies.<sup>26</sup> Fetal genetic factors, such as certain human leukocyte antigen (HLA) polymorphisms, may modify susceptibility to the development of CHB.<sup>27</sup> **Although many clinicians routinely test pregnant women with SLE for anti-Ro/SSA and anti-La/SSB antibodies, this practice is not without controversy given that CHB is infrequent, antenatal treatment to alter outcome is of uncertain efficacy, and a positive test result may cause unnecessary maternal anxiety.**

**Complete CHB is irreversible and is associated with an overall mortality rate of at least 20% (5% stillborn).<sup>28</sup> The majority of survivors require a pacemaker.** In one series of 102 cases, a prenatal diagnosis of CHB was associated with a 43% risk of mortality in the first two decades of life.<sup>29</sup> Among a registry of 325 offspring with cardiac manifestations of NLE, predictors of a stillbirth or postnatal death included hydrops, endocardial fibroelastosis, earlier diagnosis, and a lower ventricular rate.<sup>30</sup> In addition, the case fatality rate was significantly higher among minorities (32.1% for blacks compared with 14.3% for whites).<sup>30</sup>

### Management of Pregnancies Complicated by Systemic Lupus Erythematosus

Because SLE commonly affects women at some point during their reproductive years, the clinician should be familiar with the high-risk nature of these pregnancies and the altered management and increased surveillance required. **Ideally, women with SLE would present for a preconceptional visit such that disease remission could be ensured, medications reviewed, and counseling performed.**

Table 46-2 outlines recommendations for the management of pregnancies complicated by SLE. **Key components include the assessment of disease activity and renal manifestations, surveillance for preeclampsia, surveillance of fetal growth, and antenatal testing.** Co-management with a rheumatologist is particularly important for women with severe manifestations

IUGR, intrauterine growth restriction; NST, nonstress test.

**or active disease.** Furthermore, some women experience a disease flare in the postpartum period; therefore the obstetrician should carefully assess disease activity at postpartum visits, and follow-up with rheumatology in the 1 to 3 months following delivery is usually recommended.

### Management of Congenital Heart Block

Given that complete CHB is irreversible and that the prognosis is grave, efforts have focused on trying to predict and prevent the development of CHB. Some experts have proposed serial fetal echocardiograms with Doppler monitoring of the PR interval or kinetocardiography in women with anti-Ro/SSA and anti-La/SSB antibodies, particularly in those with a prior fetus affected by CHB. However, these practices are controversial, and no formal guidelines for the type and frequency of monitoring have been established. Neither fetal Doppler PR interval monitoring nor kinetocardiography have been associated with proven benefit, in part because progression to CHB can occur rapidly and without discernable progression through first- and second-degree block. In spite of this, many experts—including expert rheumatologists and pediatric cardiologists—recommend serial PR interval monitoring of the fetus in a woman with anti-SSA/Ro and anti-SSB/La antibodies. In our experience, the inclinations of the local pediatric cardiology team play a dominant

role in deciding upon the nature and frequency of such monitoring.

**Even with early detection of cardiac conduction abnormalities or new-onset CHB, no credible evidence suggests that medical interventions alter outcomes.** Current treatment recommendations are based on expert opinion and relatively small studies, all nonrandomized. Several case series have described use of fluorinated steroids such as dexamethasone for the treatment of either cardiac conduction abnormalities or new-onset CHB.<sup>31-33</sup> The PR Interval and Dexamethasone Evaluation (PRIDE) study enrolled 40 women with anti-Ro/SSA antibodies and a fetus with any degree of heart block diagnosed echocardiographically.<sup>31</sup> Thirty women were treated with dexamethasone and 10 declined treatment. No cases of CHB reverted, treated or untreated. Among six treated fetuses with second-degree block, three remained in second-degree block, two reverted to normal sinus rhythm (NSR), and one progressed to complete block. Two treated fetuses had first-degree block, and both reverted to NSR after initiation of dexamethasone. However, the one untreated fetus with first-degree block was in NSR at birth. Although case selection in this nonrandomized study likely played a role, no perinatal deaths were reported in the nontreated group compared with deaths (20%) in the dexamethasone group. Treatment with steroids was associated with more preterm and SGA infants; the potential adverse effects of steroids must thus be weighed against the limited data that support a benefit in cases of early cardiac conduction abnormalities.

Although experts generally agree that steroid treatment should not be expected to reverse CHB, at least one group of investigators has concluded that steroid treatment might reverse or improve hydrops, reduce morbidity, and improve 1-year survival.<sup>32</sup> Others disagree.<sup>30,34</sup> In addition to steroid treatment, β-stimulation—such as with terbutaline, ritodrine, or salbutamol—has been administered in some cases of a very low fetal heart rate (<55 beats/min) in an attempt to increase the heart rate and prevent hydrops. Once again, data to support this treatment strategy are very limited.<sup>32</sup> Table 46-3 outlines management strategies for CHB.

**Strategies to prevent conduction abnormalities altogether would certainly seem attractive, and three preventive treatments have been considered.** Glucocorticoids are not recommended as preventative treatment for women at high risk of CHB due to lack of proven benefit and because most fetuses will not develop CHB. Furthermore, chronic glucocorticoid therapy is associated with some maternal and fetal risks, including potential programming effects on offspring's hypothalamic-pituitary-adrenal axis and neurodevelopment (see Chapter 5).

Two multicenter prospective observational studies have evaluated intravenous immunoglobulin (IVIG) as a preventative agent.<sup>35,36</sup> The two studies enrolled a total of 44 women at high risk for CHB. The results do not indicate that IVIG is effective at preventing the development of CHB, and it should not be used for this purpose outside of approved research protocols.

More recent data suggest a potential benefit of hydroxychloroquine (HCQ) in decreasing the risk of NLE cardiac complications among high-risk women.<sup>37-40</sup> In a historic cohort of 257 pregnancies in women with anti-Ro/SSA antibodies and a previous child affected with CHB, HCQ use beginning in the first trimester was associated with significantly decreased odds of cardiac NLE (0.23; 95% confidence interval [CI], 0.06 to 0.92), defined as second- or third- degree block or

**TABLE 46-3**    MANAGEMENT APPROACHES FOR CONGENITAL HEART BLOCK

|   |   |
|---|---|
| Anti-Ro/SSA, anti-La/SSB antibodies, no previously affected child | <ul style="list-style-type: none"><li>• Risk of CHB is 1%-2%, routine monitoring of the fetal PR interval is usually not recommended (controversial)</li></ul>  |
| Anti-Ro/SSA, anti-La/SSB antibodies, previously affected child    | <ul style="list-style-type: none"><li>• Risk of CHB is 15%-20%</li><li>• Give hydroxychloroquine beginning in the first trimester (400 mg/day)</li><li>• Consider serial monitoring of the fetal PR interval (controversial) with weekly pulsed Doppler echocardiography*</li></ul>   |
| First-degree heart block†   | <ul style="list-style-type: none"><li>• Patient may revert to normal sinus rhythm; monitor for progression</li><li>• Consider dexamethasone treatment at 4 mg/day (controversial)</li></ul>   |
| Second-degree heart block†  | <ul style="list-style-type: none"><li>• Monitor for progression</li><li>• Consider dexamethasone treatment at 4 mg/day upon diagnosis</li><li>• Discontinue dexamethasone if condition progresses to complete block except with evidence of hydrops</li><li>• Given potential adverse effects, consider discontinuation of dexamethasone if heart block reverts</li></ul> |
| First-degree (complete) heart block†                              | <ul style="list-style-type: none"><li>• Monitor for hydrops</li><li>• Give dexamethasone if hydrops develops</li><li>• Consider oral terbutaline (2.5-7.5 mg every 4-6 hr) for an FHR &lt;55 beats/min‡</li></ul>   |

\*Highest risk period for development of CHB is between 18 and 24 weeks' gestation.  
†Fetal echocardiography is recommended to rule out structural heart disease.  
‡Caution is warranted with chronic terbutaline therapy because of reported serious maternal adverse events. Terbutaline should especially be avoided in women with diabetes, hypertension, hyperthyroidism, seizures, or a history of arrhythmias.  
CHB, congenital heart block; FHR, fetal heart rate.

isolated cardiomyopathy.<sup>38</sup> Given the low risk for fetal harm (see the section on medications) and potential benefit, initiation of HCQ in the first trimester should be considered among women positive for anti-Ro/SSA antibodies who have had a prior affected child.

**Drug Used to Treat Systemic Lupus Erythematosus and Pregnancy Considerations**

It should be noted that as of June of 2015, the U.S. Food and Drug Administration (FDA) Pregnancy and Lactation Labeling Final Rule requires that the pregnancy safety letter categories of A, B, C, D, and X be removed from drug labels and replaced by a risk summary, clinical considerations, and available data. The goal of this change is to better assist health care providers in assessing the benefits versus risks of medications in pregnancy. This rule also requires that labels be updated when the information is outdated.

**Drugs with Acceptable Risk Profiles in Pregnancy (See Chapter 8)**

**HYDROXYCHLOROQUINE**

Past concerns regarding HCQ being associated with fetal ocular toxicity and ototoxicity (FDA category C) have not been confirmed by studies published within the past 15 years.<sup>39,41</sup> One study of 114 HCQ-exposed pregnancies, most in the first trimester, compared with 455 unexposed pregnancies found no significant difference in the rate of congenital anomalies.<sup>41</sup> Moreover, the continuation of HCQ during pregnancy may be beneficial; one retrospective analysis<sup>42</sup> showed that women who remained on HCQ had less severe SLE flares and

thus required lower doses of glucocorticoids. Evidence also suggests that HCQ may prevent CHB in at-risk fetuses.<sup>37,38,40</sup> Given the possible benefits and the apparent lack of harm, many experts now recommend that women on HCQ who become pregnant continue the medication during pregnancy. It is also a favored agent for the treatment of SLE flares in pregnancy, and **HCQ is compatible with breastfeeding.**

**GLUCOCORTICOIDS**

**SLE flares in pregnancy are most commonly treated with glucocorticoids. Nonfluorinated steroids, such as prednisone and methylprednisolone (both FDA category C) are preferred in pregnancy** because the placenta metabolizes these agents to an inactive metabolite, which results in limited fetal exposure. Some studies have reported a small increased risk of cleft lip and palate with first-trimester glucocorticoid use,<sup>43</sup> but other studies have not confirmed these findings.<sup>44</sup> If the risk for orofacial clefts is increased, this increase appears to be small. **Prolonged use of glucocorticoids is associated with an increased risk for maternal bone loss, gestational diabetes, hypertension and preeclampsia, and adrenal suppression.** The use of prednisone in moderate to high doses may be associated with preterm rupture of membranes (PROM) and fetal growth restriction.<sup>45</sup> Women taking glucocorticoids should be screened early for gestational diabetes, and the test should be repeated at the usual 24 to 28 weeks if normal. Those on 20 mg/day or more of prednisone for at least 3 weeks are at greatest risk of adrenal suppression and should receive **stress-dose steroids during labor and delivery.** One stress-dose regimen is 100 mg of intravenous (IV) hydrocortisone every 8 to 12 hours for two to three doses. The risk of adrenal suppression for women taking 5 mg or less per day of prednisone is very small, and stress-dose steroids are not indicated. For women who take more than 5 mg and less than 20 mg per day, many clinicians still administer stress-dose steroids, although simply continuing women on their daily steroid dose is probably adequate. In general, **prednisone is compatible with breastfeeding, although for women who take more than 20 mg per day, it may be prudent to delay feeding for 4 hours after the dose.**

**NONSTEROIDAL ANTIINFLAMMATORY DRUGS**

**Nonsteroidal antiinflammatory drugs (NSAIDs) are considered first-line treatment for autoimmune disease symptoms such as arthralgias or arthritis.** First trimester NSAID exposure was not associated with an increase in the rate of congenital malformations or a decrease in infant survival in several large population-based studies.<sup>46,47</sup> It is controversial as to whether first- and early second-trimester use of NSAIDs is associated with an increased risk of spontaneous abortion. **Third-trimester NSAID use may cause premature closure of the fetal ductus arteriosus, particularly after 30 weeks' gestation, and oligohydramnios. For these reasons, NSAIDs are FDA category C before 30 weeks and category D thereafter.** NSAIDs should be used judiciously in the late first and second trimesters of pregnancy and should be generally avoided after 28 to 30 weeks. The single exception is **low-dose aspirin, which can be taken safely throughout pregnancy. Daily low-dose aspirin may provide modest risk reduction for the development of preeclampsia among high-risk women.**<sup>48</sup> Data are limited regarding cyclooxygenase 2 (COX-2) inhibitors such as celecoxib in pregnancy, and it is recommended that these agents be avoided. **NSAIDs are compatible with breastfeeding.**

### AZATHIOPRINE

Azathioprine (FDA category D) is used in the prevention of transplant rejection and in the treatment of SLE and LN. Although teratogenicity has been documented in animal studies, the human placenta lacks the enzyme that metabolizes AZA to its active metabolite, 6-mercaptopurine. As a result, very little active drug reaches the fetal circulation. Human studies have not found an increased risk for teratogenicity. Some studies have found increased rates of IUGR, PTB, and impaired neonatal immunity with AZA use in pregnancy. However, it is difficult to determine whether these outcomes are related to AZA use or the underlying disease.<sup>49</sup> **AZA, often in combination with glucocorticoids, is thus the preferred treatment for severe or active SLE in pregnancy. Most experts consider AZA to be compatible with breastfeeding, although long-term follow-up of exposed infants is limited.** Avoiding feeding for 4 to 6 hours after a dose will markedly decrease the amount of drug in breastmilk.

### CYCLOSPORINE A

Cyclosporine A (FDA category C) is a calcineurin inhibitor sometimes used in the treatment of LN or severe arthritis. The drug is an immunosuppressive that inhibits the production and release of interleukin 2 (IL-2). Animal studies have demonstrated very low transplacental transfer of cyclosporine. Human studies are conflicting, but probably very little drug enters the fetal circulation. **Data obtained primarily from organ transplant patients indicate a very low risk of teratogenicity, but the risk for PTB and SGA infants may be increased.**<sup>45</sup> The drug may also cause a rise in maternal creatinine. **Women on cyclosporine are generally discouraged from breastfeeding, although data are limited regarding adverse outcomes.**

### Drugs with Uncertain or Higher Risk Profiles in Pregnancy

#### CYCLOPHOSPHAMIDE

Cyclophosphamide (FDA category D) is an alkylating agent used in the treatment of LN and vasculitis. **This drug is teratogenic and should not be used at all in the first trimester.** Use of cyclophosphamide may be considered in the second and third trimesters in the rare patient with very severe and progressive disease manifestations. **Cyclophosphamide is not compatible with breastfeeding.**

### Drugs Contraindicated in Pregnancy

#### MYCOPHENOLATE MOFETIL

Mycophenolate mofetil (FDA category D) is an inhibitor of purine biosynthesis and is used in the treatment of LN. **MMF is absolutely contraindicated in pregnancy due its abortifacient and teratogenic properties.** MMF is associated with an increased risk for cleft lip and palate, micrognathia, microtia, and abnormalities of the ear canals. Women should avoid pregnancy until they have been off MMF for at least 6 weeks. **No data are available regarding MMF use and breastfeeding, and it is considered contraindicated.**

## ANTIPHOSPHOLIPID SYNDROME

Antiphospholipid syndrome (APS) is an autoimmune condition associated with venous and arterial thrombosis, and adverse pregnancy outcomes that include recurrent early miscarriage (REM), fetal death, early preeclampsia, and

placental insufficiency. **Diagnosis of APS is confirmed by persistently positive aPLs**, a heterogeneous group of autoantibodies directed against either negatively charged phospholipids or glycoproteins bound to these phospholipids. **The diagnosis of APS is confirmed by the detection of one or more of three aPLs: lupus anticoagulant (LAC), anticardiolipin antibodies (aCL), and anti- $\beta_2$ -glycoprotein I (a $\beta_2$ -GP-I) antibodies.** The classification criteria for APS were most recently revised in 2006 (Box 46-1).<sup>50</sup>

### BOX 46-1 REVISED CLASSIFICATION CRITERIA FOR THE ANTIPHOSPHOLIPID ANTIBODY SYNDROME\*

#### Clinical Criteria

##### Vascular Thrombosis<sup>†</sup>

1. One or more clinical episodes of arterial, venous, or small-vessel thrombosis in any tissue or organ *and*
2. Thrombosis confirmed by objective, validated criteria (i.e., unequivocal findings of appropriate imaging studies or histopathology) *and*
3. For histopathologic confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall

#### PREGNANCY MORBIDITY

1. One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation, with normal fetal morphology documented by ultrasound or by direct examination of the fetus *or*
2. One or more premature births of a morphologically normal neonate at or before the 34th week of gestation because of eclampsia or severe preeclampsia or placental insufficiency<sup>‡</sup> *or*
3. Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation with maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal causes excluded

#### Laboratory Criteria

1. Lupus anticoagulant present in plasma on two or more occasions at least 12 weeks apart, detected according to the guidelines of the International Society on Thrombosis and Hemostasis
2. Anticardiolipin antibody of IgG and/or IgM isotype in blood present in medium or high titer (i.e., >40 GPL or MPL or >99th percentile) on at least two occasions at least 12 weeks apart, measured by standardized ELISA
3. Anti- $\beta_2$ -glycoprotein I antibody of IgG and/or IgM isotype in serum or plasma (in titer >99th percentile) present in medium or high titer on at least two occasions at least 12 weeks apart, measured by standardized ELISA

Modified from Miyakis S, Lockshin MD, Atsumi T, et al. International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome (APS). *J Thromb Haemost.* 2006;4: 295-306.

\*Must meet at least one clinical and one laboratory criterion for diagnosis of "definite" APS.

<sup>†</sup>Superficial venous thrombosis is not included in the clinical criteria.

<sup>‡</sup>Features of placental insufficiency may include: (1) abnormal or nonreassuring fetal surveillance, such as a nonreactive nonstress test; (2) abnormal Doppler flow in the umbilical artery (e.g. absent end-diastolic flow); (3) oligohydramnios; or (4) infant birthweight below the 10th percentile for gestational age.

ELISA, enzyme-linked immunosorbent assay; GPL, IgG phospholipid units; Ig, immunoglobulin; MPL, IgM phospholipid units.

## Clinical Presentation

APS may occur as a primary condition or in association with another autoimmune disease, most commonly SLE. **Prevalence and incidence are uncertain**, although definite APS in the absence of other autoimmune conditions is probably no more common than SLE. If low-titer positive tests for one or more of the three aPLs (usually aCL or  $\alpha\beta 2$ -GP-I) are included, aPLs are found in a small percentage (<5%) of healthy women<sup>51</sup> and in up to 40% of patients with SLE.<sup>52</sup> **In the absence of a history of thrombosis or pregnancy morbidity, the risks associated with an incidentally identified positive test for aPL among otherwise healthy women are not well understood, and these women should not be diagnosed with APS.**

**The most common thrombotic presentation of APS is deep venous thrombosis (DVT) of the lower extremity, which represents about two thirds of thrombotic APS cases.**<sup>53</sup> The most common arterial presentation is stroke; positive aPL results are found in up to 20% of ischemic stroke patients younger than 50 years of age.<sup>54</sup> Small vessel thrombosis may present as nephropathy. Compared with heritable thrombophilias, APS is more likely to manifest with thromboses in diverse or unusual locations such as the intracranial (stroke), hepatic, and intraabdominal venous or arterial circulations.

**APS should be considered in the differential diagnosis of venous or arterial thrombosis and also with any of the following adverse pregnancy outcomes:**

- Three or more otherwise unexplained *recurrent early miscarriages*, defined as preembryonic or embryonic losses at less than 10 weeks' gestation
- One or more otherwise unexplained fetal deaths ( $\geq 10$  weeks' gestation)
- A history of PTB occurring at less than 34 weeks' gestation secondary to severe preeclampsia or placental insufficiency

## Recurrent Early Miscarriage

Although studies have found that up to 15% of women with REM have positive aPL results,<sup>55</sup> the data are flawed by poor standardization of aPL assays, inclusion of women with other causes of REM, inconsistent selection of controls, variability in the type of aPLs or isotypes tested, and variable definitions of aPL positivity and REM.<sup>56</sup> As a result, women with REM should only be diagnosed with APS if they meet accepted international criteria.<sup>57</sup> This topic is discussed in greater detail in [Chapter 27](#).

## Stillbirth

In a recent analysis from the Stillbirth Collaborative Research Network's multicenter, population-based case-control study of stillbirths and live births, **9.6% of fetal death cases at 20 or more weeks' gestation were associated with a positive test for aPLs (aCL or  $\alpha\beta 2$ -GP-I antibodies) compared with 6% of live birth cases—a statistically significant difference.**<sup>58</sup> Among otherwise unexplained cases, immunoglobulin G (IgG) aCL and IgM aCL antibodies were associated with fivefold and twofold increased odds of fetal death, respectively. Positive IgG  $\alpha\beta 2$ -GP-I antibodies were associated with a threefold increased odds of fetal death. **The authors concluded that 14% of otherwise unexplained fetal deaths were attributable to APS.** In the recently published prospective Nimes Obstetricians and Hematologists Antiphospholipid Syndrome (NOH-APS) study,<sup>59</sup> women with well-characterized APS who had either REM or a prior fetal death suffered an 8.3% and 15.9% rate of fetal loss,

respectively, in their next observed pregnancy in spite of treatment with enoxaparin and low-dose aspirin.

## Placental Insufficiency

The association between aPL and PTB before 34 weeks due to severe preeclampsia or placental insufficiency (manifested as IUGR) is somewhat uncertain because studies are flawed by poor standardization of laboratory tests, concerns related to cases and controls selection, and the variable definitions of preeclampsia and placental insufficiency. These issues notwithstanding, several studies suggest **that a median of 7.9% of women with severe preeclampsia have positive tests for aPL, compared with 0.5% for controls.**<sup>60,61</sup> In the NOH-APS study, 10% of women with well-characterized APS developed severe preeclampsia in spite of enoxaparin and low-dose aspirin treatment.<sup>59</sup> So although PTB before 34 weeks' gestation due to severe preeclampsia or placental insufficiency is included in the clinical criteria for APS, experts agree that further study is warranted.<sup>57</sup>

**The most serious but rare thrombotic presentation of APS is catastrophic APS (CAPS).** This condition is characterized by rapid-onset, often small vessel thrombosis, multiorgan dysfunction, a systemic inflammatory response, involvement of unusual organ systems (e.g., renal or hepatic), and a high mortality rate.

Although not included in the international diagnostic criteria, aPLs are associated with other clinical features that include immune thrombocytopenia, hemolytic anemia, cardiac valvular disease, chronic skin ulcers, myelopathy, chorea, migraine, epilepsy, and cognitive impairment, particularly among patients with SLE.

## Diagnosis

### Definite Antiphospholipid Syndrome

**As defined by the international criteria, at least one clinical criterion and positive aPL are required for the diagnosis of definite APS (see [Box 46-1](#)).**<sup>50</sup> Clinicians should recognize that the clinical criteria are relatively common and nonspecific for APS, such that the final diagnosis of APS ultimately rests on positive aPL. Specifically, the laboratory criteria require that a patient have medium to high titers of aCL IgG or IgM antibodies,  $\alpha\beta 2$ -GP-I IgG or IgM antibodies, or LAC. Because other conditions can result in transiently positive aPL, persistently positive results on two or more occasions at least 12 weeks apart are needed. Laboratories are required to delineate medium or high titer results for aCL and greater than 99% results for  $\alpha\beta 2$ -GP-I antibodies. The development of standard calibrators and international "units" for the aCL assay has established greater than 40 IgG units ("GPL") or IgM units ("MPL") as being a medium or high titer. The status of IgA isotypes is a matter of ongoing investigation, but currently IgA aCL or  $\alpha\beta 2$ -GP-I antibodies are not recognized as diagnostic of APS.

**It should also be emphasized that LAC is a better predictor of pregnancy morbidity or thrombosis than aCL or  $\alpha\beta 2$ -GP-I antibodies.**<sup>62,63</sup> False-positive LAC results may occur in the setting of anticoagulant drugs. Higher titers and the IgG isotype of aCL and  $\alpha\beta 2$ -GP-I antibodies are more specific for APS-related clinical manifestations. Finally, some experts hold that triple aPL positivity (LAC, aCL, and  $\alpha\beta 2$ -GP-I) is of greater clinical significance than double or single aPL positivity.

### Catastrophic Antiphospholipid Syndrome

**Catastrophic antiphospholipid syndrome (CAPS) can occur in pregnancy and should be considered in the differential**

**diagnosis that includes hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP). According to international criteria, the diagnosis of CAPS is based on thromboses in three or more organs in less than a week, microthrombosis in at least one organ, and persistent aPL positivity.<sup>64</sup>** In practice, features of microthrombosis vary from biopsy-proven thrombosis in small vessels to clinical ischemia resulting from occlusion of arterioles and capillaries. Given the often vague features of microthromboses and the substantial mortality rate associated with CAPS, a high index of suspicion is warranted in patients who present with fewer than three organ systems involved.

### Possible or Probable Antiphospholipid Syndrome and Equivocal Cases

In certain scenarios, it may not be prudent to wait 12 weeks to confirm initially positive aPL results before considering treatment. For example, after weighing the risks and potential benefits, thromboprophylaxis might be considered in a woman with a history of fetal death who is newly pregnant and initially tests positive for aPL. In the case of CAPS, the high mortality rate should prompt consideration of aggressive treatment without waiting for confirmation of persistently positive aPL.

At the other end of the clinical spectrum are patients who meet the clinical criteria for APS but have “equivocal” aPL results. One frequent scenario is the woman with REM and persistently low-positive aCL or  $\alpha\beta 2$ -GP-I antibody results (i.e., aCL result of 20 to 39 GPL or MPL units). In such cases, clinicians are often faced with the difficult decision as to whether low-dose heparin “treatment” in the next pregnancy is reasonable, in spite of the lack of evidence of efficacy in such cases.

## Management of Antiphospholipid Syndrome in Pregnancy

### Treatment during Pregnancy

**Management of APS during pregnancy is aimed at minimizing or eliminating the risks of thrombosis, miscarriage, fetal death, preeclampsia, placental insufficiency, and iatrogenic preterm birth. With currently recommended management strategies, the likelihood of a successful pregnancy (delivery of a viable infant) in a woman diagnosed with APS exceeds 70%.**

**The combination of a heparin agent and low-dose aspirin is the current recommended treatment for APS in pregnancy** because it serves to provide thromboprophylaxis and may improve pregnancy outcomes. Ideally aspirin is started preconceptionally because of its possible beneficial effects on implantation. Because some patients with APS have immune thrombocytopenia, the platelet count should be assessed prior to starting treatment. **Heparin is usually begun in the early first trimester after demonstrating either an appropriately rising serum human chorionic gonadotropin (hCG) or the presence of a live embryo on ultrasonography.** Most APS patients with a history of thrombosis are maintained on long-term anticoagulation, frequently warfarin. To minimize the risk of warfarin embryopathy, these patients should be transitioned from warfarin to a heparin agent either prior to or very early in pregnancy.

Women with APS diagnosed on the basis of obstetric criteria who do *not* have a history of thrombosis may be classified into one of two groups: (1) those with REM or (2) those with one or more previous fetal deaths ( $\geq 10$  weeks gestation) or previous

early delivery ( $< 34$  weeks' gestation) because of severe preeclampsia or placental insufficiency. Most experts recommend prophylactic-dose heparin and low-dose aspirin for these patients.

**Heparin treatment to improve obstetric outcomes in women with APS is not without controversy.** Four heparin treatment trials have been conducted in women diagnosed with APS predominantly based on REM.<sup>65-68</sup> In two of these, the proportion of successful pregnancies substantially improved with the addition of unfractionated heparin (UFH) to low-dose aspirin.<sup>65,66</sup> The other two trials used low-molecular-weight heparin (LMWH) and did not find a significant benefit when combined with low-dose aspirin,<sup>67,68</sup> primarily because the live birth rates in the patients treated with aspirin only were quite good (70% to 75%). Two studies have compared UFH with LMWH, each paired with low-dose aspirin, in women with predominant REM and found no differences in outcomes.<sup>69,70</sup> Furthermore, several studies have reported successful pregnancy outcomes in excess of 70% among women with predominant REM who were treated with low-dose aspirin alone.<sup>71,72</sup> **A Cochrane systematic review concluded that although the quality of available studies was not high, “combined UFH and aspirin may reduce pregnancy loss by 54%” in women with APS based on REM.<sup>73</sup>** The American College of Chest Physicians recommends antepartum administration of prophylactic or intermediate-dose UFH or prophylactic LMWH in women who fulfill the laboratory criteria for APS and meet the clinical criteria for REM.<sup>74</sup> In contrast, **a recent ACOG practice bulletin states that for women with APS without a preceding thrombotic event, either clinical surveillance or prophylactic heparin may be used in the antepartum period but that “prophylactic doses of heparin and low-dose aspirin during pregnancy...should be considered.”<sup>75</sup>**

Treatment to prevent adverse pregnancy outcomes in women with APS and fetal death ( $\geq 10$  weeks' gestation) or previous early delivery ( $< 34$  weeks' gestation) due to severe preeclampsia or placental insufficiency has not been established by well-designed trials. So although heparin treatment is frequently initiated in such patients, professional guidelines have avoided making unequivocal recommendations for its use in the prevention of these later adverse pregnancy outcomes.<sup>74,75</sup>

**Box 46-2 summarizes the recommended treatment regimens for APS in pregnancy. Three important clinical points are relevant with regard to treatment aimed at preventing adverse outcomes in pregnant women with APS. First, women with APS and prior thrombosis represent a high-risk population that should be treated with appropriate anticoagulant agents during pregnancy and the postpartum period.<sup>74,75</sup> Second, even in the absence of a prior thrombosis, women with repeatedly positive tests for LAC or medium to high titers of aCL or  $\alpha\beta 2$ -GP-I antibodies are at increased risk for pregnancy-associated thrombosis, which favors at least prophylactic UFH or LMWH during pregnancy and the postpartum period. Finally, even in the absence of prior thrombosis, most women with a history of REM, fetal death, or early PTB due to severe preeclampsia or placental insufficiency will opt for “treatment” if it is felt to be relatively safe.** Considering that prophylactic UFH or LMWH regimens are rarely associated with serious adverse effects such as clinically significant osteopenia, significant bleeding, or heparin-induced thrombocytopenia, most clinicians are agreeable to treatment in these patients.

### BOX 46-2 RECOMMENDED TREATMENT REGIMENS FOR ANTIPHOSPHOLIPID SYNDROME DURING PREGNANCY

#### Recurrent Preembryonic and Embryonic Loss, No History of Thrombotic Events

Low-dose aspirin alone *or* together with:

- UFH 5000 to 7500 U/12 hr *or*
- LMWH (usual prophylactic doses)

#### Prior Fetal Death or Preterm Delivery Because of Severe Preeclampsia or Severe Placental Insufficiency, No History of Thrombotic Events

Low-dose aspirin plus:

- UFH 7500 to 10,000 U every 12 hours in the first trimester and 10,000 U every 12 hours in the second and third trimesters *or*
- UFH administered every 8 to 12 hours at a dose to maintain the midinterval aPTT\* at 1.5 times the control mean *or*
- LMWH (usual prophylactic doses)

#### Anticoagulation Regimens for Women with a History of Thrombotic Events

Low-dose aspirin plus:

- UFH administered every 8 to 12 hours to maintain the midinterval aPTT\* or anti-Xa activity in the therapeutic range *or*
- LMWH (*preferred*)
  - Weight-adjusted therapeutic doses (e.g., enoxaparin 1 mg/kg/12 hr or dalteparin 200 U/kg/12 hr)

\*Women without a lupus anticoagulant in whom the activated partial thromboplastin time (aPTT) is normal can be monitored with the aPTT. Women with lupus anticoagulant should be monitored with anti-factor Xa activity.

LMWH, low molecular weight heparin; UFH, unfractionated heparin.

**Postpartum thromboprophylaxis with UFH, LMWH, or warfarin** (international normalized ratio [INR] 2 to 3) **should be strongly considered in all women with APS and is absolutely indicated in women with prior thrombosis**, most of whom will restart their long-term anticoagulation regimen.<sup>75</sup> In patients with no previous thrombosis, treatment is usually continued for 6 weeks following delivery. **Both heparin and warfarin are safe for breastfeeding mothers.** In patients with obstetric APS and without prior thrombosis, recent data suggest that long-term low-dose aspirin may decrease the risk of an initial thrombosis event.<sup>76</sup>

In the past, case series and small trials indicated that glucocorticoid treatment of APS in pregnancy results in outcomes comparable to those achieved with heparin.<sup>77,78</sup> However, glucocorticoids are associated with adverse effects that include gestational diabetes, weight gain, and premature rupture of membranes. Randomized trials have not demonstrated a benefit from the use of IVIG, when either added to heparin or used alone.<sup>56,79,80</sup>

#### Refractory Obstetric Antiphospholipid Syndrome

Experienced clinicians are likely to encounter patients with recurrent fetal death or extreme PTB due to severe preeclampsia or placental insufficiency despite treatment with low-dose aspirin and heparin. Such “refractory obstetric APS” cases are extremely challenging because little evidence is available to guide treatment. These women should be counseled regarding the potential

for grave maternal risks and the need for extremely premature delivery in subsequent pregnancies. One group reported a 60% rate of successful pregnancies in 18 women with refractory obstetric APS when prednisolone was added to standard low-dose aspirin and heparin treatment in the first trimester.<sup>81</sup>

**Because inflammation appears to be a key component of aPL-related adverse pregnancy outcomes, modulators of excessive inflammation may be beneficial.** The authors are familiar with a handful of anecdotal reports of successful pregnancies using such agents as IVIG, HCQ, and etanercept (a tumor necrosis factor [TNF] inhibitor) in addition to low-dose aspirin and a heparin agent. Statin agents are being investigated for the prevention of recurrent preeclampsia, and therapy trials are currently underway (e.g., NCT01717586). Fluvastatin treatment reduces proinflammatory and prothrombotic biomarkers in persistently positive aPL patients.<sup>82</sup> Complement inhibitors such as eculizumab or pexelizumab may hold promise, but data are extremely limited, potential adverse effects exist, and such agents are costly.

#### Catastrophic Antiphospholipid Syndrome

The management of suspected or proven CAPS requires a multidisciplinary approach with hematologic and rheumatologic expertise. The optimal management of CAPS is not well defined. However, because the mortality rate is so high, aggressive empiric treatments are typically pursued that include anticoagulation with IV heparin, high-dose steroids, and plasma exchange. A full discussion of the management of CAPS is beyond the scope of this chapter.

#### Pregnancy Complications and Surveillance

In addition to the risk of fetal loss, women with definite APS are at significantly increased risk of developing preeclampsia and placental insufficiency. Case series of highly selected patients, many of whom had prior thrombosis or SLE, indicate that hypertensive disorders or placental insufficiency complicate 20% of pregnancies with APS and lead to a high rate of iatrogenic PTB.<sup>77</sup> In the prospective, observational PROMISSE study, 144 women with aPL, APS, or SLE and confirmed, repeatedly positive aPL were identified.<sup>62</sup> Despite contemporary management, usually with UFH or LMWH and low-dose aspirin, 19.4% of these women suffered an adverse obstetric outcome; among these, 8% suffered a fetal death after 12 weeks, and 8% required delivery prior to 34 weeks because of hypertensive disorders. Risks of adverse obstetric outcome were particularly elevated among women with repeatedly positive LAC, a history of SLE, or prior thrombosis. The NOH-APS study included 500 women with obstetric APS and excluded women with a history of thrombosis.<sup>59</sup> All were treated with low-dose aspirin and prophylactic LMWH. Overall, including miscarriages at less than 10 weeks' gestation, the live birth rate was just under 70%, similar to controls, but PTBs were observed in nearly 25% of APS cases (12% at less than 34 weeks' gestation). PTBs were largely the result of severe preeclampsia with or without IUGR. Among women with ongoing pregnancies at 20 weeks, 25% went on to suffer preeclampsia, IUGR, abruption, or a combination of these, compared with a rate of 17.5% in the controls.

**The risk of APS-related pregnancy complications is dependent on the population in which the diagnosis of APS is made. Women who meet criteria for APS because of REM but who are otherwise healthy are not at high**

**risk of thrombosis, fetal death, preeclampsia, or placental insufficiency.**<sup>65-67</sup> In the NOH-APS study, severe preeclampsia occurred in less than 3% of women with a diagnosis of APS based on REM.<sup>59</sup>

Serial ultrasounds to assess fetal growth and amniotic fluid volume are recommended in pregnancies complicated by APS. In pregnancies without evidence of maternal hypertension or fetal compromise, surveillance with nonstress tests or biophysical profiles should begin at 32 weeks. In the setting of suspected IUGR, hypertension, or thrombocytopenia, earlier institution of fetal surveillance is warranted.

## RHEUMATOID ARTHRITIS

**Rheumatoid arthritis (RA) is an autoimmune disease characterized by chronic, symmetric inflammatory arthritis of the synovial joints. RA affects 1% to 2% of U.S. adults, and as with SLE, RA is more common among females than males.** Although the incidence of RA increases with age, it is still occasionally encountered among reproductive-aged women. A genetic susceptibility to RA is evidenced by the higher disease concordance among monozygotic twins compared with dizygotic twins (15% vs. 3.6%).<sup>83</sup> Also, relatives of individuals with RA are at increased risk for RA as well as for other connective tissue diseases. Several variant alleles of the *HLA-DRB1* gene appear to play primary roles in disease susceptibility.<sup>84</sup>

### Clinical Manifestations

**The onset of RA is often insidious, with the gradual development of symmetric peripheral polyarthritis and morning stiffness. Involvement of the metacarpophalangeal and proximal interphalangeal joints is characteristic, and significant deformity of these joints may become apparent as the disease progresses.** Systemic symptoms occur commonly and include fatigue, weakness, weight loss, and malaise. Rheumatoid nodules develop in 20% to 30% of patients. These local proliferations of small vessels, fibroblasts, and histiocytes within the subcutaneous tissue occur most commonly on pressure points such as the extensor surfaces of the forearms; they may be painful and may interfere with joint and nerve function. Treatment involves local injections of glucocorticoids and an anesthetic and, in rare cases, surgical excision. A minority of patients with RA develop extraarticular manifestations that include pleuritis, pericarditis, neuropathy, vasculitis, scleritis, and renal disease.

### Diagnosis

In 2010, the ACR, in collaboration with the European League Against Rheumatism, released revised classification criteria for RA (Table 46-4).<sup>85</sup> These new diagnostic criteria represent a shift in focus to the early features of RA that are most predictive of later erosive disease. **“Definite” RA is based on confirmed synovitis in at least one joint, absence of another cause for the synovitis, and a score of at least 6 out of 10 on a standardized assessment in four clinical domains: (1) degree of joint involvement; (2) serologic testing; (3) response from acute phase reactants; and (4) duration of symptoms.**

Seventy to eighty percent of patients with RA test positive for rheumatoid factor (RF) antibodies. RF immunoglobulins are produced from B cells stimulated by CD4+ T-cell cytokines. These CD4+ T cells are activated by unknown antigens and play a key role in the inflammatory damage seen in RA. **However, RF antibodies are somewhat nonspecific because 5% to 10%**

TABLE 46-4

2010 AMERICAN COLLEGE OF RHEUMATOLOGY/EUROPEAN LEAGUE AGAINST RHEUMATISM CLASSIFICATION CRITERIA FOR RHEUMATOID ARTHRITIS

| TARGET POPULATION   | SCORE |
|---|-------|
| 1. Patients with at least one joint with definite clinical synovitis (swelling)   |       |
| 2. Patients with synovitis not better explained by another disease  |       |
| <b>CLASSIFICATION CRITERIA</b>  |       |
| (Score-based algorithm: Add score of categories A through D; a score of 6 out of 10 or greater is needed for classification of definite RA) |       |
| <b>A. Joint involvement</b>   |       |
| 1 large joint   | 0     |
| 2 to 10 large joints  | 1     |
| 1 to 3 small joints (with or without involvement of large joints)   | 2     |
| 4 to 10 small joints (with or without involvement of large joints)  | 3     |
| More than 10 joints (at least one small joint)  | 5     |
| <b>B. Serology</b> (at least one test result is needed for classification)  |       |
| Negative RF and negative ACPA   | 0     |
| Low-positive RF or low-positive ACPA  | 2     |
| High-positive RF or high-positive ACPA  | 3     |
| <b>C. Acute-phase reactants</b> (at least one test result is needed for classification)   |       |
| Normal CRP and normal ESR   | 0     |
| Abnormal CRP or normal ESR  | 1     |
| <b>D. Duration of symptoms</b>  |       |
| Less than 6 weeks   | 0     |
| At least 6 weeks  | 1     |

Modified from Aletaha D, Neogi T, Silman AJ, et al. 2010 Rheumatoid arthritis classification criteria: an American College of Rheumatology/European League Against Rheumatism collaborative initiative. *Arthritis Rheum.* 2010;62:2569-2581.

ACPA, anticitrullinated protein antibody; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; RA, rheumatoid arthritis; RF, rheumatoid factor.

**of the general, healthy population will test positive for RF.** Furthermore, RF may be detected in the setting of certain viral infections and in other autoimmune conditions such as SLE and Sjögren syndrome. Antibodies to citrullinated peptides/proteins (ACPAs) have better specificity for RA and sensitivity similar to that of RF. The laboratory evaluation for RA also includes testing of acute phase reactants such as C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR). Elevations in CRP and ESR suggest an aberrant inflammatory response. Patients with RA frequently also have anemia, thrombocytosis, leukocytosis, and a positive antinuclear antibody (ANA).

### Pregnancy Considerations

**The majority of women, perhaps as many as 80% to 90%, experience some improvement in their RA symptoms during pregnancy, although only approximately 50% have more than moderate improvement.** Improvements in joint pain and stiffness generally begin in the first trimester and persist through several weeks postpartum. Women who experience symptom improvement in one pregnancy will usually observe similar improvements in subsequent pregnancies. **Most women who experience an improvement in symptoms during pregnancy will relapse postpartum, typically in the first 3 months. It does not appear that pregnancy has any significant effects on the long-term course of RA.**

RA patients have been shown to have functionally defective regulatory T cells (T<sub>REGS</sub>), critical inhibitors of autoimmunity that suppress CD4+ and CD8+ T-cell cytokine production and B-cell immunoglobulin production. The generally favorable

course of RA in pregnancy may be related to the normal increase in circulating  $T_{REGS}$  that occurs during pregnancy. Hormonal changes may also modulate RA disease activity. Many women experience improvement in RA symptoms during the luteal phase of the menstrual cycle, when progesterone levels are highest.

**Not only do RA symptoms usually improve during pregnancy, but RA disease activity does not appear to significantly impact pregnancy outcomes.** Women with RA typically have uneventful pregnancies without increased risks for PTB, preeclampsia, or IUGR. Certain antirheumatic medications, however, are associated with increased pregnancy risks. **Disease activity and medication use should ideally be assessed during a preconceptional visit.**

## Antirheumatic Drugs

### Drugs With Acceptable Risk Profiles in Pregnancy

The use of NSAIDs, glucocorticoids, and HCQ in pregnancy were discussed in the section on [SLE](#).

### SULFASALAZINE

Sulfasalazine (FDA category B) is a combination of a sulfa antibiotic and salicylate. Most of the data regarding safety in pregnancy come from women with inflammatory bowel disease. Although sulfasalazine and its metabolite sulfapyridine cross the placenta, large studies have not found an increase in congenital malformations with use in pregnancy.<sup>86</sup> Because sulfasalazine acts as a dihydrofolate reductase inhibitor, it is recommended that women considering pregnancy take at least 0.4 mg of folic acid daily. **Sulfasalazine is compatible with breastfeeding.**

### Drugs with Uncertain or Higher Risk Profiles in Pregnancy

#### TUMOR NECROSIS FACTOR- $\alpha$ INHIBITORS

Several TNF inhibitors (all FDA category B) are used for the long-term control of RA. These include infliximab, etanercept, adalimumab, certolizumab, and golimumab. Inhibition of TNF- $\alpha$  increases circulating  $T_{REG}$  cells and restores their capacity to inhibit cytokine production. All of the TNF inhibitors except certolizumab are transferred across the placenta. Animal studies of infliximab, adalimumab, and certolizumab have not demonstrated an increase in congenital anomalies. An association between TNF inhibitors and fetal vertebral anomalies, anal atresia, cardiac defects, tracheoesophageal fistula, esophageal atresia, renal anomalies, and limb dysplasia (VACTERL) syndrome has been reported,<sup>87</sup> but a subsequent study from a European congenital malformation database did not confirm these findings.<sup>88</sup> Indeed, published experience with hundreds of pregnancies exposed to TNF inhibitors suggests that these agents are not teratogenic and are not associated with adverse pregnancy outcomes. Proceedings of the ACR Reproductive Health Summit stated that **although human data are somewhat limited, “TNF inhibitors are considered to be compatible with pregnancy.”** Some providers recommend avoiding TNF inhibitors in the third trimester in order to limit early postnatal exposure, but this should be weighed against the risk of an increase in disease activity without treatment. Small amounts of etanercept, infliximab, and adalimumab have been reported in breast milk, although it is uncertain whether this poses a risk to the neonate. **The choice to breastfeed while taking TNF inhibitors should be made after a thorough discussion of potential risks and benefits.**

## BIOLOGIC AGENTS

This continually expanding class of agents includes anakinra (interleukin-1 receptor antagonist, FDA category B), rituximab (chimeric monoclonal antibody leading to B-cell depletion, FDA category C), abatacept (inhibitor of T-cell co-stimulation, FDA category C), and tocilizumab (interleukin-6 receptor inhibitor, FDA category C). **These drugs may be used to treat autoimmune disease not sufficiently controlled with traditional therapies, but data regarding the use of these medications in pregnancy are extremely limited.** Case reports in humans generally suggest little fetal risk.<sup>89-91</sup> According to the manufacturer, when given to monkeys during organogenesis, tocilizumab caused abortion (embryo or fetal death) at doses just above those used in humans. Rituximab treatment later in pregnancy can cause B-cell lymphocytopenia in the neonate that persists for several months.<sup>92</sup> Given the overall relatively limited experience with these medications in pregnancy, **it is prudent to avoid their use unless the woman is refractory to other therapies and the severity of disease warrants continuation.** Likewise, the safety of breastfeeding while taking these medications is unknown. **Patients who choose to breastfeed should do so only after a thorough discussion of potential risks and benefits.**

### Drugs Contraindicated in Pregnancy

#### METHOTREXATE

Methotrexate (MTX, FDA category X) is a folate antagonist used for long-term, maintenance immunosuppression in patients with autoimmune conditions, including SLE and RA. **MTX is an abortifacient in early pregnancy and a potent teratogen associated with craniofacial anomalies, neural tube defects, abnormal facies, and neurodevelopmental delay.** The greatest risks are with exposure prior to 10 weeks, with one study reporting a 9% rate of congenital anomalies and a 25% risk of miscarriage.<sup>45</sup> The drug is widely distributed in maternal tissues and may persist for up to 4 months in the liver. **All reproductive-aged women taking MTX should be warned of its teratogenic risks and advised to remain on effective contraception.** For those considering pregnancy, conception should be delayed for at least three menstrual cycles after discontinuation of MTX. **MTX is found in low levels in breastmilk and is considered contraindicated in breastfeeding.**

#### LEFLUNOMIDE

Some patients with RA are treated with leflunomide, an FDA category X disease-modifying antirheumatic drug (DMARD). Leflunomide is sometimes also used to treat lupus-related skin manifestations. The drug's mechanism of action is inhibition of dihydroorotate dehydrogenase, an enzyme necessary for pyrimidine biosynthesis. **Leflunomide is teratogenic in humans and is absolutely contraindicated in pregnancy.** In a recent report, 2 of 16 exposed offspring had major anomalies and 3 had minor anomalies.<sup>93</sup> The major metabolite (teriflunomide) is detectable in the serum of patients for up to 2 years after discontinuation of the drug. Patients on leflunomide should be counseled to avoid pregnancy until serum drug levels are less than 0.02 mg/L on two tests performed 2 weeks apart. This may take up to 2 years. Drug elimination can be hastened by administering cholestyramine (8 g orally three times daily for 11 days) with follow-up of serum drug levels to assure elimination. **No data are available regarding leflunomide and breastfeeding, and it is considered contraindicated.**

## Management of Pregnancies Complicated by Rheumatoid Arthritis

Because the majority of women with RA have improvement in their disease during pregnancy, many can discontinue their anti-rheumatic drugs. **Mild to moderate joint pain can usually be managed with acetaminophen or low-dose glucocorticoids.** Physical therapy may be helpful in some cases. **No alterations to routine prenatal care are necessary for women with mild, uncomplicated RA.** Routine serial ultrasounds to assess fetal growth and antenatal testing are unnecessary. **Because the risk of postpartum disease exacerbation is high, it is important to assess symptoms at postpartum visits and to arrange appropriate follow-up with rheumatology.** Some experts recommend reinitiating antirheumatic drug treatment after delivery in all women with RA, regardless of disease activity.

## SYSTEMIC SCLEROSIS

Systemic sclerosis (SSc), or systemic scleroderma, is a heterogeneous autoimmune disorder characterized by small vessel vasculopathy, the presence of characteristic autoantibodies, and fibroblast dysfunction that leads to increased extracellular matrix deposition and progressive fibrosis of the skin and visceral tissues. The small vessel vasculopathy manifests most commonly as Raynaud phenomenon and in severe cases as renal crisis. SSc is rare and occurs in only 1 to 2 per 100,000 individuals in the United States annually. Similar to other autoimmune disorders, it is more common in women than in men. But in contrast to SLE, **SSc is infrequently encountered in pregnancy because the peak age of onset is in the fifth decade.**

## Clinical Manifestations

Early symptoms of SSc include subcutaneous swelling with muscle and joint pain, and more than 90% of patients will experience Raynaud phenomenon. When combined with skin thickening, Raynaud phenomenon is specific for SSc; however, the phenomenon also occurs in 5% of the general population, and thus will frequently be seen by obstetricians.

Two main subsets of SSc have been recognized: *diffuse cutaneous SSc* usually involves cutaneous fibrosis of the forearms and is associated with a greater risk for serious internal organ manifestations such as renal crisis, pulmonary fibrosis, and myocardial fibrosis; *limited cutaneous SSc* involves fibrosis of the distal extremities and face and is associated with digital ulcerations. CREST syndrome—calcinosis of the skin, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias—falls under this latter category.

**The most frequent visceral symptoms of SSc are heartburn and dysphagia related to esophageal dysmotility.** Involvement of the lower gastrointestinal tract can lead to malabsorption, diarrhea, and constipation. Cardiopulmonary manifestations (i.e., pulmonary hypertension, cardiac arrhythmias) are of particular concern in pregnancy.

Renal involvement is usually mild, but 10% to 20% of patients with diffuse disease will develop renal crisis, which manifests as acute onset of severe hypertension, progressive renal insufficiency, and hemolytic anemia. Renal crisis results in progression to end-stage renal disease in a significant proportion of affected individuals and is a major cause of mortality in SSc patients.

## Diagnosis

The ACR and European League Against Rheumatism released classification criteria for SSc in 2013.<sup>94</sup> These criteria were primarily designed to identify SSc patients for inclusion in studies. Because significant clinical heterogeneity exists among SSc patients, it should be noted that some individuals might not meet these strict diagnostic criteria. According to these criteria, **the presence of skin thickening of the fingers extending proximal to the metacarpophalangeal joints is sufficient for the diagnosis of SSc.** The diagnosis is supported by visceral organ involvement and the presence of certain autoantibodies. **Most patients with SSc have a positive ANA.** Antitopoisomerase I, anticentromere, and anti-RNA polymerase III antibodies are highly specific for SSc but have only moderate sensitivity.<sup>95</sup> Individuals with SSc may also be positive for aPL.

## Pregnancy Considerations

Because pregnancy in women with SSc is uncommon, relatively few data are available regarding the impact of pregnancy on the disease and the risk of pregnancy complications. **If SSc is clinically stable at the onset of pregnancy and the woman is without obvious renal, cardiac, or pulmonary disease, maternal outcomes are generally good.** Raynaud phenomenon may improve in pregnancy related to greater vasodilation, although gastrointestinal manifestations related to esophageal dysmotility may become more prominent. The risk for renal crisis during pregnancy is probably not increased for women without preexisting kidney disease, but distinguishing this complication from preeclampsia may be challenging. In the case of renal crisis, the urine sediment is either normal or shows only mild proteinuria with few cells or casts. **Hemolytic-uremic syndrome** can also have a similar presentation to SSc renal crisis and should be part of the differential diagnosis, particularly in postpartum patients. Some authors have reported that women with SSc have an increased risk of spontaneous abortion both before and after their diagnosis.<sup>96,97</sup> Other studies have not confirmed these findings,<sup>98</sup> although women with late, diffuse SSc probably do have a higher rate of miscarriage.<sup>98</sup>

**PTB is more common among women with SSc, particularly those with diffuse disease.<sup>98</sup> The risks for preeclampsia and IUGR are threefold higher among women with SSc when compared with the general population,** likely related to the vascular pathology of the disease and frequent renal involvement.<sup>99</sup> One of the largest published series found that pregnancies in women with SSc, compared with the general obstetric population, were significantly more likely to be complicated by PTB (25% vs. 12%) and IUGR (6% vs. 1%).<sup>100</sup> Indeed, PTBs among women with SSc are usually indicated, rather than spontaneous, due to hypertensive complications and IUGR.

## Management of Pregnancies Complicated by Systemic Sclerosis

**Preconceptional counseling is critical for women with SSc.**

Those with diffuse, progressive disease and significant cardiac, pulmonary, or renal involvement are at particularly high risk for adverse maternal and fetal outcomes. **Women should be evaluated for pulmonary hypertension, which is a contraindication to pregnancy.** Active renal disease increases the risk for crisis during pregnancy with the accompanying risks of end-stage renal disease and mortality.

Even among nonpregnant individuals, the treatment of SSc is challenging and noncurative. Treatment of diffuse disease is

typically organ specific. Symptomatic relief of arthralgias and myalgias should be limited to acetaminophen or low-dose glucocorticoids if possible. Ultraviolet light therapy, topical glucocorticoids, and vitamin D analogues may be used to treat cutaneous manifestations. Many women take proton pump inhibitors (FDA category C) for upper gastrointestinal symptoms, and they can be continued in pregnancy because data do not suggest significant fetal risks. Raynaud phenomenon is often treated with oral vasodilators, in particular calcium channel blockers (CCBs). Although definitive proof of fetal safety is lacking, CCBs are FDA category C drugs and are probably safe to continue in pregnancy. Avoidance of cold, stress, nicotine, caffeine, and sympathomimetic decongestants may also improve Raynaud symptoms.

**Renal crisis is specifically treated with angiotensin-converting enzyme (ACE) inhibitors.** Although these agents are usually contraindicated in pregnancy because of risks of teratogenicity and effects on fetal renal function, **SSc renal crisis carries such a high risk of morbidity and mortality that the use of an ACE inhibitor in pregnancy may be justified in this specific circumstance.** In patients with renal crisis, intensive care admission with continuous fetal monitoring may be indicated. Many patients will also require dialysis. Decisions regarding delivery should be guided by maternal stability and prognosis, gestational age, and results of fetal monitoring.

**No evidence-based guidelines have been established for prenatal care in women with SSc.** Clinicians should have a low threshold to investigate any new and unusual symptoms, especially as they might relate to visceral organ involvement. **Particular attention should be paid to those women with diffuse disease, and an increase in the frequency of prenatal visits to every 1 to 2 weeks is prudent.** Women should be closely monitored for preeclampsia because SSc appears to increase this risk. Serial ultrasounds after 18 to 20 weeks to assess fetal growth and antenatal testing at 30 to 32 weeks are also reasonable.

Delivery among women with advanced skin disease may be complicated by poor wound healing. Some women will be at increased anesthetic risk because of problems with IV access, difficult intubation, and increased risk for aspiration. **Among those with diffuse and severe disease, a multidisciplinary approach with rheumatology, anesthesiology, and even nephrology, cardiology, or pulmonology** (depending on the specific organs involved) **is recommended. Intensive care management may even be necessary in some cases.**

## SJÖGREN SYNDROME

**Sjögren syndrome (SS) is a chronic autoimmune disorder characterized by decreased lacrimal and salivary gland function, which leads to dry eyes and dry mouth.** Extraglandular manifestations commonly include fatigue, arthralgias, myalgias, and Raynaud phenomenon. Less common extraglandular manifestations include interstitial lung disease, dysphagia, liver function abnormalities, nephritis, central and/or peripheral nervous system manifestations, and an increased risk for lymphoma in the long term. SS occurs in a primary form and in a secondary form associated with other autoimmune conditions, primarily SLE and RA. **Pregnancy outcomes among women with SS are similar to those without the disease. However, women with SS may be positive for anti-Ro/SSA antibodies, with the accompanying risks for NLE and CHB.**

## KEY POINTS

- ◆ SLE is the most common serious autoimmune disease that affects women of reproductive age.
- ◆ SLE disease activity at the onset of pregnancy is the most important determinant of the course of the disease in pregnancy.
- ◆ Women with SLE should be counseled to postpone pregnancy until a sustained remission for at least 6 months has been achieved.
- ◆ For women with lupus nephritis, moderate renal insufficiency (serum creatinine 1.5 to 2 mg/dL) is a relative contraindication to pregnancy, and advanced renal insufficiency (creatinine >2 mg/dL) should be considered an absolute contraindication to pregnancy.
- ◆ The risk for NLE, and in particular CHB, in fetuses or neonates of women with SLE is low. The highest-risk group for CHB is seen in women with anti-Ro/SSA or anti-La/SSB antibodies and a prior affected child (15% to 20% recurrence).
- ◆ Women with SLE who become pregnant on hydroxychloroquine should generally continue this medication because it may decrease the risk of disease flares.
- ◆ The diagnosis of APS is incumbent upon either arterial or venous thrombosis or obstetric morbidity and repeatedly positive testing for lupus anticoagulant and/or medium to high titers of anticardiolipin or anti-B2-glycoprotein I IgG or IgM antibodies.
- ◆ All women with APS and prior thrombosis should receive full anticoagulation during pregnancy and postpartum.
- ◆ Pregnant women with an APS diagnosis based upon recurrent early miscarriage without prior thrombosis should receive either low-dose aspirin alone or combined with a prophylactic dose of heparin.
- ◆ Pregnant women with an APS diagnosis based upon fetal death, early preeclampsia, or placental insufficiency and without prior thrombosis should generally receive low-dose aspirin combined with prophylactic heparin.
- ◆ Most women with rheumatoid arthritis will experience an improvement in symptoms during pregnancy, but the risk for postpartum relapse is high.
- ◆ Women with systemic sclerosis generally have favorable pregnancy outcomes but should be carefully assessed for visceral organ (i.e., renal, cardiac, or pulmonary) involvement.

| Transjugular intrahepatic portosystemic shunt     | TIPS  |

Hepatic, biliary, and pancreatic disorders are relatively uncommon but are not rare during pregnancy. For example, during pregnancy about 3% of women develop serum liver function test abnormalities,<sup>1</sup> and about 1 in 500 develop potentially life-threatening hepatic diseases that endanger fetal viability.<sup>2,3</sup>

Hepatic, biliary, and pancreatic disorders are often complex and clinically challenging problems during pregnancy. First, the differential diagnosis during pregnancy is extensive and includes both disorders related and unrelated to pregnancy. Second, the clinical presentation and natural history of these disorders may be altered during gestation. Indeed, some disorders—such as intrahepatic cholestasis of pregnancy—are unique to gestation. Third, the diagnostic evaluation may need to be slightly altered because of pregnancy. Nonetheless, almost all radiologic tests can be done judiciously to maintain fetal safety. Fourth, **the interests of both the mother and the fetus must be considered in therapeutic decisions. Usually these interests do not conflict, because generally, what is good for the mother is good for the fetus.** Sometimes, however, maternal therapy must be modified to substitute alternative but safer therapy because of concerns about drug teratogenicity.<sup>4</sup> Rarely, maternal and fetal interests are diametrically opposed, as in the use of chemotherapy for maternal cancer, a therapy that is potentially life-saving to the mother but dangerous to the fetus.<sup>5</sup> These conflicts raise significant medical, legal, and ethical issues.

Obstetricians, hepatologists, surgeons, and internists should be familiar with hepatic, biliary, and pancreatic disorders that can present in pregnancy and how these conditions affect and are affected by pregnancy. This chapter reviews these conditions with a focus on features unique to pregnancy.

## PHYSIOLOGIC EFFECTS OF PREGNANCY AND ASSESSMENT OF LIVER DISEASE

Abdominal assessment is modified during pregnancy. The expanding gravid uterus can displace abdominal viscera and may conceal an abdominal mass on physical examination.<sup>5</sup> During the first and second trimesters of pregnancy, blood pressure normally declines modestly. A rise in blood pressure during pregnancy may, therefore, portend preeclampsia or eclampsia. Physiologic alterations of laboratory values during pregnancy include mild leukocytosis, physiologic anemia of pregnancy, and electrolyte changes, particularly mild hyponatremia<sup>6</sup> (see Chapter 3). The risk of thromboembolic phenomena is increased during pregnancy because of mild hypercoagulopathy from hyperestrogenemia and vascular stasis from vascular compression by the enlarged gravid uterus.<sup>7</sup> The changes in serum glucose levels during pregnancy are complex. Normal pregnancy is characterized by fasting hypoglycemia, postprandial hyperglycemia, and hyperinsulinemia.<sup>8</sup> Meticulous control of the serum glucose level is important in diabetic patients for proper fetal development.

Pregnancy does not affect the liver span. The liver may be pushed cephalad by the gravid uterus, but a liver span greater than 12 cm, when appreciated, remains a valid indicator of hepatomegaly. **Spider angiomas and palmar erythema, cutaneous lesions often associated with chronic liver disease, may appear transiently during normal pregnancy without underlying liver disease, presumably because of hyperestrogenemia during pregnancy.**<sup>9</sup> During pregnancy, the serum alkaline phosphatase level normally increases mildly as a result of placental synthesis; the serum albumin level also declines, primarily from hemodilution and secondarily from decreased hepatic synthesis. Serum bilirubin levels tend to change little during pregnancy because of the effect of mildly impaired hepatic excretion balanced by the opposing effects of hemodilution and hypoalbuminemia.<sup>10</sup> Serum bile acids tend to mildly increase during gestation because of impaired hepatic transport and biliary secretion. Serum levels of cholesterol, triglycerides, and phospholipids increase moderately during pregnancy as a result of increased hepatic synthesis.<sup>11</sup> The serum aminotransferase levels are largely unaffected by pregnancy. Changes of serum levels of common blood tests during pregnancy are summarized in Box 47-1 (see Appendix I, “Normal Values in Pregnancy”).

## DIFFERENTIAL DIAGNOSIS OF HEPATOBILIARY SYMPTOMS AND CONDITIONS DURING PREGNANCY

### Maternal Jaundice

As in the general population, acute viral hepatitis is the most common cause of jaundice during pregnancy.<sup>2,3</sup> The differential diagnosis of jaundice during the first and second trimesters of pregnancy also includes drug hepatotoxicity and gallstone disease such as acute cholecystitis, choledocholithiasis, ascending cholangitis, or gallstone pancreatitis. In addition to these disorders, the differential of jaundice during the third trimester includes pregnancy-related causes such as

### BOX 47-1 CHANGES IN ROUTINE LABORATORY TESTS AND LIVER FUNCTION TESTS DURING PREGNANCY

#### Mildly Decreased Serum Levels

- Sodium
- Albumin

#### Moderately Decreased Blood Level

- Hematocrit: physiologic anemia of pregnancy

#### Mildly Increased Blood or Serum Levels

- Leukocyte count
- Alkaline phosphatase
- Amylase

#### Moderately Increased Serum Levels

- Serum bile acids
- Cholesterol
- Triglycerides

#### Other

- Glucose level: fasting hypoglycemia, postprandial hyperglycemia

intrahepatic cholestasis of pregnancy; acute fatty liver of pregnancy (AFLP); and hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome. Moderate direct hyperbilirubinemia without jaundice during the third trimester may also be due to preeclampsia, eclampsia, and Budd-Chiari syndrome. Predominantly indirect hyperbilirubinemia during pregnancy is usually due to hemolysis (including the HELLP syndrome) or Gilbert syndrome.

### Right Upper Quadrant Abdominal Pain

The differential diagnosis of right upper quadrant (RUQ) abdominal pain is extensive during pregnancy (Box 47-2). In addition to hepatic, biliary, gastrointestinal (GI), and renal disorders that can occur in nonpregnant patients, the differential includes diseases related to pregnancy. In the medical history, the pain intensity, nature, temporal pattern, radiation pattern, exacerbating factors, and alleviating factors help narrow the differential diagnosis. **Biliary colic** produces a waxing and waning intensity of pain. **Acute cholecystitis** is associated with RUQ pain and pain referred to the right shoulder. The pain of **acute pancreatitis** is often boring in quality, located in the abdominal midline, and radiating to the back. Careful physical examination of the abdomen that includes inspection, palpation, and auscultation can further pinpoint the cause of the pain. **Laboratory evaluation of significant abdominal pain routinely includes a complete blood count (CBC), serum electrolytes, and liver function tests (LFTs) as well as a leukocyte differential, coagulation profile, and serum lipase determination.** In evaluating the laboratory results, gestational changes in normative values, as mentioned earlier, must be considered. Radiologic tests may be extremely helpful diagnostically, but the choice of radiologic imaging is constrained by the pregnancy, as discussed below. **RUQ pain and abnormal LFTs in the setting of new-onset hypertension should strongly suggest preeclampsia with hepatic involvement.** RUQ pain and abnormal LFTs in the setting of thrombocytopenia and microangiopathic hemolysis, as demonstrated by the presence of schistocytes in a peripheral blood smear, should strongly suggest the HELLP syndrome.

**BOX 47-2 DIFFERENTIAL DIAGNOSIS OF RIGHT UPPER QUADRANT ABDOMINAL PAIN DURING PREGNANCY****Hepatic Disorders**

- Hepatitis
- Hepatic vascular engorgement
- Hepatic hematoma
- Hepatic malignancy

**Biliary Tract Disease**

- Biliary colic
- Choledocholithiasis
- Cholangitis
- Cholecystitis

**Diseases Related to Pregnancy**

- Preeclampsia or eclampsia
- Hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome
- Acute fatty liver of pregnancy
- Hepatic hemorrhage or rupture

**Renal Disorders**

- Pyelonephritis
- Nephrolithiasis

**Gastrointestinal Disorders**

- Peptic ulcer disease
- Perforated duodenal ulcer

**Other Conditions**

- Rib fracture
- Shingles

**Referred Pain From Another Disease**

- Pneumonia
- Pulmonary embolus or infarct
- Pleural effusion
- Radiculopathy
- Inferior wall myocardial infarction
- Colon cancer

Occasionally, the pregnancy is not known by the patient or is not revealed to the physician, particularly in early pregnancy, when physical findings are absent. The physician should be vigilant for possible pregnancy in a fertile woman with abdominal pain, particularly in the setting of missed menses, because pregnancy affects the differential diagnosis, clinical evaluation, and mode of therapy. Pregnancy tests should be performed early in the evaluation of acute abdominal pain in a fertile woman.

**Nausea and Vomiting**

Nausea and vomiting may be ubiquitous during pregnancy, and nausea and vomiting of pregnancy (NVP) is the most common cause (see [Chapter 6](#)). It typically begins at about 6 weeks and abates at about 18 weeks<sup>12</sup> and is caused by the physiologic effects of the pregnancy without demonstrable mucosal or mural disease. **Hyperemesis gravidarum (HG) is a serious and potentially life-threatening form of NVP associated with loss of more than 5% of the pregravid weight.** HG is a diagnosis of exclusion, based on nausea and vomiting that occur early in pregnancy and that gradually resolve during the middle second trimester and unassociated with other symptoms. **The differential diagnosis of nausea and vomiting during pregnancy also includes hepatic and pancreatobiliary diseases such as**

**pancreatitis, viral hepatitis, symptomatic cholelithiasis, acute cholecystitis, AFLP, and occasionally intrahepatic cholestasis of pregnancy.** GI causes include gastroesophageal reflux disease (GERD), peptic ulcer disease, viral gastroenteritis, appendicitis, gastroparesis diabeticorum, and GI obstruction. Other causes include adnexal torsion, pyelonephritis, urolithiasis, and Addison disease (glucocorticoid deficiency).

**Pruritus**

The differential diagnosis of pruritus during pregnancy includes intrahepatic cholestasis of pregnancy, cholestatic viral hepatitis, primary sclerosing cholangitis, primary biliary cirrhosis, and mechanical choledochal obstruction from benign or malignant strictures. Pruritus sometimes occurs physiologically during pregnancy; this pruritus is typically mild, localized, unassociated with other symptoms, and unassociated with abnormal liver function tests (see [Chapter 50](#)). **Important clues that pruritus may be due to the intrahepatic cholestasis of pregnancy include pruritus that begins during the third trimester of pregnancy with no history of chronic liver disease, absence of abdominal pain, pruritus that affects mostly the hands and feet, and only mild to moderately elevated serum transaminase and bilirubin levels.**

**Hepatic Lesions**

Hepatic lesions identified on abdominal imaging studies are classified as cystic or solid. The differential of cystic hepatic lesions includes simple hepatic cysts, hepatic cysts associated with polycystic kidney disease, Caroli disease (a rare inherited disorder characterized by dilation of the intrahepatic bile ducts), bacterial abscesses, amebic abscesses, intraparenchymal hemorrhage, hemangiomas, echinococcal cysts, and rarely hepatic malignancies. The differential of a solid hepatic mass includes hepatic adenoma, focal nodular hyperplasia, hepatocellular carcinoma, and hepatic metastases.

**Ascites**

Hepatic causes of ascites during pregnancy include cirrhosis, AFLP, Budd-Chiari syndrome, portal vein thrombosis, hepatic fibrosis, and hepatocellular carcinoma. Other causes of ascites during pregnancy include ovarian cancer, abdominal tuberculosis, cardiac failure, protein-losing nephropathy, and severe protein malnutrition (kwashiorkor).

**Neonatal Cholestasis**

Neonatal cholestasis is characterized by conjugated hyperbilirubinemia, pale stools, and dark urine. The differential includes neonatal prematurity; anatomic anomalies such as biliary atresia; infections such as cytomegalovirus or toxoplasmosis; and metabolic defects such as cystic fibrosis, alpha 1 antitrypsin deficiency, or bile acid synthetic defects. Neonates frequently have unconjugated (indirect) hyperbilirubinemia or physiologic jaundice due to increased production and decreased clearance of bilirubin. The bilirubin may peak at 7 mg/dL several days after birth but rapidly normalizes within about 1 week thereafter. Unconjugated neonatal hyperbilirubinemia may also be due to hemolysis, sepsis, or Gilbert syndrome.

**ABDOMINAL IMAGING DURING PREGNANCY**

Fetal safety during diagnostic imaging is a concern for pregnant patients. Ultrasonography is considered safe and is the

**preferred abdominal imaging modality during pregnancy.**<sup>13</sup> Unfortunately, the test sensitivity depends on operator technique, patient cooperation, and patient anatomy. For example, test sensitivity is decreased by abdominal fat and intestinal gas.<sup>13</sup> **No reported harmful effects result from magnetic resonance imaging (MRI) during pregnancy,** but few data are available on safety during the first trimester or with use of gadolinium.<sup>14</sup> However, **gadolinium has not been associated with adverse fetal outcomes in a number of individual case reports or in limited case series.** MRI is preferable to computed tomography (CT) scanning during pregnancy to avoid ionizing radiation, but gadolinium administration should be avoided during MRI in the first trimester.<sup>15</sup> Rapid-sequence MRI is preferable to conventional MRI because of briefer exposures.

Radiation can cause fetal mortality, growth restriction, chromosomal mutations, and neurologic abnormalities that include mental retardation, and they increase the risk of childhood leukemia (see Chapter 8).<sup>16</sup> Radiation dosage is the most important risk factor, but fetal age at exposure is also important. Fetal mortality is greatest from radiation exposure during the first 2 weeks after conception, and the risk of neurologic malformations is greatest during the first trimester, when organogenesis occurs.<sup>16</sup> The patient should undergo counseling before diagnostic roentgenography. Exposure to more than 15 rads during the second and third trimesters or more than 5 rads during the first trimester should prompt consideration of termination of pregnancy.<sup>16</sup> **Diagnostic studies with high radiation exposure, such as abdominal CT, typically expose the fetus to less than 1 rad and should therefore be considered when indicated.**<sup>15</sup> The physician ordering a roentgenographic study can consult with a medical physicist to estimate the fetal exposure. Fetal radiation exposure should be minimized by shielding the abdomen above the uterus and using narrow collimation and rapid-sequence studies. When performing abdominal CT scans with contrast, precontrast films can be reduced or eliminated to reduce radiation exposure.

## THERAPEUTIC ENDOSCOPY DURING PREGNANCY

### Therapeutic Endoscopic Retrograde Cholangiopancreatography

**Cholelithiasis usually requires urgent therapy because of potentially life-threatening ascending cholangitis or gallstone pancreatitis. Symptomatic cholelithiasis is best managed by therapeutic endoscopic retrograde cholangiopancreatography (ERCP) in the nonpregnant patient to avoid complex biliary surgery during cholecystectomy.** In experienced hands, therapeutic ERCP in the general population has acceptable morbidity of about 5% and low mortality of about 0.5%.<sup>17</sup> Therapeutic ERCP is theoretically more attractive than biliary surgery for cholelithiasis during pregnancy because surgery entails a significant risk of fetal loss.<sup>18</sup> Aside from maternal risks, therapeutic ERCP during pregnancy entails theoretic risks to the fetus from induction of premature labor, medication and radiation teratogenicity, placental abruption or fetal trauma during endoscopic intubation, cardiac arrhythmias, systemic hypotension, and transient hypoxia.<sup>17</sup>

A literature review of about 350 cases of ERCP during pregnancy noted three larger studies that encompassed over 100 patients in total and numerous small case series or individual case reports.<sup>19</sup> Almost all pregnant patients in all these studies

required therapeutic intervention, mostly for choledocholithiasis. The outcome after ERCP was favorable in the three larger studies in terms of maternal health, maintenance of pregnancy, and eventual fetal outcome.<sup>19</sup> Complications included maternal pancreatitis in 5% to 16%, one spontaneous abortion 3 months after ERCP, one neonatal demise 26 hours after delivery, and a prematurity rate of 8%.<sup>19</sup> These relatively favorable results were confirmed in the review of the rest of the approximately 350 cases. Although the individual studies were generally flawed because of small study size, retrospective design, and limited follow-up after delivery, the consistency of the favorable results across so many studies argues forcefully that **ERCP is justifiable during pregnancy for appropriate indications and contemplated therapeutic intervention.** These results have been further confirmed in additional individual studies<sup>20,21</sup> and literature reviews.<sup>22</sup> In particular, **therapeutic ERCP can be performed during pregnancy to help avoid complex biliary surgery or to postpone cholecystectomy until after parturition.** Special precautions to minimize fetal risks from ERCP during pregnancy include consideration for consultation with a neonatologist, radiation physicist, and anesthesiologist before ERCP; referral to a tertiary medical center for management by a team of experts; lead shielding of the mother's abdomen except for the region of the proximal pancreas and biliary tree; use of a modern fluoroscope to minimize radiation leakage; avoidance of spot radiographs for documentation because they require considerable radiation energy; and, if possible, delay ERCP until the second trimester to reduce radiation teratogenicity.<sup>17</sup>

### Endoscopic Variceal Sclerotherapy or Banding

**Pregnancy appears to increase the risk of variceal bleeding from portal hypertension because of the gestational increase in plasma volume.**<sup>23</sup> Endoscopic ligation (banding) or sclerotherapy are particularly attractive therapies for variceal bleeding during pregnancy because the alternative of transjugular intrahepatic portosystemic shunt (TIPS) requires radiation, and the surgical alternatives can cause fetal loss. Esophagogastroduodenoscopy (EGD) can be performed during pregnancy with relatively low fetal risks and should certainly be considered when strongly indicated, such as for acute upper GI hemorrhage.<sup>17,24</sup> **Endoscopic banding and sclerotherapy raise concerns beyond that of diagnostic EGD from the additional procedure time, the typically severe underlying maternal illness, and the therapy itself.** Variceal banding is preferred over sclerotherapy in the general (nonpregnant) population. Scant clinical data exist on variceal banding during pregnancy and comprise one small case series and individual case reports. These data suggest relatively favorable maternal and fetal outcomes after variceal banding compared with the poor prognosis in untreated patients.<sup>19</sup> More clinical data exist on **sclerotherapy** during pregnancy. In one clinical series, 10 patients underwent a mean of three endoscopic sclerotherapy sessions during pregnancy, five for active variceal bleeding and five for prophylaxis.<sup>25</sup> Hemostasis was achieved in all actively bleeding patients. One patient suffered a complication from sclerotherapy of an esophageal stricture, which was successfully treated using peroral esophageal dilators. All patients had a normal vaginal delivery at term.<sup>25</sup> Nine other patients successfully underwent endoscopic sclerotherapy for actively or recently bleeding esophageal varices with delivery of healthy infants in all cases.<sup>17</sup> One study reported less favorable pregnancy outcomes after endoscopic sclerotherapy, attributable to the underlying maternal disease.

**TABLE 47-1** CLINICAL PRESENTATION AND TREATMENT DURING PREGNANCY OF COMMON PANCREATIC DISORDERS MINIMALLY AFFECTED BY PREGNANCY

| DISEASE OR DISORDER                       | SYMPTOMS AND SIGNS  | LABORATORY FINDINGS  | TREATMENT   |
|---|---|--|---|
| Acute pancreatitis                        | Epigastric pain radiating to back, nausea and vomiting, pyrexia; abdominal tenderness, guarding, distension | Increased serum lipase, leukocytosis; abdominal ultrasound can reveal pancreatomegaly, peripancreatic inflammation, inhomogeneous pancreas   | Discontinue oral intake; provide aggressive IV hydration, analgesia, and nasojejunal feeding or TPN for a prolonged bout of pancreatitis                              |
| Acute cholecystitis                       | Epigastric or RUQ pain, nausea and vomiting, tachycardia, Murphy sign                                       | Leukocytosis, variably, mildly elevated LFTs; abdominal ultrasound shows a thickened gallbladder wall, pericholecystic fluid, gallstones in gallbladder                                    | Discontinue oral intake; provide IV hydration, analgesia, and antibiotics; cholecystectomy can be performed during pregnancy, most safely during the second trimester |
| Cholelithiasis with ascending cholangitis | RUQ pain, pyrexia, jaundice (Charcot triad); epigastric tenderness  | Leukocytosis, jaundice, variably elevated other LFTs; abdominal ultrasound shows dilated choledochus, possible gallstones in gallbladder; ERCP reveals dilated choledochus, cholelithiasis | Discontinue oral intake; provide IV hydration, antibiotics; ERCP with sphincterotomy may be performed during pregnancy to address cholelithiasis                      |

ERCP, endoscopic retrograde cholangiopancreatography; IV, intravenous; LFTs, liver function tests; RUQ, right upper quadrant; TPN, total parenteral nutrition.

Four of seventeen pregnant patients undergoing endoscopic sclerotherapy for variceal bleeding due to noncirrhotic portal hypertension had adverse pregnancy outcomes of stillbirth or neonatal death.<sup>26</sup> Still, **the available data should justify endoscopic therapy during pregnancy for actively bleeding esophageal varices, after informed consent, because of poor outcomes with the alternative available therapies.**

### Team Approach and Informed Consent

A team approach with consultation and referral helps optimize the management of complex diseases during pregnancy that affect both the mother and the fetus and that require disparate areas of expertise. The obstetrician may consult with the hepatologist regarding timing of delivery in patients with obstetric-related hepatic disease. The gastroenterologist contemplating therapeutic ERCP for symptomatic cholelithiasis may consult with the obstetrician about the optimal procedure timing and with the anesthesiologist about analgesia during endoscopy. The internist may discuss with the radiologist the benefits versus risks of radiologic tests, and the radiologist may in turn consult with a physicist about methods to monitor and reduce fetal radiation exposure. **Complex hepatic problems during pregnancy are best handled at a tertiary hospital with the requisite experience and expertise.**

The patient should be informed about the consequences to both herself and her fetus of diagnostic tests and therapy and should be actively involved in medical decisions. The patient makes the decision under the vigilant guidance of the experts and with input from her partner, family, and friends. When an intervention, such as roentgenographic tests, entails significant potential fetal risk, a signed, witnessed, and informed consent is recommended even though this intervention would be routine and would not require consent in a nonpregnant patient.

## PANCREATOBILIARY DISEASE

### Acute Pancreatitis

**Acute pancreatitis occurs in about 1 per 3000 pregnancies, most commonly during the third trimester.<sup>27,28</sup> Gallstones cause about 70% of cases because alcoholism is relatively uncommon during pregnancy.<sup>29,30</sup>** The risk of cholesterol stones is increased during pregnancy because of increased cholesterol secretion into bile.<sup>28</sup> Other causes include drugs, abdominal surgery, trauma, hyperlipidemia, hyperparathyroidism,

vasculitis, and infections such as mumps or mononucleosis.<sup>29</sup> The risk of pancreatitis from hyperlipidemia is increased during pregnancy because of the significant elevation of triglyceride levels during late pregnancy.<sup>31</sup> Some cases are idiopathic.

The clinical presentation, diagnostic tests, and treatment of pancreatobiliary disorders during pregnancy are summarized in **Table 47-1**. **Pregnancy does not significantly alter the clinical presentation of acute pancreatitis.<sup>29,30</sup> Epigastric pain is the most common symptom.** The pain commonly radiates to the back, and nausea, emesis, and pyrexia frequently occur. Signs include midabdominal tenderness, abdominal guarding, hypoactive bowel sounds, abdominal distension, and increased tympany. Severe cases are associated with shock and pancreatic ascites. Turner sign, bruising of the flanks, or Cullen sign, superficial edema and bruising around the umbilicus, suggest retroperitoneal bleeding.<sup>29,30</sup>

**Acute pancreatitis is diagnosed by finding typical abnormalities in two of the following three parameters: (1) clinical presentation, (2) laboratory tests, or (3) radiologic examinations. Typical symptoms of pancreatitis include epigastric or RUQ pain and nausea and vomiting. Serum lipase is a reliable marker of acute pancreatitis during pregnancy** because the lipase level is unchanged during normal pregnancy. The serum amylase level is a less specific marker of pancreatitis because it mildly rises during late pregnancy,<sup>32</sup> and it can rise due to diabetic ketoacidosis, renal failure, bowel perforation, or bowel obstruction. Hypertriglyceridemia can falsely lower the serum amylase level in pancreatitis, but the lipase level remains elevated.<sup>4</sup> A serum alanine aminotransferase level more than three times the upper limit of normal strongly suggests biliary pancreatitis. Abdominal ultrasonography is useful in gauging pancreatic inflammation in thin patients with mild to moderate acute pancreatitis, but CT scanning is better at delineating areas of pancreatic necrosis in patients with severe pancreatitis.<sup>30</sup> Abdominal CT is, however, generally discouraged during pregnancy because of potential teratogenicity. Abdominal ultrasonography is also useful to detect cholelithiasis and bile duct dilatation, but endoscopic ultrasonography is required to reliably detect cholelithiasis. Because of fetal risks from ionizing radiation with ERCP,<sup>28</sup> magnetic resonance cholangiopancreatography (MRCP) is preferable to ERCP as a diagnostic study to visualize the common bile duct during pregnancy, unless endoscopic therapy is contemplated. **Acute pancreatitis during pregnancy is often mild and usually responds to medical**

**therapy that includes intravenous (IV) fluid administration, gastric acid suppression, analgesia, sometimes nasogastric suction, and discontinuation of oral intake.** Meperidine is the traditional choice for analgesia because it does not cause contraction of the sphincter of Oddi. Short-term administration of meperidine appears to be relatively safe during pregnancy.<sup>33</sup> Pancreatitis complicated by a pancreatic phlegmon, abscess, sepsis, or hemorrhage necessitates antibiotic therapy, total parenteral nutrition (TPN), and possible radiologic aspiration or surgical debridement with patient monitoring in an intensive care unit (ICU).<sup>30,34</sup> Large and persistent pancreatic pseudocysts require endoscopic or radiologic drainage or surgery.<sup>30</sup> Endoscopic sphincterotomy can be performed for gallstone pancreatitis during pregnancy with minimal fetal radiation exposure.<sup>35</sup> Pregnancy should not delay these therapies. **Laparoscopic cholecystectomy can be utilized during pregnancy and is best performed during the second trimester after organogenesis has occurred and before the growing gravid uterus interferes with visualization of the laparoscopic field.** Maternal mortality is low in uncomplicated pancreatitis but exceeds 10% in complicated pancreatitis.<sup>30</sup> Fetal outcome is generally good for mild to moderate pancreatitis but can be poor with severe pancreatitis. However, moderately severe pancreatitis is occasionally associated with fetal death during the first trimester and is associated with premature labor in the third trimester.<sup>36</sup> Nutritional requirements for TPN for severe pancreatitis should include the extra nutritional requirements of the gravida.<sup>37</sup>

### Cholelithiasis and Cholecystitis

Pregnancy promotes bile lithogenicity and sludge formation because estrogen increases cholesterol synthesis, and progesterone impairs gallbladder motility.<sup>38</sup> In large population surveys using abdominal ultrasonography, 12% of pregnant women in Chile had cholelithiasis,<sup>39</sup> and 8% of pregnant women in the United States<sup>40</sup> had cholelithiasis or biliary sludge detected by abdominal ultrasonography. **Most gallstones are asymptomatic during pregnancy,<sup>41</sup> although symptoms of gallstone disease during pregnancy are the same as those in other patients.<sup>39,41</sup>** The usual initial symptom is biliary colic, pain located in the epigastrium or RUQ that may radiate to the back or shoulders. The pain typically increases over several hours then plateaus and subsides over several hours. It can occur spontaneously or can be induced by eating a fatty meal. Diaphoresis, nausea, and emesis are common. Physical examination is unremarkable, other than occasional RUQ tenderness. About two thirds of patients with biliary colic will experience recurrent attacks during the ensuing 2 years.<sup>4</sup>

**More severe complications of cholelithiasis include cholecystitis, choledocholithiasis, jaundice, ascending cholangitis, hepatic abscess, and gallstone pancreatitis. Pregnancy does not increase the frequency or severity of these complications.<sup>41</sup>**

**Acute cholecystitis** is a chemical inflammation usually caused by cystic duct obstruction by a gallstone. It is **the third most common nonobstetric surgical emergency during pregnancy with an incidence of about 4 cases per 10,000 pregnancies.<sup>30</sup>**

As in biliary colic, the pain is located in the epigastrium and RUQ, but the pain is usually more severe, prolonged, and associated with other clinical findings that include nausea, emesis, pyrexia, tachycardia, right-sided subcostal tenderness, Murphy sign, and leukocytosis.<sup>42</sup> A positive Murphy sign is increased discomfort or inspiratory arrest (a catching of the breath) during deep inspiration when the examiner palpates the gallbladder

fossa just beneath the liver edge. Serum biochemical parameters of liver function and serum levels of amylase may be mildly abnormal. **Ultrasound is very helpful in diagnosing acute cholecystitis during pregnancy,** and it may demonstrate cholelithiasis. Findings compatible with acute cholecystitis include gallbladder wall thickening, pericholecystic fluid, and a positive sonographic Murphy sign in which inspiratory arrest is elicited by pressing the ultrasound transducer probe against the gallbladder fossa during inspiration. Cholescintigraphy with <sup>99m</sup>Tc hepatobiliary iminodiacetic acid (HIDA) scan is sometimes used to confirm acute cholecystitis in nonpregnant patients, but it is rarely required during pregnancy even though it is believed to be relatively safe to the fetus when strongly indicated. Jaundice suggests choledocholithiasis, and pronounced hyperamylasemia suggests gallstone pancreatitis.

**Most cases of biliary colic and some cases of very mild acute cholecystitis can be managed conservatively with close observation, expectant management, and deferral of surgery to the immediate postpartum period.<sup>34,43</sup>** However, **most patients with recurrent biliary colic or acute cholecystitis undergo cholecystectomy.<sup>39,42,44</sup>** Preoperative management includes discontinuing oral intake and then administering IV fluids, analgesia, and usually antibiotics.<sup>38</sup> Ampicillin, cephalosporins, and clindamycin are relatively safe antibiotics during pregnancy.<sup>42,45</sup> **Cholecystectomy is best performed during the second trimester; cholecystectomy during the first trimester is occasionally associated with fetal loss, and cholecystectomy during the third trimester may be associated with premature labor.<sup>42,44</sup>** Cholecystectomy has become increasingly accepted during the first and third trimesters because of improved surgical outcomes,<sup>44</sup> although tocolysis may be necessary during cholecystectomy performed in the third trimester. Intraoperative cholangiography is only performed during pregnancy for strong indications to avoid radiation teratogenicity. Laparoscopic cholecystectomy is safe during pregnancy and is best performed during the second trimester.<sup>4,45</sup> Both maternal and fetal mortality from acute cholecystitis is less than 2.5% during pregnancy.<sup>41</sup>

### Choledocholithiasis

**Symptomatic choledocholithiasis is uncommon during pregnancy.** Choledocholithiasis can produce gallstone pancreatitis manifested by pyrexia, nausea, and severe abdominal pain or ascending cholangitis manifested by pyrexia, RUQ pain, and jaundice (Charcot triad).<sup>30</sup> Endoscopic ultrasound is relatively safe in pregnancy and is sensitive in detecting choledocholithiasis.<sup>46</sup> Patients with choledocholithiasis and gallstone pancreatitis should undergo ERCP and sphincterotomy with stone extraction, as previously described. Pancreatography can be avoided to minimize fetal radiation exposure.<sup>35</sup> These patients then usually undergo cholecystectomy postpartum but can, if necessary, undergo cholecystectomy antepartum, especially during the second trimester, with acceptable maternal and fetal risks.<sup>30</sup> Cholecystectomy can be performed by laparoscopic, rather than open, techniques during the first or second trimester of pregnancy.<sup>47</sup>

### Choledochal Cysts

Choledochal cysts are rare. They typically produce a diagnostic triad of abdominal pain, jaundice, and a palpable abdominal mass in nonpregnant patients. Choledochal cysts are classified into types 1 through 4, depending upon which segment of the biliary tree is dilated.<sup>48</sup> Choledochal cysts can initially present

during pregnancy, which can exacerbate the abdominal pain and increase the jaundice because of choledochal compression by the enlarged gravid uterus. However, pregnancy can mask the palpable abdominal mass because of the size of the uterus.<sup>49,50</sup> Severe pain suggests cyst rupture or concomitant pancreatitis.<sup>49</sup> A choledochal cyst is often diagnosed by abdominal ultrasound, although cholangiography is sometimes required. MRI is preferred over abdominal CT or diagnostic ERCP for determining the anatomy. Surgical management is generally recommended for symptomatic choledocholithiasis because of the risk of recurrent cholangitis and malignant degeneration. The standard surgery is cystectomy, cholecystectomy, and reconstitution of biliary-intestinal flow by either a Roux-en-Y hepaticojejunostomy or choledochojejunostomy.<sup>50</sup> Medical management, including antibiotics and temporary percutaneous or endoscopic drainage, may sometimes suffice until delivery.<sup>49,50</sup>

## COMMON LIVER DISEASES INCIDENTAL TO PREGNANCY

### Acute Viral Hepatitis A, B, and C

Acute viral hepatitis A, B, and C present similarly in pregnancy as in the nonpregnant state (see [Chapter 52](#)). In a review of 13 cases of **hepatitis A** that occurred during the second or third trimesters of pregnancy, many of the mothers had mild to moderate gestational complications such as premature contractions or transient vaginal bleeding, but all pregnancies had favorable outcomes.<sup>51</sup> **Acute hepatitis B** is usually self-limited and mild during pregnancy. Patients with very severe or prolonged acute hepatitis B may be considered as candidates for lamivudine therapy.<sup>52</sup> Typical symptoms of acute viral hepatitis include anorexia, nausea, malaise, and RUQ discomfort. Patients with acute hepatitis A or hepatitis B typically have highly elevated serum aminotransferase levels, and jaundice may also be apparent. **Acute hepatitis C** is frequently subclinical and typically causes only mild serum aminotransferase level elevations. Maternal mortality is rare from acute hepatitis A, B, or C during pregnancy. Fetal mortality and neonatal morbidity is increased by acute hepatitis A or B but is still relatively low.

### Hepatitis E

Hepatitis E, while rare and sporadic in industrialized countries, is the most common epidemic waterborne form of hepatitis in

middle- to low-income countries. It usually spreads by fecal-oral transmission through a contaminated water supply. Infected patients typically have a prodrome with malaise and pyrexia, followed by an acute illness with anorexia, nausea, vomiting, abdominal pain, and jaundice. Patients often have hepatomegaly and usually have significant elevations of the serum aminotransferase levels. The infection is typically mild and self-limited without chronicity or clinical sequelae.

**Pregnant patients have a more severe illness, with frequent fulminant hepatitis. The mortality rate rises progressively with increasing gestational age, up to about 20% for acute infection in the third trimester.<sup>53</sup> Maternal infection is likewise associated with a high risk of fetal or neonatal mortality. Medical management is supportive, and fulminant hepatitis should be managed in an ICU and may require liver transplantation. The cause of the increased severity of hepatitis E during pregnancy is unknown but may relate to attenuated cellular immunity during pregnancy.<sup>54</sup>**

In the United States, hepatitis E infection is rare and is not routinely tested for in the evaluation of acute hepatitis. However, patients with acute hepatitis should be evaluated for hepatitis E if they have recently traveled to an endemic area and have had hepatitis A, B, and C excluded by serologic tests. Hepatitis E testing should also be considered in patients who present with fulminant hepatitis of unclear etiology who lack a travel history to endemic regions. The infection is generally diagnosed by detecting hepatitis E antibodies in the serum. Acute infection is indicated by the presence of immunoglobulin M (IgM) antibodies, whereas prior infection is characterized by detecting IgG antibodies. Detection of the virus in blood by polymerase chain reaction (PCR) is more accurate than serologic tests. Tests for hepatitis E are not commercially available in the United States but may be obtained via the Centers for Disease Control and Prevention (CDC). The infection is largely prevented by public health measures, such as a clean water supply. Pregnant women should avoid travel to endemic areas, should not drink water from the municipal water supply in endemic areas, should not consume uncooked shellfish or vegetables from endemic areas, and should wash all fruit from endemic areas using uncontaminated water. [Table 47-2](#) summarizes the clinical presentation, diagnostic tests, and treatment during pregnancy complicated by hepatitis E as well as other hepatic disorders significantly affected by pregnancy.

**TABLE 47-2** CLINICAL PRESENTATION AND TREATMENT DURING PREGNANCY OF HEPATIC DISORDERS SIGNIFICANTLY AFFECTED BY PREGNANCY

| DISEASE OR DISORDER          | SYMPTOMS AND SIGNS   | LABORATORY FINDINGS   | TREATMENT  |
|------------------------------|--|---|--|
| Hepatitis E                  | Anorexia, nausea and vomiting, RUQ abdominal pain, jaundice, hepatomegaly      | Significantly elevated aminotransferase levels, mild jaundice; IgM antibodies to hepatitis E; PCR positive for hepatitis E virus  | Supportive care and prevention by public health measures; avoid drinking municipal water in endemic areas  |
| Acute intermittent porphyria | Diffuse abdominal pain, vomiting, constipation, neuropsychiatric abnormalities | Increased porphobilinogen and $\delta$ -aminolevulinic acid levels in urine   | Hematin, parenteral glucose; avoid precipitating drugs and fasting; narcotics or phenothiazines relieve symptoms   |
| Budd-Chiari syndrome         | Abdominal pain, hepatomegaly, and ascites                                      | Moderately elevated bilirubin and alkaline phosphatase, relatively normal aminotransferase levels; Doppler ultrasound, hepatic venography, or MRA will show no flow in the hepatic vein | Low-sodium diet and diuretics manage ascites and fluid retention; consider anticoagulation, balancing benefits against risks, and thrombolytic therapy or angioplasty for an acute clot; data are limited on this therapy during pregnancy |

IgM, immunoglobulin M; PCR, polymerase chain reaction; MRA, magnetic resonance angiography; RUQ, right upper quadrant.

### Chronic Hepatitis B

**Pregnancy does not appear to significantly affect the progression of chronic hepatitis B.**<sup>55</sup> Despite immunotolerance during pregnancy, acute flares are relatively uncommon in patients with chronic hepatitis B. **Maternal chronic hepatitis B infection may, however, be transmitted to the neonate, usually during delivery.**<sup>56</sup> **The risk of vertical transmission is about 90% in mothers who are positive for the hepatitis B e antigen (HBeAg), but it is about 25% in mothers who are HBeAg negative.**<sup>57</sup> Perinatal infection is clinically important because infected neonates tend to become chronic carriers and then have a markedly increased risk of developing hepatocellular carcinoma in adulthood. All pregnant women are tested for hepatitis B surface antigen (HBsAg) in the United States.<sup>55</sup> **Infants born to mothers with acute or chronic hepatitis B infection should be passively immunized with hepatitis B hyperimmune globulin and should be actively immunized with hepatitis B vaccine immediately after birth** to prevent neonatal infection from intrapartum exposure.<sup>58</sup> Recent data suggest that treatment of chronic hepatitis B in pregnancy with lamivudine or tenofovir is feasible, safe, and effective in reducing maternal viral load. This therapy is currently an area of active research.<sup>59,60</sup>

### Chronic Hepatitis C

**Women with chronic hepatitis C may exhibit transient normalization of their serum aminotransferase levels associated with an increase in the serum viral load during pregnancy, possibly because of mildly attenuated immunity.**<sup>61</sup> The clinical significance of this phenomenon in terms of progression of the liver disease is unclear, but chronically infected patients may develop mild progression of their liver disease, as evidenced by increased hepatic fibrosis during pregnancy.

**The risk of vertical transmission of hepatitis C from a chronically infected mother with viremia to the neonate is about 5%.**<sup>62</sup> This rate of vertical transmission is much lower than that for hepatitis B. Viral transmission to the neonate is unlikely (<2%) in mothers who have an undetectable viral load. In contrast, women positive for the human immunodeficiency virus (HIV) can have hepatitis C transmission rates as high as 20% to 40%. Infants born to mothers with hepatitis C infection should undergo periodic testing for hepatitis C during the first 18 months of life to detect persistent infection. Directly acting antiviral drugs are now able to achieve a sustained undetectable hepatitis C viral load and should be considered in pregnancy as more safety data become available.<sup>63</sup>

### Wilson Disease

Noncirrhotic women treated for early Wilson disease have relatively intact fertility and may therefore become pregnant. Their serum levels of copper and ceruloplasmin increase during pregnancy,<sup>64</sup> and therefore they require maintenance therapy to prevent a flare of disease that can increase maternal morbidity and fetal mortality. Although the data are limited, trientine (triethylene tetramine dihydrochloride) or zinc therapy for Wilson disease may be continued during pregnancy without significant fetal toxicity.<sup>65</sup> D-penicillamine is potentially teratogenic; therefore its use during pregnancy should be limited when alternatives are available. Women with cirrhosis from Wilson disease have increased risks of complications during pregnancy that include intrauterine growth restriction (IUGR) and preeclampsia.

### Autoimmune Hepatitis

Women with autoimmune hepatitis should be maintained on immunosuppressive therapy during pregnancy. Glucocorticoids appear to be relatively safe during pregnancy,<sup>66</sup> and the U.S. Food and Drug Administration (FDA) rates prednisone as a category B drug during gestation. Patients with well-compensated and well-controlled autoimmune hepatitis tolerate pregnancy well while maintained on this therapy and have only a moderately increased rate of perinatal complications.<sup>66,67</sup> These patients typically have a reversible mild deterioration of serum parameters of liver function during pregnancy, particularly of serum bilirubin and alkaline phosphatase, attributed to the cholestatic effects of gestation. Patients who discontinue their immunosuppressive therapy can develop severe acute flares.

### Hepatic Hemangiomas, Cysts, and Abscesses

Hepatic hemangiomas are the most common benign tumors of the liver in the general population. The vast majority of hepatic hemangiomas smaller than 5 cm are asymptomatic in the general population. **Hepatic hemangiomas appear to behave similarly during pregnancy.** Rare symptoms attributable to hemangiomas include RUQ pain, abdominal distension, or symptoms such as nausea that are attributable to impingement of adjacent viscera. Serious complications during pregnancy include consumptive coagulopathy with hemolysis, thrombocytopenia, and hypofibrinogenemia (Kasabach-Merritt syndrome); intrahepatic hemorrhage; and spontaneous hepatic rupture. Patients with large hemangiomas are at greater risk for these complications. Warning signs include progressively increasing symptoms and rapid lesion growth, although these complications are rare during pregnancy. Among 20 patients with very large hemangiomas, only one case of hepatic rupture and one case of intrahepatic hemorrhage occurred in 27 pregnancies.<sup>68</sup> Nearly all hemangiomas, including moderately large lesions, appear to be indolent during pregnancy and can therefore be observed without interventional therapy. MRI is the imaging modality of choice to follow hemangioma size during gestation because of high sensitivity, high specificity, and reduced fetal risks compared with CT.

Focal nodular hyperplasia is the second most common cause of a benign hepatic mass. It is usually asymptomatic during pregnancy and is often detected incidentally during obstetric ultrasonography.<sup>13,46</sup> This lesion occasionally grows during gestation, possibly because of estrogen stimulation. Most cases can be observed without intervention. It rarely causes hepatic hemorrhage or biliary obstruction as a result of compression by the enlarged gravid uterus.<sup>68-70</sup> Clinical findings may include abdominal pain, jaundice, or hypotension. Surgical intervention is occasionally necessary for these complications.<sup>69,70</sup>

Hepatic cysts may be isolated or associated with polycystic kidney disease, malignancy, or amebic or echinococcal infection.<sup>69,71</sup> Pyogenic liver abscesses during pregnancy arise from ascending cholangitis, appendicitis, or diverticulitis.<sup>69,70</sup> Both antibiotics and percutaneous drainage are usually indicated.

### Hepatocellular Carcinoma and Hepatic Metastases

Hepatocellular carcinoma (HCC) usually occurs in the setting of cirrhosis secondary to chronic viral hepatitis, hemochromatosis, or alcoholism. It is rarely diagnosed during pregnancy.<sup>69,70</sup> The poor prognosis during pregnancy may result from delayed diagnosis or mild immunosuppression during pregnancy.

Screening high-risk patients with abdominal ultrasonography can detect HCC earlier.<sup>69,72</sup> The fibrolamellar variant of HCC, typically found in younger women, has a better prognosis. In addition, hepatic metastases from colon cancer can also occur during pregnancy.<sup>5</sup>

## LIVER DISEASES SIGNIFICANTLY AFFECTED BY PREGNANCY

### Hepatic Adenomas

**Hepatic adenomas are benign hepatic tumors promoted by hyperestrogenemia.** They are composed of large plates of adenoma cells, which are typically larger than ordinary hepatocytes. Pregnancy is associated with accelerated adenoma growth and consequent development of symptoms such as nausea, vomiting, and RUQ pain. Risks during pregnancy include adenoma hemorrhage or intraperitoneal rupture. On MRI, adenomas are typically well demarcated, hyperintense on T2-weighted images, and enhance further with gadolinium administration. **Hepatic adenomas that are symptomatic, larger than 5 cm in diameter, or exhibit evidence of hemorrhage should be considered for surgical excision before conception in women contemplating pregnancy, and they should be evaluated for possible excision if first diagnosed during pregnancy.**<sup>73</sup>

### Acute Intermittent Porphyria

**The porphyrias are rare diseases caused by deficiency of various heme biosynthetic enzymes that result in accumulation of toxic porphyrin precursors. Acute intermittent porphyria (AIP), the result of a porphobilinogen deaminase deficiency, is the most common hepatic porphyria and has a frequency of about 1 per 10,000 people.** It is transmitted as an autosomal trait with incomplete penetrance<sup>74</sup> and is strongly affected by environmental factors, including female sex hormone levels. Women have more severe symptoms than men, and their symptoms are exacerbated by oral contraceptive administration, menstruation, and pregnancy.<sup>74,75</sup> About one third of female patients present initially during pregnancy or immediately postpartum. Hyperemesis gravidarum is a common precipitant. Diffuse abdominal pain is frequently seen, and other symptoms include vomiting, constipation, and neuropsychiatric abnormalities.<sup>74</sup> Autonomic abnormalities can cause tachycardia, hypertension, or ileus. Unlike other porphyrias, AIP lacks dermatologic manifestations. Attacks can recur during pregnancy.

AIP should be considered in any pregnant patient with abdominal pain and a puzzling diagnostic evaluation. Increased urinary levels of porphobilinogen and  $\delta$ -aminolevulinic acid are diagnostic.<sup>74</sup> Management includes avoidance of precipitating drugs, avoidance of fasting, and possible administration of hematin or parenteral glucose.<sup>74</sup> Also, abdominal pain and nausea and vomiting should be treated with narcotic analgesics or phenothiazines. The maternal mortality is less than 10%, with a fetal mortality of 13% and frequent delivery of low-birthweight infants.<sup>74,75</sup> Genetic counseling is recommended.

### Sickle Cell Hemoglobinopathies

The sickle cell hemoglobinopathies—including hemoglobin SS, hemoglobin SC, and hemoglobin S/ $\beta$ -thalassemia—are the most common hematologic disorders during pregnancy (see Chapter 44). They primarily occur in blacks. Patients with these hemoglobinopathies are prone to develop preeclampsia,

eclampsia, or sickle cell crisis during pregnancy.<sup>76,77</sup> They can also exhibit ischemia and microinfarction of multiple organs including extremities, joints, and abdominal viscera,<sup>77</sup> and abdominal pain during a sickle cell crisis can be excruciating. Hemoglobin SS patients have an increased risk of acute cholecystitis during pregnancy.<sup>41,77</sup> Maternal mortality during pregnancy in patients with SS disease is almost 0.1% and comprises nearly six times the general maternal mortality.<sup>77</sup> These maternal hemoglobinopathies significantly increase fetal mortality.<sup>76</sup> Fetal complications related to compromised placental perfusion include IUGR, low birthweight, and preterm delivery.

### Portal Hypertension

**Pregnancy is uncommon in cirrhotic women because they frequently experience anovulation and amenorrhea secondary to abnormal estrogen and endocrine hormone metabolism.**<sup>78</sup> However, patients with well-compensated early cirrhosis occasionally become pregnant. The plasma volume gradually increases during pregnancy to a maximum of about 40% above baseline.<sup>79</sup> The primary contributing factor is sodium retention mediated by increased serum aldosterone, estrogen, and renin levels, but water retention is a secondary factor.<sup>79</sup> Maternal cardiac output increases in proportion with the plasma volume. Portal pressure appears to physiologically increase during pregnancy as a result of these increases in plasma volume and cardiac output as well as from the increased vascular resistance due to external compression of the inferior vena cava by the gravid uterus. Pregnancy can, therefore, exacerbate preexisting portal hypertension with shunting of blood into portosystemic collaterals, particularly esophageal varices, which leads to increased intravariceal pressure and an associated increased risk of variceal hemorrhage. About 30% of pregnant patients with portal hypertension develop variceal hemorrhage, as do about 75% of pregnant patients with preexisting esophageal varices.<sup>79</sup> **The risk of variceal hemorrhage is highest during the second trimester, when portal hypertension peaks, and during labor, when venous collateral resistance abruptly increases from use of the Valsalva maneuver during pushing.**

Pregnancy has variable effects on the progression of cirrhosis. **About 25% of cirrhotics experience hepatic failure during pregnancy, whereas others have relatively stable hepatic function during pregnancy.**<sup>80</sup> Some treatments for specific liver diseases must be modified during pregnancy to avoid fetal toxicity. Maternal mortality in patients with cirrhosis may be as high as 10%.<sup>78</sup> Pregnant women with cirrhosis have worse pregnancy outcomes than other patients, with only about a 60% live birth rate.<sup>81</sup> Pregnant patients with more advanced cirrhosis have worse fetal outcomes.<sup>81</sup>

Portal hypertension without cirrhosis is usually due to portal vein obstruction or hepatic fibrosis. Fertility is much better preserved in portal hypertension without cirrhosis than with cirrhosis. Pregnant patients, therefore, more frequently have portal hypertension without cirrhosis than with cirrhosis. **Non-cirrhotic patients with portal hypertension** have a much lower mortality from each episode of variceal hemorrhage than cirrhotic patients because of better preserved liver function, a lower incidence of coagulopathy or thrombocytopenia, and a much lower risk of hepatic failure precipitated by variceal hemorrhage.

**Women with prior variceal hemorrhage or with borderline liver function who are contemplating pregnancy should be advised of the high risks of maternal hepatic**

**decompensation or variceal hemorrhage during pregnancy and of the relatively poor fetal prognosis.** They should also be advised of the risk of transmitting genetic hepatic diseases, such as alpha-1 antitrypsin deficiency, or of transmitting hepatotropic viral infections, such as hepatitis B, to their offspring. **Women with well-compensated chronic liver disease without prior variceal hemorrhage should undergo EGD before conception for risk stratification.** Patients with silent esophageal varices are at high risk of variceal hemorrhage during pregnancy, whereas patients without esophageal varices are at low risk of this complication during pregnancy. Patients with esophageal varices should be informed of the benefits of  $\beta$ -adrenergic receptor antagonists during pregnancy to reduce portal pressure; however, they should also be advised of the fetal risks of these medications, which may include fetal bradycardia and growth restriction.

About 2.5% of cirrhotic patients experience splenic artery rupture during pregnancy. Pregnant patients with portal hypertension should undergo an ultrasound examination with Doppler studies of the upper abdomen to screen for splenic artery aneurysms at the time of their routine antenatal pelvic ultrasound. **Administration of iron is contraindicated in pregnant patients with hemochromatosis and is inadvisable in pregnant patients with several other types of chronic liver disease, such as chronic hepatitis C.** Routine serum parameters of liver function, including a coagulation profile, should be serially monitored during pregnancy. Variceal hemorrhage in pregnancy is managed the same as it would be in a nonpregnant patient: initial treatment includes endoscopic variceal banding or sclerotherapy, as described earlier; octreotide therapy is normally administered before the endoscopic therapy and is maintained for several days after endoscopic treatment in nonpregnant patients. Several cases of prolonged administration of octreotide for pituitary tumors have been reported in pregnant patients with good pregnancy outcomes.<sup>82</sup> Propranolol has been safely used during pregnancy to treat portal hypertension but may cause fetal problems as noted above. During parturition, the second stage of labor should be shortened to minimize portal hypertension. IV fluids should be administered cautiously to avoid volume overload, and any coagulopathy should be corrected to minimize the risk of intrapartum variceal hemorrhage.<sup>79</sup>

### Budd-Chiari Syndrome

**The Budd-Chiari syndrome refers to hepatic vein thrombosis or occlusion that increases the hepatic sinusoidal pressure, and it can lead to portal hypertension or hepatic necrosis.**<sup>83</sup> Many cases are secondary to congenital vascular anomalies or hypercoagulopathies. This syndrome is rare in general and is consequently rare in pregnancy, although pregnancy tends to promote this disorder owing to a hypercoagulable state.<sup>84,85</sup> This syndrome usually presents in the last trimester or in the puerperium. The characteristic clinical triad is abdominal pain, hepatomegaly, and ascites.<sup>84,85</sup> Acute and chronic presentations occur. The serum bilirubin and alkaline phosphatase levels are typically moderately elevated with normal to mildly elevated serum aminotransferase levels. **This syndrome is diagnosed by pulsed Doppler ultrasound, hepatic venography, or magnetic resonance angiography (MRA).**<sup>84-86</sup> Without therapy, death usually occurs within a decade of diagnosis, and the **definitive therapy is liver transplantation.** Selective thrombolytic therapy and surgical or radiologic relief of portal hypertension for intractable

ascites or variceal bleeding have also been described.<sup>84,85</sup> Anticoagulant therapy is often administered long term during pregnancy to prevent further thrombotic events but is associated with a moderate risk of bleeding events, especially during delivery.<sup>87</sup> Maternal outcome is generally good, but about 30% of pregnancies result in fetal demise.<sup>87</sup> Patients have had subsequent successful pregnancies after undergoing liver transplantation for Budd-Chiari syndrome that presented during the puerperium.<sup>86</sup>

### Pregnancy After Liver Transplantation

Although cirrhotic women are often infertile, women often regain fertility after successful liver transplantation for cirrhosis with restoration of liver function. **Immunosuppressive therapy should be maintained during pregnancy after liver transplantation.** Tacrolimus and azathioprine appear to be safe in pregnancy. Mycophenolate mofetil (MMF) should be stopped if possible before pregnancy (see Chapter 39). Pregnancy appears to be relatively well tolerated after liver transplantation provided the transplanted liver functions well before conception. Maternal complications during pregnancy include hypertension, preeclampsia, infections associated with immunosuppression, and occasionally acute hepatic rejection.<sup>88</sup> Chronic immunosuppression with prednisone may result in gestational diabetes. The fetal outcome is variable, with a large increase in fetal or neonatal mortality and a moderate increase in neonatal complications, particularly prematurity and low birthweight. However, about 70% of liveborn babies do well.<sup>88</sup>

## LIVER DISEASE STRONGLY RELATED TO OR UNIQUE TO PREGNANCY

### Alcoholism During Pregnancy

About 10% of women drink heavily or binge drink during pregnancy.<sup>89</sup> Alcohol is a teratogen that causes central nervous system defects (see Chapter 8), and alcoholism during pregnancy can result in the fetal alcohol syndrome (FAS), characterized by facial abnormalities such as a smooth philtrum, growth restriction, and neurodevelopmental deficits. Heavy drinking of alcohol during the first trimester can cause major anatomic brain abnormalities, including reduced brain volume. Affected infants occasionally develop hepatic dysfunction manifested by hepatomegaly, fatty liver, or elevations of serum aminotransferase or alkaline phosphatase levels.<sup>90</sup>

### Hepatic Involvement in Hyperemesis Gravidarum

About 15% of patients with hyperemesis gravidarum experience liver dysfunction. The most prominent abnormality is manifold elevations of the serum aminotransferase levels, but jaundice or pruritus may also occur.<sup>91</sup> The hepatic dysfunction may be related to dehydration, malnutrition, and electrolyte abnormalities. This dysfunction is typically mild and resolves with cessation of the vomiting and reversal of the underlying metabolic abnormalities (see Chapter 6).

### Herpes Simplex Hepatitis

Herpes simplex hepatitis is uncommon during pregnancy. However, about half of all cases of this hepatitis in immunocompetent adults occur during pregnancy, possibly because of attenuated immunity. This hepatitis has a high mortality during

**TABLE 47-3** CLINICAL PRESENTATION AND TREATMENT DURING PREGNANCY OF COMMON HEPATIC DISORDERS STRONGLY RELATED OR UNIQUE TO PREGNANCY

| DISEASE OR DISORDER                   | SYMPTOMS AND SIGNS   | LABORATORY FINDINGS  | TREATMENT   |
|---------------------------------------|--|--|---|
| Herpes simplex hepatitis              | RUQ abdominal pain after prodrome of upper respiratory tract symptoms and pyrexia; oral or genital cutaneous vesicular eruptions | Highly elevated serum aminotransferase levels, moderately increased serum bilirubin; viral culture or histologic analysis of infected tissue is diagnostic   | Acyclovir or similar antiviral drugs  |
| Intrahepatic cholestasis of pregnancy | Intense pruritus, occasional anorexia and nausea   | Modestly elevated serum bilirubin and alkaline phosphatase levels; moderately elevated serum aminotransferase levels; elevated total bile acid level is diagnostic   | Ursodeoxycholic acid (also antihistamines, phenobarbital, or cholestyramine); delivery rapidly and completely relieves cholestasis  |
| Acute fatty liver of pregnancy        | Anorexia, nausea and vomiting, malaise, fatigue, RUQ abdominal pain  | Variable, mildly elevated LFTs; hepatic imaging excludes other disorders; test for LCHAD mutation; long-chain 3-hydroxyacyl metabolites accumulate; liver biopsy (usually unnecessary) shows microsteatosis in hepatocytes; DIC may occur in severely ill patients | Specific treatments for specific complications (e.g., blood products for DIC); prompt delivery should occur after maternal stabilization; patients rapidly improve after delivery |

AST, aspartate aminotransferase; CT, computed tomography; DIC, disseminated intravascular coagulation; LCHAD, long-chain 3-hydroxyacyl coenzyme A dehydrogenase; LFTs, liver function tests; RUQ, right upper quadrant.

pregnancy due to a propensity for viral dissemination and delayed diagnosis.<sup>92</sup> Patients typically present with RUQ pain, very high serum aminotransferase levels, and mild to moderate hyperbilirubinemia after a brief viral prodrome with fever and upper respiratory tract symptoms. An oral or genital cutaneous vesicular eruption in association with highly elevated serum aminotransferase levels should suggest the diagnosis. The diagnosis may be confirmed by viral culture or histologic analysis of infected tissue. Unlike hepatic diseases such as AFLP or preeclampsia with liver disease, for which early delivery is often curative, early delivery is not recommended for herpes simplex hepatitis; rather acyclovir therapy is the treatment of choice. Table 47-3 summarizes the clinical presentation and treatment during pregnancy of herpes simplex hepatitis and other hepatic disorders strongly related to or unique to pregnancy.

### Intrahepatic Cholestasis of Pregnancy

**The incidence of intrahepatic cholestasis of pregnancy (ICP) ranges from about 2 per 10,000 in the United States to about 20 per 10,000 in Europe.<sup>93</sup> The cardinal symptom is pruritus due to cholestasis and accumulated bile salts in the dermis.** The pruritus typically most severely affects the palms and soles of the feet, becomes worse at night, and begins in the third trimester. The pruritus can be intense and can cause psychologic distress. Patients occasionally experience anorexia, nausea, and vomiting. Proposed etiologic factors include genetic predisposition, as illustrated by the extremely high rate in the indigenous Araucanian people of Chile and by familial clustering; gestational hyperestrogenemia, as supported by the known cholestatic effect of estrogen; and abnormal progesterone metabolism, as supported by the cholestatic effects of sulfated progesterone metabolites.<sup>79</sup> This syndrome is sometimes related to defects in the multidrug resistance type 3 (MDR-3) gene that encodes for the canalicular phospholipid pump protein.<sup>94</sup> Aside from family history, risk factors include multiple gestations and occurrence of this syndrome during previous pregnancies. Patients have elevated fasting serum levels of total bile acids, particularly conjugated bile acids and especially cholic acid.<sup>79,94,95</sup> Patients typically exhibit hyperbilirubinemia that is mild and predominantly

conjugated; about 10% of patients develop jaundice. The serum level of alkaline phosphatase is modestly elevated, and the level of  $\gamma$ -glutamyl transpeptidase (GGTP) is normal. The serum aminotransferase levels are generally severalfold higher than normal,<sup>94</sup> but hepatic imaging studies reveal normal hepatic parenchyma and anatomy. Liver biopsy demonstrates bile staining of hepatocytes and bile plugs in biliary canaliculi without necroinflammatory activity, findings consistent with cholestasis. The risk of gestational diabetes mellitus is also increased.

**Ursodeoxycholic acid is the generally recommended therapy.<sup>96</sup>** It tends to normalize the serum bile acid profile and decreases the pruritus by stimulating bile acid excretion.<sup>97</sup> Other treatments designed to ameliorate the pruritus and/or lower the serum bile acid concentration include hydroxyzine, an antihistamine, phenobarbital, cholestyramine, and S-adenosyl methionine.<sup>79</sup>

Delivery results in rapid and complete relief of the cholestasis, and maternal outcome is usually good without long-term sequelae. However, the gestational cholestasis increases the risk of postpartum cholesterol cholelithiasis. **Vitamin K deficiency that results from mild steatorrhea, associated with the cholestasis itself or the cholestyramine therapy for the cholestasis, increases the risk of postpartum hemorrhage. The prothrombin time may be monitored during pregnancy, especially near parturition, and vitamin K can be administered as necessary.** ICP results in a significantly increased incidence of poor fetal outcomes such as meconium ileus, premature delivery, or stillbirth. Antepartum fetal testing with twice-weekly nonstress tests is a reasonable plan. In the absence of nonreassuring testing, consideration should be given for delivery at about 37 weeks' gestation.<sup>98</sup> Cholestasis recurs in approximately two thirds of subsequent pregnancies.

### Acute Fatty Liver of Pregnancy

**Acute fatty liver of pregnancy (AFLP) is a rare but severe disease characterized by hepatic microvesicular steatosis associated with mitochondrial dysfunction.** It is related to an autosomally inherited mutation that causes deficiency of the long-chain 3-hydroxyacyl coenzyme A dehydrogenase (LCHAD),

a fatty acid  $\beta$ -oxidation enzyme.<sup>4</sup> The most common mutation that leads to AFLP is the G1528C mutation.<sup>99</sup> This mutation leads to accumulation of hepatotoxic long-chain 3-hydroxyacyl metabolites produced by the fetus and placenta. It usually manifests in the third trimester and is rarely observed immediately postpartum.<sup>83,100</sup> AFLP occurs in about 1 per 10,000 pregnancies<sup>2,3</sup> and is more common in primiparas and twin pregnancies. About half of these patients exhibit signs of preeclampsia.<sup>100-102</sup>

The initial symptoms—including anorexia, nausea, emesis, malaise, fatigue, and headache—are nonspecific.<sup>83,100</sup> About half of the patients have epigastric or RUQ pain and about half have hypertension.<sup>101,102</sup> Physical examination may reveal hepatic tenderness, usually without hepatomegaly. Serum aminotransferase and bilirubin levels are variably elevated, and jaundice usually manifests later in the course of the illness or after delivery.

**Characteristic laboratory findings in severely affected patients include a prolonged prothrombin time, hypofibrinogenemia, and increased serum levels of fibrin split products from DIC and/or hepatic decompensation. Other laboratory abnormalities include increased serum levels of ammonia, uric acid, blood urea nitrogen (BUN), and creatinine.**<sup>83,101,102</sup>

Hepatic imaging studies primarily help to exclude other disorders or detect hepatic hemorrhage.<sup>101</sup>

Liver biopsy is usually diagnostic but is *not* indicated for suspected AFLP unless the presentation is atypical or postpartum jaundice is prolonged.<sup>2,101</sup> Hepatic pathology reveals intracytoplasmic microsteatosis in hepatocytes, preservation of hepatic architecture, and isolated foci of inflammatory and necrotic cells.<sup>101,102</sup> Sinusoidal deposition of fibrin is usually not present in AFLP but is usually observed in preeclampsia and eclampsia. **AFLP differs from severe acute viral hepatitis in that the serum aminotransferase levels in AFLP rarely exceed 1000 U/L, the viral serologic tests are negative, and hepatic pathologic analysis reveals much less inflammatory infiltration and hepatocytic necrosis.**<sup>83,99,101,102</sup> **AFLP may be difficult to distinguish from HELLP syndrome and preeclampsia or eclampsia with DIC.**

**Fortunately, the definitive treatment for all these disorders is prompt delivery after maternal stabilization** that may include a glucose infusion to treat hypoglycemia related to hepatic dysfunction, transfusion of fresh-frozen plasma or platelets as necessary to reverse coagulopathies, transfusion of packed erythrocytes to correct anemia from bleeding related to DIC, and administration of albumin to address the hypoalbuminemia from liver dysfunction. Other complications include pulmonary edema, pancreatitis, diabetes insipidus, seizures, coma, and hepatic failure manifested by jaundice, encephalopathy, ascites, or variceal bleeding.<sup>101,102</sup> The complications may require specific therapy: lactulose for hepatic encephalopathy, hemodialysis for renal failure, blood transfusions and endoscopic therapy for GI bleeding, and desmopressin for diabetes insipidus.

Most patients improve clinically within several days after delivery, and their liver function tests normalize. The maternal mortality is low with early diagnosis, appropriate supportive therapy, and early delivery. The fetal mortality of AFLP is 10% to 15%.<sup>3,101,103</sup> The mother, her partner, and the neonate should be tested for LCHAD mutations. Genetic testing is available for the G1528C mutation, but it is unavailable for the other, less common mutations.<sup>104</sup> **AFLP rarely recurs in subsequent pregnancies.**<sup>101</sup>

## SUMMARY

Although relatively uncommon, hepatic, biliary, and pancreatic disorders during pregnancy are clinically important because of their potentially severe effects on the mother and fetus. These disorders are often complex, and such problems during pregnancy are clinically challenging. The differential diagnosis is particularly extensive during pregnancy because it includes pregnancy-related as well as unrelated conditions. The patient history, physical examination, laboratory data, and radiologic findings will usually provide the diagnosis. Abdominal ultrasound is generally the recommended radiologic imaging modality. Maternal and fetal survival have recently improved in many of these life-threatening conditions, such as liver disease during pregnancy, because of enhanced diagnostic technology, better maternal and fetal monitoring, earlier diagnosis, and more refined therapies.

## KEY POINTS

- ◆ The differential of hepatobiliary conditions is extensive in pregnancy and includes pregnancy-related disorders in addition to disorders unrelated to pregnancy. Indeed, several clinical syndromes are unique to pregnancy, such as intrahepatic cholestasis of pregnancy and acute fatty liver of pregnancy.
- ◆ Pregnancy affects the normative values of serum parameters of liver function and pancreatic injury. During pregnancy, the serum level of albumin declines, and the serum levels of amylase, alkaline phosphatase, bile acids, cholesterol, and triglycerides rise. Yet these serum parameters are still clinically important measures of liver function and pancreatic injury during pregnancy, provided the changes in normative values are appreciated.
- ◆ Many causes of significant to severe liver dysfunction during pregnancy—including preeclampsia, eclampsia, HELLP syndrome, and AFLP—are rapidly relieved and completely reversed by delivery of the baby. Delivery is generally the definitive therapy for these disorders.
- ◆ Pregnancy aggravates preexisting portal hypertension and increases the risk of variceal hemorrhage. As in nonpregnant patients, endoscopic banding and sclerotherapy appear to be first-line therapies for esophageal variceal bleeding in pregnant patients.
- ◆ Pregnancy greatly aggravates acute hepatitis E infection, hepatocellular adenomas, acute intermittent porphyria, and herpes simplex hepatitis.
- ◆ Neonates born to mothers who have acute or chronic hepatitis B are at high risk of vertical transmission of infection during delivery. Such infants should be passively immunized with hepatitis B hyperimmune globulin and actively immunized with hepatitis B vaccine at birth to prevent this infection.

Gastrointestinal (GI) complaints and disorders are common in women,<sup>1</sup> including in their childbearing years, and thus often occur during pregnancy. These complaints and disorders present unique clinical challenges during pregnancy. First, the differential diagnosis during pregnancy is extensive. Aside from GI disorders unrelated to pregnancy, their complaints may be caused by obstetric or gynecologic disorders related to pregnancy or other intraabdominal diseases incidental to pregnancy. Moreover, some GI conditions—such as hyperemesis gravidarum (HG)—are unique to pregnancy. Second, the clinical presentation and natural history of GI disorders can be altered during pregnancy, as described below for appendicitis. Third, the diagnostic evaluation may need to be altered because of pregnancy. For example, radiologic tests and invasive

examinations may raise concerns about their fetal safety during pregnancy. Fourth, the interests of both the mother and the fetus must be considered in therapeutic decisions during pregnancy. Usually, these interests do not conflict because what is good for the mother is generally good for the fetus. Sometimes, however, maternal therapy must be modified to substitute alternative but safer therapy because of concerns about drug teratogenicity (e.g., substituting a histamine 2 [H<sub>2</sub>]-receptor antagonist for misoprostol, an abortifacient that is contraindicated during pregnancy).<sup>2,3</sup> Rarely, the maternal and fetal interests are diametrically opposed, as in the use of chemotherapy for maternal cancer, a therapy that can be life-saving to the mother but life-threatening to the fetus.<sup>4</sup> These conflicts raise significant medical, legal, and ethical issues.

The obstetrician and gynecologist, as well as the gastroenterologist and surgeon, should be familiar with the medical and surgical GI conditions that can present in pregnancy and how these conditions affect and are affected by pregnancy. This chapter reviews GI symptoms and disorders during pregnancy with a focus on aspects of these disorders unique to pregnancy.

## PHYSIOLOGIC EFFECTS OF PREGNANCY ON ABDOMINAL DISORDERS

Abdominal assessment during pregnancy is modified by displacement of abdominal viscera by the expanding gravid uterus. For example, the location of maximal abdominal pain and tenderness from acute appendicitis migrates superiorly and laterally as the appendix is displaced by the growing gravid uterus.<sup>5</sup> A rigid abdomen with rebound tenderness remains a valid indicator of peritonitis during pregnancy, but abdominal wall laxity and the interposition of the gravid uterus between the appendix and the anterior abdominal wall in late pregnancy may mask the classical signs of peritonitis.<sup>6</sup> An abdominal mass may be missed on physical examination because of an enlarged, gravid uterus.<sup>4</sup>

Many extraintestinal abdominal conditions or disorders are promoted by pregnancy. Mild hydronephrosis and hydroureter are common during pregnancy, particularly during the early

third trimester, because of diminished muscle tone in the urinary tract from elevated progesterone levels and mechanical obstruction from uterine compression. Hydronephrosis in pregnancy is usually asymptomatic but can cause positional abdominal discomfort.<sup>7</sup> Mucosal immunity may be attenuated during pregnancy as part of the physiologic immunologic tolerance for the foreign fetal antigens.<sup>8</sup> This phenomenon, as well as urinary stasis during pregnancy, contributes to an increased rate of cystitis and pyelonephritis. Pregnancy also promotes cholelithiasis because of increased cholesterol synthesis and gallbladder hypomotility related to gestational hormones.

**Pregnancy modifies GI physiology. Gastroesophageal reflux is promoted by gastric compression by the enlarged gravid uterus and by decreased lower esophageal sphincter tone due to increased serum progesterone and motilin levels during pregnancy.** Pregnancy also increases the risk of aspiration of gastric contents for the same reasons, and gastric acid secretion may decrease as a result of increased progesterone levels. In addition, small bowel motility decreases during pregnancy.<sup>9</sup> Constipation is promoted by decreased intestinal motility, mild intestinal compression by the enlarged gravid uterus, and increased recumbence from bed rest during pregnancy. Physiologic nausea and vomiting of pregnancy (NVP) is described below.

Physiologic alterations of laboratory values during pregnancy include, among others, mild leukocytosis, physiologic anemia of pregnancy, mild dilutional hypoalbuminemia, mildly increased alkaline phosphatase level, and electrolyte changes, particularly mild hyponatremia (see [Appendix 1](#), “Normal Values in Pregnancy”).<sup>5,10</sup> The erythrocyte sedimentation rate is physiologically elevated and is a less reliable monitor of inflammatory activity during pregnancy.<sup>11</sup> Gestational hormones, particularly estrogen, contribute to a mild hypercoagulopathy by increasing the synthesis of clotting factors. Thromboembolic phenomena are also promoted by intraabdominal vascular stasis from vascular compression by the enlarged gravid uterus.

The fetus poorly tolerates maternal hypotension, hypovolemia, anemia, and hypoxia. This intolerance affects the type and timing of therapy for abdominal disorders during pregnancy. The gravid uterus can compress the inferior vena cava in the supine position and thereby compromise venous return, aggravating systemic hypoperfusion from hypovolemia or GI bleeding. Simply turning the patient to the left side to displace the uterus may relieve this compression, improve venous return, and normalize the blood pressure.<sup>10</sup> The heart rate increases by 10 to 15 beats/min during pregnancy, but the blood pressure normally declines modestly; therefore a rise in blood pressure during pregnancy may portend preeclampsia or eclampsia. Drugs that are normally safe and indicated in nonpregnant women must be evaluated in terms of fetal safety before administration during pregnancy.

## DIFFERENTIAL DIAGNOSIS AND EVALUATION OF GASTROINTESTINAL SYMPTOMS DURING PREGNANCY

Physiologic changes during pregnancy may cause abdominal symptoms that include nausea, emesis, early satiety, bloating, pyrosis, and abdominal discomfort. Serious disorders that produce these symptoms may, therefore, be difficult to distinguish from physiologic changes during pregnancy. **Significant symptoms should not be dismissed as normal during**

### BOX 48-1 DIFFERENTIAL DIAGNOSIS OF RIGHT LOWER QUADRANT ABDOMINAL PAIN

#### Gastrointestinal Disorders

- Appendicitis
- Crohn disease
- Ruptured Meckel diverticulum
- Intestinal intussusception
- Cecal perforation
- Colon cancer
- Ischemic colitis
- Irritable bowel syndrome

#### Renal Diseases

- Nephrolithiasis

- Pyelonephritis

#### Obstetric and Gynecologic Diseases

- Ruptured ectopic pregnancy
- Ovarian tumors
- Ovarian cyst rupture
- Ovarian torsion
- Endometriosis
- Uterine leiomyomas

#### Other

- Trochanteric bursitis

**pregnancy without a careful history, physical examination, and appropriate evaluation.**

Occasionally, the pregnancy is not known by the patient or is not revealed to the physician, particularly in early pregnancy, when physical findings are absent. The physician should be vigilant for possible pregnancy in a fertile woman with abdominal symptoms, particularly in the setting of missed menses, because pregnancy affects the differential diagnosis, clinical evaluation, and mode of therapy. Pregnancy tests should be performed early in the evaluation of significant abdominal symptoms in this situation.

## Abdominal Pain

**The differential diagnosis of abdominal pain during pregnancy is extensive in that it includes obstetric conditions in addition to the usual GI and other intraabdominal conditions in the general population.**<sup>5</sup> Abdominal discomfort without other symptoms or signs can be due to an enlarging uterus, fetal pressure against adjacent organs, and Braxton-Hicks uterine contractions associated with normal pregnancy. **The abdominal pain is typically localized to the abdominal quadrant in which the afflicted organ is located, as illustrated for pain in the right lower quadrant in Box 48-1.** This general rule has occasional exceptions in nonpregnant patients because of referred pain from nearby regions, but it has more frequent exceptions during pregnancy because of displacement of viscera by the growing gravid uterus and referred or poorly localized pain from obstetric conditions.

**In the medical history, the pain intensity, nature, temporal pattern, radiation, exacerbating factors, and alleviating factors help narrow the differential diagnosis.** Abdominal pain increases progressively in appendicitis but is nonprogressive in viral gastroenteritis. The pain from obstruction of the small

**TABLE 48-1** COMMON CAUSES OF ACUTE, SEVERE ABDOMINAL PAIN DURING PREGNANCY: PAIN CHARACTERISTICS AND DIAGNOSTIC TESTS

| CONDITION                   | LOCATION   | CHARACTER   | RADIATION                       | DIAGNOSTIC TESTS   |
|-----------------------------|--|---|---------------------------------|--|
| Ruptured ectopic pregnancy  | Lower abdomen or pelvis                                | Localized, severe   | None                            | Serum $\beta$ -hCG, abdominal ultrasound   |
| Pelvic inflammatory disease | Lower abdomen or pelvis                                | Gradual in onset, localized                                   | Flanks and thighs               | Abdominal ultrasound   |
| Appendicitis                | First periumbilical, later RLQ (RUQ in late pregnancy) | Gradual in onset, becomes focal                               | Back or flank                   | Abdominal ultrasound in appropriate clinical setting                                   |
| Acute cholecystitis         | RUQ  | Focal   | Right scapula, shoulder or back | Abdominal ultrasound, serum liver function tests                                       |
| Pancreatitis                | Epigastric   | Localized, boring   | Middle of back                  | Serum lipase and amylase, abdominal ultrasound   |
| Perforated peptic ulcer     | Epigastric or RUQ                                      | Burning, boring   | Right back                      | Abdominal ultrasound, laparotomy   |
| Urolithiasis                | Abdomen or flanks                                      | Varies from intermittent and aching to severe and unremitting | Groin                           | Urinalysis, abdominal ultrasound, and occasionally fluoroscopy with contrast urography |

*hCG*, human chorionic gonadotropin *RLQ*, right lower quadrant; *RUQ*, right upper quadrant.

intestine may be intermittent but is severe, and renal and biliary colic also produce a waxing and waning intensity of pain. Acute cholecystitis is associated with RUQ pain as well as pain referred to the right shoulder. The pain of acute pancreatitis is often boring in quality, located in the abdominal midline, and radiates to the back. Careful physical examination of the abdomen that includes inspection, palpation, and auscultation can further pinpoint the etiology. Laboratory evaluation of significant abdominal pain routinely includes a complete blood count, serum electrolytes, and liver function tests and often includes a leukocyte differential, coagulation profile, and serum lipase determination. In evaluating the laboratory results, gestational changes in normative values, as mentioned earlier, must be considered. Radiologic tests may be extremely helpful diagnostically.

**When the diagnosis is uncertain, close and vigilant monitoring by a surgical team with frequent abdominal examination and regular laboratory tests can often clarify the diagnosis. The character, severity, localization, or instigating factors of abdominal pain often change with time. For example, acute appendicitis typically changes from a dull, poorly localized, moderate pain to an intense and focal pain as the inflammation extends from the appendiceal wall to the surrounding peritoneum. The differential diagnosis of severe abdominal pain is described in Table 48-1.**

GI causes of abdominal pain are discussed below under their individual headings in this chapter, and hepatobiliary causes are discussed in the prior chapter on hepatic disorders. Obstetric causes of abdominal pain are also prominent during pregnancy. **Ectopic pregnancy (EP)** classically presents with abdominopelvic pain and vaginal bleeding after a period of amenorrhea. The pain may initially be diffuse and vague but later becomes focal and severe. Physical signs include mild uteromegaly, cervical tenderness, and an adnexal mass. EP is often differentiated from a viable intrauterine pregnancy by serial beta-human chorionic gonadotropin ( $\beta$ -hCG) determinations,<sup>12</sup> but it is better differentiated from intrauterine pregnancy by transabdominal or transvaginal pelvic ultrasonography with simultaneous  $\beta$ -hCG determination.<sup>13</sup> Rupture of an ectopic pregnancy often presents with abdominal pain, rebound tenderness, and hypotension.<sup>12</sup>

In an **abdominal (heterotopic) pregnancy**, the abdominal pain is associated with signs of abdominal tenderness; a closed, noneffaced cervix; and a palpable mass distinct from the uterus.<sup>5</sup> Sonography and other radiologic modalities, as well as serial  $\beta$ -hCG determinations, are used to detect and localize the pregnancy. Abdominal pain is the most common symptom of

heterotopic pregnancy. Abdominal ultrasound is sometimes diagnostic, but laparotomy may be required for the diagnosis.

The lower abdominal pain associated with **preterm labor** is characteristically associated with vaginal discharge or spotting. Back pain and vaginal pressure commonly occur. The diagnosis is made by cervical examination, either by transvaginal ultrasound or digitally. The abdominal pain from **spontaneous abortion**—whether threatened, incomplete, or complete—tends to be mild to moderate, crampy, and diffuse and is typically associated with vaginal bleeding. **Placenta previa** sometimes presents with abdominal pain or painful uterine contractions in late pregnancy. Vaginal hemorrhage is, however, the predominant symptom. Sonography is usually diagnostic.<sup>13</sup> Although **placental abruption** commonly causes abdominal pain, it is typically distinguished from GI disorders by the presence of vaginal bleeding. Patients typically exhibit uterine tenderness and frequent uterine contractions. **Uterine rupture** usually presents in laboring women with abnormal fetal heart rate recordings or fetal death, uterine tenderness, peritoneal irritation, hypotension, and vaginal bleeding.

**Severe preeclampsia** can present with right upper quadrant (RUQ) pain and elevated serum transaminase levels. Patients exhibit hypertension and proteinuria that starts after 20 weeks' gestation. Patients with **hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome** often have epigastric or RUQ pain. Patients have hemolysis with a microangiopathic peripheral blood smear, elevated liver transaminase levels, and thrombocytopenia. **Acute fatty liver of pregnancy (AFLP)** often presents with abdominal pain, nausea and vomiting, anorexia, and jaundice. Liver biopsy demonstrates intracytoplasmic microsteatosis in hepatocytes. The definitive treatment for these three pregnancy-related conditions of preeclampsia, HELLP syndrome, and AFLP is prompt delivery after maternal stabilization, provided that the fetus is sufficiently mature (see Chapters 31 and 47).

**Choriocarcinoma**, a malignant trophoblastic proliferation, typically presents with an abdominal mass and vaginal bleeding but may cause abdominal pain. The symptoms usually occur after term pregnancy, abortion, or incomplete evacuation of a hydatidiform mole. The diagnosis is suggested by persistently elevated  $\beta$ -hCG levels in the absence of pregnancy.

Gynecologic disorders are also in the differential of abdominal pain during pregnancy. The lower abdominal pain from pelvic inflammatory disease (PID) is typically associated with pyrexia and vaginal discharge.<sup>14</sup> Hemorrhagic infarction of large uterine

leiomyomas (fibroids), called the *painful myoma syndrome*, is characterized by severe abdominal pain, nausea, emesis, pyrexia, and uterine bleeding. Ultrasonography or magnetic resonance imaging (MRI) is usually diagnostic. The abdominal pain of a tuboovarian abscess is frequently associated with a palpable lower abdominal mass, pyrexia, and leukocytosis. Patients often have risk factors such as prior pelvic surgery, assisted reproduction, or PID.<sup>15</sup> MRI or sonography is helpful in the diagnosis, but laparoscopy is often required for confirmation.

Adnexal torsion typically causes lower abdominal pain that is sharp and sudden in onset. Signs include unilateral lower quadrant tenderness, a palpable adnexal mass, cervical tenderness, or rebound tenderness from peritonitis. Ultrasonography, including duplex scanning, is valuable in the detection of adnexal masses, particularly cysts. The abdominal pain from early ovarian cancer tends to be vague and diffuse. Patients may also complain of abdominal distension and urinary frequency. Abdominal sonography is highly sensitive at mass detection but is insufficiently accurate at distinguishing malignant from benign ovarian lesions.<sup>13</sup> Surgery may be required to confirm the diagnosis and for definitive therapy.

The differential of abdominal pain during pregnancy also includes renal disorders. Symptoms from **cystitis** may include suprapubic discomfort without frank abdominal pain, but patients usually have urinary frequency, urgency, or dysuria.<sup>16</sup> The diagnosis is made by urinalysis and urine culture in the appropriate clinical setting. Symptoms from **acute pyelonephritis** include pyrexia, chills, nausea, emesis, and flank pain. The pain may radiate to the abdomen or pelvis and may cause costovertebral tenderness. Patients often have risk factors such as nephrolithiasis, recurrent lower urinary tract infections, diabetes mellitus, or congenital ureteral abnormalities.<sup>8</sup> The diagnosis is usually made by urine and blood cultures in the appropriate clinical setting. Renal ultrasound is performed in patients who fail to respond clinically within 3 days of instituting therapy or who have recurrent infection. The abdominal pain from **uro-lithiasis** typically radiates from the back or abdomen to the groin. Other symptoms include gross hematuria, nausea, emesis, urinary urgency, and urinary frequency.<sup>17</sup> Ultrasonography is the standard initial diagnostic test during pregnancy.<sup>17</sup>

Patients with **sickle cell hemoglobinopathies** that include hemoglobin SS, hemoglobin SC, and hemoglobin S/β-thalassemia are prone to sickle cell crises during pregnancy. Patients are usually black, and the abdominal pain in sickle cell crisis can be excruciating.

## Upper Gastrointestinal Symptoms

### Nausea and Vomiting

Nausea and vomiting during pregnancy is most commonly because of NVP or HG, idiopathic disorders without demonstrable mucosal or mural disease. The differential diagnosis of nausea and vomiting includes many other conditions (Box 48-2). NVP should be diagnosed only after exclusion of organic disorders by the history, physical findings, blood tests, and appropriate diagnostic studies. Misdiagnosis of nausea and vomiting as NVP, rather than more severe diseases, can be catastrophic. However, the great majority of nausea and vomiting during the first half of pregnancy is from NVP.

### Dyspepsia or Pyrosis

The differential diagnosis of dyspepsia or pyrosis (heartburn) during pregnancy is listed in Box 48-3. During pregnancy,

#### BOX 48-2 DIFFERENTIAL DIAGNOSIS OF NAUSEA AND VOMITING DURING PREGNANCY

- Nausea and vomiting of pregnancy
- Hyperemesis gravidarum
- Pancreatitis
- Symptomatic cholelithiasis
- Viral hepatitis
- Peptic ulcer disease
- Gastric cancer
- Intestinal obstruction
- Intestinal pseudoobstruction
- Gastroparesis diabeticorum
- Gastritis
- Gastroesophageal reflux disease
- Acute pyelonephritis
- Drug toxicity
- Vagotomy
- Preeclampsia/eclampsia
- Acute fatty liver of pregnancy
- Hemolysis, elevated liver enzymes, and low platelets (HELLP syndrome)
- Anorexia nervosa/bulimia
- Other neuropsychiatric disorders

#### BOX 48-3 DIFFERENTIAL DIAGNOSIS OF DYSPESIA OR PYROSIS DURING PREGNANCY

- Gastroesophageal reflux disease
- Peptic ulcer disease
- Nausea and vomiting of pregnancy
- Hyperemesis gravidarum
- Pancreatitis
- Biliary colic
- Acute cholecystitis
- Viral hepatitis
- Appendicitis
- Acute fatty liver of pregnancy (in late pregnancy)
- Irritable bowel syndrome/nonulcer dyspepsia

**gastroesophageal reflux disease (GERD) is extremely common,<sup>18</sup> whereas peptic ulcer disease (PUD) is relatively uncommon.** The diagnosis of GERD, rather than PUD, is suggested by pain that radiates substernally, or pain exacerbated by drinking acidic citrus drinks, or recumbency. Symptoms include water brash or regurgitation of an excessive amount of acidic saliva and the presence of extraintestinal manifestations, including nocturnal asthma, hoarseness, laryngitis, or periodontal disease. Patients with dyspepsia or pyrosis during pregnancy can usually be managed symptomatically without undergoing diagnostic esophagogastroduodenoscopy (EGD), as discussed below.

### Hematemesis

Upper GI bleeding is uncommon, but not rare, during pregnancy because pregnant patients are generally relatively young adults. NVP increases the risk of hemorrhage from a Mallory-Weiss tear, and decreased lower esophageal sphincter (LES) pressure and increased intragastric pressure during pregnancy promote gastroesophageal reflux that can cause hemorrhage. **The most common causes of GI hemorrhage during pregnancy are GERD, gastritis, Mallory-Weiss tears, and ulcers.<sup>19,20</sup>**

Unusual causes include esophageal varices and gastric cancer. Patients with upper GI bleeding that causes hemodynamic instability are approached much the same as nonpregnant patients

but with a few exceptions. In the general population, the hematocrit is not a reliable indicator of the severity of bleeding because of the lag between blood loss and the decline in the hematocrit. **The hematocrit is an even less reliable indicator of bleeding severity during pregnancy because of the conflicting effects of intravascular fluid accumulation and increased erythrocyte mass during normal pregnancy.** Maternal blood pressure is not a reliable indicator of fetal well-being. Fluid, including transfusions of packed erythrocytes when indicated, should be aggressively administered to pregnant patients with acute GI bleeding because of the extraordinary fetal sensitivity to hypoperfusion, the difficulty in assessing volume status during pregnancy, and the usually satisfactory cardiac function of pregnant patients.

### Dysphagia

The differential of dysphagia during pregnancy is similar to that in the general adult population, except that esophageal cancers are uncommon in these relatively young adults. Pregnant patients with acquired immunodeficiency syndrome (AIDS) can have dysphagia or painful swallowing, odynophagia, from esophageal candidiasis or esophageal lymphoma. Dysphagia from a peptic stricture is uncommon in pregnant patients, despite their high frequency of GERD, because their GERD is typically short term and moderate. Achalasia is a motility disorder that typically presents with a high resting LES pressure, failure of the LES to relax with swallowing, nonperistaltic esophageal muscle contractions, dysphagia, and weight loss.

Definitive therapy for severe dysphagia is best performed before, rather than during, pregnancy to assure adequate nutrition during gestation, a paramount concern for normal fetal development. Thus surgery for severe achalasia or other benign esophageal diseases should be performed before pregnancy.

## Lower Gastrointestinal Symptoms

### Diarrhea

The pathogenesis and differential diagnosis of diarrhea in pregnant women is similar to that in the nonpregnant population.<sup>21</sup> Acute diarrhea is usually caused by viral, bacterial, or parasitic enteropathogens. Viral agents, such as rotavirus and Norwalk virus, typically cause an acute self-limited diarrhea with upper GI symptoms and rare long-term sequelae. Bacterial causes of diarrhea include *Campylobacter*, *Shigella*, pathogenic *Escherichia coli*, and *Salmonella*. Pseudomembranous colitis from *Clostridium difficile* infection must be considered in the differential diagnosis when the diarrhea starts after antibiotic administration. Bacterial pathogens tend to produce frequent, small-volume stools, abdominal pain, and pyrexia. Inflammation of intestinal mucosa may produce fecal blood or leukocytes. Bacterial colitis is usually diagnosed by stool analysis and stool cultures. Pregnant patients with advanced human immunodeficiency virus (HIV) infection are prone to opportunistic enteric bacterial, fungal, parasitic, and viral infections, which often cause diarrhea. Noninfectious causes of diarrhea include medications, functional causes, food intolerances, and inflammatory bowel disease (IBD); in addition, hyperthyroidism can cause hyperdefecation. The initial management of severe acute diarrhea includes intravenous (IV) hydration, correction of electrolyte disorders, and consideration of discontinuing oral feedings. Stool studies include bacterial culture and sensitivity, ova and parasites, *C. difficile* toxin, and fecal leukocytes. Flexible sigmoidoscopy can be considered despite pregnancy for persistent refractory diarrhea if the

stool studies are unrevealing. Reversal of nutritional deficiencies from profound acute or chronic diarrhea is especially important during pregnancy to maintain fetal well-being.

### Constipation

**Constipation is very common in pregnant women and affects up to one-fourth of this population.**<sup>22</sup> Pregnancy tends to promote constipation from poor fluid intake due to nausea and vomiting, iron supplementation, decreased patient mobility, slowed GI transit predominantly from the effects of progesterone,<sup>9</sup> and GI compression by the enlarged gravid uterus.<sup>21</sup>

General measures can reverse these constipating factors during pregnancy. Adequate fluid intake and moderate exercise are important. Increased fiber intake—either by increasing dietary fiber, such as with wheat bran or psyllium husks, or by administering medications such as methylcellulose—is recommended to promote stool bulk and softness. Patients should be advised to defecate in the morning or after meals when colonic motor activity is stimulated via the gastrocolonic reflex. Sorbitol and lactulose, poorly absorbed sugars that cause an osmotic diarrhea, may be effective for constipation during pregnancy; however, they may cause abdominal bloating and flatulence. They should be used with caution in patients with diabetes, and they should be avoided in pregnant patients with nausea because they can exacerbate this symptom. Stimulant laxatives such as senna or bisacodyl may be considered in patients with severe constipation who fail to respond to conservative measures, bulk laxatives, or osmotic laxatives. **Laxatives to be avoided during pregnancy include castor oil, because it may initiate premature uterine contractions, and hypertonic saline laxatives such as phospho soda, because they promote sodium and water retention, which is inadvisable during pregnancy; in addition, they may cause renal failure in patients who are dehydrated or have preexisting renal insufficiency.**<sup>21,23</sup> Rarely, constipation is the first manifestation of severe GI disease during pregnancy.

### Red Blood Per Rectum

**Hemorrhoids are the most common cause of rectal bleeding during pregnancy.** Other causes in the differential diagnosis include ulcerative colitis (UC), Crohn disease (CD), a rectal fissure, and infectious colitis as well as unusual diagnoses during pregnancy such as diverticular bleeding, bowel ischemia, or colon cancer.

## DIAGNOSTIC TESTING DURING PREGNANCY

### Radiologic Imaging

Fetal safety during diagnostic imaging is a concern for pregnant patients and pregnant medical personnel. **Ultrasonography is considered safe during pregnancy and is the preferred imaging modality for abdominal pain during pregnancy.**<sup>13</sup> Unfortunately, test sensitivity depends on operator technique, patient cooperation, and the patient's anatomy in that sensitivity is decreased by abdominal fat and intestinal gas (see [Chapter 9](#)).<sup>13</sup> MRI is preferable to computed tomography (CT) during pregnancy to avoid ionizing radiation, and gadolinium administration should be avoided if feasible during MRI in the first trimester.<sup>24</sup> Rapid-sequence MRI is preferable to conventional MRI because of briefer exposure. The patient should undergo counseling before diagnostic roentgenography.

Data concerning fetal malformations, growth restriction, and mortality from ionizing radiation are derived from past

**TABLE 48-2** GENERAL PRINCIPLES REGARDING ABDOMINAL IMAGING TESTS DURING PREGNANCY

| TEST                       | SAFETY DURING PREGNANCY   |
|----------------------------|---|
| Abdominal ultrasound       | Considered safe and is the preferred imaging modality during pregnancy; unfortunately, this test is less sensitive and less specific than other imaging modalities for many abdominal disorders   |
| Magnetic resonance imaging | Considered safe; some avoid administering gadolinium, but no firm evidence of teratogenicity or other harm exists   |
| Radiographs                | Single radiographs entail a small but acceptable fetal risk; limit fetal radiation exposure by shielding, collimation, rapid-sequence studies, and modern x-ray equipment   |
| Computed tomography        | Consider magnetic resonance imaging as alternative when abdominal ultrasound is nondiagnostic. Computed tomography may be required in rare circumstances (e.g., to avoid surgery for possible but unproven appendicitis) and is safe if not repeated several times. Consult with a radiation physicist to minimize fetal radiation exposure |

experience, particularly from survivors of the atomic bombs in Japan and the nuclear accident in Chernobyl. Radiation can cause chromosomal mutations and neurologic abnormalities, including mental retardation, and it moderately increases the risk of childhood leukemia.<sup>25</sup> Radiation dosage is the most important risk factor, but fetal age at exposure and proximity to the radiation source are also important factors (see [Chapter 8](#)). Diagnostic studies with the most radiation exposure, such as IV pyelography or barium enema, typically expose the fetus to less than 1 rad.<sup>24</sup> Thus one diagnostic fluoroscopic procedure is safe in pregnancy. In decisions regarding roentgenographic tests, the risks from radiation exposure must be weighed against the benefits of diagnosing a severe condition. Fetal radiation exposure should be minimized by fetal shielding, collimation, and rapid-sequence studies. Consultation with a radiation physicist may help reduce radiation exposure. Adverse fetal effects from iodinated contrast have not been reported, and these contrast materials can be used when indicated. The safety of radiologic abdominal imaging during pregnancy is briefly summarized in [Table 48-2](#).

### Endoscopy During Pregnancy

Endoscopy is often performed in the evaluation of abdominal symptoms in nonpregnant patients. Flexible sigmoidoscopy is used to evaluate minor lower GI complaints including rectal symptoms, whereas EGD is performed to evaluate epigastric pain, dyspepsia, or pyrosis. Although endoscopy is extremely safe in the general population, endoscopy during pregnancy raises the unique issue of fetal safety. Endoscopy could potentially cause fetal complications from the medications used, placental abruption or fetal trauma during endoscopic intubation, cardiac arrhythmias, systemic hypotension or hypertension, and transient hypoxia. The teratogenicity of medications is of particular concern in the first trimester during organogenesis.

**Sigmoidoscopy seems to be relatively safe during pregnancy.** No woman suffered endoscopic complications in a study of 46 patients undergoing sigmoidoscopy during pregnancy.<sup>26</sup> Excluding one unknown pregnancy outcome and four voluntary abortions, 38 of 41 pregnant women delivered healthy infants, including 27 at full term. Study patients did not have a worse outcome than pregnant controls matched for sigmoidoscopy

indications who did not undergo sigmoidoscopy in terms of mean infant Apgar scores at birth, the rates of fetal or neonatal demise, premature delivery, low birthweight, and delivery by cesarean section. Additionally, no endoscopic complications were reported in 13 flexible sigmoidoscopies during pregnancy analyzed by a mailed survey of 3300 gastroenterologists.<sup>20</sup> All pregnancies resulted in delivery of healthy infants at term.

These studies, in addition to scattered case reports, strongly suggest that sigmoidoscopy during pregnancy does not induce labor or cause congenital malformations and should be strongly considered in medically stable patients with clear indications. Sigmoidoscopy is not recommended during pregnancy for questionable indications, such as routine cancer screening or surveillance, which can be deferred until at least 6 weeks postpartum. Sigmoidoscopy should be performed with careful maternal monitoring that includes electrocardiography (ECG), blood pressure, and pulse oximetry after obstetric consultation and medical stabilization. Analgesic medication should be minimized during sigmoidoscopy, especially during the first trimester.

**Data are currently limited on colonoscopy during pregnancy.** The two largest studies comprised 20 and 8 pregnant patients.<sup>26,27</sup> In the study of 20 pregnant patients, 16 colonoscopies were performed during the second trimester. Excluding one successful therapeutic colonoscopy to decompress a severely dilated colon from colonic pseudoobstruction, colonoscopy was diagnostic in 10 of 19 cases, which included diagnoses of ulcerative, ischemic, Crohn, and lymphocytic colitis. Colonoscopy led to therapeutic changes in the management of seven patients, and two minor maternal procedural complications of mild transient hypotension occurred without clinical sequelae. Fetal outcomes were generally favorable: all infants were born healthy except for one spontaneous abortion and one infant born with congenital defects.

Colonoscopy should be considered, particularly during the second trimester, for very strong indications—such as suspected colon cancer—after obtaining informed consent that includes the theoretic but unsubstantiated fetal risks of colonoscopy. Colonoscopy should be considered questionable during the first trimester, even though at times it can be justified for extremely clear indications. A polyethylene glycol (PEG) balanced electrolyte solution is generally preferred over a sodium phosphate (Fleet phospho soda) solution to cleanse the colon for colonoscopy because sodium phosphate is associated with renal failure or electrolyte abnormalities in dehydrated or otherwise at-risk patients.<sup>28</sup> Colonoscopic tattooing of colonic lesions is performed using India ink or methylene blue in the nonpregnant population, but methylene blue should not be used during pregnancy because of potential fetotoxicity.

**EGD is relatively safe for the fetus and the pregnant mother.** In a case-controlled study<sup>19</sup> of 83 EGDs performed during pregnancy at a mean gestational age of 20 weeks, the indications for EGD included GI bleeding in 37, abdominal pain in 28, vomiting in 14, and other indications in 4. EGD did not cause any maternal complications and did not lead to labor. Excluding 6 voluntary abortions and 3 unknown pregnancy outcomes, 70 of 74 patients (95%) delivered healthy infants. In this study, the four adverse pregnancy outcomes—three stillbirths or deaths from severe prematurity and one involuntary abortion—occurred in high-risk pregnancies and were unrelated to EGD temporally or etiologically. No liveborn infant had any congenital malformation noted in the neonatal nursery. The pregnancy outcome in study patients included the mean Apgar scores at

1 and 5 minutes and the frequency of low birthweight, infant deaths, congenital defects, and delivery by cesarean section and was not statistically significantly different from the mean scores or rates in a group of 48 pregnant controls matched for EGD indications who did not undergo EGD because of their pregnancy. The two patient groups had similar pregnancy outcomes even though the study patients generally were sicker and had a stronger indication for EGD than the controls. This study and two other studies of 60 pregnant patients undergoing EGD during the first trimester<sup>29</sup> and of 30 pregnant patients undergoing EGD during pregnancy<sup>30</sup> suggest that EGD is at least as safe as not performing the procedure in pregnant patients with a strong indication for EGD. Similar results were noted in a report of 73 pregnant patients who underwent EGD, analyzed by a mailed survey of 3300 gastroenterologists.<sup>20</sup>

**EGD is recommended during pregnancy for hemodynamically significant upper GI bleeding.** It is rarely helpful, and rarely necessary, for nausea and vomiting or even HG during pregnancy. EGD is reserved for atypical situations, such as severe and refractory nausea and vomiting accompanied by significant abdominal pain, hematemesis, or signs of gastroduodenal obstruction. EGD is neither necessary nor indicated to evaluate typical symptoms of GERD during pregnancy and **should be reserved for cases when the presentation is atypical and severe, when the condition is refractory to intense pharmacologic therapy, when esophageal surgery is contemplated, and when complications such as GI bleeding or dysphagia supervene.** EGD is useful in diagnosing complicated PUD, including gastric outlet obstruction, malignant gastric ulcer, refractory ulcer, and persistently bleeding ulcer. EGD should be performed in relatively stable patients with ECG monitoring after obstetric consultation and after normalization of vital signs, which may require transfusion of packed erythrocytes and supplemental oxygenation. Fetal monitoring should be performed at a gestational age when intervention for nonreassuring fetal status would be considered. Informed consent is particularly important during pregnancy. The patient should be informed of the benefits and apparent safety of endoscopy, but she should also be cautioned that the potential fetal risks are incompletely characterized. **General measures to increase the risk/benefit ratio of endoscopy during pregnancy are listed in Table 48-3.**<sup>31-34</sup>

Video capsule endoscopy (VCE) is routinely used for recurrent GI bleeding after nondiagnostic EGD and colonoscopy. The most common serious complication of VCE in the general population is capsule retention.<sup>35</sup> Pregnancy may theoretically promote capsule retention because of displacement and impingement of bowel loops by the enlarged gravid uterus. Few data exist on VCE safety during pregnancy.<sup>36</sup> A review of the literature revealed only one case performed during pregnancy, in which VCE identified the bleeding site and “the patient and the fetus did well.”<sup>37</sup> VCE is currently considered experimental during pregnancy but may be considered for recurrent, life-threatening GI hemorrhage after excluding upper GI and colonic etiologies.

**Team Approach and Informed Consent**

A team approach with consultation and referral helps optimize the management of complex diseases during pregnancy that affect both the mother and the fetus and that require disparate areas of expertise. The gastroenterologist contemplating endoscopy may consult with the obstetrician about the optimal timing for the procedure and with the anesthesiologist about analgesia during endoscopy. The internist may discuss with the radiologist the benefits versus risks of radiologic tests, and the radiologist may in turn consult with a physicist about methods to monitor and reduce fetal radiation exposure. The surgeon may consult with the obstetrician about the timing of abdominal surgery in relation to the pregnancy and about performing simultaneous cesarean delivery and abdominal surgery. These complex problems during pregnancy are best handled at a tertiary hospital, where the requisite experience and expertise is available. Pregnancy complicated by significant GI disease is best managed by an obstetrician who specializes in high-risk pregnancies.

The patient should be informed about the consequences to both herself and her fetus of diagnostic tests and therapy and should be actively involved in these medical decisions. Under the vigilant guidance of medical experts, the patient makes the decision with advice provided by her partner, family, and friends. When an intervention entails significant potential fetal risk, such as roentgenographic tests, a signed, witnessed, and informed consent is recommended even though this intervention would

**TABLE 48-3      GENERAL PRINCIPLES TO IMPROVE THE RISK/BENEFIT RATIO OF GASTROINTESTINAL ENDOSCOPY DURING PREGNANCY**

| PRINCIPLE  | EXAMPLE   |
|--|---|
| Perform endoscopy only for strong indications  | Colonoscopy for suspected colon cancer  |
| Avoid endoscopy or defer it until delivery for weak or elective indications  | Colonoscopy for routine colon cancer screening  |
| Use the safest drugs (Food and Drug Administration category B preferable or at most category C) in the lowest possible dosages for sedation and analgesia  | Propofol (category B) or fentanyl (category C) but not diazepam (category D) because of possible, albeit unlikely, association with congenital cleft palate |
| Consult an anesthesiologist regarding drug safety during pregnancy   | Monitored anesthesia care (MAC) with anesthesiologist present during endoscopy  |
| It is preferable to perform endoscopy in the second trimester, if possible, to avoid potential teratogenicity during fetal organogenesis in the first trimester and to avoid premature labor or adverse effects on the neonate after delivery in the third trimester | If possible, defer endoscopy during the first trimester until the second trimester, and defer endoscopy during the third trimester until after delivery.    |
| Minimize procedure time  | Performed by an experienced, expert endoscopist   |
| Obstetric support should be available for a pregnancy-related procedure complication   | Performed in an in-hospital endoscopy suite rather than a physician's office or ambulatory surgical center  |

Modified from Cappell MS. Endoscopy in pregnancy: risks versus benefits. *Nature Clin Pract Gastroenterol Hepatol.* 2005;2(9):376-377; Cappell MS. The fetal safety and clinical efficacy of gastrointestinal endoscopy during pregnancy. *Gastroenterol Clin North Am.* 2003;32:123-79; Cappell MS. ASGE guideline: guidelines for endoscopy in pregnant and lactating women. *Gastrointest Endosc.* 2005;61(3):357-362.

be routine and would not require consent in a nonpregnant patient.

## GASTROINTESTINAL DISORDERS

Key differences during pregnancy in the clinical presentation, diagnosis, and therapy of GI disorders are summarized in Box 48-4.

### Predominantly Upper Gastrointestinal Disorders

#### Nausea and Vomiting of Pregnancy and Hyperemesis Gravidarum

Nausea and vomiting occurs in more than 50% of pregnancies. It typically begins at about 5 weeks' gestation and abates by about 18 weeks. It has been called "morning sickness" but is more accurately called *nausea and vomiting of pregnancy* (NVP) or *emesis gravidarum* because it occurs throughout the day.<sup>38</sup> This condition should be viewed as a physiologic, rather than pathologic, process during early pregnancy because it is generally associated with favorable maternal and fetal outcomes (see Chapter 6). **Hyperemesis gravidarum (HG) is a severe, pathologic form of NVP characterized by a greater than 5% loss of prepregnancy weight and otherwise unexplained ketonuria.** The weight loss is paradoxical because patients normally gain weight during pregnancy.<sup>39</sup> HG occurs in only about 0.5% of pregnancies.<sup>40</sup>

The pathophysiology of HG is unknown but is believed to be multifactorial. Human chorionic gonadotropin (hCG) has been proposed as an etiologic factor because the serum hCG level peaks when HG is most severe, and the serum hCG level is higher in patients with HG than it is in other pregnant patients.<sup>41</sup> Other postulated etiologic factors include gestational hyperthyroidism, gastric dysrhythmias, and hyperthyroidism.<sup>40</sup>

Patients with NVP have only mild to moderate symptoms, no weight loss, and lack evidence of dehydration, vitamin deficiencies, and other nutritional deficiencies. Aside from severe nausea and vomiting, symptoms of HG may include xerostomia, sialorrhea or ptyalism, and dysgeusia. Physical findings reflective of hypovolemia include dry mucous membranes, poor skin turgor, and orthostatic hypotension or hypotension. Serum electrolyte abnormalities include hyponatremia, hypocalcemia, and hypokalemia. Patients may demonstrate prerenal azotemia, and chronic vomiting of gastric contents may cause hypochloremic metabolic alkalosis. An increased hematocrit reflects hemoconcentration from hypovolemia. Patients with severe vomiting may develop abnormal liver function tests, particularly elevations of the serum aminotransferases. Patients may exhibit mild, transient hyperthyroidism that manifests as low thyroid-stimulating hormone (TSH) levels as a result of elevated serum hCG levels,<sup>42</sup> and inadequate nutrition may lead to vitamin or micronutrient deficiencies.

**NVP and HG are diagnoses of exclusion arrived at only after excluding other conditions by appropriate tests.** An abdominopelvic ultrasound is performed to exclude other causes of nausea and vomiting, as well as gestational trophoblastic disease and multiple gestation, conditions associated with HG. Patients with epigastric or RUQ pain should have determinations of serum liver function tests and serum lipase levels to rule out hepatobiliary and pancreatic disease. Patients with nausea and vomiting complicated by dysphagia or hematemesis may require EGD.

Risk factors for HG include a first pregnancy, multiple gestation, molar pregnancy, prior unsuccessful pregnancy, and prior HG.<sup>39</sup> Like NVP, HG typically begins early in pregnancy; severe vomiting that begins after the first trimester is unlikely from HG. In other pregnancy-related conditions that cause nausea and vomiting—including AFLP, preeclampsia, and HELLP syndrome—the nausea and vomiting typically begins in the second half of pregnancy.

**Patients with mild nausea during pregnancy typically require counseling and reassurance without pharmacologic therapy.** Patients with NVP often benefit from eating small, frequent meals to avoid gastric distension that may trigger nausea and from eating a bland diet that emphasizes salty crackers, soups, starches, and chicken while avoiding spicy, fatty, or fibrous foods.<sup>40</sup> Avoiding strenuous work and taking frequent naps may also be helpful. Patients with NVP associated with heartburn and regurgitation should be instructed about antireflux measures and diet and lifestyle modifications and should receive mild antireflux medications.

Patients with more severe NVP may benefit from drug therapy. Bendectin—which contains vitamin B<sub>6</sub> and doxylamine, an antihistamine—was once commonly administered for NVP but was withdrawn in 1983 due to unproven allegations of teratogenicity.<sup>40</sup> A subsequent meta-analysis reported no increase in the incidence of birth defects after in utero exposure to Bendectin.<sup>43</sup> **Vitamin B<sub>6</sub> (pyridoxine), a component of Bendectin, has been used by itself to treat mild-to-moderate NVP with some success.**<sup>44</sup> A delayed-release form of doxylamine-pyridoxine (Diclectin) is currently approved in the United States and Canada to treat NVP and should be the first-line pharmacotherapy. Dopamine antagonists, such as promethazine, or selective serotonin antagonists, such as ondansetron, have been used successfully and safely as antiemetics for these conditions.<sup>45</sup> Other therapies for HG include ginger, metoclopramide, and methylprednisone.

Therapy for HG is initially focused on aggressive IV rehydration and restoration of electrolyte deficiencies. Vitamins should be replaced, and thiamine should be administered before dextrose to prevent Wernicke encephalopathy. After IV repletion, the diet is gradually advanced as tolerated, initially to salty fluids and then to a bland diet. Nutritional consultation is recommended. Nasoenteral or nasogastric feedings are useful alternatives in patients who cannot tolerate oral feedings. Total parenteral nutrition (TPN) is rarely necessary. Patients should avoid environmental stimuli that trigger their nausea and vomiting. Patients should eat as soon as they feel hungry to avoid eating on an empty stomach, which can exacerbate nausea.

NVP is classically associated with a favorable pregnancy outcome, but in addition to the psychological stress in the expectant mother, it has been linked to possible physical and psychosocial disorders later in childhood.<sup>46</sup> The maternal and fetal prognosis of HG is relatively favorable provided that the nausea and vomiting are reversed, and the mother gains adequate weight during the remainder of the pregnancy.<sup>47</sup>

#### Gastroesophageal Reflux and Peptic Ulcer Disease

**The incidence of pyrosis approaches 80% during pregnancy.<sup>5</sup> The incidence of GERD is likewise high during pregnancy<sup>48</sup> and may relate to a hypotonic LES and delayed GI transit attributed to gestational hormones, especially progesterone, and gastric compression by the gravid uterus.** GERD manifests in pregnancy, as in nonpregnant patients, by pyrosis,

### BOX 48-4 KEY DIFFERENCES DURING PREGNANCY IN THE CLINICAL PRESENTATION AND DIAGNOSIS OF GASTROINTESTINAL DISORDERS

#### Mallory-Weiss Tear

Much more common cause of upper GI bleeding during pregnancy due to mechanical trauma at the GE junction from nausea and vomiting of pregnancy or HG.

#### Nausea and Vomiting

Extremely common during pregnancy. Nausea begins at about 5 weeks' gestation and abates between 12 and 18 weeks and is related to elevated serum hCG levels during early pregnancy.

#### Hyperemesis Gravidarum

Severe form of nausea and vomiting during pregnancy characterized by a more than 5% loss of prepregnancy weight, serum electrolyte disorders, and ketonuria. This condition requires aggressive therapy.

#### Gastroesophageal Reflux

GE reflux is extremely common during pregnancy due to reduced LES tone due to gestational elevation of serum progesterone level and gastric compression by the enlarged gravid uterus. Although it may produce bothersome symptoms during pregnancy, serious complications of GE reflux are unusual during pregnancy.

#### Acute Appendicitis

Displacement of appendix by the enlarged gravid uterus during late pregnancy may cause the point of maximal abdominal pain and tenderness to migrate several centimeters superiorly and laterally from the McBurney point. Rate of appendiceal perforation from appendicitis is increased during pregnancy attributed to delayed diagnosis. Ultrasound is the imaging test of choice during pregnancy to diagnose appendicitis to avoid fetal exposure to ionizing radiation. Appendectomy may be performed during pregnancy but is safest during the second trimester.

#### Intestinal Obstruction

More common in third trimester because of mechanical effects of the enlarged gravid uterus, IO can occur during parturition because of mechanical effects of descent of the fetal head and abrupt decrease in uterine size. Despite pregnancy, supine and upright radiographs are necessary to diagnose and monitor IO. Unrelenting, complete IO generally requires surgery despite pregnancy.

#### Intestinal Pseudoobstruction

Although risk of intestinal pseudoobstruction or adynamic ileus is increased after cesarean or vaginal delivery, this complication is still uncommon. It is generally managed medically without surgical intervention as in nonpregnant patients.

#### Colonic Pseudoobstruction

Despite limited clinical data, colonoscopy can be considered for colonic decompression when the only alternative is surgery, provided that colonic necrosis is not suspected. Parenteral neostigmine is often administered therapeutically in

nonpregnant patients but may be contraindicated during pregnancy.

#### Colon Cancer

Uncommon during pregnancy because of younger age of pregnant patients, iron deficiency anemia is common during pregnancy due to increased gestational demands and is much less often associated with colon cancer in pregnant patients than it is in the elderly. Colon cancer diagnosed during pregnancy is often located in the rectum or sigmoid colon and frequently presents at an advanced pathologic stage, attributed to delayed diagnosis. Pregnant patients have a high incidence (25%) of ovarian metastases from colon cancer. Colonoscopy may be necessary during pregnancy before surgery for colon cancer to obtain a pathologic diagnosis and to exclude synchronous lesions. When cancer is diagnosed during the first half of pregnancy, cancer surgery should be promptly performed to minimize risk of metastases. Bilateral salpingo-oophorectomy is indicated for ovarian metastases.

#### Inflammatory Bowel Disease

Ulcerative colitis does not generally affect fertility, whereas Crohn disease mildly decreases fertility. Patients with inactive or mild inflammatory bowel disease at conception tend to have the same disease activity during pregnancy. Patients with active disease at conception can have active disease during pregnancy with an increased risk of poor fetal outcomes, especially for Crohn disease. Flexible sigmoidoscopy is generally well tolerated during pregnancy and can be used to help diagnose a disease flare. Corticosteroids, sulfasalazine, and 5-aminosalicylates can be administered during pregnancy. Azathioprine is classified as FDA class D during pregnancy, but gastroenterologists sometimes continue this medication during pregnancy to maintain remission. However, the TNF inhibitors infliximab, adalimumab, and certolizumab are apparently safer alternatives and are rated as FDA category B during pregnancy. Methotrexate is contraindicated during pregnancy.

#### Hemorrhoids

Hemorrhoids are extremely common during pregnancy due to vascular engorgement, vascular compression from the enlarging gravid uterus, and increased straining at defecation because of constipation. Medical therapy is generally recommended because hemorrhoidal symptoms usually resolve spontaneously soon after delivery.

#### Mesenteric Ischemia and Infarction

Risk of mesenteric ischemia is mildly increased during pregnancy due to mild hypercoagulability from hyperestrogenemia, but risk is still relatively low because mesenteric ischemia is predominantly a disease of the elderly.

#### Splenic Artery Rupture

Risk of splenic artery aneurysm rupture markedly increases during pregnancy due to estrogen weakening the elasticity of the arterial wall, but overall risk is still relatively low.

regurgitation, water brash, dyspepsia, hypersalivation, or, rarely, pulmonary symptoms. Symptoms may be exacerbated by ingesting certain foods, such as acidic drinks, or by recumbency. Complications of GERD include hemorrhagic esophagitis, dysphagia from reflux-induced esophageal stricture, and Barrett esophagus or adenocarcinoma. These complications generally relate to severe, long-standing, poorly controlled GERD. During pregnancy, GERD tends to be mild and of short duration, coincident with the pregnancy, so these complications are rare. EGD is the best test to diagnose reflux esophagitis. Characteristic findings are erosions, exudates, erythema, or ulcers just above the gastroesophageal (GE) junction. EGD can be performed during pregnancy if necessary but is generally reserved for complications from GERD such as GI hemorrhage or dysphagia.

Symptomatic peptic ulcer disease is uncommon during pregnancy, and antecedent PUD often improves during pregnancy.<sup>49</sup> **Nausea, emesis, dyspepsia, and anorexia are so frequent during pregnancy that PUD cannot be diagnosed solely by symptomatology during pregnancy.**<sup>50</sup> The most common cause of a duodenal ulcer is *Helicobacter pylori* infection. Nonsteroidal antiinflammatory drugs (NSAIDs), including aspirin, can cause gastric or duodenal ulcers. These ulcers more commonly present with GI bleeding than abdominal pain, possibly because of the analgesic properties of NSAIDs.<sup>51</sup>

Although the efficacy of modern acid-suppressive drugs has rendered lifestyle modifications less important in the nonpregnant patient with GERD or PUD, lifestyle modifications remain important in the pregnant patient because of concern about drug teratogenicity.<sup>50,52</sup> **Pregnant patients with GERD or PUD should avoid caffeine, alcohol, smoking cigarettes, and NSAID use, although acetaminophen is safe and the cyclooxygenase 2 (COX-2) inhibitors are less gastrototoxic than the nonselective NSAIDs.**<sup>51</sup> **Patients with GERD should elevate the head of their bed and avoid wearing tight belts. They should avoid recumbency after eating and discontinue oral intake 3 hours before bedtime.**

**Antacids are generally safe for the fetus, although those that contain sodium bicarbonate should be used with caution throughout pregnancy because such antacids may cause fluid overload or metabolic alkalosis.**<sup>53</sup> Antacids and dietary measures often suffice during the first trimester for minimally symptomatic disease.<sup>2</sup> Antacids must be administered frequently because of low potency, and frequent administration can cause diarrhea or constipation and electrolyte or mineral abnormalities. Orally administered sucralfate has minimal systemic absorption and is generally believed to be safe during pregnancy, but its aluminum content is of concern to the fetus in mothers with renal insufficiency.<sup>54</sup> Misoprostol can cause labor and cervical ripening.<sup>3</sup> H<sub>2</sub>-receptor antagonists are useful in treating GERD and PUD when symptoms are more severe or occur later in pregnancy.<sup>2,54</sup> Ranitidine and famotidine are preferable because nizatidine is possibly toxic to the fetus,<sup>55</sup> and cimetidine has antiandrogenic effects.<sup>56</sup> **Proton pump inhibitors were initially reserved for refractory, severe, or complicated GERD or PUD during pregnancy but have recently been increasingly used for moderate disease because of accumulating evidence of relative fetal safety.** Lansoprazole, rabeprazole, and pantoprazole (Food and Drug Administration [FDA] pregnancy category B) appear to be relatively safe and are therefore the recommended agents in this class during pregnancy.<sup>57,58</sup> Omeprazole is rated only as FDA category C during pregnancy, but a study

in 2001 that involved 863 infants exposed to omeprazole during the first trimester revealed rates of stillbirth and congenital malformations comparable to those of unexposed controls.<sup>59</sup> Metoclopramide is probably not teratogenic, but it can cause maternal side effects. **Drug therapy for *H. pylori* eradication should be deferred until after parturition and lactation because of concern about the fetal safety of antibiotics, such as clarithromycin and metronidazole.**<sup>60</sup>

**Surgery for GERD is best performed either before or after pregnancy.**<sup>2,54</sup> Endoscopic therapy is the initial intervention for bleeding from GERD or PUD,<sup>32,49</sup> but a hemodynamically unstable patient refractory to endoscopic therapy requires expeditious surgery, because the fetus poorly tolerates maternal hypotension.<sup>61,62</sup> Patients in advanced pregnancy should undergo cesarean delivery just before gastric surgery for GI bleeding.<sup>61,62</sup> Pregnant patients with PUD may also require surgery for gastric outlet obstruction, refractory ulcer, or a malignant ulcer.<sup>63</sup>

### Diaphragmatic Rupture

In diaphragmatic rupture, abdominal contents herniate through a diaphragm weakened by congenital defects or abdominal or chest trauma. The risk of rupture is increased during pregnancy because of increased pressure on the diaphragm from recurrent vomiting during the first half of pregnancy, rapid growth of the gravid uterus during the second trimester, or the Valsalva (breath holding) and Kristeller (fundal pressure) maneuvers during labor. Even during pregnancy, diaphragmatic rupture is rare, but it is potentially catastrophic when it occurs during pregnancy, and both maternal and fetal mortality from bowel strangulation exceed 40%.<sup>64</sup> Increased intraabdominal pressure from the enlarged gravid uterus increases the risk. Herniorrhaphy is recommended during the first two trimesters for eventrated diaphragmatic hernia, even if asymptomatic, because of the high mortality without surgery.<sup>64,65</sup> Early recognition of eventrated or strangulated viscera is crucial to reduce mortality. Expectant management is advised for asymptomatic patients during the third trimester, followed by cesarean delivery and herniorrhaphy when the fetus is sufficiently mature. Cesarean delivery is the preferred route of delivery and avoids the increased abdominal pressure during active labor, which can cause bowel strangulation.<sup>65</sup>

## Predominantly Lower Gastrointestinal Disorders

### Acute Appendicitis

**Acute appendicitis is the most common nonobstetric surgical emergency during pregnancy with an incidence of about 1 per 1000 pregnancies.**<sup>6,66</sup> **Appendiceal obstruction, usually from an appendicolith, is the primary etiologic event, although stasis and other factors are also implicated. As the appendiceal lumen distends secondary to appendiceal obstruction, the patient initially experiences poorly localized periumbilical pain. Severe luminal distension, mural inflammation and edema, and bacterial translocation produce somatic pain that becomes severe and well localized at the McBurney point, which is located in the right lower quadrant one third of the way from the anterior superior iliac spine to the umbilicus. Displacement of the appendix by the gravid uterus during late pregnancy may cause the point of maximal abdominal pain and tenderness to migrate superiorly and laterally from the McBurney point, but this migration typically extends only a few centimeters away from the McBurney**

**point during late pregnancy.**<sup>5</sup> Rectal or pelvic tenderness may occur in early pregnancy but is unusual in late pregnancy as the appendix migrates from its pelvic location. Other clinical findings include anorexia, nausea, emesis, pyrexia, tachycardia, and abdominal tenderness.<sup>67</sup> Periappendiceal inflammation or peritonitis causes involuntary guarding and rebound tenderness. Involuntary guarding and rebound tenderness are less reliable signs of peritonitis in late pregnancy because of abdominal wall laxity and elevation of the anterior abdominal wall away from the inflamed appendix by the growing gravid uterus.<sup>6</sup> Patients may have significant leukocytosis and neutrophilia in the leukocyte differential.<sup>68</sup>

Radiologic imaging is indicated to reduce the incidence of negative appendectomy when the diagnosis is suspected but remains ambiguous after routine laboratory studies. Although CT is the preferred imaging test in nonpregnant patients because of its high diagnostic accuracy, **sonography is the initial imaging test of choice during pregnancy** to avoid fetal exposure to radiation from CT. In a comprehensive review, ultrasound was 86% sensitive and 81% specific in the diagnosis of appendicitis in adults or adolescents.<sup>69</sup> Diagnostic findings include appendiceal mural thickening, periappendiceal fluid, and a noncompressible tubular structure 6 mm or more in diameter that is closed at one end and open at the other. **Appendicitis cannot be excluded if the appendix is not visualized on ultrasound.** Ultrasound can also help exclude other pathology, such as an adnexal mass.<sup>13</sup> Factors associated with diminished test sensitivity include maternal obesity, the third trimester of pregnancy, and an inexperienced radiologist.

**MRI is the appropriate next test in the pregnant patient if the abdominal ultrasound is inconclusive.** In a study of 148 pregnant women with suspected appendicitis during pregnancy, MRI was 100% sensitive and 93% specific for the diagnosis of acute appendicitis.<sup>70</sup> CT can be performed with modifications to limit fetal radiation exposure to less than 300 mrad if MRI is unavailable. Abnormal CT findings with appendicitis include right lower quadrant inflammation; a nonfilling, enlarged tubular structure; and an appendicolith.

**Up to one quarter of pregnant women with appendicitis develop an appendiceal perforation.**<sup>5</sup> **This high rate is attributed to delayed diagnosis during pregnancy.** The diagnosis may be missed in pregnant patients for a number of reasons: (1) leukocytosis, a classic sign of acute appendicitis, occurs physiologically during pregnancy; (2) nausea and emesis, common symptoms of acute appendicitis, are also common during pregnancy; and (3) the abdominal pain is sometimes atypically located.<sup>68</sup> Other diseases are often confused with appendicitis. The differential diagnosis of appendicitis in pregnancy is shown in Box 48-5. Appendiceal displacement predisposes to rapid development of generalized peritonitis after perforation because the omentum is not nearby to contain the infection.

**Appendicitis during pregnancy mandates prompt appendectomy after IV hydration and correction of electrolyte abnormalities.** Appendectomy is safer for the fetus during the second trimester than during the first trimester.<sup>71</sup> Antibiotics are generally administered for uncomplicated appendicitis and are absolutely required for appendicitis complicated by perforation, abscess, or peritonitis.<sup>5</sup> Cephalosporins, clindamycin, gentamicin, and penicillins including ampicillin/sulbactam are considered safe during gestation.<sup>5</sup> Clindamycin is preferred over metronidazole for anaerobic coverage, even though both are category B drugs in pregnancy.<sup>60</sup> Clindamycin/gentamicin is a

Uterine fibroid degeneration  
Labor (preterm or term)  
Viscus perforation after abortion  
Ruptured ectopic pregnancy

##### Gastrointestinal Causes

Crohn disease  
Colonic diverticulitis (right side)  
Cholecystitis  
Pancreatitis  
Mesenteric lymphadenitis  
Gastroenteritis  
Colon cancer  
Intestinal obstruction  
Hernia (incarcerated inguinal or internal)  
Colonic intussusception  
Ruptured Meckel diverticulum  
Colonic perforation  
Acute mesenteric ischemia

##### Other Causes

Pyelonephritis  
Urolithiasis

relatively inexpensive, effective, and safe antibiotic combination; quinolones are not recommended. **Laparoscopy should be considered during the first two trimesters or even later by experienced operators for nonperforated appendicitis or when the diagnosis is uncertain.**<sup>72</sup> Appendectomy is recommended even if appendicitis is not evident at surgery.<sup>67,68</sup> Maternal mortality from appendicitis is about 0.1% without appendiceal perforation, but with perforation, mortality exceeds 4%.<sup>66</sup> Fetal mortality is about 2% without perforation but exceeds 30% with appendiceal perforation.<sup>66</sup>

#### Intestinal Obstruction

**Acute intestinal obstruction is the second most common nonobstetric abdominal emergency with an incidence of 1 per 2500 pregnancies.**<sup>73-75</sup> It may be incidental or secondary to pregnancy, and obstruction more commonly occurs in the third trimester because of the mechanical effects of the enlarged gravid uterus.<sup>76</sup> In particular, some cases occur at term because of the mechanical effects from descent of the fetal head and the abrupt decrease in uterine size at delivery.<sup>73,74</sup> Adhesions, particularly from prior gynecologic surgery or appendectomy, cause 60% to 70% of small bowel obstruction (SBO) during pregnancy.<sup>74,77</sup> Other causes of SBO include neoplasms, particularly ovarian, endometrial, or cervical malignancies; CD; external or internal

hernias; volvulus; and intussusception.<sup>73,74</sup> Rare causes of SBO include ectopic pregnancy; prior radiotherapy; and intraluminal gallstones, fecoliths, or other concretions. Colonic obstruction can be caused by adhesions, colon cancer, other neoplasms, diverticulitis, and volvulus.<sup>73,74</sup>

**Intestinal obstruction classically presents with a symptomatic triad of abdominal pain, emesis, and obstipation.**<sup>73,74</sup> The pain may be constant or periodic. SBO is more painful than colonic obstruction, and the pain with SBO may be diffuse and poorly localized and may radiate to the back, flanks, or perineum.<sup>78</sup> Abdominal pain is milder with volvulus and intussusception. Intestinal malrotation may produce nonspecific symptoms of mild, crampy abdominal pain and nonbilious emesis.<sup>79</sup> Intestinal strangulation with compromised bowel perfusion may be heralded by abdominal guarding and rebound tenderness. Emesis occurs more frequently and earlier in SBO than in colonic obstruction.<sup>73,74</sup> Constipation from complete intestinal obstruction is usually severe and unremitting and is associated with abdominal pain.<sup>74</sup> The abdomen is typically distended and tympanic to percussion because of an inability to defecate or pass flatus. Bowel sounds are high-pitched, hypoaactive, and tinkling in early intestinal obstruction and become absent in late obstruction.

**The approach to intestinal obstruction is the same in pregnancy as in the general population except that decisions are more urgently required because both the fetus and the mother are at risk.** Fetal exposure to radiation is a concern, but supine and upright abdominal radiographs are needed to diagnose and monitor intestinal obstruction.<sup>74</sup> The diagnosis is strongly suggested by radiographic findings of distended bowel loops that contain air-fluid levels, particularly with differential air-fluid levels. An abrupt transition between distended and nondistended bowel favors the diagnosis of intestinal obstruction over intestinal pseudoobstruction. Volvulus is suspected when a single bowel loop is grossly dilated.

**Surgery is recommended for unremitting and complete intestinal obstruction, whereas medical management is recommended for intermittent or partial obstruction.**<sup>73</sup> Parenteral fluids are aggressively administered in all patients with intestinal obstruction to reverse the fluid and electrolyte deficits caused by emesis and fluid sequestration but are particularly important during pregnancy to sustain uterine perfusion. Nasogastric suction helps decompress the bowel. Maternal mortality is about 5%, and fetal mortality ranges from 20% to 30%.<sup>73,77</sup> Morbidity and mortality from intestinal obstruction are increased by delayed diagnosis.

### Intestinal Pseudoobstruction

**Intestinal pseudoobstruction, adynamic ileus, is characterized by severe abdominal distension detected on physical examination and diffuse intestinal dilatation noted on abdominal roentgenogram.** Patients may also present with diffuse abdominal pain and hypoperistalsis on abdominal auscultation. Intestinal pseudoobstruction is diagnosed only after exclusion of mechanical intestinal obstruction by the clinical presentation, laboratory studies, and early clinical evolution. Patients with mechanical obstruction tend to be much sicker than those with pseudoobstruction for the same degree of intestinal dilatation as detected by abdominal imaging and tend to progress more rapidly. **Intestinal pseudoobstruction is a well-described but uncommon complication of cesarean or vaginal delivery.**<sup>80,81</sup> Patients with pseudoobstruction have

**nausea, emesis, obstipation, and diffuse abdominal pain that typically evolves over several days.**<sup>80</sup> Patients often have hypoperistalsis, whereas pyrexia, leukocytosis, and increasing abdominal tenderness may herald GI ischemia. **Treatment includes nasogastric aspiration, parenteral fluid administration, repletion of electrolytes, and rectal tube decompression. The pseudoobstruction usually spontaneously resolves.**<sup>80</sup>

Therapeutic options for severe colonic pseudoobstruction (Ogilvie syndrome), manifested by a cecal diameter greater than 10 cm on abdominal roentgenogram, include colonoscopic decompression or surgical therapies such as cecostomy, cecectomy with diverting ileostomy, or colonic resection when intestinal necrosis supervenes.<sup>82</sup> Colonoscopy can be considered for colonic pseudoobstruction during the second trimester of pregnancy when the only alternative is surgery.<sup>27</sup> Parenteral neostigmine is often administered for colonic pseudoobstruction in nonpregnant patients but may be contraindicated during pregnancy.<sup>80</sup> Mortality approaches 10% with impending perforation but reaches 70% after cecal perforation.<sup>82</sup>

### Colon Cancer

Colon cancer is uncommon during pregnancy with an estimated incidence of 1 per 13,000 to 1 per 50,000 pregnancies (see Chapter 49).<sup>4,83</sup> With approximately 4 million pregnancies annually in the United States, these incidence estimates translate into 80 to 300 colon cancers during pregnancy each year.

The clinical presentation and evaluation of colon cancer in pregnant patients is similar to that in other patients, with notable exceptions. **Common symptoms of colon cancer in pregnant patients include abdominal pain, rectal bleeding, nausea and vomiting, and abdominal distension.**<sup>4,84</sup> However, **colon cancer tends not to produce signs until it has advanced.** About one fifth of colon cancers occur in the rectum in the general population, whereas about two thirds of colon cancers occur in the rectum during pregnancy.<sup>85</sup> This shift during pregnancy may be an artifact due to increased self-referral resulting from increased patient attention to rectal symptoms because of rectal compression by the gravid uterus or from increased physician detection due to frequent pelvic and rectal examinations during pregnancy.<sup>4</sup> Rectal examination is essential in the evaluation of suspected colon cancer during pregnancy because this cancer often arises in the rectum during pregnancy and may then be palpable by digital rectal exam. Stool should be tested for the presence of occult blood. The finding of occult blood has a low positive predictive value for colon cancer or adenomas during pregnancy because of the low disease prevalence in this rather young patient population. Iron deficiency anemia is common during pregnancy due to increased gestational demands. Iron deficiency anemia, therefore, is not nearly as strongly associated with colon cancer in the pregnant patient as it is in the elderly patient.<sup>4</sup> Patients who present with colon cancer during pregnancy are relatively young and may therefore have predisposing factors, including hereditary nonpolyposis colon cancer (HNPCC), familial polyposis coli, Peutz-Jeghers syndrome, and longstanding IBD.<sup>86</sup>

During pregnancy, colon cancer often presents at an advanced pathologic stage attributed to delayed diagnosis.<sup>85</sup> Advanced pathologic stage is highly correlated with a poor prognosis. The incidence of ovarian metastases from colon cancer in women is only about 5% but increases to about 25% in women younger than 40 years.<sup>87</sup> Pregnant patients are typically younger than 40 years and seem to have a similarly high incidence of ovarian

metastases.<sup>4</sup> Although abdominal CT is the imaging modality of choice for detection of hepatic metastases from colon cancer in the general population, CT is relatively contraindicated during pregnancy, and abdominal ultrasound is substituted for hepatic evaluation. This test is highly sensitive for metastatic lesions over 2 cm in diameter but is poorly sensitive for metastatic lesions less than 1 cm in diameter. Hepatic metastases typically produce discrete echogenic masses, and MRI may be required to detect small hepatic metastases.<sup>88</sup> Complete colonoscopy is indicated preoperatively in nonpregnant patients for pathologic diagnosis and for excluding synchronous colonic lesions. Colonoscopy may, therefore, be necessary during pregnancy before colon cancer surgery for the same reasons. Colonoscopy may be technically difficult during late pregnancy because of colonic compression by the uterus. If the gestation is advanced, and the fetus is viable, it may be preferable to induce labor and then perform colonoscopy and cancer surgery.

**Surgery is the primary curative therapy for colon cancer. In the absence of distant metastases, the primary tumor is resected with wide surgical margins at least 5 cm beyond the edge of gross tumor together with resection of regional mesenteric lymph nodes.** In the presence of widespread distant metastases, only palliative surgery is considered. The timing and type of surgery during pregnancy depends on gestational age, maternal prognosis, and intraoperative findings as well as maternal desires. **When the cancer is diagnosed during the first half of pregnancy, cancer surgery should be promptly performed to minimize the risk of metastases.**<sup>4</sup> Such surgery can often be performed without removing the gravid uterus and disturbing the pregnancy.<sup>85</sup> Total abdominal hysterectomy is recommended to facilitate access to the rectum when needed for intraoperative exposure, when the mother's life expectancy is less than the time needed for the fetus to become viable, or when the cancer extends into the uterus. Otherwise, when the cancer appears resectable, curative surgery should be performed leaving the pregnancy intact.<sup>4</sup> **When the cancer is diagnosed during the second half of pregnancy, cancer surgery should ideally be delayed until but not beyond the time that good neonatal outcome is normally expected—at about 32 weeks' gestation—because further delay permits cancer growth and metastasis.**<sup>84</sup> Bilateral salpingo-oophorectomy is indicated for ovarian metastases. Colon cancer surgery is associated with a moderately increased, but still acceptable, rate of fetal death but is associated with a high risk of preterm delivery and low birthweight.<sup>89</sup> Serum carcinoembryonic antigen (CEA) levels obtained before surgery provide a baseline to monitor response to surgery and chemotherapy. Pregnancy does not significantly alter the serum CEA level.<sup>90</sup>

**Pregnant patients considering adjuvant chemotherapy should be counseled about the potential fetal risks as well as the potential maternal benefits.** Chemotherapy is generally contraindicated during the first trimester and should be restricted during this trimester to patients with Dukes stage C cancer who accept a significant teratogenic risk after informed and written consent. Chemotherapy is much less teratogenic during the second and third trimesters, after organogenesis is completed. Patients who refused preoperative chemotherapy during the first trimester because of fetal teratogenicity should consider receiving postoperative chemotherapy during the second trimester when the risk is reduced. Although pelvic radiotherapy is often performed for rectal cancer with local extramural extension, this therapy is perilous to the fetus and is contraindicated during

pregnancy. Radiotherapy is possible only after delivery or termination of pregnancy.

**Patients younger than 40 years generally have a poor prognosis from colon cancer, attributed to delayed diagnosis and advanced pathologic stage at diagnosis.**<sup>91</sup> Likewise, when diagnosed during pregnancy, the maternal prognosis from colon cancer—whether colonic or rectal—is poor. Fetal prognosis depends on the pathologic stage of the maternal cancer, gestational age at diagnosis, and type and timing of therapy. Fetal viability is endangered by severe maternal debility and malnourishment from advanced cancer because the fetus depends upon maternal homeostasis and nutrition for normal development. A few healthy infants have been born after colorectal cancer surgery, including abdominoperineal resection, early in pregnancy.<sup>4</sup> When the cancer is diagnosed late in pregnancy, the fetus is less affected by maternal illness because of improved fetal viability after delivery. The overall fetal prognosis from maternal colon cancer is generally relatively favorable because the diagnosis is usually made near term. Infant survival is about 80%.<sup>4</sup> However, liveborn infants are often born prematurely and often have a low birthweight, factors associated with an increased risk of pulmonary complications and subsequent neurodevelopmental handicaps.

Novel diagnostic modalities for colon cancer diagnosis with promising applications in pregnancy include VCE, in which the colon may be imaged by a microcamera placed within a pill-sized device swallowed by the patient,<sup>92</sup> and a large array of genetic markers that detect genetic abnormalities associated with colon cancer in minute quantities of DNA in stool shed from colonic mucosa.<sup>93</sup>

### Inflammatory Bowel Disease

**The inflammatory bowel diseases, UC and DC, are immunologically mediated disorders that peak in incidence during a woman's reproductive life. In women younger than 40 years of age, the incidence of UC is 40 to 100 per 100,000, and the incidence of CD is 5 to 10 per 100,000.**<sup>3</sup> UC is a colonic mucosal disease manifested by bloody diarrhea, crampy abdominal pain, and pyrexia. CD can involve any part of the GI tract but most commonly involves the terminal ileum or colon. It is characterized by diarrhea, abdominal pain, anorexia, pyrexia, and malnutrition. Patients with CD may have fistulae and anorectal disease. **Extraintestinal manifestations of IBD include arthritis, uveitis, sclerosing cholangitis, and cutaneous lesions.**

UC does not significantly affect fertility, although fertility decreases after colonic resection for UC.<sup>94,95</sup> CD, however, mildly decreases fertility because of extension of ileal inflammation to the nearby fallopian tubes or ovaries, scarring after surgery of the nearby reproductive organs, and the systemic effects of malnutrition.<sup>96</sup> IBD activity is mostly independent of pregnancy. **Patients with inactive or mild disease before conception tend to have the same disease activity during pregnancy. Active disease at conception increases the likelihood of active disease during pregnancy and of a poor pregnancy outcome that includes spontaneous abortion, miscarriage, stillbirth, or premature delivery.**<sup>97,98</sup> During pregnancy, the onset of CD—and to a lesser extent UC—is associated with increased fetal loss.<sup>98</sup>

Differentiating the signs and symptoms of IBD from physiologic changes related to pregnancy or from other obstetric, gynecologic, or surgical conditions may be difficult. Nausea,

**TABLE 48-4** PHARMACOLOGIC THERAPY FOR INFLAMMATORY BOWEL DISEASE DURING PREGNANCY

| DRUG                    | FDA CATEGORY DURING PREGNANCY | RECOMMENDATION DURING PREGNANCY  |
|-------------------------|-------------------------------|--|
| Sulfasalazine           | B                             | Relatively safe, but concern exists about sulfa moiety causing neonatal jaundice   |
| Mesalamine              | B                             | Mesalamine is relatively safe  |
| Infliximab (anti-TNF)   | B                             | Not teratogenic in mice exposed to an analogous antibody, but clinical data are insufficient   |
| Adalimumab (anti-TNF)   | B                             | Believed to be relatively safe drug during pregnancy based on animal data, little clinical data; drug manufacturer is placing patients receiving this drug during pregnancy on a national registry |
| Certolizumab (anti-TNF) | B                             | Animal studies have not revealed fetal toxicity, and clinical data are sparse  |
| Loperamide              | B                             | Loperamide is relatively safe  |
| Metronidazole           | B                             | Avoid during first trimester (carcinogenic in rodents)   |
| Corticosteroids         | C                             | Relatively safe, concern regarding fetal adrenal function and maternal hyperglycemia; monitor the neonates of mothers who received substantial doses of corticosteroids during pregnancy           |
| Ciprofloxacin           | C                             | Use with caution, small studies show no significant risk during pregnancy  |
| Diphenoxylate           | C                             | Avoid; a possible teratogen  |
| Cyclosporine            | C                             | Cyclosporine is embryotoxic and fetotoxic at very high doses in rats and rabbits   |
| 6-Mercaptopurine        | D                             | Avoid starting after conception, might cause IUGR  |
| Azathioprine            | D                             | Avoid starting after conception, might cause IUGR, teratogenic in laboratory animals   |
| Methotrexate            | X                             | Methotrexate is a contraindicated teratogen and abortifacient  |

FDA, Food and Drug Administration; IUGR, intrauterine growth restriction; TNF, tumor necrosis factor.

emesis, abdominal discomfort, and constipation may be noted during any pregnancy but may also signal a flare of IBD. The differential diagnosis of acute right lower quadrant abdominal pain in a pregnant woman with CD includes an exacerbation of CD, ectopic pregnancy, appendicitis, or adnexal disease. Pyrexia, bloody diarrhea, and weight loss suggest an exacerbation of CD.

The diagnostic evaluation is influenced by the pregnancy, but indicated tests should be performed. Laboratory evaluation includes a complete blood count, serum chemistry profile, and electrolyte determinations and takes into account the physiologic alterations of late pregnancy to include anemia, leukocytosis, and hypoalbuminemia. Flexible sigmoidoscopy is well tolerated during pregnancy without maternal complications or fetal toxicity.<sup>32</sup> Colonoscopy has been safely performed during pregnancy, especially during the second trimester, but the experience in the first and third trimesters is relatively limited.<sup>27</sup> Diagnostic roentgenographic tests that involve ionizing radiation, such as abdominopelvic CT, are best deferred until after delivery.<sup>97</sup>

**The beneficial effects of IBD therapy on the mother and fetus must be weighed against the potential of fetal toxicity and teratogenicity (Table 48-4; see Chapter 8).** However, **active disease poses greater risk to the fetus than most therapies.**<sup>99</sup> Corticosteroids are generally safe during pregnancy except that they may modestly increase the risk of cleft lip or palate, exacerbate gestational diabetes, and aggravate preeclampsia.<sup>100</sup> Corticosteroids should be administered at the lowest possible dose during pregnancy and should be avoided during the first trimester, when the hard palate is forming. **Sulfasalazine and 5-aminosalicylates are safe and should be used when required during pregnancy.**<sup>95,97</sup> Methotrexate is not safe, rather it is an abortifacient associated with congenital skeletal malformations.<sup>101</sup> **The FDA categorizes azathioprine and 6-mercaptopurine (6-MP) as class D drugs during pregnancy, but many gastroenterologists continue these medications during pregnancy if required to maintain remission.**<sup>97,102</sup> Anti-tumor necrosis factor (TNF) biologic therapies appear to be safer alternatives during pregnancy (see Table 48-4), although their safety during pregnancy is somewhat controversial because of limited data. One study found a high rate of congenital malformations reported to the FDA associated

with this drug class,<sup>103</sup> but another study noted a low rate.<sup>104</sup> One large investigation showed no increase in birth defects. This class of drugs should generally be discontinued before a contemplated pregnancy but may be used during pregnancy to control active current disease. Metronidazole is safe during pregnancy, but some advise avoidance during the first trimester.<sup>105</sup> The antidiarrheal agent diphenoxylate should be avoided during pregnancy because of case reports of teratogenicity when administered during the first trimester.<sup>5</sup>

Emergency surgery for toxic megacolon, intestinal obstruction, or massive bleeding should be done expeditiously, whereas elective surgery such as fistulectomy should be performed during the second trimester or postpartum.<sup>98,106</sup> Severe perianal CD may necessitate cesarean delivery because an episiotomy during vaginal delivery can exacerbate perianal disease.<sup>107</sup>

## Hemorrhoids

**Hemorrhoids are common in adults and are particularly common during pregnancy, especially during the third trimester or immediately postpartum, with an estimated incidence of 25% during pregnancy.**<sup>108</sup> Contributing factors during pregnancy include increased constipation, resulting in increased straining at defecation; expansion of the circulating blood volume, resulting in venous dilatation and engorgement; and vascular compression from the enlarging gravid uterus, resulting in venous stasis.<sup>21</sup> Hemorrhoids above the dentate line are *internal*, whereas those below the dentate line are *external*.

**Hemorrhoids characteristically produce a clinical triad of bright red blood per rectum that resembles the color of arterial blood; blood coating, rather than blood admixed with stool; and postdefecatory bleeding, most commonly noted on the toilet paper.**<sup>109</sup> Other clinical manifestations include anorectal discomfort, pruritus, or pain associated with prolapse, thrombosis, or incarceration of hemorrhoids.

When the pain from external hemorrhoids is mild to moderate, recommended conservative treatment includes stool softeners, a high-fiber diet, increased liquid intake, topical analgesics, and warm sitz baths.<sup>21</sup> Therapy for hemorrhoids is primarily directed at treating the constipation. Hemorrhoidectomy can be safely performed during pregnancy using local anesthesia for severely painful or acutely thrombosed external hemorrhoids. General measures for internal hemorrhoids similarly include

fiber supplements, fluids, and a high-fiber diet to decrease constipation; switching to a slow-release iron supplement to mitigate the constipating effects of iron; topical local anesthetics for anorectal discomfort; skin protectants applied after defecation to reduce anal pruritus; and avoidance of straining during bowel movements.<sup>21</sup> Therapies for severe or refractory symptoms from internal hemorrhoids include band ligation, injection, sclerotherapy, and coagulation. These therapies are generally safe and effective during pregnancy.<sup>110</sup> Invasive therapy, however, is rarely necessary for external or internal hemorrhoids because the symptoms spontaneously resolve soon after delivery.<sup>108</sup>

### Mesenteric Ischemia and Infarction

Bowel infarction can occur during pregnancy secondary to intestinal obstruction or mesenteric venous thrombosis.<sup>111</sup> Digoxin, ergot alkaloids, cocaine, and other vasoconstrictors are also associated with mesenteric ischemia.<sup>112</sup> Mild hypercoagulability from hyperestrogenemia during pregnancy may contribute to a mildly increased risk of mesenteric ischemia compared with other middle-aged patients, but this risk is not high because mesenteric ischemia is predominantly a disease of the elderly. Patients with mesenteric venous thrombosis typically have an insidious onset of poorly localized abdominal pain with a relatively unremarkable physical examination.<sup>113</sup> The thrombosis is diagnosed by the noninvasive modalities of MRI or CT scanning and by the invasive modality of the venous phase of angiography. Hematologic evaluation for hypercoagulopathy is recommended.<sup>111</sup>

### Irritable Bowel Syndrome

The irritable bowel syndrome (IBS) is most common in younger women, and the pathogenesis is poorly defined. Both intestinal motor and sensory abnormalities, particularly hyperalgesia, have been described.<sup>114</sup> **IBS is diagnosed, according to the Rome III criteria, by the presence of both abdominal pain and disordered defecation for at least 6 months with at least two of the following: (1) pain relief by a bowel movement, (2) onset of pain related to a change in stool frequency, and (3) onset of pain related to a change in stool appearance.**<sup>115</sup> Endoscopic, radiologic, and histologic intestinal studies reveal no evident organic disease. Young women typically have diarrhea-predominant IBS but sometimes have primarily constipation or alternating diarrhea and constipation. Abdominal bloating and distension are common symptoms.

Few data exist concerning the effect of pregnancy on IBS.<sup>116</sup> The onset of IBS typically predates the pregnancy and rarely begins during pregnancy. **IBS is believed to be generally mild during pregnancy,<sup>117</sup> and gestational hormones—particularly progesterone—may exacerbate the symptoms of IBS.**<sup>118</sup> Presumed IBS in the absence of warning signs or symptoms such as rectal bleeding, pyrexia, or weight loss should not require invasive tests such as sigmoidoscopy. However, signs and symptoms of organic disease such as rectal bleeding or involuntary weight loss should not be attributed to IBS without proper evaluation. In particular, sigmoidoscopy is indicated for significant nonhemorrhoidal rectal bleeding during pregnancy.<sup>26</sup>

**Symptoms of IBS are best treated during pregnancy by dietary modification or behavioral therapy** rather than with systemic drugs.<sup>119</sup> Patients with diarrhea-predominant IBS may benefit from elimination of foods from the diet that precipitate diarrhea, such as alcohol, caffeinated beverages, poorly digestible sugars, and fatty foods. Pregnant patients usually consume large

amounts of dairy products in their diet to ensure adequate calcium intake, and some may benefit from lactase supplements when ingesting dairy products. Dietary fiber and fluid ingestion may improve constipation-predominant IBS. Polysaccharide bulking agents, such as methylcellulose, appear to be safe because of a lack of systemic absorption.<sup>75</sup> IBS is not believed to affect fertility and pregnancy outcome in the absence of nutritional deficiencies or concomitant disorders.<sup>116</sup>

### Splenic Artery Aneurysm Rupture

**Splenic artery aneurysm rupture is associated with pregnancy, possibly because of the effects of gestational hormones on the elastic properties of the arterial wall. Rupture most commonly occurs in the third trimester.** Patients typically present suddenly in hemorrhagic shock with left upper quadrant abdominal pain and free intraperitoneal fluid. The diagnosis is suggested by demonstration of a calcified rim from the aneurysm on plain abdominal roentgenogram and is confirmed by abdominal CT scanning or angiography. Treatment consists of fluid resuscitation and prompt surgery, with ligation of the splenic artery and splenectomy. The maternal mortality exceeds 75%, and the fetal mortality exceeds 90%.<sup>120</sup> Splenic artery aneurysms should therefore be surgically corrected even if asymptomatic.<sup>120,121</sup> Abdominal aortic and renal aneurysms can also rupture during pregnancy.

## SUMMARY

The differential diagnosis of abdominal symptoms and signs is particularly extensive in pregnancy. The differential includes GI, obstetric, gynecologic, and other disorders that are related or unrelated to the pregnancy. The patient history, physical examination, laboratory data, and radiologic findings usually provide the diagnosis of abdominal disorders during pregnancy. The pregnant woman has physiologic alterations that affect the clinical presentation, including atypical normative laboratory values. Abdominal ultrasound is generally the recommended radiologic imaging modality. MRI may be performed as indicated, and gadolinium administration should be avoided during the first trimester. Flexible sigmoidoscopy and EGD can be performed during gestation when indicated. Concerns about the fetus may occasionally limit the pharmacotherapy during pregnancy. Early diagnosis is critical to improve maternal and fetal survival, which have recently improved for many life-threatening GI conditions—such as appendicitis—because of improved diagnostic modalities, better maternal and fetal monitoring, improved laparoscopic technology, and earlier and better therapy.

## KEY POINTS

- ◆ The differential diagnosis of GI symptoms and signs such as abdominal pain is particularly extensive during pregnancy. Aside from GI and other intraabdominal disorders incidental to pregnancy, the differential includes obstetric, gynecologic, and GI disorders related to pregnancy.

- ◆ Pregnancy can affect the clinical presentation, frequency, or severity of GI diseases. For example, gastroesophageal reflux disease markedly increases in frequency, and peptic ulcer disease decreases in frequency or may become inactive during pregnancy.
- ◆ Abdominal ultrasound is the safest and most commonly used abdominal imaging modality to evaluate GI conditions during pregnancy. Other common abdominal imaging modalities, particularly computed tomography, raise serious concerns about fetal safety.
- ◆ Esophagogastroduodenoscopy and flexible sigmoidoscopy can be performed when strongly indicated during pregnancy, such as for significant acute upper and lower GI bleeding, respectively.
- ◆ Most GI drugs appear to be relatively safe for the fetus (FDA categories B and C) and can be used with caution when clearly indicated during pregnancy, especially during the second and third trimesters after organogenesis has occurred. Drugs to be avoided during pregnancy include methotrexate (category X), some chemotherapeutic agents, and a few antibiotics.

## EPILEPSY AND SEIZURES

**Epilepsy affects approximately 1% of the general population and is the most frequent major neurologic complication encountered in pregnancy.** It is important that the practicing obstetrician becomes familiar with the basic treatment of epilepsy and the implications for the patient and fetus. Many of the antiepileptic drugs (AEDs) used to treat epilepsy are also used to treat psychiatric and pain disorders and are commonly prescribed to women of childbearing age; this makes an understanding of their implications for pregnancy imperative for any clinician managing these patients.

**A diagnosis of epilepsy is made in the setting of two unprovoked seizures or one seizure in a patient with clinical features that make a second seizure likely, such as findings on brain magnetic resonance imaging (MRI) or electroencephalogram (EEG) that are consistent with a diagnosis of epilepsy or a family history of epilepsy.** Epilepsy syndromes can be divided into *generalized* and *focal epilepsies*. An epilepsy syndrome is defined by the constellation of clinical features of a patient's seizures as well as their imaging and EEG findings. It is important to note that both types of epilepsy syndromes can present with a wide spectrum of seizure types. Convulsions or tonic-clonic seizures, colloquially referred to as "generalized" seizures, can occur in patients with either generalized or focal epilepsies. It is important to work with a patient's neurologist to have an understanding of the patient's epilepsy syndrome because this has significant implications for treatment and also sometimes gives insight into the etiology of the patient's seizure disorder. It may also have a role in predicting the course of the seizure disorder during pregnancy.

Genetic generalized epilepsies, also known as *idiopathic generalized epilepsies*, are presumed to be genetic in origin, although most cases do not exhibit a mendelian inheritance pattern or have varying degrees of penetrance; first-degree relatives are often not affected. Patients with genetic generalized epilepsy can have myoclonic, absence, or tonic-clonic seizures. They may have only one or a combination of those seizure types. These patients are typically treated with "broad-spectrum" AEDs that include lamotrigine, levetiracetam, topiramate, valproate, and zonisamide. The majority of other AEDs—including, but not limited to, carbamazepine, gabapentin, oxcarbazepine, phenytoin, and pregabalin—are considered "narrow spectrum" and can provoke myoclonic or absence seizures in patients with genetic generalized epilepsies, even if the patient does not have a history of these seizure types. The newest AEDs, such as lacosamide and perampanel, are approved for treatment of focal epilepsies but are being studied for use in generalized epilepsies.

**Focal epilepsy is the most common type of epilepsy in adult patients.** Whereas the etiology of most focal epilepsies often remains unknown, an underlying cause must be ruled out because **they may occur secondary to an acquired abnormality such as a tumor, vascular malformation, brain injury, or infectious or autoimmune disorder that affects the brain.** An increasing number of genetic causes of focal epilepsies have also been identified recently, including some with autosomal-dominant inheritance patterns. Patients with focal epilepsy may present with focal seizures with or without loss of consciousness, previously known as *simple partial* and *complex partial seizures*, and/or focal seizures that progress to a tonic-clonic seizure, previously known as a *secondarily generalized seizure*.

The manifestations of focal seizures depend on where in the brain the seizure begins. The most commonly encountered focal epilepsy is temporal lobe epilepsy, which frequently presents with focal seizures with loss of awareness. These seizures are characterized by alteration of awareness that typically lasts 30 seconds to 2 minutes and may be accompanied by semipurposeful movements of the face and hands. The break in awareness is often underreported by patients and even their family members because patients do not remember this part of the seizure, and they may seem to observers to be interacting with their environment. These seizures can be preceded by an aura, such as a feeling of fear or an "epigastric rising," a sensation that begins in the stomach and that may rise to the chest and head, but an aura also may not be present or remembered. These seizures have the potential to progress to tonic-clonic seizures. Patients with focal epilepsy can be treated with broad- or narrow-spectrum AEDs; however, if the diagnosis is uncertain, it is best to begin with broad-spectrum drugs. The choice of the first AED usually depends on characteristics of the patient and the side effects of the drug. In women of childbearing age, the teratogenic potential of the AEDs should be a strong consideration; this will be discussed below.

**Most women with epilepsy will need to remain on AEDs during their childbearing years and throughout pregnancy.** Exceptions include patients with childhood epilepsy, which can remit in adulthood. In select cases of adult-onset epilepsy, patients who have been seizure free for 2 to 4 years may attempt to wean from seizure medications under a neurologist's supervision. Several factors that include the patient's seizure pattern and MRI and EEG findings affect this decision. Seizure freedom in the 9 months prior to pregnancy predicts a good chance of seizure control during pregnancy.<sup>1</sup> Thus in an appropriate patient who wanted to stop AED therapy before pregnancy, weaning her off seizure medication should be started at least 1 year before becoming pregnant. **Unfortunately, women with epilepsy may abruptly stop all medications as soon as they find out that they are pregnant,<sup>2</sup> which puts both the mother and fetus at risk.**

**Uncontrolled seizures increase the risk of maternal injury and death and potentially expose the infant to transient anoxia.<sup>3</sup>** The direct fetal effects of seizures during pregnancy have only been studied in a few case reports. Tonic-clonic seizures during delivery were associated with fetal bradycardia followed by tachycardia in two cases, although the infants were reportedly unaffected on delivery.<sup>4</sup> Fetal death at 33 weeks' gestation was associated with intraventricular hemorrhage in one patient following a tonic-clonic seizure; the patient had had three tonic-clonic seizures in pregnancy.<sup>5</sup> Focal seizures with loss of consciousness were associated with prolonged uterine contraction in one patient reported by Nei and colleagues.<sup>6</sup> The fetal heart rate also fell from 140 to 78 beats/min. In a population-based study from Taiwan, Chen and colleagues<sup>7</sup> studied 1016 pregnant women with epilepsy. Women with seizures during pregnancy had increased risks of preterm delivery (odds ratio [OR], 1.63), small-for-gestational-age (SGA) infants (OR, 1.37), and low-birthweight infants (OR, 1.36) compared with women without epilepsy. When compared with women with epilepsy but without tonic-clonic seizures during pregnancy, patients with seizures had an increased risk of SGA infants (OR, 1.34).

Two studies have raised significant alarm about the risk of epilepsy in pregnancy. The U.K. confidential inquiry into maternal deaths found that **women with epilepsy were 10 times**

**more likely to die during pregnancy or during the postpartum period.**<sup>8</sup> Similarly, a recent study by MacDonald and associates<sup>9</sup> evaluated delivery hospitalization records in the United States and also reported a more than tenfold increase in deaths during delivery in women with epilepsy. In the U.K. study, 3 of 14 maternal deaths appeared to be directly related to complications of seizures (drowning, hypoxia, trauma), and the other 11 were attributed to **sudden unexpected death in epilepsy (SUDEP),<sup>10</sup> defined as the sudden and unexpected, nontraumatic, and nondrowning death of a person with epilepsy without a detected toxicologic or anatomic cause of death.** Mechanisms of SUDEP are uncertain, but risk factors include refractory and tonic-clonic seizures and noncompliance with medications. The U.K. inquiry pointed out that 8 of the 14 women with epilepsy who died in their cohort had not been referred to a provider with knowledge of epilepsy and had not received prepregnancy counseling. Additionally, they noted that one third of the women had difficult social circumstances that may have limited their access to care. Domestic abuse was present in at least two cases, and one patient had schizophrenia.<sup>8</sup> The causes of maternal mortality in the U.S. population study are not known, but it was observed that these patients had an increased risk of major comorbidities that included diabetes, hypertension, psychiatric conditions, and alcohol and substance abuse.<sup>11</sup> They were also at increased risk of preeclampsia, preterm labor, stillbirth, and cesarean delivery.<sup>9</sup>

Whereas these two studies that describe increased mortality in women with epilepsy point to the importance of further research into the optimal management of pregnant women with epilepsy and their comorbidities, they should be put into context for women with epilepsy so as not to deter them from pursuing pregnancy. Although the relative risk was significantly increased, the absolute risk of maternal death in women with epilepsy in the study by MacDonald and colleagues<sup>9</sup> was 80 per 100,000 births (0.08%). Similarly, Edey and colleagues<sup>10</sup> analyzed the U.K. inquiry and estimated the rate of deaths during pregnancy and the postpartum period among women with epilepsy to be 100 per 100,000 births (0.1%). These studies do point to the need for close medical supervision of pregnancies in women with epilepsy and the importance of prepregnancy counseling and planning. **The obstetrician and neurologist must work closely together to guide the patient through her pregnancy. Through this cooperation, the majority of pregnant women with seizure disorders can have a successful pregnancy with minimal risk to mother and fetus.**

## EPILEPSY AND FERTILITY

**Epilepsy and epilepsy treatment may adversely affect fertility in some women. Several population studies have demonstrated that birth rates are lower in both men and women with epilepsy compared with unaffected individuals.**<sup>12-15</sup> In many studies these decreased birth rates were not explained by lower marriage rates in patients with epilepsy. However, these epidemiologic studies are unable to control for nonbiologic factors that may affect reproduction rates, such as decreased libido, which has been reported in patients with epilepsy, or patients' concerns about having a child because of fears about the implications of the condition or their medications. Sukumaran and colleagues<sup>16</sup> prospectively followed 375 Indian women trying to conceive and found that 38.4% were infertile after at least 1 year of trying to conceive. Risk factors for infertility

include taking AEDs, particularly multiple AEDs. However, age and lower educational level also played a role in the study.

Many lines of evidence suggest that potentially, both epilepsy and AEDs may have adverse effects on reproductive function. Seizures, particularly temporal lobe seizures, are known to disrupt the hypothalamic-pituitary-gonadal axis, and certain AEDs can affect sex steroid metabolism and sex hormone binding globulin concentrations. Increased risks of polycystic ovarian syndrome, premature ovarian insufficiency, and hypogonadotropic hypogonadism have been reported in women with epilepsy.<sup>17,18</sup> **Miscarriage rates, however, do not seem to be increased in women with epilepsy.**<sup>19</sup>

## EPILEPSY AND PREGNANCY

### Teratogenic Effects of Antiepileptic Drugs

**Women with epilepsy are at increased risk of having pregnancies complicated by major congenital malformations. This risk appears to be related to exposure to AEDs during pregnancy rather than the epilepsy.**<sup>20</sup> Not all AEDs are the same in terms of their teratogenic potential or the patterns of malformations with which they are associated (see Chapter 8). Over the past 15 years, prospective studies of the effects of AEDs on teratogenesis have largely replaced older retrospective case series. A few prospective studies of the cognitive effects of AED exposure during pregnancy have also been pivotal in our understanding of AED-associated risks. The most well-studied AEDs in pregnancy are valproate, carbamazepine, and lamotrigine. Of these drugs, **valproate has been consistently demonstrated to carry a risk of major congenital malformations significantly greater than that of other AEDs and baseline population rates, typically 1% to 3% depending on the study population. It has also been clearly associated with adverse cognitive and behavioral developmental outcomes.**

Lamotrigine has been associated with relatively low rates of teratogenesis, and although cognitive data are mostly reassuring, this still needs further clarification. Levetiracetam is less well studied, but promising early data have led to a dramatic increase in its use in pregnant women and those planning pregnancy. **Lamotrigine and levetiracetam are now the most commonly prescribed AEDs for women of childbearing age.**<sup>21</sup> Carbamazepine also appears to be a reasonable choice for women who plan to conceive, although its use has been declining in this population.<sup>21</sup>

The section below summarizes the available information on the best-studied and most prescribed AEDs. The majority of the information we have on structural teratogenesis is derived from several international pregnancy registries (Table 49-1). It is important to note that each of these registries uses slightly different methodologies in regard to means of recruitment, infant assessment control groups, and duration of follow-up.<sup>22</sup> These differences account for some of the variability in results; however, when the findings are looked at in aggregate, clear patterns emerge regarding the relative teratogenic risk of individual AEDs.

### Valproate

**Rates of major congenital malformations with first-trimester exposure to valproate monotherapy range from 4.7% to 13.8%.**<sup>23-27</sup> In the two largest prospective cohorts from the United Kingdom and Ireland (1290 valproate exposures)<sup>28</sup> and the European Registry of Antiepileptic Drugs and Pregnancy

Data from Gerard E, Pack AM. Pregnancy registries: what do they mean to clinical practice? *Curr Neurol Neurosci Rep*. 2008;8(4):325-332.

\*Numbers in parentheses indicate number of pregnancies enrolled.

AED, antiepileptic drug; CBZ, carbamazepine; GBP, gabapentin; LEV, levetiracetam; LTG, lamotrigine; OXC, oxcarbazepine; PHB, phenobarbital; PHT, phenytoin; TPM, topiramate; VPA, valproic acid.

(EURAP, 1010 valproate exposures),<sup>29</sup> the malformation rates were 6.7% and 9.7%, respectively.

In the European Surveillance of Congenital Anomalies (EUROCAT) database, a population-based database of 14 European countries, valproate exposure was associated with an increased risk of several specific defects.<sup>30</sup> Compared with control pregnancies, those exposed to valproate monotherapy were at statistically increased risk for spina bifida (OR, 12.7), craniosynostosis (OR, 6.8), cleft palate (OR, 5.2), hypospadias (OR, 4.8), atrial septal defects (OR, 2.5), and polydactyly (OR, 2.2). These numbers, however, describe only relative risk and can be hard for a patient to understand. **Tomson and Battino<sup>24</sup> compiled the data of 22 prospective studies that reported on specific AED-associated malformations and reported the absolute risks of neural tube defects (NTDs, 1.8%), cardiac malformations (1.7%), hypospadias (1.4%), and oral clefts (0.9%).**

In addition to significantly increasing the risk of birth defects, **valproate exposure during pregnancy has also been associated with cognitive and behavioral teratogenesis.** Two prospective studies of children exposed to AEDs in utero have recently been published, the Neurodevelopmental Effects of Antiepileptic Drugs (NEAD) study<sup>31</sup> and a study by the Liverpool and Manchester Neurodevelopmental Group (LMNG).<sup>32</sup> Both recruited women with epilepsy in the first trimester of pregnancy and followed the development of their children until age 6. In contrast to many earlier studies of the cognitive effects of AEDs, both of these investigations controlled for several important confounding variables, including maternal intelligence quotient (IQ)—an important predictor of a child's cognitive performance. Of note, the two studies did overlap: 92 children from the LMNG study were also enrolled in the NEAD study. The NEAD study ultimately evaluated 224 children at age 6 who had been exposed to carbamazepine, lamotrigine, phenytoin, or valproate monotherapy. The LMNG study

assessed 198 six-year-old children born to women with epilepsy who took AED monotherapy ( $n = 143$ ) or polytherapy ( $n = 30$ ) or no medication ( $n = 25$ ) during pregnancy and a control group of 210 children of the same age. In the NEAD study, exposure to valproate monotherapy was associated with a significant decrease in mean full-scale IQ (FSIQ) by 7 to 10 points compared with children exposed to carbamazepine, lamotrigine, or phenytoin. The LMNG found that exposure to first-trimester doses of valproate greater than 800 mg/day was associated with a significant decrease in FSIQ by 9.7 points when compared with a control group.<sup>32</sup> The mean FSIQ of children exposed to low valproate doses ( $\leq 800$  mg/day) was also lower than that of controls, but this did not meet statistical significance. The low-dose group, did, however, have significantly lower verbal IQ scores and an increased need for educational intervention.<sup>32</sup>

A population study that utilized the National Psychiatric Registry and birth registries in Denmark found that school-age children whose mothers were prescribed valproate monotherapy during pregnancy had a significantly increased risk of receiving a formal diagnosis of autism or autism spectrum disorder (ASD).<sup>33</sup> In the valproate-exposed cohort, the absolute risk of autism was 2.5%, whereas the rate in the general population was 0.48%, and the risk of ASD was 4.42%, with a baseline risk of ASD of 1.53%. The rates of autism and ASD in children born to mothers with epilepsy who did not take valproate during pregnancy did not differ from baseline population rates. A recent nested study<sup>34</sup> from the Australian Pregnancy Registry also found that of 26 children between 6 and 8 years of age who were exposed to valproate monotherapy, one tested in the “autistic range” and one tested in the “concern for autistic range” on a standardized assessment. The overall risk of autistic traits was 7.7% in the monotherapy group. In this study, the risk of autistic traits was greatest in the valproate polytherapy group (7/15; 46.7%) and was dose related in the valproate monotherapy group.

The LMNG also found an increased risk of behavioral abnormalities in their antenatally recruited cohort at 6 years of age. Because of the relatively smaller numbers in this cohort, the study examined the aggregate risk of several different neurodevelopmental disorders (NDDs) in exposed children, including autism and ASD, attention-deficit/hyperactivity disorder (ADHD), and dyspraxia as based on diagnoses received from professionals outside of the study. An NDD was diagnosed in 12% of 50 children exposed to valproate monotherapy and in 15% of 20 children exposed to valproate in polytherapy.<sup>35</sup> These rates were significantly elevated compared with an NDD rate of 1.87% in the 214 control children.

### Carbamazepine

**In its 2009 guidelines, the American Academy of Neurology (AAN) stated, “Carbamazepine probably does not substantially increase the risk of major congenital malformations in the offspring of women with epilepsy.”**<sup>36</sup> This conclusion was based on one class I study<sup>37</sup> from the United Kingdom and the Ireland Pregnancy Registry that did not find a difference between the rate of malformations in carbamazepine-exposed pregnancies and those of an internal control group. At the time, carbamazepine was the only medication that the AAN felt had strong enough evidence to support this conclusion. Across seven pregnancy registries, rates of major malformations in pregnancies exposed to carbamazepine monotherapy have ranged from 2.6% to 5.5%.<sup>23-29</sup> The two largest studies, the United Kingdom and Ireland Pregnancy Registries ( $n = 1657$ ) and the EURAP registry ( $n = 1402$ ) reported rates of 2.6% and 5.6%, respectively. Of note, the two registries that reported higher rates of major anomalies with carbamazepine exposure—the Australian and EURAP registries—both follow the exposed infants to 1 year and beyond, whereas the other registries performed the last assessment for malformations at birth or 3 months.<sup>22</sup> In the EURAP registry, malformations that were most likely to be picked up between 2 and 12 months were cardiac, hip, and renal malformations.<sup>24</sup> The rates of anomalies increased for several drugs at the later assessment, but rates with carbamazepine were most affected.

In the EUROCAT database, carbamazepine exposure was specifically associated with an increased risk of NTDs compared with unexposed controls (OR, 2.6; 95% confidence interval [CI], 1.2 to 5.3).<sup>38</sup> However, the risk of spina bifida with carbamazepine exposure was still significantly lower than the risk with valproate (OR, 0.2; 95% CI, 0.1 to 0.6) and was not different from the risk of exposure to other AEDs when valproic acid was excluded. The EUROCAT study did not find a specific association between carbamazepine exposure and other major malformations that included oral clefts, diaphragmatic hernia, hypospadias, and total anomalous venous return.<sup>38</sup> In the compiled registry data prepared by Tomson and Battino,<sup>24</sup> the absolute risks of certain anomalies with exposure to carbamazepine monotherapy were reported for NTDs (0.8%), cardiac malformations (0.3%), hypospadias (0.4%), and oral clefts (0.36%).

Early studies of carbamazepine's effect on cognitive development were conflicting, and many were limited by retrospective design or did not control for important confounders. A Cochrane review<sup>39</sup> of prospective studies published prior to 2014 concluded that the reported effects of carbamazepine on developmental scores were largely accounted for by variability between studies and identified no clear risk of delayed development in infants and toddlers exposed to carbamazepine. The

meta-analysis also reported no evident adverse effect of carbamazepine exposure on the IQ of school-age children.<sup>39</sup> In the NEAD study, no specific effects of carbamazepine exposure on IQ were identified when this group of children was compared with the lamotrigine- and phenytoin-exposed cohorts at age 6.<sup>31</sup> The recent LMNG study also found no difference in the adjusted mean IQ scores between the 6-year-old carbamazepine-exposed children and controls, but verbal IQ was 4.2 points lower in the exposed children. Additionally, the relative risk of having an IQ below 85 was significantly increased in the carbamazepine cohort.<sup>32</sup> Both the NEAD and LMNG studies demonstrated that, compared with valproate exposure, prenatal carbamazepine exposure was less likely to be associated with adverse cognitive effects.<sup>31,32</sup>

The LMNG found no increased risk for formally diagnosed NDDs at 6 years in the carbamazepine-exposed children when compared with controls.<sup>35</sup> The large Danish population study by Christensen and colleagues<sup>33</sup> also found no increased risk of autism or ASD in teenagers and children with prenatal carbamazepine exposure. An earlier study in Aberdeen, Scotland reported that two of 80 (2.5%) of carbamazepine-exposed children had an ASD, which is above the population rate (0.25%) but lower than that of the valproate group (8.9%).<sup>40</sup> These findings are limited by the small number of cases, the absence of a control group, and retrospective recruitment of only 41% of the original AED-exposed cohort, which potentially introduced a selection bias. The more recent study<sup>34</sup> of autistic traits from the Australian Registry also recruited mothers retrospectively from the prospectively identified cohort (63% enrollment). This study reported scores consistent with autism in one of 34 children exposed to carbamazepine and scores that raised “concern for autism” in another child based on a standardized assessment. The overall rate of autistic traits was 5.9%. The authors advise that this increase should be interpreted with caution because no discernable dose-effect of carbamazepine and no increased risk were seen in pregnancies exposed to polytherapy regimens that excluded valproate. The majority of these polytherapy regimens did include carbamazepine.<sup>34</sup>

### Lamotrigine

**Rates of major malformations with lamotrigine exposure have been consistently low and range from 2% to 4.6%, across eight prospective registries.**<sup>24-29,41,42</sup> Initially, the North American AED Pregnancy Registry (NAAPR) reported a tenfold increased risk in oral clefts with lamotrigine monotherapy exposure. However, with a larger sample size, this risk was reevaluated and reported as a fourfold increased risk (absolute risk with lamotrigine, 0.45%).<sup>26</sup> A case-control study,<sup>43</sup> however, found no specific increased risk of oral clefting with lamotrigine, and other registries have reported much lower rates of clefting with lamotrigine exposure (0.1% to 0.25%).<sup>37,41,44</sup> The absolute risks of clefting reported by Tomson and Battino<sup>24</sup> was 0.15%. The composite risk of other specific malformations in this review were 0.6% for cardiac defects, 0.12% for NTDs, and 0.36% for hypospadias.<sup>24</sup>

**In two independent cohorts from the United Kingdom, developmental scores of infants prenatally exposed to lamotrigine did not differ from those of controls.**<sup>45,46</sup> In the LMNG cohort, at 6 years of age, the IQ scores of the lamotrigine-exposed children did not differ from those of controls.<sup>32</sup> Additionally, in the NEAD study, FSIQ scores in children exposed to lamotrigine were significantly higher than those

of valproate-exposed children and did not differ from those of carbamazepine- or phenytoin-exposed children.<sup>31</sup> However, both valproate and lamotrigine exposure were associated with decreased verbal IQ relative to nonverbal IQ.<sup>31</sup> In a Norwegian population-based mail survey, parents of lamotrigine-exposed infants also reported impaired language functioning and an increase in autistic traits observed in their children.<sup>47</sup> Parental ratings of the 6-year-old children prenatally exposed to lamotrigine in the NEAD study suggested that they may be at increased risk for ADHD, but the teacher ratings in a subgroup of these children did not substantiate this finding, and no tendency toward social impairment was detected.<sup>48</sup> In contrast to these parental observations, the LMNG found no increased risk of formally diagnosed NDDs in lamotrigine-exposed children,<sup>35</sup> and the population study by Christensen and colleagues<sup>33</sup> found no increased risk of autism or ASD.

### Levetiracetam

Levetiracetam is a relatively new AED, and to date, just over 1000 pregnancies have been reported across eight prospective registries, which have each recruited relatively small cohorts. The major malformation rates across these registries range from 0% to 2.4%.<sup>24-27,29,41,49</sup> Developmental effects of levetiracetam have been assessed in one study of 51 levetiracetam-exposed children recruited from pregnancies identified in the U.K. Epilepsy and Pregnancy Register.<sup>50</sup> At 36 to 54 months, the developmental scores of the exposed children did not differ from those of controls but were better than a group exposed to valproate. Because this is the only investigation of developmental outcomes with levetiracetam exposure, it will need to be replicated in future studies.

### Phenytoin

Despite the fact that phenytoin is one of the oldest AEDs still in use, little certainty exists in regard to its teratogenic implications. **In 1975, Hanson and Smith<sup>51</sup> described a specific fetal hydantoin syndrome associated with in utero phenytoin exposure.** They noted growth and performance delays and craniofacial abnormalities that included clefting and limb anomalies, including hypoplasia of nails and distal phalanges. They later reported that this was present in 11% of 35 exposed infants and that 31% of exposed infants had some aspects of the syndrome.<sup>52</sup> Yet other studies have not substantiated this. In 1988, Gaily and colleagues<sup>53</sup> reported no evidence of the hydantoin syndrome in 82 women exposed in utero to phenytoin. Some of the patients had hypertelorism and hypoplasia of the distal phalanges, but none had the full hydantoin syndrome. The true prevalence of this syndrome and contributing factors has not been established, and it has largely fallen out of current literature.

The more recent pregnancy registries have not focused on the description of syndromes. Of note, the major malformations studied in these registries do not include many of the skeletal abnormalities included in the fetal hydantoin syndrome. Rates of anomalies in these registries have ranged from 2.4% to 6.7% across five registries,<sup>24,26,27,29,37</sup> but only 761 pregnancies have been enrolled in these studies, and the individual cohorts are small. The largest cohort studied in the NAAPR published a major malformation rate of 2.9% among 416 phenytoin-exposed pregnancies.<sup>26</sup> Tomson and Battino<sup>24</sup> reported the **rates of specific malformations with phenytoin exposure: 0.4% for cardiac malformations, 0% for NTDs, 0.2% for oral clefts, and 0.5% for hypospadias.**

The cognitive implications of phenytoin exposure have only been evaluated in a few prospective studies. The 2014 Cochrane review<sup>39</sup> found that the methodologies of these studies were too disparate to perform a meta-analysis. The review concluded that **phenytoin exposure was associated with better developmental and cognitive outcomes than valproate exposure and that no discernable differences between phenytoin and carbamazepine exposure were present in terms of development and IQ.** In the NEAD study, average FSIQ and verbal IQ scores of the phenytoin-exposed children were significantly higher than those of the valproate-exposed cohort and were not different from those of children exposed to carbamazepine or lamotrigine. Because the study did not include an unexposed control group, it is unknown whether the phenytoin group would differ from unexposed children.<sup>31</sup> In terms of behavioral effects, Vinten and associates<sup>54</sup> reported no difference between parentally assessed adaptive behaviors in the phenytoin-exposed Norwegian children when compared with unexposed controls born to mothers with epilepsy.

### Phenobarbital

**Phenobarbital is rarely used as a first-line AED in developed countries given its adverse cognitive and metabolic side effects and the availability of alternative medications with fewer adverse effects.** It is very difficult to wean patients from phenobarbital, however, and this process often leads to worsened seizure control. Thus, unless pregnancy is planned well in advance, many women previously taking phenobarbital may remain on it. In the NAAPR, phenobarbital was associated with a risk of major malformations of 5.5% in 199 pregnancies, and cardiac malformations were the most frequent malformation reported. In a pooled analysis of 765 barbiturate-exposed pregnancies, Tomson and Battino<sup>24</sup> reported a rate of 3.5% for cardiac malformations and a 1% risk of oral clefts. The absolute risk of NTDs and hypospadias in this analysis was 0.2% for each.

Retrospective studies of the effect of phenobarbital on cognitive and educational outcomes of exposed children have reported mixed results.<sup>55-58</sup> The largest prospective study<sup>59</sup> of phenobarbital and cognitive outcomes evaluated a cohort of 114 Danish men who had been exposed to phenobarbital in utero between 1959 and 1961. The most common indication for phenobarbital was pregnancy-related hypertension, and mothers with epilepsy were not evaluated. Thus the exposure to phenobarbital was likely shorter in duration than in the children of mothers with epilepsy. The phenobarbital-exposed group had significantly lower IQ scores compared with controls, and children exposed in the third trimester were most affected. In a subset of 33 subjects, this effect was driven by lower verbal IQ compared with children exposed to other AEDs in monotherapy. In a prospective study, Thomas and colleagues<sup>60</sup> also found lower IQs in a group of 12 phenobarbital-exposed children. None of the studies to evaluate the cognitive effects of phenobarbital have accounted for the maternal IQ, which is an important predictor of the child's IQ.

### Other Antiepileptic Drugs

**A paucity of data is available to describe the teratogenic risks of other AEDs commonly used to treat epilepsy.** The rate of major malformations with oxcarbazepine exposure among 393 prospective cases in the Danish birth registry was 2.8%. Other cohorts are smaller.<sup>41</sup> In the NAAPR study,<sup>61</sup> no major

anomalies were reported in a cohort of 98 pregnancies exposed to zonisamide monotherapy, but this was interpreted with caution given the small sample size. The study did demonstrate an increased risk of low birthweight with both zonisamide and topiramate exposure. Recently, concern has been raised that topiramate is a significant teratogen, although sample sizes are still small. In the NAAPR study, the risk of major anomalies was 4.2% in 359 pregnancies.<sup>26</sup> **The registry also reported a tenfold increased risk of oral clefts in the topiramate cohort compared with that of an external control group; this corresponded to an absolute risk of 1.4%,<sup>26</sup> which resulted in the U.S. Food and Drug Administration (FDA) reclassification of topiramate from class C to class D for pregnancy. This concern has been corroborated by subsequent cohorts and meta-analyses.<sup>62,63</sup>** Studies of the effect of oxcarbazepine, zonisamide, and topiramate on cognitive and behavioral development are limited.

Little useful information is available on the effect of human in utero exposure to other AEDs that include benzodiazepines, eslicarbapazine, ethosuximide, ezogabine, felbamate, gabapentin, lacosamide, perampanel, pregabalin, rufinamide, and vigabatrin. The manufacturers of lacosamide, a recently introduced AED, caution that it is known to antagonize the collapsin response mediator protein 2, which is involved in axonal growth and neuronal differentiation and appears to have adverse effects on brain development in rodents.<sup>64</sup>

### Effect of Antiepileptic Drug Dose

**The risk of major malformations has been shown to be dose related for several AEDs.** In the EURAP registry, for example, valproate monotherapy was associated with a malformation risk of 5.6% with preconception doses of less than 750 mg/day and a risk of 24.6% with doses greater than 1500 mg/day.<sup>29</sup> Similar correlations between the risk of birth defects and preconception AED dose were also noted for carbamazepine, lamotrigine, and phenobarbital. Additionally, dose effects on cognitive and behavioral development have been noted for valproate,<sup>32,34,65</sup> although more data on the relationship between cognitive teratogenesis and dose of both valproate and other AEDs are needed. Further research is also required on the relevance of serum concentrations, instead of dose, because of the substantial differences in AED metabolism among individuals. For now, preparing a woman with epilepsy for pregnancy involves trying to identify the minimum therapeutic dose and corresponding drug level to control her seizures.

### Polytherapy

**It was previously thought that AED polytherapy always posed more of a teratogenic risk than monotherapy and that polytherapy should be avoided whenever possible.** This conclusion was based on several prior studies that demonstrated a higher rate of major malformations with polytherapy. However, a recent study from the NAAPR suggested that the results of these prior studies were largely driven by polytherapy combinations that included valproate. Within the NAAPR, Holmes and colleagues<sup>66</sup> reported that the risk of major anomalies with lamotrigine and valproate therapy was 9.1%, whereas it was 2.9% for the combination of lamotrigine and any other AED. Similarly, they reported that carbamazepine and valproate polytherapy was associated with a major malformation risk of 15.4%, which was much higher than the 2.5% risk seen with the combination of carbamazepine and any other AED. The authors also

highlighted similar findings that had been reported in the United Kingdom Epilepsy and Pregnancy Registry<sup>37</sup> and the International Lamotrigine Pregnancy Registry.<sup>42</sup> Studies on cognitive development have suggested the same trend. In an Australian cohort, Nadebaum and colleagues<sup>65</sup> found that in utero exposure to valproate polytherapy was associated with significantly lower FSIQ and verbal comprehension scores than exposure to valproate monotherapy or polytherapy combinations without valproate. The LMNG also reported that only polytherapies that included valproate were linked to decreased mean FSIQ and verbal IQ in school-age children.<sup>32</sup>

**The mainstay of epilepsy therapy, especially in women of childbearing age, is still to try to find the one AED that best controls a patient's seizures at the minimum therapeutic dose or level. However, in certain cases, polytherapy may be preferable to monotherapy.** For example, women with idiopathic generalized epilepsies have a limited number of AEDs that are appropriate for their condition. Valproate is an effective option for this type of epilepsy but is a poor choice for these women. When one AED—such as levetiracetam or lamotrigine—is ineffective for these patients, the combination of the two may sometimes be effective and likely carries a reduced risk of teratogenesis when compared with valproate monotherapy. Given the emerging information on the relationship between AED dose and malformation risk for most AEDs, more research is needed to determine whether polytherapy combinations that involve low doses of two AEDs are ever preferable to a single non-valproate AED at a high dose.

### Effects of Pregnancy on Anticonvulsant Medications

Although most pregnancy studies to date have focused on AED dose, AED levels are probably far more important and should be studied in the future. Although drug manufacturers and laboratories publish standard therapeutic windows for individual AEDs, these large ranges have little relevance for a given patient with epilepsy. **AED metabolism varies greatly by individual, and each patient has her own therapeutic drug level at which seizures are best controlled. This is typically within the standard window but may be above or below it. Therefore it is important to understand and establish this drug level prior to pregnancy whenever possible, because levels of anticonvulsant medications can change dramatically during pregnancy, and in many cases, decreasing AED levels have been associated with loss of seizure control.** When prepregnancy levels have not been obtained, they should be drawn as early as possible in the first trimester. Whereas a trough level is ideal, it is usually not practical or safe for women to hold medications for a blood draw. It is more important that they have levels drawn at a convenient and roughly standard time relative to their AED dose. For certain AEDs, including phenytoin and sometimes carbamazepine and valproate, free (unbound) drug levels are available and preferable.

**Many factors—including altered protein binding, delayed gastric emptying, nausea and vomiting, changes in plasma volume, changes in the volume of distribution, and even folic acid supplementation—can affect the levels of anticonvulsant medications. Additionally, changes in AED metabolism can be dramatically altered by the pregnant state.**

Lamotrigine is the most common AED prescribed in pregnancy, and it is utilized to treat both epilepsy and bipolar disorder. It is also the best example of the substantial effects of

pregnancy on AED metabolism. Lamotrigine clearance depends heavily on glucuronidation, a process induced by the increases in estrogen during pregnancy. **Over the course of a pregnancy, lamotrigine clearance increases by over 200% in the majority of women with epilepsy.**<sup>67</sup> Lamotrigine doses need to be increased substantially over the course of a pregnancy in order to maintain prepregnancy levels and seizure control. Doses of 600 to 900 mg/day are not uncommon by the end of pregnancy. Lamotrigine metabolism decreases rapidly after delivery and returns to baseline within 3 weeks of delivery. To avoid toxicity, it is important to give patients a postpartum dosing plan to taper their dose starting immediately after delivery. A common practice is to decrease the dose by two thirds of the increase over pregnancy in the first week after delivery and then decrease back toward the baseline dose. Leaving a patient on slightly more than her prepregnancy dose is also common, especially in patients with brittle seizure control who may be especially susceptible to the effects of sleep deprivation.

Although less well studied, oxcarbazepine clearance is also dependent on glucuronidation.<sup>68</sup> In the EURAP registry, patients taking oxcarbazepine or lamotrigine during pregnancy were noted to have poorer seizure control than those taking other AEDs.<sup>69,70</sup> Less than half of those using lamotrigine or oxcarbazepine had their doses adjusted, which suggests therapeutic drug monitoring may not have been regularly performed. In contrast, levels of free and total carbamazepine—as well as a metabolite of carbamazepine—are relatively stable throughout pregnancy,<sup>71</sup> and seizure control appears to be better in patients taking carbamazepine.<sup>72,73</sup> **Given the interindividual variation in AED metabolism and susceptibility to changes during pregnancy, checking AED drug levels monthly is recommended for all AEDs.**

### Pregnancy and Seizure Frequency

**For the majority of women with epilepsy (54% to 80%), seizure frequency will remain similar to their baseline seizure frequency.** Across several studies, seizure frequency increased in 15.8% to 32% of women and decreased in 3% to 24%.<sup>1,69,74,75</sup> **Seizure freedom for 9 months prior to pregnancy is associated with an 84% to 92% chance of remaining seizure free during pregnancy.**<sup>1</sup> Genetic generalized epilepsies seem to be associated with less of a risk of seizures during pregnancy than focal epilepsies, although both groups of patients are at increased risk of seizures in the peripartum and postpartum periods.<sup>1,69,76</sup>

A recent study from the Australian Register of Antiepileptic Drugs in Pregnancy (APR) suggested that the AEDs taken during pregnancy might predict seizure control.<sup>73</sup> The authors reported that the risk of seizures was lowest with valproate (27%), levetiracetam (31.8%), and carbamazepine (37.8%), whereas an increased risk of seizures was seen with lamotrigine (51.3%). Phenytoin (51.2%) and topiramate (54.8%) were also associated with a relatively higher risk of seizures, but the sample sizes of these groups were small. As mentioned above, the EURAP registry has also reported a higher risk of seizures in patients taking lamotrigine or oxcarbazepine.<sup>69,70</sup> In contrast to the APR, a small study by Reisinger and colleagues<sup>72</sup> found a relatively high risk of seizure deterioration in patients treated with levetiracetam monotherapy (47%) when they compared seizures during pregnancy to each patient's baseline. The NAAPR also notes that rates of seizures during pregnancies managed with levetiracetam were similar to the rates in patients treated with lamotrigine.<sup>26</sup> The increasing metabolism and falling AED levels

of many of the newer AEDs including lamotrigine likely play an important role in the variable seizure control reported. Both the APR and EURAP registries reported that lamotrigine dosing had been increased in fewer than 50% of cases analyzed.<sup>69,73</sup> Future prospective studies, during which therapeutic drug monitoring and appropriate dose adjustments are made, will be necessary to understand whether AED metabolism is the principal reason for worsening seizure control with certain AEDs or if other factors play a role.

### Obstetric and Neonatal Outcomes

**Women with epilepsy may be at increased risk for obstetric complications.** Historically, studies on obstetric complications had yielded mixed results. A 2009 evidence-based review from the AAN reported that insufficient evidence was available to support or refute an increased risk of preeclampsia or gestational hypertension in women with epilepsy. They also stated that preterm labor was probably not increased, at least not to moderate levels (1.5 times the baseline risk) except in women with epilepsy who smoked.<sup>1</sup> Since then, population studies from the United States and Norway have associated epilepsy with a mild to moderate risk of preeclampsia (OR, 1.59 to 1.7) and preterm labor (OR, 1.54 to 1.6) when compared with that of women without epilepsy.<sup>9,77</sup> *Preterm labor* was defined as labor before 34 weeks in the Norwegian study and before 37 weeks in the U.S. study. In the Norwegian study by Borthen and colleagues,<sup>78</sup> the risk of these complications in women with epilepsy who did not take AEDs was not increased. However, the possibility that these patients may have had milder epilepsy must be considered. Borthen and colleagues<sup>78</sup> also studied 205 epileptic women from a single Norwegian hospital and found an increased risk of severe preeclampsia in these patients compared with unaffected women.

**Epilepsy and AED use are typically not indications for cesarean delivery (CD);** however, CD may be more common in women with epilepsy. The reasons for this association are unclear and has not been seen consistently across all studies.<sup>9,77-79</sup> In their hospital-based study, Borthen and colleagues<sup>78</sup> found no significant increased risk of CD if preterm labor was accounted for. Induction of labor may also be more common in women with epilepsy.<sup>9,78</sup> Prospective studies are needed to determine the reasons for labor induction and CD in women with epilepsy. It is unclear if this is related to other complications in these women or physician or patient concern about seizures during late pregnancy or delivery.

**Bleeding complications at delivery may also be increased in women with epilepsy, although again studies have been conflicting on this point.**<sup>79</sup> Population studies from Norway and the United States both suggest a small but significantly increased risk of postpartum hemorrhage.<sup>9,80</sup>

According to the 2009 AAN literature review and recommendations, evidence was sufficient to suggest a near twofold **increased risk of SGA infants born to epileptic women taking AEDs**, but the group felt data were inadequate on the risk of intrauterine growth restriction (IUGR).<sup>36</sup> A recent study from a prospective registry in Norway studied 287 children born to women with epilepsy and found that they had an increased risk of being SGA and having a ponderal index below the tenth percentile.<sup>81</sup> AED exposure was the strongest predictor of a low ponderal index, but seizure frequency was not controlled for. In yet another Norwegian study,<sup>25</sup> topiramate was specifically associated with SGA infants, and in an investigation from the NAAPR, both topiramate and zonisamide were associated with

lower birthweights in exposed infants.<sup>61</sup> A Taiwanese study by Chen and colleagues found that seizures during pregnancy were associated with an increased risk of SGA.

The recent U.S. population study found a mild but significantly increased risk of stillbirth in women with epilepsy (OR, 1.27; 95% CI, 1.17 to 1.38).<sup>9</sup> Two other population studies from Denmark and Norway found a trend toward an increased stillbirth risk of similar magnitude, but the effect was not statistically significant.<sup>82,83</sup> Little else about fetal outcomes of infants born to women with epilepsy is known. The AAN did conclude that the offspring of women using AEDs were at greater risk for a low 1-minute Apgar score.<sup>84</sup>

### Preconception Counseling for Women With Epilepsy

**Ideally, preconception counseling for a woman with epilepsy should begin at the time of diagnosis and with prescription of the first AED.** Unfortunately, this is not always possible. For most patients, the obstetrician must stress that the patient has a greater than 90% chance of having a successful pregnancy that results in a normal newborn. A detailed history of medication use, seizure types, and seizure frequency should be obtained. The patient must be informed that if she has frequent seizures before conception, this pattern will probably continue. Furthermore, if she has frequent seizures, in most cases, she should be encouraged to delay conception until control is optimized. The obstetrician must stress that controlling seizures is of primary importance. For patients with seizures that have been refractory to one to two medications, inpatient video EEG monitoring is often indicated to determine whether the patient is a surgical candidate. Inpatient video EEG monitoring is also recommended in intractable cases or in any patient with atypical features to rule out a diagnosis of nonepileptic seizures. It can be very difficult to diagnose nonepileptic seizures based on clinical history, but some features that should raise suspicion of this diagnosis are closed eyes during a seizure, long duration of seizure activity that waxes and wanes, and a history of abuse.

Valproate is a poor first choice as an AED for any woman of childbearing age. In addition to the adverse effects on pregnancy, valproate is associated with weight gain, hirsutism, and signs of polycystic ovarian syndrome (PCOS). **Lamotrigine and levetiracetam are better choices and are quickly becoming the most commonly prescribed drugs for women of childbearing age.** They are often used in both focal and generalized epilepsies. Carbamazepine is also a reasonable option for women with focal epilepsy. If these medications are not effective, however, a woman may need to be switched to an AED with higher teratogenic risk or undefined risk. In these cases the patient should be counseled on the available information and unknowns, but again, the importance of seizure control should be stressed. In some women with genetic generalized epilepsies, valproate is the only drug that effectively controls their seizures. Valproate therapy is not a reason to terminate pregnancy, and despite the relatively increased risks of teratogenesis, the majority of women taking valproate will have healthy children. For all AEDs, pre-pregnancy counseling should include trying to find the minimum therapeutic dose/level needed. This is of utmost importance in women taking valproate.

**As discussed above, it is important to establish baseline AED levels prior to pregnancy in order to set a target for dose adjustment during pregnancy.** A minimum of two levels taken

at a similar time of day is advisable to establish a given individual's therapeutic range.

Unfortunately, the majority of pregnancies in women with epilepsy are unplanned,<sup>85</sup> which emphasizes the need for appropriate selection of an AED for women of childbearing age and the need for early preconception counseling. **Changing AEDs once a woman is already pregnant is usually not recommended.** Structural teratogenesis occurs early in the first trimester, and the potential effects of exposure are likely already underway by the time a woman learns she is pregnant. Additionally, switching drugs during the first trimester exposes the fetus to polytherapy and potentially breakthrough seizures during this critical time. Given the increasing knowledge of the adverse cognitive effects of valproate, which are mostly thought to occur in the third trimester, some specialists have switched women off valproate typically to levetiracetam. No available evidence supports or refutes this approach, but it should only be considered in select patients whose history suggests that they may have a good chance of responding to a different drug and are in the care of an epilepsy specialist who can monitor them closely.

**If the patient has had no seizures during the past 2 to 4 years, an attempt may be made to withdraw her from anti-convulsant medications.** This is usually done over a 1- to 3-month period, slowly reducing the medication, and should not be done close to or during pregnancy. Up to 50% of patients relapse and need to start their medications again. This withdrawal should be attempted only if the patient is completely seizure free and has a normal EEG, and it should only be done with the help of a neurologist. Based on a patient's history, many neurologists will recommend that the patient refrain from driving for a period of time during and after the wean.

### Genetic Counseling

**A detailed family history should be taken in the process of counseling women with epilepsy.** A history of congenital malformations in the family increases the chances of having an affected child. In particular, in women taking valproate, those who have had prior pregnancies complicated by a malformation have a significantly increased risk of having a second child with a malformation, regardless of whether they were taking valproate at the time of the prior pregnancy.<sup>86</sup>

It is also important to take a family history that includes seizure disorders, including febrile seizures, and intellectual disability. Many patients are concerned about the risk of passing epilepsy on to their child. Only a few epidemiologic studies have looked at the inheritance patterns of epilepsy. **For most patients with epilepsy, the risk of passing it on to their children is higher than the approximate 1% to 2% risk in the general population; however, the absolute risk remains low.** Factors associated with a low risk are late onset of epilepsy in the parent and a known acquired cause of epilepsy such as a vascular malformation, stroke, or trauma. Patients with an early onset of epilepsy, epilepsy of unknown cause, and a family history of epilepsy—particularly in a first-degree relative—have a higher risk. Epilepsy associated with intellectual disability may also be more likely to be genetic. Across many studies, the “genetic” generalized epilepsies or idiopathic generalized epilepsies have a higher risk of inheritance than focal epilepsy. Interestingly, a consistent finding in several epidemiologic studies is that mothers with epilepsy have a much higher chance of having a child with epilepsy than do fathers with epilepsy. The most recent large population study from Rochester, Minnesota

reviewed the medical records of all 660 probands with epilepsy born between 1935 and 1994 and all their first-degree relatives.<sup>87</sup> This study also found that epilepsy was more likely to be inherited from the mother, although when analyzed separately, this effect was only true for focal epilepsies, not generalized epilepsies. When all types of epilepsy were considered, the cumulative incidence to age 40 of epilepsy in a child of a woman with epilepsy was 5.39%, which correlates to a fivefold increased risk from the baseline population. The authors recommended taking the standard error into account and counseling women that **on average, the risk of passing on epilepsy is 2.69% to 8%.** In children of women with generalized epilepsy, the incidence was 8.34% (1.36% to 15.36% risk, considering standard error), and if the mother had focal epilepsy, the incidence was 4.43% (1.43% to 7.43%).

This type of epidemiologic data can be useful for patients with epilepsy of unknown cause, but they should not be used to counsel all patients indiscriminately. It is critical that the neurologist and obstetrician take a patient's individual clinical and family history into account before advising on the risks of passing on epilepsy.

An increasing number of epilepsy genes and familial syndromes have been discovered that can substantially alter the risk of inheriting an epileptic disorder.<sup>88</sup> Autosomal-dominant forms of epilepsy, such as autosomal-dominant frontal lobe epilepsy (ADFLE) and autosomal-dominant temporal lobe epilepsy (ADTLE), are highly penetrant familial epilepsies that should be considered in a patient with one or more first-degree relatives with a similar epilepsy syndrome. Mutations in the sodium channel, voltage gated, type 1 alpha subunit (*SCN1A*) gene have variable penetrance and expressivity, and they can present with a range of manifestations. Even within one family, some individuals with the mutation will be unaffected, some will have simple febrile seizures or a mild epilepsy syndrome that persists into adulthood, whereas others can have Dravet syndrome, a severe epileptic encephalopathy. Preimplantation genetic testing for these disorders is available only for some syndromes and is controversial. However, recognizing these family syndromes definitely changes the counseling on the risk of inheriting epilepsy. Other genetic syndromes associated with epilepsy have more serious complications. For example, bilateral periventricular nodular heterotopia (PVNH; Fig. 49-1) is an uncommon cause of focal epilepsy. Approximately 50% of female patients with PVNH will have a mutation in the filamin A gene.<sup>89</sup> This is an X-linked-dominant mutation that is typically lethal in males in the third trimester or in the immediate postnatal period. Female patients may have no manifestations other than the periventricular nodules, which represent aberrant neuronal migration, and epilepsy. An echocardiogram is recommended in these women, because they can have cardiac anomalies. Other examples of critical genetic diagnoses are mitochondrial disorders that can present with epilepsy. Whereas a comprehensive review of the genetics of epilepsy is beyond the scope of this chapter, **genetic counseling is an important option for many prospective parents with epilepsy, and certain clinical findings or key features in a family history, such as other affected relatives or frequent miscarriages, make specialized counseling essential.**

### Folic Acid Supplementation

The 2009 AAN practice guidelines recommend folic acid supplementation of 0.4 to 4 mg/day for all women of

**FIG 49-1** Bilateral periventricular nodular heterotopia (PVNH). Magnetic resonance imaging (MRI) of a 28-year-old primigravida with intractable focal epilepsy who presented for neurologic evaluation at 24 weeks' gestation. Her prior MRI demonstrated bilateral PVNH (white arrows point to abnormal cortical tissue lining the ventricles bilaterally). In up to 50% of women, this syndrome is associated with an X-linked dominant mutation in the filamin A gene that is often lethal in male fetuses in the third trimester or the first few postnatal days. In females, this mutation is associated with the above migrational abnormalities and focal seizures. Female patients may have normal or slightly low intelligence quotients (IQs). This case illustrates the importance of early prepregnancy neurologic evaluation and genetic counseling.

**childbearing age who take AEDs.**<sup>90</sup> These recommendations are largely extrapolated from studies that have demonstrated that folic acid supplementation reduces the risk for NTDs in the general population.<sup>91</sup> Additionally, low first-trimester serum folic acid levels have been correlated with an increased risk for congenital malformations in the offspring of women with epilepsy, and several AEDs are known to lower folic acid levels.<sup>92,93</sup> Little direct evidence is available to suggest that folic acid reduces the risk of major anomalies in women taking AEDs, although the AAN practice guidelines state that prior studies might have been underpowered to detect a benefit.<sup>90</sup> One study by Pittschieler and colleagues<sup>94</sup> suggested that folic acid may reduce the risks of miscarriage in women with epilepsy. The NEAD study<sup>31</sup> also found an association between higher IQs in children of mothers with epilepsy who took periconceptional folic acid supplementation ( $\geq 0.4$  mg). It is unclear whether this effect was specific to AED use because similar beneficial effects on cognitive development have been noted in the general population. The optimal dose of folic acid for women taking AEDs is not known. A recent study of women without epilepsy found delayed psychomotor development in children of women exposed to doses greater than 5 mg compared with women who took doses of 0.4 to 1 mg, which raises concerns about the practice of high-dose supplementation.<sup>95</sup> More research is needed to determine the optimal dose of folic acid in women with epilepsy. In the meantime, **supplementation with 0.4 to 1 mg in all women**

of childbearing age taking AEDs should be recommended. Many clinicians increase the dose to 4 mg of folic acid when a patient is trying to conceive or is pregnant.

**Vitamin D deficiency is also common in women with epilepsy.** This occurs because anticonvulsants may interfere with the conversion of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol, the active form of vitamin D. **Ideally, 25-hydroxyvitamin D levels should be checked and optimized prior to pregnancy.** A supplemental dose of 1000 to 2000 IU of vitamin D<sub>3</sub> in addition to a prenatal vitamin is reasonable during pregnancy. Additionally, because folic acid supplementation can mask the hematologic effects of vitamin B<sub>12</sub> deficiency, B<sub>12</sub> levels should also be checked in women with epilepsy.

### Care of the Patient During Pregnancy

Once the patient becomes pregnant, it is of the utmost importance to establish accurate gestational dating. This will prevent any confusion over fetal growth in later gestation. **AED levels should be checked as soon as possible and then monthly. Adjustments should be made to keep the patient's AED level around her prepregnancy or early pregnancy level.**

An early anatomic ultrasound at 14 to 15 weeks' gestation can identify signs suggestive of NTDs in women at high risk (see Chapter 9). At approximately 16 weeks' gestation, the patient should undergo blood testing with maternal serum alpha-fetoprotein screening in an attempt to detect any NTD. Coupled with ultrasonography, these data result in a detection rate of more than 90% for open NTDs (see Chapter 10). **At 18 to 22 weeks, the patient should undergo a specialized, detailed anatomic ultrasound to determine whether congenital malformations, including NTDs, are present. If adequate views of the fetal heart are not obtained, a fetal echocardiogram can be performed at 20 to 22 weeks' gestation to detect cardiac malformations, which are among the more common malformations in women taking any antiepileptic medications.** In the United States, no official recommendations have been made on the use of fetal cardiac echo studies in women with epilepsy, but the 2009 Italian guidelines do advise this examination for all women taking AEDs.<sup>96</sup>

As previously noted, there appears to be an increased risk for IUGR in fetuses exposed in utero to anticonvulsant medications. If the patient's weight gain and fundal growth appear appropriate, regular ultrasound examinations to assess fetal weight are probably unnecessary. If, however, if poor fundal growth is suspected or if the patient's habitus precludes adequate assessment of this clinical parameter, serial ultrasonography for fetal weight discernment can be performed.

**Antepartum fetal evaluation with nonstress testing is not necessary in all mothers with seizure disorders, but it should be considered for patients who have active seizures in the third trimester.**

### Vitamin K Supplementation

Third-trimester vitamin K supplementation in women taking certain enzyme-inducing AEDs (EIAEDs) is a historic practice based on a concern for an increased risk of intracranial neonatal hemorrhage and clotting factor deficiencies associated with EIAED exposure reported in early case studies.<sup>97,98</sup> EIAEDs include phenobarbital, phenytoin, carbamazepine, and oxcarbazepine. **A more recent study of 662 women with epilepsy taking EIAEDs did not find any increased risk of bleeding**

**in the neonate if the infant received 1 mg of vitamin K intramuscularly at birth.**<sup>99</sup> This problem is rare today because most neonates are given vitamin K at birth. The 2009 AAN guidelines state that evidence is insufficient to recommend for or against the practice of peripartum vitamin K supplementation.<sup>90</sup> Another recent study evaluated the risk of maternal postpartum hemorrhage in women with epilepsy and also found no significant difference in the risk of bleeding in women taking EIAEDs versus controls.<sup>100</sup> There was also no difference in the risk of bleeding in women taking EIAEDs who supplemented with vitamin K and those who did not.

### Labor and Delivery

**Although epidemiologically there may be an increased risk of induction of labor and CD in women with epilepsy, these interventions should not be recommended to women with epilepsy without specific additional obstetric, medical, or neurologic indications.** Most women with epilepsy have successful vaginal deliveries. Although no evidence exists to support or challenge epidural analgesia in patients with epilepsy, it is typically utilized to decrease stress and allow the mother to rest during a long labor.

The risk of seizures during labor in women with epilepsy is 3.5% or less, and seizures are most common in patients who have had seizures during pregnancy.<sup>69,70</sup> Whenever a seizure occurs, acute seizure management involves assessing the patient's clinical stability, including respiratory and circulatory function. Nothing should be put in the mouth of a seizing patient, but supplemental oxygen should be provided, and suctioning of secretions can be performed if possible. Ideally, the patient should be turned on her left side to increase blood supply to the fetus. Short-acting benzodiazepines, typically lorazepam 0.1 mg/kg to 0.2 mg/kg with a maximum of 10 mg, are the mainstay of acute seizure treatment. If the seizure does not resolve within 2 minutes, lorazepam should be given. In most cases this is followed by intravenous (IV) fosphenytoin or phenytoin if seizures persist. *Status epilepticus* is defined by seizures that last more than 5 minutes. In the rare case of tonic-clonic status in pregnancy, intubation and stabilization with anesthesia may be required. Fetal monitoring should begin as soon as possible after a seizure, if it is not already in place. Transient fetal heart rate changes may be seen and can be tolerated temporarily, but if fetal bradycardia persists, the clinician must assume fetal compromise or placental abruption and must proceed with CD.

### New Onset of Seizures in Pregnancy and in the Puerperium

Occasionally, seizures are diagnosed for the first time during pregnancy, which may present a diagnostic dilemma. **If the seizures occur in the third trimester, they are eclampsia until proven otherwise and should be treated as such until the physician can perform a proper evaluation.** The treatment of eclampsia is delivery, but the patient must first be stabilized (see Chapter 31). Magnesium sulfate, instead of AEDs, is the treatment of choice for eclamptic seizures. It is often difficult, however, to distinguish eclampsia from an epileptic seizure. The patient may be hypertensive initially after an epileptic seizure and may exhibit some myoglobinuria secondary to muscle breakdown, which will test as proteinuria on a routine urinalysis. The diagnosis becomes clearer over time, but in either case, rapid thoughtful action must be undertaken. The first physician to attend a patient after a seizure may not be an obstetrician/

gynecologist, and magnesium sulfate may not be started acutely; this should be remedied as soon as possible.

**If the patient develops seizures for the first time at an earlier gestational age, she should be evaluated and started on the proper medication.** The physician must look for acquired causes of seizures that include trauma, infection, metabolic disorders, space-occupying lesions, central nervous system (CNS) bleeding, and ingestion of drugs such as cocaine and amphetamines. Blood samples should be obtained for electrolytes, glucose, ionized calcium, magnesium, renal function studies, and toxicologic studies while IV access is being established. If the patient experienced a tonic-clonic seizure and the attending physician believes, based on clinical history, that this is probably new-onset epilepsy with a high likelihood of recurrence, she should be started on the appropriate anticonvulsant medication while awaiting the results of any laboratory studies. **Although lamotrigine is one of the most commonly prescribed drugs for women planning pregnancy, it is typically not practical to start it when epilepsy presents in pregnancy.** The lamotrigine titration schedule is at least 6 weeks because of an increased risk of a Stevens-Johnson reaction in patients taking this drug, especially if it is titrated quickly. In addition, accelerated lamotrigine metabolism in pregnancy makes it virtually impossible to achieve a therapeutic level in a pregnant woman over a reasonable time period. Similar considerations apply to oxcarbazepine. **For new-onset epilepsy, levetiracetam is often used first because it can be started quickly and does not carry a high risk of rash.** An unfortunate side effect of levetiracetam, however, is an increase in depressed mood or irritability; this should be assessed in women starting this drug.

Any patient who experiences seizures for the first time during pregnancy without a known cause should undergo an EEG and intracranial imaging. In studying only eclamptic patients, Sibai and colleagues<sup>101</sup> found that EEGs were initially abnormal in 75% of patients but normalized within 6 months in all women studied. Although this group found no uniform abnormalities on computed tomography (CT) in this series of eclamptic patients, they did find that 46% and 33% had some abnormal findings on EEG and CT, respectively. Most of the findings were nonspecific and were not helpful in diagnosis or treatment. An MRI is indicated in most cases of new-onset seizures and may be helpful if eclampsia is suspected.

### Breastfeeding and the Postpartum Period

The levels of anticonvulsant medications must be monitored frequently during the first few weeks postpartum (see Chapter 23) because they can rise rapidly. **If the patient's medication dosages were increased during pregnancy, they will need to be decreased over the 3 weeks after delivery to levels at or slightly higher than that of the prepregnancy period.** As discussed above, this is especially important for lamotrigine.

The benefits of breastfeeding have been well established and include the promotion of mother-infant bonding (see Chapter 24).<sup>102</sup> **Whereas AEDs taken by the mother are present in breast milk to varying degrees, few data suggest neonatal harm from exposure through breast milk.** The NEAD study<sup>103</sup> found that infants exposed to carbamazepine, lamotrigine, phenytoin, and valproate in breast milk had higher IQs and language scores at 6 years than those infants whose mothers did not breastfeed. An improvement in parent-reported developmental abilities of children was also noted in breastfed infants in a Norwegian cohort of AED-exposed children at 6 and 18 months,

although the effect was not sustained at 36 months.<sup>104</sup> Neither study found adverse effects on developmental outcomes related to breast milk exposure for the studied drugs (carbamazepine, lamotrigine, phenytoin, and valproate). Although further prospective studies of AED exposure via breast milk are necessary, for most AEDs, the theoretic concern of prolonged infant exposure likely does not outweigh the known benefits of breastfeeding. Some experts advise caution with AEDs with longer half-lives, such as phenobarbital and zonisamide, although again the concern is largely theoretic.

### Postpartum Safety

Breastfeeding should be supported and encouraged for most women with epilepsy; however the sleep deprivation associated with trying to feed a newborn may put her at risk for seizures. **A key part of managing a pregnancy in women with epilepsy is discussing seizure safety with her and her family.** Partners or other members of a patient's support system should assist with night feedings with either pumped milk or formula so that the patient can get a stretch of uninterrupted sleep, typically 6 to 8 hours depending on the patient. The patient may have to pump milk additional times during the day to maintain this supply. Other safety recommendations include giving baths only in the presence of another adult and changing diapers on a pad on the floor instead of on a changing table. Avoiding stairs when possible and using a stroller, rather than an infant carrier strapped to the mother, should also be considered. The importance of not allowing infants to sleep in the parents' bed should also be emphasized. Lastly, women with epilepsy are at increased risk for postpartum depression, a topic that should be discussed with the patient and her family prior to delivery and after.

### Contraception

Contraceptive counseling is an important part of preconception and postpartum planning in women with epilepsy, and drug-drug interactions are numerous between AEDs and hormonal contraception. Both the Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO) have released evidence-based reviews on the use of specific types of contraception in women taking AEDs.<sup>105,106</sup> The most reliable form of reversible contraception is the intrauterine device (IUD), and this is considered the contraceptive method of choice for most women with epilepsy. Both the copper and levonorgestrel IUD are appropriate. If hormonal methods are considered, the physician should review the considerations laid out by the CDC and WHO before initiating treatment.

## MULTIPLE SCLEROSIS

**Multiple sclerosis (MS) is a chronic autoimmune demyelinating disease that affects women more often than men, and the ratio of affected females to males has been increasing over time.**<sup>107</sup> **The onset of symptoms usually occurs between the ages of 20 and 40 years, and thus it commonly affects women of childbearing age.** The diagnosis of MS is often made years after the initial onset of symptoms. Common presenting symptoms include weakness, paresthesias or numbness of one or both lower extremities, visual complaints that include optic neuritis, and loss of coordination. MS primarily affects the white matter of the CNS, and lesions may involve the spinal cord, brainstem, cerebral hemispheres, and optic tracts. The hallmark of diagnosis is that it causes lesions "disseminated over space and time." **The**

**most common form of the disease, relapsing remitting MS, is characterized by periodic exacerbations with complete or partial remissions.** Only 10% to 15% of patients show steady progression at the time of onset, but over time, the majority of patients with MS will develop secondary progressive MS with continuing accumulation of neurologic deficits and disability.

Because symptoms of an MS attack can be subtle, it is often easy to attribute them to pregnancy. Many pregnant women complain of being more awkward or having some weakness. If these symptoms are persistent or progressive, they should not be ignored, and the patient should be referred for neurologic consultation. An MRI of the brain and sometimes an MRI of the spinal cord are necessary to make the diagnosis of MS. Gadolinium contrast is helpful to identify acute demyelinating lesions, but it should *not* be administered to pregnant women. Even without contrast, an MRI can be valuable in evaluating a patient with suspected MS or new symptoms in the setting of a prior diagnosis of MS.

### Multiple Sclerosis and Fertility

The relationship between MS and fertility is unclear. Similar to women with epilepsy, women with MS are less likely to have children than are unaffected women.<sup>108,109</sup> However, it is not completely clear whether this is due to biologic reasons or to the reproductive decisions of women with MS. Other factors may play a role, such as sexual dysfunction, which is common in MS patients. Translational studies have suggested that women with MS may have reduced ovarian reserve based on elevated follicle-stimulating hormone (FSH) and decreased anti-Müllerian hormone (AMH) levels; AMH is a marker of ovarian reserve.<sup>110,111</sup> Additionally, women with MS are also more likely to utilize assisted reproductive technology (ART).<sup>112</sup> It should be noted, however, that in vitro fertilization (IVF) procedures that utilize gonadotropin-releasing hormone (GnRH) agonists have been shown to increase MS disease activity, particularly if the cycle is not successful.<sup>113-115</sup>

### Effect of Pregnancy on Multiple Sclerosis

**The risk of MS relapses is reduced during gestation but may increase transiently in the postpartum period.** Convincing evidence shows that the risk of MS attacks is decreased during the course of pregnancy. It is hypothesized that the lower rate of disease activity during gestation may be attributable to a pregnancy-induced shift from thymus helper 1 (Th 1) cytokines to Th 2 cytokines to facilitate immune tolerance (see Chapter 4). The Pregnancy and Multiple Sclerosis (PRIMS) study prospectively followed 269 pregnancies in 254 women with MS across 12 European countries.<sup>116,117</sup> They found that the annual rate of relapse declined during pregnancy, especially in the third trimester. A rebound of disease activity was noted in the first 3 months postpartum, but subsequently the relapse frequency returned to baseline. Of note, the rate of relapse over the entire pregnancy year—9 months gestation plus 3 months postpartum—did not differ from the baseline rate, and only 28% of patients experienced a postpartum relapse. **Most importantly, no change in disability progression was noted over the duration of the study.**<sup>117,118</sup> A meta-analysis of 13 studies published prior to 2011 found that the annualized relapse rate significantly decreased from a baseline of 0.43 per year to 0.26 per year during pregnancy.<sup>119</sup> In the year following delivery, the average annualized rate of relapse increased to 0.7 per year.

**Despite the transient increase in postpartum relapses seen in women with MS, pregnancy likely has a neutral effect on long-term disease progression.** Weinschenker and colleagues<sup>120</sup> showed no association between long-term disability and (1) total number of term pregnancies, (2) the timing of pregnancy relative to the onset of MS, or (3) the worsening of MS in relation to a pregnancy. Verdru and associates<sup>121</sup> studied 200 women with MS and found that pregnancy delays the onset of long-term disability. As an index of progression, they used the length of time from onset of disease until wheelchair dependence. In patients with at least one pregnancy after diagnosis, the mean time to wheelchair dependence was 18.6 years compared with 12.5 years for other women. Similarly, Runmarker and Andersen<sup>122</sup> observed a decreased risk of MS onset in parous women compared with nulliparous women and reported that women who were pregnant after the onset of MS had a decreased risk of developing progressive disease. A recent retrospective study of 1317 Canadian women with MS also found that pregnancy slowed the rate of conversion to irreversible disability based on the Expanded Disability Status Scale (EDSS).<sup>123</sup> However, in terms of long-term risk of conversion to secondary progressive MS—as judged by an EDSS of 6, when a walking aid is required—women who had been pregnant had a lower risk, at trend levels, of converting to this form of the disease at 5 years but an increased risk at 10 years postpartum. These longer-term effects were not statistically significant and require further study. The apparent slowed progression of disability may also be influenced by the fact that women with more severe disease are less likely to conceive after the onset of MS. A population-based study of 2105 women, also from Canada, found that when confounding variables such as age at disease onset were considered, pregnancy had no effect on the time to progress to an EDSS score of 6.<sup>124</sup>

### Effect of Multiple Sclerosis on Pregnancy Outcomes

Although more data are needed, **MS does not seem to have any significant effect on the course of pregnancy or fetal outcomes.** Some early studies had suggested that MS may affect fetal birthweight, but important confounders were not assessed. The largest study to date by van der Kop and colleagues<sup>125</sup> also controlled for important confounders such as parity and prior preterm births but found **no association between MS and preterm birth or newborn birthweight.**

### Disease-Modifying Agents and Pregnancy

The field of MS therapy is rapidly evolving, and unfortunately, information on the risks related to MS therapies during pregnancy and lactation is sorely lacking. **The mainstay of treatment for acute MS relapses is corticosteroids or, rarely, other immunomodulatory treatments.** Corticosteroids are used symptomatically to lessen the severity and hasten recovery from acute neurologic symptoms, but they do not seem to alter the course of the disease. In 1993, the first disease-modifying agent (DMA), interferon- $\beta$ , was introduced. Since then, a steady increase has occurred in available DMAs. **These therapies are utilized to reduce relapse rates; decrease MRI progression, one marker of MS disease activity; and lessen cumulative disability in patients with MS. They are not used to treat acute MS relapses.** DMAs are divided into *first-line* and *second-line* agents (Table 49-2). Second-line therapies are usually

**TABLE 49-2** DISEASE-MODIFYING AGENTS FOR MULTIPLE SCLEROSIS: TERATOGENIC RISK AND RECOMMENDED WASHOUT PERIOD

| DISEASE MODIFYING AGENT                     | ANIMAL STUDIES   | HUMAN STUDIES  | RECOMMENDED WASHOUT   |
|---|--|--|---|
| <b>First-Line Disease-Modifying Agents</b>  |  |  |   |
| Glatiramer acetate                          | No concerns raised   | No concerns, although studies were small   | 1 month   |
| Interferon- $\beta$                         | Increased spontaneous abortion   | No changes in rates of conception, spontaneous abortion, or MCM; may be associated with preterm birth and decreased birthweight and length     | 1 month   |
| BG-12/dimethyl fumarate                     | Embryo toxicity, spontaneous abortion, neurobehavioral issues                                      | No increased risk of MCM or spontaneous abortion in 69 pregnancies   | 1 month   |
| Fingolimod                                  | Embryolethality and fetal malformations (ventricular septal defect, persistent truncus arteriosus) | In humans, spontaneous abortion rate 24% (slightly increased from baseline) in 89 pregnancies; “abnormal fetal development” also noted in 7.6% | 2 months  |
| Teriflunomide                               | Embryotoxic and teratogenic effects  | No increased risk of spontaneous abortion or MCM in 83 pregnancies where mother was exposed  | 24 months; “washout protocol” recommended to achieve plasma concentrations less than 0.02 mg/mL |
| <b>Second-Line Disease-Modifying Agents</b> |  |  |   |
| Natalizumab                                 | Increased risk of spontaneous abortion   | No increased risk of MCM in 101 pregnancies; hematologic issues in infants exposed in third trimester  | 2 to 3 months, although some advise continuation to conception                                  |
| Alemtuzumab                                 | Increased risk of fetal death  | Limited data, no increased risk of spontaneous abortion in 134 pregnancies   | 4 months  |
| Mitoxantrone                                | Limited data   | Decreased weight, increased prematurity  | 6 months; consider fertility preservation (may cause amenorrhea)                                |

MCM, major congenital malformation; MS, multiple sclerosis.

reserved for patients who have failed a first-line agent and those who have very active disease.

**Given that few data are available on the safety of DMAs in pregnancy and the fact that MS attacks are usually less frequent in pregnancy, most experts recommend stopping DMAs prior to conception.** Highly effective contraception is also recommended for women who utilize these therapies. It is worth noting that many of the observational reports of MS, including the prospective PRIMIS study, took place before DMAs were available. Since then, a few studies have suggested that use of DMAs prior to conception or during gestation decreases the risk for postpartum relapses.<sup>118,126,127</sup> Postpartum relapse rates are also lower in patients whose MS activity had been well controlled in the year prior to pregnancy.<sup>126,128</sup> Deciding which DMA is best for a woman with MS who is of reproductive age, as well as the appropriate time to stop the drug and contraception when trying to conceive, is a complex decision based on the patient's disease burden, the specific drug she is taking, and her personal concerns. These decisions should be made in consultation with her treating neurologist. Available information on the various DMAs available are summarized below and in Table 49-2.

### First-Line Agents

First-line DMAs include interferon- $\beta$ , glatiramer acetate, dimethyl fumarate, and teriflunomide. The Food and Drug Administration (FDA) also considers fingolimod a first-line drug for the treatment of MS, although the European Medicine Agency (EMA) does not. **Of the first-line therapies, experts agree that interferon- $\beta$  and glatiramer acetate can be continued up to the time that contraception is stopped. Some have suggested that they can even be continued until a pregnancy is confirmed.**<sup>118</sup> In some rare cases, glatiramer acetate is continued during pregnancy.

**Interferon- $\beta$**  formulations (interferon beta-1a and interferon beta-1b) are subcutaneous or intramuscular (IM) injections used at intervals that range from daily to every other week based on the formulation. These were among the first DMAs introduced for the treatment of MS, yet a relative paucity of information remains concerning the use of interferon- $\beta$  therapy in pregnancy. However, lately, the number of available studies on this topic has increased.

Of note, interferons are large molecules that must be transferred across the placenta by active transport, and this process likely does not occur until after the first trimester.<sup>129</sup> Animal studies had suggested an increased risk of spontaneous abortions with interferon- $\beta$  exposure; however, this has not held up in observational human studies. Sandberg-Wollheim and colleagues<sup>130</sup> dissected data on 1022 cases of interferon beta-1a exposure during pregnancy. To avoid bias, they only included outcomes for prospective data ( $n = 425$ ) and found 324 normal infants were delivered at term (76.2%), 4 infants were born with malformations (0.9%), 4 third-trimester stillbirths occurred (0.9%, 1 with anomalies), along with 5 ectopic pregnancies (1.2%), 49 (11.5%) first-trimester spontaneous abortions, and 39 (9.2%) elective abortions. The authors reported that these results are not dissimilar to the general population, but no control group was included. Amato and colleagues<sup>131</sup> investigated first-trimester exposure to interferon  $\beta$ -1a or -1b. They compared these patients with those who were never treated or who discontinued treatment at least 4 weeks before conception. Of the 88 exposed fetuses, no increase was found in spontaneous abortion, malformations, or developmental abnormalities over a median follow-up of 2.1 years, although the incidence of low birthweight was increased and infants were shorter at birth. **In a systematic review of reports of DMA exposure in pregnancy, Lu and colleagues<sup>132</sup> summarized that prospective cohort studies of fair to good quality have found that**

**interferon- $\beta$  exposure may be associated with preterm delivery (before 37 weeks), as well as lower weight and length at birth, but did not find an association between interferon exposure and birthweight below 2500 g, major malformations, or spontaneous abortion.** Recently, the manufacturers of interferon  $\beta$ -1b released information on the largest prospective cohort of pregnancies exposed to this interferon from their international pharmacovigilance database.<sup>133</sup> Among 1045 pregnancies, no increased risk of spontaneous abortions or major anomalies was reported compared with expected population rates. They also detected no change in preterm birth or SGA infants. It should be noted that the majority of patients in these studies had limited exposure to interferon- $\beta$  (average of 4 to 8 weeks), and no conclusions can be reached about exposure throughout pregnancy or long-term effects.

**Glatiramer acetate** is also used to treat frequent relapses in those with relapsing remitting MS. It is a large macromolecule that likely does not pass the placenta.<sup>129</sup> Preclinical studies did not demonstrate adverse effects of glatiramer acetate on offspring of exposed animals, and thus it received a class B designation from the FDA. Studies of glatiramer acetate in pregnancy are based on small cohorts, but two studies have evaluated women exposed to the drug throughout pregnancy. Salminen and coworkers<sup>134</sup> prospectively followed 13 women exposed to glatiramer from preconception through pregnancy and the postpartum period and found no congenital anomalies, and the treatment was well tolerated. Fragoso and colleagues<sup>135</sup> retrospectively evaluated 11 women who used glatiramer continuously for at least 7 months during pregnancy. Children were followed for at least 1 year after birth. No congenital anomalies, neonatal complications, or developmental abnormalities were seen in the children. Postnatal MS relapse rates remained significantly lower than antenatal rates in these women.<sup>135</sup> Although data are significantly limited by the small sample sizes, most experts feel that **glatiramer acetate is the DMA of choice if one must be used during pregnancy, although the patient's history of response to this drug must also be considered.**

**Dimethyl fumarate, teriflunomide, and fingolimod** are oral agents that have been recently introduced and have been shown to reduce relapse rates, as well as disability scores, in patients with MS. They are popular given that they are oral formulations. Animal studies have raised concern for embryoletality and teratogenicity of these medications, and clinical experience with these drugs in human pregnancy is limited to accidental exposures in clinical trials and postmarketing surveillance. It is recommended that effective contraception be used with each of these drugs and that they *not* be continued in pregnancy. In addition, given the long-term effects and half-lives of some of these oral agents, it is recommended that they be stopped prior to discontinuation of contraception (see Table 49-2). A special "washout" protocol is advised for teriflunomide.

In animal studies of **dimethyl fumarate**, an increased risk of spontaneous abortion and adverse fetal outcome (decreased fetal weight and delayed ossification) were seen at supratherapeutic doses and were thought to be due to maternal toxicity.<sup>136</sup> Neurodevelopmental effects were observed in animals at all doses tested. No increased risk of spontaneous abortion or fetal abnormalities was noted in 69 reports of human pregnancies exposed to dimethyl fumarate in clinical trials or postmarketing surveillance.<sup>137</sup>

**Teriflunomide** has been associated with embryotoxicity and teratogenicity in animals.<sup>138</sup> In 83 pregnancies of women with

MS and 22 pregnancies of partners of men with MS taking teriflunomide, the risks of spontaneous abortions or fetal abnormalities were not increased.<sup>139</sup> Because of the concern of teratogenesis, as well as the long half-life of teriflunomide, contraception is recommended during and after treatment. A "washout" protocol with activated charcoal or cholestyramine is recommended for women who plan to conceive and for those who become pregnant while taking the drug. In a systematic review, an international multidisciplinary consortium recommended that for teriflunomide, **"Conception should be tied to plasma concentration levels less than 0.02 mg/mL rather than to the 5 maximal half-lives algorithm for exponential decay."**<sup>140</sup> Because teriflunomide is also present in the sperm of men who take the drug, a similar protocol is recommended for men planning to conceive.

Animal studies of **fingolimod** have demonstrated embryoletality and teratogenic effects with doses lower than those recommended in humans.<sup>141</sup> In a report of 89 pregnancies that occurred during the clinical studies of the drug, the rate of spontaneous abortions was 24% (slightly higher than the expected baseline rate of 15% to 20% according to the authors), and five cases of "abnormal fetal development" were reported that included one case of each of acrania, bowing of the tibia, tetralogy of Fallot, intrauterine death, and failure of fetal development.<sup>142</sup>

## Second-Line Agents

**Natalizumab** is a humanized monoclonal immunoglobulin (Ig) G4 antibody to human  $\alpha 4$  integrin that works against many processes involved in human development. However, it is a large molecule that should not cross the placenta. Wehner and colleagues<sup>143</sup> set out to examine postnatal development in monkeys exposed to this medication. In the first cohort of monkeys, an increase in spontaneous abortions occurred. However, the rate in the control group was low (7%). In the second cohort studied, the spontaneous abortion rates were equivalent in both groups. These researchers found no adverse effects on the general health, survival, development, or immunologic structure or function of the newborn monkeys whose mothers were treated with natalizumab. Ebrahimi and colleagues<sup>144</sup> reported on 101 pregnancies in patients who received natalizumab during pregnancy or up to 8 weeks before the last menstrual period. The patients were ascertained from a prospective registry of MS patients and were paired with disease-matched controls. The authors found no significant difference in the presence of malformations, low birthweight, or preterm birth between the two groups. In a case series of 13 pregnancies in 12 women with highly active MS who were treated with natalizumab in the third trimester, Haghighi and colleagues<sup>145</sup> reported mild to moderate hematologic abnormalities, including thrombocytopenia and anemia, in 10 of 13 infants. In most children, the abnormalities resolved without consequence within 4 months of delivery. One child had subclinical bleeding and another was born with a cystic abnormality in the thalamic region thought to be due to prior hemorrhage, although no developmental consequences were obvious at 2 years of age. No consensus has been reached on when to stop natalizumab prior to conception. Some experts recommend, based on the above data, that the drug can be continued up to the time of conception, checking pregnancy tests before each infusion.<sup>118</sup> Others believe waiting 1 to 3 months before conceiving is appropriate.<sup>129</sup> The antibody can be removed from the blood with a series of plasma exchanges, but this is rarely thought to be necessary.

**Alemtuzumab** is another humanized monoclonal antibody approved as a second-line drug for MS in 2013. It is directed against CD52 and causes a long-lasting depletion of lymphocytes. It is given as a yearly infusion and can be complicated by immune-mediated thyroid disease in one third of patients. Animal exposure to alemtuzumab during gestation increased the risk of fetal death in rodents.<sup>138</sup> Limited data are available in humans. In the only clinical abstract,<sup>146</sup> 139 pregnancies in 104 patients were reported. The rate of spontaneous abortion was 17%, which the authors stated was comparable to that of the general population. Eleven adverse events without a clear pattern were also reported, along with one case of thyrotoxic crisis. Contraception is therefore recommended for 4 months after discontinuing alemtuzumab.<sup>138</sup>

**Mitoxantrone is a second-line agent for the treatment of MS, and cyclophosphamide is occasionally used for severe cases. Both treatments can cause amenorrhea in one third of patients, and cyclophosphamide is associated with ovarian toxicity.**<sup>138</sup> In animals, cyclophosphamide has been shown to cause genetic abnormalities in female germ cells; however, very little is known about the effects of mitoxantrone and cyclophosphamide during pregnancy. The risks of both are felt to outweigh potential benefits of both in pregnancy. It is recommended that contraception be continued for 6 months after mitoxantrone and 3 months after cyclophosphamide have been stopped.

### Prepregnancy Counseling for Patients With Multiple Sclerosis

Women with MS should be counseled about reproductive choices at the time of diagnosis and before starting a DMA. The topic should also be revisited regularly. **Patients should be reassured that the vast majority of women with MS can have healthy pregnancies and that MS in the mother does not pose an adverse risk to the fetus.** Additionally, they should be told that pregnancy will likely reduce the risk of MS flares temporarily, and although they may worsen in some women in the postpartum period, pregnancy likely does not have any adverse effect on long-term disease course. The decision of whether to start a DMA and which DMA to start depends on the patient's disease burden and timeline for conception.

Timing of conception is very important for a woman with MS, given that disease burden prior to conception may affect the course of the pregnancy. For a woman with very active disease, a neurologist might recommend treatment with a DMA for 1 year to obtain better disease control before conception. Of course, given uncertainties around ovarian function in women with MS, the patient's age and an assessment of fertility may also be considered. Women who require treatment with drugs such as cyclophosphamide or mitoxantrone may want to consider fertility preservation prior to beginning treatment. Women should be counseled on the recommended timeline to continue contraception following discontinuation of a DMA (see Table 49-2).

Some women with MS may be concerned about the risk of passing the disease on to their children. MS is a polygenic disorder and combined effects of genetic susceptibility and environment determines an individual's risk. **The risk of developing MS in a child with a single parent with MS is 2% to 2.5%.**<sup>147</sup> Whereas this is a twentyfold increase from the baseline population risk, the absolute likelihood that a mother will pass MS on to her child is still very low and usually is not a reason to avoid pregnancy.<sup>118</sup>

Women with MS should also receive general prenatal counseling that includes stressing the importance of supplementation with a prenatal vitamin. **Vitamin D deficiency** is gaining more attention as an environmental factor that affects susceptibility to MS and MS relapses. Vitamin D deficiency in a mother may also affect her child's subsequent risk of developing MS. In a small open-label trial, pregnant women with MS and low vitamin D levels were randomized to 50,000 IU of vitamin D<sub>3</sub> a week, starting at weeks 12 to 16 of gestation, or routine care.<sup>148</sup> The group of six who received "high-dose" vitamin D had normal postpartum levels of vitamin D, whereas the nine patients who received routine care did not. No adverse effects of supplementation were reported during pregnancy or 6 months postpartum, although no conclusions can be made about long-term fetal effects. Patients who received the high-dose vitamin D appeared to do better in terms of EDSS and relapse rate, but these data are limited by the small sample size and open-label methodology. The optimal dose of vitamin D in pregnancy is not known, but a consortium of experts recommended that 1000 to 2000 IU daily should be safe.<sup>140</sup> Ideally, the vitamin D level should be checked and optimized before pregnancy, and a dose of 1000 to 2000 IU can be continued in pregnancy.

### Management of Multiple Sclerosis During Pregnancy

**No specific changes in routine obstetric care are recommended for women with MS.** Women with disturbances in bladder function may be more prone to urinary tract infections and need to be monitored more frequently. Urinalysis and culture should be checked in the setting of new or worsening symptoms because infections can often exacerbate the presentation of MS.

If an acute and severe MS relapse occurs during pregnancy, treatment with corticosteroids may hasten recovery. The typical regimen is 1 g of methylprednisolone daily for 3 to 7 days, which can be given intravenously or orally; no oral taper is used. Methylprednisolone or the equivalent dose of prednisolone and prednisone are recommended if steroids are needed because less than 10% of these steroids pass across the placenta. When possible, it is recommended that steroid use be minimized in pregnancy, and ideally, it should be avoided in the first trimester. Safety information on the fetal effects of steroids is limited but some older studies associated steroid exposure with an increased risk of cleft lip and palate (see Chapter 8).<sup>140</sup> Questions were also raised by studies that suggested low birthweight and premature delivery as a result of steroid use. IV immunoglobulin (IVIG) can be used as an alternative to steroids or when steroids fail, but safety data on IVIG is also limited.<sup>140</sup> Monthly IVIG or steroids can also be considered for women with active disease during pregnancy to decrease the risk of relapses.

### Labor and Delivery

In the past, anesthesiologists had been concerned that epidural analgesia might somehow worsen the disease or promote relapses. In both the PRIMS study<sup>116,117</sup> and a large Italian cohort,<sup>149</sup> only 18% to 19% of women with MS received epidural analgesia. In the PRIMS study, a trend was seen toward a higher relapse rate in the first 3 months postpartum in women who received epidurals, but this effect did not reach statistical significance. **In the Italian study by Pastò and colleagues,<sup>149</sup> no increase was seen in relapse rate or EDSS score 1 year after delivery in women with MS who had received epidural anesthesia.**

Perceptions of the risk of anesthesia may have changed. A more recent population-based study performed in Canada found that nulliparous women with MS received epidural or spinal anesthesia at a rate similar to that of the general population. However, multiparous women with MS were more likely to receive epidural analgesia.<sup>150</sup>

**Cesarean delivery is usually not indicated in women with MS.** Only in rare cases of severe or active disease that affects the spinal cord may MS affect a patient's ability to labor safely. Across five studies assessed in a recent meta-analysis, cesarean delivery rates varied from 9.6% to 42%,<sup>119</sup> which likely reflects the variability of practice among different cultures and practitioners. Pastò and colleagues<sup>149</sup> found no association between cesarean delivery and relapse rate or disability scores in Italian women with MS.

### Breastfeeding and the Postpartum Period

**Breastfeeding in women with MS is a controversial and actively debated topic.** Some studies have suggested that breastfeeding has a protective effect on MS relapses, whereas others report no effect on disease activity. **The PRIMS study found that breastfeeding had no effect on the rate of MS relapses in the first 3 months postpartum.**<sup>116,117</sup> A more recent study of 302 pregnant women with MS treated at Italian MS centers also found no effect of breastfeeding on disease activity. The authors noted that breastfeeding may not be possible for women with high disease burden.<sup>128</sup> Other studies have suggested, however, that breastfeeding—particularly exclusive breastfeeding—may reduce the likelihood of MS relapses in the postpartum period.<sup>151,152</sup> A 2012 meta-analysis of 12 studies of MS and breastfeeding found that women who did not breastfeed were nearly twice as likely to have at least one relapse in the postpartum period.<sup>153</sup> This result was significant but was limited by the variability of the studies available. The authors cautioned that it is not possible to completely control for the possibility that women with more benign disease may also be more likely to breastfeed.

The decision to breastfeed is made more complicated by a woman or her doctor's desire for her to resume DMAs. **Most experts state that DMAs should not be resumed while a woman is breastfeeding.**<sup>118,129,138</sup> However, **this recommendation is based on a lack of evidence about the safety of these drugs in breastfeeding rather than evidence of harm.** Unfortunately, this conservative approach will likely prevent the ability to gather important data on the safety of some of these therapies during breastfeeding, as has been done with AEDs, and may make patients more reluctant to breastfeed.

Both interferons and glatiramer acetate are large molecules that are not orally bioavailable. It is unlikely that they pass into breastmilk, although this has not been studied systematically. Interferon  $\beta$ -1a transfer into breastmilk was assessed in six women, and the relative infant dose was estimated at 0.006%. No adverse effects were noted in the infants who were exposed through breastmilk.<sup>154</sup> In another small study of glatiramer acetate and breastfeeding, no problems were noted in nine infants exposed through breastmilk for an average of 3.6 months.<sup>135</sup> Nevertheless, official recommendations continue to state that all DMAs should be held in women who plan to breastfeed, and thus most women must make a choice between breastfeeding and resuming a DMA. A minority of physicians are comfortable with patients breastfeeding while taking glatiramer acetate.<sup>129</sup> It is important to note, however, that the

onset of action of these first-line therapies is delayed, typically by 2 months, and even if they are started immediately postpartum, they may not provide protection from relapses in the immediate postpartum period. Pulse doses of IVIG<sup>155-157</sup> or methylprednisolone<sup>158</sup> have been tried to prevent relapses in the postpartum period, but differing results and methodologic limitations make it difficult to draw firm conclusions about the benefit of this approach.<sup>118</sup>

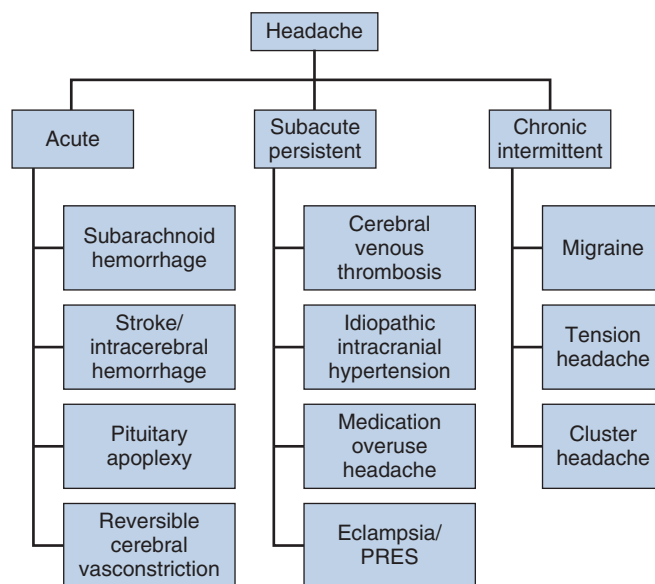

Postpartum, women with MS will often need help with their own care and the care of their infant. This depends greatly on the patient's level of disability and whether she experiences a relapse. For all patients who are pregnant or considering pregnancy, it is helpful to discuss the need for support from friends and family members in the postpartum period as well as to prepare a contingency plan for infant care in the event of a disabling MS relapse.

## HEADACHE

Headache disorders can be divided into two classes, primary and secondary. *Primary headache disorders* include migraine and tension-type headaches as well as cluster headaches, although the latter are rare in women. Both migraine and tension-type headaches improve in pregnancy, although some may persist. The biggest challenge in evaluating headache is to rule out *secondary headache disorders* (Fig. 49-2), which are symptomatic of underlying and potentially deleterious pathologies. Most patients with primary headaches such as migraine have a prior history of a similar headache pattern. Any new symptoms or headache pattern and all new-onset headaches, even if they have a migrainous quality, should prompt evaluation for underlying causes. It is also important to be aware of the appropriate treatments for these conditions.

### Migraine

Headaches are extremely common in women, and the majority of migraine headaches occur in women of childbearing age. Migraines are associated with vasodilation of the cerebral

**FIG 49-2** Differential diagnosis of headaches in pregnancy. PRES, posterior reversible encephalopathy syndrome.

vasculature and typically last several hours. Onset is usually subacute and the headache is often unilateral and pounding and is often accompanied by photosensitivity and/or phonosensitivity and nausea. Migraines can be classified as those with aura and those without. *Migraines with aura* are characterized by reversible focal neurologic symptoms that occur before the headache. Visual auras are common, but aphasia or unilateral numbness or weakness may also occur, which sometimes makes such headaches difficult to distinguish from transient ischemic attacks. The migraine aura should be fully reversible in 5 to 60 minutes, and sometimes the aura can occur without a headache.

**Migraine symptoms tend to improve during pregnancy.** Maggioni and colleagues<sup>159</sup> found that 80% of patients experienced either complete remission or a 50% reduction in headaches during pregnancy. Improvement was more common after the first trimester. Migraine type does not seem to be a prognostic factor. Those with menstrual (catamenial) migraines had the most improvement. However, 4% to 8% show significant worsening during pregnancy. In a study by Ertresvåg and colleagues,<sup>160</sup> 58% of subjects with migraine reported having no headache during pregnancy. Transient neurologic symptoms were more common in patients with a history of migraine. Chen

and Leviton<sup>161</sup> examined data from the large, prospective Collaborative Perinatal Project of 55,000 pregnancies. They found that less than 2% of women in the sample were considered to have migraines at their initial prenatal visit. Of the 484 (of 508) women with a complete data set, 17% experienced complete cessation of headache throughout pregnancy, and an additional 62% had two or fewer headaches in the third trimester. Only 21% of these women had no improvement in their headache. The authors examined all available demographic and pregnancy factors and could find none that could be used to predict headache improvement during pregnancy.

Using a nationwide population-based database in Taiwan, Chen and colleagues<sup>162</sup> identified 4911 women with migraines who delivered from 2001 to 2003. After adjusting for confounders, they found an increased risk for low birthweight (OR, 1.16), preterm birth (OR, 1.24), cesarean delivery (OR, 1.16), and preeclampsia (OR, 1.34). Although these increases were not large, they were all statistically significant.<sup>162</sup> More research needs to be undertaken to determine whether these increases apply to different populations and if they are clinically significant.

Migraine treatment is divided into abortive and prophylactic treatments (Tables 49-3 and 49-4). Given the anticipated improvement of migraines during pregnancy, most women do

**TABLE 49-3 ABORTIVE TREATMENTS FOR PRIMARY HEADACHES IN PREGNANCY**

|                           | <b>BEST STUDIED/<br/>RECOMMENDED</b> | <b>MALFORMATION RISK</b>  | <b>OTHER COMMENTS</b>   | <b>BREASTFEEDING<br/>COMPATIBLE</b>   |

| Lithium                   | Lithium   | Associated with fetal cardiac anomalies as well as polyhydramnios, cardiac arrhythmias, hypoglycemia, diabetes insipidus, and thyroid abnormalities | Not indicated for the treatment of migraine; used for cluster headache; contraindicated for headache treatment in pregnancy; associated with neonatal withdrawal                      | Possibly compatible, but caution is advised because of hypotonia and ECG changes in infant; lithium can be considered in closely monitored patients |

CNS, central nervous system; ECG, electrocardiogram; FDA, U.S. Food and Drug Administration; GI, gastrointestinal; IQ, intelligence quotient; MCM, major congenital malformation; SGA, small for gestational age.

not need to take prophylactic treatment, and such treatment is usually weaned prior to conception. Nonpharmacologic measures such as sleep, hydration, and relaxation techniques are the first-line treatment for migraines during gestation. For drug therapy, acetaminophen is initially recommended. Ibuprofen can be used in the first and second trimester, but the use of nonsteroidal antiinflammatory drugs (NSAIDs) should be avoided if possible after 24 weeks' gestation. When used for more than 48 hours, these agents can cause oligohydramnios and premature closure of the ductus arteriosus. Although opiates are often prescribed during pregnancy, these are actually not preferred for migraine treatment because they are typically ineffective, increase nausea, and decrease gastric motility. Antiemetic therapy may be helpful, but barbiturates should be avoided if possible.

Sumatriptan, a serotonin receptor agonist, is very successful in treating migraines acutely. In a review by O'Quinn and colleagues,<sup>163</sup> no untoward effects were reported in 76 first-trimester

exposures to sumatriptan. Using logistic regression, Olesen and colleagues<sup>164</sup> compared 34 pregnancies with sumatriptan exposures with 89 migraine controls and 15,995 healthy women. They found that the risk of preterm birth was elevated with exposure (OR, 6.3) as was the risk of IUGR.<sup>164</sup> They do state that they did not control for disease severity. A larger study by Källén and Lygner<sup>165</sup> did not confirm these findings. **In 658 infants whose mothers used sumatriptan during pregnancy, no significant difference in prematurity or low birthweight was noted.**<sup>165</sup> Hilaire and colleagues<sup>166</sup> found birth defects in 3% to 5% of infants exposed to sumatriptan in the first trimester, a rate not greater than expected.

**Recent studies have demonstrated that sumatriptan can be used during pregnancy. In a large Norwegian database, no increase in congenital anomalies or other adverse pregnancy outcomes was reported.** However, increases were seen in intra-partum bleeding (OR, 1.5) and uterine atony (OR, 1.4). Ephross and Sinclair<sup>167</sup> reviewed 528 first-trimester exposures to

sumatriptan and 57 to naratriptan and observed an anomaly rate similar to that of the background population; however, this study had no control group. Evans and Lorber described all available studies from 1990 through 2007 and also contacted the manufacturers of seven triptan medications; **they concluded that data are sufficient to recommend the use of sumatriptan for treatment of migraine in the first trimester** and also feel that naratriptan and rizatriptan are probably safe. Although these medications are acceptable for use in the second and third trimesters, little information is available regarding their use in late pregnancy. **Soldin and colleagues<sup>168</sup> confirm these findings and also stress that sumatriptan should be the triptan of choice because more data are available concerning its use in pregnancy.**

**Ergotamine should be avoided during pregnancy.** Previous reports have suggested that it may cause birth defects that have a vascular disruptive etiology. In addition, ergots are uterotonic and have an abortifacient potential.

**Dietary factors may precipitate migraine attacks.** Therefore careful history may uncover foods that should be avoided, including foods that contain monosodium glutamate (MSG), red wine, cured meats, and strong cheeses that contain tyramine. Relative hypoglycemia and alcohol can also trigger migraine attacks. Many individuals have recommended, without supporting evidence, dietary supplements and vitamins for migraine prevention. In a small study, Maizels and colleagues<sup>169</sup> demonstrated a possible role for riboflavin and magnesium in the prevention of migraines.

## Secondary Headache in Pregnancy

**Headaches during pregnancy can be a symptom of underlying intracranial pathology.** Concerning causes of secondary headache in pregnancy include idiopathic intracranial hypertension, cerebral venous thrombosis (CVT), subarachnoid hemorrhage, and stroke. **Symptoms that should prompt further evaluation include abrupt onset of symptoms, persistent headache, and positional component. Any associated focal neurologic signs or vision changes should also prompt additional investigation unless they are a typical part of a patient's migraine aura. Patients with primary headache disorders can get secondary headaches, so any change in pattern or new symptoms should also be considered evidence of a possible underlying problem.**

### Idiopathic Intracranial Hypertension (Pseudotumor Cerebri)

Idiopathic intracranial hypertension (IIH) may complicate 2% to 12% of pregnancies.<sup>170</sup> It had been thought to occur more frequently in pregnant women, particularly those who are obese. However, in a study by Ireland and colleagues,<sup>171</sup> the incidence in pregnant women and in oral contraceptive users was no higher than that in control groups. The headache of IIH is usually subacute in onset and is present daily. It may be aggravated by lying down and may be worse in the morning. However, the positional component is not always typical. **More than 90% of patients with IIH have headaches, and 40% have horizontal diplopia.**<sup>170</sup> Patients with IIH may also report transient visual obscurations that last less than one minute and may also report pulsatile tinnitus. **Papilledema is a characteristic feature of the condition and is present in the majority of cases. If left untreated, IIH can progress to permanent visual loss.** To establish the diagnosis, other causes of intracranial

hypertension must be excluded, such as an intracranial mass or CVT, and elevated cerebrospinal fluid (CSF) pressure (>250 mm H<sub>2</sub>O) with normal CSF composition must be demonstrated.<sup>172</sup> MRI and magnetic resonance venogram (MRV) of the brain without contrast are the imaging modalities of choice and must be performed before a lumbar puncture to avoid herniation in the setting of a mass lesion. The pathogenesis of this disorder is unknown, but CSF prolactin is markedly elevated. Prolactin appears to have an affinity for receptors in the choroid plexus, where CSF is produced. Prolactin has osmoregulatory functions and therefore may have a role in the increased CSF production found in IIH, although some believe that reduced CSF reabsorption is the etiology. **Pregnancy outcome appears to be unaffected by IIH,<sup>172</sup> and no increase in fetal wastage or congenital anomalies are reported.**

**The main objectives of treatment for IIH are relief of pain and preservation of vision.** The patient should be followed closely with visual acuity and visual field determinations at intervals indicated by the clinical condition. In patients with mild disease, analgesics and close follow-up may be adequate. Moderate weight loss is recommended. For patients without improvement or those at risk for visual deterioration, acetazolamide—a carbonic anhydrase inhibitor that reduces CSF production—is the first-line treatment. Lee and colleagues<sup>173</sup> treated 12 patients with acetazolamide during pregnancy and reported no adverse fetal outcomes. They reviewed the English language literature and found nothing to contradict this assertion. The usual dose of acetazolamide is 500 mg twice daily. Steroids are rarely used for IIH; they are reserved for cases with impending vision loss in patients awaiting a surgical intervention. Serial lumbar punctures to reduce CSF pressure are rarely necessary but can effectively lower intracranial pressure transiently. Surgical approaches are reserved for refractory patients in whom rapid visual deterioration occurs. The two most common procedures are optic nerve sheath fenestration and lumboperitoneal or ventriculoperitoneal shunt.

**IIH is not usually an indication for cesarean delivery.** A review of the literature reveals that 73% of the reported patients delivered vaginally. Although no data are available to confirm this, the Valsalva maneuver—which can increase CSF pressure—should be minimized when possible. Therefore the second stage of labor should be shortened by operative vaginal delivery if possible. **Both epidural and spinal anesthesia, when expertly administered, can be safely used in patients with IIH.** However, in patients with lumboperitoneal shunts, the anesthetic should be directed away from the spinal canal. Month and Vaida<sup>174</sup> reported a successful spinal epidural technique during which 5 to 6 mL of CSF withdrawn at the time of analgesia provided additional relief.

### Cerebral Vein Thrombosis

In patients with cerebral venous thrombosis (CVT), the chief symptoms are similar to those of IIH because the initial manifestations are due to increased intracranial pressure. **Patients typically present with a subacute, progressive, unremitting headache that may be worse when lying down.** As in IIH, patients may have diplopia and pulsatile tinnitus. Patients with CVT may also demonstrate papilledema. CVT can be complicated by a venous infarction with or without bleeding, which often leads to focal neurologic deficits and seizures. Severe headache with vomiting can be seen and should raise concern for acute worsening, such as associated stroke or hemorrhage. CVT

occurs most frequently during the immediate postpartum period but can occur at any stage of pregnancy. It is often attributed to a hypercoagulable state. An incidence of 1 in 10,000 pregnancies was suggested in one study.<sup>175</sup> Vora and colleagues<sup>176</sup> reviewed 37,420 pregnancies in a Mumbai, India hospital between 2002 and 2006 and found a 0.1% incidence of thrombotic phenomena. Of these, 10% were documented cortical vein thromboses, confirming the incidence of 1 in 10,000 pregnancies.<sup>176</sup> CVT can be misdiagnosed as a postepidural headache, and this should be considered in the differential diagnosis. When CVT has a positional component, it should be worse lying and better standing, whereas a low-pressure headache often exhibits the reverse. These patterns are not always observed in individual patients, however; therefore CVT should be considered in the differential of all postpartum headaches.

**MRI and MRV of the brain are the diagnostic tests of choice**, and IV contrast is not needed to make the diagnosis. Anticoagulation, typically with low-molecular-weight heparin (LMWH), is the mainstay of treatment during pregnancy and breastfeeding. Workup for underlying thrombophilias is indicated to determine the duration of treatment. Prothrombin and factor V Leiden mutations can be performed during pregnancy, but other tests of hypercoagulability should be assessed 6 weeks or more after delivery (see [Chapter 45](#)). Seizures can be treated symptomatically with anticonvulsants, although little evidence is available to suggest the appropriate duration of AED treatment. Many neurologists and neurosurgeons advocate expectant management and do not routinely use AEDs for these symptomatic seizures. **Women who have had a CVT during pregnancy should avoid hormonal contraception, and women with a history of clotting while on hormonal contraception should use prophylactic anticoagulation during pregnancy.**

### Subarachnoid Hemorrhage

**Subarachnoid hemorrhage (SAH) usually manifests with a sudden “thunderclap” headache that is often associated with vomiting, stiff neck, and fluctuations of consciousness.** Patients often refer to it as the “worst headache of their life.” This presentation is a medical emergency that necessitates an emergency head CT scan, which is better than an MRI for visualizing bleeding. Even if the CT scan is negative, a lumbar puncture is indicated in patients with a suspicious history to exclude intrathecal blood. Up to 50% of aneurysmal SAHs are preceded by a “sentinel” bleed and a headache that should not go undiagnosed. The rate of SAH complicating pregnancy is approximately 1 per 10,400.<sup>177</sup> Robinson and coworkers<sup>178</sup> evaluated 26 patients with spontaneous SAH during pregnancy and found that approximately half were caused by aneurysms and half by arteriovenous (AV) malformations. They observed that AV malformations are more common in patients younger than 25 years of age and usually bleed before 20 weeks’ gestation. Conversely, aneurysms occurred in patients older than 30 years of age and usually bled in the third trimester.

Cerebral angiography can be used to pinpoint the origin of cerebral bleeding. SAH due to aneurysms should be treated surgically whenever possible. In one study, SAH without early surgery resulted in a maternal mortality of 63% and a fetal mortality of 27%. With early surgery, the risk of mortality was lowered to 11% and 5%, respectively.<sup>179</sup> Surgery under hypothermia or hypotension appears to cause no adverse fetal effects. At an appropriate gestational age, the fetal heart rate should be monitored during the procedure. If fetal bradycardia occurs, the

patient’s blood pressure should be raised sufficiently to normalize the fetal heart rate.

### Reversible Cerebral Vasoconstriction

**Reversible cerebral vasoconstriction syndrome (RCVS) can present with a similar “thunderclap” headache. It may also present with focal neurologic deficits, seizures, and fluctuating levels of consciousness.** RCVS can be complicated by stroke, nonaneurysmal SAH, and cerebral edema. Postpartum angiopathy is a type of RCVS often seen in the immediate postpartum period and is characterized by severe headaches with reversible narrowing of the intracranial vessels. Diagnosis can often be made by MRI and magnetic resonance angiography (MRA) of the brain. Alternatively, computed tomographic angiography (CTA) may be used for imaging or, rarely, an angiogram is needed. Treatment with nimodipine appears to help the headaches.<sup>180</sup> In a review of cerebrovascular disorders of pregnancy, however, Feske and Singhal<sup>183</sup> point out that postpartum angiopathy is on the same spectrum as eclampsia and posterior reversible encephalopathy syndrome (PRES; see [Chapter 31, Figs. 31-13 and 31-14](#)). Despite the lack of proteinuria in postpartum angiopathy/RCVS, the similarities of imaging findings suggest that they are likely mediated by the same pathologic process. Thus the authors argue that magnesium sulfate infusions similar to those used in eclampsia should be given to women with postpartum angiopathy to control blood pressure and seizures.

## STROKE

Strokes can be divided into ischemic and hemorrhagic strokes. **Ischemic strokes** are usually the result of an arterial occlusion from cardioembolism and can also occur secondary to a CVT. Arterial dissection is also a common cause of stroke in young people and may be seen in pregnancy. **Hemorrhagic strokes** can be secondary to a variety of causes and may occur from severe hypertension alone or may be secondary to an underlying aneurysm or vascular malformation. Ischemic strokes can also exhibit hemorrhagic conversion. **Preeclampsia and eclampsia are risk factors for both ischemic and hemorrhagic strokes.**

### Ischemic Stroke

Ischemic stroke is diagnosed in 34 per 100,000 deliveries, with 1.4 deaths per 100,000. The risk of stroke is increased in patients older than 35 years and in black women. Del Zotto and colleagues<sup>181</sup> reviewed multiple worldwide databases and showed that varied incidences between 4 and 41 per 100,000 deliveries. The highest risk was in patients with preeclampsia. Predisposing factors such as preeclampsia, chronic hypertension, or hypotensive episodes can be demonstrated in about one third of these patients. Brown and colleagues<sup>182</sup> investigated ischemic stroke in women recruited between 1992 and 1996 and again between 2001 and 2003. They found that preeclampsia was statistically associated with an increased risk of ischemic stroke (OR, 1.59; 95% CI, 1.00 to 2.52). Of note, women with a history of preeclampsia were more likely to eventually experience a non-pregnancy-related ischemic stroke. Half of the pregnancy-related cases occurred during the immediate postpartum period, and the remainder occurred during the second and third trimesters.

**Ischemic stroke typically presents with acute focal neurologic symptoms.** Headache can be present in 17% to 34% of

cases. The workup should be done swiftly and starts with a noncontrast CT of the head. Acute treatment of disabling stroke due to arterial occlusion in nonpregnant patients is with IV or intraarterial recombinant tissue plasminogen activator (tPA). Little is known about the efficacy and safety of tPA in pregnant women because they were excluded from the clinical trials for tPA therapy. However, in acute ischemic strokes due to arterial thrombosis, the benefits of tPA likely outweigh the risks, even in pregnant women. Feske and Singhal<sup>183</sup> reviewed the case reports of 11 women who received IV or intraarterial thrombolysis. They concluded that 10 of the patients had no major complications from the thrombolysis and mentioned that the one patient who died had a major complicating illness. Seven of the exposed fetuses were delivered without complications. One fetus died along with the mother, two pregnancies were terminated, and one spontaneous abortion occurred in a fetus whose mother had bacterial endocarditis. The authors point out that **although tPA can be considered for pregnant women with arterial occlusion, it should probably be avoided in patients with preeclampsia/eclampsia given the increased risk of intracranial hemorrhage in these cases.**

Patients with acute strokes should typically be monitored in an intensive care setting, especially if tPA was given. Tight blood pressure control is required, and for major strokes, aggressive management of intracranial pressure may be needed. Further workup of ischemic stroke includes an MRI of the brain along with MRA of the head and neck. In some cases, CTA or angiography is needed. All patients with possible embolic stroke should have a transthoracic echo with agitated saline to exclude a patent foramen ovale. Blood tests should include a lipid panel, hemoglobin A1C level, erythrocyte sedimentation rate, and C-reactive protein level.

### Hemorrhagic Stroke and Vascular Malformations

Based on a review of prior epidemiologic studies, Feske and Singhal<sup>183</sup> estimated the incidence of hemorrhagic stroke in pregnancy to be between 5 and 35 per 100,000 patients. The likelihood of a hemorrhagic stroke increases more dramatically in pregnancy than the risk for an ischemic stroke.

Evidence conflicts in regard to the effect of pregnancy on the behavior of arteriovenous malformations (AVMs).<sup>178,185,186</sup> Although it is uncertain whether incidental AVMs are at greater risk of bleeding during pregnancy, one study found that in 27 women who presented with hemorrhage due to AVMs in pregnancy, 26% had recurrent bleeding during or immediately after pregnancy. This is higher than the annual 6% risk expected in nonpregnant patients.<sup>187</sup> There also appears to be a significantly heightened risk of bleeding from an AVM on the day of delivery.<sup>186</sup>

In considering the above information, a 2001 consensus statement from the American Heart Association (AHA) recommended that **a woman with a known AVM should consider treatment prior to conceiving, and when an AVM is discovered during pregnancy, risks of treatment should be weighed against the risk of hemorrhage.** The committee felt that in most cases, such a risk-benefit analysis will not support elective treatment of AVMs during pregnancy.<sup>187</sup> Typically, AVMs found incidentally without hemorrhage are managed expectantly, but surgical intervention is considered in a woman with an AVM that has hemorrhaged.<sup>183</sup>

**If the patient has undergone corrective surgery for an aneurysm or an AVM, she should be allowed to deliver vaginally.** Moderate increases in blood pressure do not cause spontaneous hemorrhage in nonpregnant patients with intracranial AVMs. If the aneurysm or AVM has not been surgically corrected, a cesarean delivery is often recommended because of concern about the effects of increased blood pressure and intracranial pressure during delivery and prior observations of increased bleeding on the day of delivery.<sup>178,183</sup> However, in truth, no direct evidence is available to show that cesarean delivery is more protective against bleeding from an AVM than vaginal delivery.<sup>187</sup>

### CARPAL TUNNEL SYNDROME

The medial border of the carpal tunnel consists of the pisiform and hamate bones, and its lateral border consists of the scaphoid and trapezium bones. They are covered on the palmar surface by the flexor retinaculum. **The median nerve and flexor tendons pass through this carpal tunnel, which has little room for expansion. If the wrist is extremely flexed or extended, the volume of the carpal tunnel is reduced. In pregnancy, weight gain and edema can produce a carpal tunnel syndrome that results from compression of the median nerve.** The association between carpal tunnel syndrome and pregnancy was first reported in 1957. Although many pregnant women complain of pain on the palmar surface of the hand, few actually have the true carpal tunnel syndrome. Stolp-Smith and colleagues<sup>188</sup> found that 50 of 14,579 pregnant patients (0.34%) who presented between 1987 and 1992 actually met criteria for carpal tunnel syndrome. **Commonly, the syndrome consists of pain, numbness, and tingling in the distribution of the median nerve in the hand and wrist. This includes the thumb, index finger, long finger, and radial side of the ring finger on the palmar aspect.** These symptoms/signs can be accompanied by dysesthetic wrist pain, loss of grip strength, and problems with dexterity. Compressing the median nerve and percussing the wrist and forearm with a reflex hammer, the Tinel maneuver, often exacerbates the pain. In severe cases, weakness and decreased motor function can occur. The definitive diagnosis is made by electromyography, but this test is often unnecessary.

McLennan and coworkers<sup>189</sup> studied 1216 consecutive pregnancies. Of these patients, 427 (35%) reported hand symptoms. Fewer than 20% of these 427 affected women described the classic carpal tunnel syndrome. No patient required operative intervention. Most symptoms were bilateral and commenced in the third trimester of pregnancy. **Ekman-Ordeberg and colleagues<sup>190</sup> found a 2.3% incidence of carpal tunnel syndrome in a prospective study of 2358 pregnancies. The syndrome appeared to be more common in primigravidae with generalized edema.** Increased weight gain during pregnancy also raises the risk.<sup>189</sup> A recent prospective study of 639 Dutch pregnant women found a 34% prevalence of carpal tunnel syndrome based on a standardized questionnaire.<sup>191</sup> Symptoms were more likely to occur after 32 weeks' gestation and were associated with symptoms of fluid retention when adjusting for body mass index (BMI), age, parity, and depression scores.

Padua and colleagues<sup>192</sup> conducted a systematic literature review concerning carpal tunnel syndrome in pregnancy. Of the 214 studies reviewed, only six fulfilled their criteria for inclusion. Neurophysiologically confirmed carpal tunnel syndrome

ranged from 7% to 43% of those who presented with symptoms. Clinically diagnosed carpal tunnel syndrome ranged from 31% to 62%. Of note in 50% of cases, symptoms persisted for more than a year, and in 30%, symptoms were still present 3 years postpartum.

**Supportive and conservative therapies are usually adequate for the treatment of carpal tunnel syndrome.** Symptoms often subside in the postpartum period as total body water returns to normal.<sup>193</sup> Pain scores fall by half during the first week after delivery and by half again during the next week. The reduction in score is strongly correlated with loss of the weight gained during pregnancy. However, about half of the women with carpal tunnel syndrome during pregnancy still have some symptoms 1 year later. This occurs more commonly in those whose symptoms started early in pregnancy. Carpal tunnel syndrome that develops during breastfeeding may also last longer.<sup>193</sup>

**Splints placed on the dorsum of the hand, which keep the wrist in a neutral position and maximize the capacity of the carpal tunnel, often provide dramatic relief.** Local injections of glucocorticoids may also be used in severe cases. Although diuretics may help to control the symptoms of carpal tunnel syndrome over a short period of time, their use is not recommended because the symptoms return rather rapidly after the cessation of treatment.

Surgical correction of this syndrome should not be delayed in patients with deteriorating muscle tone and/or motor function. Even small changes can be documented by electromyography (EMG), which can be performed without harm during pregnancy. Decompression surgery for carpal tunnel syndrome is a simple procedure that can be safely carried out during pregnancy using local anesthesia, an axillary block, or a Bier block. With new endoscopic approaches, the procedure is even less invasive. Assmus and Hashemi<sup>194</sup> describe the outcomes for 314 hands surgically treated during pregnancy or in the puerperium for carpal tunnel syndrome. One hundred thirty-three cases were performed during pregnancy, most in the last trimester, and included four who had both hands treated simultaneously; 98% of patients reported good or excellent results. Local anesthesia was used in all cases, and no complications were reported. These authors recommend surgery if sensory loss is present or if motor latency is more than 5 msec on nerve conduction studies. **It is important to warn patients that carpal tunnel syndrome can persist for several years postpartum and can recur in future pregnancies.**<sup>192</sup>

### KEY POINTS

- ◆ Epilepsy affects approximately 1% of the general population and is the most frequent neurologic complication of pregnancy.
- ◆ Prepregnancy counseling is imperative in the patient with epilepsy.
- ◆ Valproic acid has been associated with a significantly increased risk of major congenital malformations and adverse cognitive outcomes, including lower IQs and an increased risk of autism, when compared with other AEDs and with the general population.
- ◆ AEDs known to have a low risk of structural teratogenesis—such as lamotrigine, levetiracetam, or carbamazepine—should be tried as first-line agents in

women with epilepsy over AEDs that have been less well studied or valproic acid.

- ◆ Ultimately, the AED that best controls the patient's seizures should be used during pregnancy. Efforts to reach the minimum therapeutic dose should be attempted well in advance of pregnancy.
- ◆ Because of the changes in plasma volume, drug distribution, and metabolism that occur during pregnancy, anti-convulsant levels should be checked prior to conception and monthly during pregnancy. Dose adjustments to maintain prepregnancy levels are an important part of seizure control for many AEDs, especially lamotrigine.
- ◆ Women using AEDs should take folic acid 0.4 mg to 4 mg daily prior to and throughout pregnancy. They should also be offered a specialized ultrasound for careful assessment of major congenital malformations.
- ◆ Understanding a patient's epilepsy syndrome is necessary to give appropriate counseling on the risk of inheritance of epilepsy in offspring.
- ◆ Assisted reproductive techniques can precipitate MS relapses.
- ◆ Pregnancy does not hasten the onset or progression of MS. In fact, exacerbations are decreased during pregnancy.
- ◆ DMAs used to decrease the rate of relapses and disability in MS are typically not recommended during pregnancy because MS relapses tend to be less frequent during gestation, and data on exposure risk are still limited. A washout period is recommended for many DMAs.
- ◆ Increasing data on DMA use in pregnancy is available; for some patients, certain DMAs—such as glatiramer acetate and interferon- $\beta$ —can be used in pregnancy.
- ◆ Breastfeeding in MS is controversial. Exclusive breastfeeding may reduce the risk of MS relapses, but treatment with DMAs is typically not recommended for women who are breastfeeding.
- ◆ Any new headache or new headache type that presents in pregnancy requires workup for an underlying potentially deleterious cause.
- ◆ Nonpharmacologic treatments are considered first-line therapies for migraine in pregnancy, which typically improves without treatment.
- ◆ Although opiates are commonly prescribed for migraine in pregnancy, they are actually not very effective migraine medications.
- ◆ Carpal tunnel syndrome is common in pregnancy and usually responds to conservative splinting, glucocorticoid injection, or both. Surgery can be safely undertaken if indicated during pregnancy.

The juxtaposition of life and death can present numerous emotional and ethical conflicts to the patient, her family, and her physicians. The diagnosis of cancer for anyone is understandably frightening. To deal with cancer in the context of pregnancy is particularly burdensome, because the patient may have to balance competing maternal and fetal interests. On occasion, a pregnant woman may be required to make decisions that affect her life or longevity versus the life or the well-being of her unborn child. Cancer in pregnancy complicates the management of both the cancer and the pregnancy. Diagnostic and therapeutic interventions must carefully address the associated risks to both the patient and the fetus. Informed decisions

require evaluation of a number of factors, and with counseling, these considerations are the foundation on which treatment decisions are made. An evolution has taken place in the philosophy of care, from one of total disregard of the pregnancy with frequent immediate termination to a more thoughtful approach in which management decisions consider both maternal and fetal outcomes so as to limit risk of death or morbidity to both.

It is estimated that approximately 20% to 30% of malignancies occur in women younger than age 45 years.<sup>1</sup> **Although cancer is the second most common cause of death for women in their reproductive years, only about 1 in 1000 pregnancies is complicated by cancer.**<sup>2</sup> Because no large prospective studies have addressed cancer treatment in pregnancy, physicians tend to base treatment strategies on small retrospective studies or anecdotal reports that occasionally present conflicting information.<sup>1,2</sup> **A successful outcome is dependent on a cooperative multidisciplinary approach.** The management plan must be formulated within a medical, moral, ethical, legal, and religious framework that is acceptable to the patient and guided by communication and educational resources of the health care team.

**Delays in diagnosis of cancer during pregnancy are common for various reasons:** (1) many of the presenting symptoms of cancer are often attributed to the pregnancy; (2) many of the physiologic and anatomic alterations of pregnancy can compromise physical examination; (3) serum tumor markers such as β-human chorionic gonadotropin (β-hCG), alpha-fetoprotein (AFP), and cancer antigen 125 (CA 125) are increased during pregnancy; and (4) the ability to optimally perform either imaging studies or invasive diagnostic procedures may be altered during pregnancy. Because the gestational age is significant when evaluating the risks of treatments, it is important to determine gestational age accurately. An early ultrasound evaluation may be useful to ensure accurate dating.

The malignancies most commonly encountered in the pregnant patient are breast cancer, cervical cancer, and melanoma—cancers that most commonly occur in this age group—but also ovarian, thyroid, and colorectal cancer as well as leukemia and lymphoma.<sup>2,3</sup> The frequencies of these diseases complicating pregnancy may increase secondary to the trend to delay child-bearing, and age is the most potent predictor of cancer. Before specific malignancies are discussed below, some general principles are reviewed.

CHEMOTHERAPY DURING PREGNANCY

Pharmacology of Chemotherapy During Pregnancy

Because pregnancy profoundly changes maternal physiology (see Chapter 3), the potential exists for altered pharmacokinetics associated with chemotherapy. Orally administered medications are subject to changes in gastrointestinal (GI) motility. Peak drug concentrations are decreased owing to the 50% expansion in plasma volume, which produces a longer drug half-life unless a concurrent increase occurs in metabolism or excretion. The increase in plasma proteins and fall in albumin may alter drug availability, and amniotic fluid may act as a pharmacologic third space that potentially increases toxicity because of delayed metabolism and excretion. Hepatic oxidation and renal blood flow are both elevated during pregnancy and may influence the metabolism and excretion of most drugs.<sup>4</sup> However, because pharmacologic studies in pregnant women are lacking, we currently assume that initial drug dosages are similar to those given to the nonpregnant woman, and adjustments to dose are based on toxicity on a course-by-course basis. **Because most antineoplastic agents can be found in breast milk, breastfeeding is contraindicated** (see Chapter 24).<sup>4</sup>

Drug Effects on the Fetus

All drugs undergo animal teratogenicity testing, and based on these results, the drugs are assigned risk categories (Table 50-1) by the U.S. Food and Drug Administration (FDA).<sup>5</sup> Based on this system, most chemotherapeutic agents are rated as C, D, or X. However, animal teratogenicity testing cannot always be reliably extrapolated to humans. For example, a drug (e.g., aspirin) may show teratogenic effects in animals but will not affect humans. The opposite is also true and, as such, has serious potential to do harm; for example, a drug may demonstrate no animal teratogenicity (e.g., thalidomide), but it can cause serious human anomalies (see Chapter 8). Because detailed ultrasonography may fail to identify subtle anatomic but serious functional abnormalities before 20 weeks' gestation, patients should be appropriately counseled and may want to consider the option of pregnancy termination if first-trimester chemotherapy is planned or administered. **The risk of teratogenicity during the second and third trimesters is significantly reduced and is likely no different from that for pregnant women who are not exposed to chemotherapy.**<sup>4</sup>

Although the literature that addresses chemotherapy administration during pregnancy is somewhat limited and dated, literature reviews provide us with some information regarding the frequency of affected offspring.<sup>4,6</sup> Because antineoplastic agents target the rapidly dividing malignant cell, it could be expected that the exposed fetus would be particularly susceptible to serious toxicity. Clear documentation of such is not the case. Excluding the intentional use of abortifacients, it is difficult to

TABLE 50-1  
FOOD AND DRUG ADMINISTRATION  
RISK CATEGORIES FOR DRUG USE  
DURING PREGNANCY

| CATEGORY | DEFINITION  |
|----------|---|
| A        | Controlled studies have demonstrated no risk in the first trimester, and the possibility of fetal harm appears remote.  |
| B        | <i>Either</i> animal studies have failed to identify a risk but no controlled studies have been done in women <i>or</i> animal studies have shown an unconfirmed adverse effect.  |
| C        | <i>Either</i> animal studies have revealed adverse effects and no controlled studies have been done in women <i>or</i> studies in women and animals are not available. Use the drugs only if the potential benefit justifies the potential risks. |
| D        | Evidence of fetal risk exists, but the benefits may be acceptable despite the risk in either a life-threatening situation or a serious disease for which safer drugs are ineffective.   |
| X        | Studies in animals or humans have demonstrated fetal abnormalities, and the risk of the drug clearly outweighs any possible benefit.  |

From Amant F, Han SN, Gziri MM, Dekrem J, Van Calsteren K. Chemotherapy during pregnancy. *Curr Opin Oncol.* 2012;24:580-586.

clearly demonstrate that the use of chemotherapy results in an increase in the clinically recognized spontaneous abortion rate over the expected 15% to 20%. However, **if continuation of the pregnancy is desired, chemotherapy is not advised in the first trimester because of an increased rate of major malformations that ranges from 10% to 17% with single-agent therapy and up to 25% with combination chemotherapy.**<sup>6</sup> Administration in the second and third trimester has been associated with intrauterine growth restriction (IUGR), stillbirth, and low birthweight.<sup>6,7</sup> Maternal effects such as chemotherapy-induced nausea and vomiting may also affect fetal growth and birthweight.<sup>8</sup> Because early induction of labor or surgical delivery is often a component of the overall treatment plan, it has been difficult to identify premature birth as a specific result of the chemotherapy. Preterm delivery has been reported to occur in more than half of pregnancies associated with malignancies, with a majority being iatrogenically induced and associated with increased neonatal morbidity.<sup>6</sup> Therefore the timing of delivery and consideration of delay of therapy in the case of early-stage disease should be part of the treatment planning.

When chemotherapy is administered during the latter half of gestation, fetal organ toxicity has not been reported as a major problem, although neonatal myelosuppression and hearing loss have been reported.<sup>6,9</sup> Although second malignancies, impaired growth and development, intellectual impairment, and infertility have been reported after chemotherapy administration to children, the delayed effects of in utero exposure are less well documented.<sup>6,9</sup> Although few data are available, concerns regarding cognitive development have been evaluated, and the outcomes are comparable to those of individuals not exposed to chemotherapy in utero. Growth and fertility in these children have also been shown to be similar to those not exposed.<sup>9</sup>

Classification of Chemotherapy Agents  
Antimetabolites

Historically, the antimetabolite aminopterin was used as an abortifacient, and in cases of failed abortion, the risk of fetal

malformation was about 50%. Methotrexate has replaced aminopterin for chemotherapeutic purposes, and although similar types of anomalies occur, a lower overall frequency (<10%) has been reported.<sup>8</sup> **In the first trimester, methotrexate has been associated with skeletal and central nervous system (CNS) defects.** Although no anomalies were reported in the second and third trimesters, methotrexate was associated with low birthweight and neonatal myelosuppression.<sup>9</sup> The use of low-dose methotrexate for systemic diseases (e.g., rheumatic disease and psoriasis) does not appear to produce teratogenicity.<sup>10</sup> In a prospective study, 5-fluorouracil, in combination with other agents, was well tolerated and resulted in no perinatal deaths.<sup>8</sup>

### Alkylating Agents

Alkylating agents such as **cyclophosphamide and chlorambucil** are commonly used for the management of malignancies. Unfortunately, most of these agents have demonstrated some teratogenic potential when administered in the first trimester, with defects that include renal agenesis, ocular abnormalities, and cleft palate.<sup>8</sup> In the second and third trimesters, alkylating agents have been shown to be acceptably safe.<sup>1,9</sup>

### Antitumor Antibiotics

Even when administered in early pregnancy, antitumor antibiotics—such as **doxorubicin, idarubicin, bleomycin, and daunorubicin**—appear to demonstrate a low risk of teratogenicity. Doxorubicin has been associated with one case of multiple anomalies; however, the patient was receiving combination chemotherapy.<sup>9</sup> One potential reason for the low rate of anthracycline-associated teratogenicity is its questionable ability to cross the placenta.<sup>4</sup>

### Vinca Alkaloids

**Although potent teratogens in animals, vincristine and vinblastine do not appear to be as teratogenic in humans.**<sup>8</sup> In limited studies, vinca alkaloids were well tolerated in both early and later stages of pregnancy.<sup>9</sup>

### Platinum Agents

Platinum agents have been used with relatively acceptable risks, and normal outcomes have been reported along with cases of IUGR. In addition, case studies have reported hearing loss and ventriculomegaly in 2.7% of patients exposed to cisplatin.<sup>1</sup> One case of bilateral hearing loss was noted in the offspring of a woman treated with carboplatin in the second trimester of pregnancy. However, the cause cannot be fully attributed to the platinum agent because other causes of hearing loss were also present, including prematurity and administration of gentamicin in the neonatal period.<sup>8</sup>

### Miscellaneous

Taxane chemotherapy is used in the treatment of malignant tumors of multiple sites, and experience with this class of drugs remains limited, although a few reports to date are favorable.<sup>8,9</sup>

### Targeted Therapies

Despite the emerging role of targeted agents in cancer treatment, they have been used only inadvertently in pregnancy. Trastuzumab has been linked to oligohydramnios, and its use is not recommended in pregnancy.<sup>1</sup> Rituximab has been associated with transient neonatal lymphopenia, and further studies are

necessary to determine an accurate safety profile. Imatinib has been associated with low birthweight and premature delivery, whereas erlotinib showed no adverse effects in one case. The antiangiogenic agents (bevacizumab, sunitinib, and sorafenib) are not recommended for use in pregnant women.<sup>1</sup>

## RADIATION THERAPY

**Ionizing radiation is a known teratogen, and the developing embryo is particularly sensitive to its effects. Doses higher than 0.20 Gray (Gy) are considered teratogenic.** Effects during early pregnancy are typically lethal or result in congenital malformations. During late gestation, radiation may cause specific organ damage in addition to mental retardation, skeletal anomalies, and ophthalmologic abnormalities. Reports have indicated that radiation exposure in utero increases the risk of malignancies such as leukemia and other childhood tumors, particularly when exposure occurred in the first trimester.<sup>1,9</sup> It is important to remember that these data are conflicting and are extrapolated from data derived from atomic catastrophes.<sup>9</sup> Regardless, recommendations for radiation exposure in pregnancy should be less than 0.05 Gy.<sup>1,9</sup> **Radiation therapy should be postponed until the postpartum period, and consideration should be given to suitable alternative therapies such as surgery or chemotherapy. If delay of therapy is not possible, termination of the pregnancy may be required.**

## SURGERY AND ANESTHESIA

Aspects of surgery are addressed later in the sections on specific cancers, but some general principles should be considered first. Although complications of surgery can threaten the fetus, extra-peritoneal surgery is not related to spontaneous abortion or preterm labor. Surgery can be performed safely in all three trimesters.<sup>11</sup> **If flexibility in timing exists, abdominal or pelvic surgery is best performed in the second trimester to limit the risk of first-trimester spontaneous abortion or preterm labor.** In the first trimester, progesterone therapy is indicated (weeks 7 to 12) following resection of the corpus luteum. When laparoscopy is selected for abdominal surgery, the open technique is recommended to avoid injury to the uterus.<sup>11</sup> Perioperative cautions include attention to the relative safety of all drugs administered. When appropriate, antibiotic prophylaxis can be safely administered.<sup>11</sup> Fever secondary to either infection or atelectasis should be treated promptly because it may be associated with fetal abnormalities.

No evidence suggests that significant risks of anesthesia exist independent of coexisting disease (see Chapter 16).<sup>12</sup> Preoxygenation is critical due to the increase in oxygen consumption, which can lead to desaturation.<sup>11</sup> In the second and third trimesters, careful attention to positioning is required so as to avoid compression of the vena cava from the enlarged uterus. Use of local or regional anesthesia should be considered. Finally, continuous or intermittent fetal monitoring should be used when extrauterine survival is possible.

## PREGNANCY FOLLOWING CANCER TREATMENT

With improved survival rates for many childhood and adolescent malignancies, the clinician must be prepared to offer prenatal counseling to the young woman who presents with a

**BOX 50-1 COUNSELING ISSUES FOR PREGNANCY FOLLOWING CANCER TREATMENT**

What is the risk of recurrence of the malignancy?

If a recurrence were to be diagnosed, depending on the most likely sites, what would be the nature of the probable treatment?

How would such treatment compromise both the patient and the fetus?

Will prior treatments—such as pelvic surgery, radiation to pelvis or abdomen, or chemotherapy—affect fertility or reproductive outcome?

Will the hormonal milieu of pregnancy adversely affect an estrogen receptor–positive tumor?

cancer history. Issues worthy of review and in need of clarification for the obstetrician and the patient are listed in [Box 50-1](#).

Previous abdominal irradiation for a Wilms tumor appears to adversely affect the risk of pregnancy complications, including increased perinatal mortality, low birthweight, and abnormal pregnancy. In contrast, a review of pregnancies following treatment for Hodgkin lymphoma revealed no increase in poor pregnancy outcome.<sup>13</sup> However, the rate of ovarian failure following the multiple drug combinations is greater than 50% in some reports.<sup>13</sup> Also, a combination of pelvic irradiation and chemotherapy for Hodgkin disease results in an even higher rate of ovarian failure. Over recent years, a number of women with early cervical cancer have received fertility preservation surgery with radical trachelectomy and regional lymphadenectomy. The preliminary fertility and pregnancy outcomes have been favorable.<sup>14</sup>

**Will pregnancy increase the risk of recurrence or accelerate recurrence?** Even in women with estrogen receptor–positive breast cancer, there is no evidence that subsequent pregnancy adversely affects survival. In addition to the altered hormonal milieu, concern is also directed toward the potential for accelerated tumor activity associated with alterations in the pregnant patient's immune system. No available data support this concern; however, **it has been recommended that after a cancer diagnosis, pregnancy should be delayed for at least 2 years, during which recurrence risk is highest.**

**CANCER DURING PREGNANCY****Breast Cancer**

The estimated number of breast cancer cases in women in the United States exceeds 230,000 cases with approximately 40,000 deaths each year.<sup>15</sup> Although the lifetime risk of developing breast cancer is 1 in 8, the risk is 1 in 206 for women 40 years or younger. Each year, this results in approximately 7% to 15% of premenopausal breast cancers being diagnosed in women who are pregnant or lactating or within 1 year after delivery.<sup>16-18</sup> Although an increase in the frequency of breast cancer complicating pregnancy has been predicted because of delayed childbearing, **recent publications are consistent with a frequency of breast cancer concurrent with pregnancy of 1 per 3000 to 10,000 live births.**<sup>17</sup>

In general, the risk of breast cancer is directly related to the duration of ovarian function. Therefore both early menarche and late menopause appear to increase the likelihood of developing breast cancer. However, interruption of the normal cyclic ovarian

function by pregnancy appears to be protective. This apparent protective effect may be secondary to the normal hormonal milieu of pregnancy that produces epithelial proliferation, followed by marked differentiation and mitotic rest. Multiparous women, particularly those who breastfeed, have a lower risk of developing breast cancer than do nulliparous women. However, based on one study of almost 90,000 women, breastfeeding may not be an independent protective factor.<sup>19</sup> Paradoxically, carriers of *BRCA1* and *BRCA2* mutations may have an increased risk of developing breast cancer by having children.<sup>20</sup>

**Diagnosis and Staging**

**Breast abnormalities should be evaluated in the same manner as in a nonpregnant patient.** The most common presentation of breast cancer in pregnancy is a painless lump discovered by the patient. Because the breast changes become more pronounced in later pregnancy, it is important to perform a thorough breast examination at the initial visit (see [Chapter 24](#)). Despite the striking physiologic breast changes of pregnancy, including nipple enlargement and increases in glandular tissue that result in engorgement and tenderness, a newly found or persistent breast mass should be evaluated promptly. Diagnostic delays may increase the risk of nodal involvement and are often attributed to physician reluctance to evaluate breast complaints or abnormal findings in pregnancy.<sup>21</sup> **The lengths of delays in diagnosis of breast cancer in pregnancy are commonly 3 to 7 months or longer and may result in more advanced stages of diagnosis compared with the general population.**<sup>18,21</sup>

Although bilateral serosanguinous discharge may be normal in late pregnancy, less common presentations such as **bloody nipple discharge should be evaluated with mammography and ultrasound.**<sup>16</sup> In cases of mastitis or breast abscesses or for evaluation of breast edema or inflammation, a skin biopsy should be considered to evaluate for inflammatory breast cancer.

Mammography in pregnancy is controversial. Although the radiation exposure to the fetus is negligible, the hyperproliferative changes in the breast during pregnancy are characterized by increased tissue density, which makes interpretation more difficult.<sup>9,16</sup> **Breast ultrasound has a high sensitivity and specificity and can distinguish between solid and cystic masses, which makes it the preferred imaging modality for pregnant women.** Magnetic resonance imaging (MRI) without gadolinium has also been used; however, data are limited in regard to its accuracy in this population. Percutaneous biopsy is recommended for any lesion that does not meet criteria for a simple cyst.<sup>18</sup> Fine-needle aspiration (FNA) of a mass for cytologic study may be used, but it is often misleading because of changes in the breast during pregnancy. **For breast masses, a core needle biopsy is the preferred method for histologic diagnosis.**<sup>18</sup>

**Before proceeding with treatment, staging should be undertaken.** All draining lymph nodes should be evaluated. Recent studies have evaluated the role of sentinel lymph node dissection in pregnant women with breast cancer. Although blue dye is associated with a risk of anaphylaxis and should not be used, several reports have demonstrated the safety of sentinel lymph node biopsy using a low-dose lymphoscintigraphy with 99m-Technetium–labeled sulfur colloid. This technique may be considered in select cases at an experienced center.<sup>18,22,23</sup> **The contralateral breast must be carefully assessed. Laboratory tests should include baseline liver function tests and serum tumor markers, carcinoembryonic antigen (CEA), and also cancer antigen 15-3 (CA 15-3), which appears to be a useful**

**tumor marker for monitoring breast cancer in pregnancy.**<sup>24</sup>

A chest radiograph is indicated, and if the liver function tests are abnormal, the liver can be evaluated by ultrasound. If bone metastases are suspected, a bone scan can be performed in pregnancy. In a symptomatic patient, radiographs of the specific symptomatic bones are advised. However, in an asymptomatic patient with normal blood tests, because the yield is low, bone scanning is usually not performed.

**Treatment**

The treatment of breast carcinoma at any time is often overshadowed by psychological and emotional factors. Because of potential risks to the developing fetus, treatment decisions carry an additional burden. **Therapy must be individualized in accordance with present knowledge and with the specific desires of the patient, gestational age, and tumor stage and biology; at all times, maternal treatment should adhere to standard recommendations.** At the time of diagnosis, it is important to have a baseline assessment of fetal growth and development by ultrasound as well as routine fetal monitoring throughout the pregnancy and treatment.<sup>11</sup>

**LOCAL THERAPY**

The usual criteria for breast-preserving therapy versus modified radical mastectomy pertain to the patient with breast cancer in stages I to III.<sup>2,16</sup> Although breast surgery can be safely performed in all trimesters with minimal fetal risks, the use of radiation is complicated by the presence of the pregnancy.<sup>18,21</sup> **Consideration should be given to the delay of irradiation until after delivery.** Experimental calculations suggest that when the fetus is within the true pelvis, a tumor dose of 5 Gy will expose the fetus to 0.010 to 0.015 Gy. Later in pregnancy, parts of the fetus may receive as much as 0.200 Gy.<sup>21</sup> Because these levels exceed the upper limit of safety, alternative approaches should be considered, and reports have shown that in the late second or third trimester, delaying treatment without impacting maternal outcome may be reasonable.

**PREGNANCY TERMINATION**

Because early studies suggested more unfavorable outcomes in pregnant women, it was assumed that the hormonal changes of pregnancy contributed to rapid tumor growth; therefore therapeutic abortion was frequently advised. At present, a harmful effect of continuing pregnancy has *not* been demonstrated in most published series.<sup>2</sup> Although data are limited, **studies have shown similar survival outcome if the patient had a spontaneous pregnancy loss, chose to terminate, or continued the pregnancy.**<sup>8,25</sup> However, it is difficult to evaluate potential selection bias toward performing an abortion in patients with advanced disease. Because young women tend to have hormone receptor-negative tumors, it is difficult to make an argument, based on hormonal concerns, for either termination of pregnancy or oophorectomy as an adjunct to therapy.<sup>16</sup>

**CHEMOTHERAPY**

In general, **women who present with either metastatic breast carcinoma or rapidly progressive inflammatory carcinoma should avoid any delays in therapy.** Immediate initiation of chemotherapy is critical to providing the patient with inflammatory carcinoma with any chance for long-term survival. **If the patient has a clinical indication for adjuvant chemotherapy other than inflammatory carcinoma, the delay of instituting**

**chemotherapy and awaiting fetal pulmonary maturity should be considered in select third-trimester situations.** Current literature shows that the use of cytotoxic agents for breast cancer in pregnancy is relatively safe; and anthracycline-based regimens, which are the most widely used, are associated with a favorable safety profile.<sup>22</sup> Additional agents such as 5-fluorouracil, cyclophosphamide, and taxanes have also been used, but data on these agents are limited.<sup>21,22</sup> Others concur with the use of chemotherapy in the second and third trimesters in the management of breast cancer.<sup>16,18</sup> Pregnancy is a contraindication to the use of tamoxifen because of the risk of adverse fetal outcomes, including craniofacial malformations and ambiguous genitalia. Data regarding the safety of trastuzumab in pregnancy are limited, and currently it is not recommended because of reports of oligohydramnios and neonatal deaths as a result of respiratory and renal failure.<sup>18,21</sup>

**Prognosis**

As with any malignant disease, prognosis best correlates with the anatomic extent of disease at the time of diagnosis. **Outcomes in stage I and II disease are favorable, and survival rates approach 86% to 100%; however, the presence and extent of nodal involvement is especially predictive of prognosis in both nonpregnant and pregnant patients.**<sup>8</sup> Although nodal status is of prognostic significance, the number of positive nodes is also important. In the pregnant patient, the 5-year survival rate is 82% for patients with three or fewer positive nodes and 27% if greater than three nodes contain tumor.<sup>26</sup> **Probably because of the associated delays in diagnosis, pregnancy appears to increase the frequency of nodal disease, with 53% to 71% of patients exhibiting nodal involvement at diagnosis.**<sup>26,27</sup>

Reports have demonstrated that up to 60% to 80% of breast cancer cases in the pregnant population are estrogen receptor negative and have a rate of *ERBB2* positivity between 25% and 58%.<sup>20,25</sup> In addition to a higher incidence of lymph node metastases, breast tumors in pregnant women are more frequently reported to be larger and to be of a higher grade than those of their nonpregnant counterparts.<sup>16,27</sup> However, these rates are histologically identical to the nonpregnant patient of similar age, and when controlled for age and stage, pregnancy does not seem to affect prognosis adversely.<sup>25,27</sup> Of note, pregnant women with early-stage disease who had a delay in therapy did not experience a negative effect on disease-free survival.<sup>28</sup> However, breast cancer therapy during pregnancy is feasible, and patients should be counseled thoroughly.<sup>21</sup> Although infants exposed to chemotherapy for breast cancer in utero had a lower birthweight and more complications, this was not clinically significant, and most adverse outcomes were associated with preterm delivery; thus full-term delivery should be planned when possible.<sup>28</sup>

**SUBSEQUENT PREGNANCY**

Although the consensus is that subsequent pregnancies do not adversely affect survival, recommendations have been made regarding the timing of a subsequent pregnancy.<sup>29</sup> **It is generally advised that women with node-negative disease wait 2 to 3 years, and this interval should be extended to 5 years for patients with positive nodes.** Others have advised that no delay is indicated for the patient with a good prognosis who does not receive postoperative adjuvant chemotherapy.<sup>29</sup> It has been advised that patients should undergo a complete metastatic workup before a subsequent pregnancy.

Lactation and Breast Reconstruction

Lactation is possible in a small percentage of patients after breast-conserving therapy for early-stage breast cancer.<sup>30</sup> Lumpectomy using a radial incision, rather than the cosmetically preferred circumareolar incision, is less likely to disrupt ductal anatomy (see Chapter 24). Disruption of the ductal system may increase the rate of mastitis. Breastfeeding is contraindicated in women receiving chemotherapy, because significant levels of the drug can be found in breast milk.

Breast reconstruction with the use of autologous tissue has increased secondary to questions about the use of silicone-filled implants. The transverse rectus abdominis myocutaneous (TRAM) flap is one popular method of breast reconstruction. Because the donor site is a portion of the anterior abdominal wall, there is potential concern when the patient develops abdominal distension from pregnancy. In one case report and review of the literature, nine women who became pregnant following breast reconstruction experienced no problem with anterior abdominal wall integrity.<sup>31</sup> However, because data are limited, it may be best to address reconstruction in the postpartum period.

Lymphoma  
Hodgkin Lymphoma

Approximately 36,000 cases of lymphoma were expected to be diagnosed in women in the United States in the year 2015, and only about 11% of these would have been Hodgkin lymphoma (HL).<sup>15</sup> **HL is the second most commonly diagnosed cancer in women aged 15 to 29 years, and it presents at a mean age of 32 years.** Lymphomas complicate approximately 1 in 6000 pregnancies, and few large series have evaluated the many issues that affect these women.<sup>17,32</sup> However, spontaneous abortion, stillbirth rates, preterm births, and adverse pregnancy outcomes do not appear to be increased or affected by the course of the disease, and **termination of pregnancy should not be routinely advised.**<sup>32,33</sup> Although some advocate therapeutic abortion for the patient with a first-trimester pregnancy and HL to allow complete staging, others limit therapeutic abortion to those women who require infradiaphragmatic radiation or those with extensive systemic symptoms or visceral disease.

Women with HL frequently present with enlarged cervical or axillary lymph nodes, and the diagnosis is established by biopsy of the suspicious nodes. The presence of systemic symptoms such as night sweats, pruritus, or weight loss suggests more extensive disease. In a series of 17 women diagnosed with HL during pregnancy, the average time of diagnosis was 22 weeks' gestation, and systemic symptoms were uncommon.<sup>33</sup> Clinical staging for lymphoma requires systemic evaluation by history, laboratory findings, bone marrow, and radiographic imaging. Clinical treatment and staging are individualized. Although pathologic staging for HL in the nonpregnant patient may involve laparotomy and splenectomy, these are not generally performed in pregnancy. **The routine evaluation for HL during pregnancy includes a single anterior/posterior view chest radiograph, liver function tests, serum creatinine clearance, complete blood count, erythrocyte sedimentation rate, and lymph node and bone marrow biopsy.** Evaluation of the abdomen is compromised by the gravid uterus, and MRI is preferred because it can accurately assess nodes, liver, and spleen. Chest tomography or computed tomographic (CT) scan of the mediastinum may be necessary to evaluate nodal enlargement in the chest. Isotope scans of the liver and bone are best avoided

TABLE 50-2      STAGING CLASSIFICATION OF HODGKIN DISEASE

| STAGE | DESCRIPTION   |
|-------|---|
| I     | Involvement of a single lymph node region (I) or of a single extralymphatic organ site (I <sub>E</sub> )  |
| II    | Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ site and of one or more lymph node regions on the same side of the diaphragm (II <sub>E</sub> )            |
| III   | Involvement of lymph node regions on both sides of the diaphragm (III), which also may be accompanied by localized involvement of an extralymphatic organ or site (III <sub>E</sub> ), the spleen (III <sub>S</sub> ), or both (III <sub>SE</sub> ) |
| IV    | Diffuse or disseminated involvement of an extralymphatic organ with or without localized lymph node involvement (liver, bone marrow, lung, skin)  |

Symptoms of unexplained fever, night sweats, and unexplained weight loss of 10% of normal body weight results in classification of patients as B; absence of these symptoms is denoted as A.

during pregnancy, but ultrasonography is safe and may provide useful information.

Disease stage is the most important factor in treatment planning and prognosis (Table 50-2). The survival rate for early-stage HL exceeds 90%, whereas patients with disseminated nodal disease have a 5-year survival rate of about 50%. As expected, patients with stage IV disease have poor survival rates. Radiation therapy is the mainstay of treatment for early-stage HL, and combination chemotherapy is used for the treatment of advanced-stage disease with organ involvement. **Most investigators agree that treatment should not be withheld during pregnancy except in early-stage disease, particularly if the diagnosis is made in late gestation.**

**Radiotherapy to the supradiaphragmatic regions may be performed with abdominal shielding after the first trimester.** When this approach is chosen, irradiation should be delayed until after the first trimester, total fetal dose should be limited to 0.1 Gy or less, and the goal is partial therapy with completion therapy after delivery. Spontaneous abortion has been reported with an estimated first-trimester fetal dose of 0.09 Gy secondary to scatter from delivering 44 Gy to the chest of a patient receiving treatment for a recurrence.<sup>34</sup> In general, if the estimated exposure to a first-trimester fetus is expected to exceed 0.1 Gy or if combination chemotherapy is planned for the first trimester, therapeutic abortion should be considered because of an increased risk of fetal malformations.<sup>35</sup> Asymptomatic early-stage disease that presents in the second half of pregnancy may be followed closely while preparations are made for early delivery.<sup>34</sup> The use of corticosteroids and single-agent chemotherapy have been proposed for the patient with systemic symptoms.

Subdiaphragmatic or advanced disease requires chemotherapy, and commonly used regimens include doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) and mechlorethamine, vincristine, procarbazine, and prednisone (MOPP).<sup>32,34</sup> Because many of these chemotherapeutic agents are known teratogens, such treatment is best avoided in the first trimester. A systematic review found 42 pregnancies in which HL was treated with chemotherapy, and 17 were exposed to chemotherapy in the first trimester, which resulted in six congenital anomalies and three spontaneous abortions.<sup>36</sup> Similar treatments should also be approached with caution later in pregnancy, although most case reports have documented only IUGR and neonatal

**FIG 50-1** Probability of regular menses after chemotherapy, total lymphoid irradiation (TLI), and TLI and chemotherapy in patients with Hodgkin disease. The synergistic effect is more apparent in younger women. (From Horning SJ, Hoppe RT, Kaplan HS. Female reproduction after treatment for Hodgkin disease. *N Engl J Med*. 1981;304:1377.)

neutropenia as complications. Long-term follow-up toxicity studies are lacking.

**Following therapy for HL, it has been suggested that pregnancy planning should take into consideration that about 80% of recurrences manifest within 2 years.** Treatments for HL may compromise the reproductive potential of young patients.<sup>13,37</sup> As reflected in Figure 50-1, ovarian failure is more likely to occur in older patients even if treated with fewer courses of chemotherapy.<sup>37</sup> Early studies reported normal ovarian function in only 12% of women following therapy for HL, and combined treatment with radiation and chemotherapy have been found to lead to the highest risk of ovarian failure. **More recent series have shown the pregnancy rate among reproductive-age HL survivors to be similar to that of the normal female population.** Regimen changes that have occurred since the earlier reports include improved pelvic shielding during primary irradiation, ovarian transposition when pelvic radiation is required, and more frequent use of the ABVD regimen instead of MOPP. Depending on their availability, new reproductive technologies that include oocyte donation and embryo cryopreservation can be considered in select situations.

Patients who become pregnant after treatment for HL do not demonstrate increased adverse perinatal outcomes such as fetal wastage, preterm birth, and birth defects when compared with sibling controls.<sup>32</sup> Although fetal anomalies have occurred after treatment for HL, chromosomal abnormalities or a new gene mutation have not been diagnosed.<sup>37</sup> The absence of a repetitive pattern of malformations makes it difficult to imply a causal relationship between any birth defects observed and previous therapy for Hodgkin disease.

**General recommendations, therefore, include delaying therapy until at least the second trimester due to the increased first-trimester fetal risk. After the first trimester, therapy should not be delayed for patients with symptomatic, subdiaphragmatic, or progressive HL.** Treatment options include supradiaphragmatic radiation therapy for early-stage disease and combination chemotherapy for bulky, subdiaphragmatic, progressive, or advanced disease. Radiation fields should be tailored to limit fetal dose, and a maximal fetal dose calculation should be performed prior to treatment. Pregnant women with HL should be managed by a maternal-fetal medicine specialist, and

whether pregnancy termination should be pursued will depend on the clinical situation.

### Non-Hodgkin Lymphoma

Non-Hodgkin lymphoma (NHL) occurs at a mean age of 42 years and is therefore observed less frequently than Hodgkin lymphoma with approximately 100 cases reported in pregnancy. **In general, NHL is more likely to complicate pregnancy because more patients have an aggressive histology and advanced-stage disease.** Indolent lymphomas are less common in younger patients and are rarely described in pregnancy. Up to 70% of NHL in pregnancy is diffuse large B-cell lymphoma.<sup>38</sup> Interestingly, reproductive organs—particularly the breasts and ovaries—are commonly involved in pregnancy-associated lymphoma compared with aged-matched counterparts.<sup>32</sup>

With the exception of aggressive histologic types, the management of lymphoma may be deferred in the first trimester because of the typical indolent nature of the disease. When initiated, treatment often includes chemotherapy and targeted therapy. If required, radiotherapy can be considered in local fields away from the pelvis in late gestational stages; however, it is typically postponed until after delivery.<sup>32</sup>

Treatment regimens evaluated in pregnancy include cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) with or without bleomycin, which did not have an adverse effect on pregnancy outcomes.<sup>36</sup> Non-CHOP regimens were associated with several unfavorable outcomes that included miscarriage, intrauterine fetal demise, and transient neonatal leukopenia. The anti-CD20 antibody rituximab has been evaluated in limited cases with acceptable toxicities; however, further studies are warranted.<sup>32</sup>

### Acute Leukemia

Although the incidence of leukemia in pregnancy is not specifically known, it is estimated to occur in fewer than 1 in 75,000 to 100,000 pregnancies.<sup>17</sup> **Acute leukemia represents about 90% of leukemias that coexist with pregnancy. Acute myeloid leukemia (AML) accounts for about 60% and acute lymphoblastic leukemia (ALL) for about 30% of cases. More than three fourths of the cases are diagnosed after the first trimester.**<sup>32,39</sup> **The prognosis for acute leukemia in pregnancy is guarded.**<sup>39</sup> Although no evidence suggests that pregnancy adversely affects the prognosis of acute leukemia, optimal and immediate care of the pregnant patient with acute leukemia necessitates a team effort and is best achieved in a cancer referral center.<sup>40,41</sup>

The diagnosis of acute leukemia is rarely difficult. The signs and symptoms of anemia, granulocytopenia, and thrombocytopenia include fatigue, fever, infection, and easy bleeding or petechiae, which usually prompts a complete blood count. A normal or elevated white blood cell count (WBC) is present in up to 90% of patients with ALL, although a WBC in excess of 50,000 is found in only one fourth of patients. In contrast, patients with acute nonlymphocytic leukemia (ANLL) may present with a markedly elevated WBC, although one third may exhibit leukopenia. The diagnosis of leukemia should be confirmed by bone marrow biopsy and aspirate. The biopsy material is usually hypercellular with leukemic cells. The smear of the aspirate reveals decreased erythrocyte and granulocytic precursors as well as megakaryocytes. Leukemic cells comprise greater than half of the marrow's cellular elements in most patients. The morphology of the marrow and the peripheral leukemic cells

help to distinguish between lymphocytic and nonlymphocytic leukemias. This latter group includes acute myelocytic (granulocytic), promyelocytic, monocytic, and myelomonocytic leukemias and erythroleukemia. Acute myelocytic leukemia is the most common form of ANLL. Patients who develop ANLL as a result of previous chemotherapy have a particularly poor response to treatment.

**Acute leukemia requires immediate treatment regardless of gestational age because delay may result in poorer maternal outcomes.** When ALL is diagnosed in the first trimester, termination is recommended due to the effect on both the fetus and the mother. This is in part due to the need for intensive treatment that includes stem cell transplantation, which is contraindicated in gestation.<sup>42</sup> **However, numerous reports have documented successful pregnancies in patients with acute leukemia who were aggressively treated with leukapheresis and combination chemotherapy in the second and third trimesters.**<sup>32</sup> Although reports have shown no serious long-term effects of in utero exposure to chemotherapy, it is important to counsel patients that acute leukemia and its therapy are associated with a high rates of spontaneous abortion, stillbirth, preterm delivery, and fetal growth restriction.<sup>40,42,43</sup> **If the mother is exposed to cytotoxic drugs within 1 month of delivery, the newborn should be monitored closely for evidence of granulocytopenia or thrombocytopenia.**

**Chronic Leukemia**

Chronic leukemia accounts for approximately 10% of cases of leukemia during pregnancy. A majority of cases are chronic myelocytic leukemia (CML) because the median age is 35 years, compared with chronic lymphocytic leukemia (CLL), which has a median age of 60 years and makes cases during pregnancy rare.<sup>40</sup>

CML is characterized by excessive production of mature myeloid cell elements, with granulocyte counts that average 200,000/dL. Most patients have thrombocytosis and a mild normochromic normocytic anemia. Platelet function is often abnormal, although hemorrhage is usually limited to patients with marked thrombocytopenia. CML tends to be indolent, and normal hematopoiesis is only mildly affected in the early stages of disease. Therefore delay of aggressive treatment is more feasible than with acute leukemia. Unless complications such as severe systemic symptoms, autoimmune hemolytic anemia, recurrent infection, or symptomatic lymphatic enlargement occur, treatment for chronic leukemia should be withheld until after delivery. When necessary, therapy may consist of interferon-alfa, steroids, and chemotherapy agents or more recently, tyrosine kinase inhibitors such as imatinib. However, whereas the data are limited, **it does appear that early exposure to imatinib is associated with a high rate of congenital anomalies and miscarriage.**<sup>44,45</sup> Imatinib therapy initiated in the second and third trimesters may not add significant additional risk, but better outcome data are necessary before this can be ensured.<sup>44</sup>

**Melanoma**

**The incidence of malignant melanoma is increasing in the childbearing years, with reported ranges from 1% to 3.3% in pregnant or lactating women; it accounts for 8% of malignancies diagnosed in gestation.**<sup>1,2,46</sup> A topic of continued debate is whether pregnancy exerts a negative effect on the course of malignant melanoma. Prognostic features of the primary tumor include tumor thickness, ulceration, and location.<sup>46,47</sup> Reports

**TABLE 50-3      STAGES I AND II STUDY OF MALIGNANT MELANOMA**

| RELATIONSHIP TO TIME OF PREGNANCY | NO. OF PATIENTS | MEAN TUMOR THICKNESS (mm) |
|-----------------------------------|-----------------|---------------------------|
| Before                            | 85              | 1.29                      |

From MacKie RM, Bufalino R, Morabito A, et al. Lack of effect on pregnancy outcome of melanoma. *Lancet*. 1991;337:653.  
\**P* = .004. When corrected for tumor thickness, survival rates were not different. Multivariate analysis identified tumor thickness as an independent prognostic variable, not pregnancy.

have suggested that melanoma that arises during pregnancy is associated with an aggressive clinical course; it is more likely to be diagnosed at an advanced stage, to have an increased tumor thickness, to be found in locations associated with a poor prognosis and therefore to have a shorter disease-free interval.<sup>9,48-51</sup> A meta-analysis of melanoma suggested that pregnancy-associated melanomas did appear to have poorer outcomes.<sup>52</sup> **However, after correcting for tumor thickness, survival rates were similar, and other studies show no increase in poor prognostic location of lesions in the pregnant patient and comparable survival outcomes to nonpregnant cohorts (Table 50-3).**<sup>46,47</sup> A large population-based study found no data to support the notion of advanced stage, thicker tumors, increased rate of lymph node metastases, or worsened survival in women with melanoma diagnosed during pregnancy when compared with nonpregnant women.<sup>53</sup> This series also noted that maternal and neonatal outcomes were equivalent to those of pregnant women without melanoma.<sup>53</sup>

Once the diagnosis is suspected, biopsy is recommended. **The methods used to describe the depth of invasion for melanoma are depicted in Figure 50-2. Wide surgical excision with appropriate margins remains the most effective modality for the treatment of melanoma.** Sentinel or complete lymph node dissection has been used successfully.<sup>9</sup> Because adjuvant chemotherapy has not demonstrated improved survival, it is not recommended for the pregnant patient because of the potential risk to the fetus. However, it may be appropriate to plan for early delivery to allow initiation of therapy.

Despite rare reports of regression after delivery, no studies support any benefit associated with therapeutic abortion.<sup>51</sup> Given the aggressive nature of the current therapies available for metastatic disease, it is appropriate to consider termination of pregnancy when managing advanced disease that presents in the first trimester.<sup>51</sup>

The patient who has undergone apparent successful treatment for a malignant melanoma may express concern about the safety of a future pregnancy. No adverse impact on recurrence or survival has been identified in most studies that have addressed this issue.<sup>48</sup> However, the timing of subsequent pregnancy deserves some consideration. The probability for survival of a specific cancer should be evaluated based on the known prognostic variables. The 5-year survival rate for the patient with a melanoma less than 1.5 mm thick is 90%. For a tumor of intermediate thickness (1.5 to 4 mm), the 5-year survival rate is 50% to 75%, and for a more deeply invasive tumor, survival is less than 50%. Some studies report that approximately 60% to 70% of patients develop their recurrence within 2 years, and 80% to 90% within 5 years.<sup>51</sup> Based on this information, **it is generally**

**FIG 50-2** Schematic comparison of the different levels of invasion for melanoma. (From Gordon AN. Vulvar tumors. In Copeland LJ [ed]: *Textbook of Gynecology*, ed 2. Philadelphia: WB Saunders; 2000:1202.)

recommended that patients wait 2 to 3 years before attempting another pregnancy, especially with nodal disease.<sup>48</sup>

### Cervical Cancer

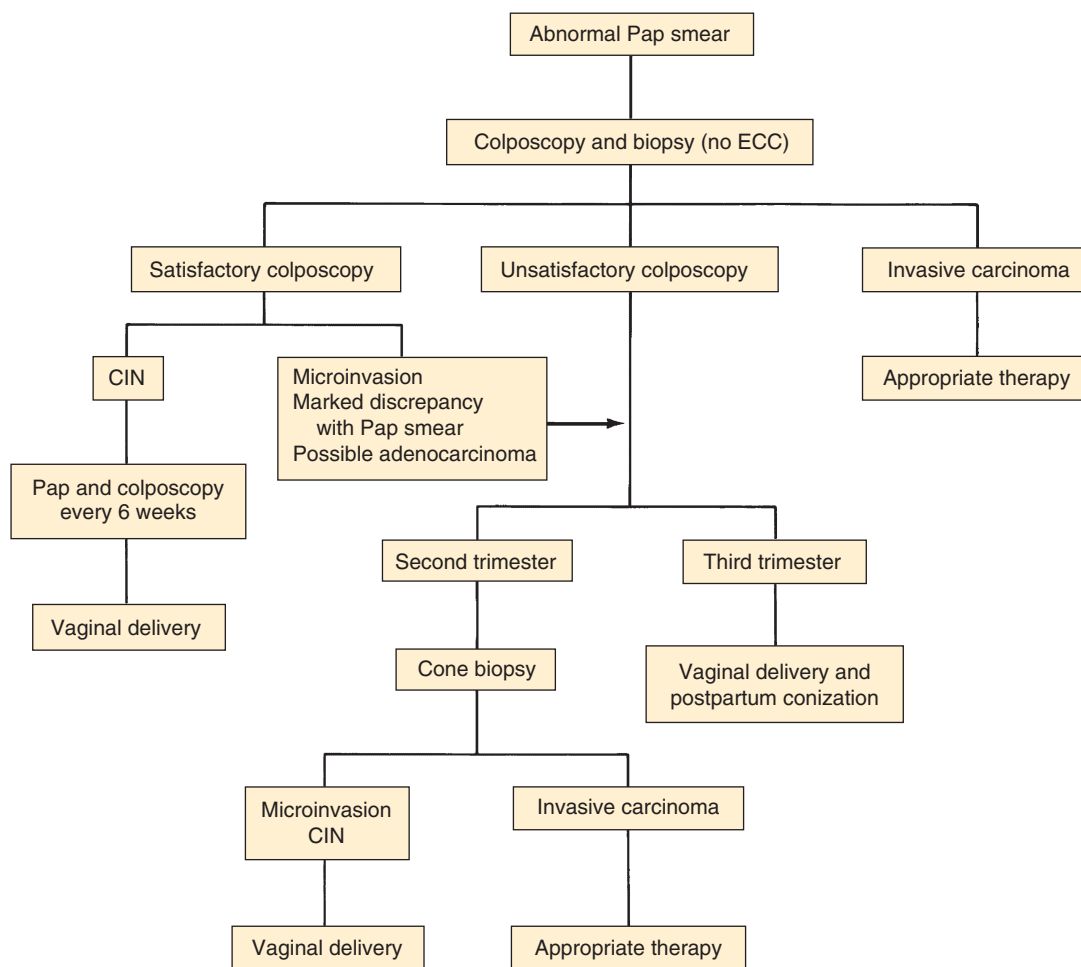

Cervical cancer is the most common gynecologic malignancy associated with pregnancy. It occurs in approximately 1 to 2 per 2000 to 10,000 pregnancies, and approximately 3% (1 in 34 cases) of all invasive cervical cancers occur during pregnancy.<sup>1,2,17</sup> Although it is the only cancer whose screening is part of the prenatal evaluation, the true incidence is difficult to ascertain because of the reporting biases associated with the reports that originate from large referral centers. Also, various reports may include patients who have preinvasive lesions as well as those diagnosed in the postpartum period.

The initial obstetric visit should include visualization of the cervix and cervical cytology, if indicated. If the cervix appears friable, cervical cytology alone may not be sufficient to alert the physician to the presence of a malignant tumor. **False-negative cervical cytology is at increased risk in pregnancy owing to excess mucus and bleeding from cervical eversion; therefore it is necessary to obtain a biopsy to ensure that tissue friability or a lesion is not secondary to tumor.** The most common symptoms for cervical cancer are vaginal bleeding or discharge, although approximately one third of pregnant patients with cervical cancer are asymptomatic at the time of diagnosis.

Cervical cytology suggestive of a squamous intraepithelial lesion or a report of atypical glandular cells during pregnancy requires appropriate clinical evaluation (Fig. 50-3). Colposcopy

during pregnancy is usually enhanced by the physiologic eversion of the lower endocervical canal. However, vascular changes and redundant vagina may alter or obscure normal visualization and may make interpretation difficult, and referral to a gynecologic oncologist may be appropriate. During pregnancy, failure to visualize the entire transformation zone and squamocolumnar junction is uncommon. **Although endocervical curettage is not recommended during pregnancy, lesions that involve the lower endocervical canal can often be directly visualized and biopsied.** Whereas the pregnant cervix is hypervascular, **serious hemorrhage from an outpatient biopsy is uncommon, and the risk of bleeding is offset by the risk of missing an early invasive cancer.** Following a colposcopy evaluation with appropriate tissue sampling, most patients with preinvasive lesions can be followed with repeat colposcopy at 6- to 8-week intervals to delivery and postpartum.<sup>17</sup>

When necessary during pregnancy, cone biopsy should ideally be performed during the second trimester because of increased risks of abortion in the first trimester and rupture of membranes or premature labor in the third trimester.<sup>54</sup> Because complications from conization of the pregnant cervix are common, **therapeutic conization for intraepithelial squamous lesions is contraindicated during pregnancy.** **Diagnostic cone biopsy in pregnancy is reserved for patients whose colposcopic-directed biopsy has shown superficial invasion (suspected microinvasion) or in other situations in which an invasive lesion is suspected but cannot be confirmed by biopsy.** When a cone biopsy is necessary during pregnancy, the clinician should

**FIG 50-3** Suggested protocol for evaluation of abnormal cervical cytology in pregnancy. ECC, endocervical curettage; CIN, cervical intraepithelial neoplasia. (From Hacker NF, Berek JS, Lagasse LD, et al. Carcinoma of the cervix associated with pregnancy. *Obstet Gynecol.* 1982;59:735.)

keep in mind the anatomic alteration of the cervix secondary to pregnancy. A shallow disklike cone is usually satisfactory to clarify the diagnosis with a minimum of morbidity. Of importance, patients who have had a conization during pregnancy are at higher risk for residual disease, therefore close follow-up is essential.

Considering the routine practice of cervical evaluation in early pregnancy, a preponderance of early-stage disease diagnosed in the first trimester would be expected. Surprisingly, this is not the case, **and the diagnosis of cervical cancer is commonly made postpartum rather than during pregnancy. Furthermore, although stage IB disease is the most common stage found, all stages are represented in significant numbers.** Both patient and physician factors contribute to the delays in diagnosis, and these include lack of prenatal care, failure to obtain cervical cytology or biopsy of gross cervical abnormalities, false-negative cytology, and failure to evaluate abnormal cytology or vaginal bleeding properly.

Following the diagnosis of invasive cervical cancer, a staging evaluation is indicated. The standard cervical staging is clinical and is usually based on the results of physical examination and modification of routine testing, such as chest radiograph with abdominal shielding and sonography to detect hydronephrosis. If additional retroperitoneal imaging is desired for the evaluation

of lymphadenopathy, consideration should be given to using MRI because it does not involve ionizing radiation.

### Microinvasion

**In patients with a microinvasive squamous carcinoma with negative margins on cone biopsy, consideration can be given to conservative management until delivery.** The risk of occult metastatic disease is predominantly dependent on two pathologic features: (1) the depth of invasion and (2) the presence or absence of lymph-vascular space involvement.<sup>55</sup> Whether the cone biopsy can be considered sufficient long-term therapy or whether a postpartum hysterectomy with or without lymphadenectomy should be performed is also based on the detailed analysis of the pathologic features of the cone biopsy. In these cases, consultation with a gynecologic oncologist is appropriate.

### Invasive, Early-Stage Disease

**Because the definitive treatment of invasive cervical cancer is not compatible with continuation of pregnancy, the clinical question that must be addressed is when to proceed with delivery so that therapy can be completed. Considering this requirement, treatment options will be influenced by gestational age, tumor stage and metastatic evaluation, and maternal desires and expectations regarding the pregnancy. The**

management of early invasive cervical cancer (stages IA2, IB, and IIA) in the young patient usually includes radical hysterectomy, pelvic lymphadenectomy, and aortic lymph node sampling.<sup>56</sup> The primary advantage of this treatment approach over radiation therapy for these patients is preservation of ovarian function. For the woman with a high probability of having a poor prognostic lesion that would require postoperative irradiation, consideration can be given to performing a unilateral or bilateral oophoropexy at the time of the hysterectomy. The ovarian suspension should be intraperitoneal, because retroperitoneal placement seems to predispose to subsequent ovarian cyst formation. In the first trimester, this surgery is usually carried out with the fetus in utero. In the third trimester, the radical hysterectomy and lymphadenectomy are performed after completion of a high classical cesarean delivery. Delays in therapeutic intervention have not been reported to increase recurrence rates for patients with small-volume stage I disease.<sup>56</sup> Although the pelvic vessels are large, the dissection is enhanced by more easily defined tissue planes.<sup>56</sup>

Second-trimester presentations are more problematic. Studies have supported delay in management of early-stage disease until after fetal viability in women diagnosed after 20 weeks' gestation.<sup>17,57</sup> Other reports have suggested the administration of one to three cycles of platinum-based chemotherapy, allowing an additional 7 to 15 weeks of fetal maturation. This neoadjuvant approach, chemotherapy before either surgery or irradiation, has been reported in nine cases of cervical cancer diagnosed during pregnancy; three patients, all with advanced disease, ultimately died of disease, but all neonatal outcomes were normal.<sup>57</sup> In terms of general fetal salvage and outcome, the risk of extreme prematurity would far outweigh the risk of the chemotherapy exposure. Although this management of second-trimester cervical cancer presentations seems logical, little information is available about this treatment approach. In cases diagnosed remote from fetal maturity, between 20 and 30 weeks' gestation, assessment of nodal involvement should be considered and will dictate further recommendations for management.<sup>57</sup>

### Invasive, Locally Advanced Disease

The management of the patient with more advanced local disease is based on treatment with chemotherapy and irradiation, both external beam to treat the regional nodes and shrink the central tumor and brachytherapy to complete the delivery of a tumoricidal dose to the cervix and adjacent tissues.<sup>57</sup> Coordinating a chemoradiation treatment plan for pregnant patients with stage IIB, stage III, and stage IVA disease is challenging. **The patient with a first-trimester pregnancy can usually be treated in the standard fashion with initiation of chemotherapy and external radiation therapy to the pelvis or an extended field, as dictated by standard treatment guidelines. Most of these patients proceed to abort spontaneously within 2 to 5 weeks of initiating the radiation.** Patients in the late first trimester are least likely to abort spontaneously, and it may be necessary to perform a uterine evacuation on the completion of external therapy in some patients. Following either spontaneous abortion or uterine evacuation, the brachytherapy component of the radiation therapy can proceed in the standard fashion. Second- or third-trimester patients should have a high classic cesarean delivery before starting standard chemotherapy and irradiation. Again, it would seem appropriate to strongly consider neoadjuvant chemotherapy for this group of patients, especially the patient with a second-trimester or early third-trimester

presentation, when the opportunity for further fetal maturation can be provided.

### Invasive, Distant Metastasis

Metastatic disease to extrapelvic sites carries a poor prognosis. Although a select few patients with aortic node metastasis may receive curative therapy, it is unlikely for the patient with either pulmonary, bone, or supraclavicular lymph node metastases to be cured. Personal patient choices and ethical considerations are the major factors guiding treatment in these situations.

Small cell neuroendocrine tumors of the cervix associated with pregnancy are rare. Neoadjuvant or adjuvant chemotherapy may be used, and long-term survivors have been reported.<sup>58</sup> These tumors are considered to be histologically aggressive, and pregnancy preservation is not recommended. However, each case should be individualized.<sup>47,48</sup>

### Method of Delivery

Controversy continues to surround the issue of the method of delivery for the term patient with cervical cancer. It seems unjustifiably risky to encourage vaginal delivery of a patient with a large, firm, barrel-shaped tumor or a large, friable, hemorrhagic exophytic tumor. However, many patients with small-volume stage IB, IIA, and early IIB tumors are potential candidates for vaginal delivery. **Whether vaginal delivery promotes systemic dissemination of tumor cells is unknown, although the general opinion is that survival rates are not influenced by the mode of delivery.**

Although systemic tumor dissemination secondary to vaginal delivery has not been documented, there are reports of episiotomy implants for both squamous carcinoma and adenocarcinoma following vaginal delivery.<sup>59</sup> Episiotomy implants are sufficiently rare that the risk should not be a determining factor for a given patient. However, **the episiotomy should be carefully followed in a cervical cancer patient who delivers vaginally.** Episiotomy nodules in these patients must be promptly evaluated by biopsy, because an early diagnosis may permit curative therapy.<sup>59</sup> Diagnostic delays secondary to suspicion of the nodules representing a stitch abscess should be avoided.

### Survival

**Although some authors have suggested that the survival of patients with cervical cancer associated with pregnancy is compromised, most reports indicate that the prognosis is not altered.**<sup>57</sup>

### Ovarian Cancer

Although adnexal masses are often observed in pregnancy, only 2% to 5% are malignant ovarian tumors.<sup>60</sup> Ovarian cancer occurs in approximately 1 in 10,000 to 1 in 56,000 pregnancies.<sup>17,60</sup> With the increased use of diagnostic ultrasound, ovarian cysts and neoplasms are more frequently encountered in early pregnancy.<sup>60,61</sup> Ultrasonic features associated with an increased risk of malignancy include the presence of excrescences/papillary structures, irregular borders, septations/complex appearance, and presence of ascites; any of these features should prompt further evaluation.<sup>61</sup>

**Whereas the three major categories of ovarian tumors—epithelial, including borderline tumors; germ cell; and sex-cord stromal—occur during pregnancy, the majority are diagnosed in early stages and result in favorable outcomes.**<sup>60</sup> Germ cell tumors account for 30% to 50%, followed by sex-cord

**FIG 50-4** Magnetic resonance imaging of an ovarian malignancy diagnosed during pregnancy.

stromal tumors and epithelial tumors; the remainder are metastatic tumors to the ovary.<sup>60</sup> This distribution is undoubtedly skewed by the reporting bias associated with rare tumors. Of note, **the majority of epithelial ovarian tumors that complicate pregnancy are grade 1, or low malignant potential, or early stage; and not uncommonly, these tumors are both low grade and stage I.**

Management of the adnexal mass in pregnancy is controversial. The risks of surgical intervention may favor a conservative approach.<sup>60,61</sup> Serial sonograms may be of some value in determining the nature and biologic potential of the tumor. A number of opposing risks require consideration before following a conservative approach. The risk of greatest concern is that a delay of surgical intervention could permit a malignant ovarian tumor to spread, resulting in a decreased opportunity for cure. However, considering the rarity of advanced-stage poorly differentiated epithelial tumors in this age group, this risk is relatively small. Although ovarian tumors may be the cause of obstructed labor, this is uncommon.<sup>61</sup> **Skilled sonographic examination or MRI (Fig. 50-4) is essential to determining the potential for malignancy based on size and imaging characteristics.** Serial sonographic evaluations will also identify the rare tumor that remains in the pelvis as the gestation progresses. Because most ovarian masses relocate to the abdomen as the pregnancy advances, other explanations should be considered for persistent pelvic masses, including pelvic kidney, uterine fibroids, and colorectal or bladder tumors.

There does appear to be an increased probability that an adnexal mass during pregnancy will undergo torsion or rupture, and surgical intervention for these events is associated with higher fetal loss than with an elective procedure.<sup>60</sup> **Prompt surgical exploration is also performed for the mass associated with ascites or when metastatic disease is evident.** Because surgical exploration during pregnancy is associated with an increase in pregnancy loss and neonatal morbidity, it is ideal to delay surgical intervention until term or after delivery. However, if intervention is required during pregnancy, surgery should be performed after 16 weeks of gestation to reduce the risk of spontaneous abortion and allow the resolution of functional cysts.<sup>60,61</sup>

**When a malignant ovarian tumor is encountered at laparotomy, surgical intervention should be similar to that for the nonpregnant patient.** If the gestation is preterm, and the tumor appears confined to one ovary, consideration should be given to limiting the staging to removal of the involved ovary, cytologic washings, omentectomy, pelvic and paraaortic lymph node dissection, and a thorough manual exploration of the abdomen and pelvis.<sup>62</sup> The potential benefit of more extensive staging may be offset by higher pregnancy loss or neonatal morbidity. Before surgery, a comprehensive discussion with the patient should guide the extent of surgery if metastatic disease, especially a high-grade epithelial lesion, is encountered. Depending on the gestational age and the patient's desires, limited surgery followed by chemotherapy and additional extirpative surgery following delivery may be offered in select cases.<sup>62</sup>

Preoperative serum tumor markers are of limited value during pregnancy secondary to the physiologic increases in  $\beta$ -hCG, AFP, and CA 125. The mean CA 125 level increases slightly during the first trimester and then normalizes during the second trimester.<sup>63</sup> However, following diagnostic confirmation of a malignant ovarian tumor, the appropriate serum markers may be useful to monitor the course of the disease.

**Virilizing ovarian tumors during pregnancy are most commonly secondary to theca-lutein cysts, and their evaluation and management should be conservative.** These benign exaggerated physiologic "tumors" may redevelop with subsequent pregnancies.<sup>60,61</sup>

### Postoperative Adjuvant Therapy

Postoperative adjuvant therapy should follow the treatment guidelines for the nonpregnant patient. Although it may be reasonable for patients with low-risk, low-stage tumors to have adjuvant therapy delayed until after delivery, **patients with advanced epithelial tumors should receive combination chemotherapy. The standard therapy is the combination of a platinum agent and paclitaxel, and tolerability of this regimen in pregnancy has been demonstrated.**<sup>62</sup> A number of favorable treatment outcomes has also been reported in pregnant patients who have malignant germ cell and sex cord stromal tumors, and consultation with a gynecologic oncologist is warranted.<sup>64</sup>

### Vulvar and Vaginal Cancer

**Because vulvar and vaginal cancers usually occur after age 40, the diagnosis of either disease concurrent with pregnancy is rare.** Fewer than 30 cases of vulvar carcinoma diagnosed and treated during pregnancy have been reported.<sup>62,65</sup> Vulvar carcinoma in pregnancy is typically diagnosed in early stages. The diagnosis is based on biopsy, and neither pregnancy nor the young age of a patient should discourage the biopsy of a vulvar mass. Because verrucous squamous carcinoma tends to be misdiagnosed as condyloma, it is important to inform the pathologist of the clinical characteristics of unusually large or aggressive condyloma-like lesions. Surgical management is similar to that used in the nonpregnant patient, with the preference being to perform surgery in the second trimester to avoid the fetal risks of exposure to anesthesia in the first trimester and the maternal risks associated with operating on the hypervascular vulva in the third trimester. If vulvar carcinoma is diagnosed after 36 weeks' gestation, treatment is generally deferred until the postpartum period.<sup>57,62</sup> Vaginal delivery has been reported following surgical resection of vulvar cancers during pregnancy.<sup>62</sup>

Vaginal carcinoma is less common than vulvar carcinoma. The same limitations apply to vaginal cancer as apply to locally advanced cervical cancer in pregnancy. The cornerstone of treatment is irradiation therapy. Clear cell adenocarcinoma of the vagina has been reported in 16 pregnant patients, and 13 were long-term survivors.<sup>66</sup>

## Endometrial Cancer

Approximately 35 cases of endometrial cancer associated with pregnancy have been reported in the literature, and only 30% of cases are associated with a viable fetus.<sup>67</sup> Although more than half of these cases were diagnosed in the first trimester, abnormal bleeding later in pregnancy or postpartum may be the presenting symptom of this tumor. Fortunately, a majority of cases of endometrial cancer in pregnancy are diagnosed with stage I disease (88%) and grade 1 tumors (80%). With extensive counseling and a thorough evaluation to exclude metastatic disease, these patients may be candidates for conservative treatment with hormonal manipulation, repeat endometrial evaluation, and modifications of risk factors to preserve fertility.<sup>67</sup>

## Gastrointestinal Cancers

### Upper Gastrointestinal Cancers

The diagnostic delay in detecting pregnancy-related upper GI cancers is often attributable to the frequency and duration of GI symptoms in pregnancy. In the United States, stomach cancer is rarely diagnosed in women during the reproductive years. During pregnancy, persistent severe upper GI symptoms are best evaluated by gastroduodenoscopy rather than radiologic studies.<sup>17</sup> Because curative resection of localized stomach cancer is possible in only approximately 30% of patients, it is imperative that treatment not be delayed.

Malignant hepatic tumors are rare during the reproductive years. Hepatocellular tumors detected during pregnancy should be resected, because the maternal and fetal mortality associated with subcapsular hemorrhage and liver rupture during pregnancy is high. In patients with unresectable hepatomas, therapeutic abortion can be considered to decrease the risk of subsequent rupture and bleeding.

### Colon and Rectal Cancer

The incidence of colon cancer during pregnancy is about 1 in 13,000 liveborn deliveries.<sup>68</sup> Because pregnancy is often accompanied by constipation and exacerbations of hemorrhoids and anal fissures, the symptoms of colorectal carcinoma—namely, rectal bleeding, anemia, altered bowel movements, abdominal pain, and backache—tend to be attributed to the pregnancy, and diagnostic delay is common. **The majority of colorectal carcinomas during pregnancy are rectal and palpable on rectal examination, in contrast to more proximal lesions found in the nonpregnant patient.**<sup>68</sup> Patients with unexplained hypochromic microcytic anemia should be evaluated with stool guaiac testing. If a colorectal lesion is suspected, endoscopic methods of evaluation are preferred to radiologic imaging studies. Unfortunately, most cases of colorectal cancer are not diagnosed until late pregnancy or at the time of delivery. Delays in diagnosis are probably responsible for a higher likelihood of advanced-stage colorectal cancer in pregnancy and an associated poor prognosis.<sup>68</sup>

**Management of colon cancer is determined by gestational age at diagnosis and tumor stage. During the first half of pregnancy, colon resection with anastomosis is indicated for**

**colon or appendiceal cancers.**<sup>69</sup> Abdominoperineal resection or low anterior resection has been accomplished up to 20 weeks' gestation without disturbing the gravid uterus. In some cases, access to the rectum may not be possible without a hysterectomy or uterine evacuation.

In late pregnancy, a diverting colostomy may be necessary to relieve a colonic obstruction and allow the development of fetal maturity before instituting definitive therapy. Some patients with a diagnosis after 20 weeks may opt to continue the pregnancy to fetal viability. Vaginal delivery is planned unless the tumor is obstructing the pelvis or is located on the anterior rectum. If cesarean delivery is performed, tumor resection can be accomplished immediately. Although reports are limited in regard to chemotherapy with oxaliplatin, 5-fluorouracil (FU), and leucovorin in pregnancy, neoadjuvant chemotherapy or radiation therapy for colorectal carcinoma in the pregnant patient has not demonstrated sufficient response to risk fetal exposure.<sup>70</sup>

## Urinary Tract Cancers

Just over 100 cases of renal cell carcinoma have been reported during pregnancy.<sup>71</sup> Diagnosis is typically made by a combination of symptoms that include the presence of a palpable mass, flank pain, refractory urinary tract symptoms, or hematuria. Initial evaluation consists of ultrasound followed by MRI. Although each case should be individualized based on stage, symptoms, and risks to pregnancy, surgery is the mainstay of treatment. Cases of successful nephrectomy during pregnancy have been reported.

Bladder cancer during pregnancy is rare with fewer than 30 cases reported.<sup>71,72</sup> The most common symptoms are painless hematuria and abdominal pain. Diagnostic evaluation consists of urethroscopy, urinary cytology, and renal ultrasonography, which can all be performed safely in pregnancy.<sup>72</sup> **Bladder cancer has even been diagnosed on routine obstetric ultrasound examination,** and it can be managed by local fulguration or resection if it is well differentiated and superficial. Less differentiated, deeply invasive, and recurrent tumors may require a partial or complete cystectomy. Treatment of urethral carcinoma varies with the size and location and may include surgical excision or interstitial brachytherapy implants.

## CENTRAL NERVOUS SYSTEM TUMORS

**The spectrum of CNS tumors found in pregnant patients is similar to those found in nonpregnant patients.**<sup>73</sup> In pregnancy, 32% of brain tumors are gliomas, 29% are meningiomas, 15% are acoustic neuromas, and the other 24% are divided among other, more rare subtypes. Spinal tumors account for only one eighth of the CNS tumors and are most often vertebral hemangiomas (61%) and meningiomas (18%). Unfortunately, the presenting symptoms of headache, nausea, and vomiting are often attributed to normal complaints of pregnancy, which results in a delay of diagnosis. Meningiomas, pituitary adenomas (see Chapter 43), acoustic neuromas, and vertebral hemangiomas may demonstrate rapid enlargement during pregnancy. This may be secondary to fluid retention, increase in blood volume, or hormonal stimulation. MRI is the preferred imaging technique used to diagnose intracranial neoplasms.<sup>73</sup>

**Whereas high-grade glial tumors should undergo prompt diagnosis and treatment, low-grade glial tumors such as astrocytomas and oligodendrogliomas do not usually require**

**immediate intervention.** Adjuvant cranial radiotherapy with abdominal shielding should be considered for patients with high-grade tumors. Successful surgical removal of a variety of CNS tumors has been reported.<sup>74,75</sup> Corticosteroids are recommended to reduce the surrounding edema of intracranial masses. The role of adjuvant chemotherapy should be individualized.<sup>73</sup> Although rare, if a prolactin-secreting adenoma enlarges or is symptomatic, bromocriptine may be used with a favorable safety profile (see Chapter 43). Because painful contractions and pushing increase intracranial pressure, it is recommended that labor be as pain free as possible, and the second stage of labor should be assisted with forceps to reduce the risk of herniation.

## NEONATAL OUTCOMES

In addition to maternal outcomes, the impact of cancer and its therapy on the fetus/neonate needs to be considered. Consultation with maternal-fetal medicine and a neonatology team as soon as possible is recommended.<sup>17</sup> In a series of 180 pregnancies affected by cancer, the mean gestational age at delivery was 36.2 ( $\pm 2.9$ ) weeks' gestation.<sup>6</sup> Over 45% of all deliveries occurred before 37 weeks, and 8% occurred before 32 weeks. Induction was performed in 89.7% of the preterm deliveries for maternal cancer (88%) and obstetric indications (12%).<sup>6</sup>

Over 50% of the neonates were admitted to the neonatal intensive care unit (NICU) with prematurity as the most common indication.<sup>6</sup> Of note, neonates exposed to chemotherapy for ALL near the time of delivery may experience hematologic toxicity.<sup>6,76</sup> When assessing neonatal outcomes, the rates of major and minor malformations were comparable to those of the general population.<sup>6,76</sup>

## FETAL-PLACENTAL METASTASIS

Metastatic spread of a maternal primary tumor to the placenta or fetus is rare, with approximately 100 cases reported. In general, the biologically aggressive spectrum of malignancies seem to carry the highest risk for fetal metastases. **Malignant melanoma is the most frequently reported tumor metastatic to the placenta, and it also has a high rate of fetal metastases.**<sup>77,78</sup> Other cancers that have been reported to metastasize to the products of conception include hematologic malignancies, breast cancer, lung cancer, sarcoma, and gynecologic cancers.<sup>77</sup> When the diagnosis of cancer in pregnancy is present, recommendations include a thorough macroscopic and microscopic evaluation of the placenta and cytologic examination of maternal and umbilical cord blood. Neonates should be examined every 6 months for 2 years with a physical examination, chest radiograph, and liver function tests.<sup>77</sup>

## FERTILITY PRESERVATION

It is estimated that every year, approximately 55,000 cases of cancer will be diagnosed in Americans under the age of 35 years.<sup>79</sup> Because of better treatments, survival rates among young patients has improved, which highlights the need to address the impact of cancer and its treatment on fertility. **The risk of infertility may be a direct result of the disease, surgery, chemotherapy agents and dose, radiation, and age.**<sup>79</sup> Although based on limited studies and selection bias, the use of fertility preservation techniques in appropriately selected patients has

not been shown to have inferior oncologic outcomes when compared with standard therapy. Surgical options for fertility preservation include radical trachelectomy and ovarian transposition for cervical cancer and retention of the contralateral ovary and uterus in ovarian cancer. Additional options include the use of medical management for endometrial cancer and pelvic shielding for radiation therapy.

Infertility is associated with psychosocial distress, and options for fertility preservation should be addressed as soon as possible.

When treatment renders a high risk of resultant infertility, consultation with a reproductive specialist may be warranted. Options for fertility preservation vary depending on the age and potential impact of the treatment on fertility.<sup>17</sup> Embryo cryopreservation is the most established method, and in those women who do not have a partner, oocyte cryopreservation can be performed. However, these options require hormonal stimulation and a possible delay in cancer treatment. Although less well studied, other options include the use of oocyte collection and ovarian tissue cryopreservation.<sup>79,80</sup> Once thought to be beneficial, the use of gonadotropin-releasing hormone (GnRH) agonists in women receiving chemotherapy for breast cancer was not associated with a higher rate of ovarian function preservation.<sup>81</sup> When fertility cannot be preserved, patients should be advised on options such as gestational surrogacy and adoption.

Cancer survivors should be counseled on contraception options to reduce the risk of unintended pregnancy. Selection of contraception is based on status and type of malignancy and compliance. Additionally, hormonal contraception may be contraindicated because of a negative impact on cancer outcomes (e.g., breast cancer) or an increase in the risk of adverse side effects, such as thrombosis.<sup>17</sup>

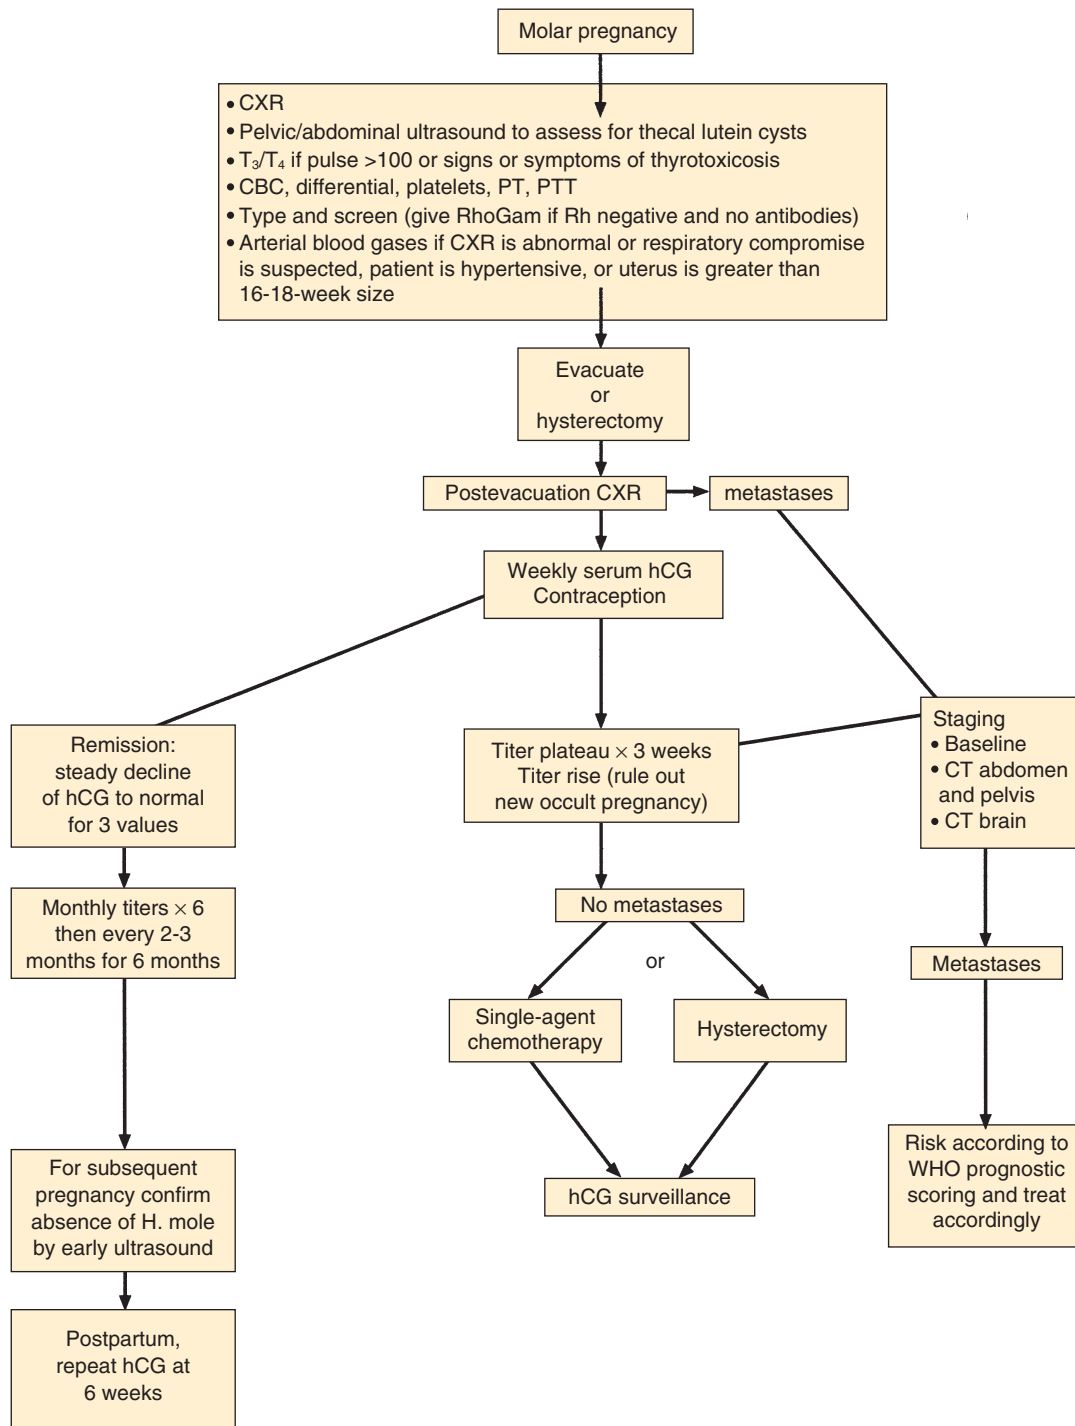

## GESTATIONAL TROPHOBLASTIC DISEASE AND PREGNANCY-RELATED ISSUES

It is uncommon for a normal viable pregnancy to be complicated by gestational trophoblastic disease (GTD). A comprehensive summary of the evaluation and management of the complete spectrum of GTD is beyond the scope of this chapter. However, the aspects of GTD related to general obstetric and postpartum care are reviewed.

### Hydatidiform Mole (Complete Mole)

**The incidence of hydatidiform mole has great geographic variability. In the United States, it occurs in approximately 1 in 1000 to 1 in 1500 pregnancies.** The two clinical risk factors that carry the highest risk of a molar pregnancy are (1) the extremes of the reproductive years (age 50 or older is associated with a relative risk of over 500) and (2) the history of a prior hydatidiform mole (the risk for development of a second molar pregnancy is 1% to 2%, and the risk of a third after two is approximately 25%).<sup>82,83</sup> Patients with these risk factors should have an ultrasound evaluation of uterine contents in the first trimester. Although historically, approximately 50% of patients were not diagnosed with a molar pregnancy before vaginal expulsion of molar tissue, currently, in developed countries, most patients are diagnosed either by ultrasound while asymptomatic or by ultrasound for the evaluation of vaginal spotting or cramping symptoms. Approximately 95% of complete hydatidiform moles have a 46,XX paternal homologous chromosomal pattern.

**FIG 50-5** Algorithm for the management of molar pregnancy. CBC, complete blood count; CT, computed tomography; CXR, chest x-ray; hCG, human chorionic gonadotropin; H. mole, hydatidiform mole; PT, prothrombin time; PTT, partial thromboplastin time; WHO, World Health Organization. (From Finfer SR: Management of labor and delivery in patients with intracranial neoplasms. *Br J Anaesth* 1991;67:784.)

**The safest technique for evacuating a hydatidiform mole is with the suction aspiration technique. Oxytocin should not be initiated until the patient is in the operating room and evacuation is imminent in order to minimize the risk of embolization of trophoblastic tissue.** The alternative management for the older patient who requests concurrent sterilization is hysterectomy. Following either evacuation or hysterectomy, weekly  $\beta$ -hCG levels are drawn until the hCG titer is within

normal limits for 3 weeks. The titers are then observed at monthly intervals for 6 to 12 months. [Figure 50-5](#) illustrates an algorithm for molar pregnancy management.

**For the patient with a complete molar pregnancy, the risk of requiring chemotherapy for persistent GTD is approximately 20%.** Clinical features that increase this risk include delayed hemorrhage, excessive uterine enlargement, theca-lutein cysts, serum hCG greater than 100,000 mIU/mL, and maternal

**FIG 50-6** Partial mole with dead fetus of abnormal karyotype. (From Finfer SR. Management of labor and delivery in patients with intracranial neoplasms. *Br J Anaesth.* 1991;67:784.)

age older than 40. It is important not to misinterpret a rising  $\beta$ -hCG level because of a new intervening pregnancy as persistent GTD because intervention with chemotherapy would be a significant risk to a new gestation, inducing either abortion or possible teratogenic defects.

**Invasive Mole (Chorioadenoma Destruens)**

Because invasion of the myometrium by molar tissue is clinically occult, it is difficult to assess the true incidence, although it is estimated to be between 5% and 10%. The clinical hallmark of an invasive mole is hemorrhage, which can be severe, and the bleeding may be either vaginal or intraperitoneal.

**Partial Hydatidiform Mole**

Most partial moles have a triploid (paternally inherited, diandric) karyotype, and the next most common are tetraploidies. A minority of partial moles exhibit a mosaic or partially diploid karyotype. Karyotype analysis of the accompanying fetus is important in planning therapeutic intervention. A partial mole associated with a nonviable fetal chromosomal abnormality requires either mechanical or medically induced uterine evacuation (Fig. 50-6).<sup>84</sup> In the presence of an abundance of hydropic tissue, there is always the concern that trophoblastic tissue embolization may occur during uterine contractions induced to evacuate molar tissue. **The management of a patient with sonographic findings suggestive of a diagnosis of a partial mole is particularly challenging if the karyotype analysis of the fetus is diploid, especially if the diagnosis is made in the second or third trimester.** When a normal karyotype exists, it is appropriate to consider diagnostic possibilities other than partial mole, such as a twin gestation—one normal developing fetus and one molar pregnancy. Also, degenerative changes (hydropic villi), retroplacental hematomas, placental abnormalities (chorioangiomas), degenerative uterine myomas, and aborted tissue—sometimes referred to as a “transitional mole”—may lead to imaging abnormalities that are difficult to interpret.

Approximately 2% to 6% of patients develop persistent GTD after a partial molar pregnancy.<sup>85</sup> Therefore because choriocarcinoma can follow a true partial mole, these patients require the

**TABLE 50-4**      COMMON SITES FOR METASTATIC CHORIOCARCINOMA

| SITE             | PERCENT |
|------------------|---------|
| Lung             | 60-95   |
| Vagina           | 40-50   |
| Vulva/cervix     | 10-15   |
| Brain            | 5-15    |
| Liver            | 5-15    |
| Kidney           | 0-5     |
| Spleen           | 0-5     |
| Gastrointestinal | 0-5     |

Frequencies vary depending on whether data are based on autopsy studies or obtained from pretreatment imaging.

same postevacuation surveillance and management as the patient with a complete mole, with a follow-up of at least 6 months.<sup>86</sup>

**Placental Site Trophoblastic Tumor**

Less than 1% of all patients with GTD have placental site trophoblastic tumor. Although this tumor usually presents with abnormal vaginal bleeding following a term pregnancy, it can also be a sequela to a molar pregnancy or abortion. The postpartum presentation is characterized by a slightly enlarged uterus; persistent bleeding, or occasionally amenorrhea; and a slightly elevated  $\beta$ -hCG level. **The  $\beta$ -hCG may not reliably reflect disease progression.** The histologic diagnosis may be obtained by uterine curettage, possibly hysteroscopically directed. Because this disease tends to metastasize late and be somewhat resistant to chemotherapy, surgical excision (hysterectomy) should be considered. If the patient is desirous of future childbearing, management considerations that have been reported with some success include systemic chemotherapy, regional infusion chemotherapy, uterine curettage, and local excision of tumor by hysterotomy and uterine reconstruction.<sup>87</sup>

**Choriocarcinoma**

**Choriocarcinoma develops in approximately 1 in every 40,000 term pregnancies, and this clinical presentation represents about one fourth of all cases of choriocarcinoma.** The other cases follow molar disease or an abortion (spontaneous, therapeutic, or ectopic). GTD following a term pregnancy is always either choriocarcinoma or a placental site trophoblastic tumor, assuming a singleton pregnancy.

**Choriocarcinoma is notorious for masquerading as other diseases.** This is secondary to hemorrhagic metastases that produce symptoms such as hematuria, hemoptysis, hematemesis, hematochezia, stroke, or vaginal bleeding. The common sites for metastatic disease are listed in Table 50-4. The diagnosis of choriocarcinoma is based on history, imaging studies, and a serum  $\beta$ -hCG level. Histologic confirmation is neither necessary for the diagnosis nor as a prerequisite to initiate therapy. Again, it is essential to exclude the presence of a new gestation as the source of a rising  $\beta$ -hCG level before extensive diagnostic imaging or therapeutic intervention. **It is also important to rule out phantom  $\beta$ -hCG production if the clinical scenario warrants, such as situations with low titers and no histologic or convincing imaging evidence of GTD.**

The complexities of the general treatment approach or treatment for special situations is beyond the scope of this chapter. It is recommended that the reader refer to a gynecology or

gynecologic oncology resource for discussions of the therapeutic subtleties and pitfalls. Choriocarcinoma should be managed by a gynecologic oncologist, preferably one with a special interest in the disease.

### KEY POINTS

- ◆ Because many of the common complaints of pregnancy are also early symptoms of metastatic cancer, pregnant women with cancer are at risk for delays in diagnosis and therapeutic intervention.
- ◆ The safest time for most cancer therapies in pregnancy is in the second and third trimesters, thereby avoiding induction of teratogenic risks or miscarriage in the first trimester. For most malignancies diagnosed during the second trimester, chemotherapy should be undertaken as indicated because fetal risk is generally lower than the risk of delaying treatment or proceeding with preterm delivery.
- ◆ Antimetabolites and alkylating agents present the greatest hazard to the developing fetus.
- ◆ Diagnostic delays for breast cancer in pregnancy are often attributed to physician reluctance to properly evaluate breast complaints or abnormal findings in pregnancy.
- ◆ Treatment for Hodgkin disease may compromise the reproductive potential, and combined treatment with irradiation and chemotherapy are associated with the highest risk of ovarian failure.
- ◆ If a mother is exposed to cytotoxic drugs within 1 month of delivery, the newborn should be monitored closely for evidence of granulocytopenia or thrombocytopenia.
- ◆ The effect of pregnancy on the clinical course of melanoma has been the subject of debate. When corrected for tumor thickness, pregnancy does not appear to be an independent prognostic variable for survival.
- ◆ After stratifying for stage and age, patients with pregnancy-associated cervical carcinoma have survival rates similar to those of the nonpregnant patient.
- ◆ Because most malignant ovarian tumors found in pregnancy are either germ cell tumors or low-grade, early-stage epithelial tumors, the therapeutic plan will usually permit continuation of the pregnancy and preservation of fertility.
- ◆ Although rare, most colorectal carcinomas in pregnancy are detectable on rectal examination, underscoring the need for a rectal examination at the patient's first prenatal visit.
- ◆ Phantom  $\beta$ -hCG should be ruled out in patients suspected of having gestational trophoblastic disease when not documented by other clear clinical evidence (histology, imaging, and clinical history), especially when  $\beta$ -hCG titers are low.

This chapter reviews the physiologic skin changes induced by pregnancy, along with preexisting skin diseases and tumors, and also outlines the diagnosis and treatment of melanoma, pruritis, and specific dermatoses of pregnancy. Common skin conditions discussed in the text are defined in [Table 51-1](#).

## PHYSIOLOGIC SKIN CHANGES INDUCED BY PREGNANCY

The human skin undergoes substantial changes during pregnancy, induced by the combined effect of endocrine, metabolic, mechanical, and blood flow alterations. **Although they may prompt cosmetic complaints, such physiologic changes are not associated with risks to the mother or fetus and can be expected to resolve or improve postpartum (Box 51-1).**<sup>1,2</sup> However, some changes such as melasma, varicosities, and pregnancy-associated hyperkeratosis of the nipple<sup>3</sup> may persist postpartum.

## Pigmentary Changes

**Mild forms of localized or generalized hyperpigmentation occur to some extent in up to 90% of pregnant women** and are most noticeable in the areolae, nipples, genital skin, axillae, and inner thighs. Familiar examples include the darkening of the *linea alba* (*linea nigra*) and periareolar skin. Melasma, also termed *chloasma* or *mask of pregnancy*, refers to the facial hyperpigmentation reported in up to 70% of pregnant women.<sup>2</sup> Hyperpigmented, symmetric, poorly demarcated patches are commonly seen on the malar areas (*malar pattern*) and are often distributed over the entire central face (*centrofacial pattern*; [Fig. 51-1](#)). In 16% of cases, hyperpigmentation occurs on the ramus of the mandible (*mandibular pattern*).<sup>4,5</sup> Melasma results from melanin deposition in the epidermis (70%), dermal macrophages (10% to 15%), or both (20%). It is likely secondary to the hormonal changes of gestation with increased expression of  $\alpha$ -melanocyte-stimulating hormone. Melasma typically is exacerbated by exposure to ultraviolet and visible light.<sup>5,6</sup> Hyperpigmentation is often more pronounced in brunettes and women with more melanocytes than in women with lighter baseline skin tone; the use of a broad-spectrum sunscreen with a high sun protection factor (SPF) during pregnancy may decrease the severity of hyperpigmentation.

**Melasma usually resolves postpartum but may recur in subsequent pregnancies or with the use of oral contraceptives.**<sup>4</sup> Troublesome persistent melasma can be treated postpartum with topical hydroquinone 2% to 4% and sunscreen, with or without a topical retinoid and mild topical steroid.<sup>7</sup> Despite treatment postpartum, melasma persists in approximately 30% of patients, especially in women with the dermal or mixed subtypes in which the deeper level of pigmentation results in decreased efficacy of topical agents. Combination therapies including laser treatment<sup>8,9</sup> and chemical peels<sup>10</sup> may be effective in resistant cases. There have been no reports of adverse fetal effects from laser skin treatment during pregnancy. Most laser

TABLE 51-1 COMMON SKIN CHANGES AND DISEASES

| CONDITION   | DESCRIPTION   |
|---|---|
| Pseudoacanthosis nigricans                        | Hyperpigmentation of the skin folds and neck that mimic acanthosis nigricans  |
| Dermal melanocytosis                              | Clusters of melanocytes abnormally located in the dermis that result in ill-defined bluish-gray patches   |
| Vulvar melanosis                                  | Irregularly distributed patches of pigmentation on the vulva  |
| Pregnancy-associated hyperkeratosis of the nipple | Focal hyperkeratosis, at times with wartlike papules, of the apex of the nipple   |
| Miliaria  | Sweat retention that reflects obstruction of eccrine sweat ducts  |
| Hyperhidrosis                                     | Skin disorder characterized by increased sweat secretion  |
| Dyshidrosis                                       | Recurrent vesicular eruption of palms and soles   |
| Fox-Fordyce disease                               | Chronic pruritic disorder of the apocrine glands characterized by blockage of the apocrine duct and sweat retention                                   |
| Onycholysis                                       | Detachment of the nail plate from the nail bed  |
| Subungual hyperkeratosis                          | Deposition of keratinous material on the distal nail beds   |
| Palmoplantar pompholyx eczema                     | See <i>dyshidrosis</i> above (former name for <i>pompholyx</i> )  |
| Acne conglobata                                   | Variant of acne vulgaris characterized by severe eruptive nodulocystic lesions without systemic manifestations  |
| Pemphigus vulgaris                                | Autoimmune bullous disorder of the skin and oral mucosa produced by antidesmoglein-3 antibodies that cause intraepidermal acantholysis                |
| Pemphigus vegetans                                | Variant of pemphigus vulgaris characterized by pustules that form fungoid vegetations or papillomatous proliferations                                 |
| Pemphigus foliaceus                               | Autoimmune bullous skin disorder produced by antidesmoglein-3 antibodies that cause subcorneal acantholysis   |
| Spitz nevi  | Seen predominantly in children or young adults and characterized by prominent epithelioid and/or spindled melanocytes that can have atypical features |

experts agree that laser radiation does not penetrate through the skin into deeper soft tissues; therefore it should not affect the fetus or the placenta. Still, because of potential liability issues, most dermatologists and plastic surgeons prefer not to perform laser procedures during gestation.

Uncommon pigmentary patterns such as pseudoacanthosis nigricans,<sup>11</sup> dermal melanocytosis, vulvar melanosis, and verrucous areolar hyperpigmentation can also be seen in pregnancy (see Box 51-1).<sup>12</sup> Postinflammatory hyperpigmentation secondary to specific dermatoses of pregnancy (see the section “[Specific Dermatoses of Pregnancy](#)”) is also common in women with more highly pigmented skin types.

Vascular Changes

As a result of the combination of rising estrogen levels and increased blood volume in pregnancy, blood flow to the skin increases 4 to 16 times in the first 2 months of pregnancy and doubles again during the third month; this results in significant vascular sequelae (see Box 51-1). Spider nevi (spider angiomas) and telangiectasias develop in approximately two thirds of white women and 10% of black women between the second and fifth months of pregnancy and usually resolve within 3 months postpartum (Fig. 51-2, A).<sup>1,4</sup> Approximately 10% of women have

persistent spider nevi; treatment with electrocauterization or pulsed dye laser is effective in women who find these cosmetically troubling.

Palmar erythema, likely secondary to capillary engorgement, is also very common and occurs in up to 70% of white and 30% of black women. Whereas varicosities of the distal leg veins and hemorrhoidal veins develop in more than 40% of women, thrombosis within these superficial varicosities occurs infrequently (<10%). Nonpitting edema can be seen on the ankles (70%) and face (50%) and is most pronounced in the early months of gestation. Varicosities may regress postpartum but usually not completely and are likely to recur in subsequent pregnancies.

Gum hyperemia and gingivitis are common and frequently result in mild bleeding from the gums during routine oral hygiene. This is most prominent during the third trimester and resolves postpartum. Good dental hygiene will minimize symptoms. Periodontal disease has been associated with adverse pregnancy outcomes, so women without a recent dental examination should be referred.<sup>13</sup>

**FIG 51-1** Centrofacial type of melasma involving the cheeks, nose, upper lip, and forehead.

The **pyogenic granuloma of pregnancy**, known as *granuloma gravidarum* or *pregnancy epulis*, is a **benign proliferation of capillaries that usually occurs in the gingiva** but can occasionally be identified on the lip or extramucosal sites (see Fig. 51-2, B). Pyogenic granulomas commonly appear between the second and fifth months of pregnancy and affect up to 2% of pregnancies.<sup>4</sup> Presenting as a vascular, deep red or purple, exuberant, often pedunculated nodule between the teeth or on the buccal or lingual surface of the marginal gingiva, a pyogenic granuloma may be more likely after mucosal trauma. Spontaneous shrinkage of the tumor usually occurs postpartum, and most cases do not require treatment. Surgical excision or electrosurgical destruction should be reserved for cases complicated by excessive bleeding or severe discomfort.

### Connective Tissue Changes

*Striae gravidarum*, also called *striae distensae* or “stretch marks,” develop in up to 90% of white women between the sixth and seventh months of gestation.<sup>4</sup> Risk factors include younger maternal age, excessive pregnancy weight gain, and concomitant use of corticosteroids; however, genetic susceptibility plays a key role. Striae are most prominent on the abdomen, breasts, buttocks, groin, and axillae; whereas usually asymptomatic, a proportion of patients complain of mild to moderate pruritus. The treatment of striae gravidarum is a challenge; at present, no optimal treatment is available. The erythema (red color) of early striae responds well to various pulsed-dye lasers or intense pulsed light. The red color tends to become pale over time, with or without treatment, but the atrophic lines never disappear completely and do not respond to laser treatment. Topical tretinoin 0.1% cream has been shown to improve the appearance of the striae, decreasing the length by 20%, and is occasionally used in combination with topical glycolic acid (up

**FIG 51-2 A**, Numerous telangiectasias and spider angiomas on the arm of a pregnant woman. **B**, Pyogenic granuloma of pregnancy (*granuloma gravidarum*), a benign vascular proliferation, is typically seen as a nodule on the gingivae and is shown here at a less common extramucosal site.

to 20%) in an effort to increase elastin content of the affected areas.<sup>14</sup> Nevertheless, tretinoin can be very irritating to the skin and does not make striae completely disappear. No topical therapy prevents or affects the course of striae; they become less apparent postpartum but may never disappear.

Skin tags (*molluscum fibrosum gravidarum*) present as 1- to 5-mm fleshy, pedunculated, exophytic growths on the neck, axillae, inframammary region, or groin and usually appear during the later months of gestation. Treatment can be postponed until completion of the pregnancy because lesions may regress postpartum. Cryotherapy with liquid nitrogen or shave removal is effective for persistent or enlarging lesions. Skin tags do not have malignant potential, and treatment is unnecessary unless inflammation or ulceration develops.

### Glandular Changes

Increased eccrine function has been reported during pregnancy and may account for the increased prevalence of miliaria, hyperhidrosis, and dyshidrosis.<sup>4,12</sup> Conversely, apocrine activity may decrease during gestation, which contributes to the decreased prevalence of Fox-Fordyce disease and possibly hidradenitis suppurativa in pregnancy.<sup>2</sup> Changes in sebaceous function are variable, and the effects of pregnancy on acne vulgaris are unpredictable. Treatment for acne vulgaris during pregnancy is discussed below. During pregnancy, the sebaceous glands on the areolae enlarge (*Montgomery's glands or tubercles*).

### Hair and Nail Changes

Most pregnant women develop mild hirsutism that affects their face, trunk, and extremities that commonly regresses within 6 months postpartum. In addition, **postpartum hair shedding (telogen effluvium) may be noted as a greater proportion of hairs enter the telogen phase (Fig. 51-3).** The severity of *telogen effluvium* varies considerably, and the hair loss becomes noticeable when more than 40% to 50% of the hair is affected. Recovery is spontaneous, and no effective treatment is available. Patients can be counseled that hair thinning usually resolves

within 1 to 5 months but that complete resolution may occasionally take up to 15 months.<sup>1,4</sup> Frontoparietal hair recession and diffuse hair thinning in the later months of pregnancy have been noted in some women. Nail changes can be seen as early as the first trimester of gestation that include brittleness, onycholysis, subungual hyperkeratosis, and transverse grooving. No specific treatment is available for nail changes during pregnancy, and most are expected to resolve postpartum. An attempt should be made to eliminate external sensitizers, such as nail polish removers, and infections. The nails should be kept short if they are brittle or prone to onycholysis.<sup>6</sup>

## PREEXISTING SKIN DISEASES AND TUMORS AFFECTED BY PREGNANCY

**Pregnancy can aggravate or, less often, improve many skin conditions and primary skin tumors** (see Video 51-1).<sup>15</sup> Diseases that may improve during pregnancy include atopic dermatitis, acne, chronic plaque psoriasis, Fox-Fordyce disease, hidradenitis suppurativa, linear immunoglobulin A (IgA) dermatosis, sarcoidosis, Behçet disease, urticaria, and autoimmune progesterone dermatitis (see Table 51-1).

### Atopic Eczema and Dermatitis

Atopic dermatitis (AD), also known as *atopic eczema*, is a very common skin condition and is often exacerbated by pregnancy, although remission has been noted in up to 24% of cases.<sup>16</sup> Two large studies that used diagnostic criteria established in pediatric populations indicated a high prevalence of AD in pregnancy, including “new AD” (AD presenting for the first time in pregnancy); however, the true prevalence may be revised as the criteria for gestational AD are refined.<sup>16-20</sup> Risk factors include a history of prior atopy (27%), family history of atopy (50%), and offspring with infantile AD (19%). Other risk factors for AD include black or Asian race and tobacco use.<sup>21,22</sup> The prevalence of intrinsic (“nonallergic”) versus extrinsic (IgE associated) AD<sup>23</sup> during gestation is unknown, although a small study showed that intrinsic AD is more affected by pregnancy.<sup>24</sup>

Most patients present with lesions in the flexural surfaces of the extremities, occasionally with concomitant lesions on the trunk. Less common presentations are palmoplantar pompholyx eczema and follicular and facial eczema. In pregnancy, eczematous lesions can develop bacterial or viral superinfection (i.e., *eczema herpeticum* secondary to herpes simplex virus); treatment with dicloxacillin or a first-generation cephalosporin should be used as necessary in these cases. *Eczema herpeticum* and disseminated herpetic infection, the latter of which may lead to fetal risk, should be promptly treated with intravenous (IV) acyclovir to minimize maternal and fetal risks.

AD is not associated with an increased risk of adverse fetal outcomes. The effects of breastfeeding and maternal food antigen avoidance during pregnancy on AD in the offspring are controversial. **Treatment for gestational exacerbations of AD is primarily symptomatic. A moisturizer and low potency to midpotent topical steroid is the first-line treatment.** Systemic antihistamines, such as chlorpheniramine or diphenhydramine, can also be used as necessary for relief of pruritus. A short course of oral steroids may be required for severe AD. Ultraviolet light B (UVB) is a safe second-line treatment for eczema in pregnancy. There is less experience with the newer topical immunomodulators (pimecrolimus, tacrolimus).<sup>25</sup> Although their bioavailability is limited (<5%) and no pattern of anomalies has been reported

**FIG 51-3** Telogen effluvium that develops within 5 months postpartum typically presents with temporal recession and hair thinning.

after exposure to these drugs in utero, several infants have had neonatal hyperkalemia.<sup>26</sup> Therefore these immunomodulators should be used as third-line treatment for refractory AD that has not responded to UVB. If systemic agents are needed for refractory AD, cyclosporine is the safest option.

The course of gestational AD in the postpartum period has not been studied. Irritant hand dermatitis and nipple eczema are often seen postpartum.<sup>1</sup> Irritant hand dermatitis is treated with emollients and hand protection. Nipple eczema can evolve into painful fissures and can be complicated with bacterial superinfection, most commonly with *Staphylococcus aureus*. Superinfected nipple eczema should be treated with a topical steroid combined with a topical or systemic antibiotic.

### Acne Vulgaris

The effects of pregnancy on acne vulgaris are unpredictable. **In one study, pregnancy affected acne in approximately 70% of women, with 41% reporting improvement and 29% reporting a worsening with pregnancy.**<sup>27</sup> Two patients had improvement in one pregnancy and exacerbation in another. Some patients may develop acne for the first time during pregnancy or in the postpartum period (*postgestational acne*). Comedonal acne should be treated with topical keratolytic agents, such as benzoyl peroxide, whereas inflammatory acne should be treated with azelaic acid, topical erythromycin, topical clindamycin, or oral erythromycin base. Although first-trimester use of topical tretinoin has not been associated with an increased rate of congenital malformations in controlled studies, the number of reported exposures is too small to exclude a small increased risk. A theoretic concern remains, and the use of tretinoin during pregnancy is therefore not recommended (see Chapter 8).

### Other Inflammatory Skin Diseases

Recurrent flares of urticaria may worsen in pregnancy. Of interest, these flares show common features with hereditary angioedema and may have been exacerbated in the past by oral contraceptive use or prior to menses. Chronic plaque psoriasis may develop for the first time during pregnancy. **Women with existing chronic psoriasis can be counseled that between 40% and 63% of women have symptomatic improvement, compared with only 14% of women who have symptomatic deterioration;** postpartum flares are common (80%).<sup>28</sup> Topical steroids and topical calcipotriene are relatively safe treatment options for localized psoriasis in pregnancy.<sup>29</sup> For severe psoriasis that has not responded to topical medications, UVB or a short course of cyclosporine are considered second-line treatment options.

### Autoimmune Progesterone Dermatitis

**Autoimmune progesterone dermatitis is caused by hypersensitivity to progesterone through autoimmune or nonimmune mechanisms.** Although this rare dermatosis can take various forms (urticarial, papular, vesicular, or pustular), the hallmark is recurrent cyclic lesions that usually appear during the luteal phase of the menstrual cycle. Limited information is available regarding the effects of pregnancy on autoimmune progesterone dermatitis. Case series report instances of both improvement and exacerbation.<sup>30</sup> Increased cortisol levels and/or the gradual increase in the sex hormone levels during pregnancy with subsequent hormonal desensitization in some patients are both possible mechanisms for observed improvement. Diagnosis is based on either an immediate local urticarial reaction or, more

frequently, a delayed hypersensitivity reaction following intradermal challenge with synthetic progesterone. Intramuscular administration of progesterone should be avoided in these patients because it has been associated with angioedema. Circulating antibodies to progesterone or the corpus luteum have been detected by indirect immunofluorescence in several patients. The sensitivity of this test seems to be lower than that of the intradermal progesterone challenge, therefore these antibodies are not widely used to confirm this diagnosis. No specific therapy for the condition during pregnancy has been proposed. Autoimmune estrogen dermatitis has also been reported in a patient who presented with urticaria in early pregnancy.<sup>31</sup>

### Impetigo Herpetiformis

**Impetigo herpetiformis is a rare variant of generalized pustular psoriasis that develops primarily during pregnancy, often in association with hypocalcemia<sup>32</sup> or low serum levels of vitamin D.<sup>33</sup>** Although familial occurrence has been reported, more commonly a personal or family history of psoriasis is absent. The eruption usually develops in the third trimester but can also start in earlier trimesters and postpartum. Whereas the overwhelming majority of cases resolve postpartum, persistent cases have been reported and can be associated with oral contraceptive use.<sup>34</sup> Various infections during pregnancy may also trigger a flare of pustular psoriasis in a genetically predisposed individual.<sup>35</sup>

Impetigo herpetiformis is characterized by numerous grouped, discrete, sterile pustules at the periphery of erythematous patches (Fig. 51-4, A). Lesions typically originate in the major flexures (axillae, inframammary areas, groin, and gluteal fold) and progress onto the trunk, usually sparing the face, hands, and feet. Painful mucosal erosions may also develop. Onycholysis, or complete nail shedding secondary to subungual lesions, has been reported. Constitutional symptoms are common and include fever, malaise, diarrhea, and vomiting with resultant dehydration. Rarely, patients develop complications secondary to hypocalcemia that include tetany, convulsions, and delirium. Common laboratory findings are leukocytosis and elevated erythrocyte sedimentation rate; rarer perturbations include hypocalcemia, decreased serum vitamin D levels, and signs of hypoparathyroidism. Historically reported maternal risks such as tetany, seizures, delirium, and death from cardiac or renal failure or septicemia are uncommon. Fetal risks such as stillbirth and fetal abnormalities secondary to placental insufficiency<sup>33</sup> have been reported even when the condition was well controlled.<sup>36</sup> **Whereas maternal prognosis is excellent with early diagnosis, aggressive treatment, and supportive care, an increased risk of perinatal mortality may persist despite maternal treatment.**<sup>37</sup> The risk is difficult to quantify because it is based on sparse case reports that span decades. Intensive fetal monitoring should be considered until the mother is stabilized. After acute treatment, the appropriate degree of fetal surveillance is not known; however, periodic assessment of fetal well-being is prudent after viability.

Definite diagnosis of impetigo herpetiformis is based on histopathology that shows typical features of pustular psoriasis (see Fig. 51-4, B). Direct and indirect skin immunofluorescence is negative. Systemic steroids are first-line therapy for impetigo herpetiformis, and 20 to 40 mg/day of prednisone is usually effective. Cases of pustular psoriasis exacerbated by pregnancy have been treated with cyclosporine.<sup>37</sup> Calcium and vitamin D replacement therapy should be undertaken if necessary and can

**FIG 51-4** **A**, Impetigo herpetiformis: discrete, grouped, sterile pustules at the periphery of an erythematous crusted plaque. **B**, Histopathology of impetigo herpetiformis shows the characteristic Kogoj spongiform pustule, formed of neutrophils in the uppermost portion of the spinous layer (hematoxylin-eosin stain). (Courtesy Aleksandr Itkin, MD.)

lead to remission of the eruption.<sup>25</sup> Systemic antibiotics should be administered if bacterial superinfection is suspected. Post-inflammatory hyperpigmentation may develop, but scarring is usually absent. Impetigo herpetiformis has been treated postpartum with oral steroids, oral retinoids,<sup>38</sup> and photochemotherapy (psoralen with ultraviolet light A [PUVA])<sup>39</sup> as single agents or in combination. Resistant cases can be treated with a combination of PUVA and clofazimine or methotrexate postpartum (methotrexate is contraindicated during pregnancy [category X], and both methotrexate and clofazimine are contraindicated during breastfeeding).

### Cutaneous Manifestations of Autoimmune Disorders

Cutaneous lesions may be prominent in some individuals affected by autoimmune disorders, and these patients often have questions regarding how pregnancy will affect the appearance of these lesions. The cutaneous manifestations of chronic discoid lupus are not affected by pregnancy. Cutaneous flares of systemic lupus erythematosus can usually be managed with oral steroid treatment. Dermatomyositis/polymyositis may show exacerbation of the characteristic heliotrope rash in approximately half

of affected individuals.<sup>40</sup> The cutaneous progression of scleroderma is not significantly altered by pregnancy, and symptoms of Raynaud phenomenon may improve. Pregnant women with limited skin disease do significantly better than those with diffuse scleroderma.<sup>41</sup> The medical and obstetric management of pregnancies complicated by collagen vascular disease is discussed in detail in [Chapter 46](#).

### Bullous Disorders

Bullous dermatologic disorders develop secondary to autoantibodies that target constituents of the skin and oral mucosa. **Pemphigus vulgaris,<sup>42</sup> vegetans, or foliaceus may develop or worsen during pregnancy,** whereas linear IgA disease may improve.<sup>43</sup> In more than 50% of cases of pemphigus vulgaris, lesions may initially appear within the oral cavity. Diffuse skin involvement with multiple flaccid vesicles follows with confluence of vesicles forming large eroded areas. Skin biopsy with immunofluorescence studies are needed for a definitive diagnosis. Biopsy for routine histopathology and immunofluorescence is indicated in patients with new-onset lesions, most critically to differentiate pemphigus from herpes (*pemphigoid*) gestationis (see that section below). In cases of pemphigus, fetal and neonatal skin lesions can occur secondary to transplacental transfer of IgG antibodies, but these resolve spontaneously within 2 to 3 weeks after birth. Pemphigus should be treated with oral corticosteroids, and high doses may be required. A recent study of 49 pregnancies complicated by pemphigus vulgaris showed a 12% perinatal mortality. Forty-five percent of live neonates had pemphigus lesions at birth.<sup>44</sup> Increased fetal surveillance is prudent in pregnancies affected by active pemphigus, although the effectiveness of this surveillance in preventing morbidity and fetal loss is not known.

Acrodermatitis enteropathica is a rare autosomal-recessive disorder of zinc deficiency characterized by dermatitis, diarrhea, and alopecia. Vesiculobullous and/or eczematous skin lesions can develop on the extremities and at periorificial sites such as the mouth and perianal and genital areas. The disease usually flares early in gestation<sup>45</sup> as serum zinc levels decrease, but it may also flare with oral contraceptive use.

### Skin Tumors

Most skin neoplasms that present or enlarge during pregnancy are benign, and this includes pyogenic granuloma, hemangioma, hemangioendothelioma, glomus tumor, glomangioma, dermatofibroma, dermatofibrosarcoma protuberans, leiomyoma, keloid, desmoid tumor, and neurofibroma. **Melanocytic nevi may develop, enlarge, or darken during pregnancy, but these changes are less dramatic than previously thought.** A mild degree of histopathologic atypia has been reported in a few studies. Pennoyer and colleagues<sup>46</sup> compared photographs of moles taken during the first trimester and again in the third trimester. Only 3% of nevi enlarged during pregnancy, and another 3% regressed. In contrast, dysplastic nevi in women with familial dysplastic nevus syndrome do have a tendency to increase in size and undergo color change during pregnancy.<sup>47</sup> Spitz nevi, another class of common pigmented benign neoplasms, may also increase in size or erupt during pregnancy.<sup>48</sup> Studies that used dermoscopy showed that the pigment network of nevi becomes thicker and more prominent, and the globules darken during pregnancy; these features, however, return to their original state within 1 year after delivery.<sup>49</sup> Any suspicious pigmented skin lesion should prompt a dermatologic referral. The

“ABCDE” clinical criteria for pigmented lesions—*asymmetry*, *border* irregularity, *color* variegation, *diameter* greater than 6 mm, and *evolution* (i.e., an enlarging or otherwise changing lesion)—are helpful in determining which lesions are of higher malignant potential.<sup>50</sup> Seborrheic keratoses are also common and may enlarge or darken during gestation. None of these benign lesions requires treatment during pregnancy; the pregnant patient should be reassured that these changes are benign and may improve postpartum.

### Malignant Melanoma

Malignant melanoma (MM; see [Chapter 50](#)) is the most common malignancy in pregnancy and accounts for 31% of all malignant tumors diagnosed in pregnancy<sup>51</sup> with an overall incidence that ranges between 2.8 and 8.5 cases per 100,000 women.<sup>52,53</sup> Some studies have shown that melanomas that develop during pregnancy are thicker than those in nonpregnant women,<sup>54</sup> possibly because of a delayed diagnosis due to a shared misconception by the patient and/or her physician that darkening and changing of a nevus is normal in pregnancy. However, after correcting for tumor thickness, no effect on prognosis was apparent. Despite initial concerns, **several epidemiologic studies to evaluate the effect of pregnancy status at diagnosis suggest that the 5-year survival rate is not affected after controlling for confounding factors.**<sup>53,55-57</sup> However, data are insufficient for stage III and IV disease.<sup>58</sup> The major prognostic determinants of survival in patients with localized melanoma are tumor (Breslow) thickness and ulceration status,<sup>59</sup> and level of invasion is only significant in women with tumors more than 1 mm in thickness.

Inconclusive evidence supports the role of estrogen receptors (ERs) in melanoma. Most studies did not show an increased risk of melanoma recurrence with oral contraceptives or hormone replacement therapy (HRT) use.<sup>60,61</sup> Some studies have found melanoma cell lines that lack type I ERs,<sup>62,63</sup> but others have demonstrated an inhibitory effect of estrogens on melanoma cell lines through type II ERs.<sup>61</sup> In fact, decreased levels of ER $\beta$  expression, which antagonizes the proliferative behaviors of ER $\alpha$ , have been seen in more invasive MM with increased Breslow thickness.<sup>64</sup> Higher levels of ER $\beta$  have been demonstrated in melanoma cells of pregnant women compared with melanoma cells in men, thus potentially implicating ER $\beta$  and female sex as a protective and prognostic factor in MM.<sup>65,66</sup>

**Wide local excision of the primary melanoma should be performed in stages I through III, and conservative excision should be undertaken in stage IV.**<sup>58,67</sup> Sentinel lymph node biopsy (SLNB) is indicated for a tumor stage of T1b or greater if thickness is greater than 0.75 mm. **SLNB is the most powerful prognostic factor in clinically localized melanoma.** However, because allergic reactions to the isosulfan blue dye used in the procedure have been reported, Schwartz and colleagues<sup>67</sup> proposed the use of radiocolloid alone for SLNB in the first trimester. The authors also proposed that wide local excision and SLNB with blue dye can be delayed until after delivery in women who are in the second half of pregnancy and have already undergone narrow excision of their MM with negative margins. Regarding other staging procedures, chest radiography with appropriate shielding and ultrasound of the abdomen and liver should be performed in stage IIB/IIIA.<sup>58</sup> In stages greater than IIIA, magnetic resonance imaging (MRI) of the head and positron emission tomography (PET)/computed tomography (CT) scans should be performed; MRI carries a

risk for tissue overheating and should not be used in the first trimester.<sup>58</sup>

Complete lymph node dissection is warranted in stages I and II if SLNB is positive, and therapeutic lymph node dissection should be undertaken in stage III.<sup>58</sup> As far as management of stage IV patients, elective termination and tailored treatment should be considered in the first trimester, whereas tailored treatment and induction when the fetus is viable should be considered in the second and third trimesters.<sup>58</sup> However, termination of pregnancy in stage IV patients does not affect the outcome of MM in the mother,<sup>68</sup> and the risk of fetal metastasis remains remote.

**Melanoma is the most common type of malignancy to metastasize to the placenta and fetus, and it represents 31% of such metastases.**<sup>69</sup> However, it should be emphasized that placental and/or fetal metastases are extraordinarily rare (27 cases) and that even in the setting of placental metastasis, fetal metastasis only occurs in 17% of cases. Histologic evaluation of the placenta should be performed because of potentially microscopic placental metastasis with known association to fetal melanoma. The presence of placental metastases is associated with widespread disease and dismal maternal survival. The role of systemic therapy in preventing metastases to the placenta and fetus has not been adequately studied.

No standard guidelines are available for patients who desire to become pregnant after the diagnosis and treatment of melanoma. A nonsignificant decrease in mortality in pregnancy subsequent to a melanoma diagnosis has been reported.<sup>53</sup> The primary reason to delay pregnancy following a recent diagnosis of melanoma is the time-dependent risk of tumor recurrence and subsequent maternal mortality. One study showed that 83% of stage II MM recurrences were within 2 years of initial treatment.<sup>55</sup> Schwartz and colleagues<sup>67</sup> suggested waiting 2 years in patients with thin melanomas and 3 to 5 years in thicker lesions before becoming pregnant again. Patients should be counseled on a case-by-case basis depending primarily on risk of recurrence, taking into account the thickness of their original tumor and other prognostic factors. Women with a significant risk of recurrence may want to delay pregnancy until they can be assured of a low recurrence risk. In women with a thin tumor with a low risk of recurrence, no delay may be necessary.

## PRURITUS IN PREGNANCY

Itching is the most common dermatologic symptom of pregnancy. Mild pruritus attributed to pregnancy (*pruritus gravidarum*) is common and occurs most frequently over the abdomen. Pruritus has been reported in up to 17% of pregnancies,<sup>70</sup> but a more recent report suggests that significant pruritus that requires a more thorough evaluation occurs in only 1.6% of patients.<sup>71</sup> **A broad differential diagnosis needs to be considered; the constellation of clinical and laboratory findings will help establish a diagnosis and guide management decisions.** Pruritic skin diseases not specifically related to pregnancy, such as AD and scabies, should be considered. In cases of pruritus without eruption, systemic diseases are more likely. Intrahepatic cholestasis of pregnancy (ICP) is a common etiology (see Chapter 47 for diagnosis and management); however, other conditions—such as lymphoma and liver, renal, and thyroid disease—should also be considered.<sup>12</sup> In the patient with pruritus and skin lesions other than excoriations, referral to a dermatologist for evaluation of a specific dermatosis of pregnancy (see

below) is appropriate, unless a clear etiologic agent for a systemic or topical allergic reaction can be elucidated.

## SPECIFIC DERMATOSES OF PREGNANCY

The term *specific dermatoses of pregnancy* refers to a group of skin diseases encountered predominantly during or immediately following pregnancy and includes **only those skin diseases that result directly from the state of gestation or the products of conception** (see Video 51-2).<sup>16</sup> Included in this definition are pemphigoid (herpes) gestationis (PG); polymorphic eruption of pregnancy (PEP), also called *pruritic urticarial papules and plaques of pregnancy* (PUPPP); prurigo of pregnancy (PP); and pruritic folliculitis of pregnancy (PFP; Table 51-2). A recent reclassification<sup>17</sup> included ICP in the specific dermatoses of pregnancy and grouped AD, PP, and PFP under “atopic eruption of pregnancy” (AEP). However, some studies have not confirmed the association of PP and PFP with atopy, and some features of AEP need to be further clarified.<sup>18</sup>

### Pemphigoid (Herpes) Gestationis

**Pemphigoid gestationis (PG) is a rare autoimmune skin disease that affects between 1 in 7000 and 1 in 50,000 pregnancies.**<sup>20</sup> Although PG and bullous pemphigoid recognize the same antigen<sup>72</sup> and share certain features, PG is confined to pregnant women and those affected by gestational trophoblastic disease (GTD). Some authors<sup>73</sup> have suggested that exposure to paternal antigens may play a critical role in disease initiation, but “skip pregnancies” with the same partner have been reported and would argue against this association. Of interest, expression of the PG antigen in the placenta begins in the midtrimester, which correlates with the timing of clinical symptoms. The antibody that incites the pathology in PG belongs to the IgG1 subclass and recognizes the NC16A2 (MCW-1) epitope in the noncollagenous domain (NC16A) of the transmembrane 180-kd antigen (bullous pemphigoid antigen 2).<sup>74</sup> PG primarily affects whites with only scattered case reports in blacks<sup>75</sup>; this observation is consistent with the association between PG and the human leukocyte antigens (HLAs) DR3 (61% to 80%), DR4 (52%), or both (43% to 50%), which are less frequent in the black population.

Clinically, **PG usually presents in the second or third trimester of pregnancy with extremely pruritic urticarial lesions that typically begin on the abdomen and trunk and commonly involve the umbilicus** (Fig. 51-5, A). These urticarial plaques rapidly progress to widespread bullous lesions (see Fig. 51-5, B) that may affect the palms and soles but rarely the face and mucous membranes. Tense bullous lesions arise in both inflamed and clinically normal skin and usually heal without scarring. Up to 25% of cases can present in the postpartum period, although these may represent recrudescences of previously undiagnosed mild PG. The most important clinical and laboratory features of PG are summarized in Table 51-2.

**Although the differential diagnosis of PG includes drug eruption, erythema multiforme, and allergic contact dermatitis, the most common diagnosis to exclude is the far more common PEP** (see below). **PEP can manifest with urticarial and/or vesicular lesions almost indistinguishable from those of PG, although PEP classically begins in the abdominal striae and spares the umbilicus.** Definitive diagnosis should be based on immunofluorescence of perilesional skin that demonstrates the hallmark finding of PG: linear C3 deposition along

Ig, immunoglobulin; SGA, small for gestational age.

the basement membrane zone, which is absent in PEP.<sup>1</sup> Interestingly, a small recent study showed C4d positivity at the basement membrane zone on paraffin sections in PG but not in PEP; this may eliminate the second biopsy for immunofluorescence but needs confirmation.<sup>76</sup> Skin histopathology shows a spongiotic epidermis, marked papillary dermal edema, and an eosinophilic infiltrate. Serum antibody titers with conventional indirect immunofluorescence do not correlate with the course of disease but parallel disease activity when BP-180 NC16A enzyme-linked immunosorbent assay (ELISA) was used.<sup>77</sup>

**Oral corticosteroids remain the cornerstone of treatment in PG.** The majority of patients will respond rapidly to treatment with relatively low-dose prednisone (20 to 40 mg/day). In resistant cases, doses as high as 180 mg/day have been tried. Once new blister formation has been suppressed, prednisone should be tapered to 5 to 10 mg/day. Typically, up to 75% of patients will experience spontaneous resolution or improvement in the late third trimester, and steroid treatment can often be discontinued. However, because PG typically flares at delivery or within the days following delivery, steroid doses can be increased in anticipation. A subset of patients will have persistent PG or recurrent flares that last weeks or months. Patients at risk for prolonged or chronic PG tend to be older with higher parity, with more widespread lesions and a history of PG in prior pregnancies.<sup>78</sup> Oral contraceptive use has been implicated in postpartum flares; 20% to 50% of patients who use oral contraceptives within 6 months of delivery have associated flares. This association should be considered when counseling patients on their contraceptive options. Breastfeeding was associated with a significantly shorter duration of active lesions in one study,<sup>79</sup> but this has been debated. PG recurs in 95% of future pregnancies, and lesions may be more severe, appear earlier in gestation, and persist longer postpartum. Treatment for chronic, recalcitrant PG is generally unsatisfactory, although case reports

have described success with plasmapheresis; immunoapheresis; chemical oophorectomy with goserelin; ritodrine; rituximab; and high-dose intravenous immune globulin (IVIg) combined with cyclosporine or other immunosuppressant medications. Minocycline or doxycycline combined with nicotinamide and immunosuppressive and antiinflammatory agents such as cyclophosphamide, azathioprine, rituximab, pyridoxine, sulfapyridine, gold, methotrexate, or dapsone have been used postpartum in refractory cases with some success, but their use is limited to nonlactating patients.<sup>20</sup>

The maternal effects of PG are largely limited to symptomatic pruritus and a small risk of lesion superinfection. An association between PG and Graves disease has been reported, and PG<sup>80</sup> is an indication for performing both immediate and periodic screening tests of thyroid function. **An association with small-for-gestational-age (SGA) infants and preterm delivery has been reported,** but the effect of PG on the fetus remains difficult to estimate from the small study cohorts due to the rarity of the disease. The largest cohort to date compared fetal outcome between the affected and unaffected pregnancies of 74 women; 16% of pregnancies with active PG delivered prior to 32 weeks, compared with 2% of the unaffected pregnancies.<sup>81</sup> Mild placental insufficiency has been postulated as a mechanism, therefore sonographic evaluation of fetal interval growth and third-trimester fetal surveillance is appropriate. Finally, **approximately 5% to 10% of neonates will manifest bullous skin lesions (neonatal PG) secondary to passive transplacental transfer of PG antibody.**<sup>82</sup> Parents should be reassured that these lesions will resolve spontaneously without scarring over a period of a few weeks as the maternal antibodies clear from the infant's blood. However, parents should be counseled about the signs and symptoms of bacterial superinfection so that timely treatment can prevent progression to systemic infection.

**FIG 51-5** **A**, Pruritic abdominal urticarial plaques develop in the early phase of pemphigoid (herpes) gestationis and typically involve the umbilicus. **B**, Characteristic tense vesicles on an erythematous base on the forearm in a patient with PG. (From Kroumpouzou G: Skin disease. In James DK, Steer PJ, Weiner CP, Gonik B, Crowther CA, Robson SC: *High-Risk Pregnancy: Management Options*, 4<sup>th</sup> ed, Philadelphia: Elsevier Saunders; 2011, p. 929.)

### Polymorphic Eruption of Pregnancy

**Polymorphic eruption of pregnancy (PEP)**, also known as *pruritic urticarial papules and plaques of pregnancy (PUPPP)*, is the most common specific dermatosis of pregnancy and affects between 1 in 130 and 1 in 300 pregnancies. It occurs classically in primigravidae in the mid to late third trimester and has been associated with a slight predominance of male babies (55%).<sup>20,83,84</sup> **Lesions typically begin in the abdominal striae and spare the periumbilical region in up to two thirds of cases (Fig. 51-6, A).**<sup>1,85</sup> PEP can be difficult to characterize because the eruption is polymorphous and can include urticarial and occasionally vesicular, purpuric, polycyclic, or targetoid lesions reminiscent of erythema multiforme or herpes gestationis (see Fig. 51-6, B).<sup>84</sup> Although lesions can spread over the trunk and extremities, they usually spare the palms and soles, and involvement of the face is very unusual.

Generalized PEP may resemble a toxic erythema or atopic dermatitis (see Fig. 51-6, C).

Skin histopathology is often nonspecific and shows spongiotic dermatitis with variable numbers of eosinophils. In contrast to PG, immunofluorescence studies and serologic tests are typically negative. IgE elevation (uncontrolled) was reported in 28% of PEP cases in a recent study,<sup>86</sup> but the significance and specificity of IgE elevations in pregnancy remain unclear.<sup>18</sup> The high prevalence (55%) of a personal or family history of atopy<sup>86</sup> has not been confirmed by other studies. The pathogenesis of PEP has not been established, but the immunohistologic profile of skin lesions<sup>87</sup> suggests a delayed hypersensitivity reaction to an unknown antigen. Some authors have proposed that rapid abdominal wall distension in primigravidae may trigger an inflammatory process; this has been supported by the association between PEP and multiple-gestation pregnancy, excess

**FIG 51-6** **A**, Pruritic urticarial papules and plaques of pregnancy (PUPPP) include urticarial lesions that typically start in the abdominal striae. **B**, Vesicular lesions superimposed on urticarial plaques and targetoid lesions reminiscent of erythema multiforme or pemphigoid (herpes) gestationis. **C**, Widespread PUPPP may resemble a toxic erythema or atopic dermatitis. (Courtesy Helen Raynham, MD.)

maternal weight gain, and fetal macrosomia.<sup>88,89</sup> A meta-analysis revealed a tenfold higher prevalence of multiple gestation in pregnancies affected by PEP.<sup>85</sup> Multiple-gestation pregnancy is associated with higher estrogen and progesterone levels, and progesterone has been shown to aggravate the inflammatory process at the tissue level. Interestingly, increased progesterone receptor levels have been detected in skin lesions of PEP.<sup>90</sup> Finally, fetal DNA has been detected in PEP lesions.<sup>91</sup> Still, the importance of microchimerism in the pathogenesis of PEP remains uncertain.

**PEP is not associated with adverse maternal or fetal outcomes.** The association with cesarean delivery in two recent studies needs to be clarified.<sup>92</sup> The goal of therapy is the relief of maternal discomfort. Mild PEP can be treated with antipruritic topical medications, topical steroids, and oral antihistamines. In cases of severe itching, a short course of oral prednisone may be necessary. UVB has been used anecdotally.<sup>85</sup>

### Atopic Eruption of Pregnancy

AEP is a clinical entity that encompasses prurigo of pregnancy (PP), pruritic folliculitis of pregnancy (PFP), and atopic dermatitis (AD); this includes *new* AD, defined as AD that develops for the first time in gestation.<sup>17,93,94</sup> This reclassification was suggested given the clinical overlap of an atopic diathesis—that is, a personal or family history of atopy or elevated IgE levels—seen in 79% of all affected patients. Further, AEP patients had an earlier eczematous onset, and 75% of patients developed symptoms prior to the third trimester.<sup>17</sup> Features of patchy eczema (*E-type* AEP, seen in 67%) and papular/prurigo (*P-type* AEP, seen in 33%) can coexist.<sup>17,93,94</sup> In addition, up to 34% of patients with AEP had a history of AEP in prior pregnancies.<sup>17</sup> Atopic sites—flexural surfaces; face and neck, including the vee of the neck and upper chest; and the trunk (68%)—were the most frequently involved areas.<sup>16,17</sup> Hand and

**FIG 51-7** Pruritic folliculitis of pregnancy appears as discrete follicular erythematous or pigmented papules on the abdomen.

foot eczema and, less commonly, eczema of the nipple/areola, dyshidrosis, and follicular eczema have been reported. The likelihood for eczematous flares in nonpregnant and postpartum states has not been elucidated.

Differential diagnoses include obstetric cholestasis, contact dermatitis, drug eruptions, and infestations such as scabies. **The earlier onset, prior to the third trimester, may help distinguish AEP from other pregnancy dermatoses such as pemphigoid gestationis and PEP.** No histopathologic distinction exists between AEP and PEP. Maternal and fetal prognosis is unaffected in the absence of superinfection. As with all AD, the risk of bacterial or viral infection is increased. Management is as discussed in the AD section.

### Prurigo of Pregnancy

**Prurigo of pregnancy (PP) affects between 1 in 300 and 1 in 450 pregnancies. It manifests itself with grouped excoriated or crusted pruritic papules over the extensor surfaces of the extremities and occasionally on the trunk and elsewhere** (see Table 51-2).<sup>1</sup> The condition lacks pathognomonic histopathologic features, and skin immunofluorescence is negative. Serologic tests may show elevated IgE levels.<sup>16</sup> Early reports<sup>95</sup> of a dismal fetal outcome in patients with PP have not been confirmed by subsequent studies, and **PP has not been associated with increased maternal risk.** PP should be differentiated from pruritic dermatoses unrelated to pregnancy, other specific dermatoses of pregnancy, drug eruptions, arthropod bites, and infestations such as scabies. PP is treated with moderately potent topical steroids, if necessary intralesional or under occlusion, and oral antihistamines.<sup>85</sup> A short course of oral steroids is rarely required.

PP has been associated with a family history of intrahepatic cholestasis of pregnancy (ICP; see Chapter 47). **It has been proposed that PP and ICP are closely related conditions, distinguished only by the absence of primary lesions in ICP.**<sup>16</sup> These authors reported an association with a personal or family history of AD and elevation of serum IgE (uncontrolled) and suggested that PP may be the result of ICP in women with an atopic predisposition. A reclassification of PP under AEP by the

same group<sup>17</sup> has been debated<sup>18</sup> because some PP patients have no history of AD and no established atopic background, and several PP patients fulfill only minor criteria of atopy.<sup>17</sup> Furthermore, the association with atopy has not been confirmed by other groups, and the importance of mild serum IgE elevations in pregnancy has been controversial.<sup>18,20</sup>

### Pruritic Folliculitis of Pregnancy

**Pruritic folliculitis of pregnancy (PFP) is a rare specific dermatosis of pregnancy,** the exact prevalence of which remains unknown (see Table 51-2). Approximately 30 cases have been reported.<sup>20</sup> **PFP presents with pruritic follicular erythematous papules and pustules that affect primarily the trunk** (Fig. 51-7).<sup>96</sup> PFP resolves spontaneously at delivery or postpartum but may recur in subsequent pregnancies.<sup>71</sup> The histopathology is that of folliculitis, and special stains for microorganisms are negative. Skin immunofluorescence studies and serology are negative. The differential diagnosis of PFP includes an infectious folliculitis and specific dermatoses of pregnancy. An infectious folliculitis can be ruled out with stains for microorganisms and cultures from the pustular lesions. PFP was associated with decreased birthweight and a male to female ratio of 2:1 in one study.<sup>16</sup> Preterm delivery was reported in one case, but no other maternal or fetal risks have been noted.

The pregnant patient should be reassured that **PFP resolves postpartum and has not been associated with substantial risks for the fetus.** PFP has been treated with low potency or midpotent topical steroids, benzoyl peroxide, and UVB.<sup>97</sup> The etiology of PFP remains unknown. Increased serum androgen levels in PFP or association with ICP have been reported but were probably coincidental. It has been postulated that PFP may be a form of hormonally induced acne, based on clinical similarities with the acne that develops after the administration of systemic steroids or progestogens.<sup>98</sup> Other authors<sup>71</sup> have considered PFP to be a variant of PEP based on reports of follicular lesions in some PEP patients. Nevertheless, the clinical presentation and histopathology of PFP differs overall from those of PEP. An association with *Pityrosporum* has been debated.<sup>99</sup> A reclassification<sup>17</sup> of PFP under AEP on the basis of personal and family

history of eczema in a patient with PFP has been debated<sup>18</sup> because history of atopy has not been reported in other PFP cases. Further studies are required to define whether PFP is a distinct specific dermatosis of pregnancy.

### KEY POINTS

- ◆ With the physiologic skin changes of pregnancy, no risks are incurred for the mother or fetus. The changes should be expected to resolve postpartum.
- ◆ Preexisting melanocytic nevi may show mild changes in pregnancy, but no increased risk for malignant transformation exists.
- ◆ Preexisting skin disorders are more likely to worsen than improve in pregnancy; atopic dermatitis (eczema) is the most common dermatosis in pregnancy.
- ◆ Prognosis of melanoma is not adversely affected by pregnancy.
- ◆ Pruritus occurs in up to 3% to 14% of pregnancies. A constellation of clinical and laboratory findings is crucial to establishing etiology.
- ◆ Impetigo herpetiformis (pustular psoriasis of pregnancy) is often associated with reduced calcium or vitamin D. Serious maternal and fetal risks are associated with this disease.
- ◆ PG typically flares at delivery, and treatment is with oral steroids. Mild fetal risks—such as small-for-gestational-age infants, preterm delivery, and neonatal PG—have been associated with this disease.
- ◆ PEP commonly starts in the abdominal striae and spares the periumbilical area. It is associated with multiple gestation pregnancy, but no maternal or fetal risks are apparent.
- ◆ PP and PFP carry no maternal or fetal risks.

Maternal and perinatal infections represent common complications of the peripartum interval. In many industrialized nations, the role of sexually transmitted pathogens is declining in its relative contribution to infections in women; however, in the United States and developing nations, the epidemic persists. Many of these pathogens are either proved or presumed to play an integral role in infectious morbidities of pregnancy and the neonatal period, and thus understanding the social, economic, and pathophysiological burden is essential. Indeed, as our ability to readily

screen the population as a whole has improved for the most prevalent or serious of these infectious agents—*Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and *Treponema pallidum*—epidemiologic statistics have provided evidence for their implied role in preterm labor, preterm premature rupture of the membranes, intrauterine growth restriction, neonatal conjunctivitis, neonatal pneumonia, and congenital syphilis. Thus a greater understanding of the role of these prevalent pathogens in mediating disease pathogenesis has mandated that the obstetrician be well versed in the identification and management of these organisms. In this chapter, we review current trends in epidemiology, diagnosis, treatment, and prevention of common sexually transmitted infections.

## CHLAMYDIA

### Epidemiology

The two most valuable sources of incidence and prevalence data on sexually transmitted pathogens are provided by the Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO). The CDC reports sexually transmitted disease (STD) estimates for the United States using reported cases and estimates after accounting for under-reporting. The Institute of Medicine (IOM) provides WHO estimates on worldwide incidences and prevalence of the four curable sexually transmitted infections: *Chlamydia*, gonorrhea, syphilis, and *Trichomonas*. **Overall, the WHO 2008 global estimate places the incidence at 105.7 million new cases of chlamydia infection, 106.1 million new cases of gonorrhea, and 10.6 million new cases of syphilis among people aged 15 to 49 years.** In addition, epidemiologic studies have revealed a number of basic principles regarding STDs: (1) sexually active adolescents have the highest rates of STDs of any age group<sup>1</sup>; (2) sex differences are observed in the transmission of the most prevalent STDs, with more efficient transmission from men to women; (3) curable STDs (i.e., not human immunodeficiency virus [HIV], human papillomavirus [HPV], or chronic recurrent herpes simplex virus [HSV]) are associated with more serious long-term consequences in women than in men; (4) having one or more STDs predisposes an individual to acquisition and

transmission of other STDs; (5) STDs in developing nations are often constantly prevalent at a high rate and affect all age groups; and (6) marked racial disparity is apparent.

**Genital tract chlamydial infections are generally ascribed to *C. trachomatis* and account for the most prevalent reported infectious disease in the United States.** In 2013, more than 1.4 million cases were reported to the CDC.<sup>2</sup> However, the actual presumed number of new cases in the United States, accounting for estimates of underreporting, is estimated at 3 million annually.<sup>1</sup> **These infections present unique problems for public health control programs because 50% to 70% of these infections are clinically silent in women.** Unrecognized and untreated, the bacteria may remain infectious in the host for months and is readily transmitted to sex partners. Furthermore, **most reported infections occur in the 15- to 24-year-old age group**, individuals who often do not participate in preventive health care programs. Estimates on worldwide exposure approximate that 90 million new cases of *C. trachomatis* infection occur on an annual basis, which accounts for a rising majority of perinatal and neonatal complications.<sup>3-6</sup> Of note, a primary goal of the Healthy People 2010 U.S. health promotion initiative is the elimination of racial disparities among multiple sexually transmitted pathogens. An assessment of the racial disparities of nationally notifiable disease for the year 2002 revealed a nearly tenfold increased rate for *Chlamydia* in blacks compared with whites (805.9 vs. 90.2 per 100,000).<sup>7</sup> In 2013, the rate of *Chlamydia* remained 6.4 times higher among blacks compared with whites, although the rate in whites doubled in that same span of time (1147.2 vs. 180.3 per 100,000).<sup>2</sup>

The cost of treatment, prevention, and management of complications of chlamydial infections is estimated at \$2.4 billion annually.<sup>4,6</sup> Taken together, these factors have resulted in **the endorsement of a nationwide broad-based screening program by both the CDC and IOM.**

## Pathogenesis

*Chlamydia* is a sexually transmitted pathogen generally associated with endocervical infection.<sup>8,9</sup> Species of *Chlamydia* were initially serotyped according to their biologic and biochemical properties, and a greater than 95% homology in their 16s ribosomal ribonucleic acid (RNA) sequences was observed. Subsequent molecular analyses led to the reclassification of some *C. psittaci* strains as *C. pneumoniae*, a human pathogen, and *C. pecorum*, a pathogen of ruminants. Nevertheless, of the four species mentioned here, **only *C. trachomatis* and *C. pneumoniae* claim primates as their endogenous hosts.** Each of the species bears multiple strains based on serotype, which in turn are associated with distinct clinical entities. These are summarized in Table 52-1.

**Chlamydiae are obligate intracellular bacteria that grow in eukaryotic epithelial cells, and they have a unique growth cycle, distinct from all other pathogens.** During the 1970s, the infectivity and growth cycle of chlamydiae was initially characterized.<sup>10-14</sup> Known to specifically infect the cuboidal or nonciliated columnar epithelial cells common to the endocervix, urethra, and conjunctiva, this growth cycle involves infection of a susceptible host cell through a receptor-specific phagocytic process. This phagocytic process involves chlamydiae *elementary bodies* (EBs) that bind to the host cell through a heparin sulfate-like molecule to glycosaminoglycan receptors, and these subsequently are phagocytosed into cytoplasmic vacuoles termed *phagosomes*.<sup>15</sup> In this fashion, chlamydiae may be considered to

**TABLE 52-1** SPECTRUM OF HUMAN AND MAMMALIAN DISEASES CAUSED BY CHLAMYDIAE SEROTYPES

| SPECIES SEROTYPE                                   | ACUTE DISEASES   | CLINICAL SEQUELAE  |
|--|--|--|
| <i>Chlamydia trachomatis</i><br>A, B, Ba, C<br>D-K | Conjunctivitis, acute urethral syndrome, cervicitis, endometritis, salpingitis, inclusion conjunctivitis, neonatal pneumonia | Trachoma, proctitis, epididymitis, Reiter syndrome, pelvic inflammatory disease, ectopic pregnancy, tubal infertility, Fitz-Hugh–Curtis syndrome |
| L1, L2, L3   | Lymphogranuloma venereum   | Reactive airway disease  |
| <i>Chlamydia pneumoniae</i>                        | Pharyngitis, sinusitis, bronchitis, community-acquired pneumonia   | Infection is often asymptomatic or mild with only rare life-threatening infection  |
| <i>Chlamydia psittaci</i><br>Parrots, cats, ewes   | Atypical pneumonia, conjunctivitis   | Spontaneous abortion   |

have a unique biphasic life cycle with dimorphic forms that are functionally and morphologically distinct. Once endocytosed, the EB differentiates into a larger pleomorphic form called the *reticulate body* (RB), which replicates by binary fission. The chlamydiae remain in the phagosome throughout their growth cycle, presumptively as an acquired means of escaping host lysosomes.<sup>12-13</sup> The endosome is transported to the distal region of the Golgi apparatus and incorporates host-derived sphingolipids into the inclusion membrane. Thus it appears that chlamydiae are able to intercept host vesicular traffic bound for the plasma membrane to sequester lipids and possibly other host substances synthesized in the Golgi. Subversion of host vesicular traffic may represent a dual advantage for chlamydiae in obtaining materials from the host for its metabolism as well as in modifying the inclusion membrane to evade lysosomal fusion and immune detection.

**Because chlamydiae depend on their host cell for the generation of adenosine triphosphate (ATP), they require viable cells for survival.**<sup>16</sup> Chlamydiae are incapable of de novo nucleotide biosynthesis and thus are dependent on host nucleotide pools. In this manner, this unique pathogen may be considered to be viruslike. On the other hand, chlamydiae resemble a bacterial pathogen in that they contain both DNA and RNA; have a modified rigid cell wall with a lipopolysaccharide (LPS) similar to that in the outer membrane of gram-negative bacteria, albeit lacking the intervening peptidoglycan layer; and multiply by binary fission.<sup>12-16</sup>

Some interesting insights into the interaction of chlamydiae and the host immune system have emerged in the past decade. These new observations include the extensive but unexpected polymorphism of the major outer membrane protein (MOMP), the evidence for genetic susceptibility to disease, and the association of antibody response to the 60-kDa heat shock protein CHSP60 with the development of adverse sequelae following ocular and genital infections. By way of summary, **MOMP is a major target for protective host immune responses, such as neutralizing antibodies and possibly protective T-cell responses.**<sup>17,18</sup> The basis for MOMP antigenic variation is allelic polymorphism at the *omp-1* locus, and immune selection appears to be occurring in host populations frequently exposed

to *C. trachomatis*.<sup>19</sup> Combined with the observations that clear genetic susceptibility to disease is apparent, because only a subset of infected individuals appear to have long-term complications after acute or repeated chlamydial infections, it is now believed that **chronic immune activation plays a role in propagating clinical disease**.<sup>20</sup> Thus susceptibility to chlamydial pelvic inflammatory disease (PID) in a study of sex workers in Nairobi, Kenya has been associated with a human leukocyte antigen (HLA) class I allele, HLA-A31.<sup>21-23</sup> Similarly, allelic variation in the class II allele (DQ) have been shown to be positively associated with *C. trachomatis* tubal infertility.<sup>23,24</sup>

In addition to host genotype playing a role in determining the severity of *Chlamydia*-mediated disease, **aberrations in humoral immunity also appear to modulate clinical disease**. Antibody response to a 57-kDa chlamydial protein was initially observed more frequently in women with tubal infertility than in controls.<sup>9,20</sup> This protein was subsequently identified as a heat shock protein (HSP) of the GroEL family of stress proteins. The association between antibody response to CHSP60 and PID, ectopic pregnancy, tubal infertility, and trachoma has been subsequently observed in a number of population-based serotype studies.<sup>9,10</sup> Suffice it to say that although it remains unclear whether antibody to CHSP60 is causally involved in chlamydial immunopathogenesis or is merely a marker of persistent chlamydial infection, in cells that remain infected with *C. trachomatis*, the constitutive expression of CHSP60 may provide continued antigenic stimulation for the CHSP60 antibody response observed in persons with long-term sequelae. Moreover, observed immunopathology may also result from aberrations in self-tolerance mediated by shared and similar epitopes between CHSP60 and endogenous HSP60, which in turn results in a classic immune cascade that leads to tissue damage.

## Diagnosis

**Because curative antibiotic therapies for chlamydial infections are available and inexpensive, early diagnosis is an essential component of management and prevention.** Historically, isolation of *Chlamydia* in cell culture was the traditional method for laboratory diagnosis, and it has remained the gold standard because of its specificity. However, culture requires expensive equipment, technical expertise, and stringent transport conditions to preserve specimen viability. Thus **chlamydial culture has been replaced by nucleic acid amplification tests (NAATs)**, which are currently recommended for screening for urogenital *C. trachomatis* in men and women, regardless of symptoms.<sup>25</sup> The common characteristic among NAATs is that they are designed to amplify nucleic acid sequences that are specific for the organism being detected and thus do not require viable organisms. The increased sensitivity of NAATs is attributable to their ability to produce a positive signal from as little as a single copy of the target DNA or RNA. **NAATs can be utilized to test for *C. trachomatis* in endocervical swabs from women, urethral swabs from men, first-catch urine from both men and women, and vaginal swabs from women.**<sup>25</sup> The ability of NAATs to detect *C. trachomatis* without a pelvic examination is a key advantage of NAATs, and this ability facilitates screening men and women in nontraditional screening venues. Although false-positive and false-negative results can occur, the performance of NAATs for testing for *C. trachomatis* is superior to both culture and other nonculture tests. The sensitivity of NAATs is generally greater than 90%, and specificity is greater than 99%.<sup>25</sup> Given the performance of the NAATs,

\*Cell culture, direct immunofluorescence, enzyme immunoassay, and nucleic acid hybridization of endocervical specimens are also available.

supplemental testing of NAAT-positive specimens is no longer recommended by the CDC. An additional consideration when using NAATs for detection of *C. trachomatis* is that they are not approved by the Food and Drug Administration (FDA) for test of cure because nucleic acid may remain from noninfective bacteria following treatment for up to 3 weeks after infection with *C. trachomatis*.

**Other antigen-detection methods—such as enzyme immunoassay (EIA), direct fluorescence assay (DFA), nucleic acid hybridization/probe tests, and nucleic acid genetic transformation tests—are also available but are generally not recommended for routine testing for genital tract specimens.** Additionally, serology screening has limited or no value in testing for uncomplicated genital *C. trachomatis* infection and should not be used for screening because previous chlamydial infection frequently elicits long-lasting antibodies that cannot be easily distinguished from the antibodies produced in a current infection. Table 52-2 summarizes the screening recommendations for *C. trachomatis* in pregnancy.

## Treatment

The recommended treatment regimen for uncomplicated genital *Chlamydia* infection has remained largely unchanged since 1998, with the exception of amoxicillin now being considered an alternative regimen due to treatment failures in response to penicillin-class antibiotics in vitro and in animal studies. **In pregnancy, the CDC recommends azithromycin in a single 1-g oral dose (Box 52-1).** Amoxicillin 500 mg orally three times daily for 7 days and various erythromycin formulations are also available with dosing that can be utilized as an alternative regimen (see Box 52-1). **Doxycycline, ofloxacin, and levofloxacin are part of the treatment options in a nonpregnant patient; however, they are contraindicated in pregnancy and should not be used in this population.** To minimize transmission and reinfection, patients should be instructed to abstain from sexual intercourse for 7 days after single-dose therapy or until completion of a 7-day regimen and should also be instructed to abstain from sexual intercourse until all of their sex partners have been treated for the same duration. **A repeat chlamydial test should be performed 3 to 4 weeks after treatment is completed.** Longitudinal studies of *Chlamydia*-infected adolescent female patients have demonstrated a high risk for *Chlamydia* reinfection and for other STD infections within a few months of initial diagnosis. Because of the high incidence of

\*The Centers for Disease Control and Prevention recommends treating individuals with a positive *Chlamydia*-sensitive nucleic acid amplification test (NAAT). Although tetracycline and doxycycline have the greatest activity against *C. trachomatis*, these drugs should not be used in pregnancy because of their effects on bone and on dental enamel of the developing fetus (see Chapter 8). Owing to gastrointestinal side effects with erythromycin, azithromycin is the drug of choice in pregnancy.

†Sex partners within the preceding 60 days of diagnosis or the most recent sex partner, if that has been longer than 60 days, should be evaluated and treated also.

*Chlamydia* infection that can occur in the months following a treated infection, CDC guidelines recommend that health care providers repeat testing 3 months after infection.<sup>26</sup> Additionally, **women under the age of 25 and patients at high risk for *Chlamydia* infection should be retested in the third trimester of pregnancy.** In addition to treating the pregnant woman, any sex partners within the preceding 60 days of diagnosis—or the most recent sex partner, if that has been longer than 60 days—should be evaluated and treated to help reduce the rate of reinfection as well as infection of others.<sup>26</sup>

## GONORRHEA

### Epidemiology

The reported incidence of *Neisseria gonorrhoeae* infection was 333,004 cases in the United States in 2013 (106.1 cases per 100,000).<sup>2</sup> However, the actual number of reported cases may be underrepresented by as much as 40%, yielding a U.S. estimate of 700,000 cases annually.<sup>27</sup> In contrast to *Chlamydia*, the worldwide prevalence of gonorrhea may be significantly less than that observed in the United States, as supported by epidemiologic data from Canada and Western Europe.<sup>28</sup>

Historically, a review of trends in the incidence of reported gonorrhea in the United States from 1941 to 1997 reveals peak increases among both men and women in the interval around World War II and again in 1975, peaking at 473 cases per 100,000.<sup>27</sup> The steady decline since 1975 has been accompanied by three interesting observations. First, the male-to-female ratio of reported cases not only declined from a high of 3:1, it changed to a female prevalence in 2013, by a ratio of 1:2.<sup>2,8</sup> Second, racial disparity is noted, with a 12.4-fold higher rate among blacks compared with whites (426.6 vs. 34.5 per 100,000).<sup>2</sup> Third, the single greatest determinant of

gonorrhea incidence since 1975 has so far been age: annual reported cases are highest in adolescents aged 15 to 19 years (459.2 per 100,000) and in young adults aged 20 to 24 years (541.6 per 100,000).<sup>2</sup>

### Pathogenesis

In contrast to chlamydiae species, the pathogenesis of *N. gonorrhoeae* and human disease is more straightforward and reflects classic bacterial pathogenesis. *N. gonorrhoeae* is a **gram-negative diplococcus for which humans are the only natural host.** Like the other endocervical infectious pathogens, gonorrhea also bears a predilection for the columnar epithelium, which lines the mucous membranes of the anogenital tract.<sup>27,29</sup> Gonococcal pathogens adhere to these mucosal cells through attachment of pili and other surface proteins, which results in the release of lipopolysaccharide and likely instigates mucosal damage. Following adherence, *N. gonorrhoeae* is pinocytosed and is thereby transported into epithelial cells. Unlike chlamydiae, the gonococcus does not replicate in the phagosome, and hence it evades lysosomal degradation. **Rather gonococci persist in the host by virtue of their ability to alter the host environment.** In sum, multiple structures of *N. gonorrhoeae* enable pathogenesis by a variety of immune-evasive mechanisms that include immunoglobulin A (IgA) protease, iron repression, and cell-adherence mechanisms.<sup>27,29</sup>

### Diagnosis

**The gold standard for diagnosis of gonorrhea infection was previously isolation of the organism by culture.** Traditionally, specimens are streaked on a selective (Thayer-Martin or Martin-Lewis) or nonselective (chocolate agar) medium. Inoculated media are incubated at 35° to 36.5°C in an atmosphere supplemented with 5% CO<sub>2</sub> and are evaluated at 24 and 48 hours. Subsequent diagnosis is made by identification of the organism with growth on the medium, with a Gram stain and oxidase test on colonies identifying Gram-negative, oxidase-positive diplococci morphology. A confirmed laboratory diagnosis of *N. gonorrhoeae* cannot be made on the basis of these tests alone. However, **antimicrobial therapy should be initiated following an initial presumptive test result, but additional tests must be performed to confirm the identity of an isolate as *N. gonorrhoeae*.** Whereas culture isolation is also suitable for non-genital tract specimens, using selective media is necessary if the anatomic source of the specimen normally contains other bacterial species.

The advantages of gonorrheal culture are high sensitivity and specificity, low cost, suitability for use with different types of specimens, and the ability to retain the isolate for additional testing. The major disadvantage of culture for *N. gonorrhoeae* is that specimens must be transported under conditions adequate to maintain the viability of organisms. Another disadvantage is that a minimum of 24 to 48 hours is required from specimen collection to the report of a presumptive culture result.<sup>25</sup> Due to the technical difficulties with culture, other nonculture tests were developed. However, the importance of maintaining the option of culture remains important for *N. gonorrhoeae*. **Indications for culture for *N. gonorrhoeae* include testing in suspected cases of treatment failure, monitoring antibiotic resistance, and testing in cases of suspected extragenital infection and exposure due to sexual abuse.**

As with *C. trachomatis*, the **current recommended test for routine screening for *N. gonorrhoeae* is NAATs** regardless of

\*Cell culture and nucleic acid hybridization of endocervical specimens are also available.

symptoms.<sup>25</sup> NAATs can be utilized to test for *N. gonorrhoeae* in endocervical swabs from women, urethral swabs from men, first-catch urine from both men and women, and vaginal swabs from women.<sup>25</sup> The ability of NAATs to detect *N. gonorrhoeae* without a pelvic examination is a key advantage of NAATs, and this ability facilitates screening men and women in nontraditional screening venues. Whereas false-positive and false-negative results can occur, the performance of NAATs for testing for *N. gonorrhoeae* is superior to both culture and other nonculture tests. The sensitivity of NAATs is generally greater than 90%, and specificity is greater than 99%.<sup>25</sup> Given the performance of NAATs, supplemental testing of NAAT-positive specimens is no longer recommended by the CDC. An additional consideration when using NAATs for detection of *N. gonorrhoeae* is that they are not FDA approved for test of cure because nucleic acid may remain from noninfective bacteria following treatment for up to 2 weeks.

Additional tests have been studied for *N. gonorrhoeae* testing. Nucleic acid hybridization assays are available to detect *N. gonorrhoeae*, although they are not recommended for routine use and are no longer routinely available. A large number of EIA tests for detecting *N. gonorrhoeae* infection have been studied, but their performance and cost characteristics for *N. gonorrhoeae* infection have not made them competitive with other available tests.<sup>25</sup> Similar to EIAs, DFA is also not appropriate as a diagnostic test for the direct detection of *N. gonorrhoeae* in clinical specimens.<sup>25</sup> A serologic screening or diagnostic assay is not available for *N. gonorrhoeae*. Table 52-3 reviews the recommended screening for *N. gonorrhoeae* in infections in pregnancy.

## Treatment

Although uncomplicated genital gonorrhea infections can be treated with single-dose therapy, fewer oral treatment options are available compared with the efficacious therapies available for chlamydial infections (Box 52-2). Moreover, recent emergence of quinolone-resistant *N. gonorrhoeae* in California, Hawaii, Asia, and the Pacific Islands has led to the generalized recommendation that these agents should not be used to treat gonorrhea infections acquired in these areas or in areas with an increased prevalence of quinolone resistance.<sup>25</sup> The CDC recommendations became somewhat complicated in July 2002, when Wyeth Pharmaceuticals discontinued cefixime. However, in April of 2008, Lupin Pharmaceuticals began manufacturing and providing cefixime tablets. Currently, cefixime is only recommended for the treatment of uncomplicated genital *N. gonorrhoeae* infections if ceftriaxone is not available. In addition, because of the risk for coinfectivity with *N. gonorrhoeae* and

## BOX 52-2 RECOMMENDED TREATMENT REGIMEN\* FOR UNCOMPLICATED GENITAL *NEISSERIA GONORRHOEAE* INFECTIONS IN PREGNANCY†

### Standard Regimen

Ceftriaxone, 250 mg intramuscularly in a single dose  
Plus azithromycin, 1g orally in a single dose

Modified from Workowski KA, Bolan GA; Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Morb Mortal Wkly Rep.* 2015;64(RR-03):1-137.

\*The Centers for Disease Control and Prevention recommends treating individuals with a positive gonorrhea test result for both gonorrhea and Chlamydia. Consult with an infectious disease specialist if the patient has cephalosporin allergy and spectinomycin is not available.

†Sex partners within the preceding 60 days of diagnosis, or most recent sex partner if that has been longer than 60 days, should be evaluated and treated for *Neisseria Gonorrhoeae*.

*C. trachomatis*, the CDC recommends empirically treating patients with positive gonorrhea test results for both gonorrhea and Chlamydia.<sup>25</sup>

In 2007, the Gonococcal Isolate Surveillance Project (GISP) found 27% of *N. gonorrhoeae* infections were resistant to penicillin, tetracycline, ciprofloxacin, or a combination of these antibiotics. In 2009, the CDC Working Group for Cephalosporin-Resistant Gonorrhea Outbreak Response Plan was convened to address the growing resistance to these antibiotics by *N. gonorrhoeae*.<sup>30</sup> In their *Morbidity and Mortality Weekly Report* from May of 2011, the CDC reviewed five cases of urethral gonorrhea with high mean inhibitory capacities (9.1%) of azithromycin, which represented 10% of those treated for *N. gonorrhoeae* in San Diego County from August to October of 2009.<sup>31</sup> In this monograph, the CDC reinforced the 2010 STD Treatment Guidelines that recommend dual therapy with 250 mg ceftriaxone and 1 g of azithromycin orally for uncomplicated urogenital, rectal, and pharyngeal gonorrhea. The CDC does not recommend azithromycin as monotherapy in the treatment of gonorrhea due to the concern over development of resistance and reported treatment failures. Spectinomycin can be used to treat uncomplicated urogenital infections with good success; however, it is expensive and not produced in the United States. As with chlamydial infections, any sex partners within the preceding 60 days of diagnosis—or the most recent sex partner, if the interval has been longer than 60 days—should be evaluated and treated for gonorrhea to help reduce the rate of reinfection as well as the infection of others. These guidelines are also consistent with the 2015 CDC recommendations (see Box 52-2).

## SYPHILIS

### Epidemiology

Historically, syphilis has long been recognized as a chronic systemic infectious process secondary to infection with the spirochete *Treponema pallidum*. Throughout the centuries, epidemics of syphilis have been periodically reported. In the United States, the observed incidence of primary and secondary syphilis initially mirrored that of gonorrhea (reflecting the principle that epidemiologic synergy among the STDs occurs), with a rising peak during and shortly after World War II to 76 per 100,000 population to its reported nadir of 4 per 100,000 from 1955 through 1957.<sup>32</sup> Since the mid-1950s, recurrent epidemics

have occurred, the most recent in 1985 to 1990, with a peak incidence of 23.5 cases per 100,000.<sup>33</sup> Beginning in 2001, syphilis increased each year to 13,997 cases in 2009.<sup>1</sup> In 2010 there was a decline in the rate of syphilis, with a subsequent increase of 22% between 2011 and 2013.<sup>2</sup> The increased rate of syphilis during this period was seen for men only; the rates for women remained the same.<sup>2</sup>

Of concern are observations from both the WHO and CDC that the prevalence of syphilis in both the United States and developing nations has fluctuated over the past two decades. Noted again are elements of racial disparity, with a disproportionate number of cases in blacks compared with whites (16.8 vs. 3.0 per 100,000), and sex and age disparity, with a predilection for women aged 20 to 24 years.<sup>2,27</sup>

## Pathogenesis

**Syphilis is a chronic disease caused by the spirochete *Treponema pallidum*.** *T. pallidum* belongs to the order Spirochaetales, characterized by slender, nonflagellated, flexuous, tightly spiraled protozoa-like organisms. It is an anaerobic and obligate human parasite. Motility is attained by the flexuous bending of its long slender body. **This motility is responsible for the attainment of access through disrupted integument, mostly mucous membranous, primarily during sexual contact.** *T. pallidum* invades the host and evades the host defense mechanisms while **being completely dependent on the host for survival.** It lacks the fundamental biosynthetic machinery to create complex molecules and fatty acids.<sup>34,35</sup> The ability to evade the host defense mechanisms stems from its basic construct of an inner membrane with few integral membrane proteins that protrude through the surface to gain exposure through the outer membrane.<sup>36</sup> Berman<sup>37</sup> concluded that this construct “may provide some understanding of how the organism elicits such a vigorous inflammatory and immunological response but manages to evade immunological clearance, although a paucity of surface proteins means that its surface presents few targets for a host immune response.”

**Following mucosal invasion, an incubation period of about 1 week to 3 months ensues until the chancre appears to herald the primary infection.** The chancre arises at the point of entry by the spirochetes and is a broad-based, typically nontender ulcerated lesion that gives a characteristic “woody” or “rubbery” feel on palpation. It is seldom secondarily infected, and it resolves without medical treatment in 3 to 6 weeks. The organism then hematogenously spreads through the body during the period in which the immune system has responded, usually about 4 to 10 weeks.<sup>27</sup> Secondary syphilis is characterized by a generalized maculopapular eruption, constitutional symptoms, major organ involvement, and lymphadenopathy. Like the other major organ systems, the central nervous system (CNS) is invaded in about 40% of individuals during this hematogenous phase.<sup>38,39</sup> Secondary syphilis resolves over 2 to 6 weeks as the patient enters the latent phase of the disease.<sup>27</sup> The latent phase is divided into *early latent* (<1 year) and *late latent* (>1 year) disease, during which no symptoms or signs of clinical disease are noted. If left untreated, progression to tertiary disease with cardiovascular system, CNS, and musculoskeletal system involvement occurs. The organism has an affinity for the arterioles, and the inflammatory response that follows results in obliterative endarteritis and subsequent end-organ destruction.<sup>40</sup> In immunocompromised individuals (e.g., those

on immune-suppressive medications, those with HIV infection), the progression to tertiary disease, especially of the CNS, is known to occur early after the onset of disease.

## Diagnosis

**The ability to diagnose infection with *T. pallidum* has been problematic for two primary reasons. The first is the failure of the organism, as of yet, to be cultured on an artificial medium. The second lies in the long-recognized tendency of the clinical manifestations to mimic a variety of other diseases.** Reports continue to surface touting the difficulty with which syphilis is recognized at any stage.<sup>41</sup> Primary syphilis often goes unrecognized by the infected individual. Although the primary genital lesion of syphilis, the chancre, is commonly recognized by affected males, women more often than not fail to identify this lesion because it typically occurs without associated constitutional symptoms. **If primary syphilis is suspected, examination of the serous exudates from the chancre under darkfield microscopy can definitively diagnose the condition by identification of the flexuous-bodied (spiral) organism.** Unfortunately, darkfield microscopy lacks sensitivity, owing in part to specimen collection technique. The lesion must be abraded with a gauze sponge or cotton-tipped applicator until bleeding ensues; the clinician must then squeeze the lesion to express clear serum, which is pressed onto a microscope slide. DFAs have the advantage that they can be performed on slides that are air dried as well as on stored paraffin-embedded tissue.<sup>42</sup> Polymerase chain reaction (PCR) has increased the sensitivity for detection in samples obtained from genital lesions, cerebrospinal fluid (CSF), amniotic fluid, serum, and paraffin-embedded tissue.<sup>43</sup>

**Because most individuals infected with *T. pallidum* are in the asymptomatic latent phase of the disease, serologic testing is the primary means of diagnosis.** Two types of serologic tests are currently available, nontreponemal tests and treponemal tests. The *nontreponemal tests* include the rapid plasma reagin (RPR) and the Venereal Disease Research Laboratories (VDRL) tests. False-positive reactions occur with nontreponemal tests secondary to viral infections or autoimmune disease.<sup>26</sup> If a nontreponemal test is positive, a *treponemal test* is subsequently performed to confirm the diagnosis of syphilis. The treponemal tests include the fluorescent treponemal antibody absorbed (FTA-ABS) tests, the *T. pallidum* passive particle agglutination assay (TP-PA), as well as other EIAs and chemiluminescence immunoassays.<sup>26</sup> Once appropriately treated, most individuals—pregnant or not—lose reactivity to these nontreponemal serologic tests. **For most individuals, the treponemal tests remain positive lifelong.**<sup>44</sup> Table 52-4 reviews the recommended screening for syphilis infections in pregnancy.

Although in most HIV-infected individuals serologic testing is accurate and reliable, occasionally a clinician will encounter patients with expressed lesion exudates or biopsy-proven disease, and serologic testing is negative.<sup>44</sup> **The following recommendations for diagnosing syphilis in HIV-infected individuals have been made by the CDC.**<sup>45</sup> First, individuals with HIV should be screened for syphilis, and all sexually active individuals with syphilis should be screened for HIV. If clinical examination and findings suggest syphilis in the presence of negative serologic testing, DFA for *T. pallidum* staining of lesion exudates and biopsy or darkfield microscopic examination should be performed. In these individuals, all laboratories should titrate the nontreponemal tests (RPR, VDRL) to the exact final end point

Cell culture and nucleic acid hybridization of endocervical specimens are also available.

to better guide response to therapy. Finally, neurosyphilis must be entertained as a diagnosis in HIV-infected individuals, and appropriate consultations should be obtained to better interpret serologic results.

Neurosyphilis is diagnosed in non-HIV-infected and in HIV-infected patients by examination of CSF obtained by a spinal tap. Individuals in whom CSF testing should be considered include those with neurologic or ophthalmologic symptoms, active tertiary disease, or treatment failure and HIV-positive individuals.<sup>26</sup> Spinal tap and examination of CSF is not currently recommended in non-HIV-infected individuals who have early asymptomatic syphilis.<sup>26</sup>

## Treatment

It was not long after the introduction of penicillin, about the time of World War II, that it became recognized as the primary antimicrobial for the treatment of syphilis. **Penicillin has been effective in the treatment of disease and in the prevention of disease progression in both nonpregnant and pregnant women, and it has also been used in the prevention and treatment of congenital syphilis (Box 52-3).**<sup>26,46</sup> CDC 2015 treatment guidelines recommend benzathine penicillin G—2.4 miU intramuscularly (IM) as a single dose—for primary, secondary, and early latent syphilis in both pregnant and nonpregnant women.<sup>26</sup> Late latent syphilis and latent syphilis of unknown duration are treated with benzathine penicillin G, 2.4 miU IM weekly for three doses (7.2 miU total).<sup>26</sup> If a dose is missed during pregnancy it is recommended that a full treatment course be repeated. Treatment can precipitate a Jarish-Herxheimer reaction, which can lead to preterm labor and or fetal distress. Women being treated for syphilis in pregnancy should be counseled to seek evaluation if they develop fever, contractions, or decreased fetal movement.

Individuals with documented allergies to penicillin present a particular treatment problem. Treatment recommendations differ depending on whether the penicillin-allergic individual is pregnant. Due to the increased risk for treatment failure with alternative therapies, close follow-up is crucial to determine treatment response. Penicillin is the only therapy that has been proven to be effective in the treatment of congenital syphilis, syphilis in pregnant women, and neurosyphilis, and the alternative therapies should not be considered for these.<sup>26</sup> These aforementioned patients should be managed in conjunction with an infectious disease specialist and should undergo penicillin desensitization and penicillin therapy. **The initial evaluation of patients with a penicillin allergy should begin with skin testing with both major and minor determinants.**<sup>26</sup>

## BOX 52-3 RECOMMENDED TREATMENT REGIMENS\* FOR *TREPONEMA PALLIDUM* INFECTIONS

### Primary, Secondary, Early Latent Disease

Benzathine penicillin G, 2.4 million U IM as a single dose

### Late Latent and Latent Disease of Unknown Duration

Benzathine penicillin G, 2.4 miU IM weekly for three doses (7.2 miU total)

### Tertiary Disease

#### NEUROSYPHILIS

Aqueous crystalline penicillin G, 18 to 24 miU/day IV (3 to 4 miU every 4 hours or continuous infusion) for 10 to 14 days *or*

Procaine penicillin G, 2.4 miU IM once daily with probenecid 500 mg PO four times a day for 10 to 14 days if compliance can be ensured

#### WITHOUT NEUROSYPHILIS

Benzathine penicillin G, 2.4 miU IM weekly for 3 weeks (7.2 miU total)

### Penicillin Allergy (Documented)

#### IN PREGNANCY

Desensitization and penicillin therapy as above

Modified from Workowski KA, Bolan GA; Centers for Disease Control and Prevention (CDC): Sexually transmitted diseases treatment guidelines, 2015. *MMWR Morb Mortal Wkly Rep.* 2015;64(RR-03):1-137.

\*The CDC recommends penicillin as the treatment of choice in individuals with syphilis.

IM, intramuscularly; IV, intravenously; miU, million units; PO, per os.

**Those with a reported penicillin allergy and negative skin testing may receive penicillin therapy. However, patients who have had a positive skin test should undergo penicillin desensitization with subsequent administration of penicillin therapy.**<sup>26,47</sup>

Therapy for tertiary syphilis is dependent on the presence or absence of neurosyphilis. Provided CSF examination is negative, individuals are treated with benzathine penicillin G, 2.4 miU IM weekly for 3 weeks (7.2 miU total).<sup>26</sup> If neurosyphilis has been diagnosed, aqueous crystalline penicillin G, 18 to 24 miU IV daily (3 to 4 miU every 4 hours or continuous infusion) is given for 10 to 14 days. An alternative therapy in compliant individuals is procaine penicillin, 2.4 miU IM once daily, along with probenecid, 500 mg orally four times a day for 10 to 14 days.<sup>26</sup> A follow-up CSF evaluation is recommended to assess response to therapy.

## CONGENITAL SYPHILIS

Congenital syphilis continues to be a problem worldwide, and as such, the WHO has established elimination of congenital syphilis as one of the millennium goals.<sup>48</sup> **In 2008, it was estimated that approximately 1.86 million cases of syphilis occurred in pregnant women around the world. In their most recent report, the CDC summarized congenital syphilis surveillance data for 2013, which indicated that congenital syphilis rates decreased among all racial and ethnic minority populations from 2009 to 2013, with the exception of Native Americans and Alaska Natives.<sup>2</sup> However, the rates of congenital syphilis remain disproportionately high in blacks and Hispanics.<sup>2</sup> The**

rates of congenital syphilis per 100,000 liveborn infants were determined from U.S. natality data and demonstrated a decrease from 10.4 to 8.4 cases per 100,000 live births between 2009 and 2012, respectively. **This reflects a decrease in primary and secondary syphilis rates among reproductive-aged women, a decline from 1.5 to 0.9 cases per 100,000.**<sup>2</sup>

**Congenital syphilis infection results from transplacental migration of the organism to the fetus. Congenital disease can occur at any stage of maternal infection and at any gestational age.**<sup>49</sup> Past theories of a placental impasse during the first half of gestation were disproved by pathologic examination of infected first-trimester abortuses and by the demonstration of living organisms in amniotic fluid obtained by amniocentesis in the early second trimester.<sup>49,50</sup> It is now believed that **transplacental infection must be close to 100% during the early stages of maternal disease because of the known hematogenous spread, with rates of transmission falling to 10% as bacteremia abates with the subsequent mounting of the maternal immunologic response during late latent disease.**<sup>51-</sup>

<sup>53</sup> Also of importance in the pathogenesis of fetal disease is knowledge of fetal immunologic development. Disease early in gestation incites little response because the fetal immune system functions little until midgestation. Following this period, the fetus is able to mount a vigorous response with marked endarteritis and end-organ involvement. **The risk for adverse pregnancy outcome in pregnant women with syphilis that was untreated is approximately 52%.<sup>54</sup> The specific risks include a higher risk for miscarriage or stillbirth (21%), neonatal death (9.3%), premature birth or low birthweight (5.8%), and clinical evidence of congenital infection (15%) when compared with the risks in women without syphilis.**<sup>54</sup>

Nonimmune fetal hydrops, polyhydramnios, and intrauterine fetal demise have long been associated with congenital syphilis. Recent reports confirm the constellation of nonimmune hydrops (ascites, pleural effusion, scalp or skin edema), hepatomegaly, polyhydramnios, and placentomegaly as markers for congenital syphilis.<sup>55,56</sup> **Hollier and colleagues<sup>57</sup> prospectively identified and followed 24 women with untreated syphilis to better define the pathophysiology of fetal disease.** Ultrasound examination with amniocentesis and funipuncture was performed. The infected pregnant women were treated with benzathine penicillin G given IM per the CDC guidelines (see Box 52-3). Six women had primary, 12 had secondary, and 6 had early latent syphilis disease. Sixteen of these fetuses (67%) had either congenital syphilis or *T. pallidum* identified in the amniotic fluid specimens. **Maternal stage of disease—primary, secondary, and early latent—correlated with fetal infection rates of 50%, 67%, and 83%, respectively. Ultrasound examination was abnormal in 16 of the 24 fetuses (67%).** Thirteen of these fetuses had hepatomegaly, three had hepatomegaly and ascites, and one had nonimmune hydrops. Increased placental thickness was seen in 17 (71%), and hydramnios was observed in only one fetus with an abnormal ultrasound. **This study demonstrates the utility of ultrasound examination in the diagnosis and management of the syphilis-infected gravida and her unborn child. This is supported by the CDC, which recommends sonographic evaluation of the fetus for evidence of congenital infection if syphilis is diagnosed after 20 weeks' gestation.**

In an effort to reduce the incidence of congenital syphilis, the CDC recommends screening all pregnant women at the time of their first prenatal visit, and again early in the third

**trimester. In addition, women should be screened at delivery if not previously screened, or if they are at high risk.**<sup>26</sup> If prenatal screening is not available, patients should be screened at delivery.<sup>42</sup>

The implementation of appropriate screening and treatment of pregnant women should theoretically result in the elimination of congenital syphilis.<sup>37,51</sup> Despite these screening recommendations, attempts at targeted mass treatment for syphilis in populations at risk in order to reduce outbreaks and ultimately wipe out congenital syphilis have met with failure.<sup>58</sup> **It was estimated by the WHO that approximately one third of women who received prenatal care were not tested for syphilis.**<sup>48</sup> Children continue to be born with increased prematurity, low birthweight, hepatomegaly, and cutaneous and bone lesions in both developing and developed nations.<sup>59</sup> **Almost 90% of stillbirths attributed to congenital syphilis occur among women who are never treated or who are treated inappropriately.**<sup>60</sup> Alexander and colleagues<sup>61</sup> examined the CDC guidelines for the treatment of maternal syphilis among 340 gravidae and found better than 95% success for all stages of clinical disease in preventing congenital disease. Sheffield and associates<sup>62</sup> evaluated 43 women who received antepartum therapy with treatment failure and revealed that preterm delivery (<36 weeks), a short interval between treatment and delivery, a higher VDRL titer at the time of treatment and delivery, and early stage of maternal disease were associated with treatment failure. The optimal management (transplacental through maternal therapy vs. neonatal) of the fetus with severe or advanced clinical disease remains unknown and requires consultation with experienced clinicians.<sup>63</sup>

### KEY POINTS

- ◆ All pregnant women younger than 25 years or those at increased risk should be screened for *Chlamydia* and gonorrhea during pregnancy.
- ◆ Women younger than 25 and those at high risk for sexually transmitted infections should be rescreened for *Chlamydia* during the third trimester.
- ◆ Syphilis screening should be performed at the first prenatal visit as well as early in the third trimester. Repeat testing should be performed at the time of delivery in patients at high risk for syphilis.
- ◆ If syphilis testing was not done during pregnancy, it should be performed postpartum prior to the patient's discharge from the hospital.
- ◆ NAATs of urine, the endocervix, or the vagina is the preferred screening test for both *Chlamydia* and gonorrhea.
- ◆ Screening for syphilis can be performed using either a treponemal or nontreponemal test.
- ◆ Penicillin is the antimicrobial of choice in treating syphilis among pregnant women and for reducing the incidence of congenital syphilis.
- ◆ Pregnant women with a penicillin allergy and syphilis infection should undergo penicillin desensitization with subsequent penicillin therapy.

Viruses have been identified in virtually all organisms. They are among the simplest of living organisms, yet they have significantly influenced history and are an important causative factor for infectious disease. **Viruses are obligate intracellular parasites that utilize the host cell's structural and functional components while exhibiting remarkably diverse strategies for gene expression and replication.** Viral infection ranges from asymptomatic or subclinical to overwhelming and highly lethal, with findings such as meningoencephalitis or hemorrhagic fever with shock. Viral infection is highly variable; many viruses are limited to acute, time-limited infection. However, some viruses establish long-lasting infection. Latent viruses have the capacity to reactivate gene expression many years after acute infection, retroviruses integrate into the host cell genome, and multiple viruses have oncogenic potential.

Virus particles contain nucleic acid and structural proteins, which together are referred to as a *nucleocapsid*. Viral nucleic acid is composed of either DNA or RNA, which may be single or double stranded. Viral genomes can be linear or circular and can exist in multiple segments or as a single segment. Viral genome size ranges from two genes in parvovirus B19 to over 200 genes in cytomegalovirus (CMV). Some viruses have lipid bilayer envelopes external to the nucleocapsid; these envelopes are derived from the host cell and contain viral proteins. Herpes viruses have an additional layer, called a *tegument*, between the nucleocapsid and envelope. Viruses are classified by the International Committee on Taxonomy into orders, families, subfamilies, genera, and species. Classification is based on morphology, nucleic acid type, the presence or absence of an envelope, genome replication strategy, and homology to other viruses.

**Infection is typically initiated by the virus binding to a specific host cell receptor.** Receptors are normally functional host cell membrane proteins but are also recognized by a viral protein ligand within the viral envelope or nucleocapsid. The viral protein and cellular receptor interaction defines, in part,

the host range of the virus, which limits infection to cells that display the appropriate receptor. Virus enters the host cell via translocation of the virion across the plasma membrane; this involves endocytosis or fusion of the viral envelope with the cell membrane. The virus then uncoats its nucleic acid for replication, ultimately leading to viral gene expression and replication. This may occur in either the cytoplasm or nucleus of the cell and may involve integration into the host genome, as in the case of retroviruses. Intracellular assembly of progeny virions occurs followed by release of newly formed virions by cell lysis or by budding from the cell surface, as in the case of most enveloped viruses.

Despite their inability to replicate independently, viruses play a central role in infectious disease, altering the structure and/or the function of the host cell. **For productive infection to occur, viruses must enter cells, replicate their genome, and release infectious virions.** The inability of a virus to complete any of these required steps results in a "nonproductive infection." Viral pathogenesis occurs via several mechanisms and does not require productive infection. These include direct effects on infected host cells, which may result in cell death via lysis or apoptosis. Infected cells can also be killed by antiviral antibody and complement or by cell-mediated immune mechanisms. In addition, some viral genomes encode oncogenes, which can mediate transformation of infected host cells. Viral proteins can also impact the function of uninfected cells, including those of the immune system. Finally, **the host immune response to viral infection encompasses both local and systemic effects via activation of immune cells, the induction of an adaptive immune response, and the release of cytokines, chemokines, and antibodies.** Thus the immune response contributes to or causes the signs and symptoms associated with viral infections, which includes fever, rash, arthralgias, and myalgias. The outcome of viral infection is dependent on host factors such as immune status, age, nutritional status, and genetic background. Genetic factors can alter susceptibility to viral infection, the immune response

generated following infection, and the long-term consequences of viral infection.

This chapter discusses many of the viral infections relevant to pregnancy that have significant impact on maternal health and/or pregnancy outcome. The virology, epidemiology, diagnosis, clinical manifestations, management during pregnancy, and impact on the fetus/neonate are reviewed for the viruses listed in Table 53-1.

## HUMAN IMMUNODEFICIENCY VIRUS

### Virology

Human immunodeficiency virus (HIV) is a member of the Retroviridae family, characterized by spherical, enveloped viruses. The virus envelope surrounds an icosahedral capsid that contains the viral genome and consists of two identical pieces of positive-sense, single-stranded RNA about 9.2 kb long. HIV has a total of nine genes that include three main genes—*gag*, *pol*, and *env*—which are surrounded by long terminal repeat (LTR) regions. The *gag* gene encodes the precursor for the virion capsid proteins, which include the full-length p55 polyprotein precursor and its cleavage products p17 matrix, p24 capsid, p9 nucleocapsid, and p7. The *pol* gene encodes the precursor polyprotein for several viral enzymes including protease, reverse transcriptase, RNase H, and integrase. The *env* gene encodes the envelope glycoprotein (gp160), which is cleaved to the surface unit (gp120) and the transmembrane protein (gp41) necessary for fusion. **Retroviruses are unique because the viral genome is transcribed into DNA via the viral enzyme reverse transcriptase, followed by integration into the host cell genome via the viral enzyme integrase. HIV also has the capacity to become latent within quiescent infected cells, which has made eradication of the virus thus far impossible.**

The HIV envelope glycoprotein (gp120) is a ligand for CD4, the cellular HIV receptor; thus **HIV predominantly infects CD4<sup>+</sup> cells, including T cells, monocytes, and macrophages.** Coreceptors required for viral entry and infection have been identified. The two primary HIV coreceptors are the chemokine receptors CXCR4 and CCR5. New infections almost always occur with an HIV strain that utilizes the CCR5 coreceptor, which potentially reflects viral fitness. Individuals homozygous for a 32-base pair deletion within the CCR5 gene are much less likely to become HIV infected, even following significant exposure; moreover, some CCR5 polymorphisms correlate with disease progression of HIV in perinatally infected children and adults.

### Epidemiology

The Centers for Disease Control and Prevention (CDC) estimates that over 1.2 million people in the United States are infected with HIV, and 14% of infected individuals are undiagnosed or unaware of their infection.<sup>1</sup> **Most HIV-infected individuals reside outside the United States. Global HIV burden is estimated at 37 million individuals; moreover, women account for more than half of all people living with HIV. In contrast, approximately 50,000 Americans are diagnosed with HIV infection annually; women account for 20% of new HIV infections and 23% of existing infections. Women typically acquire HIV infection by heterosexual contact, and about 65% of new infections occur in black Americans. White women have the highest percentage of HIV infections attributable to injection drug use (25%), whereas injection drug**

use accounts for only 14% of HIV infections in Hispanic women and only 11% in black women. Factors associated with an increased prevalence of HIV infection and transmission risk include a high number of sexual contacts, high-risk sexual exposure, receptive anal intercourse, sexual contact with an uncircumcised male, IV drug and/or crack cocaine use, residing in the “inner city,” and the presence of other sexually transmitted diseases (STDs), particularly those that cause genital ulcers (herpes, syphilis, chancroid).

HIV infection is limited to humans and chimpanzees, and most infections in the United States are caused by HIV-1, which is divided into three groups: M, N, and O. Over 95% of HIV-1 infections are caused by group M, which is divided into subtypes, or *clades*, A through K. The predominant type of HIV within the United States is clade B, whereas other clades predominate in other regions of the world. HIV-2, a related strain of HIV, is endemic in Africa, Portugal, and France and appears to have a lower vertical transmission rate compared with HIV-1. Much less is known about the treatment of these related viruses given their prevalence in areas of the world where treatment with antiretroviral (ARV) agents is not readily available.

### Diagnosis

**Historically, HIV infection was diagnosed via virus-specific antibody detection; initial serologic screen was via enzyme-linked immunosorbent assay (ELISA) and either Western blot (WB) or immunofluorescent antibody assay was performed for confirmation.** The Western blot identifies antibodies and recognizes specific viral antigens, and it is considered positive when any two of the following three antigens are identified: p24 (capsid), gp41 (envelope), and gp120/160 (envelope). Several salivary and/or rapid blood tests are available with efficacy comparable to ELISA. These tests have a limited ability to diagnose early HIV and HIV-2 infection because they detect HIV-specific immunoglobulin (Ig) G antibodies. **Current recommendations are to screen with an HIV-1/2 antigen/antibody combination immunoassay, or “combo assay,” with confirmation of infection with an HIV-1/HIV-2 antibody differentiation immunoassay and HIV-1 nucleic acid test (NAT; Fig. 53-1).**<sup>2</sup> This strategy enables diagnosis of *acute* HIV-1 infection, detection of HIV-2 infection, and faster turnaround time. Enhancements of the combo assay include more accurate HIV-2 diagnosis, p24 antigen assessment (measurable 15 days postinfection), and detection of IgM antibodies (measurable 3 to 5 days after p24 antigen positivity), which enables confirmation of HIV infection days to weeks before the HIV WB becomes positive. Combined with an HIV-1 NAT, this narrows the window between the time of infection and immunoassay reactivity and enables the diagnosis of acute HIV-1 infection, which was not possible using ELISA/WB assessment.<sup>2</sup> Because the risk of HIV transmission from persons with acute and early infection is increased, this strategy may reduce perinatal HIV transmission.

Given the increasing prevalence of HIV infection and studies that demonstrate that identification of HIV-infected pregnant women and early antiretroviral therapy (ART) most effectively prevents perinatal HIV transmission, **both the American College of Obstetricians and Gynecologists (ACOG) and the CDC recommend an “opt out” approach to ensure routine HIV screening for all pregnant women, ideally performed at the first prenatal visit.** The CDC also advocates for repeat testing in the third trimester, citing its cost effectiveness even in areas of low prevalence.<sup>3</sup> A second HIV test in the third trimester

**TABLE 53-1** SUMMARY OF ETIOLOGY, DIAGNOSIS, AND MANAGEMENT OF MAJOR PERINATAL VIRAL INFECTIONS

| Virus             | COMPLICATIONS   |  | DIAGNOSIS  |  | TREATMENT/MANAGEMENT   |   |
|-------------------|---|--|--|--|--|---|
|                   | Maternal  | Fetal/Neonatal   | Maternal   | Fetal/Neonatal                                     | Maternal   | Fetal/Neonatal  |
| HIV               | Opportunistic infection   | Perinatal infection  | Immunoassay                                      | PCR  | cART   | cART to reduce perinatal transmission   |
| Influenza         | Pneumonia, increased maternal mortality                         | NA   | RT-PCR or immunofluorescence, RIDT for screening | NA   | Oseltamivir prophylaxis and treatment, supportive care, vaccinate annually | Maternal vaccination to protect the neonate   |
| Parvovirus B19    | Rare  | Anemia, hydrops, death                                       | PCR or antibody detection                        | PCR, ultrasound for anemia                         | Supportive care  | Intrauterine transfusion for severe anemia  |
| Rubeola (measles) | Otitis media, pneumonia, encephalitis                           | Abortion, preterm delivery                                   | RT-PCR or antibody detection                     | NA   | Supportive care, vaccinate prior to pregnancy                              | NA  |
| Rubella           | Rare  | Congenital infection   | Antibody detection or RT-PCR                     | RT-PCR, ultrasound for congenital rubella syndrome | Supportive care, vaccinate prior to pregnancy                              | Consider pregnancy termination for fetus with CRS   |
| CMV               | Chorioretinitis   | Congenital infection   | PCR  | PCR, ultrasound for detection of sequelae          | Ganciclovir for severe infection   | Consider pregnancy termination for infected fetus with primary maternal infection                                 |
| HSV               | Disseminated infection, primarily in immunocompromised patients | Neonatal infection, intrauterine infection is extremely rare | Examination, PCR, antibody detection             | Examination, PCR, antibody detection               | Antiviral Tx for infection and prophylaxis to reduce recurrences           | Cesarean delivery when mother has active genital lesions  |
| Varicella         | Pneumonia, encephalitis, zoster                                 | Congenital or perinatal infection                            | History, PCR, antibody detection                 | Ultrasound   | VZIG, antivirals for prophylaxis and/or treatment                          | VZIG, antivirals for prophylaxis and/or treatment   |
| Hepatitis A       | Rare  | None   | RT-PCR or antibody detection                     | NA   | Supportive care, vaccination   | IG to neonate if mother acutely infected at delivery  |
| Hepatitis B       | Chronic liver disease   | Perinatal infection  | HBsAg detection, HBV PCR                         | NA   | Supportive care, vaccination; HBIG for exposed, unvaccinated individuals   | HBIG and HBV vaccine immediately following delivery. Consider antepartum tenofovir to further reduce transmission |
| Hepatitis C       | Chronic liver disease   | Perinatal infection  | HCV antibody screen, NAT confirmation            | NA   | Supportive care, consider antiviral Tx                                     | Maternal treatment may reduce transmission  |
| Hepatitis D       | Chronic liver disease   | Perinatal infection  | Antigen and antibody detection                   | NA   | Supportive care  | HBIG and HBV vaccine immediately following delivery   |
| Hepatitis E       | Increased mortality   | Neonatal infection   | RT-PCR, antibody detection                       | NA   | Supportive care  | None  |

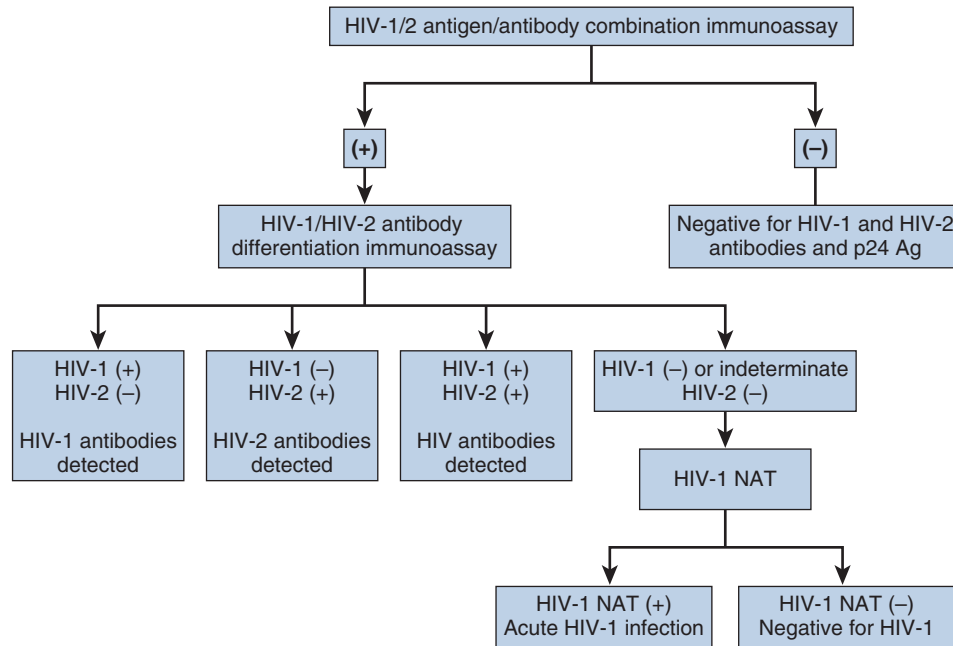

cART, combination antiretroviral therapy; CMV, cytomegalovirus; CRS, congenital rubella syndrome; HBIG, HBV immune globulin; HBsAg, HBV surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; IG, immune globulin; NA, not applicable; NAT, nucleic acid test; PCR, polymerase chain reaction; RIDT, rapid influenza diagnostic test; RT-PCR, reverse transcriptase PCR; VZIG, varicella zoster immune globulin; Tx, treatment.

is recommended for women at increased risk of HIV infection and those living in areas of elevated HIV incidence, which includes residents of Alabama, Connecticut, Delaware, the District of Columbia, Florida, Georgia, Illinois, Louisiana, Maryland, Massachusetts, Mississippi, Nevada, New Jersey, New York, North Carolina, Pennsylvania, Puerto Rico, Rhode Island, South Carolina, Tennessee, Texas, and Virginia as well as women

who receive health care in facilities at which prenatal screening identifies at least one HIV-infected pregnant woman per 1000 women screened.

### Clinical Manifestations and Staging

The clinical presentation of HIV infection and/or acquired immunodeficiency syndrome (AIDS) depends on when infection

**FIG 53-1** Diagnosis of human immunodeficiency virus (HIV) infection. Ag, antigen; HIV, human immunodeficiency virus; NAT, nucleic acid test; +, reactive test result; –, nonreactive test result.

**TABLE 53-2** STAGES OF HIV INFECTION

| CDC STAGE               | CD4+ T-LYMPHOCYTE COUNT AND PERCENTAGES                          |
|-------------------------|--|
| Stage 1 (HIV infection) | CD4+ T-lymphocyte count $\geq 500$ cells/ $\mu$ L or $\geq 29\%$ |
| Stage 2 (HIV infection) | CD4+ T-lymphocyte count 200 to 499 cells/ $\mu$ L or 14% to 29%  |
| Stage 3 (AIDS)          | CD4+ T-lymphocyte count $< 200$ cells/ $\mu$ L or $< 14\%$       |

AIDS, acquired immune deficiency syndrome; CDC, Centers for Disease Control and Prevention; HIV, human immunodeficiency virus.

occurred and whether immunodeficiency resulted. **Following exposure and primary infection, 50% to 70% of individuals infected with HIV develop the acute retroviral syndrome.** At this time patients may have “mononucleosis-like” symptoms that include fever, rigors, pharyngitis, arthralgias, myalgias, maculopapular rash, urticaria, abdominal cramps, diarrhea, headache, and lymphocytic meningitis. The acute phase of infection usually occurs 4 to 6 weeks following HIV exposure and can last several weeks. However, it is uncommon for individuals to be diagnosed during acute infection. Following acute HIV infection, patients enter latent-phase infection, which can last approximately 5 to 10 years in untreated patients and comprises stage 1 and 2 of infection (Table 53-2). During this asymptomatic phase of infection, in the absence of ART, chronic immune activation and progressive destruction of lymphatic tissue ensues.<sup>4</sup> If untreated, most patients will develop stage 3 infection, AIDS, which typically includes one or more of the conditions listed in Box 53-1.

### Evolution of Human Immunodeficiency Virus Infection and Treatment

The diagnosis, treatment, and prognosis of HIV infection has improved considerably over the past 30 years. Subsequent to the availability of effective ARVs with fewer adverse effects, HIV

### BOX 53-1 AIDS-DEFINING CONDITIONS IN ADULTS

Candidiasis of bronchi, trachea, or lungs  
 Candidiasis of esophagus\*  
 Cervical cancer, invasive<sup>†</sup>  
 Coccidioidomycosis, disseminated or extrapulmonary  
 Cryptococcosis, extrapulmonary  
 Cryptosporidiosis, chronic intestinal ( $> 1$  month duration)  
 Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age  $> 1$  month  
 Cytomegalovirus retinitis (with loss of vision)<sup>†</sup>  
 Encephalopathy, HIV related  
 Herpes simplex: Chronic ulcers ( $> 1$  month duration) or bronchitis, pneumonitis, or esophagitis (onset at age  $> 1$  month)  
 Histoplasmosis, disseminated or extrapulmonary  
 Isosporiasis, chronic intestinal ( $> 1$  month duration)  
 Kaposi sarcoma\*

AIDS, acquired immune deficiency syndrome; HIV, human immunodeficiency virus.

infection has evolved from a terminal diagnosis to a chronic but treatable life-long disease. **Treatment objectives for all infected individuals are to maximally and durably suppress viral load.<sup>5</sup> Effective treatment prevents HIV disease progression and transmission, including perinatal transmission.** As treatment has progressed to preserve immunologic function, reducing HIV-related morbidity, and prolonging the duration and quality of life for infected individuals, management recommendations have changed to focus on tolerability, toxicity, and prevention of resistance. **Historically, Pediatric AIDS Clinical Trial Group (PACTG) 076 was the first study to show that ART reduces perinatal HIV transmission.<sup>6</sup>** This randomized, placebo-controlled study comprised treatment-naïve HIV-infected women beyond the first trimester of pregnancy with a CD4 count above 200/mm<sup>3</sup>. Treatment included prenatal oral zidovudine (ZDV) and intrapartum intravenous (IV) ZDV, and infants received oral ZDV for 6 weeks following delivery; randomization was ethical because the safety within pregnancy and efficacy of ZDV at the time the study was initiated was unknown. Secondary to reduced HIV transmission, ZDV became the backbone of perinatal HIV treatment for over 20 years. Conversely, updated guidelines limit the recommended use of this drug secondary to toxicity (bone marrow suppression; gastrointestinal [GI] and mitochondrial toxicities such as lipoatrophy, lactic acidosis, and hepatic steatosis; skeletal muscle myopathy; and cardiomyopathy) and the availability of highly effective, well-tolerated therapies with fewer toxic side effects.<sup>5,7</sup> Moreover, combination antiretroviral therapy (cART) has been shown to more effectively limit perinatal HIV transmission.

### Ethical Considerations

Pregnant patients should be offered ART based on the same principles used for nonpregnant individuals, taking into account pregnancy-specific maternal or fetal safety issues. **When caring for HIV-infected pregnant women, two separate but related goals emerge: (1) treatment of maternal infection and (2) chemoprophylaxis to reduce the risk of perinatal HIV transmission.** Providers who care for HIV-infected women may encounter patients who decline to start or continue ART. For guidance, the author supports the recommendations of the Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission.<sup>5,7</sup> In summary, the provider is responsible for providing information to enable the woman to make an informed choice regarding this and other medical recommendations, including elective cesarean delivery. Coercive and punitive policies undermine trust and the provider-patient relationships. Results can include prenatal care discontinuation or failure to disclose her HIV status to other health care providers, preventing the adoption of behaviors to enhance maternal and fetal well-being. Respecting patient autonomy, we consider it unethical to consider punitive actions against a patient secondary to her decisions regarding her HIV treatment or disclosure of her HIV status. Moreover, disclosure carries risks that range from discrimination to intimate partner violence, making it critical to respect the patient's decision. **Clinicians should be aware of local legal requirements in regard to confidentiality and disclosure of HIV-related health information.**

### Management During Pregnancy

#### Initial Evaluation

Beyond the standard initial antenatal assessment for all pregnant women, including a first-trimester ultrasound to confirm gestational age, evaluation of an HIV-infected pregnant woman

### BOX 53-2 ASSESSMENT OF HIV DISEASE STATUS

#### HIV History Review

1. HIV infection duration, transmission route (if known), prior HIV-related illnesses and hospitalizations
2. Prior and ongoing ARV drug use, duration, whether treatment was for maternal benefit and/or to prevent perinatal HIV transmission, adherence and tolerance issues
3. Outcome of HIV-impacted pregnancies
4. CD4 cell counts and HIV viral loads (plasma HIV RNA copies/mL of plasma) and their relationship to ARV, results of prior HIV ARV drug-resistance studies
5. Assess need for opportunistic infection prophylaxis
6. Immunization/infection/serology status with attention to HAV, HBV, HCV, tuberculosis, pneumococcus, and Tdap

#### Laboratory Assessment

1. CD4 count and HIV viral load
2. ARV drug-resistance studies (genotype preferred) prior to starting or modifying ARV regimens in patients with HIV RNA levels above the threshold for resistance testing (e.g., >500 to 1000 copies/mL)
3. Baseline complete blood cell count with platelets and renal and liver function testing
4. Serologic assessment as required by history and CD4 count (for CD4 <200 cells/mm<sup>3</sup>, serology for cytomegalovirus and *Toxoplasma gondii* is indicated)
5. HLA-B\*5701 testing, if abacavir use is anticipated
6. In PPD-positive patients, chest x-ray to rule out active pulmonary disease
7. If abnormal PAP smear, HPV testing and colposcopy as indicated

ARV, antiretroviral; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HLA, human leukocyte antigen; HPV, human papillomavirus; PAP, Papanicolaou; PPD, purified protein derivative; Tdap, tetanus, diphtheria, and pertussis (vaccine).

should include status assessment as described in [Box 53-2](#). **Plasma HIV RNA (viral load) is determined using reverse transcriptase–polymerase chain reaction (RT-PCR) technology.<sup>5</sup>** If the patient's HIV viral load is undetectable in the absence of treatment, retesting and/or using an alternative assay is recommended (bDNA signal amplification or nucleic acid sequence-based amplification [NASBA] technique).<sup>8</sup> Some patients may have an undetectable viral load; however, the patient could be infected with a non-clade B HIV-1 isolate or HIV-2. None of the above-mentioned assays detect HIV-2 plasma RNA. Consultation with an infectious disease physician with experience in the management of HIV disease can be helpful in these cases or when the woman's genotype and phenotype assay demonstrate significant resistance to ART. Following complete evaluation, recommendations for a plan of HIV-related medical care that includes antepartum, intrapartum, and postpartum care should be provided, taking into account issues described in the following sections.

#### Antepartum Care

**Combination care with at least three drugs from at least two classes of ARVs is standard care for HIV infection in the United States.** Patients who enter pregnancy on ART with complete viral suppression should continue their current therapy;

**TABLE 53-3** TREATMENT RECOMMENDATIONS FOR ANTIRETROVIRAL-NAIVE PREGNANT WOMEN

| PREFERRED BACKBONES AND REGIMENS |  |  |
|----------------------------------|--|--|
| FDCs                             |  | COMMENT  |
| <b>Two-NRTI Backbones</b>        |  |  |
| TDF/FTC or TDF/3TC               | Truvada<br>200 mg FTC+ 300 mg TDF tablet               | The recommended NRTI backbone for nonpregnant adults; can be administered once daily. TDF has potential renal toxicity and should be used with caution in patients with renal insufficiency.   |
| ABC/3TC                          | Epzicom<br>300 mg 3TC + 600 mg ABC tablet              | Can be administered once daily; ABC is associated with HSRs and should not be used in HLA-B*5701–positive patients; it may be less efficacious than TDF/FTC in patients with HIV RNA level >100,000.   |
| ZDV/3TC                          | Combivir<br>150 mg 3TC + 200 mg ZDV tablet             | Backbone with the most experience in pregnancy, disadvantages include twice-daily administration and increased toxicity; not a preferred backbone in nonpregnant adults.   |
| <b>PI Regimens</b>               |  |  |
| ATV/r + two-NRTI backbone        |  | Once-daily administration of ATV/r; no longer preferred in nonpregnant adults secondary to increased toxicity-related discontinuation compared with DRV- and RAL-based regimens.   |
| DRV/r + two-NRTI backbone        |  | Twice-daily administration of DRV/r in pregnancy; preferred PI in nonpregnant adults, increasing experience with use in pregnancy.   |
| <b>NNRTI Regimen</b>             |  |  |
| EFV + two-NRTI backbone          | Atripla<br>200 mg FTC + 300 mg TDF + 600 mg EFV tablet | Atripla enables once daily administration of a single tablet regimen; concern due to observed birth defects in primates, although human risk is unconfirmed; postpartum contraception must be ensured; preferred regimen in women who require coadministration of drugs with significant PI interactions.  |
| <b>INSTI Regimen</b>             |  |  |
| RAL + two-NRTI backbone          |  | Twice-daily administration of RAL; preferred NRTI regimen in nonpregnant adults, increasing experience and established PK in pregnancy. Rapid viral load reduction; however, twice daily dosing required.  |
| <b>Alternative Regimens</b>      |  |  |
| RPV/TDF/FTC                      |  | Available in coformulated single-pill, once-daily regimen with PK pregnancy data. However, relatively little clinical experience in pregnancy and not recommended for pretreatment HIV RNA >100,000 or CD4 count <200 cells/mm <sup>3</sup> .  |
| LPV/r + two-NRTI backbone        |  | Twice-daily administration; once-daily LPV/r is not recommended for use in pregnant women; not a preferred PI in adults secondary to higher rates of GI side effects, hyperlipidemia, and insulin resistance.  |
| <b>No Longer Recommended</b>     |  |  |
| SQV/r + two-NRTI backbone        |  | Not recommended based on potential toxicity and dosing disadvantages. Baseline ECG recommended before initiation secondary to potential PR and QT prolongation; contraindicated with preexisting cardiac conduction system disease; large pill burden.   |
| NVP + two-NRTI backbone          |  | No longer recommended secondary to higher adverse event potential, complex lead-in dosing and low resistance barrier. NVP is administered twice daily; caution should be used when initiating ART in women with CD4 count >250 cells/mm <sup>3</sup> . Use NVP and ABC together with caution; both can cause HSRs within the first few weeks after initiation. |

From Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission. Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-1-Infected Women for Maternal Health and Interventions to Reduce Perinatal HIV Transmission in the United States. Available at <http://aidsinfo.nih.gov/contentfiles/lvguidelines/PerinatalGL.pdf>. 3TC, lamivudine; ABC, abacavir; ART, antiretroviral therapy; ATV/r, atazanavir/ritonavir; DRV/r, darunavir/ritonavir; ECG, electrocardiogram; EFV, efavirenz; FDC, fixed-dose combination; FTC, emtricitabine; GI, gastrointestinal; HIV, human immunodeficiency virus; HLA, human leukocyte antigen; HSR, hypersensitivity reaction; INSTI, integrase strand transfer inhibitor; LPV/r, lopinavir/ritonavir; NNRTI, nonnucleotide reverse transcriptase inhibitor; NRTI, nucleotide/nucleoside reverse transcriptase inhibitor; NVP, nevirapine; PI, protease inhibitor; PK, pharmacokinetic; RAL, raltegravir; SQV, saquinavir; TDF, tenofovir disoproxil fumarate; ZDV, zidovudine.

if a component of their regimen is contraindicated in pregnancy, the regimen should be altered without therapy interruption. If pregnancy-associated vomiting interferes with ongoing adherence to therapy, antiemetics should be aggressively used prior to discontinuing therapy. Treatment recommendations for ARV-naïve pregnant women are delineated in Table 53-3, and the most commonly used ARTs in pregnancy are described in Table 53-4. **Commonly used drug classes include nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), and protease inhibitors (PIs).** Fusion inhibitors (FIs), CCR5 antagonists, and integrase strand transfer inhibitors (INSTIs) have been less commonly used in pregnancy; however, the number of INSTI-treated women who become pregnant will increase because most recommended treatment regimens for nonpregnant adults are INSTI based. Therapeutic considerations include timing of therapy initiation, dosing changes secondary to pregnancy-associated physiologic changes, side effects, drug interactions, teratogenicity, comorbidities, convenience and adherence potential, viral resistance, and the pharmacokinetics and toxicity of transplacentally transferred drugs.

**The ideal regimen demonstrates durable virologic suppression with immunologic and clinical improvement, is well tolerated with a simple dosage regimen, and has been shown to be effective in pregnancy in terms of reducing perinatal HIV transmission.** ARV drug regimens used today are more convenient and better tolerated than previously utilized regimens, and this has resulted in greater efficacy and improved adherence. At least one NRTI with high placental transfer should be included within the ART regimen if possible; consultation with HIV medicine specialists is advised for women with previous ARV use for maternal indications who demonstrate significant ARV resistance upon testing or when there is a suboptimal response to ART.<sup>7</sup> Up-to-date U.S. treatment recommendations, including a comprehensive review of drug interactions within the adult treatment guidelines, are available online at [www.AIDSinfo.nih.gov](http://www.AIDSinfo.nih.gov), and the National Perinatal HIV Hotline (888-448-8765) provides free clinical consultation on all aspects of perinatal HIV care.<sup>7</sup>

Maternal cART should be started as soon as possible and should not be delayed for resistance testing results. Resistance testing should still be performed because it provides important

**TABLE 53-4** COMMONLY USED ANTRIRETROVIRAL DRUGS IN PREGNANCY

| DRUG DOSAGE   | FDA PREGNANCY CATEGORY | PHARMACOKINETICS IN PREGNANCY   | PREGNANCY CONCERNS AND RECOMMENDATIONS   |
|---|------------------------|---|--|
| <b>NRTIs</b>  |                        |   |  |
| Tenofovir disoproxil fumarate (TDF; Viread), 300 mg QD  | B                      | AUC lower in third trimester than postpartum with adequate trough levels in the majority of women. Placental transfer is high.  | Twofold increase in birth defects ruled out, 2.2% birth defect prevalence (47 of 2141 births); clinical studies in humans (particularly children) show reversible bone demineralization with chronic use; with HBV coinfection, possible HBV flare when drug is stopped; monitor renal function secondary to potential toxicity.   |
| Lamivudine (3TC; Epivir), 150 mg BID or 300 mg QD   | C                      | PKs are not significantly altered in pregnancy; no change in dose is indicated. Placental transfer is high.   | A 1.5-fold increase in birth defects ruled out, with a 3.2% birth defect prevalence (137 of 4418 births). Short-term safety demonstrated for mother and infant; 3TC has antiviral activity against HBV; if coinfecting, HBV flare is possible if drug is stopped postpartum.   |
| Emtricitabine (FTC; Emtriva), biologically active form of 3TC, 200 mg QD  | B                      | PK study shows slightly lower levels in third trimester compared with postpartum; no need to increase dose. Placental transfer is high.   | Twofold increase in birth defects ruled out, 2.3% birth defect prevalence; antiviral activity against HBV; if coinfecting, HBV flare is possible if drug is stopped postpartum.  |
| Abacavir (ABC; Ziagen), 300 mg BID or 600 mg QD   | C                      | PKs are not significantly altered in pregnancy; no change in dose is indicated. Placental transfer is high.   | Twofold increase in birth defects ruled out, 3.0% birth defect prevalence (27 of 805 births); hypersensitivity reactions occur in ~5% to 8% of nonpregnant persons; a much smaller percentage are fatal, usually associated with rechallenge. Patients should be educated regarding symptoms, and HLA-B*5701 testing identifies patients at risk.  |
| Zidovudine (ZDV; Retrovir), 300 mg BID  | C                      | PKs are not significantly altered in pregnancy; no dose change is indicated. Placental transfer is high.  | 1.5-fold increase in birth defects ruled out, 3.2% birth defect prevalence (129 of 4034 births). Short-term safety demonstrated for mother and infant. ZDV is associated with macrocytic anemia.   |
| Didanosine (ddI; Videx), ≥60 kg: 400 mg QD, with TDF 250 mg QD; <60 kg: 250 mg QD, with TDF 200 mg QD   | B                      | PKs are not significantly altered in pregnancy; no change in dose is indicated. Placental transfer is moderate.   | Human birth defect rate was 4.8% (20 of 418), compared with 2.7% in the general population; no pattern of defects was discovered. Cases of lactic acidosis, some fatal, have been reported in pregnant women receiving ddI and d4T together; only use if no other alternative is available.  |
| Stavudine (d4T; Zerit), ≥60 kg: 40 mg BID; <60 kg: 30 mg BID  | C                      | PKs are not significantly altered in pregnancy; no change in dose is indicated. Placental transfer is high.   | Twofold increase in birth defects ruled out, 2.6% prevalence in birth defects (21 of 809 births); antagonistic with ZDV; cases of fatal lactic acidosis have been reported in pregnant women receiving ddI and d4T together.   |
| <b>NNRTIs</b>   |                        |   |  |
| Efavirenz (EFV; Sustiva), 600 mg QD at or before bedtime  | D                      | AUC decreased during third trimester, compared with postpartum, but nearly all third-trimester subjects exceeded target exposure; no dosage change is indicated. Placental transfer is moderate.  | Antiretroviral Pregnancy Registry (prospective) documented birth defects in 20 of 852 live births (2.3%) following first-trimester EFV exposure, including a single NTD with fetal alcohol syndrome and a single case of bilateral facial clefts, anophthalmia, and amniotic band (2.3% birth defect prevalence, twofold increase in overall birth defects ruled out). Retrospective data include six case reports of CNS defects following EFV exposure; however, a meta-analysis of more than 2000 first-trimester EFV-exposed live births showed no increase in overall birth defects (2.0%) and a single NTD (overall incidence 0.07%). <sup>7</sup> |
| Nevirapine (NVP; Viramune), 200 mg QD for 14 days, then 200 mg BID  | C                      | PKs are not significantly altered in pregnancy; no dose change is indicated. Placental transfer is high.  | Twofold increase in birth defects ruled out, 2.9% birth defect prevalence (31 of 1068 births); increased risk of symptomatic, rash-associated, potentially fatal liver toxicity in women with CD4 <sup>+</sup> counts >250/mm <sup>3</sup> when initiating therapy; pregnancy does not increase this risk. Women who become pregnant while taking NVP-containing regimens but are tolerating them well should continue therapy independent of CD4 <sup>+</sup> count.  |
| Etravirine (ETR; Intelence), 200 mg BID   | B                      | PK data suggest increased exposure in pregnancy of 1.2-1.6 fold. Limited data suggest high placental transfer.  | Fewer than 200 first-trimester exposures reported to the Antiretroviral Pregnancy Registry, precluding conclusions regarding birth defect risk.  |
| Rilpivirine (RPV; Edurant), 25 mg QD  |                        | Limited PK studies suggest 20% reduced AUC in second trimester and 30% reduction in the third trimester. Placental transfer is unknown.   | The limited number of first-trimester exposures reported to the Antiretroviral Pregnancy Registry precludes conclusions regarding birth defect risk.   |
| <b>Protease Inhibitors</b>  |                        |   |  |
| Atazanavir (ATV; Reyataz), PK enhancement required (low-dose RTV), ATV 300 mg + RTV 100 mg QD (increase ATV dose to 400 mg for TDV, EFV, or H2 blocker) | B                      | PK studies with RTV boosting during pregnancy suggests that standard dosing yields decreased AUC; however, for most pregnant women, no dose adjustment was needed. TDF reduces ATV AUC in all patients by 25%. Placental transfer is low. | Twofold birth defect increase ruled out, 2.2% birth defect prevalence (16 of 922 births). Neurodevelopmental delays have been reported in two studies. ATV-treated adults often have elevated indirect bilirubin levels; increased bilirubin was reported in some infants born to mothers receiving ATV, associated with UGT1A1 genotypes linked to decreased UGT function. Neonatal hypoglycemia has been reported in 3 of 38 ATV-exposed infants.  |

**TABLE 53-4** COMMONLY USED ANTRIRETROVIRAL DRUGS IN PREGNANCY—cont'd

| DRUG DOSAGE   | FDA PREGNANCY CATEGORY | PHARMACOKINETICS IN PREGNANCY   | PREGNANCY CONCERNS AND RECOMMENDATIONS   |
|---|------------------------|---|--|
| Lopinavir/ritonavir (LPV/r; Kaletra), built in low-dose RTV boosting 400/100 mg BID<br>In second and third trimesters, 600/150 mg BID | C                      | Once-daily dosing is not recommended in pregnancy. AUC is decreased in second and third trimesters with standard dosing. LPV/r 600 mg/150 mg BID resulted in AUC similar to that of nonpregnant adults receiving LPV/r 400 mg/100 mg. Alternative strategy adds a pediatric LPV/r tablet (100/25 mg) to the standard adult dose. Placental transfer is low. | Twofold increase in birth defect ruled out, 2.2% birth defect prevalence (26 of 1174). Well-tolerated, short-term safety has been demonstrated in Phase I and II studies.  |
| Ritonavir (RTV; Norvir), 100 mg to 400 mg in one or two divided doses as PK enhancer  | B                      | RTV levels are reduced in pregnancy, including low-dose RTV PK enhancement to boost the concentrations of other PIs. Minimal placental transfer to fetus.   | Limited experience at full dose in human pregnancy; this agent is currently used as low-dose RTV boosting with other PIs. No evidence of human teratogenicity (twofold increase in birth defects ruled out).   |
| Saquinavir HGC (SQV; Invirase), use with PK enhancement (low-dose RTV), SQV 1000 mg + RTV 100 mg BID                                  | B                      | PK data suggest that 1000 mg SQV HGC/100 mg RTV twice daily achieves adequate SQV drug levels in pregnant women. Placental transfer to fetus is minimal.  | Well-tolerated, short-term safety has been demonstrated for mother and infant for SQV in combination with low-dose RTV boosting. Baseline ECG is recommended before starting because PR and/or QT interval prolongations have been observed.   |
| Indinavir (IDV; Crixivan), prescribe with low-dose RTV boosting (IDV 800 mg + RTV 100 mg) BID   | C                      | Studies using IDV alone showed markedly lower pregnancy levels, compared with postpartum, although HIV RNA suppression was seen. Use only with RTV PK enhancement. Placental transfer to the fetus is minimal.  | Twofold increase in birth defect ruled out, 2.4% birth defect prevalence (7/289).<br>Pill burden and renal stone potential are concerns. In rhesus monkeys, neonatal IDV exacerbated transient physiologic hyperbilirubinemia; this was not seen following in utero exposure. Given limited data regarding dosing, trough drug levels should be monitored. |
| Nelfinavir (NFV; Viracept), 1250 mg BID   | B                      | Using 625-mg tablets, lower AUC and peak levels were seen in the third trimester versus postpartum; however, viral load was suppressed in most women. Placental transfer is minimal.  | Twofold increase in overall birth defects ruled out; well-tolerated, short-term safety demonstrated for mother and infant; consider in special circumstances when alternative agents are not tolerated given extensive experience in pregnancy.  |
| Darunavir (DRV; Prezista), PK enhancement required; ARV exp with mutations or pregnancy (DRV 600 mg + RTV 100 mg) BID                 | C                      | Used in pregnancy with low-dose RTV boosting; reduced third-trimester plasma concentrations have been observed. Placental transfer is low to moderate.  | Experience in human pregnancy is limited with 2.3% (6 of 258 births) birth defect prevalence. Once-daily dosing is not recommended in pregnancy, although 800 mg plus RTV 100 mg twice daily is being investigated.  |
| Fosamprenavir (FPV; Lexiva)<br>Amprenavir prodrug; must use low-dose RTV boosting (FPV 700 mg + RTV 100 mg) BID                       | C                      | With RTV boosting, AUC is reduced in the third trimester; however, trough levels appear adequate for patients without PI resistance mutations. Placental transfer is low.   | Data are insufficient to assess human teratogenicity. Unboosted FPV and once-daily dosing are not recommended in pregnancy.  |
| Tipranavir (TPV; Aptivus), low-dose RTV PK enhancement required (TPV 500 mg + RTV 200 mg) BID   | C                      | Unknown rate of placental transfer to fetus. Safety and PK data in pregnancy are insufficient to recommend use.   | Exposures are insufficient to establish birth defect prevalence.   |
| <b>Integrase Inhibitors</b>   |                        |   |  |
| Raltegravir (RAL; Isentress), 400 mg BID  | C                      | PKs are variable in pregnancy; however, there is no clear relationship between raltegravir concentration and virologic effect in nonpregnant adults. Placental transfer is high.  | Severe, potentially life-threatening and fatal skin and hypersensitivity reactions have been reported in nonpregnant adults. One case of markedly elevated liver transaminases was reported with use in late pregnancy. This agent rapidly suppresses viral load, but experience in pregnancy is limited.  |
| Dolutegravir (DTG; Tivicay), 50 mg QD for INSTI-naïve patients  | B                      | No studies of DTG use in pregnancy have been reported; placental transfer occurs in animals.  | Exposures are insufficient to establish birth defect prevalence.   |
| Elvitegravir (EVG; Stribild, which includes COBI/ TDF/FTC), 1 tablet daily  | B                      | No studies of EVG use in pregnancy have been reported; breast milk secretion in animals has been reported.  | Exposures are insufficient to establish birth defect prevalence.   |

AUC, area under the curve; AZT, azidothymidine; BID, twice per day; CNS, central nervous system; COBI, cobicistat; ECG, electrocardiograph; FTC, emtricitabine; H<sub>2</sub>, histamine 2; HBV, hepatitis B virus; HGC, hard gel capsule; INSTI, integrase strand transfer inhibitor; NRTI, nucleotide/nucleoside reverse transcriptase inhibitor; NTD, neural tube defect; PI, protease inhibitor; PK, pharmacokinetic; QD, once per day; UGT, uridine diphosphate glucuronosyltransferase; UGT1A1, uridine diphosphate glucuronosyltransferase 1.

information for ongoing patient care, and results can be used to modify treatment if needed. Early initiation of therapy is based on the knowledge that comprehensive regimens that comprise antepartum and intrapartum maternal treatment and postpartum infant treatment provide the best protection against perinatal HIV transmission. Additionally, the European National Study of HIV in Pregnancy and Childhood demonstrated that **with longer duration of antenatal ARV prophylaxis, starting prior to 28 weeks' gestation, each additional week of therapy corresponds to a 10% reduced risk of HIV transmission after adjusting for viral load, mode of delivery, and sex of the infant.**<sup>7</sup> Moreover, expanding infant postexposure prophylaxis does not fully substitute for the protective effect of increased maternal ART duration, which also supports early effective maternal treatment. Women with undetectable viral loads should also receive cART because their risk of perinatal transmission is 9.8% if untreated.<sup>9</sup>

### Nucleoside/Nucleotide Reverse Transcriptase Inhibitors

Nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs) are used within combination regimens that usually include two NRTIs with either an NNRTI, INSTI, or a PI. Tenofovir (TDF)—emtricitabine (FTC) is the preferred NRTI backbone in treatment-naïve nonpregnant adults, and Table 53-3 shows recommended NRTI backbones for ARV-naïve pregnant women. FTC is the biologically active form of lamivudine (3TC), thus these drugs can be used interchangeably, and there is no benefit to using FTC and 3TC together. Abacavir (ABC) is associated with hypersensitivity reactions. Human leukocyte antigen B (HLA-B) \*5701 testing identifies patients at risk; testing should be performed and documented prior to initiating this therapy, and NRTIs are described in Table 53-4. ZDV and 3TC remain a preferred treatment option for treatment-naïve pregnant women, despite their toxicity, secondary to extensive experience.<sup>7</sup> **All NRTIs bind to mitochondrial  $\gamma$ -DNA polymerase, potentially causing dysfunction that manifests as clinically significant myopathy, cardiomyopathy, neuropathy, lactic acidosis, or fatty liver—which resembles hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome.** Lactic acidosis and hepatic failure have been noted with long-term combined stavudine and didanosine use, linked to a genetic defect in mitochondrial fatty acid metabolism; therefore this regimen should not be used in pregnancy.<sup>7</sup> Mitochondrial toxicity has been observed in children born to HIV-infected mothers treated with NRTIs, although no increase in mortality was observed.

### Nonnucleoside Reverse Transcriptase Inhibitors

Nonnucleoside reverse transcriptase inhibitors (NNRTIs) are typically used with two NRTIs. Efavirenz (EFV) remains the preferred NNRTI in pregnancy; however, tolerability concerns and potential suicidality association led to reclassification to an alternative regimen in nonpregnant adults. EFV is associated with a 2.3% birth defect incidence following first-trimester exposure<sup>9a</sup>; however, EFV remains classified as U.S. Food and Drug Administration (FDA) pregnancy category D based on retrospective studies that have reported central nervous system (CNS) defects. **Current perinatal HIV treatment guidelines support initiation of EFV after the first 8 weeks of pregnancy.**<sup>7</sup> Continuing EFV in virologically suppressed women who present for care in the first trimester is also endorsed because the potential neural tube defect risk is restricted to the first 5 to

6 weeks of pregnancy. This recommendation considers the low likelihood of early pregnancy diagnosis, potential loss of viral control if ARV drugs are changed, and the increased perinatal HIV transmission risk associated with therapy interruption in the first trimester (4.8%).<sup>7</sup> Nevirapine (NVP) is no longer recommended based on its low resistance barrier, high potential for adverse events, and complex lead-in dosing. NVP should not be used for initial treatment in ART-naïve pregnant women with CD4<sup>+</sup> cell counts greater than 250 cells/mm<sup>3</sup>; however, it is safe to continue this drug in women who become pregnant while taking NVP-containing regimens.

### Protease Inhibitors

Protease inhibitors (PIs) are characterized by minimal transplacental passage and few adverse side effects, and they are typically paired with two NRTIs. These drugs are ideal for patients who require therapy initiation prior to receiving genotyping results because PI-resistant viruses in ARV-naïve patients are uncommon. And because their short half-life protects against the emergence of resistance with therapy discontinuation, PIs are also a good choice for women who may discontinue therapy postpartum; however, these agents are associated with hyperglycemia in adults, although pregnancy does not seem to increase hyperglycemia.<sup>10</sup> An early glucose challenge test followed by repeat testing after 28 weeks is reasonable in high-risk patients. Conflicting data exist regarding preterm delivery in women who receive PIs. During pregnancy, lower serum concentrations of lopinavir/ritonavir (LPV/r), atazanavir (ATV), and nelfinavir (NFV) have been reported; pregnancy-adjusted dosage regimens are detailed in Table 53-4.<sup>7</sup> Pharmacokinetic (PK) enhancers or boosters—cobicistat (COBI) or low-dose ritonavir, as well as the INSTI elvitegravir (EVG)—improve the PK profiles of several of these drugs via cytochrome (CY) P3A4 inhibition. Although more experience has been reported in pregnancy using ritonavir PK enhancement, multiple fixed-dose combination (FDC) products that incorporate cobicistat are available. Thus providers are likely to encounter women entering pregnancy using cobicistat-containing regimens.

### Integrase Strand Transfer Inhibitors

INSTIs are a recently developed class of ARV drugs inhibiting HIV integrase, the enzyme catalyzing insertion of HIV DNA into the human cell genome. Integration is required for replication and stable maintenance of the viral genome, also enabling the establishment of persistent infection. Enzymatic activity consists of two steps: a preparatory step excising two nucleotides from one strand at both ends of the HIV DNA and a final “strand transfer” step inserting viral DNA into an exposed region of cellular DNA. Current integrase inhibitor drugs target the second integration step, strand transfer. Because HIV integrase represents a distinct therapeutic target, integrase inhibitors are expected to maintain activity against HIV that is resistant to other classes of ARV drugs. INSTIs are characterized by their ability to rapidly reduce HIV viral load. Raltegravir (Isentress, RAL) is FDA pregnancy category C and a component of the preferred INSTI regimen in pregnancy.

### Hepatitis Coinfection

**All HIV-infected women should be screened for hepatitis B virus (HBV) and hepatitis C virus (HCV) unless they are already known to be infected.** Recommended screening is via antibody detection, and for HIV-infected women, HBV

**TABLE 53-5** PROPHYLACTIC ANTIBIOTIC REGIMENS FOR COMMON OPPORTUNISTIC INFECTIONS

| CONDITION   | INDICATION FOR PROPHYLAXIS                                   | ANTIBIOTIC REGIMEN  |
|---|--|---|
| <i>Pneumocystis jiroveci</i> pneumonia  | Prior infection or CD4 <200/mm <sup>3</sup>                  | TMP-SMX 1 DS tablet QD indefinitely   |
| <i>Toxoplasma gondii</i> encephalitis   | CD4 <100/mm <sup>3</sup> , <i>Toxoplasma</i> IgG+ +PPD >5 mm | TMP-SMX 1 DS tablet QD indefinitely   |
| <i>Mycobacterium tuberculosis</i> infection (i.e., treatment of latent infection) | No active disease on chest radiograph                        | 300 mg INH and 50 mg pyridoxine QD for 9 months   |
| Disseminated <i>Mycobacterium avium</i> complex disease                           | CD4 <50/mm <sup>3</sup>                                      | 1200 mg azithromycin weekly   |
| Cryptococcosis  | CD4 <50/mm <sup>3</sup>                                      | Prophylaxis is not recommended in the absence of documented infection; patients treated for acute cryptococcal infection should receive 200 mg fluconazole QD indefinitely. |

From Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents. Guidelines for the prevention and treatment of opportunistic infections in HIV-infected adults and adolescents: recommendations from the Centers for Disease Control and Prevention, the National Institutes of Health, and the HIV Medicine Association of the Infectious Diseases Society of America. Available at [http://aidsinfo.nih.gov/contentfiles/lvguidelines/adult\\_oi.pdf](http://aidsinfo.nih.gov/contentfiles/lvguidelines/adult_oi.pdf).

DS, double strength; IgG, immunoglobulin G; INH, isoniazid; PPD, purified protein derivative; QD, once per day; TMP-SMX, trimethoprim-sulfamethoxazole.

screening should include hepatitis B surface antigen (HBsAg), anti-HBs, and anti-HBc (hepatitis B core). Women with negative screens should receive the HBV vaccine series. Women found to be HBV coinfecting should receive ART that uses an NRTI backbone with two drugs active against HIV and HBV; TDF/3TC and TDF/FTC are the preferred NRTI backbones for HIV/HBV coinfecting pregnant women. Women with HBV coinfection should have transaminase testing 1 month after initiating ARV and every 3 months thereafter. Differentiating among an HBV flare, immune reconstitution, and drug toxicity can be challenging, and consultation with an expert in HIV and HBV coinfection is recommended.<sup>7</sup> For prophylaxis, the infant should receive HBV immune globulin and the first dose of the HBV vaccine series within 12 hours of birth. HCV therapy is rapidly evolving, and some regimens are safe in pregnancy; therefore HCV coinfecting women should be referred to a hepatologist for treatment evaluation. For coinfecting patients, delivery planning should be solely based on standard obstetric and HIV-related indications. Coinfecting patients should be screened for hepatitis A virus (HAV); and women who are negative for HAV IgG should receive the HAV vaccine series.

### Opportunistic Infection Prophylaxis

**Patients with a CD4 count below 200 cells/mm<sup>3</sup> should also receive prophylaxis against opportunistic infections (OIs).**

Transient CD4 count decreases may occur secondary to pregnancy-associated hemodilution; in these cases, the relative percent of CD4+ cells (see Table 53-2) can be used to guide decisions regarding OI prophylaxis. Prophylaxis regimens for *Pneumocystis jiroveci* pneumonia (PJP), toxoplasmosis, tuberculosis (TB), *Mycobacterium avium* complex (MAC), and cryptococcosis are listed in Table 53-5; additional prophylaxis is listed in the Guidelines for the Prevention and Treatment of Opportunistic Infection in HIV-Infected Adults and Adolescents.<sup>4</sup> Prophylactic pyridoxine is increased to 50 mg/day in pregnancy to prevent maternal and fetal neurotoxicity. When untreated HIV patients are diagnosed with a treatable OI—including TB, MAC, PJP, toxoplasmosis, histoplasmosis, HBV, cytomegalovirus (CMV), varicella zoster virus (VZV), or cryptococcal meningitis—providers should be aware of the potential for immune reconstitution inflammatory syndrome (IRIS) when ART is started. In short, IRIS may be observed when the immune system begins to recover and responds to the previously acquired OI with an exaggerated inflammatory response. However, given the goal of reducing perinatal HIV transmission, ART should be started prior to or concurrent with OI treatment.<sup>11</sup>

### BOX 53-3 FACTORS THAT INCREASE THE RISK OF PERINATAL HIV TRANSMISSION

History of previous child with HIV infection  
 Mother with AIDS  
 Preterm delivery  
 Decreased maternal CD4 count  
 High viral load  
 Firstborn twin  
 Chorioamnionitis  
 Modifiable factors (cigarette smoking, illicit drug use, STDs, unprotected sexual intercourse with multiple partners during pregnancy)  
 Intrapartum blood exposure (e.g., episiotomy, vaginal laceration, forceps delivery)  
 Delivery following prolonged rupture of membranes  
 Breastfeeding

AIDS, acquired immune deficiency syndrome; HIV, human immunodeficiency virus; STD, sexually transmitted disease.

### Ongoing Management

In addition to routine prenatal care and evaluation, viral load should be performed monthly when starting a new medication regimen or when a change in viral load is detected. **Patients on stable ART regimens and with suppressed viremia can have viral loads checked each trimester.** CD4 counts can be performed every 3 to 6 months. Vaccinations for pneumococcus and influenza should be given as needed. Coordination of services among prenatal care providers, primary care and HIV specialty care providers, mental health and drug abuse treatment services, and public assistance programs are essential to ensure that infected women remain active participants in their care and that they adhere to their ARV drug regimens.

### Factors That Influence Transmission

Perinatal HIV transmission risk is associated with cigarette smoking, illicit drug use, genital tract infections, and unprotected sexual intercourse with multiple partners during pregnancy. Elimination of modifiable risk factors reduces perinatal HIV transmission and improves maternal health. Key factors that influence perinatal HIV transmission are listed in Box 53-3. **Most perinatal HIV transmission occurs within the intrapartum period; thus effective cART or scheduled cesarean delivery in patients without viral suppression substantially reduces transmission.** A minority of infected

infants acquire HIV in utero, as characterized by an infant who is positive by polymerase chain reaction (PCR) testing at birth. Most studies were not designed or powered to prevent in utero HIV transmission, however data suggest that early, sustained control of viral replication prevents in utero HIV transmission. The study evaluated perinatal transmission risk factors in women with HIV RNA of fewer than 500 copies/mL at delivery; the overall HIV transmission rate was 0.5% in this population. HIV transmitters were less likely to have received ARV drugs at the time of conception than non-transmitters. Moreover, HIV transmitters were less likely to have HIV RNA of fewer than 500 copies/mL at 14, 28, and 32 weeks of gestation. Among women starting ARV during pregnancy, viral load decreased earlier in nontransmitting women, and both groups initiated therapy at the same time (30 weeks' gestation). **This suggests that early and sustained control of viral replication is associated with decreased HIV transmission, which supports cART initiation as early in pregnancy as possible for all women not treated preconceptionally.**<sup>7,12</sup>

HIV treatment reduces maternal disease progression, and both ART and viral load at delivery are independent risk factors for HIV transmission; **therefore ART is recommended for all women, independent of viral load suppression.** In addition to maternal benefit, this strategy protects neonates born following spontaneous rupture of membranes (SROM) or spontaneous labor that occurs prior to a planned elective cesarean delivery. Mechanisms of protection include using ARVs with good placental transfer and permitting adequate systemic drug levels to be reached in infants at birth. This is likely important when the infant is exposed to virus within the birth canal and is the recipient of a maternal-fetal blood transfusion during uterine contractions. ARVs can also decrease genital tract viral load and can be excreted into genital tract secretions; ZDV and 3TC are present at high concentrations within genital secretions, another potential mechanism of protection against HIV transmission. **Most perinatal HIV transmission in the United States occurs in women who are not known to be HIV infected prior to the birth of their child.** Given this knowledge, it is critical to emphasize the importance of prenatal care, universal HIV testing, and strategies to diagnose acute HIV infection in late pregnancy and prior to delivery and breast feeding.

### Invasive Prenatal Testing

If invasive prenatal diagnostic testing is desired, the risks and benefits should be discussed and referral to a genetic counselor made (see [Chapter 10](#)). One study assessed vertical HIV transmission following amniocentesis; 1 of 61 infants was infected, which was not significantly different than the transmission rate in women who defer amniocentesis.<sup>13</sup> A second prospective cohort study reported no increase in mother-to child transmission (MTCT) rates in the 162 women who underwent amniocentesis (of 9302 HIV-infected pregnancies); moreover, no cases of MTCT were identified in 81 women who received ART at the time of amniocentesis.<sup>14</sup> Larger studies are needed to better estimate the risk of HIV transmission following amniocentesis or chorionic villus sampling. However, evidence to date suggests no increased risk of HIV transmission in women with fully suppressed viral loads. Consideration can also be given to noninvasive screening tests such as cell-free fetal DNA (see [Chapter 10](#)).

## Intrapartum Management of Human Immunodeficiency Virus

**Intrapartum IV ZDV is no longer recommended for HIV-infected women who receive a combination ARV with sustained viral suppression (HIV RNA consistently  $\leq 1000$  copies/mL during late pregnancy) and no medication adherence concerns.**<sup>14</sup> All HIV-infected women should continue ART during the intrapartum period, both for maternal health and to reduce perinatal transmission. Intrapartum ZDV is no longer recommended in virally suppressed women because ZDV therapy to reduce perinatal HIV transmission in cART-treated women has not been evaluated in randomized clinical trials. In addition, multiple studies have shown extremely limited perinatal HIV transmission in women with HIV RNA of fewer than 1000 copies/mL who did not receive intrapartum ZDV. **Thus the newest perinatal HIV treatment guidelines suggest intrapartum ZDV administration consistent with the elective cesarean delivery recommendations.**<sup>7</sup> For virally suppressed patients, neither intervention is expected to further reduce perinatal HIV transmission. Clinicians may also elect to use intrapartum IV ZDV based on clinical judgment.

For intrapartum patients with viral loads greater than 1000, IV ZDV should be given as a loading dose of 2 mg/kg administered over 1 hour, followed by a maintenance dose of 1 mg/kg/hr. Other ART should be taken with a sip of water except stavudine, which is antagonistic to ZDV, therefore it should be withheld. ZDV should be given independent of maternal resistance; it crosses the placenta readily and is metabolized to the active triphosphate form within the placenta, which provides prophylaxis to the infant both before and after exposure. When delivery is indicated for obstetric reasons, delivery must not be delayed for ZDV administration.

**During labor, every effort should be made to avoid instrumentation that increases the neonate's exposure to infected maternal blood and secretions.** Recommendations include leaving the fetal membranes intact as long as possible, avoiding fetal scalp sampling and fetal scalp electrode placement, and reserving episiotomy and assisted vaginal delivery for select circumstances. If SROM occurs, augmentation and/or induction of labor with pitocin should not be delayed. In cases of uterine atony, methergine should be avoided if possible. PIs are CYP3A4 inhibitors, and concomitant ergotamine use is associated with exaggerated vasoconstrictive responses. NNRTIs are CYP3A4 inducers that have the potential to decrease methergine levels and result in inadequate treatment effect.<sup>7</sup>

### Elective Cesarean Delivery

**Scheduled cesarean delivery at 38 weeks' gestation, confirmed by early ultrasonography, is recommended for women with HIV RNA levels greater than 1000 copies/mL and for women with unknown HIV RNA levels near the time of delivery.** Patients should receive IV ZDV for 3 hours prior to surgery, and prophylactic antibiotics should be administered. These recommendations are based on studies conducted when the majority of HIV-infected women received ZDV monotherapy or no ART, whereas a more recent study of 4864 European women showed that the perinatal HIV transmission rate in women who received at least 14 days of ART was 0.8% regardless of the mode of delivery.<sup>12</sup> CD after onset of labor or SROM does not protect against HIV transmission, so delivery for obstetric indications is recommended in these patients irrespective of viral load.

Scheduled CD is not indicated to prevent HIV transmission in women receiving cART who have plasma HIV RNA levels below 1000 copies/mL. Perinatal HIV transmission in this group of women is 1.0% or less, and no evidence to date suggests any benefit from scheduled CD in patients receiving cART with virologic suppression.<sup>7</sup> Timing and route of delivery influence maternal and neonatal morbidity, and HIV-infected women have increased morbidity and mortality following CD. The risk of complications is related to the degree of immunosuppression and receipt of suppressive cART. Vaginal delivery has the lowest risk of maternal morbidity, scheduled CD is associated with an intermediate risk, and urgent CD has the highest risk of postpartum morbidity.<sup>7,15</sup> Neonatal adverse event risk at 38 weeks' gestation that includes death, respiratory complications, hypoglycemia, sepsis, or neonatal intensive care unit (NICU) admission is 11%, compared with 8% at 39 weeks' gestation; furthermore, infants of HIV-infected mothers have a 4.4% risk of respiratory distress syndrome (RDS) following scheduled CD, compared with 1.6% after vaginal delivery. Given the increased risk of maternal and neonatal adverse events, it is critical to appropriately counsel patients and to respect the patient's autonomy in decision making regarding the route of delivery. In addition, scheduled CD in women with HIV RNA less than 1000 should be performed at 39 weeks or for standard obstetric indications.

### Spontaneous Rupture of Membranes

Increasing duration of ruptured membranes is associated with perinatal HIV transmission, but the incremental increased risk of transmission is not clinically significant. Meta-analysis of 4721 deliveries determined that the risk of HIV transmission increases by 2% over the baseline transmission risk (after adjusting for all other factors that influence transmission) for each hour increment following rupture of membranes.<sup>16</sup> Presuming a patient on ART with an undetectable viral load has a baseline perinatal HIV transmission rate of 2%, the risk of transmission after 1 hour of ruptured membranes would be 2.04%, and after 8 hours, the risk of HIV transmission would be 2.32%. Given that prolonged SROM does not appreciably increase HIV transmission risk in term patients, we do not recommend elective CD because it is unlikely to reduce perinatal HIV transmission risk in patients being actively managed using oxytocin for augmentation or induction.

### Untreated Women

For HIV-infected women who do not receive ART before labor, IV ZDV should be given during labor. Maternal single-dose NVP is not recommended because there is no added efficacy and a high likelihood of maternal harm, specifically the emergence of a resistant virus. The safest, most effective option to reduce perinatal HIV transmission in this setting is expanded infant prophylaxis.<sup>7</sup> These patients should be referred for HIV care postpartum.

### Intrapartum Testing

**Rapid HIV testing should be performed for all laboring women without documented HIV status during pregnancy** unless the patient declines (opt-out screening) because 40% to 85% of HIV-infected infants in the United States are born to women whose HIV status is unknown prior to delivery. Women with positive rapid HIV testing should be given intrapartum IV ZDV immediately, without awaiting confirmatory testing, and

the pediatrician should be alerted to begin postpartum infant prophylaxis.<sup>7</sup> Following confirmatory HIV antibody testing, these women should receive appropriate assessments to determine their health status, including a CD4 T-lymphocyte count and HIV-1 RNA viral load, and arrangements should be made for establishing HIV care and for providing ongoing psychosocial support after discharge.

### Postpartum Care of Women with Human Immunodeficiency Virus

Ideally, women should establish a relationship with an HIV-medicine provider during the latter part of pregnancy to transition into ongoing care after delivery. **Guidelines for managing HIV infection in adults recommend cART for all infected individuals to reduce the risk of disease progression and to prevent HIV transmission, presuming patients are willing and able to commit to therapy and understand the importance of adherence.** This recommendation is based on growing evidence that uncontrolled viremia is associated with the development of non-AIDS-defining diseases that include cardiovascular, renal, and liver diseases; neurologic complications; and malignancies.<sup>5</sup>

Further support is provided by two studies that show delayed disease progression in women who continue cART postpartum. However, the postpartum period poses unique challenges to adherence secondary to the demands of caring for a newborn.<sup>7</sup> Factors to consider regarding postpartum therapy include current treatment guidelines that recommend cART for all HIV-infected individuals to reduce pretreatment CD4 cell counts and trajectory, HIV RNA levels, and adherence issues, and thereby reduce the risk of disease progression and transmission; however, any therapy must consider partner HIV status, future childbearing plans, and patient preference.<sup>5,7</sup>

For patients who continue cART postpartum, standard medication doses can be used immediately following delivery that predominantly affects PIs. If ART is discontinued following delivery, all drugs should be stopped simultaneously unless the patient is on a regimen that contains an NNRTI. Women who receive NNRTI-based regimens should continue the dual-NRTI backbone for at least 7 days after stopping the NNRTI to reduce the development of NNRTI resistance. An alternative, more conservative strategy is to replace the NNRTI with a PI while continuing the NRTIs then to discontinue all the drugs at the same time. The optimal interval between discontinuing an NNRTI and stopping the other ARV drugs is unknown, but at least 7 days is recommended. Drug concentrations may be detectable for more than 3 weeks after EFV discontinuation; therefore some experts recommend continuing other ARV agents or substituting a PI for EFV in addition to the other agents for up to 30 days.<sup>7</sup>

Infant and maternal postpartum ARV prophylaxis significantly lowers, but does not completely eliminate, the risk of postnatal HIV transmission through breast milk. Studies to discern this were performed in areas of the world where formula feeding is not a viable alternative. **Because the benefits of breastfeeding in the United States do not outweigh the risk of HIV transmission, breastfeeding is not recommended for HIV-infected women in the United States.** Contraceptive counseling is a critical aspect of postpartum care. Women should be offered highly effective contraceptives that include long-term reversible methods, implants, injectables, and intrauterine devices (IUDs) to be used in conjunction with condoms to prevent unintended pregnancy.

## Infant Screening and Diagnosis

Because the fetus receives maternal IgG by transplacental passage, serologic tests of the HIV-exposed neonate will almost always be positive. In infants, the diagnosis of HIV infection is made by PCR amplification of HIV DNA (more sensitive for the neonatal period) or RNA assays. Virologic tests to diagnose HIV infection should be performed within the first 14 to 21 days of life, at 1 to 2 months, and at 4 to 6 months of age. Two positive tests on different specimens, excluding cord blood, are required to diagnose HIV infection; one positive test is a presumptive diagnosis. HIV is presumptively excluded with two negative tests, one at age 14 days or older and the second at age 1 month or older. Definitive exclusion in a non-breastfed infant is based on two negative tests at age 1 month or older and at age 4 months or older. Further details on case definitions for HIV infection are available from the CDC at [www.cdc.gov](http://www.cdc.gov).<sup>17</sup>

## Preconception Counseling for Women With Human Immunodeficiency Virus

**Providers should discuss childbearing intentions, including preconception counseling and care, with all patients in a nonjudgmental manner as recommended by the ACOG and the CDC.** Issues relevant to HIV-infected women include HIV disease status assessment, hepatitis status assessment, the need for prophylaxis or treatment of opportunistic infections, and evaluating and potentially changing therapy based on the effectiveness and teratogenic potential of drugs in the ARV regimen. Because approximately half of all pregnancies in the United States are unintended, avoiding drugs with teratogenic potential (i.e., EFV) in women of reproductive age should be considered. HIV-infected women are recommended to attain a stable, maximally suppressed viral load prior to conception, because early and sustained control of HIV replication is associated with maximally decreasing perinatal transmission and also reduces sexual transmission.<sup>7</sup> Counseling should review (1) the influence of HIV on pregnancy; (2) appropriate contraceptive options that reduce the likelihood of unintended pregnancy, because ART reduces hormonal contraceptive efficacy (predominantly NNRTIs and PIs); and (3) safe sexual practices that minimize the risk of acquiring sexually transmitted infections or acquiring more virulent or resistant HIV strains.<sup>7</sup> The perinatal treatment guidelines contain detailed, specific information regarding ARV and hormonal contraceptive interactions. Depot medroxyprogesterone acetate (DMPA) can be used without restriction with all ARV, whereas other contraceptives are influenced by ARVs.<sup>7</sup> Women contemplating pregnancy should take a daily multivitamin that includes 400 mg of folic acid to help prevent birth defects.

## Human Immunodeficiency Virus Discordant Couples

HIV-uninfected pregnant women with HIV-infected partners may present for consultation. **Recommendations are to review and encourage safe sexual practices, including consistent use of barrier contraception, preexposure prophylaxis (PrEP), and a plan for HIV screening.** As a high-risk patient, first- and third-trimester screening is appropriate. This does not need to include viral load determination, because fourth-generation screening protocols are sufficiently sensitive and have a lower false-positive rate. If women present to labor and delivery without documented negative serology at 36 weeks, rapid intrapartum testing should be performed. Women should also be

counseled to recognize the signs and symptoms of acute HIV infection and should be advised to seek immediate care if they experience these symptoms.

Consultation in the preconception period should include screening and treatment of genital tract infections in both partners, because inflammation is associated with viral shedding and increased HIV acquisition for both partners. The HIV-infected partner should be on an ARV regimen with maximal or complete suppression of viral load, which reduces sexual transmission by as much as 96%.<sup>5</sup> Methods of safe conception depend on which partner is HIV infected. For an HIV-infected woman, the safest conception method is artificial insemination. This can be performed in the periovulatory period by the patient at home using a syringe. In discordant couples with an HIV-infected man, the safest reproductive option is using donor sperm from an HIV-uninfected man. If this is not acceptable, semen analysis is recommended (HIV and ARV may reduce sperm count and quality) to prevent unnecessary exposure to infectious genital fluid if the likelihood of getting pregnant is low. Sperm preparation techniques coupled with intrauterine insemination (with or without ovulation induction), in vitro fertilization, or intracytoplasmic sperm injection has been reported to be effective in avoiding seroconversion in uninfected women and offspring. The National Perinatal HIV Hotline (1-888-448-8765) is a resource for a list of institutions that offer reproductive services for HIV-serodiscordant couples. In patients without resources to enable assisted reproductive technology, timed periovulatory unprotected intercourse (condoms should be used at all other times) with a maximally suppressed partner may reduce sexual HIV transmission.

Periconception preexposure prophylaxis (PrEP) may minimize HIV transmission risk within discordant couples. **PrEP is the use of ARV medications by HIV-uninfected individuals to maintain blood and genital drug levels sufficient to prevent HIV acquisition.** Whereas studies have demonstrated that PrEP reduces the risk of HIV acquisition in both men and women, with minimal risk of incident ARV resistance, others have not shown benefit, likely related to adherence issues. One study that investigated PrEP with timed intercourse gave oral TDF at the luteinizing hormone peak with a second oral dose 24 hours later. None of the women became HIV infected, and pregnancy rates were high, plateauing at 75% after 12 attempts. Combination TDF/FTC, currently being evaluated in ongoing trials, is recommended for anyone at ongoing risk of HIV acquisition. Pregnancy is not a contraindication to PrEP.

## Counseling and Coordination of Care

**Ongoing care of the HIV-infected pregnant woman is enhanced by having a multidisciplinary team, which may include physicians, social workers, a nutritionist, psychologists, and peer counselors.** Management should include frequent visits and ongoing discussion regarding adherence to medication regimens to prevent the development of resistance to ARV therapy and to reduce perinatal HIV transmission. Patients should be counseled about the impact of HIV infection on pregnancy, including the risk of perinatal transmission, side effects of medications, potential methods of delivery, and treatment options. **Studies have shown that pregnancy does not affect the progression of HIV disease.** It is unclear whether ART influences preterm delivery, although some reports have shown an increased risk. However, a recent prospective cohort study of over 800 patients who received cART between 2002

and 2008 did not find an increased incidence of preterm birth in women who received PIs.<sup>18</sup> Although a potential increased risk of preterm birth with ART cannot be fully ruled out, the clear maternal health benefits and reduced perinatal HIV transmission support the use of ART during pregnancy. Ascertaining whether the patient has disclosed her HIV serostatus to sex and needle-sharing partners is appropriate. Addressing barriers that prevent disclosure, including recommendations and/or referral for assistance regarding how to safely disclose HIV serostatus, is warranted. Some state and local governments require that clinicians report any known partners of HIV-infected patients to the local health department; thus providers should be aware of regulations that will influence their practice.

For both HIV-infected and exposed women, HIV prevention should be discussed using a straightforward, nonjudgmental approach. Ongoing risk identification should be performed that includes sexual behaviors, IV drug use, sexually transmitted diseases, and untreated psychiatric issues that potentially increase a person's likelihood of engaging in risky behaviors. Behavior interventions, treatment, and avoidance of risk factors should be discussed, emphasizing the importance of consistent condom use and consideration of PrEP even though ART decreases the risk of HIV transmission. Although no reliable data on HIV serodiscordance rates in the United States exist, data on women from sub-Saharan Africa show that women in serodiscordant relationships may be particularly vulnerable to HIV infection.<sup>7</sup>

## INFLUENZA

### Virology and Epidemiology

Influenza is in the Orthomyxoviridae family, which includes the genera *Influenzavirus A*, *Influenzavirus B*, and *Influenzavirus C*. Influenza B and C are found almost exclusively in humans, whereas the host range of influenza A includes mammalian and avian species. Influenza virus has a negative-stranded, segmented RNA genome that enables *reassortment*, the rearrangement of viral gene segments in cells infected with two different influenza viruses. This results in the rapid generation of new influenza virus strains (recombinants), which have been responsible for pandemic outbreaks, and is termed *antigenic shift*. Point mutations within the viral genome result in minor, gradual antigenic changes defined as *antigenic drift*. These genetic strategies, combined with a wide host range and our inability to generate a protective immune response against the entire genera, enable *Influenzavirus* to remain an important pathogen that requires annual vaccination. **The World Health Organization (WHO) and U.S. Public Health Service recommend strains to be included in the annual vaccine based on recent prevalence.**

Influenza viruses are enveloped; hemagglutinin (H or HA) and neuraminidase (N or NA) viral glycoproteins are present on the surface, and the virus capsid proteins are M1 and M2. HA binds the cell surface receptor (neuraminic acid), is highly antigenic, and is the target of neutralizing antibodies that protect against infection. NA does not induce neutralizing antibodies; however, antibodies that recognize NA are disease suppressive but permit infection. NA cleaves sialic acid from the infected cell surface, which facilitates virus release (budding) from these cells, and it may remove sialic acid from mucin, enabling cell-free virus to reach epithelial cells. Viral entry begins when HA binds the cell receptor, followed by endocytosis of the viral particle. Within the endocytic compartment, low pH triggers conformational changes in HA, which are required for fusion.

Viral uncoating also requires M2, an ion channel protein that permits influx of H<sup>+</sup> ions into the virus particle, which enables the viral nucleoprotein to enter the cytoplasm.

Influenza strains are named according to their genus (type), the species from which the virus was isolated (omitted if human), and the H and N subtypes. H subtypes confer species specificity, and there is only a single NA subtype for influenza B. **Influenza is spread by respiratory droplets, is highly contagious, and occurs as an epidemic typically during the winter months.** Approximately 50 million cases occur annually in the United States. Children younger than 2 years old and the elderly have the highest hospitalization rates. In 2009, a novel influenza A, H1N1, emerged secondary to complex genetic reassortment. A unique pandemic ensued; 90% of hospitalizations and 87% of deaths occurred in people younger than 65 years. In addition, **788 pregnant women with confirmed or probable H1N1 that resulted in 280 intensive care unit (ICU) admissions and 56 deaths were documented during this pandemic.** The documented case reports potentially underreport infection and overestimate the prevalence of severe illness. The influence of this pandemic can be extrapolated from the mortality rate: **5% of H1N1-related deaths occurred in pregnant women, which represented only 1% of the population; this suggests that pregnant women infected with influenza had an elevated risk of serious illness and death, according to multiple published studies.**<sup>19,20</sup>

### Clinical Manifestations

Influenza viruses cause acute upper respiratory tract illness, characterized by the abrupt onset of fever, chills, headache, myalgias, malaise, a dry cough, and nasal discharge. GI manifestations and conjunctivitis can also be present. The incubation period ranges from 1 to 5 days, and most cases of influenza are self-limited. Complications include pneumonia, which occurs in up to 12% of influenza-infected pregnant women,<sup>21</sup> along with Reye syndrome and disseminated intravascular coagulation (DIC). Changes in the immune, cardiac, and respiratory systems likely increase the risk of severe illness in pregnant women infected with influenza.

### Diagnosis

Rapid influenza diagnostic tests (RIDTs) are immunoassays that identify influenza A and B viral nucleoproteins in 15 minutes or less. RIDTs are very specific (90% to 95%) but the sensitivity is limited (10% to 70%), with the potential for false-negative results during periods of high influenza incidence. False-positive results occur when influenza is at low prevalence. Some RIDTs distinguish between influenza A and B, but they cannot determine viral subtype. The optimal time of specimen collection is within 48 to 72 hours of illness onset. Confirmation is via RT-PCR, culture, ELISA, or immunofluorescence of respiratory secretions; immunofluorescence and RT-PCR have the most rapid turnaround.

### Management of Influenza During Pregnancy

**Pregnant women suspected to be infected with influenza should be treated immediately, independent of vaccination status, without waiting for diagnostic confirmation.** The recommended treatment for both seasonal and pandemic influenza infection is oseltamivir (Table 53-6); acetaminophen should be used as an antipyretic, and additional recommendations regarding adjunctive therapy are presented in Chapter 38.

**TABLE 53-6** ANTIVIRAL MEDICATION DOSING RECOMMENDATIONS FOR INFLUENZA

| ANTIVIRAL AGENT       | ACTIVITY          | ACTION       | USE                      | DOSAGE                                  | DURATION         | CONTRAINDICATIONS   |

#### BOX 53-4 RISK FACTORS FOR SEVERE ILLNESS AND DEATH IN INFLUENZA VIRUS-INFECTED PREGNANT WOMEN

Asthma  
Smoking  
Obesity  
Chronic hypertension  
Delayed treatment

The preterm birth rate following pandemic H1N1 infection was 30%. Increased preterm parturition also occurs following seasonal influenza infection, so appropriate monitoring should be undertaken, particularly in women with respiratory compromise.<sup>19,22,23</sup> Early antiviral treatment reduces the duration of the illness, secondary complications, and hospitalizations. Initiating treatment up to 5 days after symptom onset still confers benefit. The risk of severe illness and death is highest in the latter part of pregnancy, compared with the first trimester. Other risk factors are described in [Box 53-4](#).<sup>19,22</sup> The pregnancy-associated risk of illness persists for 2 weeks postpartum.

Chemoprophylaxis should be considered for high-risk, unvaccinated women exposed within 48 hours of presentation (see [Table 53-6](#)). Alternative therapy for infection includes amantadine or rimantadine, both of which block M2 channel activity in influenza A. However, significant viral resistance to these drugs limits their effectiveness. **To prevent maternal influenza infection and associated perinatal morbidity and mortality, both the ACOG and the CDC recommend annual vaccination of all pregnant women during influenza season (October to May) using the intramuscular inactivated vaccine.**<sup>24</sup> Maternal vaccination also protects infants up to 6 months of age from influenza infection, has no adverse fetal effects, and is safe in breastfeeding women. **The intranasal vaccine contains live virus and should not be used during pregnancy.** The optimal time to vaccinate patients is in October and November to minimize the risk of acquiring influenza. However, vaccination is safe and effective at any time of the year and at any gestational age.

## PARVOVIRUS

### Virology and Epidemiology

Parvoviruses are small, nonenveloped viruses that contain negative-stranded DNA that encodes two major genes: the REP, or NS, gene encodes functions required for transcription and DNA replication; and the CAP, or S, gene encodes the coat proteins VP1 and VP2. Parvovirus B19 was identified in the 1970s in blood bank specimens and was first linked to sickle cell disease patients with transient aplastic crisis. Parvovirus B19 was then associated with fifth disease, or erythema infectiosum (EI),

and was later linked to hydrops fetalis. Parvoviruses preferentially infect rapidly dividing cells, which explains the observed fetal and neonatal susceptibility. Parvovirus B19 infection is restricted to humans, and the cellular receptor is erythrocyte P antigen, which explains the propensity of this virus to infect red blood cells and their precursors. P antigen is also expressed on megakaryocytes, endothelial cells, placenta, fetal liver, and fetal heart. Parvovirus B19 is spread via respiratory droplets, infected blood products, with hand-to-mouth contact, and perinatally. The incubation period ranges from 4 to 20 days following exposure. Seroprevalence increases with age, and 65% of pregnant women have evidence of prior infection and are immune. Conversely, susceptible women have approximately a 50% risk of seroconversion following exposure to parvovirus B19. Daycare workers, teachers, and parents have all been shown to be at increased risk of seroconversion.

### Clinical Manifestations

**The most common presentation of B19 parvovirus infection is EI, which is characterized by a facial rash consistent with a slapped-cheek appearance and a reticulated or lacelike rash on the trunk and extremities ([Fig. 53-2](#)).** The rash is immune-complex mediated and may reappear secondary to temperature changes, sunlight exposure, and stress for several weeks. Infection can also be accompanied by fever, malaise, lymphadenopathy, and symmetric peripheral arthropathy. The hands are most frequently affected followed by the knees and wrists. Symptoms are typically self-limiting but may last for several months. Asymptomatic infection occurs 20% of the time. Persistent parvovirus infection is rare and presents as pure red cell aplasia in patients who fail to mount a neutralizing antibody response.<sup>25</sup> **Fetal infection can be asymptomatic or characterized by aplastic anemia of varying severity. Severe anemia can lead to high-output congestive heart failure and nonimmune hydrops.** Direct infection of the myocardium may also contribute to fetal heart failure.

### Diagnosis

Serologic testing via ELISA detects IgG and IgM against B19 parvovirus. However, PCR amplification of viral DNA from maternal or fetal blood is a more sensitive method to confirm acute parvovirus infection because viremia occurs prior to the development of specific antibodies, and viral protein-antibody complexes can result in false-negative serology. Maximum sensitivity is achieved with concurrent serologic and nucleic acid testing.

### Management of Parvovirus During Pregnancy

Following exposure to B19 parvovirus in a presumed seronegative woman, serologic and DNA testing should be performed.

**FIG 53-2** **A**, Characteristic “slapped cheek” rash of erythema infectiosum. **B**, Note lacelike rash on upper extremity. (From Ferri F, et al. *Ferri’s Fast Facts in Dermatology*. Philadelphia: Saunders; 2011.)

**TABLE 53-7** ASSOCIATION BETWEEN GESTATIONAL AGE AT TIME OF EXPOSURE AND RISK OF FETAL PARVOVIRUS INFECTION

| TIME OF EXPOSURE<br>(WEEKS OF GESTATION) | FREQUENCY OF SEVERELY<br>AFFECTED FETUSES |
|--|---|
| 1-12                                     | 19%                                       |
| 13-20                                    | 15%                                       |
| >20                                      | 6%  |

The presence of IgG antibody is consistent with prior exposure and/or infection, and no further workup is needed. Susceptible women should have repeat testing performed in about 3 weeks. Pregnant women with confirmed infection should be treated with supportive care because maternal B19 parvovirus infection is usually self-limited. The relationship between the gestational age at the time of exposure to B19 parvovirus and the risk of fetal parvovirus infection that results in a severely affected fetus is shown in [Table 53-7](#). **Serial ultrasounds to evaluate the fetus for hydrops should be performed for 8 to 10 weeks after maternal illness.** If no signs of hydrops are seen during this period, further evaluation is unnecessary. Recent studies have shown that measurement of the fetal middle cerebral artery peak systolic velocity can be useful in documenting fetal anemia prior to the development of hydrops in cases of congenital B19 parvovirus infection.<sup>26</sup>

**Fetal infection occurs following approximately 33% of maternal infections.**<sup>27</sup> However, the rate of fetal death

secondary to intrauterine B19 parvovirus infection is dependent on when maternal infection occurs. Fetal death is rare when maternal infection occurs beyond 20 weeks of gestation, but fetal mortality associated with fetal hydrops is approximately 11% when maternal B19 infection occurs during the first 20 weeks of pregnancy.<sup>28</sup> Although 33% of fetal hydrops will resolve without treatment,<sup>29</sup> there are no reliable predictors for the resolution of hydrops versus fetal death. Thus cordocentesis and intrauterine transfusion are recommended when fetal hydrops is present.<sup>30</sup> Recent studies have documented thrombocytopenia in parvovirus B19–infected fetuses at the time of cordocentesis.<sup>31</sup> However, it is unclear whether any benefit exists to providing platelets at the time of red blood cell transfusion. The majority of fetuses infected with parvovirus B19 demonstrate normal long-term development.<sup>32-34</sup> Rare cases of neurologic morbidity, persistent infection with severe anemia, and other sequelae have been reported following fetal infection.

## MEASLES

### Virology and Epidemiology

Measles, or rubeola, is an enveloped, negative-stranded RNA virus that is part of the Paramyxoviridae family, which includes respiratory syncytial, canine distemper, mumps, and parainfluenza viruses. Measles’ host range is limited to humans, and the envelope of this virus contains fusion and hemagglutinin (HA) proteins; HA binds the cellular receptor, which is a complement regulatory protein, and the fusion protein permits viral entry into the cell. **Rubeola (measles) is one of the most infectious viruses, spread primarily via respiratory droplets; with exposure, 75% to 90% of susceptible contacts become infected.** Although a live, attenuated vaccine is readily available, measles outbreaks in the United States occur among unvaccinated preschoolers, which includes those younger than 15 months; previously vaccinated school-age children; college students; and persons who originated from outside the United States. The incidence of outbreaks in previously vaccinated individuals has been reduced since implementation of a two two-dose vaccination strategy. Until 2014, fewer than 200 cases of measles were diagnosed in the United States annually. However, over 600 measles cases were documented in 2014, which included a large, multistate outbreak linked to an amusement park in California.

### Clinical Manifestations

Rubeola has an incubation period of 10 to 14 days. Infected individuals first manifest prodromal symptoms, which may include fever, malaise, myalgias, and headache. This is followed by ocular symptoms that include photophobia and a nonexudative conjunctivitis. Koplik spots, tiny white spots on a red base on the buccal mucosa lateral to the molar teeth, may appear during the prodrome and are pathognomonic for measles infection. If Koplik spots are visualized, they typically appear a day or so prior to the rash and disappear within two days of its appearance. The rash of measles appears between 2 and 7 days following the prodrome and is initially present behind the ears or on the face as a blotchy erythema. The rash then spreads to the trunk, followed by the extremities; the hands and feet may be spared. The rash is initially macular and blanches with pressure but becomes papular and coalescent with a red, nonblanching component ([Fig. 53-3](#)). The rash tends to fade after about 5 days, although fever can persist for up to 6 days and may reach

41°C. A productive cough may develop that can persist after defervescence. Lymphadenopathy accompanies the fever and can persist for several weeks.

Complications of rubeola can include laryngitis, bronchiolitis, pneumonia, and otitis media due to secondary bacterial infections. Rare complications include hepatitis, encephalitis, atypical measles, and acute encephalitis. Encephalitis occurs in about 1 in 1000 cases of measles and results from either viral infection of the CNS or a hypersensitivity reaction to systemic viral infection. Symptoms include recurrence of fever and headache, vomiting, and a stiff neck followed by stupor and convulsions. The mortality is 10%, and permanent neurologic sequelae—including mental retardation—develop in 50% of individuals. Atypical measles, which occurs in adults vaccinated with the formalin-inactivated measles vaccine, is characterized by high fever, pneumonia with pleural effusions, obtundation, and a hemorrhagic exanthema. Patients usually have high antibody titers to measles but lack antibodies to the fusion protein. Atypical measles is usually self-limiting, and patients are not contagious to others. A rare complication of measles infection is subacute sclerosing panencephalitis (SSPE), which occurs in 0.5 to 2 per 1000 cases of measles years after the acute infection. SSPE is most common in children who contracted measles prior to 2 years of age and is characterized by progressive neurologic debilitation and a virtually uniformly fatal outcome.

## Diagnosis

**The diagnosis of measles is usually made based on clinical presentation;** as mentioned earlier, Koplik spots are pathognomonic for measles infection. In their absence, diagnosis is based on a history of recent exposure or the presence of a rash. An increase in antibody titer may be detected as early as the first or second day of the rash. Assays for detection of IgM and viral

**FIG 53-3** Maculopapular rash of measles, or rubeola, showing coalescence of lesions. (Courtesy Centers for Disease Control and Prevention, Dr. Heinz F. Eichenwald.)

RNA are also available. Differential diagnoses include rubella, scarlet fever, infectious mononucleosis, secondary syphilis, toxic shock syndrome, Kawasaki disease, erythema infectiosum, and drug rash. A guide to differentiating some of these illnesses is shown in Table 53-8.<sup>35</sup>

## Management of Measles During Pregnancy

Pregnant women with rubeola infection should receive supportive care and should undergo careful observation for evidence of complications. **The largest, most recently reported study of measles in pregnancy revealed that pregnant women were twice as likely to require hospitalization (60%), three times as likely to acquire pneumonia (26%), and six times as likely to die of complications (3%) compared with nonpregnant adults.**<sup>36</sup> Given the higher rate of maternal morbidity and mortality in the setting of measles infection, secondary bacterial infections should be treated promptly with antibiotics. Ribavirin can be considered for cases of viral pneumonia, but it has not been conclusively shown to be of benefit.

**The risk of spontaneous abortion and preterm delivery following measles infection during pregnancy is 20% to 60%.**<sup>36</sup> If miscarriage does not occur, patients should be counseled that measles does not appear to be associated with an increased risk of congenital malformations and that the risk of congenital measles infection appears to be well below 25%. No congenital measles infections were reported in two recent studies of 98 cases of maternal measles.<sup>36,37</sup> Detailed serial ultrasounds may be performed; evidence of in utero infection includes microcephaly, growth restriction, and oligohydramnios. Reports conflict regarding whether an association exists between measles infection in pregnancy and Crohn disease in offspring, and others have reported an association between measles exposure at the time of birth and the development of Hodgkin disease in children.

**The most effective way to prevent measles infection in pregnancy is to ensure vaccination prior to pregnancy using a two-dose series, usually a component of the trivalent measles, mumps, and rubella (MMR) vaccine.** This live attenuated vaccine should *not* be given to pregnant women, and patients are recommended to use effective contraception for 3 months after vaccination, although no cases of congenital measles infection have been reported secondary to the measles vaccine.<sup>38</sup> Although most pregnant women will have been previously vaccinated against measles, between 3.2% and 20.5% of pregnant women have either absent or low antibody titers, which would classify them as seronegative.<sup>39</sup> Any pregnant women exposed to measles should have an IgG titer drawn. Seronegative (susceptible) women should be treated with immune globulin intravenously within 6 days of exposure.<sup>38</sup> Neonates delivered

| Scarlet fever            | ±              | ±        | ++          | —        | +            | +                         |
| Infectious mononucleosis | —              | —        | ++          | ±        | ±            | +                         |
| Drug rash                | —              | —        | —           | —        | —            | —                         |

to a parturient who developed measles within 7 to 10 days of delivery should receive intramuscular (IM) immune globulin. These children should also receive the MMR vaccine at 12 to 15 months of age.<sup>38</sup>

## RUBELLA

### Virology and Epidemiology

Rubella is a small, spherical, enveloped, single-stranded RNA virus, which is part of the *Togaviridae* family. Transmission occurs via respiratory droplets and close personal contact. Following infection of respiratory mucosa, virus is found within cervical lymph nodes and disseminates hematogenously. Rubella outbreaks occur in school-age children and in settings where crowded conditions exist such as military bases, religious communities, college campuses, and prisons. As a result of routine vaccination, no recent major outbreaks have occurred in the United States. Elimination of endemic rubella is a national health goal. From 2005 to 2011, a median of 11 rubella cases occurred annually.<sup>38</sup> Most infections occur in foreign-born unvaccinated individuals.

### Clinical Manifestations

The incubation period following exposure is 12 to 19 days. However, acute rubella infection is not always diagnosed because 20% to 50% of infections are asymptomatic, and there is no associated prodromal illness. Symptomatic infected patients present with a rash, malaise, fever, conjunctivitis, and generalized lymphadenopathy. The rash is nonpruritic, begins on the face and neck as a faint macular erythema, and spreads rapidly to the trunk and extremities (Fig. 53-4). The rash lasts approximately 3 days and blanches with pressure. Transient polyarthralgias and/or polyarthritis that lasts 5 to 10 days may appear in adolescents and adults following the rash. Rare complications include thrombocytopenic purpura, encephalitis, neuritis, and orchitis.

### Diagnosis

Serology is most commonly used to document exposure and/or infection with rubella. IgM specific for rubella is detectable prior to the onset of the rash. Isolation and culture of the virus is possible as is detection of viral RNA by RT-PCR. In cases of suspected congenital rubella infection, RT-PCR can be used to

**FIG 53-4** This patient presented with a generalized rash on the abdomen caused by German measles (rubella). The rash usually lasts about 3 days and may be accompanied by a low-grade fever. Rubella is caused by a different virus from the one that causes regular measles (rubeola), and immunity to rubella does *not* protect a person from measles, and vice versa. (Courtesy Centers for Disease Control and Prevention.)

detect viral RNA within chorionic villi, fetal blood, and amniotic fluid specimens.

### Management of Rubella Infection During Pregnancy

Maternal rubella infection is usually self-limited. However, **congenital rubella infection is associated with miscarriage and stillbirth and can have significant deleterious effects on the fetus.** The primary purpose of the rubella vaccine is to prevent congenital rubella infection, and IVIG administration does not do this. Although this live attenuated vaccine is contraindicated during pregnancy, **no cases of congenital rubella syndrome have been reported in approximately 1000 infants born following inadvertent vaccination during pregnancy.**<sup>38</sup> This indicates that rubella vaccination during pregnancy does not carry a significant risk of birth defects secondary to congenital rubella infection. Therefore therapeutic termination of pregnancy is not recommended in these cases.<sup>38</sup> **Rubella serology is typically performed at the initial prenatal visit to identify women with inadequate levels of antibody.** These women should receive rubella vaccine in the postpartum period. The vaccine is available in monovalent, bivalent (measles-rubella), or trivalent forms (MMR).

### Congenital Infection

Only four cases of congenital rubella syndrome (CRS) were documented in the United States from 2005 through 2011.<sup>38</sup> Several retrospective studies have established relationships between the frequency and severity of CRS and the timing of rubella infection in pregnancy. In general, infection in early pregnancy is associated with increased CRS severity. **When maternal infection occurs within the first 12 weeks of pregnancy and is accompanied by a rash, over 80% of fetuses become infected with rubella.**<sup>40</sup> Of these infants, 67% will have findings consistent with CRS.<sup>41</sup> First-trimester infection with rubella is also associated with miscarriage, although some of the women in these studies terminated their pregnancy secondary to exposure. As the pregnancy progresses, the risk of congenital rubella infection decreases: the risk is 54% at 13 to 14 weeks and 25% at the end of the second trimester.<sup>40</sup> The association of congenital rubella infection with CRS also decreases with increasing gestational age, with fetal defects being rare in fetuses infected beyond the 16th week of pregnancy.<sup>40,41</sup> Given that the association of congenital rubella infection and CRS is not absolute at any gestational age, ultrasound may be a useful adjunct in determining whether a fetus is affected, although this technique cannot detect many of the associated abnormalities.

**The most common manifestation of congenital rubella infection is growth restriction. Sensorineural hearing loss is the most common single defect associated with CRS and affects up to 90% of congenitally infected infants, and the rate of hearing loss is inversely related to the gestational age of congenital rubella infection.**<sup>42</sup> When infection occurs prior to 12 weeks' gestation, other common defects include cardiac lesions (13%), most commonly patent ductus arteriosus, and eye defects (13%) such as cataracts, glaucoma, or retinitis.<sup>41</sup> Other findings consistent with CRS include microphthalmia, microcephaly, cerebral palsy, mental retardation, and intrauterine growth restriction (IUGR). Most of these findings are seen only in fetuses infected within the first 12 weeks of gestation. However, virtually all fetuses infected prior to the 11th week of

gestation have CRS.<sup>40</sup> Severe disease can also include thrombocytopenic purpura or hepatosplenomegaly. Fetuses infected between 13 to 16 weeks of gestation have up to a 35% risk of being affected by CRS<sup>40</sup> and typically have hearing loss as their principal manifestation of CRS. Fetuses infected at more advanced gestational ages rarely have sequelae associated with CRS. Following congenital rubella infection, infants may shed virus for up to 1 year after birth. Even in neonates who are asymptomatic at birth, up to one third can manifest long-term complications that include type 1 diabetes mellitus and progressive panencephalitis in the second decade of life.<sup>43,44</sup>

## CYTOMEGALOVIRUS INFECTION

### Virology and Epidemiology

Cytomegalovirus (CMV) is a large, enveloped, double-stranded DNA virus that is a  $\beta$ -herpesvirus. Herpesviruses have large, complex genomes that replicate in the nucleus of infected cells and enable these viruses to establish acute, persistent, and latent infection. Recurrent CMV infection occurs following reactivation from latently infected cells or by superinfection with a different strain or serotype of virus. CMV is not highly contagious; transmission primarily occurs by contact with infected saliva or urine, and it can also be transmitted via blood or by sexual contact. The incubation period is about 40 days following exposure. Within the United States, primary CMV infection in pregnant women ranges from 0.7% to 4%, and recurrent infection can be as high as 13.5%. Young infants and children with subclinical infection are a major source of infectious CMV; approximately 50% of children who attend daycare actively shed CMV virus in their saliva and/or urine, and fomites within daycare centers are potential sources of CMV infection. Thus **daycare workers are at high risk for infection**. Small children pose an infection risk to family members with annual seroconversion rates of approximately 10% for parents and uninfected siblings.<sup>45</sup> CMV seroprevalence correlates with lower socioeconomic status, birth outside North America, increasing parity and age, abnormal PAP smears, *Trichomonas* infection, and the number of sex partners. CMV infection is also increased in immunocompromised patients. Between 0.2% and 2.2% of infants born in the United States become infected with CMV in utero secondary to maternal infection, and **congenital CMV is the leading cause of hearing loss in children**. Another 6% to 60% of children become infected within the first 6 months of life secondary to intrapartum transmission, environmental exposure, or breastfeeding. However, infants infected peripartum rarely demonstrate serious sequelae of CMV infection.<sup>46</sup>

### Clinical Manifestations

Infected patients may be asymptomatic or they may have a mononucleosis-like syndrome with fever, malaise, myalgias, chills, and cervical lymphadenopathy. Infrequent complications include pneumonia, hepatitis, Guillain-Barre syndrome, and aseptic meningitis. Laboratory abnormalities include atypical lymphocytosis, elevated hepatic transaminases, and a negative heterophile antibody response (which distinguishes CMV from Epstein-Barr virus infection).

### Diagnosis

Active, maternal CMV infection is best diagnosed by culture, detection of CMV antigens, or DNA PCR of blood, urine,

saliva, amniotic fluid, or cervical secretions. Serologic tests are available, but antibody levels may not be detectable for up to 4 weeks after primary infection, and titers can remain elevated; this makes a serologic diagnosis of reinfection difficult. A four-fold increase in IgG titers within multiple specimens suggests active infection. IgM is used to diagnose recent or active infection, but both false-positive and false-negative results can occur. **Routine CMV screening during pregnancy is not recommended secondary to high seroprevalence.** Fetal infection is documented by amniotic fluid culture or PCR, and PCR sensitivity approaches 100% in gestations greater than 21 weeks.<sup>46</sup> Fetal serology and blood culture are much less sensitive. Fetal CMV infection can occur weeks to months following maternal infection; thus repeat testing may be considered at 7-week intervals.<sup>46</sup> **Antepartum CMV detection does not predict the severity of congenital CMV infection, and 80% to 90% of children with congenital CMV infection have no neurologic sequelae.**

### Management of Cytomegalovirus During Pregnancy

**Pregnant women should be counseled regarding preventive measures: careful handling of potentially infected articles such as diapers, clothing, and toys; avoidance of sharing food and utensils; and frequent hand washing.** Antiviral therapy is not indicated in immunocompetent infected individuals, and ganciclovir is not effective for intrauterine treatment of congenital CMV infection. In one trial, passive antepartum maternal immunization of women with primary CMV infection with CMV-specific hyperimmune globulin was associated with decreased congenital CMV infection and fewer infants born with symptomatic CMV disease.<sup>47</sup> However, a follow-up randomized, placebo-controlled trial failed to show reduced infection or reduced sequelae.<sup>48</sup> Thus at this time, **avoiding maternal CMV infection is the only effective prevention for congenital CMV infection.**

### Congenital Infection

Congenital CMV infection is diagnosed by the detection of virus or viral nucleic acid within the first 2 weeks of life. **Intra-uterine CMV transmission is highest in the third trimester with an overall 30% to 40% risk of fetal transmission.**<sup>49</sup> **However, serious sequelae occur most frequently following first-trimester infection: 24% of infected fetuses have sensorineural hearing loss and 32% have other CNS sequelae.** After the second trimester, 2.5% of infected fetuses demonstrated sensorineural hearing loss and 15% had CNS sequelae.<sup>50</sup> Congenital CMV infection may occur following primary or recurrent CMV infection of pregnant women, but the incidence of serious sequelae is lower following recurrent infection.<sup>51</sup> Most infants with congenital CMV infection exhibit no obvious clinical findings at birth. Nonetheless, **15% of subclinical congenital CMV infection is associated with hearing loss.**<sup>51</sup>

After primary maternal CMV infection, approximately 5% to 18% of infants exhibit serious sequelae, typically following infection during the first half of pregnancy. Clinical findings in these infected infants may include jaundice, petechiae, thrombocytopenia, hepatosplenomegaly, growth restriction, and nonimmune hydrops. Long-term neurologic sequelae include developmental delays, seizure activity, and gross neurologic impairment as well as sensorineural hearing loss.<sup>51</sup> **Ultrasound can be useful in identifying a congenitally infected infant with likely**

**impairment.** Findings consistent with fetal infection include microcephaly, ventriculomegaly, intracerebral calcifications, ascites, hydrops, echogenic bowel, IUGR, and oligohydramnios. Unusual findings include fetal heart block and meconium peritonitis.<sup>52,53</sup> In the setting of confirmed fetal infection with serial normal ultrasounds, the risk of clinical symptoms of congenital CMV infection following birth is approximately 10%. Thus ultrasound findings, or their absence, are an important factor to consider when counseling.

## HERPESVIRUS

### Virology and Epidemiology

Herpes simplex virus (HSV) is another large, enveloped, double-stranded DNA virus that replicates in the host cell nucleus. Epithelial cells are the primary targets. However, HSV establishes latency within dorsal root ganglia and can disseminate via hematogenous spread. Latent viral infection can be associated with integration of the viral genome into the host cell DNA. The HSV genome is complex and encodes over 80 polypeptides, including several envelope glycoproteins. Glycoprotein G permits differentiation of two well-defined antigenic and biologic viruses, HSV-1 and HSV-2. HSV-1 is typically associated with nongenital infection, and mouth and lips are the most common sites of viral replication. HSV-1 infection is most prevalent in lower socioeconomic populations, in which 75% to 90% of individuals have antibodies that recognize HSV-1 by 10 years of age. HSV-2 infection is also associated with socioeconomic status and is usually acquired via sexual contact. In the United States, 25% to 65% of individuals have antibodies that recognize HSV-2, and seroprevalence risk correlates with the number of sexual partners. Some individuals have asymptomatic or subclinical primary HSV infections, which account for seropositive patients without a clinical history of infection.

### Clinical Manifestations

**HSV-1 infection is normally manifested by herpes simplex labialis (cold sores), whereas HSV-2 infection customarily involves the genitals and includes the vulva, vagina, and/or cervix.** Painful vesicles appear 2 to 14 days after viral exposure and rupture spontaneously, leaving shallow eroded ulcers (Fig. 53-5). Later in the infection, a dry crust forms, and lesions heal without scarring. Primary infection can be associated with fever, malaise, anorexia, and bilateral inguinal lymphadenopathy, and it is infrequently associated with aseptic meningitis. Women

**FIG 53-5** Ulcerated lesions characteristic of herpes simplex infection. (From Ferri F, et al. *Ferri's Fast Facts in Dermatology*. Philadelphia: Saunders; 2011.)

may have dysuria and urinary retention secondary to urethral involvement. Rates of symptomatic and subclinical HSV shedding from the cervix and vulva during the first 3 months following primary infection are 1% to 3%.

Healing of primary HSV-2 infection may take several weeks and is less severe in individuals with prior HSV-1 infection. Nonprimary first episodes of genital HSV occur when a second HSV strain, either HSV-1 or HSV-2, establishes infection in the presence of preexisting antibodies from a previous infection at a nongenital site. Secondary or recurrent HSV infections usually represent viral reactivation that varies in frequency and intensity. Recurrent infections are typically less severe than primary infections and are associated with fewer lesions and a shorter duration of viral shedding. **One third of HSV-infected individuals have no recurrences, one third have approximately three recurrences per year, and another third have more than three recurrences per year.** Table 53-9 compares clinical findings during primary and recurrent HSV infection. Disseminated HSV infection is rare and arises primarily in immunocompromised individuals, but it can also occur in pregnancy. Disseminated infection is characterized by skin, mucous membrane, and visceral organ involvement, and it may include ocular involvement, meningitis, encephalitis, and ascending myelitis. Prompt treatment with IV acyclovir is indicated for suspected cases of disseminated HSV.

### Diagnosis

**Definitive diagnosis of active HSV infection is made by viral culture or by nucleic acid detection of HSV, which is faster and more sensitive.** Both methods differentiate between HSV-1 and HSV-2. Culture specimens should be collected from fresh vesicles or pustules because viral recovery from crusted lesions is poor; this is not as critical for PCR-based assays. Serology can assess and differentiate primary infection from secondary infection via IgM detection. Cytologic preparations (Tzanck test) show characteristic multinucleated giant cells and intranuclear inclusions. However, this test is rarely performed given the enhanced sensitivity and specificity of culture and nucleic acid detection.

### Management of Herpesvirus During Pregnancy

**Maternal primary infection with HSV prior to labor does not usually impact the fetus.** Intrauterine HSV infection is rare and occurs in approximately 1 in 200,000 deliveries. Sequelae of intrauterine infection include skin vesicles and/or scarring, eye disease, microcephaly, or hydranencephaly. An association between HSV infection in the third trimester of pregnancy and IUGR has also been reported. However, this observation was based on only five patients. Birthweight of infants born to asymptomatic HSV-shedding mothers is lower than those of

**TABLE 53-9** COMPARISON OF PRIMARY VERSUS RECURRENT HERPES SIMPLEX VIRUS INFECTION

| STAGE OF ILLNESS                  | PRIMARY (DAYS) | RECURRENT (DAYS) |
|-----------------------------------|----------------|------------------|
| Incubation period and/or prodrome | 2-10           | 1-2              |
| Vesicle, pustule                  | 6              | 2                |

| Total                             | 22-30          | 13-14            |

**TABLE 53-10** HERPES SIMPLEX VIRUS TREATMENT

| DRUG         | PRIMARY INFECTION           | RECURRENT INFECTION   | PROPHYLAXIS       |
|--------------|-----------------------------|---|-------------------|
| Acyclovir    | 400 mg TID for 7 to 10 days | 800 mg BID for 5 days or 800 mg TID for 2 days                | 400 mg BID        |
| Valacyclovir | 1 g BID for 7 to 10 days    | 500 mg BID for 3 days or 1 g QD for 5 days                    | 500 to 1000 mg QD |
| Famciclovir  | 250 mg TID for 7 to 10 days | 500 mg followed by 250 mg BID for 2 days or 1 g BID for 1 day | 250 mg BID        |

BID, twice daily; TID, three times a day; QD, once per day.

nonshedding mothers, but this small observed effect may be due to differences in gestational age at birth.<sup>54</sup> Treatment regimens are described in Table 53-10. **Women with more than two HSV recurrences per year should be offered prophylaxis to decrease the frequency and severity of recurrences.**

**Intrapartum HSV exposure is associated with neonatal infection, which complicates approximately 1 in 3500 deliveries in the United States and is associated with significant neonatal morbidity and mortality.** Seventy percent of neonatal infection is caused by HSV-2, with a 50% estimated risk of neonatal HSV during primary maternal infection. The incidence of neonatal HSV incidence ranges from 0% to 3% in the setting of recurrent maternal infection.<sup>55</sup> Thus **primary maternal HSV infection, not recurrent infection, accounts for the vast majority of neonatal HSV infections.** ACOG recommends elective cesarean delivery for women with demonstrable genital herpes lesions or prodromal symptoms in labor to reduce the incidence of neonatal HSV infection.<sup>55</sup> However, because 60% to 80% of neonatal HSV infections occur following asymptomatic primary maternal infection, our capacity to prevent neonatal HSV infection by performing cesarean delivery is limited. Cost-benefit analysis of current guidelines for prevention of neonatal HSV infection found that, given the low risk of neonatal HSV transmission with recurrent maternal infection, it requires 1580 elective cesarean deliveries to prevent one neonatal HSV infection.<sup>56</sup>

The duration of ruptured membranes prior to delivery increases the risk of neonatal HSV infection. However, no evidence shows any period of time beyond which cesarean delivery is no longer beneficial. Positive antepartum HSV cultures are not associated with positive cultures at the time of delivery and are not recommended.<sup>57</sup> Prophylactic acyclovir or valacyclovir decreases HSV shedding and outbreaks and reduces the number of cesarean deliveries performed to prevent neonatal HSV infection.<sup>58</sup> This strategy should be considered for women with HSV recurrence during pregnancy. In the case of premature rupture of membranes, acyclovir or other antivirals should be considered in women with active HSV lesions being managed expectantly and taking steroids to enhance fetal lung maturity.<sup>55</sup> In these patients, decisions regarding prophylactic cesarean delivery should be based on the presence of lesions at the time of labor. The risk of neonatal HSV infection in cases of nongenital maternal HSV lesions (i.e., lesions of the thigh, buttocks, or mouth) is low, therefore cesarean delivery is not recommended for these women.

### Neonatal Herpes Infection

Factors that predict neonatal HSV transmission include cervical HSV shedding, invasive monitoring, preterm delivery, maternal age younger than 21 years, and HSV viral load.<sup>59</sup> Three patterns of neonatal HSV infections occur with equal frequency. *Local disease* is limited to the skin, eyes, and mouth—so-called SEM disease; this pattern has limited morbidity. *Disseminated*

*infection* involves multiple visceral organs and includes lungs, liver, adrenal glands, skin, eyes, and brain. Both SEM and disseminated disease are characterized by early presentation (10 to 12 days of life); however, disseminated disease is associated with significant morbidity and mortality. *CNS disease*, which may be associated with skin involvement, occurs later, during the second or third week of life. Following high-dose neonatal acyclovir therapy, 1-year mortality for CNS disease is 29%, and it is 4% for disseminated disease. Despite higher mortality, 83% of disseminated disease survivors have normal neurologic development, whereas only 31% of CNS disease survivors are neurologically intact.<sup>60</sup> Complications of neonatal HSV infection also include DIC and hemorrhagic pneumonitis.

## VARICELLA

### Virology and Epidemiology

Varicella, or chickenpox, is caused by the varicella zoster virus (VZV), part of the  $\alpha$ -herpesvirus subfamily. This enveloped virus contains double-stranded DNA and has at least 69 genes. Viral replication initially occurs within respiratory epithelial cells and is followed by systemic viremia. Long-term latent infection occurs within the nonneuronal cells of the dorsal root ganglia. Humans are the only known host for varicella, a highly contagious disease transmitted by respiratory droplets or close contact. Approximately 95% of susceptible household contacts become infected following exposure, and a 14-day incubation period precedes the emergence of symptoms. Patients are infectious from one day prior to rash appearance until lesions are crusted; immunity following infection is usually life long. Prior to VZV vaccine availability, most natural varicella infections occurred in early childhood, a time when VZV infection is usually self-limited. However, over 50% of varicella-associated mortality occurs in adults, who represent less than 10% of all varicella infections.<sup>61</sup> Most adults (>90%) are VZV immune, even in the absence of a clinical history of chickenpox.

### Clinical Manifestations

Infected patients classically present with a centripetal rash characterized by highly pruritic erythematous macules, papules, and vesicles that appear in crops. The rash spreads to the extremities, and evidence of excoriation and scabbed lesions are typically seen. Bacterial superinfection of skin lesions can occur. Fever is common, and infected adults frequently present with malaise, myalgias, arthralgias, and headache. Cough and dyspnea usually occur about 3 days after the appearance of the first skin lesions. Cyanosis, hemoptysis, and pleuritic chest pain are common.

**Patients should be carefully observed for the development of varicella pneumonia, which occurs in almost 20% of infections during pregnancy.**<sup>62</sup> Encephalitis is a rare complication of adult VZV infection. Reactivation of latent VZV infection causes herpes zoster or shingles and occurs primarily in the elderly and immunocompromised. Shingles is characterized by

a segmentally distributed rash that correlates with specific dermatomes. Pain, itching, and/or paresthesias can occur as a prodrome or with rash appearance. Zoster is usually self-limited, although patients shed infectious virus and can transmit VZV to susceptible individuals.

### Diagnosis

Diagnosis is usually made based on exposure history and/or rash. Acute infection can be rapidly diagnosed by PCR amplification of VZV-specific DNA from vesicular fluid and/or throat swabs. Serologic confirmation of exposure via ELISA, which can quantify VZV-specific IgG and IgM, is most useful for confirming prior exposure. The Tzanck stain identifies multinucleated giant cells within lesions, and varicella can be cultured.

### Management of Varicella During Pregnancy

Pregnant women infected with VZV should be offered supportive care that includes calamine lotion, antipyretics, and if necessary, systemic antipruritics. **Oral acyclovir** (800 mg by mouth five times per day) **or valacyclovir** (1 g by mouth three times a day) **are safe in pregnancy and should be given to all infected women because they decrease illness duration if instituted within 24 hours of rash emergence.** Maternal varicella pneumonia is associated with a 5% maternal mortality and presents 3 to 5 days following the rash; patients should be treated with 10 to 15 mg/kg IV acyclovir every 8 hours. **If maternal varicella occurs within 5 days before and 2 days after delivery, varicella zoster immune globulin (VZIG) should be given to the newborn to prevent neonatal varicella.** The infant should be isolated from the mother until all vesicles have crusted over to prevent VZV transmission. If possible, delivery should be delayed 5 to 7 days following the onset of maternal illness to potentially prevent neonatal VZV, which has a 20% to 30% mortality rate.<sup>62</sup>

**Prevention includes ascertaining VZV status prior to pregnancy in women without a clinical history of infection and offering live attenuated VZV vaccine (Varivax, Merck) to susceptible women prior to conception.** Adults should receive two subcutaneous doses of vaccine 4 to 8 weeks apart. The vaccine is 70% to 80% effective in preventing natural infection, but **this live vaccine is contraindicated during gestation. Pregnancy should be deferred for 3 months following vaccination, although there is no evidence of congenital VZV infection following vaccination during pregnancy.**<sup>63</sup> If a pregnant woman without clinical history of VZV infection or vaccination is exposed to varicella, serology should be performed within 96 hours of exposure. Most patients will be varicella IgG seropositive and not at risk for infection. **With confirmed VZV susceptibility or the inability to obtain serology within 96 hours of exposure, the preferred prophylaxis is high-titer VZIG.**

VariZIG (Emergent Biosolutions) can be obtained 24 hours a day from authorized distributors (1-800-843-7477 in the United States or online at [www.fffenterprises.com](http://www.fffenterprises.com) or at [www.asdhealthcare.com/home](http://www.asdhealthcare.com/home)); the recommended IM dose is 125 U per 10 kg of body weight up to a maximum of 625 U. In the absence of VZIG, IV immune globulin (IVIG) can be substituted at a dose of 400 mg/kg.<sup>64</sup> Prophylactic acyclovir given 800 mg orally five times daily for 5 to 7 days, beginning within 9 days of exposure, is 85% effective at preventing VZV infection in children.<sup>65</sup> Prophylaxis may be combined, which potentially further reduces the risk of maternal varicella infection; a small

study that compared postexposure prophylaxis in children found that acyclovir and VZIG together are more efficacious than VZIG alone.<sup>66</sup> Given the time constraints for prophylactic treatment following exposure, consider varicella serologic assessment at the first prenatal visit for women denying a history of VZV infection/vaccination. Results can guide pregnancy management and can identify patient candidates for postpartum vaccination.

### Congenital Infection

Congenital varicella infection can lead to spontaneous abortion, intrauterine fetal demise (IUFD), and varicella embryopathy. Congenital varicella syndrome (CVS) is characterized by cutaneous scars, limb hypoplasia and malformed digits, muscle atrophy, microcephaly, cortical atrophy, microphthalmia, cataracts, chorioretinitis, and psychomotor retardation. The frequency of anomalies is low following exposure prior to 13 weeks. Only 0.4% of neonates were born with CVS features in a study of 472 women. The highest risk occurs with maternal infection between 13 and 20 weeks' gestation, with a 2% CVS incidence.<sup>67</sup> No congenital malformations have been observed following maternal infection after 20 weeks' gestation, but neonatal skin lesions and scarring have been noted at birth. Ultrasound examination is preferred for prenatal assessment because serology and VZV DNA do not predict fetal injury.<sup>68</sup> Ultrasound findings suggestive of CVS can include polyhydramnios, hydrops, echogenic foci within abdominal organs, cardiac malformations, limb deformities, microcephaly, and IUGR.<sup>69</sup>

### HEPATITIS

Viral hepatitis comprises a spectrum of syndromes that range from subclinical to fulminant disease, and it is caused by several unrelated viruses. Symptoms of acute viral hepatitis may include jaundice, malaise, fatigue, anorexia, nausea, vomiting, and right upper quadrant pain. Hepatic transaminases and bilirubin are moderately to markedly elevated, and liver biopsy shows extensive hepatocellular injury with prominent inflammatory infiltration (Fig. 53-6). Most viral hepatitis infections are self-limited and resolve without treatment, but certain viruses can establish persistent infection, which leads to chronic liver disease (see Chapter 47). The majority of infections in the United States are caused by hepatitis viruses A, B, C, and D, whereas hepatitis E is endemic to Asia, Africa, and Mexico. Other viruses associated

**FIG 53-6** Photomicrograph of liver biopsy showing characteristic histologic changes of acute viral hepatitis. Note the intense inflammatory infiltrate.

with liver infection and inflammation (hepatitis) include CMV, HSV, Epstein-Barr virus (EBV), rubella, and yellow fever.<sup>70</sup>

## Hepatitis A

Hepatitis A virus (HAV) is a small, single-stranded RNA virus of the Picornaviridae family and is the causative agent for approximately one third of acute hepatitis infections in the United States. HAV transmission primarily occurs via oral-fecal contact. The incidence of HAV in pregnancy is approximately 1 in 1000, and diagnosis is based on HAV IgM and IgG serology or viral nucleic acid detection. The incubation period is approximately 28 to 30 days following exposure. HAV risk factors include contaminated food or water exposure, recent travel outside the United States, illicit drug use, and having a child in daycare. HAV infection is usually self-limited and is restricted to acute infection (not chronic), and fewer than 0.5% of patients require hospitalization. Physical activity should be limited to prevent hepatic trauma, and drugs with potential hepatotoxicity should be avoided. Sexual and household contacts of infected individuals should receive immunoprophylaxis with a single dose of HAV immune globulin and should receive HAV vaccine, an inactive vaccine safe for use in pregnancy.<sup>71</sup>

**Perinatal transmission has not been documented; however, infants delivered to an acutely infected mother should receive HAV immune globulin to prevent horizontal transmission following delivery.**<sup>71</sup> HAV infection may be complicated by cholestatic hepatitis, characterized by pruritis, dark urine, direct hyperbilirubinemia, and elevated alkaline phosphatase. This syndrome can last several months. However, long-term prognosis is good, and corticosteroid therapy alleviates symptoms.<sup>70</sup>

## Hepatitis B

### Virology and Epidemiology

Hepatitis B virus (HBV) is a small, enveloped double-stranded DNA virus in the Hepadnaviridae family. HBV is the etiologic agent of 40% to 45% of hepatitis infections, and it is estimated that 1 million individuals in the United States are chronic viral carriers with 350 million chronically infected individuals worldwide. **In the United States, 5 to 15 per 1000 pregnant women have chronic HBV infection, whereas 1 to 2 per 1000 have acute HBV infection.** The prevalence of HBV is increased in certain populations, which includes Asians, Eskimos, drug addicts, dialysis patients, prisoners, and residents and employees of chronic care facilities.<sup>70</sup> **HBV is transmitted parenterally via sexual transmission and perinatal exposure. Without intervention, infants born to HBsAg-positive mothers have a 90% risk of perinatal HBV infection** (combined prophylaxis to reduce infection is described in the management section). As many as 40% of males and 15% of females with perinatally acquired HBV will die of hepatocellular carcinoma or cirrhosis, which highlights the need for effective prevention.<sup>72</sup>

The postexposure incubation period ranges from 4 weeks to 6 months and is inversely related to viral inoculum. Acute infection is characterized by hepatic inflammation (see Fig. 53-6)<sup>70</sup>; however, less than 1% of acutely infected patients develop fulminant HBV, characterized by massive hepatic necrosis and possible pancreatitis. **Most newly infected adults (85% to 90%) clear their infection, whereas the remaining 10% to 15% become chronically infected. Chronic HBV infection has a 15% to 30% risk of liver cirrhosis and a substantially increased probability of hepatocellular carcinoma.**<sup>70</sup> The three clinically relevant HBV proteins are surface antigen

(HBsAg) or viral envelope glycoprotein; core antigen (HBcAg), associated with viral nucleic acid; and early antigen (HBeAg), a viral protein secreted from infected cells that is not incorporated into virus particles. HBeAg detection normally correlates with HBV DNA greater than  $10^6$  IU/mL and was used prior to HBV DNA assessment as a marker of viral replication and infectivity. Transition from HBeAg positivity to anti-HBe positivity usually heralds decreased viral replication; however, mutations that induce HBeAg loss with ongoing high-titer HBV replication are documented in long-term infected patients.

### Diagnosis

Acute HBV infection is diagnosed by detection of both HBsAg and HBc IgM or HBV DNA detection in HBsAg-negative patients (early acute infection). HBsAg persistence for more than 6 months delineates chronic infection; serologic findings are reviewed in Figure 53-7. Further testing is warranted to assess HBV DNA and hepatic injury, manifested by elevated aminotransferase concentrations. Chronic HBV infection has multiple phases. The immune-tolerant phase is delineated by positive HBsAg and HBeAg and by high HBV DNA in the absence of liver disease. The immune-active phase can be heralded by HBeAg-positive, HBeAg-negative, or anti-HBe-positive serology, with high levels of HBV DNA and fluctuating hepatic inflammation. The inactive phase, or carrier status, is apparent when a person is HBsAg positive and HBeAg negative with an HBV DNA that ranges from  $10^1$  to  $10^5$  IU/mL. Patients can transition between phases, which includes reversion from inactive to immune-active infection; therefore ongoing HBV DNA assessment is warranted. Anti-HBs is detected following either infection or vaccination, whereas antibody recognizing HBc or HBe is only detected in HBV-infected patients. Interpretation of HBV serology is reviewed in Table 53-11.

### Management of Hepatitis B Virus Infection During Pregnancy

**HBV infection is prevented by a recombinant vaccination that is safe in pregnancy and should be offered to patients with significant risk factors, including those with a history of sexually transmitted diseases (STDs), health care workers, and those with infected household or sexual contacts.**<sup>73</sup> Several therapies—including lamivudine, tenofovir, and telbivudine—have been used to treat HBV infection during pregnancy. Antepartum treatment for maternal benefit should be coordinated with a hepatologist because optimal treatment duration exceeds that of pregnancy. Amniocentesis is safe in chronically infected women.<sup>74</sup> HBV-infected pregnant women should be vaccinated against HAV to prevent further liver injury. **HBV-infected women can breastfeed because perinatal transmission is not increased in these patients.**<sup>75</sup>

**In the United States, all newborns are vaccinated against HBV as part of the CDC's recommendation to decrease HBV prevalence.**<sup>76</sup> Infants born to HBsAg-positive mothers should receive the HBV vaccine series and HBV immune globulin (HBIG) within 12 hours of birth.<sup>73</sup> Combined active-passive immunization is 85% to 95% effective at preventing perinatal HBV transmission, but this prophylactic regimen is substantially less effective in women with immune-tolerant HBV infection or HBV DNA greater than 200,000 IU/mL (1,000,000 copies/mL). Similar to HIV, perinatal HBV transmission correlates with maternal viral load, but consensus regarding the timing of therapy and HBV DNA concentrations above which antiviral

therapy should be considered has yet to be established.<sup>72,77,78</sup> Thus it is reasonable to measure maternal viral load and use the information obtained to educate patients regarding perinatal transmission risk and to consider additional prevention strategies beginning in the third trimester. Antepartum nucleoside/nucleotide analogue therapy combined with HBIG limits intrauterine HBV transmission better than HBIG alone and is recommended in high-risk pregnancies (e.g., in women with prior HBV transmission or high HBV DNA and in those with immune-tolerant infection).<sup>78,79</sup> Oral tenofovir (300 mg once daily) is the first-line HBV treatment secondary to its efficacy, favorable side effect profile, and low rate for the development of drug resistance (compared with lamivudine).<sup>80</sup> Tenofovir has also demonstrated safety in pregnancy secondary to its use as a first-line therapy for HIV infection. Thus preventing drug-resistance development while limiting antepartum/intrapartum HBV transmission risk should be the focus when evaluating patients for adjunctive therapy. Up to 80% to 90% of infants born to women acutely infected with HBV in the third trimester

will be HBsAg positive at birth.<sup>71</sup> However, it is unknown whether antiviral therapy lowers this risk.

## Hepatitis C

### Virology and Epidemiology

Hepatitis C virus (HCV) is an enveloped, single-stranded RNA virus that consists of six genotypes (1 through 6), and it is part of the Flaviviridae family. HCV is mainly transmitted parenterally and via vertical transmission. The incubation period following exposure is 5 to 10 weeks, and 75% of acute infections are asymptomatic. Sexual HCV transmission risk is substantially lower than with HBV. However, **50% of HCV infections become chronic, which makes it the most common chronic bloodborne pathogen in the United States.** Epidemiologic risk factors include IV drug use, history of blood product transfusion, obesity, and high gravidity. The prevalence of HCV among women of childbearing age in the United States is 1%. However, prevalence in pregnant women using IV drugs may be as high as 70% to 95%.<sup>78</sup> The recent development of highly effective,

**BOX 53-5 RISK FACTORS FOR HEPATITIS C VIRUS INFECTION****Definite Indications for Screening**

Any history of intravenous drug use (even once)  
 HIV infection  
 Unexplained chronic liver disease including elevated aminotransferase levels  
 Hemodialysis  
 Blood transfusion or organ transplant prior to 1992  
 Receipt of clotting factor concentrates before 1987  
 Sexual contact with an individual infected with HIV, HBV, or HCV  
 History of incarceration  
 Intranasal illicit drug use  
 Individuals born to HCV-infected women  
 History of unregulated tattooing or body piercing  
 Health care worker with history of needle-stick injury  
 Persons born between 1945 and 1965

**Consider Screening (Need Uncertain)**

In vitro fertilization from anonymous donors  
 Known sexually transmitted disease or multiple partners  
 Steady sex partner of individual with history of injection drug use

HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus.

genotype-specific, HCV-specific protease inhibitors has radically improved disease management. Therapy now has a high likelihood of attaining a sustained virologic response (i.e., cure), reducing morbidity and mortality in infected individuals with a secondary benefit of reducing transmission.

**Diagnosis**

Recommended screening consists of HCV antibody testing with infection confirmed via a nucleic acid test (NAT) to detect and quantify HCV RNA.<sup>81</sup> **Universal screening is not recommended, but individuals with risk factors should be tested once (Box 53-5), and annual testing is recommended for persons injecting drugs or with ongoing HCV exposure risk factors.** Viral load and hepatic transaminase levels vary over time; therefore a single undetectable HCV RNA or normal hepatic transaminase level does not rule out chronic carrier status. HCV RNA also fails to correlate with hepatic inflammation/fibrosis and necessitates ongoing transaminase monitoring.

**Hepatitis C Virus in Pregnancy**

Perinatal HCV transmission correlates with maternal HCV viral load, and a recent study associated increased transmission with a viral load greater than 600,000 IU/mL. **Perinatal HCV transmission occurs in 3% to 10% of patients with detectable HCV RNA, whereas transmission in the absence of detectable viremia is rare.** Other risk factors for perinatal HCV transmission are maternal IV drug use and HIV coinfection. However, treatment of maternal HIV infection lowers both HIV and HCV transmission.<sup>82</sup> Although HCV transmission risk is increased with invasive fetal monitoring and rupture of membranes more than 6 hours previously, elective cesarean delivery does not reduce perinatal HCV transmission.<sup>83</sup> HCV-infected pregnant women should be immunized against HAV and HBV

if not immune, and breastfeeding by women chronically infected with HCV is not contraindicated.

Until recently, HCV treatment did not offer a high likelihood of virologic cure and was contraindicated in pregnancy secondary to the use of ribavirin. The FDA has designated ribavirin as pregnancy category X based on animal teratogenicity. Preliminary data published by the Ribavirin Pregnancy Registry reported birth defects in 3 of 49 live births (6.1%) and an updated executive summary that included data through February 7, 2014 reported a birth defect rate in liveborn infants following direct exposure of 6.49 (5/77, 95% confidence interval [CI], 2.14 to 14.51).<sup>84</sup> Recent recommendation of a limited duration (12 weeks) of ribavirin-sparing HCV therapy expands treatment options within pregnancy.<sup>78,81</sup> Daily fixed-dose ledipasvir, which inhibits viral phosphoprotein NS5A, and sofosbuvir, an HCV polymerase inhibitor, have been designated as pregnancy category B and are first-line therapy for HCV genotype-1a infection. Sofosbuvir combined with simeprevir, a pregnancy category C protease inhibitor, is another first-line treatment option for HCV genotype-1a infection. In summary, first-line therapeutic regimens compatible with use during pregnancy are available to treat HCV genotypes 1, 4, and 6.<sup>78,81</sup> Recommended regimens for HCV genotypes 2, 3, and 5 contain ribavirin and should be avoided in pregnancy when possible. **Given the potential for curative therapy, patients diagnosed with active HCV infection should be referred to a practitioner prepared to provide comprehensive ongoing management of their HCV disease.** Updated management recommendations are available at [www.hcvguidelines.org](http://www.hcvguidelines.org).<sup>81</sup>

**Hepatitis C Virus Preconceptional Counseling**

Given the newly developed capacity to effect virologic cure and the ancillary benefit of reducing perinatal transmission, consideration should be given to diagnosing and treating HCV infection prior to conception. No effective HCV vaccine is currently available.

**Hepatitis D**

Hepatitis delta virus (HDV) is an incomplete RNA virus related to plant viruses. The hepatitis D genome encodes a single nucleocapsid protein, hepatitis delta antigen (HDAg), which is present as two peptides. The short form is required for RNA replication, and the long form is packaged with HDV RNA and the HBsAg envelope glycoprotein. Because HDV utilizes HBV as a helper virus (providing envelope glycoprotein), simultaneous or chronic HBV infection is required for viral replication. HDV is present worldwide with a high prevalence in the Mediterranean basin, Middle East, Central Asia, West Africa, and the Amazon basin. Risk factors include IV drug use and infected blood product exposure. Chronic HDV infection occurs in 1% to 3% of individuals who are simultaneously infected with both HBV and HDV. However, there is a 70% to 80% risk of chronic HDV infection following HDV superinfection of chronic HBV-infected individuals. Patients with chronic HBV and HDV coinfection have a 70% to 80% risk for developing cirrhosis and portal hypertension, and 25% die of hepatic failure. Acute HDV infection is characterized by HDV antigen positivity in the absence of HDV antibody. Chronically infected individuals will have both detectable HDV antigen and HDV antibody. Acute hepatitis D infection is associated with fulminant hepatic failure and a 2% to 20% mortality rate. HDV can be perinatally transmitted.<sup>85</sup> However, **perinatal HBV prophylaxis also effectively**

**prevents perinatal HDV transmission given the requirement for HBV coinfection.<sup>71</sup>**

### Hepatitis E

Hepatitis E virus (HEV) is an enveloped RNA virus that is most closely related to the *Togaviridae* family, which also includes rubella. Hepatitis E is transmitted by oral-fecal contact and is endemic outside of the United States in regions such as Africa, Asia, and Latin America. Similar to hepatitis A, hepatitis E infection causes only acute disease. Diagnosis can be made by the presence of a specific IgM or of viral nucleic acid (RT-PCR). HEV has four genotypes: genotypes 1 and 2 are nonzoonotic and are present in developing countries, and genotypes 3 and 4 are zoonotic and are present in industrialized countries. The mortality rate following acute hepatitis E infection in the general population is 1%. Significantly higher mortality (up to 20%) has been observed in pregnant women infected with hepatitis E, and genotypes 1 and 2 cause most infections.<sup>86</sup> Maternal morbidity and mortality escalates with increasing gestational age,<sup>71,87</sup> and the preterm delivery rate is estimated to be as high as 66%.<sup>87</sup>

**Perinatal hepatitis E transmission is associated with significant perinatal morbidity and mortality.<sup>88</sup>**

### COXSACKIE VIRUS

Coxsackie virus is the causative agent of hand, foot, and mouth disease, an enterovirus transmitted through the fecal-oral route. Several serotypes exist, and adult infection typically results in a self-limited febrile illness that requires no treatment.<sup>89</sup> One reported case of coxsackie B virus infection in pregnancy led to acute liver failure, which resolved following expectant management.<sup>90</sup> Coxsackie virus infection during pregnancy has also been associated in several studies with an increased rate of miscarriage<sup>89,91</sup> and an increased rate of insulin-dependent diabetes in offspring,<sup>89,92</sup> although a causative relationship has not been established.

### HUMAN PAPILLOMAVIRUS

Human papillomaviruses (HPV) are a group of small DNA viruses. Some types (6 and 11) cause warts, whereas other types (16, 18, 31, 33, 52b, and 58) do not cause warts but are instead highly associated with cervical and oral cancers. Infections are sexually and/or vertically transmitted, and nearly 50% of college-aged women have evidence of infection. Thus prior HPV infection is common in pregnancy; moreover, HPV DNA has been detected in 37% of pregnant women without prior documented infection, which demonstrates an unexpectedly high rate of asymptomatic HPV infection.<sup>93</sup> Anogenital warts, caused by nononcogenic HPV types, are one manifestation of infection and may be managed expectantly. Hormonal effects may cause rapid wart proliferation and growth that necessitates treatment. **Trichloroacetic acid and/or cryotherapy are used to treat anogenital warts in pregnancy because podophyllin is contraindicated.** Little is known regarding the safety of imiquimod cream in pregnancy (category C), and treatment is required for months. Vaginal delivery is not contraindicated, unless the wart burden and position would result in dystocia. Maternal HPV infection with HPV types 6 and 11 is associated with pediatric laryngeal papillomatosis. However, given the high prevalence of maternal HPV infection and the rarity of laryngeal papillomatosis, prophylactic cesarean delivery is not recommended.<sup>93</sup>

Cervical dysplasia is another sequelae of HPV infection. Appropriate workup of abnormal PAP smears should be undertaken independent of pregnancy.

### EPSTEIN-BARR VIRUS

The causative agent of infectious mononucleosis is Epstein-Barr Virus (EBV), a member of the *Herpesviridae* family. Clinical presentation includes malaise, headache, fever, pharyngitis, lymphadenopathy, atypical lymphocytosis, heterophile antibody, and transient mild hepatitis. Infection is typically self-limited. EBV establishes latent, reactivatable infection in B lymphocytes and is also associated with Hodgkin and non-Hodgkin lymphoma. Most adults (>95%) are EBV seropositive, so primary EBV infection in pregnancy is rare. Primary infection and/or reactivation of EBV is not associated with significant adverse pregnancy outcome.<sup>94</sup> An association has been found between EBV reactivation within pregnancy and the development of childhood acute lymphoblastic leukemia in the neonate.<sup>95</sup> In utero EBV transmission has been demonstrated by detection of EBV DNA in neonatal lymphocytes.<sup>96</sup> However, in utero infection has not been directly associated with adverse outcomes. Routine testing is not indicated given the extremely high seroprevalence and the lack of impact on pregnancy.

### SMALLPOX

Variola virus is the causative agent of smallpox. Infection is restricted to humans, but it is highly transmissible via airborne droplet inhalation or by direct contact with smallpox lesions.<sup>97</sup> Secondary to widespread vaccination, the last reported smallpox case in the United States was in 1949, and the WHO declared global eradication in 1980. Concerns regarding the potential for variola virus to be used as a bioterrorism agent has led to renewed interest in the presentation and treatment of smallpox disease.

Smallpox infection first presents with a high fever, chills, headache, backache, and vomiting; this differentiates it from chickenpox (varicella), which has a minimal prodrome.<sup>97</sup> Delirium is present in 15%, with some infections progressing to encephalitis. Skin lesions appear 2 to 3 days following the symptom onset and progress from macula to papule to vesicle (Fig. 53-8), vesicle to pustule to scabs, and ultimately form

**FIG 53-8** Smallpox vesicles, day 3 of clinical infection. (From Tying S, et al. *Tropical Dermatology*. Edinburgh: Saunders; 2005.)

pitted scars. Smallpox lesions appear in a centrifugal distribution and affect soles and palms, whereas varicella infection exhibits a centripetal lesion distribution that spares the palms and soles. Diagnosis confirmation is via PCR reaction of pustular fluid and/or scabs in a biocontainment facility.

Maternal treatment is supportive; vaccination and containment are critical. Historically, the maternal mortality rate of unvaccinated women was over 60%.<sup>97</sup> Death usually occurs secondary to viral pneumonitis, bacterial pneumonia, or cardiovascular collapse; pregnant women are also at increased risk for hemorrhagic smallpox, a more severe and lethal manifestation of infection. When infection occurs prior to 24 weeks, 75% of pregnancies end in loss or premature delivery. During the latter half of pregnancy, smallpox infection is associated with a 55% preterm delivery rate. Variola virus crosses the placenta, which enables intrauterine infection. During epidemics, the rate of congenital variola infection has ranged from 9% to 60%.

Vaccination within 2 to 3 days of initial exposure affords almost complete protection against disease.<sup>97,98</sup> The currently available vaccine, Dryvax, is composed of live attenuated variola virus. This vaccine has a higher complication risk than other vaccines; sequelae include postvaccinal encephalitis (incidence 12 per million vaccinations, 40% mortality rate), mild generalized vaccinia, and eczema vaccinatum. **Smallpox vaccination is currently restricted to women in military service and researchers who utilize related viruses.** Data on women vaccinated during pregnancy are being compiled in the National Smallpox Vaccine in Pregnancy Registry.<sup>98</sup> Fetal infection following maternal vaccination (fetal vaccinia) is rare and is characterized by skin lesions and internal organ involvement, but it is not associated with fetal malformations. Therefore vaccination is not considered an indication for pregnancy termination. The CDC recommends deferring elective smallpox vaccination during pregnancy; however, immediate vaccination is indicated following smallpox exposure, independent of pregnancy, secondary to the risk of clinical smallpox infection to the mother and fetus.<sup>97</sup>

## EBOLA

### Virology and Epidemiology

Ebola is an enveloped RNA virus member of the Filoviridae family. The envelope gene encodes two transcription products, GP and sGP, a secreted nonstructural protein. Virus-associated GP binds to target cells and undergoes posttranslational cleavage into GP<sub>1</sub> (attachment) and GP<sub>2</sub> (fusion) subunits within the endosome, which enables fusion/entry. Ebola is a zoonotic pathogen, and fruit bats are the likely native host and viral reservoir. Transmission occurs via direct contact with body fluids of a person who is sick with or has died of Ebola (blood, vomit, urine, feces, sweat, semen, spit, other fluids) or infected animals (meat). Ebola has been isolated from semen for 3 months following recovery, and **transmission via breastfeeding has been documented.** The incubation period is 2 to 21 days following exposure, and individuals become infectious at symptom onset. Ebola infects macrophages, which leads to massive inflammation, complications, and an outbreak-dependent mortality rate that ranges from 50% to 90%. As of early 2015, only a few cases of Ebola virus disease (EVD) had been reported in the United States (none in pregnancy). The 2015 outbreak involved multiple West African countries: Guinea, Liberia, Nigeria, Senegal, and Sierra Leone. For

up-to-date information and recommendations, visit the CDC or WHO sites online.

High-risk exposure includes percutaneous (e.g., needle stick) or mucous membrane contact with blood or body fluids from an EVD patient, exposure to blood or body fluids of a symptomatic EVD patient without appropriate personal protective equipment (PPE), processing blood or body fluids from a symptomatic EVD patient without appropriate PPE or biosafety precautions, or undertaking the following activities without appropriate PPE: direct contact with a dead body (including funeral rites) in Ebola-affected areas, household contact, or providing direct care to a symptomatic EVD patient. Some risk is associated with direct contact with EVD patients with PPE or any direct patient care in EVD-endemic countries and even with a prolonged period within 3 feet of a patient with symptomatic EVD. Low-risk situations include visiting an EVD-endemic country within the past 21 days (with no known exposures), brief proximity to a symptomatic EVD patient, caring for an EVD patient with PPE in a nonendemic country, or air travel with a symptomatic EVD patient.

### Clinical Manifestations

Early symptoms include fever, weakness, arthralgias, myalgias, headache, anorexia, and hiccups. Progressive symptoms can include nausea, vomiting, diarrhea, dysphagia, conjunctivitis, abdominal or hepatic tenderness, and unexplained bleeding or bruising. Late symptoms include seizures, chest pain, rash, and miscarriage. Bleeding occurs in approximately 50% of patients and may be solely internal. Otherwise, EVD presents as a non-specific, severe viral syndrome.

### Diagnosis

A *person under investigation* (PUI) is someone who has both an epidemiologic risk factor within the 21 days prior to the onset of symptoms and consistent symptoms that include a fever greater than 38.6°C or subjective fever, severe headache, muscle pain, vomiting, diarrhea, abdominal pain, or unexplained hemorrhage. Case confirmation requires laboratory-confirmed diagnostic evidence of Ebola infection. While diagnosis is being considered, the patient should be isolated in a private room with a bathroom. Contact, droplet, and environmental control precautions should be implemented, and appropriate PPE should be consistently used.

All specimens should be collected by staff wearing appropriate PPE and should be handled as category A infectious substances. This includes placing specimens in a leak-proof secondary container, transporting specimens to the laboratory by hand, and avoiding high-traffic areas. Laboratory Response Network laboratories conduct presumptive testing with diagnostic confirmation made by the CDC. Confirmatory testing is via RT-PCR, although virus isolation and serology can also be performed. A negative RT-PCR 72 hours after the onset of symptoms excludes EVD, and a negative RT-PCR more than 48 hours after a positive test fulfills criteria for discontinuing isolation. Given non-specific symptomatology and the presence of other infectious diseases with similar presentation in EVD endemic areas, differential diagnosis should include malaria, bacterial infection, and Lassa fever, a disease endemic to portions of West Africa with a prevalence of greater than 10,000 cases per year and similar symptoms to early EVD. Diagnostic tests to rule out Lassa fever in patients who test negative for EVD are RT-PCR, antigen detection, and serology.<sup>99</sup>

## Management of Ebola in Pregnancy

The critical element of clinical management is prompt patient isolation and implementation of recommended infection-control measures (standard contact and droplet precautions) using appropriate PPE when caring for any PUI and patients with confirmed EVD. CDC guidelines for PPE may be accessed at [www.cdc.gov/vhf/ebola/healthcare-us/ppe/guidance.html](http://www.cdc.gov/vhf/ebola/healthcare-us/ppe/guidance.html). Ongoing management consists of supportive care, which includes aggressive IV fluid resuscitation and assessment and correction of electrolyte abnormalities, hypoglycemia, anemia, and coagulopathy. Patients should be assessed for bleeding, secondary infections, and other complications. Empiric broad-spectrum antibiotics should be instituted for suspected infection without awaiting cultures; this is because EVD patients are at risk for sepsis and associated sequelae such as increased vascular permeability, vasodilation, multiple organ failure, and shock. We recommend advanced hemodynamic and fetal monitoring for pregnant women with suspected EVD, maintaining O<sub>2</sub> saturation above 95%, and utilizing vasopressors and inotropic agents as needed to maintain cardiac output, blood pressure, and tissue perfusion. Symptomatic management of fever, nausea, vomiting, diarrhea, and abdominal pain is warranted.<sup>99</sup>

No evidence suggests that pregnancy increases EVD susceptibility. However, pregnancy is thought to increase disease severity and mortality in the third trimester. Epidemiologic reports suggest a high incidence of miscarriage and fetal loss (greater than 80%). No reports exist of neonatal survival, although intrauterine Ebola transmission was recently reported in two patients: both women recovered, but neither fetus survived.<sup>100</sup> High maternal mortality combined with potentially absent neonatal survival dictates that the primary focus be directed toward optimizing maternal status, recognizing that enhanced monitoring and the capacity for intervention in the United States could be associated with a reduced mortality. Updated guidance can be accessed at [www.cdc.gov/vhf/ebola/healthcare-us/hospitals/pregnant-women.html](http://www.cdc.gov/vhf/ebola/healthcare-us/hospitals/pregnant-women.html).

### KEY POINTS

- ◆ Rubella immunization and HBV and HIV infection screening is standard. HIV screening should be performed via an “opt out” approach, and in high prevalence areas, repeat screening in the third trimester should be considered. Varicella screening may be considered in women without a history of infection. Routine CMV screening is not recommended secondary to high seroprevalence.
- ◆ The ACOG and the CDC recommend seasonal influenza vaccination (October through May) for all pregnant women with intramuscular inactivated vaccine. HAV and HBV vaccination are also safe in pregnancy and should be offered based on risk and susceptibility. Live attenuated vaccines for rubeola, rubella, and varicella infection should be deferred until after pregnancy.
- ◆ Rapid intrapartum HIV testing should be accessible to women without documented HIV status because most perinatally infected infants are born to women unaware of their HIV status.

- ◆ The standard of care for HIV infection is cART with at least three drugs from at least two classes of antiretrovirals. Early, sustained control of viral replication is associated with decreased HIV transmission. Fully suppressive preconception therapy is recommended, and cART should be started as early in pregnancy as possible for women entering pregnancy not already on cART.
- ◆ Pregnant women suspected to be infected with influenza should receive treatment immediately, without delay for diagnostic confirmation.
- ◆ Fetal parvovirus infection may result in fetal anemia and hydrops. Women with documented infection should be screened serially with ultrasound. Middle cerebral artery Doppler studies may also be used.
- ◆ Rubeola (measles) is one of the most infectious viruses, and 75% to 90% of exposed, susceptible contacts become infected. Measles infection can cause SSPE, a progressive, uniformly fatal neurologic disease. Infection may originate in individuals born outside the United States, but gaps in vaccination permit the spread of outbreaks in the United States.
- ◆ CMV transmission is highest during the third trimester with a 30% to 40% fetal transmission risk. Serious sequelae are most common following first-trimester infection, whereby 24% of infected fetuses have sensorineural hearing loss and 32% have other central nervous system sequelae.
- ◆ Susceptible varicella-exposed women should receive VZIG to reduce the risk of infection and transmission. The addition of prophylactic acyclovir may further reduce maternal infection risk.
- ◆ Infants born to HBsAg-positive mothers should receive both HBIG and HBV vaccine within 12 hours of birth to reduce perinatal HBV infection. Antepartum tenofovir treatment should also be considered for women at high risk for HBV transmission (HIV coinfection, prior HBV transmission, high HBV loads, or immune-tolerant infection).
- ◆ Given the potential to effect virologic cure and the ancillary benefit of reducing perinatal transmission, consideration should be given to diagnosing and treating HCV infection prior to conception. Ribavirin-sparing regimens permit therapy initiation during pregnancy.
- ◆ EVD severity and mortality is increased in the third trimester of pregnancy, with almost universal fetal loss. Appropriate infection control combined with hemodynamic monitoring and aggressive maternal care, independent of fetal effects, is recommended.

**Bacterial infections are the single most common complication encountered by the obstetrician.** Some infections, such as puerperal endometritis and lower urinary tract infection, are of principal concern to the mother and pose little or no risk to the fetus or neonate. Others, such as listeriosis and toxoplasmosis, are of greatest threat to the fetus. Still others—such as group B streptococcal infection (GBS), pyelonephritis, and chorioamnionitis—may cause serious morbidity, even life-threatening complications, for both the mother and baby. The purpose of this chapter is to review in detail the major bacterial infections and the key protozoan infection (toxoplasmosis) that the obstetrician confronts in daily clinical practice.

## GROUP B STREPTOCOCCAL INFECTION

### Epidemiology

*Streptococcus agalactiae* is a gram-positive encapsulated coccus that produces  $\beta$ -hemolysis when grown on blood agar. **On average, about 20% to 25% of pregnant women in the United States harbor this group B *Streptococcus* (GBS) in their lower genital tract and rectum. GBS is one of the most important causes of early-onset neonatal infection.** The prevalence of neonatal GBS infection now is about 0.5 per 1000 live births, and about 10,000 cases of neonatal streptococcal septicemia occur each year in the United States.<sup>1</sup>

Neonatal GBS infection can be divided into early-onset and late-onset infection, and Table 54-1 summarizes characteristics of both. **About 80% to 85% of cases of neonatal GBS infection are early in onset and result almost exclusively from vertical transmission from a colonized mother.** Early-onset infection presents primarily as a severe pneumonia and overwhelming septicemia. **In preterm infants, the mortality rate from early-onset GBS infection may approach 25%. In term infants, the mortality rate is lower, averaging about 5%.<sup>2</sup>** Late-onset neonatal GBS infection occurs as a result of both vertical and horizontal transmission. It is typically manifested by bacteremia, meningitis, and pneumonia. The mortality rate from late-onset infection is about 5% for both preterm and term infants.<sup>1</sup> Unfortunately, obstetric interventions have proved ineffective in preventing late-onset neonatal infection. Therefore the remainder of this discussion focuses on early-onset infection.

**Major risk factors for early-onset infection include preterm labor, especially when complicated by preterm premature rupture of the membranes (PROM); intrapartum maternal fever (chorioamnionitis); prolonged rupture of membranes, defined as greater than 18 hours; previous delivery of an infected infant; young age; and black or Hispanic ethnicity.<sup>1</sup>** About 25% of pregnant women have at least one risk factor for GBS infection. The neonatal attack rate in colonized patients is 40% to 50% in the presence of a risk factor and less than 5% in the absence of a risk factor. In infected infants, neonatal

**TABLE 54-1** CHARACTERISTICS OF EARLY- AND LATE-ONSET NEONATAL GBS SEPSIS

| TYPE OF GBS SEPSIS | TIMING                            | % OF CASES | RISK FACTORS   | INCIDENCE                               | MORTALITY RATE  |
|--------------------|-----------------------------------|------------|--|---|---|
| Early onset        | Within first week                 | 85%        | <ul style="list-style-type: none"> <li>Gestational age &lt;37 weeks</li> <li>Preterm premature rupture of membranes</li> <li>Longer duration of membrane rupture</li> <li>Intraamniotic infection</li> <li>Young maternal age</li> <li>Black or Hispanic race</li> <li>Prior delivery of an infant with GBS disease</li> </ul> | 0.34 to 0.37 cases per 1000 live births | 2% to 3% (term infants); 20% to 30% (preterm infants) |
| Late onset         | After first week (up to 3 months) | 15%        | <ul style="list-style-type: none"> <li>Gestational age &lt;37 weeks</li> <li>Black race</li> <li>Maternal GBS colonization</li> </ul>  | 0.3 to 0.4 cases per 1000 live birth    | 1% to 2% (term infants); 5% to 6% (preterm infants)   |

GBS, group B *Streptococcus*.

\*Sensitivities for identification of heavily colonized women ranged from 29% to 100%.

<sup>†</sup>Specimens were grown in culture for 3.5 hours before the DNA probe was used.

mortality approaches 30% to 35% when a maternal risk factor is present but is less than 5% when a risk factor is absent.<sup>2,3</sup>

## Maternal Complications

Several obstetric complications occur with increased frequency in pregnant women who are colonized with GBS. The organism is one of the major causes of **chorioamnionitis** and **postpartum endometritis**. It may cause **postcesarean delivery wound infection**, usually in conjunction with other aerobic and anaerobic bacilli and staphylococci. The organism also is responsible for approximately 2% to 3% of **lower urinary tract infections** in pregnant women.<sup>1</sup> GBS urinary tract infection, in turn, is a risk factor for preterm PROM and preterm labor. For example, Thomsen and colleagues<sup>4</sup> reported a study of 69 women at 27 to 31 weeks' gestation who had streptococcal urinary tract infections. Patients were assigned to treatment with either penicillin or placebo. Treated patients had a significant reduction in the frequency of both preterm PROM and preterm labor.

Other investigations have confirmed the association between GBS colonization and preterm labor and preterm PROM. Women with the latter complication who are colonized with GBS tend to have a shorter latent period and higher frequency of chorioamnionitis and puerperal endometritis compared with noncolonized women.<sup>5</sup>

## Diagnosis

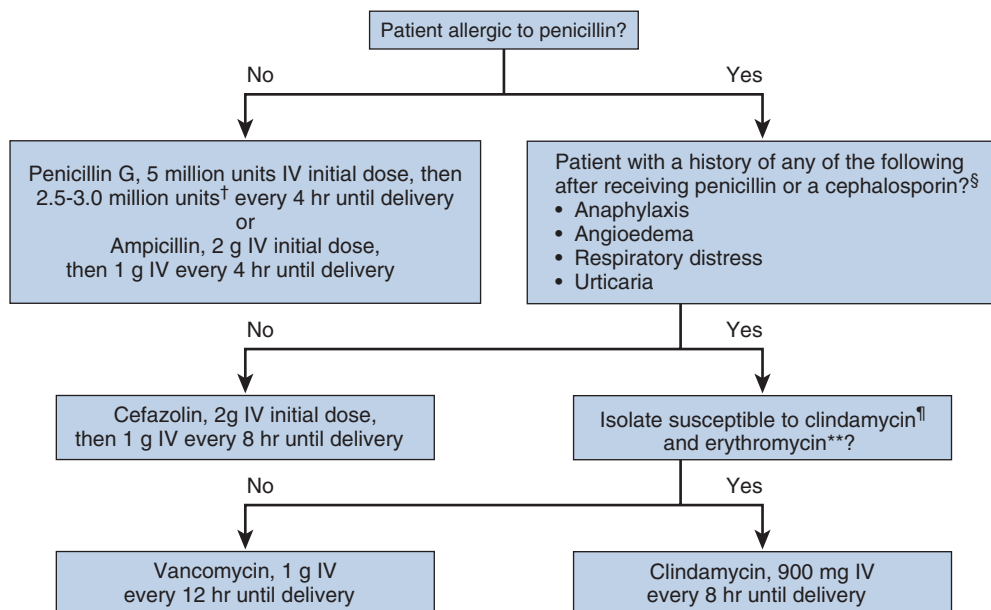

**The gold standard for the diagnosis of GBS infection is bacteriologic culture.** Todd-Hewitt broth or selective blood agar is the preferred medium. **Specimens for culture should be obtained from the lower vagina, perineum, and perianal area using a simple cotton swab.** In recent years, considerable research has been devoted to assessment of rapid diagnostic tests for the identification of colonized women. Table 54-2 summarizes the results of several investigations of rapid diagnostic

tests.<sup>6,7</sup> The information in this table is based on the review by Yancey and associates.<sup>6</sup> These authors noted that, although the rapid diagnostic tests had reasonable sensitivity in identifying heavily colonized patients, they had poor sensitivity in identifying lightly and moderately colonized patients.

Although the first-generation rapid diagnostic tests were not as valuable as originally hoped, Bergeron and colleagues<sup>8</sup> reported exceptionally favorable results with a new polymerase chain reaction (PCR) assay for GBS. In a series of 112 patients, the authors documented a sensitivity of 97%, specificity of 100%, positive predictive value of 100%, and negative predictive value of 99%. This PCR assay now is commercially available and offers clear promise as a rapid test for screening patients at the time of admission for labor. Ahmadzia and colleagues<sup>9</sup> recently reviewed the diagnostic accuracy of intrapartum nucleic acid amplification tests (NAATs) for GBS and reported that the sensitivity ranged from 91% to 94%.

## Prevention of Group B Streptococcal Infection

In the past 20 years, several strategies have been proposed for the prevention of neonatal GBS infection.<sup>2,3,10-12</sup> Each strategy has had major imperfections. In 1996, however, the Centers for Disease Control and Prevention (CDC) published a series of recommendations that incorporated the major advantages of previous protocols and minimized some of the more problematic aspects of selected strategies.<sup>12</sup> The initial CDC guidelines recommended either universal culturing of all patients at 35 to 37 weeks' gestation and intrapartum treatment of all colonized women or selective treatment on the basis of identified risk factors. Subsequently, in a large population-based survey, Rosenstein and Schuchat<sup>13</sup> assessed the theoretic impact of the CDC recommendations and showed that a strategy of universal culturing and treatment of all colonized patients would prevent 78% of cases of neonatal infection. In contrast, only 41% of cases

\* Broader spectrum agents, including an agent active against GBS, might be necessary for treatment of chorioamnionitis.

† Doses ranging from 2.5 to 3.0 million units are acceptable for the doses administered every 4 hours following the initial dose. The choice of dose within that range should be guided by which formulations of penicillin G are readily available to reduce the need for pharmacies to specially prepare doses.

§ Penicillin-allergic patients with a history of anaphylaxis, angioedema, respiratory distress, or urticaria following administration of penicillin or a cephalosporin are considered to be at high risk for anaphylaxis and should not receive penicillin, ampicillin, or cefazolin for GBS intrapartum prophylaxis. For penicillin-allergic patients who do not have a history of those reactions, cefazolin is the preferred agent because pharmacologic data suggest it achieves effective intraamniotic concentrations. Vancomycin and clindamycin should be reserved for penicillin-allergic women at high risk for anaphylaxis.

¶ If laboratory facilities are adequate, clindamycin and erythromycin susceptibility testing should be performed on prenatal GBS isolates from penicillin-allergic women at high risk for anaphylaxis. If no susceptibility testing is performed, or the results are not available at the time of labor, vancomycin is the preferred agent for GBS intrapartum prophylaxis for penicillin-allergic women at high risk for anaphylaxis.

\*\* Resistance to erythromycin is often but not always associated with clindamycin resistance. If an isolate is resistant to erythromycin, it might have inducible resistance to clindamycin, even if it appears susceptible to clindamycin. If a GBS isolate is susceptible to clindamycin, resistant to erythromycin, and testing for inducible clindamycin resistance has been performed and is negative (no inducible resistance), then clindamycin can be used for GBS intrapartum prophylaxis instead of vancomycin.

**FIG 54-1** Recommended regimens for intrapartum antibiotic prophylaxis for prevention of early-onset group B *Streptococcus* (GBS) disease. IV, intravenously.

were prevented when patients were targeted for prophylaxis just on the basis of risk factors. In addition, Locksmith and colleagues<sup>14</sup> confirmed that universal culturing also was of value in decreasing the rate of maternal infection compared with a strategy of only treating on the basis of risk factors.

In 2010, the CDC issued its most recent guidelines for prevention of early-onset GBS infection.<sup>1</sup> **The newest guidelines recommend universal cultures in all patients as the optimal method of prevention. Cultures should be performed at 35 to 37 weeks' gestation. All patients who test positive should receive intrapartum antibiotic prophylaxis with one of the regimens outlined in Figure 54-1. Ideally, antibiotics should be administered at least 4 hours before delivery.** DeCueto and coworkers<sup>15</sup> demonstrated that the rate of neonatal GBS infection was reduced significantly when patients were treated for at

least this long. In a subsequent investigation to assess timing of antibiotic prophylaxis, McNanley and associates<sup>16</sup> showed that mean vaginal GBS counts decreased fivefold within 2 hours of antibiotic administration, fiftyfold within 4 hours, and almost a thousandfold within 6 hours.

The new CDC guidelines also addressed issues that previously had been imprecisely defined.<sup>1</sup> **Colonized patients scheduled for a planned cesarean delivery do not require intrapartum prophylaxis. Patients who tested positive for GBS in a previous pregnancy should not be assumed to be colonized and should be retested with each pregnancy.** This recommendation is supported by a later report from Edwards and coworkers.<sup>17</sup> These authors noted that only 59% of patients who were culture positive in a previous pregnancy were positive in the current pregnancy. Conversely, however, **patients who**

GBS, group B *Streptococcus*; NAAT, nucleic acid amplification test.

have GBS bacteriuria in pregnancy, even if treated, should be considered heavily colonized and should be targeted for intrapartum prophylaxis. Moreover, patients who had a previous infant with GBS infection also should be considered colonized and should be treated during labor. Table 54-3 outlines indications and nonindications for intrapartum prophylaxis against GBS.

## URINARY TRACT INFECTIONS

### Acute Urethritis

Acute urethritis, or acute urethral syndrome, is usually caused by one of three organisms: coliforms (principally *Escherichia coli*), *Neisseria gonorrhoeae*, and *Chlamydia trachomatis*. Coliform organisms are part of the normal vaginal and perineal flora and may be introduced into the urethra during intercourse or when wiping after defecation. *N. gonorrhoeae* and *C. trachomatis* are sexually transmitted pathogens.<sup>18</sup> Patients affected by urethritis typically experience frequency, urgency, and dysuria. Hesitancy, dribbling, and a mucopurulent urethral discharge also may be present. On microscopic examination, the urine usually has white blood cells, but bacteria may not be consistently present. Urine cultures may have low colony counts of coliform organisms, and cultures of the urethral discharge may be positive for gonorrhea and chlamydia. A rapid diagnostic test, such as a NAAT, is now the preferred method for identification of gonorrhea and chlamydia.<sup>18</sup>

Most patients with acute urethritis warrant empiric treatment before the results of laboratory tests are available. Infections caused by coliforms usually respond to the antibiotics described later for treatment of asymptomatic bacteriuria and cystitis. **If gonococcal infection is suspected, the patient should be treated with intramuscular ceftriaxone (250 mg in a single dose) plus 1000 mg oral azithromycin.**<sup>19</sup> If the patient is allergic to  $\beta$ -lactam antibiotics, an effective alternative is azithromycin 2000 mg orally in a single dose. This high dose of azithromycin is more likely to be associated with gastrointestinal side effects than more conventional lower doses. An alternative choice in the penicillin-allergic patient is ciprofloxacin 500 mg orally in a single dose. **If chlamydial infection is suspected or**

confirmed, the patient should be treated with azithromycin 1000 mg in a single dose.<sup>1</sup>

### Asymptomatic Bacteriuria and Acute Cystitis

The prevalence of asymptomatic bacteriuria in pregnancy is 5% to 10%, and most cases antedate the onset of pregnancy. The frequency of acute cystitis in pregnancy is 1% to 3%. Some cases of cystitis arise de novo, whereas others develop as a result of failure to identify and treat asymptomatic bacteriuria.<sup>20</sup>

*E. coli* is responsible for at least 80% of cases of initial infections and about 70% of recurrent cases. *Klebsiella pneumoniae* and *Proteus* species also are important pathogens, particularly in patients who have a history of recurrent infection. Up to 10% of infections are caused by gram-positive organisms such as GBS, enterococci, and staphylococci.<sup>18,20</sup>

All pregnant women should have a urine culture at their first prenatal appointment to detect preexisting asymptomatic bacteriuria. If the culture is negative, the likelihood of the patient subsequently developing an asymptomatic infection is less than 5%. **If the culture is positive—defined as greater than  $10^5$  colonies/mL urine from a midstream, clean-catch specimen—prompt treatment is necessary to prevent ascending infection. In the absence of effective treatment, about one third of pregnant women with asymptomatic bacteriuria will develop acute pyelonephritis.** In a recent report, treatment of asymptomatic bacteriuria was also associated with a reduction in the incidence of low-birthweight babies (relative risk [RR], 0.66; 95% confidence interval [CI], 0.49 to 0.89), but no difference in preterm delivery was seen.<sup>21</sup>

Patients with acute cystitis usually have symptoms of frequency, dysuria, urgency, suprapubic pain, hesitancy, and dribbling. Gross hematuria may be present, but high fever and systemic symptoms are uncommon. In symptomatic patients, the leukocyte esterase and nitrate tests are usually positive. When a urine culture is obtained, a catheterized sample is preferred because it minimizes the probability that urine will be contaminated by vaginal flora. With a catheterized specimen, a colony count greater than  $10^2$ /mL is considered indicative of infection.<sup>22</sup>

**TABLE 54-4** ANTIBIOTICS FOR TREATMENT OF ASYMPTOMATIC BACTERIURIA AND ACUTE CYSTITIS

| DRUG (TRADE NAME)   | STRENGTH OF ACTIVITY   | ORAL DOSE                | COST     |
|---|--|--------------------------|----------|
| Amoxicillin   | Some <i>Escherichia coli</i> , most <i>Proteus</i> species, GBS, enterococci, some staphylococci | 500 mg TID or 875 mg BID | Low      |
| Amoxicillin-clavulanic acid (Augmentin)   | Most gram-negative aerobic bacilli and gram-positive cocci                                       | 875 mg BID               | High     |
| Ampicillin  | Some <i>E. coli</i> , most <i>Proteus</i> species, GBS, enterococci, some staphylococci          | 250-500 mg 4 times daily | Low      |
| Cephalexin (Keflex)   | Most <i>E. coli</i> , most <i>Klebsiella</i> and <i>Proteus</i> species, GBS, staphylococci      | 250-500 mg 4 times daily | Low      |
| Nitrofurantoin monohydrate macrocrystals—sustained-release preparation (Macrobid) | Most uropathogens except enterococci and <i>Proteus</i> species                                  | 100 mg BID               | Moderate |
| Double-strength trimethoprim-sulfamethoxazole (Bactrim DS, or Septra DS)          | Most uropathogens except some strains of <i>E. coli</i>  | 800 mg/160 mg BID        | Low      |

BID, twice a day; DS, double strength; GBS, group B streptococci; TID, three times a day.

**Asymptomatic bacteriuria and acute cystitis characteristically respond well to short courses of oral antibiotics.** Single-dose therapy is not as effective in pregnant women as in nonpregnant patients. However, **a 3-day course of treatment appears to be comparable to a 7- to 10-day regimen for an initial infection.**<sup>18</sup> Longer courses of therapy are more appropriate for patients with recurrent infections. Table 54-4 lists several antibiotics of value for treatment of asymptomatic bacteriuria and cystitis.

When sensitivity tests are available—for example, for patients with asymptomatic bacteriuria—they may be used to guide antibiotic selection. When empiric treatment is indicated, the choice of antibiotics should be based on established patterns of susceptibility. **In recent years, 20% to 30% of strains of *E. coli* and more than half the strains of *Klebsiella* have developed resistance to ampicillin.** Thus this drug should not be used when the results of sensitivity tests are unknown unless the suspected pathogen is enterococci, in which case ampicillin or amoxicillin is the drug of choice.<sup>23,24</sup>

When choosing among the drugs listed in Table 54-4, the clinician should consider several factors. First, the sensitivity patterns of ampicillin, amoxicillin, and cephalexin are the most variable. Second, these drugs—along with amoxicillin-clavulanic acid—also have the most pronounced effect on normal bowel and vaginal flora and thus are the most likely to cause diarrhea or monilial vulvovaginitis. In contrast, **nitrofurantoin monohydrate has only minimal effect on vaginal and bowel flora.** Moreover, it is more uniformly effective against the common uropathogens, except for *Proteus* species, than trimethoprim-sulfamethoxazole. Third, amoxicillin-clavulanic acid and trimethoprim-sulfamethoxazole usually are the best empiric agents for treatment of patients with suspected drug-resistant pathogens. However, sulfonamides should be avoided in the first trimester of pregnancy because of possible teratogenicity, and they should be avoided immediately prior to delivery because of concern about displacement of bilirubin from protein binding sites, with resultant neonatal jaundice (see Chapter 8).<sup>25</sup>

For patients who have an initial infection and experience a prompt response to treatment, a urine culture for test of cure may not be clinically necessary or cost effective.<sup>18,24</sup> **Cultures during or immediately after treatment are indicated for patients who have a poor response to therapy or who have a history of recurrent infection.** During subsequent clinic appointments, the patient's urine should be screened for nitrites and leukocyte esterase. If either of these tests is positive, repeat urine culture and retreatment are indicated.

**FIG 54-2** Intravenous pyelogram in a pregnant woman shows marked dilation of the right ureter and mild dilation of the renal collecting system.

### Acute Pyelonephritis

**The incidence of pyelonephritis in pregnancy is 1% to 2%.<sup>20</sup> Most cases develop as a consequence of undiagnosed or inadequately treated lower urinary tract infection.** Two major physiologic changes occur during pregnancy that predispose to ascending infection of the urinary tract. First, the high concentration of progesterone secreted by the placenta has an inhibitory effect on ureteral peristalsis. Second, the enlarging gravid uterus often compresses the ureters, particularly the right, at the pelvic brim, thus creating additional stasis. Stasis, in turn, facilitates migration of bacteria from the bladder into the ureters and renal parenchyma (Fig. 54-2).

About 75% to 80% of cases of pyelonephritis occur on the right side, 10% to 15% are left sided, and a slightly smaller percentage are bilateral.<sup>20</sup> ***E. coli* is again the principal pathogen.**<sup>20,23</sup> *K. pneumoniae* and *Proteus* species also are important causes of infection, particularly in women with recurrent episodes of pyelonephritis. Highly virulent gram-negative bacilli such as *Pseudomonas*, *Enterobacter*, and *Serratia*

are unusual isolates except in immunocompromised patients. Gram-positive cocci do not frequently cause upper tract infection. Anaerobes also are unlikely pathogens unless the patient is chronically obstructed or instrumented.

**The usual clinical manifestations of acute pyelonephritis in pregnancy are fever, chills, flank pain and tenderness, urinary frequency or urgency, hematuria, and dysuria.** Patients also may have signs of preterm labor, septic shock, and acute respiratory distress syndrome (ARDS). Urinalysis is usually positive for white blood cell casts, red blood cells, and bacteria. Urine colony counts greater than  $10^2$  colonies/mL in samples collected by catheterization confirm the diagnosis of infection.

Pregnant patients with pyelonephritis may be considered for outpatient therapy if their disease manifestations are mild, they are hemodynamically stable, and they have no evidence of preterm labor.<sup>25</sup> If an outpatient approach is adopted, the patient should be treated with agents that have a high level of activity against the common uropathogens. Acceptable oral agents include amoxicillin-clavulanic acid 875 mg twice daily or double-strength trimethoprim-sulfamethoxazole twice daily for 7 to 10 days. Alternatively, a visiting home nurse may be contracted to administer a parenteral agent such as intravenous (IV) or intramuscular (IM) ceftriaxone 2 g once daily. Although an excellent drug for lower tract infections, nitrofurantoin monohydrate does not consistently achieve the serum and renal parenchymal concentrations necessary for successful treatment of more serious infections.

**Patients who appear to be moderately to severely ill or who show any signs of preterm labor should be hospitalized for IV antibiotic therapy.** They should receive appropriate supportive treatment and should be monitored closely for complications such as sepsis, ARDS, and preterm labor. **One reasonable choice for empiric IV antibiotic therapy is ceftriaxone 2 g every 24 hours.** Compared with a first-generation cephalosporin like cefazolin, ceftriaxone has expanded coverage against aerobic gram-negative bacilli and has the advantage of once-daily dosing.<sup>19</sup> If the patient is critically ill or is at high risk for a resistant organism, a second antibiotic, such as gentamicin (7 mg/kg/ideal body weight every 24 hours) or aztreonam (500 mg to 1 g every 8 to 12 hours) should be administered, along with ceftriaxone, until the results of susceptibility tests are available.

**Once antibiotic therapy is initiated, about 75% of patients defervesce within 48 hours. By the end of 72 hours, almost 95% of patients are afebrile and asymptomatic.<sup>20</sup> The two most likely causes of treatment failure are a resistant microorganism and obstruction.** The latter condition is best diagnosed with computed tomography (CT) scan or renal ultrasonography and typically results from a stone or physical compression of the ureter by the gravid uterus.

Once the patient has begun to defervesce and her clinical condition has improved, she may be discharged from the hospital. **Oral antibiotics should be prescribed to complete a total of 7 to 10 days of therapy.** Selection of a specific oral agent should be based on considerations of efficacy, toxicity, and expense. A repeat urine culture should be obtained after therapy is completed to ensure that the infection has been adequately treated.

About 20% to 30% of pregnant patients with acute pyelonephritis develop a recurrent urinary tract infection later in pregnancy. **The most cost-effective way to reduce the frequency of recurrence is to administer a daily prophylactic dose of an**

**antibiotic such as nitrofurantoin monohydrate 100 mg.** Patients receiving prophylaxis should have their urine screened for bacteria at each subsequent clinic appointment. They also should be questioned about recurrence of symptoms. If symptoms recur, or the dipstick test for nitrite or leukocyte esterase is positive, a urine culture should be obtained to determine whether retreatment is necessary.

## UPPER GENITAL TRACT INFECTIONS

### Chorioamnionitis

Chorioamnionitis—or amnionitis, intraamniotic infection—may present with fever and fetal tachycardia. Because both the mother and infant may experience serious complications when chorioamnionitis is present, prompt diagnosis is imperative.

### Epidemiology

**Chorioamnionitis occurs in 1% to 5% of term pregnancies.<sup>26</sup>**

**In patients with preterm delivery, the frequency of clinical or subclinical infection may approach 25%.<sup>27</sup>** Although chorioamnionitis may result from hematogenous dissemination of microorganisms, it more commonly is an ascending infection caused by organisms that are part of the normal vaginal flora. **The principal pathogens are *Bacteroides* and *Prevotella* species, *E. coli*, anaerobic gram-positive cocci, GBS, and genital mycoplasmas.**

Several clinical risk factors for chorioamnionitis have been identified. The most important are young age, low socioeconomic status, nulliparity, extended duration of labor and ruptured membranes, multiple vaginal examinations, and preexisting infections of the lower genital tract (e.g., bacterial vaginosis and GBS infection).<sup>26</sup> Antibiotic use in preterm PROM is associated with a statistically significant reduction in chorioamnionitis.<sup>28</sup> In term PROM, consideration should also be given to minimizing use of vaginal digital examinations intrapartum once membrane rupture has occurred, as well as antibiotic prophylaxis, especially when latency greater than 12 hours is expected (see Chapter 30).<sup>29</sup>

### Diagnosis

**In most situations, the diagnosis of chorioamnionitis can be established on the basis of the clinical findings of maternal fever and maternal and fetal tachycardia in the absence of other localizing signs of infection.** In more severely ill patients, uterine tenderness and purulent amniotic fluid may be identified. The disorders that should be considered in the differential diagnosis of intrapartum fever include respiratory tract infection, pyelonephritis, viral syndrome, and appendicitis, but chorioamnionitis should always be the principal consideration.<sup>26</sup>

Laboratory confirmation of the diagnosis of chorioamnionitis is not routinely necessary in term patients who are progressing to delivery. However, in preterm patients who are being evaluated for tocolysis or corticosteroids, laboratory assessment may be of value in establishing the diagnosis of intrauterine infection. In this clinical context, amniotic fluid should be obtained by transabdominal amniocentesis. Table 54-5 summarizes the abnormal laboratory findings that may be present in infected patients.<sup>26,30-33</sup>

### Management

Both the mother and infant may experience serious complications when chorioamnionitis is present. Bacteremia occurs in

**TABLE 54-5** DIAGNOSTIC TESTS FOR CHORIOAMNIONITIS

| TEST                                  | ABNORMAL FINDING   | COMMENT  |
|---------------------------------------|--|--|
| Maternal white blood cell count (WBC) | ≥15,000 cells/mm <sup>3</sup> with preponderance of leukocytes | Labor and/or corticosteroids may also result in elevation of WBC count.  |
| Amniotic fluid glucose                | ≤10 to 15 mg   | Correlation is excellent with positive amniotic fluid culture and clinical infection.  |
| Amniotic fluid interleukin-6          | ≥7.9 ng/mL   | Correlation is excellent with positive amniotic fluid culture and clinical infection.  |
| Amniotic fluid leukocyte esterase     | ≥1 <sup>+</sup> reaction                                       | Correlation is good with positive amniotic fluid culture and clinical infection.   |
| Amniotic fluid Gram stain             | Any organism in an oil immersion field                         | Identification of particularly virulent organisms, such as group B streptococci, is possible; however, the test is very sensitive to inoculum effect. In addition, it cannot identify pathogens such as mycoplasmas.   |
| Amniotic fluid culture                | Growth of aerobic or anaerobic microorganism                   | This test is the gold standard, although results are not immediately available for clinical management.  |
| Blood cultures                        | Growth of aerobic or anaerobic microorganism                   | Cultures will be positive in 5% to 10% of patients; however, they will usually not be of value in making clinical decisions unless the patient is seriously ill, at increased risk for bacterial endocarditis, immunocompromised, or has a poor response to the initial treatment. |

3% to 12% of infected women. When cesarean delivery is required, up to 8% of women develop a wound infection, and about 1% develop a pelvic abscess. Fortunately, maternal death due to infection is exceedingly rare.<sup>26</sup>

**Of neonates delivered to mothers with chorioamnionitis, 5% to 10% have pneumonia or bacteremia.** The predominant organisms responsible for these infections are GBS and *E. coli*. Meningitis occurs in less than 1% of term infants and in a slightly higher percentage of preterm infants. Mortality due to infection ranges from 1% to 4% in term neonates but may approach 15% in preterm infants because of the confounding effects of other complications such as hyaline membrane disease, intraventricular hemorrhage, and necrotizing enterocolitis.<sup>26</sup>

**To prevent maternal and neonatal complications, parenteral antibiotic therapy should be initiated as soon as the diagnosis of chorioamnionitis is made, unless delivery is imminent.** Three separate investigations have demonstrated that mother-infant pairs who receive prompt intrapartum treatment have better outcomes than patients treated after delivery.<sup>32-34</sup> The principal benefits of early treatment include decreased frequency of neonatal bacteremia and pneumonia and decreased duration of maternal fever and hospitalization.

**The most extensively tested IV antibiotic regimen for treatment of chorioamnionitis is the combination of ampicillin (2 g every 6 hours) or penicillin (5 million U every 6 hours) plus gentamicin (1.5 mg/kg every 8 hours or 5 to 7 mg/kg/ideal body weight every 24 hours).<sup>35,36</sup> The latter regimen of gentamicin is the most cost-effective.<sup>37,38</sup> These antibiotics specifically target the two organisms most likely to cause neonatal infection: GBS and *E. coli*.** With rare exceptions, gentamicin is preferred to tobramycin or amikacin because it is available in an inexpensive generic formulation. Amikacin should be reserved for immunocompromised patients who are particularly likely to be infected by highly virulent, drug-resistant aerobic gram-negative bacilli. In patients who are allergic to  $\beta$ -lactam antibiotics, clindamycin (900 mg every 8 hours) should be substituted for ampicillin.<sup>37</sup>

**If a patient with chorioamnionitis requires cesarean delivery, a drug with activity against anaerobic organisms should be added to the antibiotic regimen. Either clindamycin (900 mg) or metronidazole (500 mg) is an excellent choice for this purpose.** Failure to provide effective coverage of anaerobes may result in treatment failures in 20% to 30% of patients.<sup>37</sup>

Extended-spectrum cephalosporins, penicillins, and carbapenems also provide excellent coverage against the bacteria that

**TABLE 54-6** SINGLE AGENTS OF VALUE IN TREATMENT OF CHORIOAMNIONITIS AND PUERPERAL ENDOMETRITIS

| DRUG                                    | DOSAGE AND DOSE INTERVAL | RELATIVE COST TO THE PHARMACY* |
|---|--------------------------|--------------------------------|
| <b>Extended-Spectrum Cephalosporins</b> |                          |                                |
| Cefepime                                | 2 g every 12 hours       | Intermediate                   |
| Cefotaxime                              | 2 g every 8-12 hours     | Intermediate                   |
| Cefotetan                               | 2 g every 12 hours       | Low                            |
| Cefoxitin                               | 2 g every 6 hours        | Intermediate                   |
| Ceftizoxime                             | 2 g every 12 hours       | Intermediate                   |
| <b>Extended-Spectrum Penicillins</b>    |                          |                                |
| Ampicillin-sulbactam                    | 3 g every 6 hours        | Low                            |
| Mezlocillin                             | 3 to 4 g every 6 hours   | Intermediate                   |
| Piperacillin                            | 3 to 4 g every 6 hours   | Intermediate                   |
| Piperacillin-tazobactam                 | 3.375 g every 6 hours    | Intermediate                   |
| Ticarcillin-clavulanic acid             | 3.1 g every 6 hours      | Low                            |
| <b>Carbapenem</b>                       |                          |                                |
| Ertapenem                               | 1 g every 24 hours       | High                           |
| Imipenem-cilastatin                     | 500 mg every 6 hours     | High                           |
| Meropenem                               | 1 g every 8 hours        | High                           |

\*Cost estimates do not include dose preparation fees and administration charges.

cause chorioamnionitis. Dosages and dose intervals for several of these agents are listed in Table 54-6.<sup>19</sup> As a general rule, these drugs are more expensive than the generic combination regimens outlined earlier.

**Patients with chorioamnionitis are at increased risk for dysfunctional labor.** About 75% require oxytocin for augmentation of labor, and up to 30% to 40% require cesarean delivery, usually for failure to progress in labor. Although chorioamnionitis by itself should not be considered an indication for cesarean delivery, affected patients need close monitoring during labor to ensure that uterine contractility is optimized. In addition, the fetus also needs close surveillance. Fetal heart rate abnormalities such as tachycardia and decreased variability (Fig. 54-3) occur in more than three fourths of the cases, and additional tests such as scalp stimulation may be necessary to evaluate fetal well-being.

Antibiotics usually can be discontinued soon after delivery. Edwards and Duff<sup>39</sup> reported a randomized clinical trial in which patients were treated intrapartum with ampicillin plus gentamicin. In one group of patients, treatment was discontinued after the first postpartum dose of each antibiotic. In the

**FIG 54-3** Fetal heart tracing from a patient with chorioamnionitis. Note the tachycardia of 170 beats/min and the striking decrease in variability.

second group, patients were treated until they had been afebrile and asymptomatic for 24 hours. Patients in both groups received at least one dose of clindamycin if they delivered by cesarean section. No significant differences in treatment outcome were apparent in the two groups. However, in a follow-up study to the report by Edwards and Duff, Black and colleagues<sup>40</sup> showed that certain patients with chorioamnionitis require more extended treatment. Specifically, those women who are obese—defined as those with a body mass index (BMI) greater than 30—or who have prolonged rupture of membranes (>24 hours) have a significantly increased risk of treatment failure if they receive only a single postpartum dose of antibiotic; they recommended these women be treated postpartum until they have been afebrile and asymptomatic for 24 hours. A recent Cochrane review of antibiotic regimens for chorioamnionitis, however, concluded that limited evidence was available to reveal whether antibiotics should be continued during the postpartum period, which antibiotic regimen should be used, or for what treatment duration.<sup>41</sup> Based on published experience from our institution, we follow the guidelines recommended by Black et al.<sup>40</sup>

## Puerperal Endometritis

### Epidemiology

The frequency of puerperal endometritis in women who deliver vaginally ranges from 1% to 3%. In women having a scheduled cesarean delivery before the onset of labor and rupture of membranes, the frequency of endometritis ranges from 5% to 10% without antibiotic prophylaxis and is less than 5% with prophylaxis. When cesarean delivery is performed after an extended period of labor and ruptured membranes, the incidence of infection is 30% to 35% without antibiotic prophylaxis and about 60% less with prophylaxis. In indigent patient populations, the frequency of infection may be even higher.<sup>42</sup>

Similarly to chorioamnionitis, endometritis is a polymicrobial infection caused by microorganisms that are part of the normal vaginal flora. These bacteria gain access to the

upper genital tract, peritoneal cavity, and occasionally the bloodstream as a result of vaginal examinations during labor and manipulations during surgery. **The most common pathogens are GBS, anaerobic gram-positive cocci, aerobic gram-negative bacilli—predominantly *E. coli*, *K. pneumoniae*, and *Proteus* species—and anaerobic gram-negative bacilli, principally *Bacteroides* and *Prevotella* species.** *C. trachomatis* is not a common cause of early-onset puerperal endometritis but has been implicated in late-onset infection. The genital mycoplasmas may be pathogens in some patients, but they usually are present in association with more highly virulent bacteria.<sup>42</sup>

**The principal risk factors for endometritis are cesarean delivery, young age, low socioeconomic status, extended duration of labor and ruptured membranes, and multiple vaginal examinations. In addition, preexisting infection or colonization of the lower genital tract (gonorrhea, GBS, bacterial vaginosis) also predisposes to ascending infection.**

### Clinical Presentation and Diagnosis

The diagnosis of postpartum endometritis is based on the presence of fever of 38°C or higher in the absence of any other cause. The presence of either uterine tenderness or purulent or foul-smelling lochia are often used as secondary criteria for the diagnosis of endometritis. Associated findings include malaise, tachycardia, and lower abdominal pain and tenderness. A small number of patients also may have a tender, indurated inflammatory mass in the broad ligament, posterior cul de sac, or retrovesical space.

**The initial differential diagnosis of puerperal fever should include endometritis, atelectasis, pneumonia, viral syndrome, pyelonephritis, and appendicitis.** Distinction among these disorders usually can be made on the basis of physical examination and a limited number of laboratory tests such as white blood cell count, urinalysis and culture, and in select patients, chest radiograph. Blood cultures should not be done *routinely* because of their expense and their lack of impact on

**TABLE 54-7** COMBINATION ANTIBIOTIC REGIMENS FOR TREATMENT OF PUERPERAL ENDOMETRITIS

| ANTIBIOTICS               | INTRAVENOUS DOSE                                      | RELATIVE COST* |
|---------------------------|---|----------------|
| <b>Regimen 1</b>          |   |                |
| Clindamycin <i>plus</i>   | 900 mg every 8 hours                                  | Intermediate   |
| Gentamicin                | 7 mg/kg ideal body weight every 24 hours <sup>†</sup> | Low            |
| <b>Regimen 2</b>          |   |                |
| Clindamycin <i>plus</i>   | 900 mg every 8 hours                                  | Intermediate   |
| Aztreonam                 | 1 to 2 g every 8 hours                                | High           |
| <b>Regimen 3</b>          |   |                |
| Metronidazole <i>plus</i> | 500 mg every 12 hours                                 | Low            |
| Penicillin <i>or</i>      | 5 million U every 6 hours                             | Low            |
| Ampicillin <i>plus</i>    | 2 g every 6 hours                                     | Low            |
| Gentamicin                | 7 mg/kg ideal body weight every 24 hours <sup>†</sup> | Low            |

\*Cost estimate does not include dose preparation fees and administration charges.

<sup>†</sup>Single daily dosing of aminoglycoside antibiotics is more effective and less expensive than multidosing treatment. In addition, daily dosing is less likely to cause ototoxicity or nephrotoxicity.

clinical decision making. However, they are indicated in patients who have a poor initial response to therapy and in those who seem seriously ill, are immunocompromised, or are at increased risk for bacterial endocarditis.

### Management

**Patients who have mild to moderately severe infections, particularly after vaginal delivery, can be treated with short IV courses of single agents such as the extended-spectrum cephalosporins and penicillins or carbapenem antibiotics such as imipenem-cilastatin, meropenem, and ertapenem.** Table 54-6 lists several antibiotics that have acceptable breadth of coverage against the polymicrobial genital tract flora. Combination antibiotic regimens should be considered for more severely ill patients, particularly those who are indigent and in poor general health. Table 54-7 lists several antibiotic combinations of proven value in treatment of puerperal endometritis. As a general rule, the combination generic drug regimens are less expensive than the single agents whose brand-name patents have yet to expire.

**Once antibiotics are begun, approximately 90% of patients defervesce within 48 to 72 hours. When the patient has been afebrile and asymptomatic for 24 hours, parenteral antibiotics should be discontinued and the patient should be discharged. As a general rule, an extended course of oral antibiotics is not necessary after discharge.**<sup>37,43</sup> There are at least two notable exceptions to this rule. First, patients who have had a vaginal delivery and who defervesce within 24 hours are candidates for early discharge. In these individuals, a short course of an oral antibiotic such as amoxicillin-clavulanate (875 mg every 12 hours) may be substituted for continued parenteral therapy. Second, patients who have had staphylococcal bacteremia may require a more extended period of administration of parenteral and oral antibiotics with specific antistaphylococcal activity.<sup>44</sup>

**Patients who fail to respond to the antibiotic therapy outlined earlier usually have one of two problems. The first is a resistant organism.** Table 54-8 lists possible weaknesses in coverage of selected antibiotics and indicates the appropriate change in treatment. **The second major cause of treatment failure is a wound infection,** which may take the form of an

**TABLE 54-8** TREATMENT OF RESISTANT MICROORGANISMS IN PATIENTS WITH PUERPERAL ENDOMETRITIS

| INITIAL ANTIBIOTICS                      | PRINCIPAL WEAKNESS IN COVERAGE                                | MODIFICATION OF THERAPY  |
|--|---|--|
| Extended-spectrum cephalosporins         | Some aerobic and anaerobic gram-negative bacilli, enterococci | Change treatment to clindamycin or metronidazole plus penicillin or ampicillin plus gentamicin |
| Extended-spectrum penicillins            | Some aerobic and anaerobic gram-negative bacilli              | As above   |
| Clindamycin plus gentamicin or aztreonam | Enterococci, some anaerobic gram-negative bacilli             | Add ampicillin or penicillin*<br>Consider substitution of metronidazole for clindamycin        |

\*Ampicillin alone is highly active against enterococci. The combination of penicillin *plus* gentamicin works synergistically to provide excellent coverage against this organism.

incisional abscess or a cellulitis with no actual purulent collection. Incisional abscesses should be opened completely to provide drainage, and a specific antistaphylococcal antibiotic should be added to the treatment regimen. If extensive cellulitis at the margin of the incision is present, an antibiotic with specific coverage against staphylococci should be added, but the wound should not be opened. Vancomycin (1 g IV every 12 hours) is an excellent antistaphylococcal antibiotic, particularly against methicillin-resistant *Staphylococcus aureus* (MRSA).<sup>37</sup> Other possible antistaphylococcal regimens include dalbavancin (1 g in a single dose, repeated in 7 days if necessary), linezolid (600 mg IV every 12 hours), oritavancin (1200-mg single dose), quinupristin/dalfopristin (7.5 mg/kg IV every 8 hours), and telavancin (10 mg/kg IV every 24 hours).<sup>44</sup> Antibiotics may be discontinued once the patient has been afebrile and asymptomatic for a minimum of 24 hours.

When changes in antibiotic therapy do not result in clinical improvement and no evidence of wound infection is present, several unusual disorders should be considered. The differential diagnosis of persistent puerperal fever is summarized in Table 54-9.<sup>42</sup>

Group A *Streptococcus* (GAS) infection is a rare, life-threatening cause of puerperal fever due to *Streptococcus pyogenes*.<sup>45</sup> **Mortality is 30% to 50% when associated with sepsis, known as streptococcal toxic shock syndrome.** GAS infections are invasive, and toxin production allows the organism to spread across tissue planes and cause necrosis while evading containment and abscess formation by the maternal immune system. **Presentation is atypical and may involve extremes of temperature, unusual and vague pain, and pain in extremities. Endometrial biopsy may be a useful rapid diagnostic tool.** When suspected, invasive GAS infections should be treated emergently with aggressive fluid resuscitation, antibiotic administration (penicillin and clindamycin), and source control that may be extensive and may involve hysterectomy.

### Prevention of Puerperal Endometritis

**Prophylactic antibiotics clearly are of value in reducing the frequency of postcesarean delivery endometritis, particularly in women having surgery after an extended period of labor and ruptured membranes.**<sup>46</sup>

**TABLE 54-9** DIFFERENTIAL DIAGNOSIS OF PERSISTENT PUERPERAL FEVER

| CONDITION                           | DIAGNOSTIC TESTS  | TREATMENT   |
|-------------------------------------|---|---|
| Resistant microorganism             | Blood culture   | Combination antibiotics to cover all possible pelvic pathogens                          |
| Wound infection                     | Physical examination<br>Needle aspiration<br>Ultrasound                                 | Incision and drainage if abscess is present; add antibiotic to cover staphylococci      |

| Mastitis                            | Physical examination  | Add antibiotic to cover staphylococci   |

Historically, IV prophylactic antibiotics for cesarean delivery were delayed until cord clamping based on several prior studies,<sup>47-50</sup> which showed that the delay decreased the probability that neonates would require evaluations for sepsis without compromising effectiveness. However, a recent Cochrane review of the timing of IV prophylactic antibiotics for cesarean delivery showed that preoperative administration significantly decreases the incidence of composite maternal postpartum infectious morbidity, as compared with administration after cord clamping, with no differences in adverse neonatal outcomes reported.<sup>51</sup>

**Women undergoing cesarean delivery should receive antibiotic prophylaxis preoperatively to reduce maternal infectious morbidities.**<sup>52-55</sup>

Tita and associates<sup>56,57</sup> showed that extending the spectrum of antibiotic activity by adding azithromycin (500 mg) to cefazolin (1 g) further reduced the risk for endometritis (RR, 0.41). The use of the broader-spectrum regimen also significantly decreased the rate of wound infection (1.3% vs. 3.1%;  $P < .002$ ). However, a subsequent systematic review revealed that preoperative antibiotic administration *or* the use of extended-spectrum regimens after cord clamping may reduce post-cesarean delivery maternal infection by up to 50%, although the lack of their impact relative to each other has not been studied; therefore a firm recommendation of extended-spectrum antibiotics for all cesarean deliveries is premature.<sup>58</sup> **If preoperative antibiotic prophylaxis is given as it should be, extended-spectrum antibiotics do not seem justified at this point for the vast majority of women.**

**Another important step in prevention of endometritis relates to the method of placental delivery.** In 1997, Lasley and colleagues<sup>59</sup> conducted a prospective randomized trial (level I evidence) to compare manual removal of the placenta with removal by gentle traction on the umbilical cord. One hundred sixty-five women were randomized to the manual removal arm of the study, and 168 had spontaneous removal of the placenta. All patients in this study received prophylactic antibiotics, usually cefazolin, after the umbilical cord was clamped. In the patients whose placenta was removed by traction on the cord, the rate of endometritis was reduced from 27% to 15% (RR, 0.6; 95% CI, 0.4 to 0.9;  $P = .01$ ).

Subsequently, the Cochrane database<sup>60</sup> evaluated 15 randomized trials ( $n = 4694$  patients) to compare different methods of removing the placenta. **A consistent finding in these trials was decreased blood loss, a decreased rate of endometritis, and, subsequently, a shorter duration of hospitalization in women**

**whose placenta was removed by gentle traction on the umbilical cord.**

A previous report by Yancey and associates<sup>61</sup> provides a logical explanation for why manual removal of the placenta is associated with an increased risk for infection. In that study, the authors specifically evaluated the contamination of the surgeon's dominant hand as a result of delivering the infant's head from the lower uterine segment. After this step of the operation, the bacterial contamination of the surgeon's glove was markedly increased. When the surgeon then places this hand behind the placenta to manually extract it, this inevitably introduces many microorganisms into the raw vascular bed beneath the placenta.

Based on the studies outlined earlier, **we recommend that both low- and high-risk patients having cesarean delivery receive antibiotics 30 to 60 minutes before the start of surgery. We recommend use of cefazolin, 1 g if BMI is less than 30 m<sup>2</sup>/kg (or <80 kg) and 2 g if BMI is greater than 30 m<sup>2</sup>/kg (or >80 kg), given as a rapid IV infusion.**<sup>62</sup> **We also recommend that, whenever possible, the placenta be removed by traction on the umbilical cord rather than by manual extraction.**

Patients who have an immediate hypersensitivity to  $\beta$ -lactam antibiotics pose a special problem. The best alternative is to administer a single dose of clindamycin (900 mg) plus gentamicin (1.5 mg/kg) before surgery. Although these antibiotics commonly are used for treatment of overt infections, their administration still is warranted in penicillin-allergic patients who are at high risk for postoperative infection.<sup>37</sup>

## Serious Sequelae of Puerperal Infection

### Wound Infection

Wound infection after cesarean delivery may occur in association with endometritis or as an isolated infection. About 3% to 5% of patients who have a cesarean delivery develop a wound infection (see Chapter 19). The major risk factors for wound infection are listed in Box 54-1. **The principal causative organisms are skin flora (*S. aureus*, aerobic streptococci) and the pelvic flora (aerobic and anaerobic bacilli).**<sup>63</sup>

**The diagnosis of wound infection should always be considered in patients who have a poor clinical response to antibiotic therapy for endometritis.** Clinical examination characteristically shows erythema, induration, and tenderness at the margins of the abdominal incision. When the wound is probed with either a cotton-tipped applicator or fine needle, pus

### BOX 54-1 PRINCIPAL RISK FACTORS FOR POSTCESAREAN WOUND INFECTION

- Poor surgical technique such as inadequate preparation of the incision site, removal of hair with a razor rather than electric clippers, failure to close the bottom half of the subcutaneous layer in women with 2 cm or more of subcutaneous layer, use of staples instead of sutures
- Low socioeconomic status
- Extended duration of labor and ruptured membranes
- Preexisting infection such as chorioamnionitis
- Obesity
- Insulin-dependent (type 1) diabetes
- Immunodeficiency disorder
- Corticosteroid therapy
- Immunosuppressive therapy
- Connective tissue disorder
- Smoking

usually exudes. Some patients, however, may have an extensive cellulitis without harboring frank pus in the incision. Clinical examination should be sufficient to establish the correct diagnosis. Nevertheless, culture of the wound exudate is indicated to identify particularly virulent microorganisms such as MRSA.

When pus is present in the incision, the wound must be opened and drained completely. Antibiotic therapy should be modified to provide coverage against staphylococci because some regimens for endometritis may not specifically target this organism. Vancomycin 1 g IV every 12 hours is an excellent choice to cover MRSA.

**Once the wound is opened, a careful inspection should be made to be certain that the fascial layer is intact. If it is disrupted, surgical intervention is necessary to reapproximate the fascia.** Otherwise, the wound should be irrigated two to three times daily with a solution such as warm saline, a clean dressing should be applied, and the incision should be allowed to heal by secondary intention. In complicated infections, a wound vacuum device may be applied to the wound to facilitate healing. Antibiotics should be continued until the base of the wound is clean and all signs of cellulitis have resolved. Patients usually can be treated at home once the acute signs of infection have subsided.

**Necrotizing fasciitis is an uncommon but extremely serious complication of abdominal wound infection.** It also has been reported in association with infection of the episiotomy site.<sup>64</sup> This condition is most likely to occur in patients with type 1 diabetes mellitus, cancer, or an immunodeficiency disorder. Multiple bacterial pathogens, particularly anaerobes, have been isolated from patients with necrotizing fasciitis.

**Necrotizing fasciitis should be suspected when the margins of the wound become discolored, cyanotic, and devoid of sensation.** When the wound is opened, the subcutaneous tissue is easily dissected free of the underlying fascia, but muscle tissue is not affected. If the diagnosis is uncertain, a tissue biopsy should be performed and examined by frozen section.

**Necrotizing fasciitis is a life-threatening condition that requires aggressive medical and surgical management. Broad-spectrum antibiotics with activity against all potential aerobic and anaerobic pathogens should be administered. Intravascular volume should be maintained with infusions of crystalloid, and electrolyte abnormalities should be**

**corrected. Finally, and most importantly, the wound must be debrided and all necrotic tissue must be removed.** In many instances, the required dissection is extensive and may best be managed in consultation with an experienced general or plastic surgeon.<sup>65</sup>

### Pelvic Abscess

With the advent of modern antibiotics, pelvic abscesses after cesarean or vaginal delivery have become extremely rare. **Less than 1% of patients with puerperal endometritis develop a pelvic abscess.**<sup>42</sup> When present, abscesses typically are located in the anterior or posterior cul de sac, most commonly the latter, or within the broad ligament. The usual bacteria isolated from abscess cavities are coliforms and anaerobic gram-negative bacilli, particularly *Bacteroides* and *Prevotella* species.<sup>66</sup>

**Patients with an abscess typically experience persistent fever despite initial therapy for endometritis.** In addition, they usually have malaise, tachycardia, lower abdominal pain and tenderness, and a palpable pelvic mass anterior, posterior, or lateral to the uterus. The peripheral white blood cell count is usually elevated, and there is a shift toward neutrophils and bands. Ultrasound, CT scan, and magnetic resonance imaging (MRI) may be used to confirm the diagnosis of pelvic abscess.<sup>67</sup> Although CT and MRI may be slightly more sensitive, ultrasound offers the advantages of decreased expense and ready availability.

**Patients with a pelvic abscess require surgical intervention to drain the purulent collection.** When the abscess is in the posterior cul de sac, colpotomy drainage may be possible, although availability of modern imaging modalities and support from interventional radiologists has made this practice near obsolete. For abscesses located anterior or lateral to the uterus, drainage may be accomplished by CT- or ultrasound-guided placement of a catheter drain.<sup>68</sup> When access is limited or the abscess is extensive, open laparotomy is indicated.

**Affected patients should also receive antibiotics with excellent activity against coliform organisms and anaerobes.**<sup>37,66</sup>

One regimen that has been tested extensively in obstetric patients with serious infections is the combination of penicillin (5 million U IV every 6 hours) or ampicillin (2 g IV every 6 hours) plus gentamicin (7 mg/kg of ideal body weight every 24 hours) plus clindamycin (900 mg IV every 8 hours) or metronidazole (500 mg IV every 12 hours). If a patient is allergic to  $\beta$ -lactam antibiotics, vancomycin (1 g IV every 12 hours) can be substituted for penicillin or ampicillin. Aztreonam (1 g IV every 8 hours) can be used instead of gentamicin when the patient is at risk for nephrotoxicity. Alternatively, the single agents imipenem-cilastatin (500 mg IV every 6 hours), meropenem (1 g every 8 hours), and ertapenem (1 g every 24 hours) provide excellent coverage against the usual pathogens responsible for an abscess. Antibiotics should not be discontinued until the patient has been afebrile and asymptomatic for a minimum of 24 to 48 hours.

### Septic Pelvic Thrombophlebitis

**Like pelvic abscess, septic pelvic thrombophlebitis is extremely rare; it occurs in 1 in 2000 pregnancies overall and in less than 1% of patients who have puerperal endometritis.**<sup>69</sup> Intrauterine infection may cause seeding of pathogenic microorganisms into the venous circulation; in turn, these organisms may damage the vascular endothelium and initiate thrombosis.

**Septic pelvic thrombophlebitis occurs in two distinct forms.<sup>69</sup> The most commonly described disorder is acute thrombosis of one, usually the right, or both ovarian veins (ovarian vein syndrome).<sup>70</sup>** Affected patients typically develop a moderate temperature elevation in association with lower abdominal pain in the first 48 to 96 hours postpartum. Pain usually localizes to the side of the affected vein but may radiate into the groin, upper abdomen, or flank. Nausea, vomiting, and abdominal bloating may be present.

On physical examination, the patient's pulse usually is elevated. Tachypnea, stridor, and dyspnea may be evident if pulmonary embolization has occurred. The abdomen is tender, and bowel sounds are often decreased or absent. Most patients demonstrate voluntary and involuntary guarding, and 50% to 70% have a tender, ropelike mass that originates near one cornua and extends laterally and cephalad toward the upper abdomen. The principal conditions that should be considered in the differential diagnosis of ovarian vein syndrome are pyelonephritis, nephrolithiasis, appendicitis, broad ligament hematoma, adnexal torsion, and pelvic abscess.

**The second presentation of septic pelvic vein thrombophlebitis is termed enigmatic fever.<sup>71</sup>** Initially, affected patients have clinical findings suggestive of endometritis and receive systemic antibiotics. Subsequently, they experience subjective improvement, with the exception of temperature instability. They do not appear to be seriously ill, and positive findings are limited to persistent fever and tachycardia. Disorders that should be considered in the differential diagnosis of enigmatic fever are drug fever, viral syndrome, collagen vascular disease, and pelvic abscess.

The diagnostic tests of greatest value in evaluating a patient with suspected septic pelvic vein thrombophlebitis are CT scan and MRI (Fig. 54-4).<sup>72</sup> These tests are most sensitive in detecting large thrombi in the major pelvic vessels. They are not as useful in identifying thrombi in smaller vessels. In such cases, the ultimate diagnosis may depend on the patient's response to an empirical trial of heparin.<sup>69,73</sup>

**Patients with septic pelvic vein thrombophlebitis should be treated with therapeutic doses of either IV unfractionated heparin or low-molecular-weight heparin. Therapy should be continued for 7 to 10 days.** Long-term anticoagulation

with oral agents is probably unnecessary unless the patient has massive clotting throughout the pelvic venous plexus or has sustained a pulmonary embolism. Patients should be maintained on broad-spectrum antibiotics throughout the period of heparin administration.

**Once medical therapy is initiated, the patient should have objective evidence of a response within 48 to 72 hours. If no improvement is noted, surgical intervention may be necessary.<sup>69,73</sup>** The decision to perform surgery should be based on clinical assessment and the relative certainty of the diagnosis. The surgical approach, in turn, should be tailored to the specific intraoperative findings. In most instances, treatment requires only ligation of the affected vessels. Extension of the thrombosis along the vena cava to the point of origin of the renal veins may necessitate embolectomy or placement of an umbrella filter. Excision of the infected vessel and removal of the ipsilateral adnexa and uterus is indicated only in the presence of a well-defined abscess. Whenever any of the previously mentioned procedures are being considered, consultation with an experienced vascular surgeon or interventional radiologist is imperative.

### Severe Sepsis

The systemic immune response syndrome (SIRS) is defined by a temperature greater than 38°C, respiratory rate greater than 20/min, heart rate over 90 beats/min, and a peripheral white blood cell count above 12,000/mm<sup>3</sup> or below 4000/mm<sup>3</sup> or with greater than 10% immature (band) forms. Sepsis is SIRS that results from infection. Severe sepsis is defined by the criteria outlined above plus multiorgan dysfunction. Septic shock is diagnosed when sepsis-induced hypotension is present in association with perfusion abnormalities such as lactic acidosis (serum lactate level of 4.0 mmol/L or more), oliguria, and altered mental status.<sup>74,75</sup>

**Septic shock in obstetric patients usually is associated with four specific infections: (1) septic abortion, (2) acute pyelonephritis, (3) chorioamnionitis, or (4) endometritis.<sup>75</sup>** Fortunately, fewer than 5% of patients with any of these infections develop septic shock. In the past, **the most common organisms responsible for septic shock were the aerobic gram-negative bacilli, such as *E. coli* and *K. pneumoniae* and *Proteus*** along with *Pseudomonas*, *Enterobacter*, and *Serratia* species.<sup>74</sup> Today, gram-positive organisms have become increasingly important as causative pathogens.<sup>74</sup>

**In the early stages of septic shock, patients are usually restless, disoriented, tachycardic, and hypotensive. Although hypothermia is occasionally present, most patients have a relatively high fever (39° to 40°C).** Their skin may be warm and flushed owing to an initial phase of vasodilation (warm shock). Subsequently, as extensive vasoconstriction occurs, the skin becomes cool and clammy. Cardiac arrhythmias may be present, and signs of myocardial ischemia may occur. Jaundice, often due to hemolysis, may be evident. Urinary output typically decreases, and frank anuria may develop. Spontaneous bleeding from the genitourinary tract or venipuncture sites may occur as a result of disseminated intramuscular coagulation. Acute respiratory distress syndrome (ARDS) is a common complication of severe sepsis and is associated with manifestations such as dyspnea, stridor, cough, tachypnea, and bilateral rales and wheezing.<sup>74</sup> In addition to these systemic signs and symptoms, affected patients also may have findings related to their primary site of infection such as purulent lochia, uterine tenderness, peritonitis, or flank tenderness.

**FIG 54-4** Computed tomography scan shows a thrombus (arrow) in the right ovarian vein.

**The differential diagnosis of septic shock in obstetric patients includes hypovolemic and cardiogenic shock, diabetic ketoacidosis, anaphylactic reaction, anesthetic reaction, and amniotic fluid or venous embolism.** Distinction among these disorders usually can be made on the basis of a thorough history and physical examination and a limited number of laboratory studies. The white blood cell count initially may be decreased but, subsequently, it is elevated in most patients. A large percentage of bands is usually evident, and the hematocrit may be decreased if blood loss has occurred. Tests of coagulation such as platelet count, serum fibrinogen concentration, serum concentration of fibrin degradation products, prothrombin time, and activated partial thromboplastin time are frequently abnormal. Serum concentrations of the transaminase enzymes and bilirubin often are increased. Similarly, increased concentrations of blood urea nitrogen and creatinine reflect deterioration of renal function. A chest radiograph is indicated in patients with septic shock to determine whether pneumonia or ARDS is present. In addition, CT scan, MRI, and ultrasound may be of value in localizing an abscess.<sup>68</sup> Affected patients also require electrocardiographic monitoring to detect arrhythmias or signs of ischemic injury.

**The first goal of treatment of septic shock is to correct the hemodynamic derangements precipitated by endotoxin.** Two large-bore IV catheters and a urinary catheter should be inserted. Isotonic crystalloid such as Ringer's lactate solution or normal saline should be administered, and the infusion should be titrated in accordance with the patient's pulse, blood pressure, and urine output. If the patient is bleeding, packed red cells should be administered; the goal is to maintain a hemoglobin concentration of 7 g/dL. A more restrictive transfusion threshold (7 rather than 9 g/L) has recently been shown to reduce the number of transfusions by approximately 50% without adversely affecting overall mortality.<sup>76</sup>

The goals of fluid resuscitation are to achieve the following:

- Central venous pressure (CVP) of 8 to 12 mm Hg
- Mean arterial pressure of at least 65 mm Hg
- Urine output of at least 0.5 mL/kg per hour
- Central venous oxygen or mixed venous oxygen saturation of 70% or more<sup>76</sup>

**If fluid resuscitation is not successful, a vasopressor should be administered. The initial drug of choice is norepinephrine** (5 to 15 µg/min), although vasopressin (0.01 to 0.03 U/min) and epinephrine (2 to 10 µg/min) are acceptable alternatives. As a general rule, dopamine should no longer be used as a vasopressor because of its propensity to provoke arrhythmias.<sup>66</sup> Dobutamine (0.5 to 1 µg/kg/min, maximum 40 µg/kg/min) should be used in patients who have a normal CVP but poor cardiac output.<sup>76</sup>

Hydrocortisone (200 to 300 mg/day for 7 days in three or four divided doses or by continuous infusion) should be administered early in the course of septic shock. Although ultimate mortality is not improved, patients who receive corticosteroids have a more rapid reversal of the shock state than those who are not treated.<sup>77,78</sup>

**The second objective of treatment is to administer broad-spectrum antibiotics targeted against the most likely pathogens.**<sup>19</sup> For genital tract infections, the combination of penicillin (5 million U IV every 6 hours) or ampicillin (2 g IV every 6 hours) plus clindamycin (900 mg IV every 8 hours) or metronidazole (500 mg IV every 8 hours) plus gentamicin (7 mg/kg ideal body weight IV every 24 hours) or aztreonam (1 to 2 g IV

every 8 hours) is an appropriate regimen. Alternatively, imipenem-cilastatin (500 mg IV every 6 hours), meropenem (1 g every 8 hours), or ertapenem (1 g IV every 24 hours) can be administered as single agents. Patients also may require surgery; for example, to evacuate infected products of conception, drain a pelvic abscess, or remove badly infected pelvic organs. **Indicated surgery never should be delayed because a patient is unstable; operative intervention may be precisely the step necessary to reverse the hemodynamic derangements of septic shock.**

**Patients with septic shock require meticulous and aggressive supportive care.** Core temperature should be maintained as close to normal as possible by use of antipyretics and a cooling blanket. Coagulation abnormalities should be identified promptly and treated by infusion of platelets and coagulation factors, as indicated. Finally, patients should be given oxygen supplementation and should be observed closely for evidence of ARDS, one of the major causes of mortality in cases of severe sepsis.<sup>75</sup> Oxygenation should be monitored by means of a pulse oximeter or radial artery catheter. If evidence of respiratory failure develops, the patient should be intubated and supported with mechanical ventilation.

The prognosis in patients with septic shock clearly depends on the severity of the patient's underlying illness. In previously healthy patients, mortality should not exceed 15%.<sup>79</sup> Fortunately, most obstetric patients are in the latter category; therefore the prognosis for complete recovery is excellent provided that the patient receives competent, timely intervention.

## Toxoplasmosis

### Epidemiology

***Toxoplasma gondii* is a protozoan that has three distinct forms: (1) trophozoite, (2) cyst, and (3) oocyst. The life cycle of *T. gondii* is dependent on wild and domestic cats, which are the only host for the oocyst.** The oocyst is formed in the cat intestine and is subsequently excreted in the feces. Mammals, such as cows, ingest the oocyst, which is disrupted in the animal's intestine, thus releasing the invasive trophozoite. The trophozoite then is disseminated throughout the body, ultimately forming cysts in brain and muscle.<sup>80</sup>

**Human infection occurs when infected meat is ingested or when food is contaminated by cat feces through flies, cockroaches, or fingers.** Infection rates are highest in areas of poor sanitation and crowded living conditions. Stray cats and domestic cats that eat raw meat are most likely to carry the parasite. **The cyst is destroyed by heat.**<sup>80</sup>

About 40% to 50% of adults in the United States have antibody to this organism, and the prevalence of antibody is highest in lower socioeconomic populations. The frequency of seroconversion during pregnancy is 5%, and about 3 in 1000 infants show evidence of congenital infection. **Clinically significant congenital toxoplasmosis occurs in about 1 in 8000 pregnancies.** Toxoplasmosis is more common in Western Europe, particularly France, most likely because of the practice in that country of eating rare or raw meat. More than 80% of women of childbearing age in Paris have antibody to *T. gondii*, and the incidence of congenital toxoplasmosis is about twice as frequent as that in the United States.<sup>81</sup> **Universal screening of pregnant women for toxoplasmosis is not recommended in the United States at this time.**<sup>82</sup> Testing is indicated, however, if clinical infection is suspected or if the patient is immunocompromised (e.g., HIV infection). Because the presence of antibodies

before pregnancy indicates immunity, the ideal time to test for immunity to toxoplasmosis in women at risk is before conception.<sup>83</sup>

### Clinical Manifestations

The ingested organism invades across the intestinal epithelium and spreads hematogenously throughout the body. Intracellular replication leads to cell destruction. Clinical manifestations of infection are the result of direct organ damage and the subsequent immunologic response to parasitemia and cell death. Host immunity is mediated primarily through T lymphocytes.<sup>80</sup>

**Most infections in humans are asymptomatic.** Even in the absence of symptoms, however, patients may have evidence of multiorgan involvement, and clinical disease can follow a long period of asymptomatic infection. **Symptomatic toxoplasmosis usually presents as an illness similar to mononucleosis.**

**In contrast to infection in the immunocompetent host, toxoplasmosis can be a devastating infection in the immunosuppressed patient.** Because immunity to *T. gondii* is cell mediated, patients with HIV infection and those treated with chronic immunosuppressive therapy after organ transplantation are particularly susceptible to new or reactivated infection. In these patients, dysfunction of the central nervous system is the most common manifestation of infection. Findings typically include encephalitis, meningoencephalitis, and intracerebral mass lesions (Fig. 54-5). Pneumonitis, myocarditis, and generalized lymphadenopathy also occur commonly.<sup>80</sup>

### Diagnosis

**The diagnosis of toxoplasmosis in the mother can be confirmed by serologic and histologic methods. Serologic tests that suggest an acute infection include detection of immunoglobulin M (IgM)-specific antibody, demonstration**

**of an extremely high IgG antibody titer (and low IgG avidity), and documentation of IgG seroconversion from negative to positive.** Clinicians should be aware that serologic assays for toxoplasmosis are not well standardized. When initial laboratory tests appear to indicate that an acute infection has occurred, repeat serology should be performed in a well-respected reference laboratory (e.g., the Toxoplasma Serology Laboratory of Palo Alto Medical Foundation [[www.pamf.org](http://www.pamf.org)]). In addition, toxoplasmic DNA can be identified in the patient's serum using the PCR test.

*T. gondii* is most easily identified in lymphatic or brain tissues. Histologic preparations can be examined by light and electron microscopy. For light microscopy, specimens should be stained with either Giemsa or Wright stain.<sup>81,84</sup>

### Congenital Toxoplasmosis

Congenital infection can occur if a woman develops acute primary toxoplasmosis during pregnancy. Chronic or latent infection is unlikely to cause fetal injury except perhaps in an immunosuppressed patient. **About 40% of neonates born to mothers with acute toxoplasmosis show evidence of infection. Congenital infection is most likely to occur when maternal infection develops in the third trimester. However, fetal injury is most likely to be severe when maternal infection occurs in the first half of pregnancy.** Less than half of affected infants are symptomatic at birth (Box 54-2).<sup>81,84-85</sup>

**The most valuable tests for antenatal diagnosis of congenital toxoplasmosis are ultrasound and amniocentesis.**<sup>81,84-85</sup>

Ultrasound findings suggestive of infection include ventriculomegaly, intracranial calcifications, microcephaly, ascites, hepatosplenomegaly, and growth restriction. In addition, Hohlfeld and coworkers<sup>86</sup> have now identified a specific gene of *T. gondii* in amniotic fluid using polymerase chain reaction (PCR). In this investigation, 34 of 339 infants had congenital toxoplasmosis confirmed by serologic testing or autopsy. All amniotic fluid specimens from affected pregnancies were positive by PCR, and test results were available within 1 day of specimen collection.

In a subsequent investigation, Romand and colleagues<sup>87</sup> reported that the PCR test had an overall sensitivity of 64% (95% CI, 53% to 75%) for diagnosing congenital toxoplasmosis. No false-positive results were noted, and the positive predictive value was 100%.

### Management

Toxoplasmosis in the immunocompetent nonpregnant adult is usually an asymptomatic or self-limited illness and does not require treatment. Immunocompromised patients, however, should be treated, and the regimen of choice is a combination

**FIG 54-5** Magnetic resonance imaging shows a prominent intracerebral abscess due to toxoplasmosis. (Courtesy Dr. Richard Beegle, Department of Radiology, University of Florida.)

#### BOX 54-2 CLINICAL MANIFESTATIONS OF CONGENITAL TOXOPLASMOSIS

- Rash
- Hepatosplenomegaly
- Ascites
- Fever
- Chorioretinitis
- Periventricular calcifications
- Ventriculomegaly
- Seizures
- Mental retardation
- Uveitis

of oral sulfadiazine (4 g loading dose, then 1 g four times daily) plus pyrimethamine (50 to 100 mg initially, then 25 mg daily). In such patients, extended courses of treatment may be necessary to cure the infection.<sup>84</sup>

Treatment also is indicated when acute toxoplasmosis occurs during pregnancy. Treatment of the mother reduces the risk for congenital infection and decreases the late sequelae of infection.<sup>81,85,88</sup> Pyrimethamine is not recommended for use during the first trimester of pregnancy because of possible teratogenicity, although specific adverse fetal effects have not been documented. Sulfonamides can be used alone, but single-agent therapy appears to be less effective than combination therapy. In Europe, spiramycin has been used extensively in pregnancy with excellent success. It is available for treatment in the United States through the CDC but only after confirmation of maternal infection in a reference laboratory.

Aggressive early treatment of infants with congenital toxoplasmosis is indicated and consists of combination therapy with pyrimethamine, sulfadiazine, and leucovorin for 1 year. Early treatment reduces but does not eliminate the late sequelae of toxoplasmosis, such as chorioretinitis.<sup>89</sup>

In the management of the pregnant patient, prevention of acute toxoplasmosis is of paramount importance. Pregnant women should be advised to avoid contact with cat litter if at all possible, particularly when the cat is allowed to roam outside the home. If they must change the litter, they should do so daily, wear gloves, and wash their hands afterward. They should always wash their hands after preparing meat for cooking and should never eat raw or rare meat. Meat should be cooked thoroughly until the juices are clear. Fruits and vegetables also should be washed carefully to remove possible contamination by oocysts.

## Listeriosis

*Listeria monocytogenes* (LM) is a gram-positive bacillus responsible for severe infections in humans and in a large variety of animal species. It is a facultative intracellular pathogen that invades macrophages and most tissue cells of infected hosts, where it can proliferate. **LM can cause meningitis, encephalitis, bacteremia, and gastroenteritis.** In infected hosts, the bacteria cross the intestinal wall at Peyer patches to invade the mesenteric lymph nodes and blood. The main target organ is the liver, where the bacteria multiply inside hepatocytes. Most disease occurs in patients with impaired cell-mediated immunity; therefore LM is an important cause of severe infections in neonates, pregnant women, elderly people, and transplant recipients. Although dramatic epidemics have received the most publicity, most cases of perinatal listeriosis are isolated.

LM is widespread in nature and can be readily found in soil and vegetation. Seroepidemiologic studies show that the infection is foodborne. Heightened surveillance and quality control by the food industry have been instituted (Box 54-3) and have led to a reduction in the number of cases and deaths from this infection in the past decade. However, most parents are still not aware of the risks of listeriosis and recommended practices for listeriosis prevention, thus they are not taking precautions during their pregnancy to prevent listeriosis.<sup>90</sup> **Because LM can grow and multiply at temperatures as low as 0.5°C (or 32.9°F), refrigerating contaminated foods does not always prevent infection, but cooking contaminated foods at high temperatures consistently destroys the bacteria.** LM can also be contracted through the handling of the products of

### BOX 54-3 U.S. DEPARTMENT OF AGRICULTURE'S FOOD SAFETY AND INSPECTION SERVICE AND U.S. FOOD AND DRUG ADMINISTRATION'S ADVICE FOR PREGNANT WOMEN TO PREVENT LISTERIOSIS DURING PREGNANCY

- Do not eat hot dogs, luncheon meats, or deli meats unless they are reheated until steaming hot.
- Do not eat soft cheeses such as feta, Brie, Camembert, blue-veined cheeses, or Mexican-style cheeses such as *queso blanco fresco*. Hard cheeses, semisoft cheeses such as mozzarella, pasteurized processed cheese slices and spreads, cream cheese, and cottage cheese can be safely consumed.
- Do not eat refrigerated pâté or meat spreads. Canned or shelf-stable pâté and meat spreads can be eaten.
- Do not eat refrigerated smoked seafood unless it is an ingredient in a cooked dish such as a casserole. Examples of refrigerated smoked seafood include salmon, trout, whitefish, cod, tuna, and mackerel, which are most often labeled as "nova style," "lox," "kippered," "smoked," or "jerky." This fish is found in the refrigerated section or sold at deli counters of grocery stores and delicatessens. Canned fish such as salmon and tuna or shelf-stable smoked seafood may be safely eaten.
- Do not drink raw (unpasteurized) milk or eat foods that contain unpasteurized milk.

conception of animals when the miscarriage is due to listeriosis. Therefore it is important for pregnant women who work with animals to avoid hand-to-tissue contact with these materials if possible or to wear gloves if contact cannot be avoided. Owing to the ubiquity of the organism in the environment, outbreaks and sporadic disease continue to occur.<sup>91</sup> A recent outbreak in the United States was attributed to contaminated ice cream.

The incubation period of LM ranges from as little as 1 to 90 days, making identification of the exposure that caused the listeriosis extremely difficult. **Maternal symptoms can vary from flulike or "like food poisoning" to septicemia, meningitis, or pneumonia.** Because no serologic evaluation is reliable, listeriosis is a difficult infection to test for outside the septic peak, when it can be demonstrated in blood cultures. **An exposed pregnant woman with a fever higher than 38.1°C (100.6°F) and signs and symptoms consistent with listeriosis for which no other cause of illness is known should be simultaneously tested and treated for presumptive listeriosis.**<sup>92</sup> **Diagnosis is made primarily by blood culture, and placental cultures should be obtained in the event of delivery.** *Listeria*-specific antibody testing is not routinely available and is neither useful nor recommended in the setting of potential *Listeria* exposure. Amniocentesis may also be considered when clinically appropriate in a symptomatic patient: in such cases, amniotic fluid should be cultured for *Listeria* in addition to other indicated testing. The clinical laboratory should be notified of the clinical concern for *Listeria* specifically because targeted culture techniques are important.<sup>93</sup> **An overall perinatal mortality rate of 50% due to late miscarriage, premature delivery, and stillbirth was recorded before the use of modern therapies.**<sup>94</sup> The clinical characteristics of neonatal listeriosis are similar to neonatal GBS sepsis, with early- and late-onset forms of disease. The mortality rate among liveborn infants is about 10%.<sup>95</sup>

The standard therapy for listeriosis is a combination of ampicillin and gentamicin or, for patients who are intolerant

of  $\beta$ -lactam agents, trimethoprim-sulfamethoxazole. If LM chorioamnionitis is diagnosed preterm, in contrast to other types of chorioamnionitis, in utero therapy with high-dose penicillin or trimethoprim-sulfamethoxazole is possible, and preterm delivery may be avoided.

### KEY POINTS

- ◆ Overall, without screening and treatment, 85% of neonatal GBS infections are early in onset and result from transmission from a colonized mother.
- ◆ All pregnant women should be cultured for cervicovaginal GBS at 35 to 37 weeks' gestation. Culture-positive patients should receive intrapartum antibiotic prophylaxis to prevent early-onset neonatal infection.
- ◆ Pregnant patients with GBS bacteriuria should be targeted for intrapartum prophylaxis.
- ◆ All pregnant women should have a urine culture at their first prenatal appointment to detect asymptomatic bacteriuria. Infected patients should be treated and then monitored on subsequent prenatal appointments to identify recurrent infection.
- ◆ Most cases of pyelonephritis occur as a consequence of undiagnosed or inadequately treated lower urinary tract infections.
- ◆ The organisms most likely to cause chorioamnionitis and puerperal endometritis are GBS, *E. coli*, and gram-positive and gram-negative anaerobes.
- ◆ Prophylactic antibiotics are highly effective in preventing post-cesarean delivery endometritis and wound infection. They should be administered before the surgical incision in all cesarean deliveries.
- ◆ Resistant organisms and wound infection are the most common causes of persistent fever in patients being treated for puerperal endometritis.
- ◆ Septic pelvic thrombophlebitis is another important cause of refractory postoperative fever. This condition is best diagnosed by CT or MRI and is treated with broad-spectrum antibiotics and IV heparin.
- ◆ The most common causes of septic shock in obstetric patients are septic abortion, pyelonephritis, chorioamnionitis, and endometritis.
- ◆ The two most common methods of transmission of toxoplasmosis are consumption of undercooked beef and contact with cat litter.
- ◆ The best diagnostic tests for congenital toxoplasmosis are identification of toxoplasmic DNA in amniotic fluid by polymerase chain reaction and identification of specific fetal injury by ultrasound.
- ◆ Pregnant women and immunocompromised patients may reduce their risk for contracting listeriosis by avoiding unpasteurized dairy products.

## OVERVIEW

**“Mental health is fundamental to health.”** This statement, made by Surgeon General David Satcher, emphasized the foundation that emotional well-being provides for health. In medical practice, we compartmentalize symptoms and diseases into

manageable units; however, the patient comes as an integrated whole. The effect of pathology in any part of the body affects the entire patient. Psychiatric disorders are defined in the *Diagnostic and Statistical Manual of Mental Disorders* (version 5, or *DSM-V*),<sup>1</sup> a classification system that divides mental disorders into types based on criteria sets with defining features. This

**FIG 55-1** Integrated perinatal health framework: a multiple-determinants model with a life-span approach. Illustrative examples are in brackets. (Modified from Misra DP, Guyer B, Allston A. Integrated perinatal health framework. A multiple determinants model with a life span approach. *Am J Prev Med.* 2003;25:65.)

chapter covers the major categories of disorders that affect women of childbearing age. For the pregnant woman and her family, the capacity to function optimally, enjoy relationships, manage the pregnancy, and prepare for birth is critical.

**Perinatal health can be conceptualized within a model that integrates the complex social, psychological, behavioral, environmental, and biologic forces that shape pregnancy outcome.** Misra and colleagues<sup>2</sup> presented a perinatal framework that integrates a life-span approach with multiple determinants (Fig. 55-1). The model contains four levels that provide a paradigm for the determinants of perinatal health outcomes. The first level in the model is *distal determinants*, which focuses on *distal* (in time) risk factors that place a woman at greater susceptibility to *proximal* (current) risk factors. Distal determinants from biologic, physical, and social domains increase or decrease a woman's likelihood of developing health problems, engaging in high-risk behaviors, or being exposed to potential toxins. Some of the most powerful influences on pregnancy outcome are related to historic women's health factors that occur long before pregnancy, such as maltreatment during childhood.<sup>3</sup> At the next level, *proximal determinants*, risk factors that have a direct impact on a woman's health,

are represented by biomedical and behavioral responses; for example, cigarette smoking. The interaction between *distal* and *proximal* risk factors determines an individual's current overall health status. The relationship between a woman's health status directly before conception and the demands of pregnancy affect perinatal health outcomes. The third level, *processes*, emphasizes the dynamic interaction of preconceptional, interconceptional, and intraconceptional factors on reproductive health. At the fourth level, *outcomes*, the model includes disease, function, and well-being, which provide a comprehensive view of health status.

Each patient comes to pregnancy with sets of malleable risks and assets. To the extent that biopsychosocial exposures with negative impact upon pregnancy outcome can be diminished, eliminated, or replaced with positive factors, pregnancy outcome can be improved. **The role of the physician is to influence the patient's exposures and behaviors to improve the probability of positive reproductive outcomes** (see Fig. 55-1). Childbearing is an ideal time for health interventions because women have contact with professionals and access to health care coverage and are motivated toward positive behaviors to invest in the welfare of their offspring. The role of fathers has recently been identified as a research gap, and opportunity, in perinatal mental health.

The father, partner, or a significant other can be engaged in interventions<sup>4</sup> to reduce maternal stress, encourage prenatal care, and eliminate drug and alcohol use.<sup>5,6</sup>

Our discussion of psychiatric disorders includes five major diagnostic categories that commonly occur in women of childbearing age: (1) mood, (2) anxiety, (3) eating disorders, (4) substance use disorders, and (5) schizophrenia. Our review focuses on the interrelationships among these disorders and their courses during pregnancy and postpartum and during lactation. The impact of childbearing on existing disorders or vulnerabilities in the female patient is reviewed along with episodes that are etiologically related to childbearing.

## MOOD DISORDERS

### Major Depressive Episode

#### Diagnosis and Prevalence During Pregnancy and Postpartum

In the DSM-V,<sup>1</sup> a *major depressive episode* (MDE) is defined as at least a 2-week period of either persistent depressed mood or loss of interest or pleasure in daily activities, so-called **gatekeeper symptoms**, plus four associated symptoms (three if both gatekeeper symptoms are present; see Box 55-1). *Persistent* means the symptom must be present for most of the day nearly every day. The patient also must have impairment of function in interpersonal relationships or work. It is possible to have a *diagnosis* of MDE without the *symptom* of depression. A woman could have persistent loss of interest or pleasure but no sadness and yet have four other symptoms noted in the DSM-V criteria for major depressive disorder. Note that appetite, sleep, and motor activity can be either decreased or increased relative to the woman's norm. A fatigued woman who derives no pleasure from previously enjoyable activities, sleeps 15 hours per day, sits immobile for long periods, and is gaining weight has MDE. A guilt-ridden woman with sadness, 4 hours of sleep nightly, weight loss of 15 pounds, and pacing also has MDE, which may be episodic or chronic.

Nearly twice as many women (12.0%) as men (6.6%) suffer from an MDE each year.<sup>7</sup> Women are at the greatest risk for MDE between 25 and 44 years, the primary age for childbearing. **The period prevalence of MDE is 12.7% during pregnancy** (with 7.5% of women having a new episode), **and 21.9% the year after parturition<sup>8</sup>; therefore, MDE is among the most common complications of childbearing.** Mothers at increased risk are disadvantaged,<sup>9</sup> have preterm infants,<sup>10</sup> and are

in adolescence.<sup>11</sup> Depression persists from months to years after childbirth, with lingering limitations in physical and psychological functioning after recovery.<sup>12</sup> Of women with postpartum MDE, 25% to 50% have episodes that last 7 months or more.<sup>13</sup>

As predicted by the multiple determinants model (see Fig. 55-1), MDE has contributions from several risk factor domains. In women,<sup>14</sup> the strongest predictors were stressful life events, genetic factors, history of an MDE, and high emotional sensitivity. Similarly, stressful life events<sup>15</sup> and a history of MDE in the woman or her family<sup>13</sup> are predictors of postpartum-onset MDE. Women with postpartum MDE are at increased risk (about 25% to 33%) for recurrence after a subsequent birth, and over 40% have nonpostpartum MDE.<sup>16</sup>

The DSM-V<sup>1</sup> allows the designation *with peripartum onset* to specify episodes that begin during pregnancy or within the first 4 weeks postpartum. Epidemiologists have defined the duration of *postpartum* based on data about the break point between elevated risk for psychiatric illness after birth and the baseline risk for episodes in childbearing-aged women. Kendell<sup>18</sup> and Munk-Olsen<sup>19</sup> and their colleagues found a significant peak in the rate of mood disorders in the 90-day period after childbirth. Although the definition of *postpartum* varies, the adverse effects of the disorder for the woman and her family are independent of time of onset.

**The most commonly used measure to screen for MDE during childbearing is the Edinburgh Postnatal Depression Scale (EPDS; Fig. 55-2),<sup>20</sup>** which has been validated for use both during and after pregnancy. This self-report measure contains 10 items ranked from 0 to 3. Scored by simple addition, the EPDS is free to health care professionals and is available in 23 languages. A cutoff score of greater than or equal to 13 (the sensitivity for identifying MDE is 86%, specificity is 78%, positive predictive value is 73%) was recommended for screening for MDE in clinical settings.<sup>21</sup> For pregnant women the recommended cutoff score is greater than or equal to 15.<sup>22</sup> As with any screening tool, a positive test must be followed by diagnostic evaluation and treatment guidance.<sup>23</sup> The differential diagnosis of MDE in the early postbirth period includes the “baby blues,” a transient syndrome that occurs in 80% of mothers that resolves by day 10 postpartum (see Chapter 23).

### Natural History Across Childbearing

Periods of hormonal fluctuation—menstrual cycle, pregnancy, postpartum, and perimenopause—are associated with MDE. Investigators have suggested that the rapid change in gonadal steroid concentrations contributes to the etiology of postpartum-onset MDE.<sup>24</sup> The neurobiology of women who develop postpartum depression (PPD) appears especially vulnerable to the mood-destabilizing effects of withdrawal from gonadal steroids.

Postpartum MDE does not differ from MDE at other periods during the childbearing years with respect to clinical presentation and duration of untreated episodes.<sup>23</sup> However, aggressive obsessional thoughts occur more commonly in women who have postpartum-onset MDE compared with those whose depression falls outside the 1-year postbirth period. **Delusions must be differentiated from the far more common obsessional thoughts in the context of depression.<sup>25,26</sup>** **Obsessions are recurrent and persistent thoughts, impulses, or images that are experienced as intrusive and inappropriate and cause marked anxiety or distress.** For example, some mothers have obsessional thoughts about drowning their baby and refuse to

#### BOX 55-1 DSM-V CRITERIA FOR MAJOR DEPRESSIVE DISORDER

Over the last 2 weeks, most of the day nearly every day, five of the following (one symptom must be mood or interest) must cause marked distress or impairment in important areas of functioning:

- Depressed mood
- Markedly diminished interest or pleasure
- Significant weight loss or gain unrelated to dieting
- Insomnia or hypersomnia
- Psychomotor agitation/retardation
- Fatigue or loss of energy
- Feelings of worthlessness/guilt
- Diminished ability to concentrate
- Recurrent thoughts of death

How are you feeling?

As you have recently had a baby, we would like to know how you are feeling now. Please check the answer which comes closest to how you have felt in the past 7 days, not just how you feel today.

|     |   |       |
|-----|---|-------|
| 1.  | I have been able to laugh and see the funny side of things: | Score |
|     | As much as I always could                                   | 0     |
|     | Not quite so much now                                       | 1     |

|     | Sometimes   | 2     |
|     | Hardly ever   | 1     |
|     | Never   | 0     |

**FIG 55-2** Edinburgh Postnatal Depression Scale. (From Cox, JL, Holden JM, Sagovsky R. Detection of postnatal depression. Development of the 10-item Edinburgh Postnatal Depression Scale. *Br J Psych*. 1987;150:782-786.)

bathe the child. Women often have “what if” questions such as, What if I throw the baby over the banister? Obsessions differ from psychotic symptoms because the patient recognizes that the thoughts, impulses, or images are a product of her own mind (not imposed by an external force as might occur in psychosis). Additionally, obsessional visual images may occur but are brief and are perceived as being in the “mind’s eye” as opposed to an external hallucination. For example, a woman might have frightening images of her dead baby in a bathtub, but she is aware that the image does not reflect reality. The distinction is important clinically because women with obsessional thoughts are vigilant about preventing any action related to the thought content (e.g., insisting that all kitchen knives be locked away), whereas women with psychosis are at risk for taking action. Although these symptom sets are not mutually exclusive, co-occurrence is very rare.

**The physiologic milieu created by MDE adversely impacts maternal function during pregnancy and postpartum.<sup>27</sup> MDE is associated with poor prenatal care compliance, inadequate nutrition, obesity, smoking, alcohol and drug use, and suicide.** A meta-analysis affirmed that MDE during pregnancy was associated with both low birthweight (LBW) and preterm birth (PTB).<sup>28</sup> Offspring of pregnant women with MDE are at risk for insecure attachment and sleep and eating disorders.<sup>29</sup> Children with in utero exposure to maternal MDE are four times more likely to be depressed at age 16 years.<sup>30</sup>

Psychiatric illness during rapid development of the infant creates a new generation at risk. Maternal depression increases the risk for long-lasting adverse effects such as insecure attachment and poor cognitive performance.<sup>30,31</sup> Other sequelae of maternal mental illness are increased rates of accidental injury, child abuse, neglect, and infanticide.<sup>32</sup> Early identification and intervention for postpartum MDE has the potential to prevent negative sequelae for women and their families. **The relationship between maternal MDE and multiple childhood problems is a continuum that often becomes apparent during pregnancy.**

### Treatment of Major Depressive Episode During Pregnancy

The emergence of MDE during childbearing compels a complete medical and family history, review of systems, and physical exam to assess for contributions to depressive symptoms, particularly thyroid abnormalities and anemia. Our experience is that MDE seldom remits with correction of hypothyroidism alone,<sup>33</sup> and treatment for both is required. The use of prescribed and over-the-counter medications, herbal therapies, drugs, and alcohol must be assessed.

**Although MDE is a highly prevalent condition, only 1 in 5 Americans receives any guideline-concordant intervention,<sup>34</sup> and the rate is lower in pregnant women than in nonpregnant women.<sup>35</sup>** In nearly 6500 Medicaid recipients with established MDE treatment, women who became pregnant had a significantly greater drop in both outpatient psychotherapy visits and antidepressant prescription claims compared with matched nonpregnant women, and care did not resume after birth.<sup>36</sup>

**Evidence-based treatments for MDE are psychotherapy and antidepressants.<sup>37,38</sup>** Studies of interpersonal psychotherapy and pharmacotherapy<sup>39</sup> document both reduced depressive symptoms and improved maternal function following treatment during pregnancy. Psychotherapy is the preferred treatment for most women<sup>34</sup>; however, it is not available in all practice settings,

nor is it feasible for many mothers. Barriers to clinic-based depression care include the physical demands of pregnancy, transportation, childcare for other children, and cost. Adult outpatient settings do not typically offer flexible appointment schedules or allow children on site. If psychotherapy is not feasible, or the woman prefers pharmacotherapy, decision making tends to focus on the potential adverse effects of medication rather than the adverse effects of MDE. The result is often the choice by the woman or her physician to avoid or stop drug treatment to obviate fetal exposure without equal consideration of the risks of MDE to both the mother and fetus.<sup>39</sup> **For most pregnant women, the reality is that accessible and acceptable mental health treatment is very limited.** Low treatment rates are a public health concern given accumulating evidence that MDE increases risk to the pregnant woman and fetus. Federally funded home visitation programs for disadvantaged women are potential adjuncts for collaborative care with obstetricians and mental health professionals to improve rates of depression treatment.<sup>40</sup>

The risk-benefit decision-making process for treatment of MDE during pregnancy was described by representatives from the American Psychiatric Association.<sup>27</sup> **Individually tailored interventions are considered for their capacity to maximize maternal wellness while minimizing adverse effects for the maternal-fetal pair.** The patient and physician both contribute expertise to the process, because the patient’s assignment of her own values dictates her choice. For example, some women will not consent to pharmacotherapy during pregnancy regardless of the impairment related to the MDE. Others choose pharmacotherapy because they are not confident that other treatments will be efficacious or because discontinuing medication invariably has been followed by recurrence with psychosocial consequences. The verbal informed consent process promotes the treatment alliance, recognizes the patient’s responsibility to make choices for herself and her baby, and provides an opportunity for ongoing assessment of the woman’s competence to make decisions.<sup>27</sup>

Although used commonly, the word *safe* is problematic because it implies no possibility of an adverse effect. Confirming any exposure as harmless presents the impossible task of proving no effect on a monumental number of reproductive and developmental outcomes throughout the exposed offspring’s lifespan. What can be estimated from available studies is the magnitude of a subset of reproductive risks in antidepressant-treated women.<sup>41</sup> The risks for multiple domains of reproductive toxicity considered in this chapter are miscarriage, intrauterine fetal demise, structural malformations, growth effects, neurobehavioral teratogenicity, and neonatal effects (see Chapter 8). A prominent observation from the literature is the methodologic difficulty of separating the reproductive effects of the drug exposure from the sequelae, both physiologic and psychosocial, of the underlying MDE.

### Side Effects of Medical Treatment of Major Depressive Episode During Pregnancy

#### MISCARRIAGE

In a cohort study<sup>42</sup> of all registered pregnancies in Denmark from 1997 to 2010, the adjusted hazard ratio for miscarriage after exposure to a selective serotonin reuptake inhibitor (SSRI) was 1.27 (95% confidence interval [CI], 1.22 to 1.33) compared with no exposure. However, women who discontinued SSRI treatment 3 to 12 months before pregnancy also had a similar

increased hazard ratio of miscarriage (1.24; 95% CI, 1.18 to 1.30). In a population-based Danish cohort study, stillbirth and neonatal mortality were not associated with first-trimester SSRI use.<sup>43</sup>

### STRUCTURAL MALFORMATIONS

Studies of first-trimester SSRI exposure do not demonstrate consistent data to support an increased risk for structural malformations. **Two large-scale case control studies<sup>44,45</sup> revealed no increased risk rates overall for malformations, including cardiac anomalies, with SSRI exposure** (combined drugs). Louik and colleagues<sup>45</sup> compared the rates of malformation among 9849 cases and 5860 control infants. Analyses of the associations between individual SSRIs and specific defects showed significant associations between the use of sertraline and omphalocele (odds ratio [OR], 5.7; 95% CI, 1.6 to 20.7) and cardiac septal defects (OR, 2.0; 95% CI, 1.2 to 4.0) and between the use of paroxetine and right ventricular outflow tract obstruction defects (OR, 3.3; 95% CI, 1.3 to 8.8). At the same time, Alwan and colleagues<sup>44</sup> published outcomes from 9622 infants with major birth defects and 4092 control infants born from the National Birth Defects Prevention Study. Maternal SSRI use was associated with anencephaly (OR, 2.4; 95% CI, 1.1 to 5.1); craniosynostosis (OR, 2.5; 95% CI, 1.5 to 4.0), and omphalocele (OR, 2.8; 95% CI, 1.3 to 5.7). In an accompanying editorial, Greene<sup>46</sup> noted that the malformations reported in each study were different and that most had not been previously associated with SSRI exposure.

**The relationship between SSRI use in pregnancy and cardiovascular defects has been the focus of recent studies.** Bérard and colleagues<sup>47</sup> conducted a population-based cohort study in Quebec of 18,493 depressed or anxious women who were exposed to sertraline ( $n = 366$ ), other SSRIs ( $n = 1963$ ), or a non-SSRI antidepressant ( $n = 1296$ ) and unexposed women in the first trimester. Sertraline use was not significantly associated with the risk of overall major malformations when compared with the no-exposure group. However, sertraline exposure was associated with an increased risk of atrial/ventricular defects (relative risk [RR], 1.34; 95% CI, 1.02 to 1.76) and craniosynostosis (RR, 2.03; 95% CI, 1.09 to 3.75). Exposure to SSRIs other than sertraline during the first trimester of pregnancy was associated with craniosynostosis (RR, 2.43; 95% CI, 1.44 to 4.11) and musculoskeletal defects (RR, 1.28; 95% CI, 1.03 to 1.58). Although analyses were adjusted for potential confounders, data on smoking, folic acid intake, alcohol use, and body mass index (BMI) were missing. Whereas the design included women with a history of depression or anxiety, antidepressant-treated women differ from unmedicated women, which is inherent in observational studies in which randomization is not used.<sup>48,49</sup>

In a Danish study, the rate of congenital heart malformations was similar for pregnancies exposed to continuous SSRI use throughout the first trimester (OR, 2.01; 95% CI, 1.60 to 2.53) and for pregnancies in which SSRI treatment was paused during pregnancy (OR, 1.85; 95% CI, 1.07 to 3.20;  $P = .94$ ).<sup>50</sup> Similar risk estimates for specific cardiac malformations were found for individual SSRIs, and no dose-response relationship was observed. Similarly, in a recent American population-based cohort study, Huybrechts and colleagues<sup>51</sup> found no increase in the risk of cardiac malformations attributable to antidepressant use during the first trimester. A total of 64,389 women (6.8%) used antidepressants during the first trimester. Overall, 6403

infants who were not exposed to antidepressants were born with a cardiac defect (72.3/10,000 infants), compared with 580 infants with exposure (90.1/10,000 infants). **Associations between antidepressant use and cardiac defects were attenuated with increasing levels of adjustment for confounding.** The relative risks of any cardiac defect with the use of SSRIs were 1.25 (95% CI, 1.13 to 1.38) in the unadjusted analysis, and markedly attenuated, 1.12 (95% CI, 1.00 to 1.26), in the analysis restricted to women with depression. Importantly, substantial differences in the characteristics of the patients who were treated, compared with untreated subjects, remained. Stratification according to propensity scoring achieved that comparisons were made between groups with almost identical characteristics. This strategy further attenuated the remaining positive association to 1.06 (95% CI, 0.93 to 1.22). No significant association was observed between the use of paroxetine and right ventricular outflow tract obstruction or between sertraline and ventricular septal defects. A similar pattern of increased risk was reported for cardiac malformations in unadjusted analyses, which became insignificant after adjustment was noted for tricyclic antidepressants (TCAs), serotonin-norepinephrine reuptake inhibitors (SNRIs), bupropion, and other antidepressants.<sup>51</sup>

### PRETERM BIRTH AND GROWTH EFFECTS

**In a meta-analysis, Grote and colleagues<sup>28</sup> reported that maternal MDE or depressive symptoms during pregnancy increase the risk of PTB and LBW.** The associations between antenatal depression and adverse outcome included PTB (RR, 1.13; 95% CI, 1.06 to 1.21) and LBW (RR, 1.18; 95% CI, 1.07 to 1.30) but not intrauterine growth restriction (IUGR). The magnitude of risk for PTB and LBW from gestational depression is comparable to the risk of smoking 10 or more cigarettes a day, but it is modest compared with the higher risks associated with black race and substance abuse.<sup>28</sup> In a prospective study ( $n = 238$ ) of pregnant women with MDE, MDE with SSRI treatment, and controls with neither exposure,<sup>48</sup> women with MDE who were either continuously treated with an SSRI (23%) or continuously exposed to MDE (21%) experienced PTB. The rates of late and early PTB were similarly distributed. Postnatal weight, head circumference, and length growth trajectories did not differ across the first year in infants exposed to a selective SNRI or to depression or to neither during pregnancy.<sup>52</sup>

### BEHAVIORAL TERATOGENICITY

*Behavioral teratogenicity* refers to long-term postnatal effects on offspring behavior due to prenatal exposure to agents that affect the central nervous system. Cognitive function, temperament, and overall behavior were similar in children who were exposed prenatally to tricyclics or fluoxetine compared with controls.<sup>53,54</sup> Few data about the postbirth development of individuals exposed in utero to SSRIs have been published; however, all converge on the finding that mental development is similar in exposed compared with unexposed children.<sup>55,56</sup> Nulman and colleagues<sup>57</sup> conducted intelligence testing on 3- to 7-year-old children who had been exposed in utero to an SSRI ( $n = 62$ ) or venlafaxine ( $n = 62$ ) or depression without medication ( $n = 54$ ) and controls ( $n = 62$ ). Exposure group, drug dose, and duration of drug treatment during pregnancy did not significantly affect cognitive function.

In a longitudinal study,<sup>58</sup> 68 infants with prenatal SSRI ( $n = 41$ ) or MDE exposure ( $n = 27$ ) and 98 nonexposed controls were evaluated with the Bayley Scales of Infant Development.

Neither prenatal exposure to an SSRI nor an MDD significantly impacted overall scores; however, SSRI exposure was associated with lower psychomotor development scores at 26 and 52 weeks compared with nonexposed infants, although this difference was no longer significant at 78 weeks. Although lower psychomotor scores were observed in the first year, the scores remained well within the normative range and were transient.

### NEONATAL EFFECTS

**Direct serotonergic effects and/or withdrawal signs can occur in neonates after prenatal exposure to antidepressants.** Compared with early gestational SSRI exposure or no exposure, late SSRI exposure incurs an overall risk ratio of 3.0 (95% CI, 2.0 to 4.4) for neonatal behavioral syndrome.<sup>59</sup> Most SSRI-related neonatal case reports involve paroxetine and fluoxetine.<sup>48,59</sup> Neonatal signs include central nervous system, motor, respiratory, and gastrointestinal signs that are usually mild and transient with resolution by 2 weeks of age.<sup>60</sup> A severe syndrome that consists of seizures, dehydration, excessive weight loss, and hyperpyrexia is rare in full-term infants (1/313 cases).<sup>59</sup> Based on the premise that neonatal signs are due to direct pharmacologic effects, tapering and discontinuation of the antidepressant over 10 days to 2 weeks before the delivery date with reintroduction of drug immediately after birth has been suggested<sup>59</sup>; however, data to demonstrate improved outcomes for mothers or newborns have not been published. **If a woman has a history of rapid decompensation during antidepressant taper or discontinuation, this strategy is likely to carry more risk to the maternal-fetal pair than continued treatment.**

### Recommendations for Treatment During Pregnancy

The American College of Obstetricians and Gynecologists (ACOG) and the American Psychiatric Association developed a consensus document for antidepressant treatment during pregnancy.<sup>61</sup> For mild cases of MDE in pregnant women, psychotherapy is the treatment of choice as the initial intervention. Depressed pregnant women treated with interpersonal psychotherapy had a significant symptomatic improvement compared with a parenting education control group, and 60% of women achieved remission criteria.<sup>37</sup> Other focused, short-term therapies such as cognitive behavioral therapy (CBT) are also effective options for MDE and may be delivered by nonphysician professionals such as psychologists, psychiatric nurse clinicians, or licensed clinical social workers. The cost and accessibility of depression treatment also impacts treatment selection.

**For moderate to severe MDE with marked functional impairment, antidepressant pharmacotherapy or combination therapy (medication and psychotherapy) is appropriate. Established efficacy and tolerability of any antidepressant for the individual woman is a strong consideration in drug choice during the risk-benefit decision-making process.** Women with chronic or highly recurrent MDE may be on maintenance antidepressant medication when pregnancy occurs. Maintenance antidepressant treatment is recommended after three or more MDEs due to the near-certain likelihood of recurrence. For pregnant women studied in an academic setting, the risk of relapse for those who discontinued antidepressant usage proximate to conception was significantly greater than women who maintained treatment. Among 82 women who continued their medication, 21 (26%) relapsed compared with 44 (68%) of 65 women who discontinued medication.<sup>62</sup> In contrast, Yonkers and colleagues<sup>63</sup> found that pregnant women who

continued antidepressants experienced the same rate of MDE recurrence as women who stopped in a community sample of obstetric patients. A predictive factor for recurrence in both studies were highly recurrent MDE (four or more episodes prior to pregnancy).

### DOSAGE CHANGES ACROSS PREGNANCY

**All TCAs and SSRIs are at least partially metabolized by cytochrome P450 (CYP) 2D6,<sup>64</sup> which is induced in pregnancy and results in declining serum concentrations.** In a publication about managing tricyclic dosages across pregnancy,<sup>65</sup> a strategy to determine the minimum *effective* dose across gestation was suggested. The women selected a target depressive symptom that was most disturbing, typically insomnia or irritability. Women were asked to contact the physician each time the symptom emerged, and an incremental dose was added. **The dosages increased during the second half of pregnancy and rapidly accelerated in the third trimester. The final dose near term was an average of 1.6 times the nonpregnant dose.**

Similarly, the dose requirements and concentration-dose (C/D) ratios of the SSRIs fluoxetine,<sup>66</sup> citalopram, escitalopram, and sertraline<sup>67</sup> changed during pregnancy and postpartum. In the majority of women, the C/D ratios for the parent compound and primary metabolites decreased between 20 weeks' gestation and delivery, which reflects increased drug metabolism. Pharmacogenetic characterization is not a standard of care for antidepressant therapy; however, Ververs and colleagues<sup>68</sup> showed that CYP 2D6 genotypes predicted plasma paroxetine concentrations during pregnancy. Women who were extensive metabolizers ( $n = 43$ ) and ultrarapid metabolizers ( $n = 1$ ) showed steadily *decreasing* plasma paroxetine concentrations across pregnancy. In contrast, plasma paroxetine levels of intermediate metabolizers ( $n = 25$ ) and poor metabolizers ( $n = 5$ ) *increased* during pregnancy. Weight gain, maternal age, and smoking did not influence drug concentrations. In extensive and ultrarapid metabolizers, the depressive symptoms increased significantly during the course of pregnancy. Paroxetine is unique among the SSRIs in having 2D6 as the sole metabolic pathway. **For TCAs and most SSRIs, dose requirements often increase during the second half of pregnancy to offset greater drug metabolism. Serial administration of a quantitative depression measure is recommended to identify early symptoms of relapse. The goal is to provide optimal drug dosing across the changing milieu of pregnancy to maximally reduce disease burden.**

### INTEGRATIVE TREATMENTS

Known as a treatment for seasonal (winter) MDE, **light therapy** is also efficacious for nonseasonal MDE. Bright light, delivered as an early morning bolus of 10,000 lux illuminance with commercially available boxes, is an efficacious treatment for MDE. The light units conform to stringent standards, with illumination of a broad visual field, lighting from above to avoid glare, and ultraviolet screening. Light therapy for pregnant women with MDE was explored in a small randomized controlled trial (RCT)<sup>69</sup> with bright white versus dim (inactive) arms. The response rates were significantly greater for bright compared with dim light after 5 weeks of 1 hour of early morning light and were comparable to antidepressant treatment. A clinician's guide is available.<sup>70</sup>

Manber and colleagues<sup>71</sup> performed an RCT ( $n = 150$ ) of **acupuncture treatment** specific to MDE, acupuncture treatment

targeted to a condition other than MDE, and a comparison group that received massage. Women who received acupuncture specific for MDE had a significantly greater response rate than those who received the other treatments; again, this response was comparable to that of standard MDE treatments.

Poor nutrition may contribute to the pathogenesis of MDE. Folate and vitamin B<sub>12</sub> are needed for single-carbon metabolism involved in the synthesis of serotonin and other monoamine neurotransmitters and catecholamines. Folate, B<sub>12</sub>, iron, zinc, and selenium deficiencies are more common among depressed than nondepressed persons.<sup>72</sup> The depletion of nutrient reserves throughout pregnancy and lactation may increase a woman's risk for MDE. Marginal or low folate status also increases the likelihood of nonresponse to antidepressant medication as well as the probability of relapse. Several RCTs have demonstrated that **folinic acid** is an efficacious augmentation strategy for antidepressant medications.<sup>72</sup>

**Omega-3 fatty acids** are essential long-chain polyunsaturated fatty acids found in nerve cell membranes. Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are derived primarily from fish. The American diet is relatively deficient in omega-3 compared with omega-6 fatty acids and other fats. Increased requirements during pregnancy raise the risk of deficiency and potentially of MDE. In cross-national studies, an inverse relationship has been shown between per capita fish intake and prevalence rates of MDE, postpartum MDE, and bipolar disorder.<sup>73</sup> Supplementation with 1 gram of EPA and DHA has been recommended for patients with mood disorders.<sup>74</sup> Omega-3 fatty acids have been used to treat perinatal MDE in small RCTs, but efficacy beyond placebo has not been convincingly demonstrated.<sup>73</sup> However, DHA supplementation may attenuate the effects of maternal stress during late pregnancy and can reduce fetal exposure to glucocorticoids in women living in urban low-income environments.<sup>75</sup> Women who received supplementation reported less stress and had lower levels of stress hormones in the third trimester than placebo-treated women. Omega-3 fatty acids have antiinflammatory effects<sup>76</sup> that may contribute to the mechanism of action.

### Treatment of Major Depressive Episode in the Postpartum Period

Medications effective for MDE in women outside of childbearing are effective during childbearing. In a randomized comparative efficacy trial, the tricyclic nortriptyline (NTP;  $n = 54$ ) was compared with sertraline ( $n = 55$ ),<sup>78</sup> and the response rates were equal. The dosing started with 10 mg for NTP and 25 mg sertraline for 2 days then 25 mg/day NTP and 50 mg/day sertraline thereafter, and it was increased every 2 weeks to a maximum of 150 and 200 mg/day, respectively. The total side effect burden for both drugs was similar, although the types differed for each drug. A major finding was that the dose of sertraline required for remission in this 8-week, double blind protocol was 100 mg/day or more, with many women requiring 150 to 200 mg/day. **The starting dose of sertraline 50 mg/day was not efficacious in the majority of women, and dose adjustment should be anticipated approximately 2 weeks after treatment initiation.** An RCT of sertraline versus placebo demonstrated efficacy for sertraline<sup>79</sup> with a mean dose of  $100 \pm 54$  mg/day.

In a small novel RCT of the efficacy of estradiol treatment, women with severe postpartum MDE were randomized to placebo or estradiol delivered by transdermal patch (200 µg/day) for 6 months.<sup>80</sup> By 3 months, 80% of the estradiol-treated

and 31% of the placebo-treated group responded. Endometrial changes were found in three participants at the end of the study, despite coadministration of dydrogesterone (10 mg/day, 12 days/month in the final 3 months of the RCT). The changes resolved at follow-up. The inclusion of women who took concurrent antidepressant medications limits the ability to discern an estradiol-specific effect. Little is known about estradiol secretion into breast milk; however, it was not detected in the milk of 18 women who used transdermal estradiol 50 to 100 µg/day for 12 weeks.<sup>81</sup>

### Prevention of Postpartum-Onset Major Depressive Episode

To reduce the risk for postpartum MDE, an interpersonal therapy-based group intervention was provided to pregnant women on public assistance. Within 3 months after delivery, 20% of the women in standard care developed postpartum MDE compared with 4% of women who received the intervention.<sup>82</sup> Studies of antidepressants or hormones for the prevention of postpartum MDE are limited to three RCTs,<sup>77</sup> with one small RCT demonstrating the efficacy of sertraline.<sup>83</sup> Women with a history of MDE were treated with sertraline immediately following birth to prevent the onset of MDE. The dosing protocol was, in mg/day, 25 for 4 days, then 50 mg through week 4, and 75 thereafter. The duration of preventive treatment was a minimum of 6 months. The explanation for sertraline's efficacy is based on its serotonergic impact; therefore, use of another serotonergic drug, particularly one to which the woman had previously responded, is appropriate. Although open studies supported that progesterone prevented recurrence, a placebo-controlled RCT of a synthetic progesterone *increased* the risk of depression after birth.<sup>84</sup>

### Treatment During Breastfeeding

The magnitude of antidepressant exposure through breast milk is substantially lower than during pregnancy (Table 55-1). Comprehensive reviews of antidepressant drugs in maternal serum, breast milk, and infant serum have been published.<sup>77</sup> Sertraline or paroxetine (among SSRIs) and nortriptyline (among TCAs) are agents of choice. These drugs are characterized by undetectable or very low breastfed-infant serum concentrations and no reports of adverse events. However, established efficacy of another drug for the woman must be considered strongly in the decision-making process. Although TCAs are reasonable treatments for postpartum MDE, they are second-line drugs due to their toxicity in overdose. More recently released antidepressants are second-line choices for breastfeeding women unless efficacy in prior episodes has been established.

The clinical condition of breastfed infants, particularly those who are sick or LBW, should be monitored to detect adverse effects that may be associated with the maternal drug (behavioral activation or sedation, new-onset feeding or sleeping problems; see Chapter 24). Routine laboratory measurement of serum drug levels in healthy full-term infants is not warranted; however, serum concentrations in preterm and sick infants have not been described and would be a welcome contribution to the literature.

### Psychiatric Disorders and Suicidal Ideations

Oates<sup>85</sup> performed an evaluation of the Confidential Enquiry into Maternal Deaths from the United Kingdom. Psychiatric disorder, and suicide specifically, was the leading cause of

**TABLE 55-1** SELECTED ANTIDEPRESSANT LEVELS IN BREASTFED INFANTS' SERA

| ANTIDEPRESSANT DRUG <sup>†</sup>   | SERUM LEVEL RANGE IN BREASTFED INFANTS   | TYPICAL MATERNAL DOSE RANGE (mg/day)                          |
|------------------------------------|--|---|
| Nortriptyline*                     | Nortriptyline, below limit of quantifiability to 10 ng/mL  | 50-150; maternal therapeutic serum levels are 50 to 150 ng/mL |
| Nortriptyline metabolites          | E-10-OH-nortriptyline = <4-16 ng/mL<br>Z-10-OH-nortriptyline = <4-17 ng/mL   |   |
| Sertraline                         | Sertraline, below limit of quantifiability to 8 ng/mL  | 50-200  |
| Sertraline metabolites             | Norsertaline, below limit of quantifiability to 26 ng/mL   |   |
| Paroxetine                         | Paroxetine, below limit of quantifiability   | 10-60   |
| No active metabolites              |  |   |
| Fluoxetine                         | Fluoxetine, below quantifiability to 340 ng/mL   | 20-60   |
| Fluoxetine metabolite <sup>‡</sup> | Norfluoxetine, below quantifiability to 265 ng/mL  |   |
| Citalopram                         | Citalopram, below quantifiability to 12.7 ng/mL  | 20-40   |
| Citalopram metabolite              | Desmethylcitalopram, below quantifiability to 3.1 ng/mL  |   |
| Venlafaxine                        | Venlafaxine, below quantifiability to 5 ng/mL  | 75-300  |
| Venlafaxine metabolite             | O-desmethylvenlafaxine, below quantifiability to 38 ng/mL  |   |
| Bupropion                          | Average infant exposure expected to be 2% of the standard maternal dose on a molar basis; infant serum levels not measured in largest series ( <i>n</i> = 10) <sup>§</sup> | 300   |
| Multiple metabolites               |  |   |

\*The most-studied tricyclic antidepressant during breastfeeding, this class of drugs is now used infrequently.

<sup>†</sup>Established efficacy of an antidepressant in a woman is a strong consideration in drug selection.

<sup>‡</sup>As active as fluoxetine, this metabolite has a longer half-life than the parent drug.

<sup>§</sup>Haas JS, et al. Bupropion in breast milk: an exposure assessment for potential treatment to prevent post-partum tobacco use. *Tobacco Control*. 2004;13(1):52-56.

mortality and accounted for 28% of maternal deaths. Women also died of other complications related to psychiatric disorders and substance abuse, and they died violently. In a large scale study<sup>86</sup> of 10,000 women screened with the EPDS, the proportions of response on item 10—"The thought of harming myself has occurred to me"—were for 0, or *never*, 96.81% (*n* = 9681); for 1, or *hardly ever*, 2.46% (*n* = 246); for 2, or *sometimes*, 0.65% (*n* = 65); and for 3, or *yes quite often*, it was .08% (*n* = 8). In this group of 10,000 women screened by phone, 3.2% of women had some degree of suicidal ideation.

**Suicide assessment requires direct questioning of the patient about her desire to live or die, specific thoughts about killing herself, plans for carrying out the act, and access to and lethality of means.**<sup>87</sup> The American Psychiatric Association guidelines for the assessment of suicidal behaviors provide a comprehensive list of questions that help clinicians assess suicidal thoughts, plans, and behaviors.<sup>88</sup> Initial questions address patients' feelings about living (Have you ever thought that life was not worth living? Did you ever wish you could go to sleep and just not wake up?) and are followed by questions that address specific thoughts about death, self-harm, and suicide (Have things ever reached the point that you've thought of harming yourself?). If thoughts of self-harm are disclosed, clinicians should evaluate the details such as the intensity, frequency, timing, persistence, and circumstances. Physicians must also ask whether the patient has made a specific plan for self-harm. Ask about pills, household poisons, and firearms. Has the patient made preparations to enact the plan or for after her death (purchasing the means, writing a will, arranging for child care)? If the safety of the patient is at risk, emergency psychiatric consultation or involuntary commitment is indicated.

The practice guidelines<sup>88</sup> identify situations in which suicide assessment is warranted: emergency department evaluation, an abrupt change in clinical symptoms, lack of improvement or worsening despite treatment, anticipation or experience of an interpersonal loss or stressor (divorce, loss of custody of children, financial loss, legal problems), or a physical illness associated with a threat to life, severe pain, or loss of function. Patients with increased risk are those with previous suicide attempts,

major mood disorders (particularly bipolar disorder), schizophrenia, and substance use.

## Bipolar Disorder

### Diagnosis and Prevalence

**The diagnosis of MDE is limited to the lifetime experience of normal mood with episodes of depression, whereas bipolar disorder (BD) includes normal, depressed, and elevated or irritable mood states** (mania or its less intense form, hypomania). Changes in energy and activity levels parallel variations in mood. *Mania* is a persistent, abnormally euphoric, expansive or irritable mood state with inflated self-esteem, agitation, heightened energy, racing thoughts, pressured speech, impulsive behaviors, distractibility, and poor judgment for a minimum of 1 week. Impairment in function must be present. *Hypomania* is defined by a minimum of 4 continuous days of persistent increased creativity, productivity, and sociability or increased irritability that family or coworkers notice. The woman's function may be enhanced by creativity and increased energy. In women, **depression is the predominant mood state and is frequently mistaken for unipolar depression**. Atypical depression—characterized by increased appetite, weight gain, hypersomnia, low energy, heaviness—is more common in women with BD and typically starts in the fall or winter and resolves in spring.

The lifetime prevalence of BD is 1% to 2%.<sup>89,90</sup> BD type I, which affects women and men equally, is characterized by MDE and periods of mania or hypomania.<sup>91</sup> Bipolar variants that are more common in women than men include BD type II (MDE and hypomania), mixed episodes (intermingled manic and depressive symptoms), and rapid cycling (four or more episodes of opposite polarity in one year). Women with BD often have comorbid anxiety disorders, alcohol or substance (especially *Cannabis*) use disorders, bulimia nervosa,<sup>92</sup> childhood or adult physical and/or sexual abuse, and medical problems that include migraines, metabolic syndrome, pain disorders, and hypothyroidism.

**The differentiation of MDE from BD is a major challenge, and delays of 7 to 11 years until diagnosis of BD is**

**common.**<sup>93</sup> Prescribing antidepressants without an antimanic drug can complicate treatment by increasing rapid cycling, mania, or mixed episodes. The most commonly used measure is the Mood Disorders Questionnaire (MDQ)<sup>94</sup> shown in Figure 55-3, which assesses lifetime history of mania with 13 yes/no symptoms and two questions: a yes/no query about whether symptoms occurred during the same time period and a designation of the magnitude of the resulting problems (none, minor, moderate, serious). A positive screen requires seven or more symptoms during the same period that caused moderate or serious problems. Our team studied use of the MDQ with the EPDS as a combined screening tool in a postpartum population with follow-up diagnosis by a research psychiatric interview.<sup>95</sup> The addition of the MDQ to the EPDS identified BD in 50% of women with traditional scoring, and it reached almost 70% when the MDQ was scored without the impairment criterion. **Based on this study, we recommend the MDQ or a diagnostic assessment for BD be given prior to prescribing antidepressants for a postpartum depressed woman.**

### Natural History Across Childbearing

The course of episodes is useful in evaluating recurrence risk during pregnancy. Women with episodes that occur only after delivery are not likely to relapse during pregnancy even without medication.<sup>96</sup> However, women with a chronic course are likely to be symptomatic during pregnancy, and maintenance medication is appropriate. For women with chronic BD, discontinuation of drug treatment proximal to conception incurred a high risk for recurrence (86%) compared with patients who continued treatment (37%).<sup>97</sup> **After delivery, all women with BD are at high risk for recurrent mood episodes.**<sup>98,99</sup>

**Postpartum psychosis is typically a manifestation of BD such as mania, mixed state, or depression with psychotic features.**<sup>100</sup> It occurs in 1 to 2 per 1000 births in the first month following delivery. Women are more vulnerable to psychosis in the post-birth period than at any other time during their lives. In the first 30 days after birth, a woman is 21.7 times more likely to develop psychosis than in the 2-year period prior to childbirth. If she has not had a child before, she is 35 times more likely to suffer psychosis than women who have children.<sup>101</sup> The magnitude of these relative risks demonstrates that postpartum psychiatric morbidity is a major public health problem.<sup>102,103</sup> The mechanism for the vulnerability of postpartum women with BD for decompensation and psychosis have not been elucidated. Sleep deprivation and marked interference with circadian rhythms related to labor are likely contributors to mood instability.<sup>100</sup> Hormone elevations near the end of gestation and massive postpartum withdrawal also contribute to the risk.<sup>104</sup> **The clinical picture of postpartum psychosis is characterized by rapid onset of hectic mood fluctuations; marked cognitive impairment suggestive of delirium; bizarre behavior; insomnia; visual and auditory hallucinations, including unusual (tactile and olfactory) hallucinations; and impaired judgment and insight.**<sup>105</sup> Specific types of delusional thoughts are related to the risk for infanticide. Delusional altruistic homicide, often associated with maternal suicide, to save both mother and infant "from a fate worse than death" was reported in a review of filicides,<sup>106</sup> that is, killing one's son or daughter. Resnick<sup>106</sup> observed that 40% of the perpetrators of filicide had seen physicians shortly before the tragedy. Sensitive, direct questions about thoughts of harm to the infant are imperative in the examination. Nonjudgmental inquiry can be made as follows: "Some

new mothers have thoughts such as wishing the baby were dead or about harming the baby; has this happened to you?"

The risk for adverse pregnancy outcomes is increased in women with mental illness. A population cohort study demonstrated that women with BD had an increased frequency of placenta previa and antepartum hemorrhage compared with euthymic women.<sup>107</sup>

### Treatment of Bipolar Disorder During Childbearing

**Medication maintenance is the mainstay of treatment for BD, although psychotherapy and education are also important.** Early identification of BD and rapid initiation of treatment results in lower rates of relapse, increased time to recurrence, improved medication adherence, and better function.<sup>108</sup> Because abrupt discontinuation of mood stabilizers increases the risk for recurrence,<sup>109</sup> education about adherence and drug tapering for discontinuation is advisable.

Several classes of drugs are effective for the treatment of mania. Lithium, some antiepileptic drugs (AEDs), and atypical antipsychotic drugs are efficacious; however, these treatments provide response in only 36% to 50% of cases,<sup>1</sup> and patients often receive more than one drug to manage their mood symptoms. **To minimize fetal exposure, strategies include (1) use using the lowest effective doses, (2) minimizing the number of drugs taken, and (3) dividing daily doses to avoid high peak serum concentrations, unless compliance will be compromised.**

### LITHIUM

Lithium is the standard drug for acute and maintenance therapy for BD. Before initiating lithium treatment, assessment of renal and thyroid function is necessary. The starting dose is 300 mg twice daily. Serum drug concentration and renal function tests should be repeated after 5 to 7 days of treatment. The target serum trough concentration is 0.4 to 1.0 mEq/L at 12 hours. Treatment response is usually achieved at 900 to 1200 mg daily. Due to the physiologic changes of pregnancy, monthly lithium levels are recommended in the first and second trimester with dose adjustment to achieve the prepregnancy concentration that was efficacious. In the final gestational and first postpartum month, weekly lithium levels may need to be measured.<sup>100</sup> Common side effects of lithium include sedation, tremor, renal dysfunction, weight gain, nausea, vomiting, and diarrhea. Toxic effects are associated with somnolence, confusion, severe tremors, renal dysfunction, and intractable vomiting. Women with vomiting are especially vulnerable to toxicity due to fluid loss. Lithium toxicity is managed with drug discontinuation, rehydration therapy, and monitoring of fluid and electrolyte balance and renal function. Diuretics and nonsteroidal antiinflammatory drugs (NSAIDs), which can impair renal clearance, should be avoided in lithium-treated patients.

Lithium exposure during the first trimester was associated with an increased risk for Ebstein anomaly. Subsequent prospective studies demonstrated that the risk was overestimated due to voluntary reporting to a registry, which inflated the number of cases (numerator) and underestimated the magnitude of population exposed (denominator).<sup>100</sup> **The absolute risk of Ebstein anomaly with first-trimester exposure is 1/1000 to 1/2000, 20 to 40 times higher than in the general population.**<sup>100</sup> Lithium-exposed neonates are at risk for being large for gestational age and for hypotonia, feeding difficulties, depressed reflexes, cyanosis, apnea, bradycardia, hypothyroidism,

# THE MOOD DISORDER QUESTIONNAIRE

**Instructions:** Please answer each question to the best of your ability.

|   | YES                   | NO                    |
|---|-----------------------|-----------------------|
| 1. Has there ever been a period of time when you were not your usual self and...  |                       |                       |
| ...you felt so good or so hyper that other people thought you were not your normal self or you were so hyper that you got into trouble?   | <input type="radio"/> | <input type="radio"/> |
| ...you were so irritable that you shouted at people or started fights or arguments?   | <input type="radio"/> | <input type="radio"/> |
| ...you felt much more self-confident than usual?  | <input type="radio"/> | <input type="radio"/> |
| ...you got much less sleep than usual and found you didn't really miss it?  | <input type="radio"/> | <input type="radio"/> |
| ...you were much more talkative or spoke much faster than usual?  | <input type="radio"/> | <input type="radio"/> |
| ...thoughts raced through your head or you couldn't slow your mind down?  | <input type="radio"/> | <input type="radio"/> |
| ...you were so easily distracted by things around you that you had trouble concentrating or staying on track?   | <input type="radio"/> | <input type="radio"/> |
| ...you had much more energy than usual?   | <input type="radio"/> | <input type="radio"/> |
| ...you were much more active or did many more things than usual?  | <input type="radio"/> | <input type="radio"/> |
| ...you were much more social or outgoing than usual, for example, you telephoned friends in the middle of the night?  | <input type="radio"/> | <input type="radio"/> |
| ...you were much more interested in sex than usual?   | <input type="radio"/> | <input type="radio"/> |
| ...you did things that were unusual for you or that other people might have thought were excessive, foolish, or risky?  | <input type="radio"/> | <input type="radio"/> |
| ...spending money got you or your family into trouble?  | <input type="radio"/> | <input type="radio"/> |
| 2. If you checked YES to more than one of the above, have several of these ever happened during the same period of time?  | <input type="radio"/> | <input type="radio"/> |
| 3. How much of a problem did any of these cause you – like being unable to work; having family, money or legal troubles; getting into arguments or fights?<br><i>Please circle one response only.</i> |                       |                       |
| No Problem      Minor Problem      Moderate Problem      Serious Problem  |                       |                       |
| 4. Have any of your blood relatives (i.e. children, siblings, parents, grandparents, aunts, uncles) had manic-depressive illness or bipolar disorder?   | <input type="radio"/> | <input type="radio"/> |
| 5. Has a health professional ever told you that you have manic-depressive illness or bipolar disorder?  | <input type="radio"/> | <input type="radio"/> |

and diabetes insipidus.<sup>100</sup> The neonatal symptoms are temporary and are associated with maternal serum concentrations at delivery of greater than 0.64 mEq/L.<sup>110</sup> The suspension of lithium dosing 24 to 48 hours before a scheduled delivery or at onset of labor reduces the risk for perinatal complications.<sup>110</sup> Developmental milestones are normal in infants exposed in utero to lithium.<sup>100</sup>

### VALPROIC ACID

Valproic acid (VPA) was the first AED for mania approved by the Food and Drug Administration (FDA). The starting dose is 500 to 750 mg daily in divided doses, and therapeutic levels range from 50 to 125 µg/mL. Adverse effects include nausea, weight gain, fatigue, tremor, ataxia, diarrhea, abdominal pain, alopecia, hepatitis, thrombocytopenia, and pancreatitis.

**Exposure to VPA is associated with increased risk for serious adverse outcomes that include all birth defects (OR, 10.7; 95% CI, 8.2 to 13.3),<sup>111</sup> developmental delay, and fetal death compared with other AEDs (see Chapters 8 and 48.)<sup>112</sup>** With exposure to multiple AEDs, women have a twofold to fivefold increased risk for major malformations and for having offspring with cognitive impairment compared with monotherapy.<sup>113</sup> Rates of malformations from polytherapy were 6.0% compared with 3.7% for monotherapy.<sup>113,114</sup> VPA is concentrated in the fetal compartment, and provision of the lowest effective dose in divided doses is recommended to avoid high single peak levels.<sup>100</sup> Complications associated with VPA use near delivery include fetal decelerations and infant irritability, jitteriness, feeding difficulties, abnormal tone, hepatic toxicity, hypoglycemia, and reduction in neonatal fibrinogen levels. At birth, cord blood concentrations of VPA can reach twice the maternal levels.<sup>100,113,115</sup>

Meador and colleagues<sup>116</sup> evaluated the intelligence quotient (IQ) in 6-year-old children ( $n = 224$ ) who had been exposed to AEDs in utero, with adjustment for maternal IQ, AED drug type, standardized dose, gestational birth age, and use of periconceptional folate. **The offspring IQs were lower after exposure to VPA (mean 97; 95% CI, 94 to 101) than after carbamazepine (mean 105; 95% CI, 102 to 108;  $P = .00015$ ) or lamotrigine (mean 108; 95% CI, 105 to 110;  $P = .00003$ ).** A dose-response relationship was observed for VPA, but no other AED, with negative impact on offspring IQ, verbal and nonverbal ability, memory, and executive function. For all AED exposures, the mean IQs were higher in children whose mothers received folate (108; 95% CI, 106 to 111) than in the offspring of non-folate treated mothers (101; 95% CI, 98 to 104;  $P = .00009$ ). Because over half of pregnancies are unplanned and the impact on neural tube development occurs 17 to 30 days post-conception, women treated with maintenance VPA are exposed during this critical period, often *before* awareness of pregnancy. **These findings dictate against use of VPA as a first-line drug for childbearing-aged women.**<sup>117</sup>

### CARBAMAZEPINE AND OXCARBAZEPINE

Carbamazepine (CBZ) is prescribed at doses between 400 and 1600 mg daily to achieve a target range of 4 to 12 µg/mL. Drug-induced toxicity is usually detectable from clinical symptoms, and the serum level provides objective evidence. During pregnancy, the total AED levels drop, but the amount of unbound bioavailable drug remains constant. Serum concentrations are useful in the assessment of patients with exacerbation of mood symptoms, side effects, and questionable treatment adherence. Hepatitis, leukopenia, thrombocytopenia, rash, sedation, and

ataxia are CBZ side effects. Due to the additive effects on bone marrow suppression, combining CBZ and the antipsychotic clozapine is contraindicated.

The American Academy of Neurology (AAN) committee<sup>113</sup> found no increased risk of major malformations in the offspring of women who received CBZ for epilepsy. However, infants exposed to CBZ had twice the risk for being small for gestational age (SGA) and to have low Apgar scores (<7) at delivery. Exposed children did not have reduced cognitive function on measures of IQ and developmental milestones compared with children who were not exposed to AEDs.<sup>113</sup> Fetal serum levels of CBZ are 50% to 80% of maternal levels.<sup>118</sup> **Because adequate levels of vitamin K are necessary for normal midfacial growth and for the functioning of clotting factors, CBZ exposure in utero could increase the risk of neonatal bleeding.**<sup>100</sup> **Some experts recommend treatment with vitamin K 20 mg/day throughout pregnancy<sup>119</sup> and 1 mg intramuscularly to neonates.**

Oxcarbazepine has been used to treat mania in divided doses totaling 600 to 1200 mg/day. The parent compound is rapidly metabolized to an active hydroxy metabolite, which undergoes hepatic glucuronidation and renal excretion. Adverse effects are hyponatremia, hypersensitivity reactions, and decreased thyroxine levels (without altered triiodothyronine or thyroid-stimulating hormone [TSH]). Side effects include headaches, dizziness, gait disturbance, fatigue, and concentration changes. In 55 infants exposed in utero to oxcarbazepine (20 combination therapy, 35 monotherapy), one cardiac malformation was reported in an infant also exposed to phenobarbital.<sup>120</sup>

### LAMOTRIGINE

Lamotrigine (LTG) is indicated for bipolar depression maintenance therapy.<sup>121</sup> Typical doses range from 50 to 200 mg/day, but doses up to 500 mg/day have been used for long-term treatment of patients with BD. Side effects include headaches, rash, dizziness, diarrhea, abnormal dreams, and pruritus. Aseptic meningitis is a rare but serious potential complication of treatment with LTG. The rash associated with LTG is maculopapular or erythematous in appearance<sup>122</sup> and is associated with rapid dose escalation, combination with VPA, and treatment in adolescents.<sup>123</sup> A retrospective analysis from 12 studies<sup>122</sup> indicated that the rates of benign rash were 8.3% in LTG-treated and 6.4% in placebo-treated patients. In contrast, serious rash occurred in none of the LTG-treated and in only 0.1% of placebo-treated patients. One case of Stevens-Johnson syndrome occurred in an LTG-treated patient. Although this syndrome may be life threatening, the very low risk of serious rash must be weighed against the much more common risks associated with untreated BD.<sup>122</sup>

**Continuing LTG reduces the risk of recurrences in pregnant women with BD.** Thirty percent of women who continued, versus all who stopped LTG, relapsed during pregnancy (OR, 23.2; 95% CI, 1.5 to 366).<sup>124</sup> Patients who stopped treatment suffered relapses within 2 weeks. Because LTG clearance increases by 65% to 90% in the second and third trimesters compared with preconception, patients usually require higher doses during pregnancy. Guidelines for managing dosing across childbearing have been published.<sup>125</sup> The LTG serum concentration that was efficacious before pregnancy is the target level to be maintained by dose adjustment throughout pregnancy. The metabolism of LTG returns to the prepregnancy state rapidly after birth. To avoid maternal toxicity (dizziness, tremor, and diplopia), the dose should be reduced by 20% to 25% within 3 days of birth and across the first weeks postpartum based on serum concentrations.

The rate of congenital malformations is similar in infants exposed in utero to LTG compared with the general population, but the rate increases when LTG is combined with other AEDs.<sup>113</sup> The risk for orofacial cleft malformations is not increased in LTG-exposed offspring.<sup>126</sup>

### ATYPICAL ANTIPSYCHOTICS

Antipsychotic drugs, including the first-generation agents (“typical,” such as haloperidol) and the second-generation agents (“atypical,” such as olanzapine) are effective treatments for BD and also for schizophrenia (see the discussion of atypical antipsychotics in the section “[Treatment Interventions for Women With Schizophrenia](#)” later in this chapter). Indications include maintenance therapy to prevent recurrence, bipolar depression (quetiapine and combined olanzapine-fluoxetine), and treatment-resistant depression. The usual daily dose ranges are 5 to 20 mg for olanzapine; 1 to 6 mg for risperidone; 100 to 400 mg, maximum 800 mg, for quetiapine; 80 to 160 mg for ziprasidone; 20 to 80 mg for lurasidone; and 5 to 30 mg for aripiprazole. The initial treatment is started at a lower dose and is titrated against response and tolerance.

The atypical agents are associated with fewer extrapyramidal side effects (tardive dyskinesia, tremor, rigidity, internal restlessness, slowed movements, and dystonia) compared with the older typical antipsychotic agents. Side effects include somnolence, increased hepatic transaminases, and hyperprolactinemia.<sup>127</sup> **In pregnancy, the metabolic side effects of the psychotropic drugs, particularly the atypical agents, are a major concern.**<sup>128</sup> **Patients are at risk for weight gain, metabolic syndrome, elevated triglycerides, and glucose intolerance.**<sup>129</sup> Obesity is associated with complications that include gestational diabetes, preeclampsia, caesarean delivery, and large-for-gestational age (LGA) infants.<sup>130,131</sup>

The reproductive risks of atypical antipsychotics have received minimal research attention. Pregnant women who received either typical or atypical drugs had increased risks for PTB, LBW, and major malformations compared with the general population, but these complications may reflect the effects of the underlying psychiatric disorder. Genetic liability and gene-environment interactions contribute to these outcomes, and maternal risk factors, substance abuse, nutritional status, and the biologic and behavioral concomitants of severe mental illness are likely to be the major determinants of increases in reproductive pathology. Rates of malformations, mainly atrial and ventricular septal defects, are variable. Some reports suggest that only infants with exposure to the typical agents were affected,<sup>131</sup> whereas other data demonstrate an increased risk for malformations in women exposed to atypical antipsychotic drugs compared with controls (OR, 2.17; 95% CI, 1.20 to 3.91).<sup>132</sup>

**Rates of PTB are increased in patients treated with antipsychotics.** However, infants with fetal exposure to the typical drugs weighed less (3158 g  $\pm$  440) than the infants exposed to the atypical (3391 g  $\pm$  446) or non-antipsychotic drugs (3382 g  $\pm$  384).<sup>133</sup> Infants who were significantly LGA were born to mothers who received atypical (20%) compared with typical agents (2%) or non-antipsychotic drugs (3%).<sup>133</sup> In addition, postnatal complications occurred significantly more often in infants prenatally exposed to atypical (15.6%) and typical (21.6%) antipsychotics compared with 4.2% of non-drug exposed women. The frequency of stillbirth or neonatal deaths was not increased compared with the baseline population.

A national pregnancy registry for atypical antipsychotics has been established (<http://womensmentalhealth.org/posts/>

[pregnancy-registry](#)). As of December 2014, 303 women had completed the study and were eligible for inclusion in the analysis. Of 214 live births with first-trimester exposure to second-generation antipsychotics, three major malformations were confirmed. In the control group ( $n = 89$ ), one major malformation was confirmed. The absolute risk of major malformations was 1.4% for exposed infants and 1.1% for unexposed infants. The odds ratio for major malformations comparing exposed infants with unexposed infants was 1.25 (95% CI, 0.13 to 12.19), a nonsignificant difference but a small sample.

### ALTERNATE AND SUPPLEMENTAL TREATMENT OPTIONS

An inverse correlation between omega-3 fatty acid consumption and the prevalence of BD has been demonstrated.<sup>134</sup> An increased duration of remission in patients with BD who were randomized to fish oil versus placebo was reported.<sup>73</sup> Electroconvulsive therapy (ECT) is highly effective for the management of treatment-resistant depression, acute mania, and severe mixed episodes.<sup>100,135</sup> ECT involves delivering an electrical stimulus with a brief pulse device to induce a limited grand mal seizure blocked from peripheral expression by succinylcholine. During ECT, the patient receives short-acting anesthetic agents, which are not likely to cause adverse impact on the mother-infant pair.<sup>100,135</sup>

### Prevention of Bipolar Disorder Recurrence Postpartum

**The risk for recurrence of mania, depression, or mixed states postpartum is the highest at any point in a woman's life.** In women who discontinued lithium therapy,<sup>136</sup> the rates of recurrence in the postpartum period were almost three times that of the nonpregnant women over a similar time (70% vs. 24%). Moreover, among women who had previous postpartum psychosis, more than 40% experienced relapse after declining immediate postpartum lithium prophylaxis, and no woman who began medication immediately postpartum had a recurrence.<sup>96</sup> The postpartum pharmacotherapy plan includes selection of the drug(s) of past response<sup>100</sup> and educating partners to observe and report early symptoms to prevent episodes.

### Breastfeeding for Women with Bipolar Disorder

The mother's desire to breastfeed is an important consideration in the postpartum management (see [Chapter 24](#)). Successful lactation may be compromised by not breastfeeding through the night in the early postpartum period; however, sleep deprivation is a major factor in precipitating mania. If a partner or family member can provide support and feed the baby at night, sleep can be prioritized.

The American Academy of Pediatrics (AAP)<sup>137</sup> and the AAN<sup>138</sup> concluded that most medications used to treat BD produce breast milk concentrations less than 10% of the mother's weight-adjusted concentrations. A multicenter longitudinal observational study of monotherapy of AEDs examined the impact of breastfeeding on IQ at 3 years age for CBZ, LTG, and VPA.<sup>139</sup> Breastfed children did not differ from formula-fed children. However, the concentrations of LTG in breastfed infants averaged 30% to 35% of that of the mother. The risk for toxicity may be increased in breastfeeding infants of women who receive additional similarly metabolized agents such as lorazepam, aspirin, olanzapine, acetaminophen, and VPA.

Lithium treatment can be managed in breastfeeding women with education and close follow-up.<sup>137,140</sup> In a case series of 10 mother-infant pairs,<sup>140</sup> infant serum lithium concentrations

were 25% of maternal levels. In another study of three infants,<sup>141</sup> infant concentrations ranged from 10% to 17% of maternal levels. Caregivers should monitor the infant for signs of toxicity (poor feeding, lethargy, and hypotonia), especially in situations that increase the risk for dehydration (reduced feeding/oral intake, excessive fluid loss or fever).<sup>100</sup> To avoid spuriously high levels of lithium, infant blood samples must be collected in tubes that do not contain lithium heparin as the stabilizing agent.

## ANXIETY DISORDERS

### Diagnosis and Prevalence

Anxiety disorders include panic disorder, generalized anxiety disorder, obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), and agoraphobia and other phobias. Each of these disorders is distinct and is defined by specific diagnostic criteria according to DSM-V.<sup>1</sup> Many individuals have subclinical anxiety symptoms. **To meet criteria for the diagnosis of an anxiety disorder, the symptoms must cause impairment of functioning.** In women, the lifetime prevalence of anxiety disorders is 5%; panic disorder, 5%; generalized anxiety disorder, 3%; OCD, 6%; social phobia and other specific phobias, 13%; and 10% for and PTSD.<sup>142-144</sup> Multiple anxiety disorders are often present in an individual. Without treatment, anxiety disorders usually have a chronic course. **Although rates of OCD are similar in men and women, all other anxiety disorders are 1.5 to 2 times more common in women. In addition, women with anxiety disorders have an increased risk for development of comorbid MDE.**

**Panic attacks** are characterized by brief (5- to 15-minute) intense episodes of fear or discomfort that occur in many anxiety disorders and in healthy individuals exposed to acute stress. Symptoms include palpitations, sweating, shortness of breath, choking, nausea, abdominal discomfort, dizziness, unsteadiness, numbness or tingling, chills, hot flashes, or a fear of dying or losing control. Panic disorder is diagnosed when attacks are recurrent or associated with a fear of future attacks. The most disabling consequence of panic disorder is agoraphobia, which occurs in 30% to 40% of women with untreated panic disorder. Patients with agoraphobia restrict activities outside the home or insist on being accompanied by a trusted person due to fear of having a panic attack where help is unavailable.

**Generalized anxiety disorder** is characterized by excessive worrying about multiple problems. The issues of concern to persons with generalized anxiety disorder are realistic, but the level of worry is much more intense than appropriate. For example, a woman might worry for hours about whether a friend received a thank you note for a gift. Individuals with generalized anxiety disorder have symptoms associated with worry, such as muscle tension, fatigue, headache, nausea, diarrhea, or abdominal pain.

In contrast to generalized anxiety disorder, women with **obsessive-compulsive disorder** focus on more idiosyncratic and often unrealistic concerns. OCD is characterized by disturbing intrusive thoughts and performance of compulsions to temporarily relieve the distress generated by the intrusive thoughts. Obsessional thoughts usually focus on a few key themes: contamination, causing harm, offensive violent or sexual images, religious preoccupations, and urges for symmetry or ordering. Compulsions performed to relieve these intrusive worries include cleaning or washing, checking, repeating, ordering, hoarding, and mental rituals like counting and praying. During pregnancy

and postpartum, contamination concerns and intrusive violent thoughts are particularly common.<sup>145</sup> Differentiating obsessional thoughts and images from delusions and hallucinations can be challenging.<sup>146</sup> **New mothers with OCD may experience disturbing obsessions and mental images of harming their baby. They are highly distressed by these thoughts yet are not at increased risk of harming their infant.**

Exposure to trauma in which a woman experienced or witnessed an event that involved actual or threatened death or serious injury is required for a diagnosis of **posttraumatic stress disorder (PTSD)**. The traumatic event is persistently reexperienced in one or more of the following ways: (1) recurrent and intrusive distressing recollections, (2) recurrent distressing dreams, (3) acting or feeling as if the event were occurring in the present (flashbacks), (4) intense distress at cues that remind her of the event, (5) physiologic hyperarousal, and (6) exaggerated startle responses. Symptoms must persist for at least 1 month to meet diagnostic criteria for PTSD. Minimal study has been done about whether birth trauma can result in a new onset or recurrence of PTSD. Preliminary estimates suggest an incidence of 3% for delivery-related PTSD in community samples and as high as 15% in high-risk samples.<sup>147</sup>

**Separation anxiety** is another type of anxiety focused on potential harm coming to self or others that would disrupt a close relationship. Women with separation anxiety can experience mental distress, nightmares, and physical anxiety symptoms associated with separation or the threat of separation.

Finally, excessive fear of a discrete object or situation constitutes a **phobia**. *Social phobia* refers to disabling fears of speaking or eating in public and fears of humiliation in social interactions. Other common specific phobias are body injury phobia (medical procedures), acrophobia (heights), arachnophobia (spiders), and claustrophobia (enclosed spaces). Individuals with panic disorder often have fear of situations from which they could not escape if they had a panic attack (airplanes). These fears are a feature of panic disorder and agoraphobia and would not warrant a diagnosis of phobia.

### Fear of Labor and Delivery

Some women have intense fear of pregnancy and childbirth. About 5% to 10% of pregnant women have extreme fear of delivery, which may be considered a type of phobia. These women often request surgical deliveries to avoid labor. Risk factors for intense fear of delivery and requesting cesarean delivery include preexisting mental illness, history of abuse, poor social support, unemployment, and previous complicated delivery. Focused, short-term psychotherapy may enable these women to accept a vaginal delivery and improve the birth experience.<sup>148</sup>

### Natural History Across Childbearing

Pregnancy, delivery, and lactation produce profound changes in physiology, including changes in multiple hormonal and neurotransmitter systems that modulate anxiety symptoms. However, there has been relatively little study of the course of anxiety symptoms or anxiety disorders during pregnancy and postpartum. In one large prospective study, more women scored above threshold on an anxiety scale during weeks 18 and 32 of pregnancy compared with 8 weeks and 8 months postpartum, which suggests that **nonspecific anxiety symptoms worsen during pregnancy. Antenatal anxiety symptoms and anxiety disorders are associated with an increased risk of postpartum**

**depression, even after controlling for antenatal depression.**<sup>149</sup>

Anxiety disorders are common comorbidities to MDE in the postpartum period.<sup>86</sup> With respect to specific anxiety disorders, preliminary evidence suggests that panic disorder can improve during pregnancy but can recur postpartum. In addition, cessation of breastfeeding may precipitate relapse of panic disorder.<sup>150</sup> Pregnancy and childbirth can trigger the onset of or an exacerbation of preexisting OCD.<sup>145,151</sup> Obsessive-compulsive symptoms are very common in postpartum depression.<sup>152</sup> Intrusive violent thoughts and contamination concerns are quite common in new mothers without psychiatric disorders.<sup>153,154</sup> No information was found on the effects of pregnancy on the course of generalized anxiety disorder, phobias, or PTSD.

Beta-adrenergic agonists such as terbutaline may precipitate panic attacks and other anxiety symptoms during the treatment of premature labor. **Hyperthyroidism is associated with panic attacks, and it and should be considered in the differential diagnosis of postpartum-onset anxiety episodes.**

**Effects of Anxiety During Childbearing**

**Anxiety symptoms and anxiety disorders are associated with an increased risk of preeclampsia and reduced birth-weight.**<sup>155,156</sup> PTSD, an anxiety disorder associated with marked hyperarousal symptoms including severe insomnia has been associated with increased risk of PTB.<sup>157,158</sup> Less is known about other anxiety disorders and their relationship to delivery complications.<sup>159</sup> Psychosocial stress also has been linked to higher rates of PTB, and several physiologic pathways have been proposed to mediate the association, including autonomic arousal, elevated levels of cortisol and corticotropin-releasing hormone, and systemic inflammation.<sup>160</sup> Lack of sleep, a common symptom of anxiety disorders, can increase inflammatory load and is associated with PTB.<sup>161</sup>

**Prenatal anxiety also has been associated with adverse effects on offspring.** Fetuses of anxious women show increased heart rate reactivity to maternal stressors, and newborns of highly anxious mothers have reduced heart rate variability and poor autonomic regulation.<sup>162,163</sup> Poor autonomic regulation of heart rate has been linked to impaired emotional regulation in older children and adults. In utero and as newborns, the offspring of anxious women spend more time in deep sleep<sup>162,164</sup> and are more likely to cry excessively.<sup>165</sup>

Maternal anxiety during pregnancy is associated with attention deficits, motor immaturity, and difficult temperament in offspring. In two large prospective longitudinal studies, anxiety during pregnancy increased the risk for hyperactivity, conduct disorder, and anxiety in childhood after controlling for obstetric and sociodemographic risks and for maternal depression.<sup>166-168</sup> Research is needed to understand the contributions of genetic risk factors, parenting behaviors, and the altered uteroplacental milieu to developmental and psychiatric problems in the offspring of anxious mothers.

**Treatment of Anxiety Disorders**

The boundary between normal and pathologic anxiety cannot be drawn with great precision. **When anxiety substantially impairs work, family, or social adjustment, mental health evaluation is indicated, and treatment is appropriate. Panic disorder responds to most antidepressant medications, which are first-line therapies for this disorder.** Benzodiazepines are also effective but are associated with abuse and physical dependence in a subset of patients. Cognitive behavior therapy (CBT)

is a time-limited, structured psychotherapy that is also effective for panic disorder.

In contrast, OCD is effectively treated specifically with serotonergic antidepressants. A behavioral therapy technique, exposure and response prevention, is also effective for OCD. Generalized anxiety disorder responds to a variety of antidepressant medications and to cognitive therapy. PTSD is partially responsive to antidepressants, but psychotherapy or combination treatment is often more effective. The first-line medication treatment for social phobia includes SSRIs and CBT. Specific phobias are treated with focused desensitization therapy rather than medication. An excellent patient educational workbook on anxiety disorders is available (see the [resource list](#) at the end of this chapter).

A risk-benefit evaluation for treatments during pregnancy must be individualized for the pregnant woman with anxiety disorder because, like MDE, anxiety can have a negative impact on pregnancy outcome (see [Chapter 8](#)). If psychotherapy treatment is refused, not available, or ineffective, pharmacologic treatment should be considered. The use of antidepressants in pregnancy and lactation has been reviewed in the section on major depression. Evidence from the available studies indicates that the teratogenic risk from benzodiazepine exposure, if any, is very small.<sup>169</sup> However, less is known about the effect of benzodiazepines on neurodevelopment. At delivery, neonates exposed to higher doses can have withdrawal seizures or hypotonia.<sup>170</sup>

Benzodiazepines enter breast milk but the concentration in milk varies by drug, dose, and frequency of use. Because alternative treatments are available for anxiety disorders, benzodiazepines often can be avoided or used to treat targeted symptoms for limited periods during pregnancy and lactation. Intermittent use of short half-life benzodiazepines is preferred because chronic use of long-acting benzodiazepines can result in infant sedation, and mothers must be educated to observe for drowsiness and poor feeding. Also, little is known about the degree to which benzodiazepines are absorbed into the circulation of breastfed infants.

**EATING DISORDERS****Diagnosis and Prevalence**

The classifications of eating disorders have been substantially updated in the “Feeding and Eating Disorders” section of DSM-V.<sup>1</sup> Eating disorders are particularly relevant during pregnancy and lactation, when the increased requirement for food intake can be directly affected by disordered eating. This section will review anorexia nervosa (AN) and bulimia nervosa (BN).

**AN is characterized by the restriction of energy intake relative to requirements, which leads to low bodyweight, an intense fear of gaining weight or of becoming fat, or persistent behavior that interferes with weight gain.**<sup>1</sup> In addition, women with AN have a disturbance in the way in which their body weight or shape is experienced, they allow an undue influence to be placed on body shape or weight in self-evaluation, and a persistent lack of recognition of the seriousness of the current low body weight is evident. In AN, the body mass index (BMI) is usually less than 18.5 kg/m<sup>2</sup>. Although amenorrhea is no longer a required criterion, most women have secondary amenorrhea. The prevalence of AN in adolescents and young adult women is 0.4%. The longitudinal course of AN is variable and includes remission, residual partial symptomatology, or a

fluctuating or chronic course. However, the majority of individuals with AN experience remission within 5 years.<sup>1,172</sup> AN is associated with elevated mortality rates (5% per decade) due to both medical complications and increased suicide rates.<sup>1</sup>

*Bulimia nervosa* (BN) is defined as recurrent episodes of binge eating, a sense of lack of control over eating during the binge episode, and recurrent compensatory methods to prevent weight gain.<sup>1</sup> BN is common and occurs in 1% to 1.5% of young adult women. A *binge* is eating in a discrete period of time (e.g., within 2 hours) an amount of food that is larger than what most people would eat during a similar period of time. Inappropriate compensatory behaviors include self-induced vomiting; laxative, diuretic, or other medication (e.g., ipecac) abuse; fasting; and excessive exercise. The binge eating and compensatory behaviors must occur at least once a week for 3 months. Women with BN maintain body weight at or above a normal range. Self-evaluation that is unduly influenced by body shape and weight is also part of the disorder. The longitudinal course of BN can include remission, chronicity, intermittent recurrence, and prolonged disturbed eating behavior. BN has an elevated mortality risk (2% per decade).<sup>1</sup> In women who report lifetime binge eating, both amenorrhea and oligomenorrhea are more common than in women who do not report binge eating.<sup>173</sup> The ratio of women to men with both AN and BN is striking at 10:1. The etiology of eating disorders has contributions from multiple domains: the societal ideal of thinness and encouragement of women to define themselves by the way others perceive them; families that demand conformity and high achievement; genetic susceptibility (50% to 80% of the variance in liability to AN and BN is accounted for by genetic factors); personality traits that include low self-esteem, impulsivity, obsessionality, perfectionism, and emotional instability; and chronic disease, such as diabetes mellitus.<sup>174,175</sup> Dysregulation of neurotransmitters, neuropeptides, and endocrine factors also likely contribute to etiology. Dieting frequently triggers the onset of an eating disorder in vulnerable individuals.<sup>174</sup>

Women with eating disorders rarely voluntarily disclose their maladaptive eating behaviors, but they may present to their obstetrician-gynecologist with complaints of irregular menses, infertility, sexual dysfunction, unexplained vomiting, fatigue, or palpitations.<sup>174</sup> The obstetrician-gynecologist or primary care clinician can screen for eating disorders with questions about restricted eating, binge eating, purging behavior, and compulsive exercise. Medical examination should include obtaining the patient's weight and evaluation for loss of dental enamel and abrasions on the hands from self-induced vomiting.<sup>174</sup> AN or BN can also present with disruption or cessation of ovulation, and these disorders are included in the differential diagnosis of secondary amenorrhea. Laboratory investigations may disclose abnormalities of electrolytes, blood urea nitrogen, creatinine, amylase, and thyroid indices. The medical consequences of AN and BN are numerous, and the medical complications may be life threatening (Box 55-2). Cardiac rhythm disturbances are common in patients with AN and are usually reversible with improvement in nutritional status. Cardiomyopathy due to chronic ipecac (emetine) abuse in BN may not be reversible.<sup>176</sup> Osteopenia occurs in more than 90% of adult women with AN, and about 40% have osteoporosis at one or more sites.<sup>177</sup> The lumbar spine is most affected. Weight restoration and nutritional replenishment are the ideal treatments for improving bone density. Whereas estrogen supplementation may have a promising role, oral contraceptives have not demonstrated

## BOX 55-2 PHYSICAL AND LABORATORY FINDINGS IN WOMEN WITH EATING DISORDERS

### Common in Women With Eating Disorders

Bradycardia  
Hypotension and orthostasis  
Hypothermia  
Dry skin

### More Common in Anorexia Nervosa Due to Severe Calorie Restriction

Emaciated; may wear oversized clothes  
Sunken cheeks, sallow skin  
Lanugo (fine downy body hair)  
Atrophic breasts/atrophic vaginitis  
Pitting edema of extremities  
Dull, thinning scalp hair  
Cold extremities, acrocyanosis  
Osteopenia, increased risk of fracture  
Constipation  
Fluid retention after laxative or diuretic withdrawal  
Laboratory: Anemia, ↑ blood urea nitrogen, ↑ cholesterol, ↑ liver function studies, ↑ amylase; ↓ platelets, ↓ magnesium, ↓ zinc, ↓ phosphates, ↓ thyroid. With laxative abuse: metabolic acidosis

### More Common in Women Who Purge

Parotitis  
Calluses on dorsal hand surface from self-induced emesis  
Oral mucosal abrasions  
Dental enamel erosion, tooth chipping, extensive cosmetic dental work  
Cardiac and skeletal myopathies from ipecac abuse  
Laboratory: Metabolic alkalosis, ↓ sodium, ↓ chloride, ↓ potassium, ↑ bicarbonate from purging

Data from American Psychiatric Association, *Diagnostic and Statistical Manual*, 5th Edition. Arlington, VA: American Psychiatric Association, 2013; Hay P, et al. Royal Australian and New Zealand College of Psychiatrists clinical practice guidelines for the treatment of eating disorders. *Aust N Z J Psychiatry*. 2014;48(11):977-1008; and Hsu LK. Eating disorders: practical interventions. *J Am Med Womens Assoc*. 2004;59(2): 113-124.

consistent benefit.<sup>177</sup> Similarly, data to support bisphosphonate use in AN are conflicting, and the potential teratogenic effects compounded by its long half-life preclude its use for osteoporosis in premenopausal women with AN.<sup>178,179</sup>

## Natural History Across Childbearing

**Due to anovulation, fertility is often diminished in women with AN or BN due to a reduction in the secretion of gonadotropin-releasing hormone and, in turn, a reduction in both luteinizing hormone and follicle-stimulating hormone.** However, if pregnancy is achieved, it can be a stimulus that moves a woman through the continuum from subthreshold symptoms to overt eating disorder.<sup>175</sup> Changing body shape and loss of control of weight gain may reactivate deviant eating patterns and concerns about body shape in women with a history of an eating disorder. Persistence of active eating disorder symptoms and the development of binge eating during pregnancy have been reported. However, several studies have suggested that many pregnant women with BN decrease binge eating and purging. Some women with active eating disorders allow themselves to eat nutritiously and do not purge, with motivation

derived from promoting the health of the growing baby.<sup>175</sup> **The optimal treatment of pregnant women with a prior or active eating disorder includes a multidisciplinary team of the obstetrician-gynecologist, nutritionist, and mental health clinician.**<sup>175</sup> Frequent prenatal visits, regular weighing, and enhanced support encourage recommended weight gain and nutrition to ensure fetal well-being. Binge eating during pregnancy may be associated with higher gestational weight gain. BN during pregnancy has been associated with elevated rates of nausea and vomiting, but the risk of hyperemesis gravidarum with BN may not be increased.<sup>180</sup>

A recent systematic review reported that children of mothers with AN have an increased risk of LBW.<sup>181</sup> Inadequate weight gain in pregnancy, elevated risk of miscarriage, IUGR, infants born SGA, microcephaly, PTB, antepartum hemorrhage, and cesarean delivery have also been reported. Some of these adverse pregnancy outcomes may be mitigated in women who gain appropriate weight during pregnancy.<sup>182-184</sup> Eating disorders and food restriction were associated with an increased risk of neural tube defects likely due to decreased folic acid levels.<sup>185</sup> Weight-controlling behaviors that can lead to nutritional deficiencies—including strict dieting, vomiting, and excessive physical exercise—may impact fetal brain development and fetal stress responses.<sup>186</sup> Negative birth outcomes in women with BN have included elevated rates of miscarriage, PTB, and cesarean delivery.<sup>187</sup> Both LBW and macrosomia have been reported in women with BN.

**The postpartum period is a time of risk for the onset of MDE and poor maternal adjustment.**<sup>174,175</sup> **Women with a history of BN have a threefold increased risk of postpartum MDE compared with women without eating disorders.**<sup>188</sup> Increased stress with a new infant, feelings of lack of control, and a desire to lose pregnancy weight may precipitate recurrence of AN or BN even if the symptoms were under control during pregnancy. The postpartum period is another critical time for a woman with an eating disorder to receive enhanced support and treatment from a multidisciplinary team. Children of mothers with active eating disorders show slower growth in the first year of life<sup>189</sup> and increased psychopathology in childhood and early adolescence.<sup>190</sup>

## Treatment of Eating Disorders

**Specific treatment goals for patients with eating disorders include establishing healthy eating behaviors; stabilizing nutritional intake and weight; correcting dysfunctional thoughts about weight; and addressing perfectionism, low self-esteem, the pursuit of thinness, mood lability, interpersonal difficulties, and poor coping skills through psychotherapy.** Addressing comorbidities such as depression, anxiety, and medical problems are also part of the treatment plan.

### Anorexia Nervosa

Women with AN may require hospitalization because of emaciation, severe electrolyte disturbances, depression, suicidality, or failure of outpatient treatment.<sup>191</sup> A structured behavioral inpatient program involves individual and group psychotherapy, meal planning and supervision, nutrition consultation, psychiatric consultation, and medical monitoring.<sup>172,191</sup> Caloric intake that increases too rapidly may lead to *refeeding syndrome*, a serious condition characterized by electrolyte and mineral abnormalities and fluid shifts. Length of inpatient hospitalization and weight achieved at discharge are prognostic predictors,

although 50% of weight-restored women with AN have a relapse in the first year after hospitalization.<sup>192</sup>

Psychotherapies for AN include family therapy, CBT, insight-oriented psychotherapy, supportive clinical management, and interpersonal psychotherapy. No medications are approved by the FDA for the treatment of AN, nor are any recommended by treatment guidelines. Comorbid depression and anxiety often improve with weight gain. Psychotropic medications are usually instituted to treat depression and anxiety or when psychotherapy alone has not been effective. The core symptoms of AN are relatively refractory to psychotropic agents. Studies have included typical antipsychotics, atypical antipsychotics, tricyclics, and SSRIs.<sup>193</sup> Meta-analyses of antipsychotic medications have not demonstrated superiority over placebo for weight gain, decreased anxiety, or improvement in eating disorder cognitions.<sup>194,195</sup>

Relapse prevention is a challenging problem in treating AN, and longitudinal studies demonstrate that AN is a chronic disorder.<sup>172</sup> CBT is helpful in weight-restored women in preventing a relapse of AN. A controlled study showed that fluoxetine was not superior to placebo in weight-restored women also receiving CBT.<sup>192</sup>

### Bulimia Nervosa

**CBT is the first-line treatment for BN, and both short-term and long-term efficacy has been demonstrated.** In CBT, the therapist identifies the stimuli to thought processes and emotions that maintain the binge-purge-starve cycle. The woman develops strategies to manage the disturbed eating, changes the dysfunctional cognitions, and builds alternative ways to manage distress. CBT is a time-limited individual or group psychotherapy. When CBT is not available, self-help manuals and web-based programs utilizing the principles of CBT can be encouraged (see the [resource list](#) at the end of this chapter).

Placebo-controlled RCTs with SSRIs, TCAs, and monoamine oxidase inhibitors (MAOIs) have been promising for the reduction of binge eating and purging, although a minority of patients achieve full remission.<sup>195,196</sup> Fluoxetine is FDA approved for BN titrated to a dose of 60 mg/day. Bupropion is contraindicated due to reduced seizure threshold in patients with eating disorders. Many studies of antidepressants also demonstrate reduction of core eating disorder psychopathology such as weight and food preoccupation. The reduction of binge eating and purging frequency with antidepressants is independent of comorbid depression. Adding an antidepressant to CBT is a prudent clinical strategy when depression is comorbid.<sup>172,196</sup> Symptomatic improvement and sustained remission may be maximized with combined CBT and antidepressant medication.

Reduction in binge eating and purging has also been reported with ondansetron and topiramate.<sup>193</sup> Ondansetron is a 5-HT<sub>3</sub> antagonist that reduced symptoms compared with placebo, possibly due to regulation of vagal activity. Topiramate has been reported to reduce the number of binge-purge days and to improve self-esteem, eating attitudes, anxiety, and body image. However, topiramate is not recommended as first-line therapy in reproductive-aged women due to increased risk of oral clefts in offspring with first-trimester use.

## SCHIZOPHRENIA

### Diagnosis and Prevalence

**Schizophrenia is a disabling brain disease that affects 1% of the population. The defining feature of schizophrenia is**

**psychosis, which refers to specific clinical symptoms not to the severity of the episode.** Schizophrenia is characterized by delusions (fixed false beliefs), hallucinations, disorganized speech, grossly disorganized behavior or catatonia (displays of bizarre posturing, rigidity, mutism, negativism, purposeless excitement, echolalia), and negative symptoms (lack of emotional expression, apathy) that result in significant social or occupational dysfunction. To have schizophrenia, an individual must exhibit at least two of the specified symptoms, which must have been present for 6 months, and include at least 1 month of active symptoms. The etiology of schizophrenia is unknown, but proposed mechanisms include (1) excessive dopamine transmission; (2) in utero exposure to influenza or other viral agents, which resulted in neurobiologic disruptions<sup>198</sup>; and (3) altered neuroplasticity or neurodevelopmental trajectories.<sup>199</sup> Schizophrenia is distinguished from mood disorders, which may also present with psychosis, by the persistence of hallucinations or delusions when mood symptoms have remitted. The mortality and morbidity of schizophrenia is high, and 10% of patients complete suicide. **Women are more likely to have a later onset, prominent mood symptoms, and a better prognosis than men. The median age of onset is in the late second decade for women. Women have less severe symptoms, fewer hospitalizations, a higher likelihood to return to work, and more social support than men.**<sup>200</sup> **About 67% of women with schizophrenia, compared with 29% of men, are married, and women are twice as likely to have children.**<sup>200</sup>

### Natural History Across Childbearing

Women with schizophrenia have lower fertility rates compared with healthy women despite low rates of contraceptive use; irreversible causes of infertility—such as hysterectomy, early menopause, and sterilization—are higher among schizophrenic women.<sup>201</sup> Concurrent maternal smoking, substance use, and socioeconomic problems increase the risk for poor pregnancy outcomes. In a population-based cohort study of over 3000 births from 1980 to 1992,<sup>107</sup> **mentally ill women were at increased risk for obstetric complications that included placental abruption (OR, 2.75; 95% CI, 1.32 to 5.74) and antepartum hemorrhage (OR, 1.65; 95% CI, 1.02 to 2.69) compared with women who did not have psychiatric disorders.** In the first year after delivery, mothers with schizophrenia had high rates of recurrent episodes of psychosis (27%) and depression (38%).<sup>202</sup> Children born to women with schizophrenia are susceptible to subtle neurodevelopmental problems, but the origins (genetic, environment, psychosocial) are complex. Data on the mothers' nutritional status, exposure to psychotropic medications, other prescription or over-the-counter drugs that impact reproductive outcomes, violence, and medical comorbidities are usually lacking from studies.<sup>107</sup>

### Extrapolating From Studies on the General Population

Because no specific data for the treatment course in pregnant women with schizophrenia are available, information from the general literature will be reviewed. Stopping antipsychotic treatment results in high relapse rates: 53% of patients who discontinued treatment, compared with 16% who continued treatment for at least 10 months, relapsed during follow-up.<sup>203</sup> Sudden treatment cessation, younger age, early age of illness onset, need for high doses of antipsychotic medication, and recent admission also predicted recurrence. **Because of the high relapse risk without treatment, patients with schizophrenia often**

**continue antipsychotic therapy during pregnancy. The preferred drug is the antipsychotic, which provided the greatest symptom reduction and the least side effects for the individual.**<sup>204</sup> If a woman elects to remain monitored without medication, a plan should be developed for reinstituting medication rapidly if prodromal symptoms occur. Services that offer **integrated obstetric and psychiatric management**, pharmacotherapy, parent education groups, and family programs are optimal for promoting positive outcomes.<sup>205</sup>

### Treatment Interventions for Women With Schizophrenia

In a large double-blind controlled trial of 1500 patients with schizophrenia, clinical outcomes were similar among groups of patients who received one of four atypical antipsychotics—olanzapine, quetiapine, risperidone, or ziprasidone—or the older antipsychotic perphenazine.<sup>206</sup> The typical antipsychotic perphenazine was as well tolerated as the newer compounds and as effective as three of the four newer agents. Although patients taking olanzapine had lower rates of drug discontinuation and hospitalization, the benefits were offset by higher rates of weight gain and metabolic side effects. Although the study excluded pregnant women, the results have implications for their treatment. The risk-benefit decision may favor the use of typical agents during pregnancy, particularly for women with insulin resistance, obesity, and hypertension. **Control of the psychotic disorder, which usually requires medication continuation, is critical for maternal and fetal health.**<sup>204</sup>

### Antipsychotic Drugs During Pregnancy

Clozapine was the first atypical agent to be released; however, burdensome side effects—such as weight gain, tachycardia, dyslipidemia, sedation, and drooling—and mandatory periodic monitoring for agranulocytosis create significant barriers to use (see the earlier section on the use of these drugs to treat bipolar disorder in women of childbearing age). Clozapine is reserved for patients whose illness is nonresponsive to treatment with less toxic drugs. Clozapine use in pregnancy has been associated with normal deliveries as well as with gestational diabetes, shoulder dystocia, hypotonia, and neonatal convulsions.<sup>207</sup>

The most available reproductive data among the atypical drugs is for **olanzapine**. Brunner and colleagues<sup>208</sup> reported the outcomes from 610 prospectively identified pregnancies tracked worldwide in Eli Lilly and Company's safety database of voluntary reports. Most women reported olanzapine exposure throughout pregnancy (44.3%) or in the first trimester only (31.5%). The rates of adverse outcomes—such as early pregnancy loss, congenital anomalies, PTB, and stillbirth—did not differ in olanzapine-exposed, compared with nonexposed, women. Olanzapine dosages ranged from 0.6 to 35.0 mg/day, with a mean dosage of 10.3 mg/day.

**Risperidone** is an atypical agent with diverse receptor-blocking activities. At dosages above 6 mg daily, hyperprolactinemia and motor side effects may emerge. In a postmarketing study of 68 prospectively reported pregnancies with a known outcome, structural malformations occurred in 3.8%, which was consistent with background rates in the general population.<sup>209</sup> Neonatal adaptation difficulties included tremor, jitteriness, irritability, feeding problems, and somnolence.

**Quetiapine** is an atypical antipsychotic with a wide dose range, with maintenance dosages from 400 to 800 mg/day after initial titration. Side effects include sedation, weight gain, and

headache. The few published cases of in utero exposure to quetiapine resulted in normal intrauterine growth, full-term deliveries, and favorable Apgar scores.<sup>204</sup> Yaeger and colleagues<sup>210</sup> presented a sophisticated case discussion of quetiapine treatment of a pregnant woman that provides a clinical review.

**Ziprasidone** is a suitable choice for managing psychosis, with its neutral effects on weight and lipid and glucose metabolism<sup>211</sup>; however, its use may be associated with prolonged QTc syndrome. Limited information on perinatal exposures with ziprasidone is available. Of 57 cases of known outcomes from gestational exposure, one malformation<sup>212</sup> was observed.

**Aripiprazole** has novel dopamine antagonist and partial agonist activity. It is indicated for schizophrenia, bipolar mania, mixed episodes, and severe MDE combined with an antidepressant. A recent report from a multicenter cohort study that used prospectively collected data from 2004 to 2011 suggested that exposure to aripiprazole was not associated with increased rates of birth defects, miscarriages, or gestational diabetes compared with nonexposure.<sup>213</sup> However, women treated with aripiprazole may experience declines in the serum concentration of aripiprazole from enhanced hepatic metabolism in pregnancy and could require higher doses.<sup>214</sup> Recent evidence of increased rates of prematurity (11 of 86 [16%] vs. 11 of 172 [7%]) and fetal growth impairment (12 of 86 [19%] vs. 11 of 172 [7%]) in exposed newborns compared with nonexposed newborns could signify concern.<sup>213</sup> However, the findings were difficult to interpret because the majority of women in the exposed group (65%) had received aripiprazole for a brief duration in the first trimester only. In addition, the women receiving aripiprazole also reported high rates of cigarette smoking, a proven risk factor for preterm birth and fetal growth problems.

The longitudinal development of 76 infants exposed throughout pregnancy to atypical antipsychotics was compared with 76 women without mental illness or antipsychotic exposure.<sup>215</sup> At 3 months, the mean scores of cognitive, motor, social-emotional, and adaptive behavior as assessed by the Bayley Scales of Infant Development were significantly lower in exposed infants. However, no significant differences between the two groups were noted at 12 months of age for any of the mean composite scores of the Bayley scales. More infants exposed to atypical antipsychotics had lower birthweight than the controls (13.2% vs. 2.6%,  $P = .031$ ), although no significant differences were reported in mean weight and height at birth between the two groups. In a separate prospective controlled study from 1999 to 2008, investigators examined the outcomes from intrauterine exposure to psychotropic drugs in mother-infant dyads.<sup>215a</sup> Findings suggested 6-month-old infants exposed to antipsychotics ( $n = 22$ ) had significantly lower neuromotor performance on the standardized Infant Neurological International Battery examination compared with infants exposed to antidepressants ( $n = 202$ ) or no psychotropic agents ( $n = 85$ ). Because impaired neuromotor functioning also was associated with maternal disorders, including major depressive disorder or a psychotic disorder, it is still not possible to disentangle the medication effects from the effects of maternal illness.

**Optimal maternal and infant outcomes are achieved through individualized treatment planning by a mental health team in collaboration with community programs. The antipsychotic agent associated with the greatest symptom reduction, balanced against its side effects, is the preferred drug for the individual pregnant woman.**<sup>204</sup> An additional consideration in risk-benefit discussions is whether that

preferred drug could be replaced by one with a more favorable reproductive risk profile *without* compromising efficacy and tolerability, but no antipsychotic has emerged as definitively more efficacious or having less adverse reproductive effects than any other.<sup>204</sup> Several factors impact the choice of a medication change, including patient and physician concern about the lack of data for the preferred drug—particularly for newer agents—and prior treatment experience with a drug that has less impact on a medical condition that existed before or developed during pregnancy. A factor in every risk-benefit decision is the fact that pregnancy outcome data for drug exposure is inextricably tied to outcomes related to the underlying illness for which the drug is being prescribed.<sup>204</sup>

### Antipsychotic Drugs During Breastfeeding

The high concentration of clozapine in breast milk has been attributed to its lipophilicity.<sup>216</sup> The excretion of olanzapine, a highly protein-bound agent, in breast milk has been assessed in small case series. The median estimated dose in infants was 1.6% to 4.0% of the maternal dose.<sup>217</sup> In a woman who took olanzapine (10 mg) daily through childbearing, maternal plasma levels were 33.4 ng/mL at delivery; the infant level was about a third of the maternal level.<sup>218</sup> The breastfed infant's levels were below 2 ng/mL at 2 and 6 weeks. Breastfed infants of mothers taking olanzapine can display somnolence, irritability, tremor, and insomnia.<sup>208</sup>

Three breastfed infants of mothers who were treated with risperidone had nondetectable serum drug metabolite levels and no evidence of adverse reactions.<sup>219</sup> A mother who was treated with risperidone (6 mg/day) provided serial samples of plasma and breast milk every 4 hours over a 24-hour period. The infant drug intake was estimated to be 0.84% of the maternal dose for risperidone, 3.5% for its metabolite, and 4.3% of the weight-adjusted maternal dose.<sup>220</sup>

Six breastfeeding women who received treatment with quetiapine<sup>221</sup> provided breast milk for assay. The total daily infant exposure was less than 0.01 mg/kg/day for five infants and less than 0.10 mg/kg/day for one infant. The estimated dose of ziprasidone received by the breastfed infants was 1.2% of the maternal dose.<sup>222</sup> A woman treated with aripiprazole throughout pregnancy breastfed her full-term infant; at 27 days, no detectable levels of drug or metabolite were found in milk samples.<sup>223</sup>

## SUBSTANCE-RELATED DISORDERS

### Diagnosis and Prevalence

Children exposed to drugs in utero are more likely to experience a range of physical and neurodevelopmental problems.<sup>224</sup> In an American national survey,<sup>225</sup> 5.4% of pregnant women reported illicit drug use in the month prior, and *Cannabis* was the most frequently used substance. Rates were higher in the first (9.0%) and second (4.8%) trimesters than in the third trimester (2.4%). All rates were lower than those found for nonpregnant women from the same age cohort (11.4%). These data demonstrate that many substance-using women discontinue use when they become pregnant. For women with ongoing substance use disorder (SUD), addiction treatment is the most effective method for improving maternal and infant/child outcomes.<sup>226</sup> Because addiction often occurs in the context of psychiatric and/or medical comorbidities, poverty, poor nutrition, and violence, comprehensive

**BOX 55-3    DSM-V CRITERIA FOR SUBSTANCE USE DISORDER**

- 1. The substance is often taken in larger amounts or over a longer period than was intended.
- 2. The desire to cut down or control substance use is persistent, but efforts to do so are unsuccessful.
- 3. A great deal of time is spent in activities necessary to obtain the substance, use the substance, or recover from its effects.
- 4. A craving, urge, or a strong desire to use the substance is evident.
- 5. Recurrent substance use results in a failure to fulfill major role obligations at work, school, or home.
- 6. Substance use is continued despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects.
- 7. Important social, occupational, or recreational activities are given up or reduced because of substance use.
- 8. Substance use is recurrent in situations in which it is physically hazardous.
- 9. Substance use is continued despite knowledge of having a persistent or recurrent physical or psychologic problem that is likely to have been caused or exacerbated by the substance.
- 10. Tolerance is evident, in either the need for markedly increased amounts of the substance to achieve the desired effect or a markedly diminished effect with continued use of the same amount of the substance.
- 11. Withdrawal occurs, with either characteristic withdrawal syndrome for the substance or with the substance, or a closely related one, being taken to relieve or avoid withdrawal symptoms.

From American Psychiatric Association (APA). *The Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition. APA; 2013. Severity ratings range from *mild* (2 to 3 criteria) to *moderate* (4 to 5 criteria) to *severe* (6 to 11 criteria).

**treatment programs that specialize in the care of pregnant and parenting women play an integral role in improving birth outcomes and increasing the likelihood of recovery from addiction.** Criminalization and incarceration of women for prenatal substance use often has deleterious effects and can compromise both maternal and fetal health.<sup>227</sup>

SUDs are diagnosed using the DSM-V,<sup>1</sup> which integrates the two previous categories of substance abuse and dependence from DSM-IV into SUD (Box 55-3). Each class of drugs is evaluated separately and receives its own severity rating based on the number of criteria met for that substance.

**Screening, Brief Intervention, and Referral to Treatment**

To invest in the health of their baby, pregnant women with SUD are more likely to participate in health care during pregnancy than at other times in their lives.<sup>228</sup> The standard obstetric history includes questions about alcohol, tobacco, and other drug use, and obstetricians can educate women that casual drug use increases risks for adverse maternal and infant outcomes.<sup>229</sup>

**Screening, brief intervention, and referral to treatment is an efficient, evidence-based approach to improve perinatal outcomes<sup>230</sup> that is endorsed by ACOG.<sup>226</sup>** Brief interventions range from practitioner advice to reduce or stop drug use to psychoeducational counseling. The practitioner can facilitate access to treatment, and level of care (outpatient, residential) is

**TABLE 55-2    SCREENING WITH THE FOUR P’S PLUS**

|           |  |
|-----------|--|
| Parents   | Did either of your parents ever have a problem with alcohol or drugs?  |
| Partner   | Does your partner have a problem with alcohol or drugs?  |

| Pregnancy | In the month before you knew you were pregnant, how many cigarettes did you smoke?<br>In the month before you knew you were pregnant, how much beer/wine/liquor did you drink? |

From Chasnoff IJ, Hung WC. *The 4P’s Plus*. Chicago: NTI Publishing; 1999.

determined by severity of addiction and other presenting medical and psychosocial needs.<sup>226</sup>

Screening for substance use and dependence is an integral component of health assessment during obstetric care.<sup>228</sup> Reliable and valid screening tools are useful to identify alcohol, tobacco, and other drug use in pregnant women.<sup>226</sup> For alcohol, the T-ACE mnemonic—which stands for *tolerance-annoyance, cutdown, eye opener*<sup>231</sup>—is a brief, psychometrically sound screening approach to detect drinking in pregnant women (see Chapter 8, Table 8-2). Women with T-ACE scores of 2 and above (range 0 to 5) require follow-up assessment.

Social pressure has increasingly contributed to underreporting of smoking by pregnant women, and multiple-choice questions are recommended to improve disclosure.<sup>232</sup> For drug use, the Drug Abuse Screening Test (DAST-10)<sup>233</sup> focuses on drug use consequences in the prior year. Alternatively, the 4Ps Plus (Table 55-2) was developed specifically to identify pregnant women at risk for prenatal use of alcohol, tobacco, and other drugs. The five-question screen takes less than 1 minute to complete: the first *P* (*Parents*) asks about substance use in family members, the second (*Partner*) asks about partner substance use, and the third (*Past*) asks about *prepregnancy* use of alcohol; questions 4 and 5 (*Pregnancy*) focus on the month prior to pregnancy awareness—one asks about cigarette smoking, the other about alcohol consumption. Targeting the month prior to pregnancy is important because women often use substances at prepregnancy levels until the pregnancy is confirmed, and they stop after early first-trimester exposure has already occurred.

Pregnant women are often reluctant to disclose information about their drug use due to stigma, concern about being judged, or legal consequences. **The practitioner’s emotional tone is critical because pregnant women are more likely to divulge substance use when asked by a nonjudgmental care provider.**<sup>228</sup> Alternative to self-report assessments are biologic measures that screen for drug exposure. They include urine, meconium, and hair<sup>234</sup>; however, all have practical limitations.

**Specific Drugs of Abuse: Impact and Treatment Approaches**

**Alcohol**

Nearly 1 in 10 pregnant women (9.4%) report alcohol consumption in the past month, 2.3% meet criteria for binge drinking (consuming five or more standard drinks on the same occasion), and 0.4% meet criteria for heavy drinking (binge drinking on each of five or more days in the past month).<sup>225</sup> These rates are lower than those found in nonpregnant women, half of whom report recent alcohol use. Nearly one fourth (24.6%) report recent binge drinking, and 5.3% meet criteria for heavy drinking.

**Fetal exposure to alcohol is the most common preventable cause of mental retardation.**<sup>227</sup> It also increases the risks

for miscarriage, stillbirth, and prematurity. Alcohol is a potent teratogen, and the most severe manifestation of in utero exposure is **fetal alcohol syndrome (FAS)** (see Chapter 8). This diagnosis requires maternal alcohol consumption, facial malformations, prenatal or postnatal growth deficits, and lifelong neurodevelopmental disabilities.<sup>235</sup> Affected children have visual, skeletal, and cardiac anomalies. **Recent studies estimate the prevalence of fetal alcohol syndrome to be between 0.2 and 7 per 1000 children<sup>236</sup> with an estimated cost of over \$4 billion annually.<sup>237</sup>** More broadly, prenatal alcohol consumption can produce a wide range of birth defects and developmental disabilities, known as *fetal alcohol spectrum disorders* (FASDs). With U.S. prevalence between 2% and 5%,<sup>236</sup> FASDs include a broad array of physical defects of the ocular, skeletal, cardiac, and other systems as well as cognitive, behavioral, and adaptive functioning deficits.<sup>238</sup>

Although the negative consequences of heavy drinking during pregnancy—one drink or more per day—are well-known and include FAS and FASD,<sup>239</sup> a meta-analysis also found adverse effects for mild to moderate (one to six drinks per week) and binge drinking (greater than four or five drinks per occasion). Binge drinking during pregnancy was associated with childhood cognitive problems, and moderate drinking was associated with childhood behavior problems.<sup>240</sup> **A question women often ask is whether it is safe to have an occasional glass of wine or a mixed drink while pregnant. No amount, gestational time, or type of alcohol use is safe during pregnancy.<sup>235</sup>** If alcohol use in pregnancy is identified, an early ultrasound to establish accurate gestational age dating is recommended. A detailed anatomic survey should be performed, and close monitoring for fetal growth restriction is also warranted.<sup>241</sup>

Research on alcohol intake and breastfeeding is limited. Approximately half of lactating women in Western countries report alcohol use.<sup>242</sup> Alcohol levels in breast milk are similar to maternal blood concentrations; therefore **the AAP recommends abstinence from alcohol during breastfeeding.** If a breastfeeding woman chooses to drink, a practical approach is to counsel her to limit intake to one drink and to wait 2 to 2.5 hours before breastfeeding to allow clearance of the alcoholic beverage from her plasma.<sup>243,244</sup>

### MANAGEMENT OF ALCOHOL WITHDRAWAL

Alcohol withdrawal can lead to fetal distress, placental abruption, and preterm delivery.<sup>245</sup> In pregnant women, withdrawal typically begins 6 to 24 hours following cessation of alcohol intake. Early withdrawal signs include anxiety, sleep disturbance, vivid dreams, anorexia, nausea, and headache. Physical signs include tachycardia, elevated blood pressure, hyperactive reflexes, diaphoresis, hyperthermia, and tremor in the hands or tongue. **The peak time for withdrawal seizures is 24 hours after the last drink and they are preceded by hyperactive reflexes. Alcohol withdrawal may progress to delirium tremens, which can be fatal to both mother and fetus.<sup>246</sup>**

**Medical withdrawal in an inpatient setting is required.** Benzodiazepines are common detoxification agents. In a critical review,<sup>247</sup> chlorthalidopoxide and diazepam were considered the agents of choice for benzodiazepine treatment during pregnancy. These drugs have differing onset and duration of action and are available in an intravenous formulation. A typical fixed-dose taper starts with chlorthalidopoxide (50 mg orally every 6 hours) or lorazepam (2 mg every 6 hours) with dose adjustment until symptoms are controlled. The dose is then tapered by 10% to

25% per day as tolerated. During inpatient care, folic acid and prenatal vitamins should be given daily. Acute management also requires thiamine replacement and maintenance of adequate hydration and electrolyte balance. **Fetal well-being should be monitored.<sup>246</sup>** A patient can be discharged to outpatient treatment when benzodiazepine treatment is no longer required to control symptoms for over 24 hours.<sup>246</sup>

Treatment schedules for medical withdrawal may be fixed dose or symptom based, with severity of withdrawal measured by the revised Clinical Institute Withdrawal Assessment of Alcohol Scale.<sup>248</sup> The withdrawal assessment takes only 2 to 5 minutes to administer and is available online. Symptom-guided withdrawal generally results in more rapid detoxification and lower total doses of benzodiazepine treatment but requires trained staff for implementation. This is particularly relevant for pregnant alcohol-dependent women, in whom lower benzodiazepine doses may suffice due to changes in maternal alcohol metabolism rates.<sup>245,249</sup>

**Like alcohol, withdrawal from benzodiazepines is associated with significant morbidity and potential mortality if untreated.** Women treated with benzodiazepine drugs that have a short half-life, such as alprazolam, are likely to develop withdrawal more rapidly than with agents with longer half-lives. Acute inpatient withdrawal is often accomplished by a fixed-dose drug taper with substitution of a long-acting benzodiazepine with dosing as needed to treat breakthrough symptoms. Once the patient has achieved a comfortable level of symptom control, the dose is tapered by 10% daily as tolerated. Disulfiram is contraindicated in pregnancy because of the association with birth defects.<sup>250</sup>

### Smoking

**National survey data<sup>225</sup> showed that 15.4% of pregnant women reported smoking cigarettes.** Whereas the overall rate of smoking for women in this age group has declined over the past 10 years, rates of prenatal smoking have remained unchanged.<sup>251</sup> Adverse maternal outcomes of prenatal cigarette smoking include thromboembolic disease and respiratory complications. Adverse infant outcomes include spontaneous pregnancy loss, PTB, restricted fetal growth, placenta previa, placental abruption, and premature rupture of membranes.<sup>252</sup> **In the United States, between 23% and 34% of sudden infant death syndrome (SIDS) deaths are attributable to prenatal smoking.<sup>253</sup>** Infants exposed to secondhand smoke are also more likely to have respiratory tract and ear infections and SIDS. An estimated \$122 million in health care costs for postpartum infant hospitalization can be ascribed to maternal smoking,<sup>254</sup> and smoking during pregnancy was associated with sleep problems in offspring through age 12.<sup>255</sup>

Women who quit smoking by the first trimester have infants with growth parameters comparable to those born to non-smokers.<sup>256</sup> **The Five A's—Ask, Advise, Assess, Assist, and Arrange—is an ACOG-endorsed, evidence-based behavioral intervention often provided as part of prenatal care.<sup>232</sup>** Trained providers spend 5 to 15 minutes at each prenatal visit counseling women who want to quit smoking. To facilitate implementation, computer-delivered Five A's-based brief interventions have been developed.<sup>257</sup> Smoking “quitlines” (1-800-QUIT-NOW) are effective in assisting pregnant women to stop smoking.<sup>258</sup> Other evidence-based psychosocial strategies to promote prenatal smoking cessation include behavioral incentives, social support, and tailored self-help materials.<sup>226</sup>

Use of nicotine replacement therapy (NRT) in pregnancy remains controversial.<sup>259,260</sup> Nicotine patch use in the second and third trimesters was not associated with maternal or fetal compromise as assessed by using fetal heart rate patterns, amniotic fluid volume, umbilical blood flow, and birthweight.<sup>261</sup> However, a recent RCT of nicotine versus placebo patch in pregnant smokers found no group differences in abstinence rates.<sup>262</sup> Nevertheless, **ACOG supports the use of NRT when nonpharmacologic therapies have proven ineffective.**<sup>263</sup> The antidepressant bupropion is efficacious for smoking cessation, but little research documents use in pregnant women. However, no increase in risk was found for congenital malformations in bupropion-treated pregnant women.<sup>264</sup>

**Women who quit smoking in pregnancy tend to relapse within 1 year postpartum.**<sup>265</sup> Motivation to breastfeed is an opportunity to support continued cessation or reduction of smoking beyond that achieved during pregnancy. Although the AAP recommends that mothers quit smoking and not smoke around their infants, smoking is not contraindicated during breastfeeding.<sup>137</sup> Nicotine replacement therapy with a patch can also be used with breastfeeding. The 21-mg patch transfers about as much nicotine into breast milk as smoking one pack of cigarettes per day, and the 14 and 7 mg patches transfer even less.<sup>266</sup> To decrease exposure, women can be encouraged to remove the patch at night.

### **Cannabis**

*Cannabis* is the most commonly used illicit drug in pregnancy, with prevalence rates that range from 2.5% to 5%,<sup>225,267</sup> and women often continue to use throughout their pregnancies.<sup>268</sup> Fewer studies of the impact of *Cannabis* during pregnancy have been conducted than for alcohol, tobacco, cocaine, and opiates. In many reports, prenatal *Cannabis* use is considered a confounding variable when looking at teratogenic effects of other drugs.<sup>269</sup>

Maternal risks of *Cannabis* smoking include carcinogenesis (such as oral cancers) and pulmonary disease. **Although in utero *Cannabis* exposure does not increase the risk for spontaneous abortion or congenital abnormalities,**<sup>270,271</sup> **it has been associated with IUGR.** *Cannabis*-exposed infants have smaller head circumferences at birth than nonexposed infants, and this difference becomes accentuated in adolescence.<sup>272</sup> Neonatal effects of prenatal *Cannabis* use include exaggerated and prolonged startle reflexes, transient high-pitched cry, and sleep disturbances.<sup>273</sup> In longitudinal studies, in utero *Cannabis* exposure had negative effects on academic achievement,<sup>274</sup> intellectual development,<sup>275</sup> response inhibition,<sup>276</sup> and delinquency.<sup>277</sup> *Cannabis*-exposed children were also more likely to smoke both cigarettes and *Cannabis* than non-*Cannabis* exposed children.<sup>278</sup>

*Cannabis* and its metabolites pass into breast milk, and concentrations in milk can be substantively higher than those in maternal plasma.<sup>267</sup> There is also some evidence that continued use during lactation can impair first-year neurodevelopment in the infant,<sup>279</sup> and its use by breastfeeding mothers is of concern and is thus contraindicated.<sup>280</sup> As more states legalize medical *Cannabis*, prenatal use for treatment of neurogenic pain or pregnancy-associated hyperemesis will become more common.<sup>281</sup> **No safe threshold limits for *Cannabis* use have been determined, and prenatal use can have long-term negative effects.**<sup>267</sup> Little is known about prenatal exposure to medicinal *Cannabis*.

Data to direct counseling about *Cannabis* use during breastfeeding are limited. **For women who use *Cannabis* daily, the**

**AAP discourages breastfeeding.**<sup>280</sup> Daily use results in high levels of *Cannabis* and its metabolites in breast milk and is associated with neurodevelopmental impairment in the first year of life.<sup>267,279</sup> Women who report infrequent *Cannabis* use should refrain from use during breastfeeding.

### **Cocaine**

Cocaine is a stimulant that can be inhaled, injected, or smoked. It crosses the placenta and the fetal blood-brain barrier. In the mid-1980s, prenatal use of cocaine received considerable media attention. Early studies reported catastrophic effects of prenatal cocaine exposure, and children born to cocaine-abusing mothers were often stigmatized at school and in the community.<sup>282,283</sup> Subsequent studies either failed to replicate previous reports<sup>284</sup> or found that effects were due to co-occurring factors and environmental stressors that form the context in which cocaine addiction often occurs.

Women who use cocaine while pregnant are at increased risk for adrenergic crises that include coronary artery vasospasms and severe hypertension. Notably,  $\beta$ -blockade of these complications is contraindicated because it can lead to unopposed  $\alpha$ -adrenergic stimulation. **Fetal consequences of maternal cocaine use include PTB, premature rupture of membranes, placental abruption, and preeclampsia.**<sup>285,286</sup> **Prenatal cocaine exposure is also associated with IUGR,**<sup>287</sup> **LBW, and SGA.**<sup>288</sup> The relationship between prenatal cocaine exposure and congenital defects is strongly affected by factors associated with cocaine use.<sup>288</sup> In a large prospective blinded study of congenital anomalies in children exposed to cocaine prenatally, no consistent increase or pattern of birth defects was found.<sup>289</sup>

Pregnant cocaine users should be encouraged to stop and be referred for substance-abuse treatment. Acute cocaine intoxication and withdrawal can be treated with supportive measures. Effective psychosocial and behavioral treatments have been developed for pregnant drug-dependent women.<sup>226,290</sup> Communication between prenatal/postpartum care providers and substance-abuse treatment staff is central to the success of such efforts. **The AAP considers cocaine use a contraindication to breastfeeding.**<sup>291</sup>

### **Methamphetamine**

Methamphetamine is a stimulant that results in increased alertness along with hypertension, confusion, decreased appetite, and weight loss.<sup>292</sup> Prenatal methamphetamine use can produce vasoconstriction and restriction of nutrients and oxygen to the fetus.<sup>293</sup> About 5% of American pregnant women have used methamphetamine.<sup>294</sup> Research on methamphetamine-exposed pregnancies remains limited. Gorman and colleagues<sup>295</sup> found that **methamphetamine users were more likely than nonusers to experience gestational hypertension (OR, 1.8; CI, 1.6 to 2.0), preeclampsia (OR, 2.7; CI, 2.4 to 3.0), intrauterine fetal death (OR, 5.1; CI, 3.7 to 7.2), and abruption (OR, 5.5; CI, 4.9 to 6.3). They were also more likely to have PTB (OR, 2.9; 2.7 to 3.1), neonatal death (OR, 3.1; CI, 2.3 to 4.2), and infant death (OR, 2.5; CI, 1.7 to 3.7). Children with in utero exposure to methamphetamine displayed greater cognitive problems at age 7.5 years than controls.**<sup>296</sup>

As with other drugs of abuse, prenatal methamphetamine use occurs amid a variety of adverse comorbidities such as psychiatric disorders, other drug use, poor nutrition, lack of health care, and stressful life experiences.<sup>297</sup> Comprehensive harm-reduction models of perinatal care contribute to improved birth outcomes.

For acute methamphetamine intoxication, benzodiazepines and antipsychotic medications calm the agitated, combative, or psychotic patient. No medication is effective for treatment of methamphetamine withdrawal. **The AAP<sup>291</sup> lists amphetamines as contraindicated during breastfeeding.**

### Opioids

In the United States, prescription opioid use and misuse has increased dramatically. In a national survey, 4.5 million Americans reported past-month nonmedical use of prescription narcotics, and 1.9 million were diagnosed with opioid use disorder.<sup>255</sup> This escalation is also occurring in pregnant women. In the past decade, prescription opioid use in pregnancy has risen more than fourfold—from 1.2 to 5.6 cases per 1000 live births. Cases of neonatal abstinence syndrome (NAS) also more than doubled during this period, rising from 1.2 to 3.4 per 1000 hospital live births.<sup>298</sup> In a study of pregnant women entering drug abuse treatment over a 20-year time span, the percentage of opioid-dependent women who reported prescription narcotics as their drug of choice rose from 2% to 28%.<sup>299</sup>

**Opioid-dependent pregnant women who use illicit drugs have a sixfold increase in complications such as PTB, IUGR, fetal distress, meconium aspiration, and LBW.<sup>300,301</sup> Neonatal problems include NAS, neurobehavioral problems, and mortality with a 74-fold increase in risk for SIDS.<sup>300</sup>**

### OPIOID AGONIST THERAPY

In a public policy statement, the American Society of Addiction Medicine recommended that pregnant opioid-dependent women be encouraged to initiate opioid agonist therapy (OAT) and continue it through delivery and postpartum. Women who were already receiving OAT prior to becoming pregnant should continue because discontinuation increases the risk for relapse, and detoxification can precipitate fetal distress and comes with higher morbidity and mortality rates. If detoxification is initiated, it should be under medical supervision during the second trimester of pregnancy, when complications are less likely to occur.<sup>227</sup>

**Since the 1970s, methadone has been the preferred treatment for opioid-dependent pregnant women (Box 55-4).** Methadone is a long acting  $\mu$ -opioid receptor agonist that provides a steady concentration of opioid in the pregnant woman's bloodstream. Methadone reduces drug craving and prevents negative fetal effects associated with repeated in utero withdrawal from heroin. Methadone maintenance also promotes better adherence to prenatal care and drug abuse counseling because visits can be scheduled to coincide with once-daily methadone dosing. However, **methadone has direct effects on fetal neurobehavioral functions.** The fetuses of women on methadone with uncomplicated pregnancies were evaluated at peak and trough methadone levels.<sup>302</sup> At peak methadone levels, the fetal heart rate was slower, less variable, and displayed fewer accelerations. Fetuses displayed less motor activity, and the integration between heart rate and motor activity was attenuated. Real-time ultrasound recordings at 34 to 37 weeks' gestation were obtained from methadone-treated and untreated women. Both a slower rate and fewer fetal breathing movements were observed for the methadone-treated group regardless of time since the mothers' daily dose.<sup>302</sup>

More recently, **buprenorphine** has been studied as an alternative to methadone. As a partial  $\mu$ -opioid receptor agonist and  $\kappa$ -receptor antagonist with a half-life of 24 to 60 hours, buprenorphine is effective in the treatment of opioid

### BOX 55-4 INITIATION OF METHADONE MAINTENANCE TREATMENT IN PREGNANCY

- A medical and substance abuse history should be taken.
- Physical examination is used to evaluate stigmata of intravenous opioid use (needle scars, phlebitis, and skin abscesses).
- Laboratory tests: urine drug testing is used to document opioid and other drug use. Serum infection screening and baseline liver function can be used if hepatitis C infection is known.
- Quantify withdrawal symptoms with a standardized assessment such as the Clinical Opioid Withdrawal Scale (COWS)<sup>320</sup> available online at [http://www.csam-asam.org/pdf/misc/COWS\\_induction\\_flow\\_sheet.doc](http://www.csam-asam.org/pdf/misc/COWS_induction_flow_sheet.doc).
- Initial dose of methadone is 10 to 30 mg with additional dosing of 5 to 10 mg every 4 to 6 hours while patient is awake for breakthrough withdrawal symptoms.
- Titrate dose up to relieve withdrawal symptoms for 24 hours with minimal or no craving.
- Methadone has been associated with rate-corrected QTc prolongation and possible consequent cardiac arrhythmia; review personal and family history for risk factors and consider screening electrocardiogram and follow-up evaluation in collaboration with an outpatient methadone clinic.
- When stable, discharge the patient to a methadone clinic to monitor subsequent dosing.
- Evaluate for methadone drug-drug interactions (tricyclic antidepressants, antipsychotic medications, and certain antiemetics and antibiotics are also associated with prolonged QT interval).
- As pregnancy progresses, the same methadone dosage produces lower blood methadone levels, so higher dosing may be required to control symptoms.
- After birth, monitor for signs of overmedication and adjust dosing as needed.

dependence. Research with buprenorphine in pregnant women is limited, but it appears to have similar effectiveness to methadone in the treatment of opioid use disorders in pregnancy. Neither methadone nor buprenorphine treatment are associated with increased risk of birth defects. Whereas induction might be easier with methadone than with buprenorphine, a randomized trial of the two **demonstrated a significant reduction in NAS severity for buprenorphine-exposed neonates.**<sup>303</sup> A meta-analysis showed equivalent maternal outcomes for methadone and buprenorphine but improved outcomes for infants.<sup>304,305</sup> If buprenorphine is used in pregnancy, it should be prescribed without naloxone.

### PRENATAL CARE

Obstetricians who provide care to pregnant women with opioid use disorder should emphasize several points. First, **maternal and infant outcomes for women who receive OAT during pregnancy are better than those associated with continued prenatal use of illicit opioids.** Both methadone and buprenorphine decrease opioid and other drug abuse, criminal activity, and rates of infection with hepatitis B and C, human immunodeficiency virus (HIV), and sexually transmitted diseases. OAT is associated with lower relapse rates, reduced fetal exposure to illicit drug use, improved adherence to obstetric care, and enhanced neonatal outcomes.<sup>306</sup> Second, **for the majority of pregnant women who receive OAT, standard prenatal care is**

**adequate.** Providing treatment in an environment where the woman feels safe and supported improves compliance.<sup>307</sup> More intensive care should be reserved for cases where there is a medical indication for closer monitoring. Third, practitioners should inform women that **the AAP<sup>289</sup> supports breastfeeding for women receiving OAT regardless of dose.** On average, infants receive 2% to 3% of the weight-adjusted maternal methadone dose via breast milk. For mothers treated with OAT, breastfeeding is associated with lower infant treatment rates for NAS and shorter hospital stays.<sup>308-310</sup>

Methadone is metabolized by CYP2B6, CYP2C19, and CYP3A4. Clearance in pregnant women is increased, which results in increased dose requirements across pregnancy, and split dosing may be beneficial.<sup>311</sup> Some women are concerned about increasing their dose and potential harm to the baby. Obstetricians can explain that the higher doses are needed to offset increased clearance related to the physical changes of pregnancy. For mothers compliant with OAT, routine antenatal fetal surveillance is not required.<sup>312</sup> However, if relapse or polysubstance use is suspected, fetal surveillance should be considered in the third trimester.

### NEONATAL ABSTINENCE SYNDROME

**Whereas 30% to 80% of infants exposed to opioids in utero require treatment for neonatal abstinence syndrome,<sup>313</sup> at this time we cannot predict which infants will require treatment.** There is increasing evidence that genetic variability in the opioid receptor may play a role in who develops NAS.<sup>314</sup> NAS is characterized by irritability, tremulousness, sweating, nasal stuffiness, poor suckling, diarrhea, vomiting, and seizures.<sup>315</sup> The incidence of NAS is higher with methadone exposure than with shorter-acting opioids. NAS onset varies across different opioid drugs and can begin as early as 24 hours and as late as 14 days after delivery. Neither the incidence nor severity of NAS correlates with maternal methadone dose at delivery, and NAS can occur in infants born to mothers whose dose is as low as 10 mg per day<sup>316</sup>; therefore **limiting methadone dose to minimize risk of NAS is not warranted.**

### ACUTE PAIN MANAGEMENT FOR WOMEN ON OPIOID AGONIST THERAPY

Treatment of acute pain in labor and after delivery is a challenge for women on OAT. After verification of the daily dose, **uninterrupted full-dose maintenance treatment is imperative.** Acute pain should be managed based on clinical evaluation because women who are opioid dependent are likely to need higher doses of narcotics for pain because of tolerance and hyperalgesia.<sup>317</sup> Labor epidural and combined spinal-epidural analgesia are effective,<sup>318</sup> and studies suggest starting analgesia early in labor. Multimodal analgesia—nonsteroidal antiinflammatory drugs (NSAIDs), acetaminophen, and adjuvant drugs that enhance opioid effects, such as TCAs—may be coadministered. For women who require opioids for pain control, dose requirements may be 30% to 100% higher than routine dosing.<sup>319,320</sup> Analgesic dosing should be continuous or scheduled rather than as needed. Mixed agonist and antagonist opioid analgesics—such as pentazocine, nalbuphine, and butorphanol—should be avoided because they may displace the maintenance opioid from receptors and can precipitate acute opioid withdrawal. If methadone or buprenorphine doses were increased antenatally, careful monitoring and consideration of a gradual postpartum dose reduction over 1 to 2 weeks should be considered.<sup>311</sup>

### KEY POINTS

- ◆ Mental health is fundamental to health. To the extent that maternal biopsychosocial exposures with negative impact on pregnancy outcomes can be diminished, eliminated, or replaced with positive factors, the risk of poor pregnancy outcome can be reduced.
- ◆ Major depression is a treatable illness that is the leading cause of disease burden among girls and women worldwide. The period prevalence of depression is 12.7% during pregnancy, and 7.5% of women have a new (incident) episode.
- ◆ A brief and efficient 10-item self-report screening instrument, the Edinburgh Postnatal Depression Scale, is available to screen for perinatal depression. For clinical practice screening, the cutoff scores for probable major depression in postpartum women is 13 or more; for pregnant women, it is 15 or more.
- ◆ Women with postpartum depression should be evaluated for bipolar disorder—which is characterized not only by depression but also by episodes of hypomania, mania, or mixed states—before prescribing antidepressant treatment, because antidepressants without a mood stabilizer can result in symptomatic worsening.
- ◆ The first-line antidepressant choice for a pregnant or breastfeeding woman is the drug with established efficacy and tolerability. Specific congenital malformations in offspring exposed to antidepressant drugs (if any) are rare and the absolute risks are small.
- ◆ Abrupt discontinuation of any psychotropic medication creates a higher risk for recurrence than does gradual tapering and discontinuation (over at least 2 weeks).
- ◆ Postpartum psychosis is characterized by (1) rapid onset of hectic mood fluctuation, (2) marked cognitive impairment suggestive of delirium, (3) bizarre behavior, (4) insomnia, and (5) visual and auditory, and often unusual (tactile and olfactory), hallucinations. Women with acute-onset postpartum psychosis usually have bipolar disorder.
- ◆ The first-line treatment for anorexia nervosa is normalization of eating and weight restoration. Cognitive behavioral therapy is the first-line treatment for bulimia nervosa. Antidepressant medications are the second line treatment for bulimia nervosa, and they can also be useful adjuncts to CBT.
- ◆ Antipsychotic drug maintenance treatment and psychosocial support interventions aimed at maximizing function are the mainstays of treatment for schizophrenia.
- ◆ Concurrent maternal smoking, substance use, poor nutrition, and socioeconomic problems increase the risk for less optimal pregnancy outcomes.
- ◆ The perception of substance use disorders as afflictions solely of poor, minority, and young women is erroneous. Screening measures are available and easy to use, and multidisciplinary treatment intervention results in improved reproductive outcomes.

*Health care quality* has been defined by the Institute of Medicine (IOM) as, “the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge.”<sup>1</sup> Under the IOM framework, safety is part of the larger concept of health care quality.<sup>1</sup> In this chapter, we will describe ways to enhance patient safety and to attempt to measure and achieve quality care in obstetrics.

## PATIENT SAFETY

### Overview

Patient safety has become an increasing focus of the attention of the medical community. Although the reasons for the increased focus are doubtlessly multifactorial, one important contributor has been the recognition of the number of preventable adverse events that occur. The relatively high number of medical errors has been documented in the Institute of Medicine (IOM) report *To Err is Human*. That report, published in 1998, noted that between 44,000 and 98,000 people die in hospitals each year as the result of medical errors.<sup>2</sup> This report, correspondingly, noted the importance of error reduction as a means to improved health care and patient outcomes.

Because obstetric admissions are the leading cause of hospitalization for women in the United States, accounting for over 4 million hospital discharges each year,<sup>3</sup> pregnant women are at particular risk of encountering a medical error. Emphasizing the importance of obstetric safety further is the fact that each obstetric admission has the potential to affect the health not only of a single patient but of both a mother and her infant.

## FREQUENCY OF PREVENTABLE OBSTETRIC ADVERSE EVENTS

Many studies that have sought to determine the frequency of preventable obstetric adverse events have used retrospective designs and studied in detail cases in which adverse outcomes have occurred. The overall frequency of preventable adverse events on a given obstetric unit cannot be determined from these studies. This is particularly true given that adverse events, such as administration of a medication to which the patient is stated to be allergic, may occur that do not result in an actual adverse outcome (e.g., anaphylactic shock). However, these studies do give insight into the frequency with which that adverse outcome may have been preventable when such an outcome occurs.

Geller and colleagues<sup>4</sup> analyzed cases of morbidity and mortality that occurred at their institution. These cases included those with severe and “near-miss” morbidity. It should be emphasized that so-called near-miss morbidity is not so named because a woman nearly misses having morbidity but because she nearly misses a mortal event.<sup>5</sup> Thus in their framework, maternal morbidity has a spectrum of severity, and none is more severe than near-miss morbidity. In their study, morbid and mortal events were often found to be preventable, and a *preventable event* was defined as one that could have been avoided by any action or inaction on the part of the health care provider (e.g., mismanagement of patients, failure or delay in diagnosis), the system (e.g., failure in communication), or the patient (e.g., noncompliance). Moreover, women who had the most adverse

outcomes were more likely to have had preventable events: 16% of cases with severe morbidity were judged preventable versus 46% of near-miss events and 41% of mortal events.

Berg and colleagues<sup>6</sup> focused exclusively on maternal deaths that occurred in North Carolina. They studied the circumstances that surrounded the pregnancy-related deaths of 108 women between 1995 and 1999. Deaths were considered potentially preventable if (1) preconception care and counseling could have improved outcome; (2) the patient had not adhered to medical advice; (3) the structure and functioning of the health care system was suboptimal; or (4) clinical care was not satisfactory. In their study, 40% of deaths were considered to be preventable, although this frequency significantly differed on the basis of the primary underlying cause of death. For example, 93% of deaths related to hemorrhage, but only 22% of deaths related to cardiomyopathy, were thought to be preventable.

White and associates<sup>7</sup> examined 90 cases that resulted in litigation and in which the claims had been closed. It should be noted that these cases included both gynecology and obstetrics cases, although the majority were related to obstetrics. In their study, 78% of these cases were thought to have a contributing factor that was potentially avoidable. Clark and colleagues<sup>8</sup> also analyzed claims data and focused only on those claims related to perinatal care. Their findings were quite similar to those of White and associates; specifically, they noted that 70% of cases were potentially preventable and related to the care the patient received in the hospital.

Forster and coworkers<sup>9</sup> did attempt to quantify the frequency of adverse events that occur on an obstetric unit through the use of a prospective study. These investigators placed an observer in the labor and delivery unit during the weekday hours of a 6-week period. This observer was trained to ascertain poor patient outcomes, procedural errors, and unsafe working conditions. Cases of concern that were ascertained by the observer were then further evaluated by a multidisciplinary team. The primary outcome of the study was the occurrence of a “quality problem,” defined as the occurrence of either an adverse event—that is, an adverse outcome due to health care management, as opposed to progression of natural disease—or a potential adverse event (i.e., “defective processes that have a high likelihood of causing harm”). Of the over 400 patients who were cared for during the study period, 5% experienced a quality problem (i.e., 2% had an adverse event and 3% had a potential adverse event). Sixty-six percent of the adverse events that occurred were judged to be due to errors in health care delivery.

## FACTORS THAT CONTRIBUTE TO PREVENTABLE ADVERSE EVENTS

The literature that exists would suggest that multiple contributors are involved in the occurrence of adverse obstetric events. Data from the Joint Commission, for example, illustrate the contributions that multiple factors make in the occurrence of major adverse maternal and perinatal outcomes. For example, their analysis of major maternal adverse events revealed multiple root causes that included lack of adequate communication, training, staffing, and patient assessment.<sup>10</sup> Other investigators similarly have found that preventable adverse events or potential events cannot be traced to one simple and easily remediable cause but are multifactorial and due to a complex interplay of factors. Geller, White, Forster and their colleagues<sup>5,7,9</sup> all have demonstrated the many different factors present at both the

provider and systems level and that have contributed to adverse events.

Despite the many factors that have been implicated in the occurrence of preventable adverse events, it is worth noting that communication and “systems” issues that transcend simple individual error have consistently been found to be predominant etiologies in the occurrence of these events.<sup>5,7,9-11</sup> *Systems issues* is a term that refers to problems that stem not from one individual's actions but from the interconnected relationships of people and institutional policies. With regard to the sentinel events in maternal care analyzed by the Joint Commission, a communications issue was judged to be a root cause in over 80% of cases.<sup>10</sup> This frequency far outstripped the next most frequent factors, competency and patient assessment, which were present in fewer than 40% of cases. In their review of closed claims, White and associates<sup>7</sup> noted that inadequate communication among providers was the single most common preventable factor associated with the claim. Similarly, in their prospective study, Forster and colleagues<sup>9</sup> noted that “systems” issues were the most common reason that their trained observer was alerted to further assess for the possibility of a quality problem.

## APPROACHES TO IMPROVE OBSTETRIC SAFETY

The previous discussion highlighting the different factors that contribute to patient safety suggests that efforts to improve safety may require multiple different approaches. The potential need for a multifaceted approach is further suggested by the different levels within an organization at which these factors can manifest. Specifically, key components required for the prevention of adverse events occur at (1) the individual level, such as the level of education or training provided to workers; (2) the group level, as with team effectiveness and communication; and (3) the structural level, like the standardization of processes within an organization.<sup>11</sup> Correspondingly, attempts to enhance patient safety within obstetrics have utilized, in general, several different types of modalities. The theoretic underpinning to believe that these modalities should be effective—as well as the evidence supporting their use, with a focus on obstetrics—is discussed below.

### Checklists and Protocols

Because of the complexity of health care processes and the corresponding potential for errors in communication, one approach to improve patient safety has been the introduction of standardized approaches to patient care. These approaches have taken the form of *protocols*, mandatory items for completion to lead the user to a predetermined outcome, and *checklists*, a list of action items or criteria arranged in a systematic manner that allow the user to record the presence or absence of the individual items listed to ensure that all are considered or completed. Although both are concerned with standardization, checklists provide explicit lists of items, actions thought to act as a cognitive aid due to grouping related items in an organized fashion to improve recall performance.<sup>12</sup>

Pronovost and colleagues<sup>13</sup> demonstrated the potential utility of checklists in their study regarding catheter-related bloodstream infections in the intensive care unit (ICU). In this study, checklists that detailed five key actions required during any central catheter placement were introduced in 108 ICUs

throughout the state of Michigan. Of note, these key actions were evidence based; also, the checklists were not merely posted, they were supported by local leaders versed in the supporting evidence, who provided feedback with regard to optimal methods for implementation. Not only did the incidence of catheter-related bloodstream infections significantly decline by 3 months after implementation (incidence rate ratio, 0.62; 95% confidence interval [CI], 0.47 to 0.81), but this incidence continued to decline until 18 months (incidence rate ratio, 0.34; 95% CI, 0.23 to 0.50) after implementation, which was the end point of data collection.

A checklist to guide the administration of oxytocin was developed by Clark and associates,<sup>14</sup> who then implemented this checklist in a private hospital setting. The outcomes of the 100 women prior to checklist implementation were then compared with those of the 100 women who received oxytocin after the implementation. No difference was seen in the duration of labor, duration of oxytocin administration, or operative delivery after implementation, although the maximum dose of oxytocin used was significantly lower, as was the frequency of newborns with one or more complications ( $P = .049$ ).

The potential benefits of a standardized approach to the evaluation and management of preeclampsia has been demonstrated by Menzies and colleagues.<sup>15</sup> After establishing a set of best practices, this group of investigators introduced these practices for preeclampsia management at British Columbia Women's Hospital. Among women with preeclampsia who were managed after the standardized approach was put into place, 0.7% experienced the composite end point of maternal adverse outcomes, which was an 86% reduction compared with the preintervention frequency of 5.1% ( $P < .001$ ). Adverse perinatal outcomes were also reduced, although this finding did not reach statistical significance (odds [OR], 0.65; 95% CI, 0.37 to 1.16).

Nevertheless, a word of caution regarding checklists and protocols is warranted: The mere existence of one of these on a unit cannot be assumed to automatically result in improved care. As demonstrated by Pronovost and associates,<sup>13</sup> the presence of a checklist may enhance care when its components are evidence based and when its use is championed by members of the organization. Moreover, it is ideal to demonstrate—using either traditional scientific or quality improvement study designs—that its introduction is associated with improvement in the care provided or outcomes achieved.<sup>16</sup> Conversely, checklists or protocols can be present but still not translate into any tangible change in health care whatsoever. One set of investigators, for example, observed that the introduction of surgical safety checklists in Ontario, Canada, was not associated with improvements in operative complications or mortality.<sup>17</sup> Bailit and coworkers<sup>18</sup> have demonstrated a similar finding in obstetric care. In their analysis, obstetric units had similar outcomes related to postpartum hemorrhage or shoulder dystocia regardless of whether they had protocols for these events.

## Simulation

*Simulation* refers to the recreation of an actual event that has previously occurred or could potentially occur.<sup>19</sup> **Simulation may be used to enhance patient safety in that an action or procedure can be repeated, thereby improving the execution of that action or procedure without ever exposing providers or patients to harm.** Essentially, simulation of events is an opportunity for health care workers to prepare and train for interventions. Although simulation may have benefits for any

type of obstetric procedure (e.g., vaginal delivery), it has often been studied in events such as shoulder dystocia and eclampsia. In these occurrences, simulation may be particularly helpful not only for the novice but even for experienced professionals, who can maintain their skills in managing unpredictable and uncommon events.

## Shoulder Dystocia

**Data from multiple studies suggest that simulation may enhance several aspects of shoulder dystocia management, which includes communication among the team members, performance of the maneuvers necessary to relieve this problem, and documentation of the event.** Moreover, these enhancements have been demonstrated for providers during both their residency training and postresidency experiences.

In a randomized trial, Deering and colleagues<sup>20</sup> demonstrated that those residents who were assigned to train for a shoulder dystocia using an obstetric birth simulator were significantly more likely to utilize maneuvers in a timely and correct fashion in a subsequent simulation than those residents who did not undergo initial simulation training. Furthermore, when judged by a blinded observer, those residents who had undergone simulation training scored higher on measures of overall performance and preparedness.

A study that examined presimulation and postsimulation training outcomes among both residents and attending physicians was performed by Goffman and coworkers.<sup>21</sup> In this study, participants underwent a simulation of a shoulder dystocia event followed by a debriefing that included (1) a brief lecture about shoulder dystocia, (2) a review of the basic maneuvers and a basic algorithm for management of shoulder dystocia, (3) a discussion on optimizing team performance during an obstetric emergency, (4) a review of the key components of documentation, and (5) a review of the digital recording of the simulations and discussion of provider performance. During a second, unanticipated shoulder dystocia simulation, providers demonstrated significant improvements in communication, use of maneuvers, and overall performance.

Similar results were obtained by Crofts and colleagues<sup>22</sup> in their multicenter comparison of presimulation and postsimulation outcomes. This study additionally attempted to ascertain whether high-fidelity simulation using a mannequin with a high degree of biofidelity would enhance performance to a greater extent than low-fidelity simulation using a simple doll-like mannequin by randomizing participants to one of these options. Regardless of randomized group, performance during a simulated shoulder dystocia was improved subsequent to simulation training. Although some measures of performance (e.g., total applied force) were improved to a greater extent in those participants who had undergone high-fidelity training, many other measures (e.g., peak force, use of maneuvers) were no different between the high- and low-fidelity groups. Improvement in performance of simulated shoulder dystocia events has been demonstrated to persist up to 12 months after training.<sup>23</sup>

The previous studies have examined outcomes during simulation events but have not demonstrated improvements in actual clinical outcomes related to simulation training. The few observational studies of clinical outcomes that do exist, however, seem to support the assertion that exposure to simulation may improve outcomes related to shoulder dystocia. In one study at a single institution, investigators examined outcomes both before and

after initiation of a shoulder dystocia training program that utilized training in and practice of obstetric maneuvers.<sup>24</sup> After the training program, a significant increase was reported in the frequency with which appropriate maneuvers were used for shoulder dystocia, and a significant reduction was reported in neonatal injury at birth after shoulder dystocia (9.3% to 2.3%; relative risk [RR], 0.25; 95% CI, 0.11 to 0.57). Grobman and associates<sup>25</sup> also used simulation to help train providers to respond to a shoulder dystocia. They did not simulate specific maneuvers but instead emphasized the coordinated response and communication of the team once a shoulder dystocia was diagnosed. After simulation was used in this way, the frequency of brachial plexus palsy at discharge among neonates who had experienced a shoulder dystocia dropped from 7.6% to 1.3% ( $P = .04$ ).

### Eclampsia

**Studies that have evaluated simulation training for eclamptic seizure management have demonstrated improvements in response as measured during additional simulations.** For example, after having staff in a single tertiary care center participate in simulated eclamptic events with a debriefing session, Thompson and colleagues<sup>26</sup> found that patient resuscitations in posttraining simulation of eclampsia were better managed. Of note, these simulations occurred in the actual delivery unit, as opposed to a separate simulation laboratory, and these researchers used their initial simulations not only for training but also for elucidating site-specific barriers to an optimal response (e.g., an inefficient paging system). This ability of simulation to identify systems-level barriers to best practice has been noted by others as well.<sup>27</sup>

Ellis and colleagues<sup>28</sup> also examined pretraining and posttraining outcomes during eclampsia simulations. In their study, training was associated with an increase in the appropriate and timely completion of desired tasks (e.g., magnesium sulfate administration). Of note, although all participants underwent simulation training, they also were randomized to different training sites (i.e., simulation center vs. hospital unit) and to inclusion of teamwork training in their educational process. Neither site nor supplementary teamwork education was associated with additional improvement.

### Other Obstetric Events

Other obstetric events that have been examined in the context of simulation include breech delivery, postpartum hemorrhage, and cord prolapse. In one study focused on breech delivery, after undergoing a simulation of an imminent term vaginal breech, residents took part in a training session with the simulator on the proper techniques for vaginal breech delivery.<sup>29</sup> After this training, residents repeated the standardized simulation. Simulations both before and after training were videotaped and judged by an investigator who was blinded to training status. Scores for skill and safety were significantly greater for residents who participated in the simulated breech delivery after the training. With regard to postpartum hemorrhage, Toledo and colleagues<sup>30</sup> used simulated examples of blood loss volumes to improve care providers' accuracy with regard to blood loss estimation.

Siassakos and colleagues<sup>31</sup> assessed whether clinical outcomes associated with cord prolapse improved after introduction of an obstetric emergency training program that included cord prolapse drills. They found that after these drills, a significant

reduction was reported in diagnosis-to-delivery interval (25 to 14.5 minutes,  $P < .001$ ), although no significant difference was found in low Apgar scores or rate of admission to the neonatal intensive care unit (NICU).

Draycott and coinvestigators<sup>32</sup> also examined clinical outcomes after introduction of a training session that included fetal heart tracing education and drills in shoulder dystocia, postpartum hemorrhage, eclampsia, twin deliveries, breech deliveries, adult resuscitation (including cardiopulmonary resuscitation), and neonatal resuscitation. After this training, the frequency of hypoxic-ischemic encephalopathy (HIE) decreased by approximately half at their institution (27.3 to 13.6 per 10,000 births,  $P = .03$ ). This decrease did not seem to be related to other pre-existing trends in the frequency of HIE or to changes in the population during the period of study.

### Enhancement of Communication

Rather than focus on simulation of specific obstetric events, some investigators have emphasized improvement of communication processes and teamwork in general. **One approach to this is through the establishment of a specific team trained to function and be engaged specifically at the time of obstetric emergencies. One institution, for example, created a "Condition O" team, according to the precepts outlined for rapid-response systems,<sup>33</sup> including (1) case detection that triggers a medical crisis team response, (2) a medical crisis team response available at all times, (3) an evaluation and process improvement system, and (4) an administrative structure to support the system.** After implementation of this system, the investigators reported several quality improvement interventions that were able to be introduced due to case reviews associated with "Condition O" being invoked, although improvements in particular outcomes were not yet demonstrated.

A different approach, in contrast to the one above, is the training for and implementation of standardized communication processes throughout a unit or institution. **One often-cited approach to this type of intervention is crew resource management (CRM). This training began—and has continued—in the airline industry, where it was noted that accidents were primarily related to lack of coordination and poor teamwork.<sup>33</sup> CRM seeks to engender effective communication through standardized language, situational awareness, briefing and debriefing, and a leveling of hierarchy that allows all team members to voice concerns over safety.** Some evidence from both observational longitudinal studies and randomized trials suggests that communication training can improve teamwork and communication among providers.<sup>34,35</sup>

In one longitudinal observational study,<sup>36</sup> the introduction of a CRM course at a single institution was noted to be associated with a reduction in high-severity "lawsuits, claims, and observations" (i.e., when the insurance carrier reserves money) by 62%. However, in the one randomized trial that was performed—and in which this CRM course, the MedTeams Labor and Delivery Team Coordination Course, was evaluated—investigators reported that institutions randomized to the intervention were no more likely to reduce the primary measure of obstetric adverse outcomes (mean adverse outcome index) than institutions that received no intervention at all.<sup>37</sup>

### Multifaceted Approaches

**Some have asserted that the complexity of obstetric care is such that improvements in safety will come not through the**

**use of one particular intervention but with a multifaceted approach that ultimately results in a fundamental culture change within an institution.** Correspondence with principles of high-reliability organizations have helped to guide some of these efforts. Longitudinal observational studies have suggested that the introduction of such programs is associated with outcome improvements. Examples of such programs have been reported by several organizations:

Catholic Healthcare Partners (CHP)<sup>38</sup> instituted a program at 16 sites that included interdisciplinary education, routine medical record reviews to monitor ongoing adherence to appropriate practice, and standardization of forms to encourage adherence with best practices. After introduction of this program, birth trauma rates decreased from 5.0 to 0.17 per 1000 births, and the number of adverse obstetric occurrences (specified birth-related event or injury that might lead to a claim) decreased by 65%, from 7.2 to 2.5 per 1000 births.

Seton Family Hospitals<sup>39</sup> began a program at four sites that included standardization of forms and care processes, introduction of routine communication processes such as situation, background, assessment, recommendation (SBAR); active surveillance of adverse outcomes with temporally proximate feedback; and interdisciplinary obstetric crisis simulation with high-fidelity mannequins. Subsequent to the introduction of this program, birth injury rates declined from a 2-year average of 0.3% to 0.08%, and the average length of stay for infants admitted to the NICU for birth injury declined by 80%.

Yale–New Haven Hospital<sup>40</sup> obstetric department began a program of outside expert review of adverse events, anonymous event reporting, protocol standardization, creation of a patient safety nurse position and patient safety committee, and training in team skills and fetal heart monitoring interpretation. Introduction of this program was associated with a significant reduction ( $P = .01$ ) in their outcome of choice, the mean quarterly adverse outcome index. They have reported that medical liability claims and payments also have been reduced subsequent to the introduction of this program.<sup>41</sup>

Hospital Corporation of America (HCA)<sup>42</sup> instituted a program that included standardized processes, active peer review and feedback, and the empowerment of any member of the health care team to halt care considered possibly dangerous. Subsequent to this program's initiation, a significant reduction was seen ( $P < .001$ ) in the number of professional liability claims per 10,000 deliveries.

## Summary

It seems clear that at least some of the adverse outcomes that occur in obstetrics are preventable and that the root causes of these preventable events, although multiple, often involve communication and teamwork. Theory supports various approaches to error reduction, many of which have been used in obstetrics. **Whereas some but not all studies have documented improvements in outcomes related to patient safety initiatives, these studies have been predominantly observational and have used different outcomes—such as provider satisfaction and perception, demonstration of skill acquisition in simulated scenarios, actual care processes, and actual patient outcomes—to assess improvement.** Further work is necessary to understand the best combination of practices and practice methodologies (e.g., simulation on site versus simulation in a laboratory) that most effectively improve care.

## MEASUREMENT OF OBSTETRIC QUALITY OF CARE

Measurement is required to understand whether safe care is being provided and whether changes in approaches to patient safety are actually improving the quality of care. Examples of *patient safety measures* are rates of retained surgical sponge or wrong site surgery. A *quality measure* assesses the degree to which maternal and neonatal care is optimized. The following section details different approaches to measurement that have been used in an effort to optimize obstetric care.

### Overview

Many types of stakeholders have an interest in quality obstetric care. Patients, doctors, and insurers desire high obstetric quality at an affordable cost. However, each of these groups may perceive quality differently. Patients want to feel that their doctors are caring individuals who produce good outcomes. Doctors want to ensure the best possible outcomes for patients but also, regardless of outcome, they need to be sure they are using best practices. Insurers want to know that the care given is cost effective. Each of these groups wants and needs access to quality measures that reflect their own interests. Thus one of the first steps in measuring quality is to understand who will use the measure and how it will be used.

### Quality Measures

**The three major categories of quality measures are (1) structural, (2) outcome, and (3) process.**<sup>43</sup> *Structural measures* assume that if the hospital contains quality components, the product (medical care) will also be of high quality. Examples of structural measures include board certification, physician licensure, and hospital accreditation. Structural measures are appealing because they are easy to measure and reproduce; however, whereas structural measures may reflect that optimal structures are present, these measures do not guarantee that the different components of the hospital will work well together.

*Outcome measures*, as indicated by their name, reflect patient outcomes. An example of an outcome measure would be the frequency of maternal mortality or neonatal hypoglycemia. **Because obstetricians generally treat healthy women, adverse outcomes in obstetrics are relatively uncommon. Consequently, the usefulness of many outcome measures, such as maternal mortality, may be limited because most hospitals have few or none of these outcomes to measure.** Furthermore, if outcomes measures are to be maximally useful and reflective of the actual care provided at a given institution, they need to reflect outcomes that the institution can actually affect and should be **risk-adjusted** to account for differences in patients that could materially affect the outcome of interest. For example, although “preterm birth” is an adverse outcome, “frequency of preterm birth” may not be a good measure to reflect patient quality given the lack of useful interventions to prevent this adverse outcome. Also, a comparison of hospitals according to their frequency of peripartum hysterectomies may not reflect comparative quality of care if one hospital is much more likely to care for women with abnormal placentation. One recent investigation has demonstrated that for several adverse obstetric outcomes—severe postpartum hemorrhage, peripartum infection, severe perineal laceration, and a composite adverse neonatal outcome—differences in the characteristics of the patients who are admitted for delivery to different

hospitals may materially affect how a hospital is judged to be performing relative to other hospitals with regard to these outcomes.<sup>44</sup> Lastly, outcomes measures may pose distinct challenges in obstetrics, when outcomes of two patients—the mother and the baby—occur. Thus, whereas a hospital may have comparatively good maternal outcomes, it also may have comparatively poor neonatal outcomes, and examination of only one of these sets of outcomes would not fully convey the quality of the care environment.<sup>44</sup>

**Process measures** reflect practices that physicians or hospitals actually use in their care of patients. An example of a process measure is the frequency with which known group B *Streptococcus* (GBS)-positive women receive appropriate antibiotics. **If a process measure were to conceivably be an adequate reflection of patient safety, there should be evidence that the process is related to improved outcomes.** The most central advantage of a process measure is that it gives direct insight into desired actions within the health care system. Correspondingly, these measures give immediate insight into the processes that need to be attended to in order to enhance patient care. Conversely, one of the disadvantages of process measures is that outcomes are often due to the interplay of many different factors and processes, and improvements in these measures may give false reassurance that improvements in quality of care have been fully realized. Draycott and colleagues<sup>45</sup> have voiced concern that too great a dependence on process measures may obscure the fact that “improvements” in care are not translating to improvement in outcomes. Recent analyses in obstetrics have illustrated this point. Grobman and associates<sup>46</sup> studied care processes and outcomes of over 115,000 women at 25 different hospitals but could not demonstrate that differences in the care provided at the hospitals could account for variation in adverse outcomes that were seen. Similarly, Howell and colleagues<sup>47</sup> studied the frequency of cesarean and elective delivery at less than 39 weeks’ gestation among hospitals in New York, but they could find no relationship between how hospitals performed on these measures and the frequency of maternal or neonatal morbidity.

With these considerations in mind, several criteria should be considered in determining whether a measure is a good one. For example, a good measure should (1) balance maternal and neonatal outcomes—that is, it should not reflect improved care for one member of the mother-child dyad while embodying markedly worse care for the other; (2) have the potential to be altered by behaviors within the health care system of interest; (3) be affordable and applicable for use on a larger scale; (4) be acceptable to stakeholders as a meaningful marker of quality; and (5) be reliable and reproducible.<sup>43</sup>

### Attempts to Establish Quality Measures

Because measuring the quality of care is a seminal step in both improving patient safety and achieving quality care, many attempts have been made by a multitude of different organizations to determine quality measures in obstetrics. This chapter will not comprehensively review all current quality measures; rather it will present some examples of measures to illustrate the strengths and weaknesses of different choices. The examples will include traditional measures as well as those more recently suggested.

### Traditional Measures

The more traditional measures often have been raw frequencies of selected adverse outcomes. One example of this type of

measure is maternal mortality. It has been used because it is clearly a profoundly bad outcome, and little potential exists for misascertainment. However, in the modern era within developed countries, maternal mortality is so relatively uncommon that it is difficult to use within a hospital or health care system to reflect quality of health care. Most hospitals will have no maternal mortality even over many years, and few hospitals will have a sufficient number of cases to enable them to use this measure to track their adequacy of care delivery. Furthermore, the absence of this outcome does not mandate that quality care is being provided; lack of quality care may still exist, and short of death, poor outcomes may still be obtained. This does not mean that any maternal mortality should not be fully investigated as a critical part of quality assurance and improvement efforts, only that maternal mortality is unlikely to be useful as a quality marker for intrainstitutional quality tracking and inter-institutional comparisons. Alternatively, in an effort to obtain an outcome measure that still could be used to identify significant adverse maternal events but is more common than maternal mortality, Callaghan and others<sup>48</sup> have advocated that a measure of “severe maternal morbidity” be adopted. This outcome, redefined as the occurrence of an ICU admission or transfusion of at least 4 units of packed red blood cells, occurs nearly 50 times more frequently than maternal mortality.<sup>5,49,50</sup>

Neonatal mortality also has been used as a marker of obstetric quality, although it may be problematic as a marker for obstetric quality for several reasons. First, when a neonate dies, it is unclear to what extent obstetric care, pediatric care, or both may have contributed. Secondly, a large proportion of neonatal mortality is due to prematurity and lethal birth defects, neither of which can be materially affected by obstetric care.<sup>51</sup> Thus the residual fraction of obstetric-related neonatal mortality is relatively small, and once again, it may be so uncommon as to limit its use for evaluation of trends or institutional comparisons.

The cesarean delivery rate has been a common measure used to reflect obstetric quality of care. Whereas debate continues about whether cesarean delivery is a process measure or an outcome measure, it is regardless a flawed measure. First, due to perinatal regionalization, women with greater obstetric complications are concentrated at hospitals best suited to providing specialized care. Thus a comparison of cesarean delivery rates among hospitals without accounting for the differences in patient populations may be misleading. Hospitals with the highest cesarean delivery rates may be giving quality care but have high rates due to their patient population. Conversely, a hospital may be giving poor care and may have an average rate of cesarean delivery, when in fact the cesarean delivery rate should be much lower for their low-risk population.

### Newer Approaches to Measures

Although the use of “raw” cesarean delivery rates to measure quality is not ideal, cesarean delivery rates are appealing as a measure because cesarean delivery is an outcome that is easy to ascertain, and it is meaningful to multiple stakeholders. One approach to try and account for population differences among institutions is to calculate and use a “risk-adjusted” cesarean delivery rate as a measure. **Many different techniques for risk-adjustment for cesarean delivery, as well as other obstetric outcomes, have been described.<sup>52-57</sup> Fundamentally, risk adjustment creates a model that predicts what the cesarean delivery rate should be for the particular patient population and allows comparison with the actual rate.** By taking

account of differences such as parity, plurality, and comorbidities among populations, risk-adjustment seeks to reflect differences in outcomes related to the health care system rather than the patients who access it.

Risk-adjustment can be used for any outcome but requires formal statistical testing and assessment to demonstrate whether it attains the intended goal of accounting for relevant patient characteristics that contribute to the outcome of interest. For example, a series of risk-adjustment models have been developed and tested for several adverse obstetric outcomes, including severe postpartum hemorrhage, peripartum infection, third- and fourth-degree lacerations, and a composite adverse neonatal outcome.<sup>44</sup>

**Another approach to determining an outcome measure that is dependent upon the health care system, rather than the differences in patient populations, is to determine an outcome frequency for a more homogeneous group rather than for all women who receive care.** Main and coworkers<sup>58</sup> have suggested, for example, the use of a cesarean delivery rate measure that only assesses women who are nulliparous with a term singleton vertex (NTSV) fetal presentation. Using data from the Sutter Health Care network of 20 birthing units, in which more than 40,000 women deliver each year, these researchers determined age-adjusted NTSV cesarean rates and found that 53% of the variation in these rates was associated with differences in frequency of labor induction and early admission in labor. This finding suggests that some health care practices are associated with the NTSV cesarean rate, and the disadvantage of using this rate is that it excludes women having preterm deliveries or who are multiparous.

**One process measure that has recently gained attention is scheduled elective delivery prior to 39 weeks of gestation.** This measure has gained popularity as the risks of early-term birth have become better known.<sup>59,60</sup> This process measure has the advantage of being fully under the control of the health care system and does not require risk adjustment. Part of what makes this measure appealing is that it can be calculated from the International Classification of Diseases (edition 9, ICD-9) administrative data, which is already collected and available in hospitals. Nevertheless, one potential difficulty with this measure is the lack of consensus for several indications as to whether they are indeed elective. Also, some have noted that ICD-9 data are not as accurate and complete as data from the medical records and may not provide an accurate assessment. However, a study by Clark and colleagues<sup>61</sup> showed that even when ICD-9 data are used, the majority of cases found to be in violation of a policy against delivery prior to 39 weeks of gestation were true cases of non-medically indicated delivery. Only a minority of cases were due to abstractor error or poor documentation.

**The frequency with which antenatal corticosteroids are administered to infants who are delivered at less than 34 weeks is another process measure that has become widely used.** This process measure is appealing because of data that show antenatal corticosteroids improve outcomes for premature infants. Nevertheless, this measure does have its disadvantages. Ascertainment of steroid administration can be difficult, especially in a health care setting without electronic medical records (EMRs). Steroids given during the pregnancy, but not during the delivery hospitalization, are time intensive to ascertain because inpatient and outpatient records may need to be reviewed. And whereas 100% administration is the goal, it is not possible to administer corticosteroids to all women prior

to premature delivery due to late patient arrival or emergent circumstances, such as a maternal trauma.

**The frequency of neonates who weigh less than 1500 g born outside a tertiary care center is one recently suggested process measure that is appealing because it may reflect adequacy of coordination of an entire health care system.** Although data show that very-low-birthweight neonates have worse outcomes when delivered outside a tertiary care center, many incentives may work against delivery at such a location.<sup>62-64</sup> This measure is easy to calculate from birth certificates, and the items from the birth certificate that are needed to calculate the measure are reliable.<sup>42</sup>

The quality measures discussed thus far have represented inpatient care. **Outpatient quality measures do exist, although they are often process measures.** An example of such a measure is the frequency with which pregnant women receive human immunodeficiency virus (HIV) screening early in their antepartum care. One difficulty with these measures has to do with accurate ascertainment, because prenatal care happens in many different settings, and outpatient medical records data are often not in electronic form. Furthermore, whereas hospitals are required to generate administrative data that can be helpful for measuring inpatient quality, outpatient clinics are not required to generate the same kinds of data, and so they do not.

### Data Sources

Administrative data, collected primarily for billing or nonmedical purposes, is a rich source of information. Administrative data have the advantages of being complete for the population and relatively cheap to use. **Unfortunately, administrative data often lack the clinical detail needed to make meaningful quality judgments.**<sup>66</sup> Paper-based medical records contain clinical detail but are hard to obtain in a uniform manner for a population and are expensive to collect.

Increasingly, EMRs have been used to provide the basis for quality measures. These data are easy to collect within an institution and have clinical detail. However, because many different types of EMR systems exist, collating medical records information from many sources can be time intensive. **EMRs have the advantage of being able to link outpatient and inpatient information, something that is very difficult to do with administrative data or paper-based medical records.** The types of information that are available from EMRs will increase and improve with time, and there is hope that eventually vital statistics records will be based on actual medical records, rather than on data extraction, thereby making birth certificate data a richer, more accurate source of medical data.

### Quality Improvement

The main point of measuring quality of care is to use the measurement tools to improve care. Quality measurement tools allow stakeholders to assess the effects of changes in the system. **There are many ways to accomplish improved quality of care with measurement, but one of the most effective is benchmarking.**<sup>67</sup> *Benchmarking*, also known as *audit and feedback*, is a technique whereby quality is measured, compared with like entities, and then shared back with the participants, often in a blinded manner. For example, NTSV rates for all the hospitals in a city would be calculated. Each hospital would then receive a graph showing their rate (unblinded) compared with the rates of all the other hospitals (blinded) in the city.

One example of this technique being used was in the Ohio Perinatal Quality Collaborative (OPQC).<sup>68</sup> This group of 20 hospitals in Ohio came together to share data and compare techniques on how to lower the frequency of scheduled deliveries prior to 39 weeks without documentation of a medical indication. Each hospital collected data on scheduled deliveries from 36<sup>0/7</sup> to 38<sup>6/7</sup> weeks in its own institution and submitted the data to a central location for data collation. This data center then created reports that showed each hospital their own rate compared with the rates of all the other hospitals. Each hospital took that information and designed their own program to lower their own frequency. Monthly phone calls allowed hospitals to share their designs and progress. At the initiation of the project, 25% of scheduled deliveries between 36 and 38<sup>6/7</sup> weeks did not have a documented medical indication; this frequency was lowered to less than 5% ( $P < .05$ ) after a year. It was estimated that approximately 1000 births were moved from between 36<sup>0/7</sup> and 38<sup>6/7</sup> to over 39 weeks in the state of Ohio during the 12 months of this effort.

In addition to the collaborative in Ohio, many other quality collaboratives exist across the country.<sup>69</sup> Some are voluntary and others require a fee for participation for the member hospitals. A well-established quality collaborative is the California Maternal Quality Care Collaborative (CMQCC [online at [www.cmqcc.org](http://www.cmqcc.org)]). In addition to being a resource for members to interact and share data, many quality care collaboratives—including the OPQC and the CMQCC—offer toolkits that allow nonparticipating hospitals to benefit from their quality benchmarks and materials that describe what they have learned by providing data collection tools.

These collaboratives, as well as others, may help to provide insight into the most effective approaches to improving obstetric care. Clark and a group of investigators at Hospital Corporation of America (HCA)<sup>70</sup> compared three methods of implementing change in a labor and delivery unit in an effort to decrease the frequency of elective deliveries prior to 39 weeks. They compared (1) a hard-stop approach, in which physicians were not allowed to schedule deliveries prior to 39 weeks without a medical indication; (2) a soft-stop approach, in which physicians were allowed to schedule deliveries prior to 39 weeks but were told there would be a peer review process to assess whether elective deliveries prior to 39 weeks were occurring; and (3) an education-only approach, in which physicians were educated about relevant issues but no other changes were made. The results of this study showed that both the hard- and soft-stop approaches were associated with changed behavior, whereas the educational approach was not at all effective. Furthermore, the hard-stop strategy was twice as effective as the soft-stop approach.

### KEY POINTS

- ◆ A proportion of adverse obstetric events have been shown to be preventable; this proportion varies with the clinical circumstances.
- ◆ Although multiple factors have been associated with the occurrence of adverse obstetric events, issues with communication have been implicated as a frequent contributor.

- ◆ Specific approaches that have been considered to enhance obstetric patient safety include checklists and protocols, simulation, and teamwork training.
- ◆ Further investigation is required to understand what approaches and combinations of approaches most improve clinical care and outcomes.
- ◆ Quality measures assess the degree to which maternal and neonatal care is optimized.
- ◆ Major categories of quality measures include structural, process, and outcome measures.

Society has great expectations that modern medical technologies will improve longevity and the quality of human life, and nowhere are these expectations higher than in the practice of obstetrics and the desire and expectation of having a healthy child. Along with the rapidly expanding capabilities in diagnosis and treatment, physicians find themselves facing numerous ethical dilemmas while practicing in a legal and social climate in which malpractice suits can threaten even the most competent and conscientious practitioner.

We cannot address in a single chapter the wide variety of ethical and legal controversies that face contemporary obstetric practice and research. Instead, we focus on selected topics of particular relevance to the practicing obstetrician.

## REPRODUCTIVE LIBERTY

**Although only about one in four pregnancies ends in elective abortion, abortion has been the most controversial and political medical procedure in the United States for the past four decades.** The political debate over abortion has shifted among various dichotomous views of the world: life versus choice, fetus versus woman, fetus versus baby, constitutional rights versus states' rights, government versus physician, and physician and patient versus state legislature. In 2010, the abortion debate came close to derailing the Affordable Care Act, and in 2014, **the U.S. Supreme Court ruled that corporations could have religious beliefs and that these beliefs could permit them not to include some birth control methods (that the corporation inaccurately thought induced abortion) in the health insurance plans of their female employees.** Because the 1973 U.S. Supreme Court opinion on *Roe v. Wade* remains so central to the law (and ethics) regarding the physician-patient relationship, as well as federal financing and regulation of clinical medicine and research and of health care insurance itself, **it is essential that obstetricians have a clear understanding of *Roe* and its enduring influence on patient rights—especially reproductive liberty, medical practice, and politics.**<sup>1</sup>

Hundreds of statutes—including relatively new ones that require ultrasound images of the fetus be made available to pregnant women before abortion, suggesting that 20-week-old fetuses feel pain, and requiring that abortion clinics have ready access to hospital emergency departments—and almost two dozen Supreme Court decisions on abortion later, the core legal aspects of *Roe v. Wade*,<sup>2</sup> the most controversial health-related decision ever made by the Court, remain substantially the same as in 1973. Attempts to overturn *Roe* in both the courtroom and the legislature have failed, although they continue. **Pregnant women still have a constitutional right to abortion because the fetus is still not a person under the Constitution.** States still cannot make abortion a crime, either for the woman or the

<sup>†</sup>Deceased.

physician, before the fetus becomes viable with the exception of the use of a specific procedure labeled “partial-birth abortion” by Congress. States still can outlaw abortion after the fetus becomes viable, but only if there is an exception that permits abortion to protect the life or health of the pregnant woman. Also, states still can impose restrictions on abortion before fetal viability only if those restrictions do not create an “undue burden” on the pregnant woman, understood as a substantial obstacle that might actually prevent a pregnant woman’s obtaining an abortion.

The first case to embrace the concept of reproductive liberty was *Griswold v. Connecticut*, in which the Court ruled in 1965 that a Connecticut statute criminalizing the use of contraceptives violated the constitutional right to privacy that married couples had in sexual relations.<sup>3</sup> Later, in 1972, the Court found that even outside marriage, a person had a “right to privacy ... to be free from unwarranted governmental intrusion into matters so fundamentally affecting a person as the decision to bear or beget a child.”<sup>4</sup> The following year, in *Roe*, the Court struck down a Texas law that made it a crime for physicians to perform an abortion unless it was necessary to save the life of the patient; there were no exceptions for the woman’s health. **The Court held that women have a constitutional right of privacy that is fundamental and “broad enough to encompass a woman’s decision ... to terminate her pregnancy.”**<sup>2</sup> Because the right is fundamental, states that wished to restrict abortion rights were required to demonstrate a compelling interest to restrict the exercise of this right. The Court ruled that the state’s interest in the life of the fetus became compelling only at the point of viability, defined as the point at which the fetus can survive independently of its mother. Even after the point of viability, the state cannot favor the life of the fetus over the life or health of the pregnant woman. Under the right of privacy, physicians must be free to use their “medical judgment for the preservation of the life or health of the mother.”<sup>2</sup> On the same day that the Court decided *Roe*, it also decided *Doe v. Bolton*,<sup>5</sup> in which the Court defined health very broadly: “The medical judgment may be exercised in the light of all factors—physical, emotional, psychological, familial, and the woman’s age—relevant to the well-being of the patient. All these factors may relate to health. This allows the attending physician the room he needs to make his best medical judgment.”<sup>5</sup>

*Roe* and *Doe* together established that both physician and patient were protected by the constitutional right of privacy. In later cases, the Court continued to defer to the medical judgment of the attending physician. For example, in *Planned Parenthood of Central Missouri v. Danforth* in 1976, the Court concluded that state legislatures could not determine when viability occurred; rather this “essentially medical concept ... is, and must be, a matter for the judgment of the responsible attending physician.”<sup>6</sup> This remains the case today; even as viability in general moves earlier in the pregnancy, it is not up to legislatures or courts to determine when an individual fetus is viable by drawing a line based on the age of the fetus—**the viability of a specific fetus remains a matter of medical judgment to be determined by the attending physicians in a manner consistent with good and accepted obstetric practice.**

By the end of the 1980s, a pattern in Court decisions could be discerned in which abortion regulations that (1) significantly burdened a woman’s decision; (2) treated abortion differently from other, similar medical or surgical

**procedures; (3) interfered with the exercise of professional judgment by the attending physician; or (4) were stricter than accepted medical standards were struck down by the Court.**<sup>7</sup> Privacy as a constitutional right became a one-word description of liberty to make decisions regarding marriage, procreation, contraception, sterilization, abortion, family relationships, child rearing, and sexual relationships free of governmental interference.

One strategy to change *Roe* was to change the composition of the Supreme Court by appointing anti-*Roe* justices. Because of new justices on the Court in 1992, in *Planned Parenthood of Southeastern Pennsylvania v. Casey*, the Court had its first real opportunity to overturn *Roe v. Wade*. Many Court observers thought it would. Instead, in an unusual procedure for the Court, three potentially anti-*Roe* justices—Sandra Day O’Connor, David Souter, and Anthony Kennedy—joined together to write a joint opinion confirming the “core holding” of *Roe*. They were joined in most of their opinion by two justices, Harry Blackmun and John Paul Stevens, who would have simply upheld *Roe*, making this a 5-to-4 decision. Most centrally, the authors of the joint opinion believed that although the pressure to overrule *Roe* had grown “more intense,” doing so would severely and unnecessarily damage the Court’s legitimacy by undermining “the Nation’s commitment to the rule of law.”<sup>8</sup> Specifically, the three justices wrote that they were reaffirming “*Roe*’s essential holding” that before the point of viability, a woman has a right to choose abortion without undue state interference, and that after the point of viability, the state can restrict abortion “if the law contains exceptions for pregnancies which endanger the woman’s life or health,” and that “the state has legitimate interests from the outset of the pregnancy in protecting the health of the woman and the life of the fetus that may become a child.” The Court applied these principles to uphold laws that mandate much more detailed requirements for abortion, as well as a mandatory 24-hour waiting period, but it struck down a spousal-notification requirement as an “undue burden.”

Thus, after *Casey*, *Roe* stood for the proposition that **pregnant women have a “personal liberty” right—“privacy” went unmentioned—to choose to terminate their pregnancies before the point of viability and that the state cannot “unduly burden” such a right by erecting barriers that effectively prevent the exercise of that choice.**<sup>9</sup> Of course, a major problem was definitional: burdensome regulations were acceptable, “unduly burdensome” ones were not; but it was not clear what qualified as which. Put another way, the state could demonstrate its concern for fetal life by requiring that physicians make women seeking abortions jump through new and burdensome hoops—including offers of detailed and accurate information on abortion, the status of the fetus, adoption, sources of help for childbirth, and a 24-hour waiting period—as long as doing so did not “unduly burden” women by actually preventing them from being able to make a decision to have an abortion.

With the loss of a realistic expectation in 1992 that the Court would overrule *Roe* wholesale without significant changes in the Court’s membership, **anti-*Roe* advocates switched strategies dramatically, focusing on criminalizing a specific procedure that they believed would horrify most Americans and that they labeled “partial-birth abortion.”** The first such bill passed Congress in 1996 and was vetoed by President Bill Clinton because the prohibition did not contain an exception for the health of the woman, as required by *Roe* and *Casey*. In 1997,

this time with the support of the American Medical Association, the bill passed Congress again. President Clinton vetoed it, again for failure to contain a health exception.<sup>10</sup>

Proponents of the ban took their cause to the individual states, most of which enacted substantially identical laws. In 2000, Nebraska's partial-birth abortion law reached the Supreme Court. The Nebraska law carried a penalty of up to 20 years in prison for physicians who performed the procedure. The law reads in relevant part:

No partial-birth abortion shall be performed in this state, unless such a procedure is necessary to save the life of the mother whose life is endangered by a physical disorder, physical illness, or physical injury, including a life-endangering physical condition caused by or arising from the pregnancy itself.

[A "partial-birth abortion" is] an abortion procedure in which the person performing the abortion partially delivers vaginally a living unborn child before killing the unborn child and completing the delivery. ... [The statute further defines the phrase "partially delivers vaginally a living unborn child before killing the unborn child" as] deliberately and intentionally delivering into the vagina a living unborn child, or a substantial portion thereof, for the purpose of performing a procedure that the person performing such procedure knows will kill the unborn child and does kill the unborn child.

This ban applied throughout pregnancy and had no exception to protect the woman's health, only to save her life. In a 5-to-4 opinion in *Stenberg v. Carhart*,<sup>11</sup> the Court found this law unconstitutional for two reasons. First, the description of the banned procedure was too similar to dilation and evacuation (D&E), another procedure that was permitted by the law and widely used for second-trimester abortions. Therefore this law would discourage physicians from using the lawful procedure, which would place an undue burden on their patients. Second, the law failed to provide an exception for instances in which the procedure was deemed necessary by the physician to protect the woman's health, as required by *Roe* and *Casey*. Justice John Paul Stevens, in his concurring opinion, noted that the extreme anti-*Roe* rhetoric as exemplified in the partial-birth abortion debate obscured the fact that during the 27-year period since *Roe* was decided, the core holding of *Roe* "has been endorsed by all but 4 of the 17 Justices who have addressed the issue."

A notable dissenting opinion was written by Justice Kennedy, who had specifically endorsed the core of *Roe* in *Casey*. Kennedy argued that the outlawing of "partial-birth abortion" was consistent with *Casey* because of the interest the state has throughout pregnancy in protecting the life of the fetus that may become a child. In his view, the banned procedure conflates abortion and childbirth in a way that "might cause the medical profession or society as a whole to become insensitive, even disdainful, to life, including life of the human fetus." He also argued that such a ban was not unduly burdensome to women because state legislatures can determine that specific medical procedures, like this one, are not medically necessary.<sup>11</sup>

Justice Stephen Breyer, the author of the *Stenberg* majority opinion, stated that a more precise law, with a health exception, could be constitutional.<sup>11</sup> In 2003, Congress passed a slightly revised law. It did not contain a health exception, but its preface did contain a declaration that the outlawed procedure was *never* medically necessary for the health of the woman. President Bush signed it into law on November 5, 2003. By the time the Court ruled on the constitutionality of this law in April 2007, in *Gonzales v. Carhart*,<sup>12</sup> two important changes had occurred

in the composition of the Court: a new chief justice, John Roberts, replaced the consistently anti-*Roe* Chief Justice William Rehnquist; and Justice Samuel Alito replaced Justice Sandra Day O'Connor, who was consistently pro-*Roe* (as interpreted by the joint opinion in *Casey*). The federal law provides that:

(a) Any physician who, in or affecting interstate or foreign commerce, knowingly performs a partial birth abortion and thereby kills a human fetus shall be fined under this title or imprisoned not more than 2 years, or both. This subsection does not apply to a partial birth abortion that is *necessary to save the life of a mother* whose life is endangered by a physical disorder, physical illness, or physical injury, including a life-endangering physical condition caused by or arising from the pregnancy itself. ...

(b) (1) The term "partial-birth" abortion means an abortion in which the person performing the abortion

(A) *Deliberately and intentionally* vaginally delivers a living fetus until, in the case of a head-first presentation, the *entire fetal head is outside* the body of the mother, *or*, in the case of breech presentation, *any part of the fetal trunk past the navel is outside* the body of the mother, for the purpose of performing an overt act that the person knows will kill the partially delivered living fetus; and

(B) Performs the overt act, other than completion of delivery, that kills the partially delivered living fetus [emphasis added].

The Court decided, 5 to 4, that this new law was constitutional.<sup>12</sup> Justice Kennedy wrote the majority opinion for himself and for Justices Antonin Scalia, Clarence Thomas, and the two new justices. In it he substantially adopts his dissenting opinion in *Stenberg* as the Court's new majority opinion. Although he concludes that his decision is consistent with *Stenberg*, all three U.S. District courts and all three Courts of Appeal that had examined this federal law found it unconstitutional under the principles in *Casey* and *Stenberg*, primarily because of the vagueness of the definition and the lack of a health exception. As to the vagueness argument, Kennedy writes that the new law is no longer vague because it clarifies the distinction between the prohibited procedure, which he calls "intact D&E," and standard D&E abortions because the former requires the delivery of an intact fetus, whereas the latter requires "the removal of fetal parts that are ripped from the fetus as they are pulled through the cervix." In addition, the new federal law specifies fetal landmarks (e.g., the "navel") instead of the vague description of a "substantial portion" of the "unborn child."

Because the law applies to fetuses both before and after the point of viability, Kennedy concedes that under *Casey* the law would be unconstitutional "if its purpose or effect is to place a substantial obstacle in the path of a woman seeking an abortion before the fetus attains viability." Kennedy finds Congress's purpose is twofold: first, lawmakers wanted to "express respect for the dignity of human life" by outlawing "a method of abortion in which a fetus is killed just inches before completion of the birth process," because use of this procedure "will further coarsen society to the humanity of not only newborns, but of all vulnerable and innocent human life. ..." Second, Congress wanted to protect medical ethics, finding that this procedure "confuses the medical, legal, and ethical duties of physicians to preserve and promote life. ..."

The key to Kennedy's legal analysis is his conclusion that these reasons are constitutionally sufficient to justify the ban because under *Casey*: "the State, from the inception of pregnancy, maintains its own regulatory interest in protecting the life of the fetus that may become a child [and this interest] cannot be set at

naught by interpreting *Casey's* requirement of a health exception so it becomes tantamount to allowing the doctor to choose the abortion method he or she might prefer." Kennedy then goes on to write that "respect for human life finds an ultimate expression in the bond of love the mother has for her child," and that "while no reliable data" exist on the subject, "it seems unexceptionable to conclude some women come to regret their choice to abort the infant life they once created and sustained. ... Severe depression and loss of esteem can follow." Such regret, Justice Kennedy believes, can be caused or exacerbated if women later learn what the procedure entails, suggesting that physicians fail to describe it to patients because they "may prefer not to disclose precise details of the means [of abortion] that will be used. ..."

The final, critical issue is whether the prohibition would "ever impose significant health risks on women" and whether physicians or Congress should make this determination. Kennedy picks Congress: "The law need not give abortion doctors unfettered choice in the course of their medical practice, nor should it elevate their status above other physicians in the medical community .... Medical uncertainty does not foreclose the exercise of legislative power in the abortion context any more than it does in other contexts." Furthermore, Kennedy argues, the law does not impose an "undue burden" on women for another reason: alternative ways of killing a fetus have not been prohibited. In his words, "If the intact D&E procedure is truly necessary in some circumstances, it appears likely an injection that kills the fetus is an alternative under the Act that allows the doctor to perform the procedure."<sup>12</sup>

Writing for the four justices in the minority, Justice Ruth Bader Ginsburg, the only woman justice on the Court at the time, observes, "Today's decision is alarming. It refuses to take *Casey* and *Stenberg* seriously. It tolerates, indeed applauds, federal intervention to ban nationwide a procedure found necessary and proper in certain cases by the American College of Obstetricians [and Gynecologists] (ACOG). It blurs the line, firmly drawn in *Casey*, between previability and postviability abortions. And, for the first time since *Roe*, the Court blesses a prohibition with no exception safeguarding a woman's health." Ginsburg argues that the majority of the Court has overruled the conclusion in *Stenberg* that a health exception is required when "substantial medical authority supports the proposition that banning a particular abortion procedure could endanger women's health. ..." This conclusion, bolstered by evidence presented by nine professional organizations, including the ACOG, and conclusions by all three U.S. District Courts that heard evidence concerning the Act and its effects, directly contradicted the congressional declaration that "there is no credible medical evidence that partial-birth abortions are safe or are safer than other abortion procedures." Even Justice Kennedy agreed that Congress's finding was untenable.

Justice Ginsburg concludes that this leaves only "flimsy and transparent justifications" for upholding the ban. She rejects those justifications, arguing that the state's interest in "preserving and promoting fetal life" cannot be furthered by a ban that targets only a method of abortion and that cannot save "a single fetus from destruction" by its own terms but may put women's health at risk. Ultimately, she believes that the decision rests entirely on the proposition, never before enshrined in a majority opinion and explicitly repudiated in *Casey*, that "ethical and moral concerns" unrelated to the government's interest in "preserving life" can overcome what had been considered fundamental rights of citizens. The majority seeks to bolster its conclusion

by describing pregnant women as in a fragile emotional state that physicians may take advantage of by withholding information about abortion procedures. Justice Ginsburg concludes that the majority's solution to this hypothetical problem is to "deprive women of the right to make an autonomous choice, even at the expense of their safety." She continues, "This way of thinking [that men must protect women by restricting their choices] reflects ancient notions about women's place in the family and under the Constitution—ideas that have long since been discredited." Ginsburg further notes that the majority simply cannot contain its hostility to reproductive rights as articulated in *Roe* and *Casey*, calling physicians "abortion doctors," describing the fetus as an "unborn child" and as a "baby," labeling second-trimester abortions as "late term," and dismissing "the reasoned medical judgments of highly trained doctors ... as 'preferences' motivated by 'mere convenience.'"<sup>12</sup>

**The major change in the law this opinion signals is the new willingness of Congress and the Court to discount the health of pregnant women and the medical judgment of their physicians.**<sup>13</sup> This departure from precedent was made possible by categorizing physicians as unprincipled "abortion doctors" and infantilizing pregnant women as incapable of making serious decisions about their lives and health. The majority opinion ignores or marginalizes long-standing principles of constitutional law and substitutes the personal morality of Justice Kennedy and four of his colleagues.

The majority asserts that giving Congress constitutional authority to regulate medical practice is not new but identifies no case in which Congress had ever outlawed a medical procedure. Its reliance on the more than 100-year-old case of *Jacobson v. Massachusetts* is especially inapt.<sup>14</sup> *Jacobson* was about mandatory smallpox vaccination during an epidemic, refusal of which was punishable by a fine. The statute had an exception for "children who present a certificate, signed by a registered physician, that they are unfit subjects for vaccination," and the Court implied that a similar medical exception would be constitutionally required for adults. It is not just abortion regulations that have had a health exception for physicians and their patients—all health regulations have.<sup>15</sup>

On the other hand, **those who expect *Roe* to be overturned by this Court may be disappointed.** Although Justice Alito has replaced Justice O'Connor and is likely to vote in the opposite direction on *Roe*-related issues, Justice Kennedy is the new swing vote on the Court, and he insists that he is upholding the principles of *Roe v. Wade* as reaffirmed in *Casey*. Just as the question of whether a specific abortion regulation was an "undue burden" was once a determination Justice O'Connor could effectively make for the Court, the meaning of *Roe v. Wade* is, at least for now, up to Justice Kennedy. The replacement of two pro-*Roe* justices, Souter and Stevens, with Sonia Sotomayor and Elena Kagan in the Obama administration has made no change in this balance. Nonetheless, there are now three women justices on the Court, and this fact alone will make the Court take women's rights more seriously.

## ABORTION POLITICS AND "OBAMACARE"<sup>16,17</sup>

President Barack Obama made it clear during the great debate on health insurance reform that he did not want abortion politics to sabotage his legislation. In his September 10, 2009 speech about health insurance reform to a joint session of Congress, he said, "Under our plan, no federal dollars will be used to fund

abortions.” **Nonetheless, the centrality of abortion in U.S. politics made it inevitable that abortion funding would play a major role in determining whether there was any health insurance reform law at all.** The debate revolved around the Stupak amendment in the House of Representatives, which provided that “No funds authorized or appropriated by this Act ... may be used *to pay for any abortion or to cover any part of the costs of any health plan that includes coverage of abortion*, except in the case where a woman suffers from a physical disorder, physical injury, or physical illness that would, as certified by a physician, place the woman in danger of death unless an abortion is performed, including a life-endangering physical condition caused by or arising from the pregnancy itself, or unless the pregnancy is the result of rape or incest” (italics added). The House passed this amendment by a vote of 240 to 194, with 64 Democrats voting in favor (the House health care bill itself passed 220 to 215). Many thought that the Catholic bishops who lobbied fervently for passage of the Stupak amendment were the most influential in supporting it. More influential, however, was the previously secret fundamentalist Christian political leadership group known alternately as *the Family* or *the Fellowship*, which includes among its members both of the amendment’s main sponsors, Bart Stupak (D-MI) and Joe Pitts (R-PA).<sup>16</sup>

The Stupak amendment was defended as merely continuing the practice created by **the Hyde amendment, named after the late Congressman Henry Hyde (R-IL) and attached to every Health and Human Services Appropriations Act passed since 1976**; the Hyde amendment has also been added to appropriations legislation for the Defense Department, the Indian Health Service, and federal employees’ health insurance plans. **The Hyde amendment prohibits the use of federal funding for “any abortion” or for any “health benefits coverage that includes abortion” unless the pregnancy is the result of “rape or incest” or “would, as certified by a physician, place the woman in danger of death unless an abortion is performed.”** Under the Hyde amendment, states may use their own funds to finance abortion services through their Medicaid programs, and 17 states currently do so.

The U.S. Supreme Court has ruled on the constitutionality of limiting government funding for abortion twice. The first case, in 1977, involved a Connecticut regulation that limited state Medicaid funding to “medically necessary” abortions, thus excluding those not necessary to preserve a woman’s life or health. The Court ruled that women have a constitutional right to choose to have an abortion, but the state has no obligation to pay for the exercise of this right and may constitutionally encourage women to continue their pregnancies to term by providing funding for childbirth and not abortion. The state may not constitutionally create obstacles to abortion, but it has no obligation to remove obstacles not of its own making, such as poverty.

Three years after the Connecticut decision, **the Court upheld the Hyde amendment, which prohibited federal funding for medically necessary abortions. Under this ruling, even low-income women who would have devastating health outcomes if they continued a pregnancy could not have an abortion paid for by Medicaid.** In both cases, the Court ruled that the government could make “a value judgment favoring childbirth over abortion and [implement] that judgment by the allocation of public funds.” Because the federal government did not make the women poor, and because poverty was their obstacle, no

constitutional requirement exists for the federal government to fund any abortion. Federal funding is a political question to be decided by Congress.

The U.S. Senate bill on health insurance reform, which Majority Leader Harry Reid (D-NV) created by blending bills from two committees, did not contain the Stupak amendment but specifically excluded federal funding for abortions as prohibited by any federal law—including the Hyde amendment—in effect “6 months before the beginning of the plan year involved.” States must also ensure that “no federal funds pay or defray the cost” of abortion services in new health plans that cover abortion.

Three major questions were raised about the differences between the House and Senate approaches: Did they fulfill Obama’s no-federal-funding promise? Did they follow the Hyde amendment “tradition”? And did they represent good health insurance policy? As for the first question, the Senate version fulfilled the President’s promise by requiring abortion funding to come from sources other than federal tax dollars. This aspect of the provision was denigrated as a “bookkeeping trick,” but even federal employees who pay for abortions with their government salaries are using funds that came from federal tax dollars. As for the second question, the Stupak amendment goes far beyond the Hyde amendment by prohibiting the use of federal tax dollars not only for abortion itself but also for any health plan available on the proposed exchanges that covers abortion. The goal is to limit access to abortion even when no federal funds are being used for it. The third question relates to public health policy. The Hyde amendment institutionalizes the moral view of some members of Congress that even medically necessary abortions should not be considered health care. After the Democrats lost Ted Kennedy’s Senate seat in a special election in Massachusetts—and with it, the 60 votes needed to end a filibuster—the bill previously passed by the Senate became the vehicle for health insurance reform, and a budget “reconciliation” measure (requiring only 51 votes for Senate passage), negotiated by Democratic House and Senate leaders, was used to make modifications to the Senate bill to make it acceptable to the House.

Because the Stupak-Pitts abortion language was not in the Senate bill, it was uncertain whether the 216 House votes needed for passage could be found. **Stupak himself ultimately agreed to vote for the Senate bill as long as President Obama signed an executive order agreeing not to use any aspect of the legislation to fund abortions.** The bill ultimately passed 219 to 212, which suggests that the votes of Stupak and his colleagues were essential. President Barack Obama signed the executive order on March 24 at a private White House event.

**Two abortion-related battles followed: the first directly involved the Affordable Care Act (ACA) and its contraception coverage, the second involved research on human embryos.** We deal with the ACA controversy first. The ACA’s goal is to make comprehensive health insurance available to all Americans. For women, this includes the provision of contraception. Under Health and Human Services (HHS)—promulgated regulations, insurance coverage must include 20 specific contraceptives as recommended by an Institute of Medicine (IOM) panel. Two corporations objected to providing four of these contraceptives, two types of intrauterine devices (IUDs) and the emergency contraceptive Plan B (levonorgestrel) and Ella (ulipristal) to their employees because they believed they could induce abortion.

When it got to the U.S. Supreme Court,<sup>18</sup> the case was based not on the Constitution but on a federal statute, the 1993

Religious Freedom Restoration Act (RFRA), which states that “government shall not substantially burden a person’s exercise of religion even if the burden results from a rule of general applicability [unless it] is in furtherance of a compelling governmental interest and is the least restrictive means of furthering that ... interest.” For RFRA to be relevant, the term “person” must include for-profit corporations. Corporations are legal fictions created entirely by law to protect the interests of real people, including the shareholders and officers of the corporation. Nonetheless, and surprisingly (at least to us), the Court determined that for-profit corporations were persons under the Act and thus could have religious views that the state had to respect.

This left only two remaining legal issues: first, does the state have a compelling interest in covering all 20 contraceptives, and second, is the method of requiring that they be included in employer-provided health insurance policies the “least restrictive means” to do this? The Court quickly answered the first question yes and moved on to the question of least restrictive means, to which it answered no, because the government could accommodate corporations with religious views by granting them an exemption and creating an alternative funding mechanism for the four contraceptives in dispute. This conclusion got five votes but did not satisfy any of the Court’s three women justices. For them and Justice Stephen Breyer, Justice Ruth Bader Ginsburg wrote a stinging dissent, noting that the “ability to control their reproductive lives” is central to the ability of women to gain equality in “the economic and social life of the Nation.” She also noted that although the majority tried to confine its reasoning to four of the 20 FDA-approved contraceptives, “the Court’s reasoning appears to permit commercial enterprises ... to exclude from their group health plans all forms of contraceptives.” This she added was “a substantial burden on women, especially those earning low wages.”

In terms of health care, **the reaction of the ACOG to the opinion seems just about right to us: “This decision inappropriately allows employers to interfere in women’s health care decisions ... which should be made by a woman and her doctor, based on the patient’s needs and her current health.”** The ACOG went on to underline that contraceptives and family planning are mainstream medical care and should be treated as such. In their words, **“access to contraception is essential women’s health care.”**

## HUMAN EMBRYONIC STEM CELL RESEARCH FUNDING<sup>19,20</sup>

Embryo research was born political. Expressions of shock and surprise at the 2010 ruling of Federal District Court Judge Royce Lamberth that enjoined federal funding of stem cell research, which was based largely on his reading of an amendment to an appropriations bill, were thus not terribly persuasive. The amendment, known as the **Dickey-Wicker amendment**, provides that **no federal funds can be expended by the National Institutes of Health (NIH) for “1) the creation of a human embryo or embryos for research purposes; or 2) research in which a human embryo or embryos are destroyed, discarded, or knowingly subjected to risks of injury or death.”** The creation and destruction of human embryos for research are deeply tied not only to political and religious debates concerning abortion but also to assisted reproductive technology (ART). In 1979, during the Carter administration, the Ethics Advisory Board of the Department of Health, Education, and Welfare

(forerunner of the Department of Health and Human Services) recommended that the government support research on embryos in order to study and improve ART. Federal research funding was never authorized, and in vitro fertilization (IVF) was introduced into clinical medicine without a research phase. The Reagan administration dissolved the ethics board and ignored its recommendations. The issue was next taken up during the Clinton administration by an NIH Human Embryo Research Panel, which voted on 27 goals of embryo research and recommended seven of these as “acceptable for federal funding” but failed to produce a credible ethical justification for its recommendations, which were widely ignored.<sup>21</sup> Congress, however, responded to the report, and in 1996, President Clinton signed the first appropriations bill containing the Dickey-Wicker amendment, named for its sponsors, Representatives Jay Dickey (R-AR) and Roger Wicker (R-MS). It has been added to NIH appropriations bills every subsequent year, just as the Hyde Amendment restricting abortion funding is added.

The derivation of stem cells from embryos involves destroying the embryo. In 2001, President George W. Bush authorized federal funding for human embryonic stem cell (ESC) research but limited it to cell lines that had been derived before his August 9, 2001 speech—and specifically to cell lines from surplus IVF embryos used with the consent of the couple whose egg and sperm were used to create them. No one challenged this policy as a violation of Dickey-Wicker, perhaps because, as Bush said, the “life and death decision” for these embryos had already been made.

President Barack Obama was well aware that federal funding of ESC research represents a political flash point, but he had promised to rescind the Bush policy, and expanded federal funding of ESC research is widely supported. When Obama announced his new policy to authorize funding for cell lines derived after August 2001, if derived from surplus IVF embryos without the use of federal funds, he knew he could be reawakening the funding debate. He expressed his hope that “Congress will act on a bipartisan basis to provide further support for this research.”

Congress did not act. Instead, the debate shifted to the courts, where the core question was whether the new Obama guidelines are consistent with Dickey-Wicker. Lamberth said he believes Dickey-Wicker is “unambiguous” and does not permit the NIH “to separate the derivation of ESCs from research on the ESCs” because “derivation of ESCs from an embryo is an integral step in conducting ESC research.” The Obama administration appealed. **The Obama administration’s guidelines are based on the political compromise of deriving ESCs only from surplus IVF embryos, and as part of this compromise, the NIH seemed to have conceded that derivation is an integral part of stem cell research, which is why it sets strict limits on the source of the embryos used and the quality of consent obtained.** The political argument for permitting the use of surplus IVF embryos is that these embryos were created for a legitimate reproductive purpose, and when they are no longer wanted for that purpose, their donation for research is ethically preferable to their destruction without any potential societal benefit.<sup>21</sup> Of course, anyone who objects to the creation of embryos for IVF would also object to this compromise. Does Dickey-Wicker permit this political compromise as a matter of law?

President Clinton’s National Bioethics Advisory Commission argued in 1999 that it was not ethically reasonable to separate

the derivation of stem cells for research from their use in research. The commission believed that the federal government should fund both, for at least as long as the embryos used were those “remaining after infertility treatments.” Their reasons were “the close connection in practical and ethical terms between derivation and use of the cells” and the hope that permitting funding for cell derivation could advance science in this area. Lawyers asked by the commission to examine the meaning of Dickey-Wicker concluded that the NIH’s distinction between derivation and use of human ESCs was a “reasonable” interpretation of the amendment—but that “there is no indication that either proponents or opponents [of ESC research] contemplated the situation ... in which research that destroyed the embryo was separately conducted from research using the cells derived from the embryo.”<sup>22</sup>

The Clinton panel’s report got less attention than it deserved because at that time the national debate was focused on creating research embryos through cloning (somatic cell nuclear transfer). Bush’s Council on Bioethics concentrated on cloning, but it was also the only national ethics panel ever to discuss federal funding as an ethical, rather than political, issue. It concluded that “the decision to fund an activity is ... a declaration of official national support and endorsement, a positive assertion that the activity in question is deemed by the nation as a whole ... to be good and worthy.” Such rhetoric seems disconnected from special-interest legislation<sup>23</sup>; a more honest statement regarding federal funding is that since *Roe v. Wade*, funding for anything remotely related to abortion—and because no one is pregnant, embryo research is indeed only remotely related—has become a potent political liability in Congress. Obama’s own ethics panel sensibly stayed out of this political funding debate.

**Three paths were open to proponents of federal funding for human ESC research:** The first was to mount a vigorous defense in the lawsuit, aiming to persuade the courts that the Obama administration’s interpretation of Dickey-Wicker is correct. This strategy ultimately succeeded, and the federal Court of Appeals ruled 2 to 1 in 2011 that Dickey-Wicker permitted the funding of research on human ESCs that had been derived from leftover IVF embryos by nonfederal employees who did not use federal money. We thought this opinion was solid at the time and would prevail, and it has. Nevertheless, we also thought it was reasonable for the Obama administration to seek congressional authorization for its current regulations. However, because this approach would retain Dickey-Wicker and could thus lead to more legal challenges, it would be preferable—and probably more politically feasible—to amend Dickey-Wicker by adding language such as the following: “Nothing in part 2 prohibits the NIH from funding research using embryos created for procreation, including the derivation of stem cells, when the couple no longer wants to use them for procreation and has provided their informed authorization for them to be used in NIH-funded research.” Amending the language in this manner would legislatively adopt the ethics position of the Clinton bioethics commission. The third path is continued reliance on private and state funding until sufficient scientific progress is made such that the public demands federal funding for this research.

NIH Director Francis Collins has said that this issue “goes beyond politics ... to patients and their families who are counting on us to do everything in our power, ethically and responsibly, to learn how to transform these cells into entirely new therapies.” This argument, of course, is itself political; and if

Collins is right, **the only place to ultimately resolve the funding issue is in Congress.**

## GENETIC COUNSELING, SCREENING, AND PRENATAL DIAGNOSIS<sup>24-26</sup>

In 2013, the American College of Medical Genetics and Genomics (ACMG) opposed legal restrictions on abortion following prenatal diagnosis.<sup>27</sup> The College noted that the entire practice of medical genetics is to provide patients with information to enable the pregnant couple “to choose a safe and personally acceptable management plan” and concluded that “termination of pregnancy for genetic disorders or congenital anomalies that may be diagnosed prenatally is a critically important option ...” This statement was prompted by the passage of a North Dakota law outlawing abortion for a “genetic abnormality” defined as “any defect, disease, or disorder that is inherited genetically.” The law also has its own nonexclusive list of prohibited indications for abortion: “Any physical disfigurement, scoliosis, dwarfism, Down syndrome, albinism, or any other type of physical or mental disability, abnormality or disease.” This law, and proposals like it, are a direct response to the increasing number of genetic tests that can be performed on fetuses and thus the increasing number of conditions for which pregnant women might decide to terminate their pregnancies. North Dakota Governor Jack Dalrymple said he signed this law to challenge the “boundaries of *Roe v. Wade*.” **We have not had to decide what genetic conditions justify abortion before, but the rapid expansion of genetic tests of the fetus makes this a compelling contemporary quandary. Can we simultaneously reject eugenics and discrimination and at the same time provide pregnant women with ever more genomic information about their fetuses?**

Twenty years after *Roe*, a committee of the IOM suggested clinical guidelines for prenatal diagnosis. The committee prophetically anticipated that many more genetic tests would be developed and that “eventually technologies will be available to simultaneously test for hundreds of different disease-causing mutations, either in the same or different genes.” **The committee’s recommendations, which remain valid today, include the following:**

- Patients must be fully informed about the risks and benefits of testing procedures, their possible outcomes, and alternatives.
- Prenatal diagnosis should only be offered for the diagnosis of genetic disorders and birth defects, not for minor conditions or characteristics or for fetal sex selection.
- Education before and after prenatal screening should be available to patients, and ongoing counseling should be available following pregnancy termination.
- Reproductive genetic services should not be used for the eugenic goal of “improving” the human species.

The recommendations became the foundation upon which professional organizations, most importantly the ACOG and the ACMG, built their own guidelines for prenatal diagnosis. These professional guidelines are used by physicians as the standard of care for their patients. The amount of genetic information that can be obtained from fetuses is so great that it is often difficult for anyone to interpret its meaning or assess the variability and uncertainty of any genetic findings. Sometimes, however, prenatal diagnosis can identify a serious condition, and this information could lead a couple to terminate a pregnancy. The ability

to determine the health of the fetus also permits couples who would not otherwise take a chance on having a baby because of the high risk of a serious genetic condition, such as Tay-Sachs disease, to have children without risking birth of an affected child.

*Chromosomal microarray analysis* (CMA) detects not only entire extra or missing chromosomes but also small losses and gains of segments of DNA throughout the genome, whereas *karyotype analysis* allows detection of extra or missing fragments of chromosomes but only those large enough to be seen under a microscope. These losses and gains of segments of DNA are referred to as *copy number variants* (CNVs), and they can lead to genetic disorders associated with significant disabilities. The National Institute of Child Health and Human Development (NICHD) conducted a large study ( $n = 4406$ ) to compare microarray analysis to karyotype analysis. Samples were split two ways in this study of women undergoing either chorionic villus sampling (CVS) or amniocentesis: standard karyotyping was performed on one portion, and microarray analysis on the other. In 1 in 60 cases in which the karyotype was read as “normal,” microarrays revealed a clinically important CNV. When prenatal diagnosis was prompted by a structural abnormality of the fetus seen on an ultrasound and the karyotype was interpreted as “normal,” microarray analysis revealed a CNV in almost one in 17 cases.<sup>28</sup> **Clinical dilemmas are sometimes encountered when CMAs show a variant of unknown (or uncertain) significance (VOUS),** a change in DNA that has not yet been reliably characterized as benign or pathogenic. Sometimes the answer to the question, “What is the chance of this VOUS leading to a significant problem in my baby?” is that we just do not know. The vast majority of such variants are likely to be just benign variants of no clinical consequences. On the other hand, even if a VOUS is inherited from an apparently “normal” parent, the CNV may cause serious congenital and developmental abnormalities in the child. In such cases, finding a VOUS could lead to questioning whether the parent who transmitted the VOUS is really “normal,” or if we need to search for health problems that have not been recognized. In the NICHD study, a VOUS was found in 3.8% of all cases where the karyotype was read as “normal.”

The limited time available for decision making makes gathering information quickly imperative, which includes the requirement for testing the parents to determine whether the fetal findings are inherited. Even when a CNV is known to be associated with a well-described genetic syndrome, making a decision about continuing the pregnancy may still be fraught with uncertainty. Genomic information possesses a mythology of precision and determinativeness that it does not deserve. As the medical literature and databases associated with CNVs expand, such diagnostic uncertainties will be less frequent, but they will still occur. While studies continue, **ACOG has recommended that couples who choose chromosomal microarrays should receive both pretest and posttest genetic counseling.** Prenatal counseling is usually described as “nondirective,” (i.e., neither for nor against termination of the pregnancy), but this term has no meaning in the context of a genomic VOUS. Physicians must share the uncertainty of diagnosis with their patients and must advise them as best they can without guaranteeing a healthy baby.

For more than three decades, finding a noninvasive way to analyze the genetic makeup of the fetus by identifying fetal cells in the blood of the pregnant woman has been a scientific quest

because it could permit prenatal diagnosis without any risk to the fetus. The quest to dependably collect fetal cells from maternal blood has been taken up by private biotech companies. In 1997, it was first reported that fragments of cell-free fetal DNA (cfDNA) circulate in the maternal blood during pregnancy beginning in the early first trimester. About 10% of the DNA in maternal plasma is now known to be of placental origin. This offers the possibility of noninvasive prenatal diagnosis by taking a blood sample from the pregnant woman. The technology currently used for commercial testing is *massively parallel genomic sequencing*.

**Within the next few years, noninvasive prenatal detection for the majority of recognized genetic disorders will likely become a reality.** The fact that the entire fetal genome is represented in maternal blood opens up the possibility of obtaining fetal DNA fragments that can be assembled into a complete fetal genome readout. A number of substantial hurdles, including the availability of genetic counseling, remain before noninvasive fetal whole-genome sequencing is introduced into clinical practice. First, the cost will have to drop substantially. In this regard, targeting selected genomic regions may prove more efficient and cost effective than deriving the whole genome. On the other hand, isolating and analyzing fetal cells from maternal blood would be more straightforward and presumably less costly. Will noninvasive prenatal testing become “normalized” and routine because of its ease and safety? We think it is inevitable that reasonably priced and accurate genetic and genomic tests based on fetal cells or cfDNA extracted from maternal blood will be offered to all pregnant women. The primary motivation, however, will likely not be medical practice standards but fear of medical malpractice lawsuits. **Obstetricians will likely fear a malpractice lawsuit if a fetus is born with a genetic abnormality, the test for which the couple can credibly explain to a jury that they would have obtained, had they known about it, and that they would have terminated the pregnancy had they known the fetus had the particular genetic condition.** We both believe that physician fear of the extremely unlikely prospect of such a lawsuit is a terrible way to set medical practice standards. **Rather we support professional organizations that set screening standards for their members—and that their members follow them.**

Our current model for prenatal screening and diagnostic testing requires pretest counseling prior to obtaining informed consent, and the obligation to counsel can be seen as inherent in the fiduciary nature of the doctor-patient relationship. For ordinary medical procedures, the physical risks and treatment alternatives—those things that might lead a patient to reject therapy or choose an alternative—are the primary items of information that must be disclosed and should be discussed. Self-determination and rational decision making are the central values protected by informed consent. In the setting of reproductive genetics, what is at stake is the right to decide whether to have genomic testing with emphasis on the right to refuse if the potential harm in terms of stigma or unacceptable choices, including abortion, outweighs the potential benefit for the individual or her family.

New genomic screening and diagnostic tests—including exome and whole-genome sequencing, addressed in [Chapter 10](#)—will compete for introduction into routine clinical practice. Some of the critical questions include what information should be provided to which patients, when it should be provided,

and how and by whom it should be conveyed. It will soon be impossible to do meaningful counseling about all available genomic testing. Giving too much information (information overload) can amount to misinformation, and it can make the entire counseling process misleading or meaningless. **To prevent disclosure from being pointless or counterproductive, we believe that information-sharing strategies based on general or “generic” consent should be developed for genetic and genomic screening and diagnostic testing.** Their aim would be to provide sufficient information to permit patients to make informed decisions yet avoid the information overload that could lead to “misinformed consent.”

Traditionally, the goals of reproductive genetic counseling are to help the person or family to:

*Comprehend the medical facts*, including the diagnosis, the probable course of the disorder, and the available management choices

*Appreciate the way heredity contributes to the disorder* and the risk of recurrence in specified relatives

*Understand the options* for dealing with the risk of recurrence

*Choose the course of action* most appropriate to them in view of their risk and their family goals and act in accordance with that decision

*Make the best possible adjustment* to the disorder in an affected family member and/or to the risk of recurrence of the disorder

Even knowledgeable couples can become confused, frustrated, and anxious if faced with multiple options for genetic screening and testing. **An approach based on “generic consent,”** which we described in the *New England Journal of Medicine* 20 years ago and still believe in, would not even attempt to describe each of hundreds or thousands of genetic conditions and anomalies to be screened and tested for; instead, **it would emphasize broader concepts and common-denominator issues in genetic and genomic screening.**

We envision a doctor-patient relationship in which patients are told of the availability of a panel of genetic and genomic tests that can be performed on a single blood sample, either for carrier screening or for noninvasive prenatal testing. Couples would be told that these tests would focus on disorders that involve serious physical abnormalities, mental disabilities, or both. Several common examples would be given to indicate the frequency and spectrum of severity of each type or category of genetic condition for which screening or diagnostic testing was being offered. Conditions such as spina bifida and cleft lip, chromosome abnormalities such as Down syndrome and trisomy 18, and single gene disorders such as cystic fibrosis and Tay-Sachs disease might be chosen as representative examples.

**In the course of counseling, important factors common to all prenatal screening and diagnostic tests would be highlighted.** Among these are their limitations, especially the fact that negative results cannot guarantee a healthy infant. For screening tests, the couple needs to know that additional invasive tests may be needed to establish a diagnosis or clarify confusing or uncertain results. Other considerations that need to be discussed are the costs of testing; options such as adoption, egg or sperm donation, abortion, or acceptance of risks; and issues of confidentiality, including potential disclosure of the results to other family members. If the testing is for carrier status, and a recessive gene is detected in the woman, it must be emphasized that her partner should also be screened.

**For prenatal diagnosis, couples should understand that abortion of an abnormal fetus is available, but it is not the only option.** For couples who find abortion unacceptable for any indication, prenatal diagnosis may still provide important information. For example, if it becomes known that a baby will be delivered with serious birth defects, choosing to deliver at a tertiary medical center that offers specialized care may optimize the infant's outcome. In some cases, knowing that the fetus has a very serious and incurable disorder may alter the obstetric care for the mother. For example, if the fetus has trisomy 18, the likelihood is high that fetal heart monitoring during labor would show an abnormal tracing. Knowing that the fetus has trisomy 18 could avert performing a cesarean delivery because it would not benefit the infant.

**Generic consent to genetic carrier screening and diagnostic testing can be compared with obtaining consent to perform a routine physical examination.** Patients know that the purpose of the examination is to locate potential problems likely to require additional follow-up, which could present them with choices they would rather not have to make; essentially, the doctor is looking for trouble, and the patient is hoping no trouble will be found. However, the patient is not generally told about all the possible abnormalities that can be detected by a routine physical examination or routine blood work, only the general purpose of each. On the other hand, **tests that may produce especially sensitive and stigmatizing information, such as screening of blood for the human immunodeficiency virus (HIV, see Chapter 52), should not be performed without specific consent. Similarly, because of its reproductive implications, genetic testing has not traditionally been carried out without specific consent.**

What is central in generic consent for genetic and genomic screening and diagnostic testing is not a waiver of the individual patient's right to information. Rather generic consent would reflect **a decision by the medical community that we believe is consistent with the physician's fiduciary obligations to the patient; it is a decision that patients would likely support, that the most reasonable way to conduct genetic and genomic screening and diagnostic testing for multiple diseases simultaneously is to provide basic, general information to obtain consent for the testing and much more detailed information on specific conditions only after they have been detected.** In the vast majority of cases, no such conditions will in fact be found, so this method is also the most efficient and cost effective.

Some patients may require more specific and in-depth information on which to base their decision regarding testing. It is therefore essential to build into the testing program ample opportunity for patients to obtain all the additional information they want or need to help them make decisions. Clinicians, of course, must be open and responsive to the concerns and questions of patients. Counseling could be provided in person by a physician or other health professional. Alternatively, Internet-based audiovisual aids could be used to help ensure consistency in the information provided, improve efficiency, and help respond to the shortage of genetic counselors.

Generic consent for genetic and genomic screening and diagnostic testing should help prevent information overload and wasting time on useless information, especially for carrier screening. It would not, however, solve what is likely to be an even more central question in prenatal genetic testing: **Are there genetic conditions for which testing should not be offered to**

**prospective parents?** Examples might include genes that predispose a person to a particular disease that will not appear until late in life such as Alzheimer disease, Parkinson disease, or breast cancer. From the perspective of the fetus, life with the possibility or even a high probability of developing these diseases in late adulthood is much preferred to no life at all. Thus in this case—unlike that of the fetus with trisomy 18, for example—no reasonable argument could be made that precluding abortion by denying this information could amount to forcing a “wrongful life” on the child.

**We should, nonetheless, directly and publicly address the question of whether conditions should exist for which screening of prospective parents or testing of fetuses should not be offered as a matter of good medical practice and public policy regardless of the technical ability to do such testing or the wishes of the couple.** Offering genetic and genomic screening and diagnostic testing to assist couples in making reproductive decisions is not a neutral activity; rather it implies that some action should be taken on the basis of the results of the test. Simply offering carrier screening for breast cancer or colon cancer genes in the context of preconception care, for example, suggests to couples that artificial insemination, adoption, and even abortion are all reasonable choices if they are found to be carriers of such genes. On the other hand, because of a personal experience with a family member who suffered from one of these adult-onset diseases, a particular couple might see abortion as a reasonable choice under such circumstances, and a practice of keeping such information away from all couples would not be justified. However, **in general we do not believe that pregnancies in women who want to have a child should be terminated for adult-onset diseases. We are all going to die of something, and if we live long enough, that something will have a major genetic component; there can be no perfect genome, and the search for it in a fetus will inevitably fail.**

A standard of care for genomic screening and diagnostic testing will inevitably be set, as will a standard for informed consent in the face of hundreds or thousands of available genomic tests. We believe the medical profession should take the lead in setting such standards, and with public input and support, the model of generic consent for genomic screening and diagnostic testing will ultimately be accepted. Other regulators, including the Food and Drug Administration (FDA), will increasingly be involved in setting standards for genomic testing done outside of a physician-patient relationship, usually referred to as *direct-to-consumer* (DTC). In mid-2013, for example, the genetic-testing company 23andMe began running a compelling national television commercial. The ad featured attractive young people saying that for \$99, you could learn “hundreds of things about your health,” including that you “might have an increased risk of heart disease, arthritis, gallstones, and hemochromatosis.” It was the centerpiece of the company’s campaign to sign up a million consumers. In November, the FDA sent 23andMe a warning letter, ordering them to “immediately discontinue marketing the PGS [Saliva Collection Kit and Personal Genome Service] until such time as it receives FDA marketing authorization for the [class III] device.” One month later, the company announced that it was complying with the FDA’s demands and discontinued running its TV commercial.

The 23andMe services rely on single nucleotide polymorphism (SNP) technology to identify genetic markers associated with 254 specific diseases and conditions, although the list has

grown over time. The company Web page now boasts “Ongoing reports provided to you as new genetic discoveries are made and as we are able to clear new reports through the FDA.” In the past, it said their service could inform people about their health and how to take steps to improve it. In the words of 23andMe’s TV commercial, “Change what you can, manage what you can’t.” The FDA wrote that its main concern was that 23andMe failed to supply any indication that it had “analytically or clinically validated the PGS for its intended uses.” The page now states that its service includes “reports that meet FDA standards for being scientifically and clinically valid.” The FDA has not yet developed rules for DTC genetic testing, and whether government regulation or private litigation will determine the future contours of DTC genomic sequencing will probably depend on the extent to which consumers and physicians support government regulation.

**23andMe had previously framed DTC genetic testing as consumer empowerment that gave people direct access to their genetic information without requiring them to go through a physician or genetic counselor.** To oversimplify, the debate has been framed as a struggle between medical (or government) paternalism and an individual’s right to their own information. In this sense, it is not so different from the older debate about whether patients should have direct access to their medical records and test results, which was ultimately resolved in favor of direct patient access. We think the day will come when this framing is appropriate, but not until the diagnostic and prognostic capability of genomic information has been clinically validated.

It seems reasonable to predict, for example, that in the next decade or even sooner, a majority of health plans will make it easy for their members to have their entire genome sequenced and linked to their electronic health record, and they will provide software to help their members interrogate their own genomes with or without the help of their physician or a genetic counselor supplied by the health plan. This service will, of course, require a massive data bank of genome reference materials, and the FDA and the National Institute for Standards and Technology are working to establish such a data bank. **Unless genomic tests have been validated, however, genomic information can be misleading or just plain wrong, and this can cause more harm than good in health care settings.** In most cases, family history is likely to be at least as informative about an individual’s health risks as SNP-based testing such as that used by 23andMe. In this regard, the FDA’s censoring of 23andMe’s PGS advertising did not deprive people of useful information; the agency merely asserted its requirement that companies that want to sell their health-related medical devices to the public demonstrate to the FDA that they *work*—in this case, that the tests do what the company asserts that they do. That is traditional consumer protection and what the public expects from the FDA.

Privacy is a closely related issue. How can the extremely private and personal information locked in our DNA be protected from others’ using it without our consent for their own purposes or making it available to people or organizations who could use it against us, such as by denying us life or disability insurance? For example, 23andMe has suggested that its longer-range corporate goal is to collect a massive biobank of genetic information that can be used and sold for medical research and could also lead to patentable discoveries. Such uses seem reasonable so long as the consent of the DNA donors is properly obtained and their privacy is protected. Both of these

requirements are, however, much more difficult to uphold than 23andMe seems to realize.

**Informed consent to genomic testing is currently the subject of a wide-ranging debate**, touched off by testing policies published by the ACMG that require that when a physician orders a clinical sequencing test, the testing lab must also test for pathogenic (or probably pathogenic) mutations in 56 genes related to 24 serious disorders. The original report suggested doing away with informed consent, but a later revision included an opt-out provision. People have both a right to know what will be done to diagnose their condition and a right *not* to know information about their genetic predispositions if they do not want to know it. Here, 23andMe had adopted a more rights-respecting mode, telling customers what they will be looking for before they sign up for the genetic testing and giving them a second chance not to find out about the results of specific tests—such as tests for the breast-cancer mutations, Parkinson disease, and Alzheimer disease—after the test is done.

**Whether ordered by physicians or by consumers online, whole-genome screening will require more sophisticated informed consent protocols**, and we believe that individuals should also retain the right not to have specific genes sequenced at all. Geneticist James Watson set a reasonable standard for nondisclosure when he authorized the publication of his entire genome with one exception: he still refuses to have his apolipoprotein E (*APOE*) status determined because he does not want to know if he is at higher-than-average risk for developing Alzheimer disease. That should be his right and the right of every patient or consumer.

Because of the company's aggressive marketing and refusal to continue negotiations, the FDA shut 23andMe down temporarily. In 2015, the FDA decided it was ready to permit 23andMe to market genetic tests for autosomal recessive disease that could be used by couples to determine whether they both carried such a gene, which would give them a one in four chance of having an affected child. The shutdown provided the opportunity for a serious dialog that could be a basis for setting standards for the entire industry. It could also be a catalyst for creating a regulatory framework for whole-genome-sequencing platforms, which are the future of genomics.<sup>1</sup> It's already a commonplace observation that we will soon have "the \$1000 genome with the \$1,000,000 interpretation." Put another way, **it is not the cost of the sequencing or the SNP testing that is at the heart of this debate; it is whether the genomic information produced by that sequencing can be used in ways that improve our health.** The goal of both the FDA and 23andMe should be to ensure that genomic information is both accurate and clinically useful. Clinicians will be central to helping consumer-patients use genomic information to make health decisions. Any regulatory regime must recognize this reality by doing more than simply adding the tag line "Ask your physician" on most consumer ads for prescription drugs.

## FORCED CESAREAN DELIVERY

Almost 25 years ago, Kolder and colleagues<sup>29</sup> reported a U.S. national survey revealing that court orders had been obtained for cesarean deliveries in 11 states for hospital detentions in two states and for intrauterine transfusions in one state. Among 21 cases in which court orders were sought, the orders were obtained in 86%; in 88% of those cases, the orders were received within 6 hours. Most of the women involved were black, Asian, or

Hispanic, and all were poor. Nearly half were unmarried, and one fourth did not speak English as their primary language. In the survey, they also found that 46% of the heads of fellowship programs in maternal-fetal medicine thought that women who refused medical advice and thereby endangered the life of the fetus should be detained, and 47% supported court orders for procedures such as intrauterine transfusions. Until 1990, with the exception of one case in the Georgia State Supreme Court, all cases had been decided by lower courts and therefore had little precedential importance.<sup>30</sup> In most cases, judges were called on an emergency basis and ordered interventions within hours. The judge usually went to the hospital. **Physicians should know what most lawyers and almost all judges know: when a judge arrives at the hospital in response to an emergency call, he or she is acting much more like a lay person than a jurist.** Without time to analyze the issues, without representation for the pregnant woman, without briefing or thoughtful reflection on the situation, in almost total ignorance of the relevant law, and in an unfamiliar setting faced by a relatively calm physician and a woman who can easily be labeled "hysterical," the judge will almost always order whatever the doctor advises.

**There is nothing in *Roe v. Wade*,<sup>2</sup> or any other appellate decision, that gives either physicians or judges the right to favor the life or well-being of the fetus over that of the pregnant woman.** Nor is there legal precedent for a mother being ordered to undergo surgery (e.g., kidney or partial liver transplantation) to save the life of her dying child. It would be ironic and inconsistent if a woman could be forced to submit to more invasive surgical procedures for the sake of a fetus than for a child. Forcing pregnant women to follow medical advice also places unwarranted faith in that advice. Physicians often disagree about the appropriateness of obstetric interventions, and they can be mistaken.<sup>31</sup> In three of the first five cases in which court-ordered cesarean delivery was sought, the women ultimately delivered vaginally and uneventfully. In the face of such uncertainty—uncertainty compounded by decades of changing and conflicting expert opinion on the management of pregnancy and childbirth—the **moral and legal primacy of the competent, informed pregnant woman in decision making is overwhelming.**<sup>32</sup>

Physicians may feel better after being "blessed" by the judge, but they should not. First, the appearance of legitimacy is deceptive; the judge has acted injudiciously, and no opportunity for meaningful appeal exists. Second, the medical situation has not changed except that more time has been lost that should have been used to continue discussion with the woman directly. Finally, the physician has now helped to transform himself or herself into an agent of the state's authority.<sup>32</sup>

The question of how to deal with a woman who continues to refuse intervention in the face of a court order remains. Do we really want to attempt to restrain and forcibly medicate and operate on a competent refusing adult? Although such a procedure may be legal, it is hardly humane. It is not what one generally associates with modern obstetric care, and it has the potential to cause harm. It also encourages an adversarial relationship between the obstetrician and the patient. Moreover, even from a strictly utilitarian perspective, this marriage of the state and medicine is likely to harm more fetuses than it helps because many women will quite reasonably avoid physicians altogether during pregnancy if failure to follow medical advice can result in forced treatment, involuntary confinement, or criminal charges.

**Extending notions of child abuse to “fetal abuse” simply brings government into pregnancy with few if any benefits and with great potential for invasions of privacy and deprivations of liberty.** It is not helpful to use the law to convert a woman’s and society’s moral responsibility to her fetus into the woman’s legal responsibility alone.<sup>29</sup> After birth, the fetus becomes a child and can and should thereafter be treated in its own right. Before birth, however, we can obtain access to the fetus only through its mother and, in the absence of her informed consent, can do so only by treating her as a fetal container, a nonperson without rights to bodily integrity.

**In 2005, the ACOG revised and updated its 1987 Ethics Committee report on “Patient Choice: Maternal Fetal Conflict,” now titled “Maternal Decision Making, Ethics, and the Law,”<sup>33</sup> which we believe provides thoughtful and useful guidance for the medical practitioner.** The statement highlighted six considerations that we combine into three:

1. Coercive and punitive legal approaches to pregnant women who refuse medical advice fail to recognize that all competent adults are entitled to informed consent and bodily integrity.
2. Court-ordered interventions in cases of informed refusal, as well as punishment of pregnant women for their behavior that may put a fetus at risk, neglect the fact that medical knowledge and predictions of outcomes in obstetrics have limitations ... [and treat medical problems] as if they were moral failings.
3. Coercive and punitive policies are potentially counterproductive in that they are likely to discourage prenatal care and successful treatment, adversely affect infant mortality rates, and undermine the physician-patient relationship ... [and] unjustly single out the most vulnerable women ... and create the potential for criminalization of many types of otherwise legal maternal behavior.

Based on these, the Committee on Ethics made four recommendations, the most central of which are:

1. Pregnant women’s autonomous decisions should be respected. ... In the absence of extraordinary circumstances, circumstances that, in fact, the Committee cannot currently imagine, judicial authority should not be used to implement treatment regimens aimed at protecting the fetus, for such actions violate the pregnant woman’s autonomy.
2. Pregnant women should not be punished for adverse perinatal outcomes.
3. Policymakers, legislators, and physicians should work together to find constructive and evidence-based ways to address the needs of women with alcohol and other substance abuse problems.

This 2005 statement is even stronger than a 1990 opinion by the District of Columbia Court of Appeals, which ruled that the decision of the pregnant woman must be honored in all but “extremely rare and truly exceptional” cases.<sup>34</sup> ACOG’s Ethics Committee “cannot currently imagine” what that “rare and truly exceptional” case might look like.

liberty” that is “broad enough to encompass a woman’s decision whether or not to terminate a pregnancy” before fetal viability without state interference.

- ◆ In *Planned Parenthood of Southeastern Pennsylvania v. Casey* (1992), the U.S. Supreme Court reaffirmed the “core” of *Roe v. Wade* and ruled that before fetal viability, states cannot “unduly burden” a woman’s decision to terminate a pregnancy (i.e., although consent and waiting periods may be constitutionally acceptable, states cannot regulate abortion in ways that will actually prevent women from obtaining them).
- ◆ *Roe* and *Casey* are critical to understanding the rights of obstetricians, which are derived from the rights of their patients, because they are the major sources of law regarding how far states can go to regulate decisions made in the obstetrician-patient relationship.
- ◆ With the exception of a procedure Congress has labeled “partial-birth abortion,” unless they contain an exception for the health of the pregnant woman, laws that criminalize abortions are unconstitutional because they are inconsistent with both *Roe* and *Casey*.
- ◆ *Roe* has been the source of political controversy since it was decided in 1973. Congress has enacted the Hyde Amendment every year since the mid-1970s, prohibiting the use of federal funds for almost all abortions, and its constitutionality has been upheld by the U.S. Supreme Court. *Roe* motivated the exclusion of abortion funding for Obamacare and ultimately a ruling by the U.S. Supreme Court that for-profit corporations can have religious beliefs, which the government must honor, to not include contraceptive methods the corporation believes induce abortion in the health care insurance made available to their employees.
- ◆ The Hyde Amendment was the basis for another similar amendment, the Dickey-Wicker Amendment, which prohibited the use of federal funds for human embryonic stem cell research and was the basis for a temporary injunction that prohibited the NIH from funding such research in 2010 (overturned in 2011) under the Obama administration’s human embryonic stem cell research rules.
- ◆ To protect patient privacy and autonomy, no information obtained in genetic counseling or screening should be disclosed to any third party without the patient’s authorization.
- ◆ “Generic” consent for genetic screening that emphasizes broad concepts and common-denominator issues should help maximize rational decision making by preventing information overload and wasting time on useless information.
- ◆ Self-determination and rational decision making are the central purposes of informed consent, and information on recommended procedures, risks, benefits, and alternatives should be presented in a way that furthers these purposes.
- ◆ Consent of the pregnant woman is a mandatory prerequisite for both investigative procedures and therapy. Her consent must be informed, and she should be told as clearly as possible about the proposed experimental procedures or therapy, its risks to her and her fetus, and

### KEY POINTS

- ◆ In *Roe v. Wade* (1973), the U.S. Supreme Court determined that a fundamental “right to privacy existed in the Fourteenth Amendment’s concept of personal

alternatives, success rates, and the likely problems with recuperation.

- ◆ The fetal-maternal relationship is a unique one that requires physicians to promote a balance of maternal health and fetal welfare while respecting maternal autonomy. Obstetricians should not perform procedures that are refused by pregnant women, although reasonable steps to persuade a woman to change her mind are appropriate.

## MATERNAL AND REPRODUCTIVE HEALTH

This chapter can only touch the surface of the complex issues relating to the continuing yet avoidable tragedy of maternal deaths worldwide. However, for those readers for whom it provides the impetus for more in-depth study, many key documents and papers are contained within its references. First, we offer a

brief description of the main clinical, health system, and wider social causes and key actions for the prevention of deaths and obstetric complications, particularly in resource-poor countries, and conclude with a summary of the steps that need to be taken at individual, professional, facility, and health system levels and nationally and internationally to help reduce these needless deaths. The section after that provides clinical details on the challenges of preventing, identifying, and managing the main obstetric complications of pregnancy in resource-poor settings, and the final section provides some practical tips for anyone considering working abroad for longer or shorter periods of time.

## Maternal Health and the Burden of Death and Disability

*"Many Births Mean Many Burials"*

—Kenyan Proverb

Every year worldwide, around 290,000 mothers and 3 million babies die at the time of birth, and another 3 million infants are stillborn. Despite recent initiatives, which in some countries have resulted in declines in maternal death rates over the past few years, too little has happened too late. The fact is that the main causes of maternal death and preventive or remediable interventions have been well known for many years, and nearly all of these vulnerable mothers could be saved at little extra cost. Lives would be saved if women had a choice about becoming pregnant, and once pregnant, if they and their babies had access to essential health services that provide evidence-based, technologically appropriate, and affordable interventions even in the poorest countries of the world. This in turn depends on the availability of resources and the recognition and enforcement of the human rights of girls and women. For example, a recent United Nations (UN) report estimated that if all women who actually wanted to avoid pregnancy were able to access and use an effective method of contraception, the number of unintended

pregnancies would drop by 70%, and the number of unsafe abortions would drop by 74%. Further, if these women's contraceptive needs were met, and if all pregnant women and their newborn babies received the basic standards of maternity care recommended by the World Health Organization (WHO), the number of maternal deaths would fall by two thirds—from 290,000 down to 96,000—and the number of newborn deaths would fall by more than three quarters, down to 660,000.<sup>1</sup>

**Deaths are merely the tip of the iceberg. Globally it is estimated that over 300 million women are living with short- or long-term pregnancy-related complications with around 20 million new cases occurring each year.**<sup>2,3</sup> These figures do not reflect other additional yet poorly recognized burdens. In most countries postnatal depression, suicide from puerperal psychosis, and other mental health issues are not even acknowledged as pregnancy-related problems, and the stories of legions of women dying or suffering from these debilitating conditions remain untold.

Babies are affected by their mother's health in pregnancy and birth, and added to the 6 million who die before or just after birth, many more millions are left motherless and less able to thrive. The risk of death for existing children under 5 is doubled if their mother dies in childbirth, which is particularly challenging for girls.<sup>4</sup>

Every maternal death or long-term complication is not only a tragedy for the mother, her partner, and her surviving children, it is also an economic loss to her family, community, and society. Saving mothers lives is also crucial to the wider economy; for example, in Nigeria during 2005, it was estimated that maternal deaths alone led to around \$102 million in lost productivity.<sup>5</sup>

### A Place Between Life and Death

In developed countries, pregnancy is not generally considered as dangerous, and childbirth is usually regarded as a joyful and positive life-changing event. However, these 11 million births account for only 8% of the annual deliveries worldwide. The same cannot be assumed for the 92% of mothers, some 124,000 million women, living in less developed areas of the world. Of these, approximately 800 will die and 16,000 will suffer severe and long-lasting complications every day.<sup>6,7</sup> Additionally, every day, nearly 8000 babies will die around the time of birth, and another 7000 will be stillborn.<sup>8</sup> **Overall, this burden of maternal and neonatal mortality, including stillbirths, accounts for around 15,800 deaths each day, or 10 lives lost every minute.**

In Chichewa, the national language of Malawi, the word *pakati* refers to pregnancy. Its literal translation means “in the middle between life and death.” In other African countries, it is common to hear women in labor using euphemisms such as “I am going to the river to fetch water; I may not come back,” or childbirth is described as “slipping on a banana skin at the edge of a cliff with no safety net.”

These concerns are all too real for many women, and “a place between life and death” is an accurate description of the 9 months of anxiety and fear that accompany pregnancy and delivery. The World Bank classifies every economy as low, middle, or high income; it uses gross national income (GNI) per capita because GNI is considered to be the single best indicator of economic capacity and progress. Low-income and middle-income economies are collectively referred to as *developing economies*. For the 11 million mothers in high-income countries (HICs), access to quality antenatal, intrapartum, and postnatal care for both mothers and babies is readily available. Another

34 million women will deliver in middle-income countries (MICs), where hospital facilities with variable quality of care or resources such as staff, blood, drugs, or high dependency units may be available. However, for the 90 million mothers in low-income countries (LICs), the situation can be very different, with little or no access to even basic health care, which places the health of both mother and baby at significantly higher risk. The film “Why Did Mrs. X Die: Retold” is available online in several languages ([vimeo.com/50848172](https://vimeo.com/50848172)), and it provides a simple introduction.

### Where Mothers Die

Of all the maternal deaths that occur, 99% are in low and middle-income countries, the same as for newborns.<sup>6,9</sup> The WHO defines the *maternal mortality ratio* (MMR) as the number of direct and indirect maternal deaths per 100,000 live births during pregnancy or up to and including 42 days after the end of pregnancy. **The latest UN estimates for 2013 are that the overall global MMR is 210 deaths per 100,000 live births, with an even higher figure (230) for developing regions (LICs and MICs) compared with 12 for developed regions.** The highest regional MMR is 520 for sub-Saharan Africa, followed by 190 for both the Caribbean and Oceania, 170 for Southern Asia (which drops to 140 if India is excluded), 77 for Latin America, 60 for North Africa, and 39 for Central Asia.<sup>6</sup> However, these figures hide wide intercountry and intra-country variations. Overall, Sierra Leone is estimated to have the highest MMR (1100), followed by Chad (980), the Central African Republic (880), and Somalia (850). Ten other African countries have MMRs higher than 500 per 100,000 live births. Due to the sheer weight of its population, the annual deaths of 50,000 mothers in India account for 17% of the global total. This is despite the country having made significant progress in recent years with a concerted effort at national, state, and local levels: the Indian MMR fell from 600 in 1990 to 200 in 2010.<sup>6</sup>

### Adolescent Girls and Lifetime Risk of Maternal Death

Ending child marriage is a public health priority. Apart from taking away their childhood, young pregnant girls are more likely to die and are at greater risk of complications. Those under the age of 15 are five times more likely to die of a pregnancy-related cause than women in their twenties.<sup>10</sup> Every year, 3 million undergo unsafe abortions.<sup>9,11</sup> Maternal death is now the leading cause of death for young girls in developing countries, with 15% percent of all deaths worldwide occurring among adolescents.<sup>9,11-13</sup> Compared with mothers aged 20 to 24 years, girls aged between 10 and 19 years have higher risks of obstructed labor, eclampsia, puerperal sepsis, systemic infections, and preterm deliveries and require more cesarean deliveries.<sup>14,15</sup> Their babies also fare worse as a result.

**In developing countries, a 15-year-old girl faces a 1:160 risk of dying from a pregnancy-related complication during her lifetime, and this rises to an average risk of 1:38 for those who live in sub-Saharan Africa.** The average risk in the most developed countries is 1:3750. In the very worst countries to be born a girl—such as Chad, Niger, and Côte d'Ivoire—the lifetime risk is still between 1:15 and 1:29 despite the fact that these figures have actually been halved over the past 10 years.<sup>6</sup> Even in the developed world, wide variations are seen within a country depending on who the mothers are, where they live, and their social circumstances. In the United Kingdom, for example, vulnerable unemployed women are 10 times more likely to die

or suffer complications than women in families where at least one member is employed.<sup>16</sup>

### United States

The WHO estimated the overall MMR for the United States to be 28 per 100,000 live births in 2013, which is threefold greater than in Western Europe and Australasia.<sup>6</sup> Indeed, the United States is one of the few countries whose MMR has increased, rather than decreased, in recent years. This may be due to a steady rise in the number of women with advanced maternal age, chronic medical conditions, and obesity coupled with an increasing number of medical interventions, not all of which may be necessary. Recent patient safety research demonstrates that where consistent protocols for diagnosis, management, consultation, or referral of complicated cases are lacking, less optimal maternal outcomes may result.<sup>17</sup>

In the United States, as in many Western countries, the most common obstetric conditions resulting in severe maternal morbidity or mortality are obstetric hemorrhage, severe preeclampsia, and venous thromboembolism.<sup>18</sup> Recent case reviews have highlighted that a significant proportion of the morbidity and mortality from these conditions are due to missed opportunities to improve maternal outcomes. A major challenge is to identify those women who need specialist care at an early stage, without eliminating the category of lower-risk cases. To address this complex problem, a multidisciplinary group of senior health care and birth facility leaders to review and amend current recommendations and plan a national approach to implement improved strategies has recently been convened as the U.S. National Partnership for Maternal Safety.<sup>19</sup>

### Mothers Who Survive: Severe Maternal Morbidity

Whereas global maternal deaths may have been neglected until relatively recently, women who suffer from severe maternal morbidity and its long-term sequelae have fared even worse. It is estimated that 1.1 million of the annual total of 136 million births are complicated by a severe maternal “near-miss” event, after which the mother survived either by chance or following high-quality medical care. A further 9.5 million women suffer more manageable complications that are still very severe, and 20 million mothers suffer longer-term complications each year.<sup>3</sup> These are conservative estimates.<sup>20</sup>

Whatever the death-to-disability ratio, as with maternal deaths, the numbers will always be too high, and the underlying causes are disturbingly similar. Hence, reducing the risk factors for death will help to decrease the number of significant obstetric complications. Table 58-1 estimates the overall numbers and case fatality rates for the five major global *direct* obstetric complications of pregnancy and the overall numbers of women

affected.<sup>21</sup> **Direct maternal deaths** are those that result from obstetric complications of the pregnancy state (pregnancy, labor, and the puerperium), from interventions, omissions, incorrect treatment, or from a chain of events resulting from any of the above. **Indirect obstetric deaths** are those that result from previous existing disease or disease that developed during pregnancy and which was not due to direct obstetric causes but was aggravated by physiologic effects of pregnancy. **Coincidental maternal deaths** are those from unrelated causes that happen to occur in pregnancy or the puerperium. **Late maternal deaths** include the death of a woman from direct or indirect obstetric causes more than 42 days but less than 1 year after termination of pregnancy.

As stated by Zacharin, “In an unequal world, these women are the most unequal among unequals.”<sup>22</sup> Of all the long-term morbidities arising from childbirth, an obstetric fistula is one of the worst. It is estimated that in sub-Saharan Africa and in parts of Asia, between 654,000 to 2 million young women live, usually in isolation and shame, with untreated obstetric fistulae; the annual incidence is 50,000 to 100,000 new cases.<sup>23,24</sup>

Obstetric fistulae are highly stigmatizing, and affected women often become social outcasts. The constant leakage of urine and or fecal matter makes it difficult for them to remain clean, especially in areas with limited access to water, and they most likely will never have children. It is hard to find work; and having failed in their primary objective to have children, they offer little, if any, economic advantage to their families. As a result they are frequently rejected and cast out. The growth in training local surgeons in techniques for simple repair and the ever increasing number of specialist fistula repair centers who also train local staff is slowly helping restore function, fertility, and dignity to these women—but the services available are still few and far between. This is discussed in more depth in the section “[Obstructed Labor and Obstetric Fistula](#).”

### Babies Who Die

Mothers and their babies are a dyad, inextricably linked, yet all too often the newborn is overlooked when considering policies to reduce the impact of maternal ill health or death. **Around half of the annual 2.6 million stillbirths and 2.9 million deaths in the neonatal period, the first month of life, occur as a result of maternal complications during pregnancy or delivery.**<sup>8</sup> Thus improving maternal care helps more babies survive, and they survive in better condition, which provides a healthier start to life.

**Most neonatal deaths (73%) occur during the first week of life with around 36% in the first 24 hours. The major causes are complications that arise from preterm birth (36%), intrapartum asphyxia (23%), and neonatal infections such**

**TABLE 58-1** ESTIMATED NUMBERS AND INCIDENCE OF THE MAJOR GLOBAL CAUSES OF DIRECT MATERNAL DEATHS AND SEVERE MORBIDITY FOR THE YEAR 2000

| CAUSE                   | INCIDENCE OF COMPLICATION (% OF LIVE BIRTHS) | NUMBER OF CASES | CASE FATALITY RATE (%) | DEATHS  | % OF ALL DIRECT DEATHS |
|-------------------------|--|-----------------|------------------------|---------|------------------------|
| Hemorrhage              | 10.5   | 13,795,000      | 1.0                    | 132,000 | 28%                    |
| Sepsis                  | 4.4  | 5,768,000       | 1.3                    | 79,000  | 16%                    |
| Preeclampsia, eclampsia | 3.2  | 4,152,000       | 1.7                    | 63,000  | 13%                    |
| Obstructed labor        | 4.6  | 6,038,000       | 0.7                    | 42,000  | 9%                     |
| Abortion                | 14.8   | 19,340,000      | 0.3                    | 69,000  | 15%                    |

Modified from AbouZahr C. Global burden of maternal death. In *British Medical Bulletin. Pregnancy: Reducing Maternal Death and Disability*. British Council. Oxford University Press; 2003, pp. 1-13.

as sepsis, meningitis, and pneumonia, which together contribute 23%.<sup>25</sup> Two thirds of newborn deaths could be prevented if skilled health workers performed effective interventions at birth and during the first week of life.<sup>26</sup>

**Labor and the 24 hours surrounding birth are the riskiest times for mother and baby, with 46% of maternal and 40% of neonatal deaths and stillbirths occurring during this period.**<sup>27</sup> This fuels the repeated call for more skilled birth attendants to assist at delivery, which should take place in a clean and well-equipped unit with working transport links to more comprehensive facilities capable of managing emergency complications for both mother and baby.

## Why Mothers Die

### CLINICAL CAUSES

In the most recent WHO analysis of the global causes of maternal death, 73% of the deaths were considered to be due to direct obstetric causes. Of all direct and indirect deaths combined, 27% were due to hemorrhage, 14% to preeclampsia, 11% from puerperal sepsis, 8% from unsafe abortion, 3% from embolism, 3% from obstructed labor, and 7% from other direct causes combined.<sup>28</sup> Virtually all these deaths could be avoided if the maternal and reproductive health services taken for granted in developed countries were available. The other 27% of maternal deaths worldwide are due to indirect causes, most of which result from preexisting underlying medical disorders exacerbated by the mother's pregnant state.

**Deaths from illnesses related to human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS), regarded as indirect deaths, make a major contribution to maternal mortality globally and in some sub-Saharan countries cause more than half of all indirect deaths.** In Botswana they account for 56%, and in South Africa and Namibia, the rates are 60%, rising to 67% in Swaziland.<sup>6</sup> In four non-African countries—Ukraine, Bahamas, Thailand, and the Russian Federation—more than 20% of indirect deaths are due to HIV, with the majority being linked to intravenous (IV) drug use.<sup>6</sup> A recent survey predicted that 12% of all deaths during pregnancy and up to 1 year after delivery will result from an HIV-positive pregnancy prevalence rate of 2% and that the MMR will increase to 50% in areas with an HIV-positive pregnancy prevalence rate of 15%.<sup>29</sup>

In developed countries, indirect deaths predominate. The latest U.K. Confidential Enquiry into Maternal Deaths also reported that two thirds of the maternal deaths between the years 2009 and 2012 were due to indirect causes. The risk of a maternal death in the United Kingdom has significantly fallen over the past 10 years from already small numbers. The comparative U.K. MMR, calculated using WHO methods, is now 5.35 deaths per 10,000 live births.<sup>30</sup> The majority of the reported indirect deaths were due to severe medical and mental health problems becoming complicated by pregnancy, such as preexisting cardiac disease, epilepsy, autoimmune disease, and suicide. These causes are now being bolstered by conditions adversely affected by poorer lifestyles such as acquired cardiac disease, hypertension, type 2 diabetes, liver disease, alcohol and drug dependency, and other disorders associated with obesity.<sup>30</sup>

### HEALTH SYSTEM FACTORS

**A lack of health system planning and resources is one of the largest contributors to the continuing pandemic of maternal ill health and mortality.** Many women receive no antenatal care

### BOX 58-1 BASIC EMERGENCY OBSTETRIC NEWBORN CARE

**Basic emergency obstetric and newborn care** is critical to reducing maternal and neonatal death. This care, which can be provided with skilled staff in large or small health centers, includes the capabilities for:

- Administering antibiotics, uterotonic drugs (oxytocin), and anticonvulsants (magnesium sulfate)
- Manual removal of the placenta
- Removal of retained products of conception following miscarriage or abortion
- Assisted vaginal delivery, preferably with vacuum extractor
- Basic neonatal resuscitation care

**Comprehensive emergency obstetric and newborn care**, typically delivered in hospitals, includes all the basic functions above, plus capabilities for:

- Performing cesarean delivery
- Safe blood transfusion
- Provision of care to sick and low-birthweight newborns, including resuscitation

at all, and the WHO estimates that only 38% of mothers in low-income countries receive the minimum four antenatal visits they recommend.<sup>31,32</sup> Less than 50% of all women give birth accompanied by a skilled attendant, such as a midwife or doctor,<sup>33</sup> and many lack access to facilities with staff and resources capable of providing basic emergency obstetric or newborn care (Box 58-1) or to higher level services capable of dealing with serious complications or emergencies, such as undertaking life-saving cesarean delivery (CD) for mother or child.<sup>34</sup>

**A recent WHO study showed 54 countries that had CD rates lower than 10%, the minimum standard for safe motherhood services, and 69 had rates higher than 15%, all unacceptably high.** In 2008, the conservative estimate of the overall rate for Brazil was 45.9%, and it was 30.3% for the United States, compared with 0.7% for Burkina Faso.<sup>35</sup> The study also estimated that in 2008, 3.18 million additional CDs were needed, and 6.20 million unnecessary operations were performed worldwide. The cost of this global “excess” was estimated to amount to approximately \$2.32 billion, whereas the cost of the “needed” CDs globally was approximately \$432 million.

A critical lack of skilled staff, such as midwives and doctors, is also apparent. It is estimated that the world needs another 350,000 midwives,<sup>36</sup> and doctors are also extremely scarce, especially in the unattractive, remote, and poorer areas of already resource-poor countries. To help address these shortages, task shifting—the transferring of skills and competencies to other trained individuals—is becoming increasingly commonplace. In some countries such as Mozambique, cadres of ancillary staff have been trained as clinical officers—nonphysician clinicians—to perform basic life-saving skills and procedures that include CD, and the results have been impressive.<sup>37</sup>

An emerging issue is that of quality of care. To date, much of the global effort to reduce maternal mortality has focused on increasing access to care; however, the focus is now shifting toward improving and standardizing the variable quality of care that women receive from the health services they have been encouraged to attend. Clinical guidelines and protocols have been developed by the WHO and professional associations, and the use of maternal death reviews to learn lessons to improve care is also having a positive effect.<sup>38</sup>

### VULNERABILITY AND UNDERLYING SOCIAL DETERMINANTS

The underlying causes of maternal mortality are complex and multifactorial. For example, although a mother in a resource-poor country may technically be described as dying from a postpartum hemorrhage, the true underlying causes may be very different. She may have died because she had no care, or because she was unable to read the information leaflets about the warning signs and when or where to seek help. Care may have been available but beyond her reach physically or financially. Access to any form of transport in emergency situations is frequently problematic, especially at night. Furthermore, her husband or family members may have prevented her from attending care or lacked the money to pay the necessary bribes to secure her treatment. She may have refused to seek help because she has heard she would be slapped, shouted at, or treated disrespectfully in the health facility. Or she may have overcome all of these obstacles to reach a health care facility only to find poorly trained staff or no staff at all and no medicines, blood products, or equipment and no one capable of performing her life-saving operation. Added to which, she will probably have been in poor physical condition and suffering from anemia and other chronic health disorders. Thus the stated clinical factors surrounding a maternal death provide little or no indication of the underlying causes as to why the woman really died. **Without understanding the wider “causes of the causes,” the barriers to safe maternity care cannot be identified and overcome. To help quantify these, it is common for those who work in the field of international women’s health to use the “three delays” model as a checklist to help identify the barriers pregnant women face.**<sup>39,40</sup> These barriers may be financial, physical, social, cultural, or medical and may be present in the family, the community, or the health care system. These are inextricably interlinked, and some examples are given in Table 58-2.

### “CAUSES OF THE CAUSES”

A recent report into inequalities in health outcomes in England, “Fair Society, Healthy Lives,”<sup>41</sup> states that the “causes of the causes” are the circumstances and societies in which people are born, grow, live, work, and age. Social position, wealth, and education help determine each person’s health outcomes and life expectancy. **It estimates that health care services contribute only one third to improvements in life expectancy and that improving life chances and removing inequalities contribute the remaining two thirds.** If this is the case in a developed country, the ratio of inequalities in resource-poor countries must be far higher. Indeed, whether a pregnant woman lives or dies is a lottery that depends almost entirely on where she was born and lives and in what circumstances. Mothers who die are generally the least visible, most vulnerable, and poorest of the poor. Although urban poverty is an increasing problem, most maternal casualties tend to live in rural areas and lack both transport and access to skilled care in health facilities. They are more likely to be illiterate or poorly educated, undertake hard manual work, and find themselves almost permanently pregnant. In societies where social and economic deprivation is rife, so is the absence of laws to protect human rights and promote gender equality in places where those women with the lowest educational achievements are at greatest risk.<sup>42</sup>

The lowly status of girls and women frequently means that they receive the last and least of the family food. General malnourishment, coupled with anemia and micronutrient deficiencies, leads to chronic ill health and multiple comorbidities such

**TABLE 58-2** THE THREE DELAYS: EXAMPLES OF BARRIERS TO SAFE, EFFECTIVE MATERNAL CARE

Modified from Thaddeus S, Maine D. Too far to walk: maternal mortality in context. *Soc Sci Med*. 1994;1091-1110.

as malaria, HIV, or tuberculosis (TB). These women have little or no control over their health, being dependent on male or elder family members to decide whether they should seek care, even in emergencies. Many will become child brides, become pregnant, and be forced to give up any form of education. Female genital mutilation/cutting (FGM/C) is common and is associated with a higher incidence of obstructed labor, emergency cesarean delivery, fetal distress, obstetric fistula, and permanent perineal damage.<sup>43</sup> All of these factors lead to complex pregnancies and higher rates of stillbirth and neonatal death.

### WOMEN’S RIGHTS

*“Imagine a world where all women enjoy their human rights. Take action to make it happen.”*

—1998 United Nations Campaign for Human Rights

A further, critically important reason why global efforts to reduce maternal mortality and morbidity have been slow is the low value that society, political, religious, community, and family leaders have placed on women’s lives. **As the father of the Safe Motherhood movement, Professor Mahmoud Fathalla, famously said, “Women are not dying of diseases we cannot treat ... they are dying because societies have yet to decide that their lives are worth saving.”**<sup>44</sup>

In 1948, the Universal Declaration of Human Rights stated that “all human beings are born free and equal in dignity and rights.”<sup>45</sup> The 1995 UN Beijing declaration on women’s rights reported that “the full implementation of the human rights of women and of the girl child is an inalienable, integral, and indivisible part of all human rights and fundamental freedoms.”<sup>46</sup> By 2009, the UN Human Rights Council had acknowledged that preventable maternal mortality was a human rights violation, and health advocates started using human rights mechanisms to

make governments honor their commitment to ensure access to services essential for reproductive health and well-being.

**The right to health is a human right, and the health of a nation is determined by the health of its girls and women.** Healthy women are more likely to fulfill their potential, nurture healthy families, and contribute to their local and national economies. Ellen Sirleaf Johnson argued that women's socioeconomic empowerment is essential to achieve better health care outcomes, and she ended her 2011 Nobel Prize acceptance speech with a challenge: "Nations thrive when mothers survive, we must strive to keep them alive."<sup>47</sup>

The contribution made by mothers to society is far reaching, and countries that fail to protect and promote women's rights have the worst economic, educational, maternal, and child health outcomes. The application of human rights shifts the understanding of maternal deaths as mere misfortunes that are acts of fate into injustices that the state is obliged to remedy. Using a human rights approach provides valuable tools to hold governments legally accountable to address the preventable causes of maternal mortality and to distribute resources and medicines essential for reproductive health, such as effective contraception and misoprostol to reduce postpartum hemorrhage. For example, when the Sri Lankan government introduced universal education and access to health care, maternal deaths declined significantly for little extra cost.<sup>48</sup> Political will, literacy, and respect for the status and rights of women in society are key components for achieving sustainable health improvements.

Nearly 70 years after the Universal Declaration, many women still struggle to have their basic rights protected. As recently as 2013, objections were raised by certain countries and religious groups to a potential UN statement reaffirming women's rights to education, contraceptive choices, family spacing, and the introduction of declarations against domestic violence, rape, child marriage, and FGM/C. Those who objected considered that upholding these human rights could destroy society by allowing a woman to travel, work, use contraception without her husband's approval, and control her family's spending. These may be extreme views, but there are still far too many countries that turn a blind eye to gender inequalities and violence that includes child marriage, rape, and FGM/C and who do not favor girls receiving primary, let alone secondary, education.

Human rights play an important role in the fight to improve the status of women because they embody a shared set of values that have been enshrined in law. Infringements can be litigated in countries that subscribe to them, but even countries that do not often appear to be sensitive to the charge that they are infringing the human rights of their population. Where the law hinders the use of contraception or does not allow induced abortion, health care professionals invariably find it easier to provide life-saving interventions if they can be reassured that they are protecting the woman's right to life, to benefit from scientific advances, or to avoid discrimination.

**Advocacy for women is an obligation for everyone engaged in reproductive health care. This means that all health care professionals need to know how to embed human rights principles into every aspect of their delivery of care.** The International Federation of Obstetricians and Gynecologists (FIGO) women's sexual and reproductive rights committee has developed a comprehensive teaching syllabus that can be adapted for use by a wide range of professionals. The clinical knowledge and practical skills required to deliver quality reproductive health care have been built around a core checklist of 10

health-related human rights. The result is a competency-based educational approach that simultaneously advocates for human rights and health by developing standards for performance and tools for training teachers and students in both the classroom and clinical settings. The teaching materials can be freely accessed and downloaded from the Global Library of Women's Medicine (GLOWM).<sup>48b</sup> Experience from the teaching workshops with both laypersons and professional audiences confirms that this approach shifts the teaching of human rights and women's reproductive health from a marginal to a mainstream position in the learning process for all health care professionals.

## SEXUAL AND REPRODUCTIVE HEALTH

The lack of universal access to basic sexual and reproductive health services is one of the most significant barriers to reducing maternal morbidity and mortality globally. As stated at the very start of this chapter, but worth repeating here, **a recent report<sup>1</sup> estimated that if all women wanting to avoid pregnancy used an effective method of contraception, the number of unintended pregnancies would drop by 70%, and unsafe abortions would drop by 74%. If these women's contraceptive needs were met, the number of maternal deaths would fall by two thirds, and newborn deaths would decline by more than three quarters,** and the transmission of HIV from mothers to newborns would also be virtually eliminated. Furthermore, it was estimated that contraceptive use averted 272,040 maternal deaths in 2008 and that meeting unmet need for contraception could prevent an additional 104,000 deaths per year, thus preventing a further 29% of maternal mortality.<sup>49</sup> This further reduction by about one third if the unmet need for contraception were met is similar to estimates reported by others,<sup>50</sup> and it underscores the critical role that access to effective contraception plays in preventing maternal mortality and morbidity.

Sexual and reproductive health was formally defined at the 1994 International Conference on Population and Development (ICPD).<sup>51</sup> At its core is the promotion of healthy, voluntary, and safe sexual and reproductive choices for individuals and couples, including decisions about if, when, and with whom to have children. It encompasses highly sensitive and important issues such as sexuality, pregnancy prevention and abortion, gender discrimination, and male/female power relations. Its full attainment depends on the protection of human and reproductive rights. The conference also adopted the goal of ensuring universal access to sexual and reproductive health as part of its framework for a broad set of development objectives and Millennium Development Goals (MDGs) and set very similar objectives in their Target 5:B.<sup>52</sup> Despite these initiatives, an estimated 85 million unintended pregnancies occurred in 2012.<sup>53</sup>

## Unintended Pregnancy

**An unintended pregnancy is one that is mistimed, unplanned, or unwanted at the time of conception,**<sup>54,55</sup> and such pregnancies are associated with an array of negative health, economic, social, and psychological outcomes for women and children.<sup>56-60</sup> In 2012, the global unintended pregnancy rate was 53 per 1000 women aged 15 to 44, with the highest rates in Eastern and Middle Africa (108 each) and the lowest in Western Europe (27).<sup>1</sup> Of these 85 million unintended pregnancies, 50% will end in termination,<sup>1</sup> which corresponds to about 1 in 5 of all pregnancies and contributes to the pandemic of unsafe abortion.<sup>61</sup> A further 13% will end in miscarriage, and 38% will

result in an unplanned birth.<sup>1</sup> Four out of five pregnancies in the developing world occur among women with no access to modern effective contraception,<sup>59</sup> but even in settings where contraceptive use is comparatively high, unintended pregnancies may still occur when the available contraceptive method fails or because of poor adherence.

## Contraception

**Voluntary access to family planning—especially modern, effective contraceptive methods for women and men—is crucial to directly improving health outcomes and is positively associated with improvements in educational and economic status.**<sup>49,50,62,63</sup> The health benefits include sizable reductions in maternal, newborn, and child morbidity and mortality as well as deaths and complications that arise from unsafe abortion.<sup>60,49,63</sup> At the household level, improved access to family planning services leads to substantial improvements in women's earnings and children's schooling.<sup>62</sup> Nationally, higher levels of uptake correlate with lower fertility rates, which enhance economic growth.<sup>62,64</sup> Conversely, high levels of unwanted fertility correlate with poverty and inequality.<sup>65</sup>

Barriers to contraceptive usage can also be categorized according to the three-delay model described earlier<sup>38</sup> and can occur at the client, health care provider, and health systems level. The most frequently cited reasons for nonuse among women is poor understanding of their risk for pregnancy, concerns about possible side effects, infrequent sexual activity, service fees, or opposition; in the latter, desires of a male partner or religious or cultural reasons are cited. Married women may have little control over contraceptive decision making, which is particularly important when partners differ in their childbearing preferences. Unmarried women frequently have to face strong stigma from judgmental providers if they are sexually active, which in turn reduces these women's ability to obtain needed services. At the provider level, barriers include lack of knowledge or skills, motivation, and bias for or against certain methods, such as intrauterine devices (IUDs). Limiting the provision by certain provider types also blocks uptake: for example, only allowing doctors to insert IUDs or imposing non-evidence-based restrictions on when a method can be started, such as commencing only at the time of menses. Common health system barriers include inadequate human and financial resources and a failure to integrate family planning with other core services such as maternity and child health clinics, delivery, postnatal or postabortion care, and HIV services. Access may also be limited through geographic constraints and lack of equipment and supplies. Shortages of supplies are very common, especially in rural areas. In addition to overcoming provider bias, lack of competency, and health systems issues, most low-resource settings are still in need of educational interventions to increase awareness and understanding for the community as a whole, thereby reducing many of the existing barriers to effective contraceptive use.

*Contraceptive prevalence* is typically defined as the percentage of women who are currently using, or whose sexual partner is currently using, at least one method of contraception regardless of the method used; usually, it is reported for married or in-union women (women in a stable sexual relationship) aged 15 to 49. **In recent decades, general increases in contraceptive prevalence rates (CPRs) have been seen in most areas of the world, and globally, they increased from 53% in 1990 to 57% to 64% in 2011 through 2012.**<sup>66-71</sup> However, CPRs remain extremely low in parts of Africa with regional estimates of 32%,

19%, and 15% in Eastern, Middle, and Western Africa, respectively,<sup>68</sup> giving a rate of 24% to 30% for Africa overall.<sup>66-71</sup> Wide intercountry variations are also apparent: for example, since 1990, progress in contraceptive use has been made in Rwanda (18% to 50%), Malawi (12% to 45%), and Tanzania (11% to 34%); yet in Sierra Leone and Nigeria, the CPRs for 2010 were 6.7% and 8.6%, respectively.<sup>68</sup> In Southern Africa, rates are now relatively high at 62%, having risen from 47%, and in Southern Asia, rates have risen from 36% to 50% in India and from 34% to 61% in Bangladesh; in addition, substantial gains have been made in Latin America, where the regional CPR is now 73%.<sup>68</sup> Although high and most stable in Europe and North America (72% to 78%), the rates are highest in East Asia, largely attributable to China (83%).<sup>68</sup> Nevertheless, the overall global CPR remains low, and this is a serious obstacle to further improving women's health.

Unmet need for family planning is typically defined as the percentage of women who want to stop or delay childbearing but who are not using any method of contraception to prevent pregnancy. A more useful definition regards both women who use no method or women who use traditional methods as having an unmet need for modern methods, not only because traditional methods have high use-failure rates, but also because, although some women using traditional methods might choose to use these methods, such choices often imply that women perceive other options to be unavailable, or are not fully informed of contraceptive options.<sup>71</sup>

The unmet need for contraception is unacceptably high. Globally, 222 million women who would prefer and are trying to limit or space their pregnancies are not using contraception.<sup>70,71</sup> Around three-quarters of these women live in the world's poorest countries,<sup>72</sup> and the unmet need remains greatest in sub-Saharan Africa (60%) and West and South Asia (50% and 34%, respectively) with disproportionately high levels among illiterate, poor, adolescent, and rural women.<sup>58,50</sup>

**The postpartum period is crucially important for contraceptive intervention because rapid repeat pregnancies are associated with poor maternal and infant outcomes.** An analysis of data from 27 countries found that 95% of women who were 12 or fewer months postpartum did not want another birth within 2 years, yet 65% of them were not using contraception.<sup>73</sup> Similarly, although most women being treated for complications of induced or spontaneous abortion are in need of effective contraception, data from 17 low-resource countries show that only 1 in 4 of these women were discharged from care with a method in place.<sup>74</sup>

## Contraceptive Methods

The type of contraceptive method used is also variable, but choice is critical in relation to efficacy and continued usage, particularly in areas where women find it difficult to attend clinics, or where the service is unavailable or limited by shortages and failure of supplies. Traditional contraceptive techniques such as withdrawal and fertility awareness (natural family planning) are the least effective. The emphasis should be on enabling women and their partners to have access to a wide range of the most effective modern methods. WHO classifies contraceptive methods into effectiveness tiers, which are described in [Table 58-3](#). The effectiveness of the method is critically important for reducing the risk of unintended pregnancy and can be measured either with "perfect use," when the method is used correctly and consistently as directed, or with "typical use," which

**TABLE 58-3** EFFECTIVENESS OF CONTRACEPTIVE METHODS BASED ON TYPICAL USE FAILURE RATES

|   |   |
|---|---|
| <b>Tier 1 Methods: The Most Effective, Resulting in Less Than 1 Pregnancy per 100 Women in a Year</b> |   |
| Permanent contraceptive methods   | Male and female sterilization   |
| Long-acting reversible contraceptives (LARCs)   | Intrauterine devices (copper bearing or levonorgestrel [LNG] IUDs are effective for 5 to 10 years depending on the IUD)<br>Subdermal implant (progestogen only, effective for 3 to 5 years depending on the implant)  |
| <b>Tier 2 Methods: Result in 6 to 12 Pregnancies per 100 Women in a Year</b>                          |   |

Modified from World Health Organization (WHO). WHO Department of Reproductive Health and Research, Johns Hopkins Bloomberg School of Public Health/Center for Communications Programs (CCP). Knowledge for health project. Family planning: a global handbook for providers (2011 update). Baltimore/Geneva: CCP and WHO, 2011; and Hatcher RA, Trussell J, Nelson AL, Cates W, Kowal D, Policar M (eds). *Contraceptive Technology*. 20th revised edition. New York: Ardent Media; 2011.

reflects real-world actual use, including inconsistent and incorrect use.<sup>75</sup>

Sterilization, almost exclusively female, is most commonly used in Asia and Latin America. IUDs account for a third of contraceptive use in Asia and are the most commonly used method in some parts.<sup>70</sup> Injectables are the most widely used methods in sub-Saharan Africa and also in Southeast Asia.<sup>70</sup> Oral contraceptives make up nearly half of total contraceptive use in northern Africa, whereas male condoms are the most common method in Central and Western Africa.<sup>72</sup>

**The subdermal implant and IUD are the most effective reversible contraceptive methods available and are highly suitable for resource-poor countries because they have failure rates of less than 1% for both perfect and typical use.**<sup>75</sup> The failure rates for these methods are very low because they do not require any additional user intervention. Injectable contraceptives, oral contraceptive pills, the hormonal patch, and the vaginal ring all have failure rates of less than 1% with perfect use; however, with typical use, these methods are only 90% to 94% effective.<sup>75</sup> Condoms are 98% effective with perfect use, but the method failure rate increases to 18% to 21% with typical use.<sup>75</sup> *Dual contraception* is defined as the consistent use of a

condom, male or female, along with a highly effective nonbarrier method such as hormonal contraception, the copper-bearing IUD, or sterilization. Male and female condoms are the only contraceptive methods available that also protect against sexually transmitted infections (STIs) and HIV; hence using a dual-contraceptive method should be promoted routinely in areas of high STI/HIV prevalence.

**Short-acting methods such as condoms and oral and injectable contraceptives are the most commonly used methods in sub-Saharan Africa despite the fact that permanent and LARC methods are much more effective at preventing pregnancy.**<sup>76-78</sup> A recent modeling study concluded that if just 20% of the women in sub-Saharan Africa currently using oral contraceptive pills and injectables were to switch to using the more effective subdermal implant, 1.8 million unintended pregnancies, 576,000 abortions (many of them unsafe), and 10,000 maternal deaths would be averted over 5 years.<sup>78</sup> Encouragingly, efforts to achieve the ambitious goal of the 2012 London Summit on Family Planning—to enable an additional 120 million women and girls in the world's poorest countries to access and use lifesaving family planning information, services, and supplies by 2020—appears to be gaining momentum.<sup>79</sup>

## Induced Abortion

**Even though deaths from unsafe abortion worldwide dropped from 69,000 in 1990 to 47,000 in 2008, the consequences of unsafe abortion remain one of the five leading causes of maternal mortality.**<sup>80</sup> However, although the actual numbers may have declined, the proportion of women who die of unsafe abortion has remained stubbornly unchanged at around 9% to 13% of maternal deaths.<sup>28,80</sup> Such deaths can be largely prevented by the provision of safe abortion services offered by trained staff working within an enabling legal framework. Where the in-country laws prevent offering this service, many lives can still be saved by introducing accessible, nonjudgmental, and prompt care for the identification and management of the complications of clandestine unsafe abortions. Only 40% of the world's women have access to safe and legal abortion services within set gestational limits. Elsewhere, access is either absent or is restricted to a lesser or greater degree.<sup>81</sup>

Globally each year, around 44 million abortion procedures take place; about half are unsafe, and the vast majority are due to unintended pregnancies.<sup>82</sup> Unsafe abortions include those undertaken by unskilled providers under unhygienic conditions, those that are self-induced by the woman inserting a foreign object into her uterus or consuming toxic products, and those instigated by physical trauma to a woman's abdomen.<sup>83</sup> Nearly all unsafe abortions (98%), and the deaths that arise as a consequence (99.8%), occur in developing countries.<sup>83</sup> About two thirds of abortion-related deaths occur in sub-Saharan Africa, and one third occur in Asia.<sup>83</sup> **In high-resource regions of the world where safe and legal abortion services are provided, deaths are extremely rare.**<sup>83</sup> The majority of women who seek these procedures in resource-poor countries, where it is usually illegal, will already have had a number of pregnancies. They frequently view their decision to seek an abortion as a last resort—a necessary respite from the exhaustion of incessant childbearing that has left them in very poor health in addition to their family circumstances leaving them with no resources, food, or money to care for another child.

Deaths and disability from unsafe abortion continue to occur, despite major advances in the availability of safe and effective

technologies for medically induced abortion, which additionally reduce operative interventions.<sup>84</sup> Complications and causes of death from unsafe abortion include hemorrhage, sepsis, and peritonitis in addition to trauma to the cervix, vagina, uterus, and abdominal organs.<sup>85</sup> Apart from the risk of death, one in four women who undergo an unsafe procedure—an estimated 5 million each year—are likely to develop temporary or life-long disability that requires medical care and includes secondary infertility.<sup>79,83,86</sup>

Induced abortion has existed in all societies since the dawn of time, and evidence shows that wherever they live, and whoever they are, many women will seek an abortion when faced with an unintended pregnancy, irrespective of the legal circumstances.<sup>83,84</sup> For example, the abortion rate of 29 per 1000 women of reproductive age in Africa, where it is mostly illegal, is similar to that of 28 per 1000 women in Europe, where abortion is generally permitted on broad grounds but with limits for gestational age.<sup>81</sup> Where abortion is allowed, very few women resort to unsafe practices, and as a result, morbidity and mortality are extremely low. When made legal, safe and accessible, women's health improves rapidly. In South Africa, for example, the annual number of abortion-related deaths fell by 91% after the liberalization of the abortion law in 1996.<sup>87</sup> When provided in a safe environment by properly trained providers, abortion is one of the safest medical procedures.<sup>83</sup>

Reducing the number of unsafe abortions or promptly identifying and managing their complications are global health priorities. Universal access to legal, safe services for all women is unlikely to be achieved because of the diverse moral, religious, and other contextual issues. It is a highly divisive subject with no easy answers. Nevertheless, whatever stance is taken at a personal, national, or legal level, helping women who are suffering and dying of the complications of unsafe procedures must be part of all programs designed to reduce maternal deaths and disabilities. The first step is to accept that this key health issue should not be swept under the carpet as an inconvenient truth. The second is to develop a program for the management of complications through evidence-based and nonjudgmental national strategies such as the one published in Kenya in 2012 by the Ministry of Medical Services.<sup>88</sup> Bringing the issue of abortion out into the open and acknowledging the problem will go a long way in helping to save lives.

### Improving Reproductive Health and Well-Being of All Mothers

**Despite intense efforts at many levels, improving the accessibility and quality of care for all of the world's mothers and babies remains a monumental task. Progress has been made, however, in that maternal deaths rates fell 45% between 1990 and 2013 globally. However, in many pockets of the world, rates continue to stagnate or rise, such as in the United States.**<sup>6</sup> The international spotlight shone brightly on the problem when Millennium Development Goal 5, agreed to by all UN member states in 1990, challenged low- and middle-income countries to reduce their maternal mortality by 75% by 2015, but now that time has come, and the targets—perhaps in hindsight too ambitious—remain largely unmet.<sup>52,89</sup> The UN has now agreed to new targets, the Sustainable Development Goals, and as currently drafted under Goal 3, “*To ensure healthy lives and promote well-being for all at all ages,*” they propose that by 2030, the overall global MMR should be reduced to less than 70 per 100,000 live births, and preventable neonatal deaths

should be eliminated.<sup>90</sup> These hugely challenging targets will not be met unless action is taken at all levels, and in all sectors, to implement the necessary and fundamental changes that have been described in this chapter. **A recent report estimated that increased coverage and improvement in the quality of maternity services by 2025 could avert 71% of neonatal deaths, 33% of stillbirths, and 54% of maternal deaths at a cost of \$1928 for each life saved.**<sup>91</sup> Furthermore, is estimated that contraceptive use averted 272,040 maternal deaths in 2008 and that meeting unmet need for contraception could prevent an additional 104,000 deaths per year.<sup>49</sup>

Making health care welcoming and accessible to all women through improving transport links and eliminating or reducing user fees, scaling up the number of health facilities capable of providing basic emergency and comprehensive emergency obstetric and neonatal care, and increasing the numbers facilities with caring, well-trained midwives, doctors, and other health workers is essential. Developing a culture of quality care must accompany the implementation of appropriate clinical guidelines and protocols, which the WHO and others have already produced, and audits and reviews must be used to assess progress and identify and rectify problems that may be identified. Improving communications and providing a woman with holistic and comprehensive coordinated care during the continuum of her pregnancy—preconception, antenatal, intrapartum, and postnatal care along with postpartum family planning—will also prove crucial. Apart from addressing the clinical quality of care, well-conducted maternal or perinatal death or morbidity reviews also provide in-depth evidence of the underlying reasons why mothers may be dying. Here, their results help not only in the development of accessible maternal and reproductive health services but also with improvements to education and human rights.

Sustained pressure and advocacy for beneficial change, together with leadership and realistic and practical policies, are required from world leaders and influencers, the UN, other international organizations, nongovernmental organizations (NGOs), national governments, and national and local policymakers. Ministers of finance, law, education, transport, and health all need to play their part through enacting human rights legislation, promoting and funding education for girls, and providing better transport links and more medicines, commodities, and other supplies. Essential drugs such as magnesium sulfate are often unavailable or in very short supply, as are blood and fluid replacement, equipment, laboratory reagents, and even generators and clean water. Ministries of health can supply more and better equipped facilities capable of providing care at all levels, and they can create training schools for the extra maternity staff so badly needed in most of the world.

**National and local professional associations and individual health care workers can improve the quality of care they provide through the use of evidence-based practice and the development of situationally appropriate clinical guidelines and technologies.** They can also ensure continual professional updating and training. Until such time as there are enough midwives and doctors, intermediate-level health care workers trained to undertake tasks traditionally performed by doctors play an invaluable role. A functioning health system also requires an efficient system of communication, referral, and transport. Underpinning and facilitating all of this work should be a supportive national legal and ethical framework that includes policies that strive for equality in women's rights. This is not

**BOX 58-2 TWELVE PROPOSITIONS FOR SAFE MOTHERHOOD FOR ALL WOMEN**

1. A woman's life is worth saving.
2. Girls should have equal access to food, education, health care, and life opportunities as their brothers.
3. Young girls should not be subject to violence including rape, FGM, and child marriage, and women should not suffer violence in any form.
4. Women should have an equal say in decisions that affect their own and their children's health and well-being.
5. All women must have the basic human right to control their own fertility and reproductive health and plan and space their pregnancies.
6. Pregnancy must be a voluntary choice.
7. Maternity is special and every society has an obligation to make it safe. Safe motherhood is a basic human right enshrined in UN statute.
8. All pregnant women must have access to antenatal/prenatal, birth, and postnatal care as described by WHO and other organizations.
9. All deliveries must be assisted by skilled birth attendants.
10. All women must have access to quality life-saving comprehensive emergency obstetric care if needed.
11. Care must be free or affordable. There should be no bribes or "unofficial" fees.
12. All women should be treated with dignity, respect, and compassion.

Modified from Fathalla M. Ten propositions for safe motherhood for all women. From the Hubert de Watteville Memorial Lecture. Imagine a world where motherhood is safe for all women—you can help make it happen. *Int J Gynaecol Obstet.* 2011;72(3):207-213.

universal. Professor Mahmoud Fathalla once proposed ten steps for safe motherhood, which have been updated and adapted for this chapter.<sup>92</sup> These are listed in [Box 58-2](#), and if accepted by the world's leaders, policymakers, and influencers, the world would be a far safer place for pregnant women and their unborn children.

## MAJOR OBSTETRIC COMPLICATIONS: PREVENTION AND MANAGEMENT IN RESOURCE-POOR COUNTRIES

The major complications of pregnancy are similar throughout the world. The outcome for individual women depends upon the care received and the capacity of the local health systems to respond to their needs. Where comprehensive emergency obstetric care is lacking, which includes staff and facilities for cesarean delivery, severe morbidity or death results from prolonged obstructed labor and/or fetal distress and life-threatening hemorrhage.<sup>93</sup>

### Postpartum Hemorrhage

The commonest cause of postpartum hemorrhage (PPH) is uterine atony. As discussed in [Chapter 18](#), the risk is highest in mothers with multiple pregnancies, prolonged/obstructed labor, preeclampsia/eclampsia, large uterine fibroids, and grand multiparity (five or more previous deliveries). In resource-poor settings, intrapartum and postpartum hemorrhage continues to be

the leading cause of maternal mortality, accounting for 27% of deaths.<sup>94</sup>

**For many pregnant women already suffering from severe chronic anemia due to malnutrition, micronutrient deficiency, sickle cell disease, malaria, or helminthic infections, even a blood loss of 500 mL at delivery can compromise their already challenged hemodynamic state and can result in hypovolemic shock.** The prevention or early detection of bleeding and the aggressive use of methods to reduce blood loss are essential. However, blood products and storage facilities are often unavailable,<sup>95</sup> and in an emergency situation, when blood is usually obtained from family members or donors, it is rarely screened for infection and may be diluted with dirty water.

Uterine bimanual massage and uterotonic drugs, if available, should be started at the first sign of atony. Compared with placebo, prophylactic oxytocin decreases PPH greater than 500 mL and reduces the need for therapeutic uterotonics.<sup>96</sup> It is also associated with fewer side effects, specifically nausea and vomiting, and evidence is limited to suggest that prophylactic oxytocin is superior to ergot alkaloids for the routine prevention of PPH. However, once an oxytocic agent has been given, opportunity is limited for further reduction in postpartum blood loss with its use.<sup>97</sup>

Misoprostol, a synthetic prostaglandin E1 analogue, plays a key role in the management of miscarriage.<sup>98</sup> Unlike oxytocin, it is low cost, stable at high temperatures, not degraded by ultraviolet light, and can be used orally or rectally, which makes it particularly useful in areas where skilled health care providers and resources are less available. Recent studies indicate that misoprostol distributed antenatally can be used accurately and reliably by rural Ghanaian and Liberian women after delivery and should be more widely implemented in other countries with high home birth rates.<sup>99,100</sup> Using Misoprostol for PPH prevention appears acceptable to women, but community-based strategies will be needed to increase distribution rates. However, conventional injectable uterotonics are still preferable to either intramuscular prostaglandins or misoprostol for the management of the third stage of labor, especially for low-risk women.<sup>101</sup>

In cases of persistent PPH, aggressive measures to minimize blood loss and secondary infection should be taken, but the availability of facilities and skilled staff to perform balloon tamponade and surgical compression sutures is limited. In facilities unable to provide emergency care, low-technology compression devices can help to stabilize a hemorrhaging mother long enough for her to reach a hospital equipped to provide comprehensive emergency services.<sup>34</sup>

### Preeclampsia/Eclampsia

**Hypertensive disorders of pregnancy account for 14% of global maternal deaths<sup>28</sup> and are the leading cause of death in some urban areas in low-income countries.<sup>102</sup>** They fall into four categories: (1) chronic hypertension, (2) gestational hypertension or pregnancy-induced hypertension (PIH), (3) preeclampsia/eclampsia, and (4) preeclampsia superimposed on chronic hypertension (see [Chapter 31](#)).

Preeclampsia and eclampsia are associated with extremes of maternal age (under 17 and over 35 years), nulliparity, multiple pregnancies, preexisting hypertension, preeclampsia in a previous pregnancy, poor socioeconomic circumstances, and illiteracy.<sup>103,104</sup> The increased susceptibility for indigenous African women and blacks living in North America appears to be independent of socioeconomic status and is likely due to biologic or

genetic factors.<sup>105,106</sup> However, even in developed countries, identifying women at risk can be difficult.<sup>107</sup> Limited access to antenatal care, little or no screening for high blood pressure and proteinuria, and the wide variations in access to antihypertensive drugs coupled with poor maternal understanding of the signs and symptoms and the need to seek immediate care all help explain the higher mortality from eclampsia in many low- to middle-income countries. Severe morbidity increases eightfold in women with preeclampsia, and it increases sixtyfold after an eclamptic seizure,<sup>103</sup> but the life-threatening neurologic complications and wider organ dysfunctions are reversible if adequate treatment is started in time. **Magnesium sulfate is the drug of choice but is not available in many developing countries. A recent systematic review of the use of magnesium sulfate in low- and middle-income countries found that the majority of women receive less than optimal dosages, usually due to concerns about maternal safety and toxicity, cost, or available resources.**<sup>108</sup>

Training health care and community workers and raising awareness in pregnant women about the signs and symptoms of preeclampsia is essential. Recent evaluation of a clinical model and algorithm in low-income countries has shown a reasonable ability to identify women at increased risk of adverse maternal outcomes associated with hypertensive disorders.<sup>103</sup> Furthermore, a training intervention for health care providers to use an evidence-based protocol for the treatment of preeclampsia and eclampsia has been shown to be effective in reducing the associated case fatality rate.<sup>109</sup>

## Sepsis

In the nineteenth and early twentieth century, puerperal sepsis was the major cause of maternal death in industrialized countries; but improvements in hygiene and sanitation, together with the introduction of antibiotics after the Second World War, resulted in its rapid decline.<sup>110</sup> **Nevertheless, perinatal infection still underlies 11% of maternal deaths and 33% of neonatal deaths globally.**<sup>28,111</sup> Poverty contributes significantly to these poor outcomes with clear evidence of an association between poor sanitation, limited access to clean water, and maternal death.<sup>112</sup> Ignorance of both the causes and need to prevent puerperal sepsis is widespread, and in some communities, people still believe illness is due to evil spirits.<sup>113</sup>

For the 50% of women globally who deliver at home attended only by a female relative or untrained traditional birth attendant (TBA), infection is an ever-present danger. Harmful practices are common, such as cutting the cord with broken glass and dressing the stump with cow dung, and despite immunization programs, neonatal tetanus is a frequent problem. Once infected, mothers and babies often lack access to transport, and if they reach a care facility, they frequently find that essential resources such as antibiotics are unavailable.

**The WHO guidelines on “the five cleans” needed during delivery<sup>114</sup> have led to the introduction of clean birth kits that contain soap, plastic sheeting, gloves, sterile gauze, a razor, and cord ties for use at home births.**<sup>115</sup> These simple kits have achieved a relative reduction in neonatal mortality, particularly in rural areas of developing countries.<sup>116</sup> However, wider interventions that included a skilled birth attendant in the intervention were associated with a greater and more significant reduction in neonatal mortality, omphalitis, and puerperal sepsis.<sup>117</sup> It is therefore considered best practice to provide safe birth kits in the hands of skilled attendants.

## Human Immunodeficiency Virus and Malaria

Pregnant women infected with HIV and/or *Plasmodium falciparum* malaria suffer higher complication rates. The MMR for HIV-infected women increases tenfold<sup>118</sup> because their immunodeficiency places them at greater risk of dying of pregnancy-related sepsis. **A recent review estimated the excess mortality attributable to HIV among pregnant and postpartum women to be 994 per 100,000 pregnant women.**<sup>29</sup>

The maternal immune response to malaria is also altered by pregnancy, and the most serious complications—including cerebral malaria, hypoglycemia, pulmonary edema, and severe hemolytic anemia—are more common. Approximately 40% of the world's pregnant women are exposed to malaria infection, and primigravidae are more likely to develop severe maternal anemia and to have low birthweight babies than multigravidae.<sup>119</sup> The fetal and perinatal loss may be as high as 60% to 70% in nonimmune women who contract malaria, and an additional 100,000 infant deaths in Africa result from malaria-induced low birthweight in babies.<sup>120</sup> Malaria infections among pregnant women are less common outside Africa but are more likely to cause severe disease, preterm births, and fetal loss. HIV increases the risk of malaria and its adverse effects, and women with both infections are at particular risk of adverse birth outcomes.<sup>121</sup>

## Obstructed Labor and Obstetric Fistula

**Worldwide, obstructed labor occurs in an estimated 5% of live births and accounts for 8% of maternal deaths.**<sup>122</sup> In sub-Saharan Africa and parts of Asia, as many as 2 million young women are affected and 50,000 to 100,000 new cases occur every year.<sup>123,124</sup> Obstructed labor, or “failure to progress,” with or without fetal distress is the main indication for emergency CD worldwide.<sup>125</sup> The problem can be prevented by using a partogram routinely in labor and by resorting to early operative delivery when progress is slow. The partogram is a cheap, graphic record of cervical dilation against time in labor; this simple monitoring tool swiftly identifies when a labor is becoming prolonged, thereby avoiding the development of obstetric fistulae and death from a prolonged obstructed labor or a ruptured uterus.<sup>126</sup> Despite strong advocacy by the WHO and other health care agencies, the global use of partograms is extremely poor, and some senior clinicians wrongly assert that completing the monitoring paperwork is unrealistic for already overworked midwives and doctors.

Obstetric fistulae can occur at any age or parity but are most common in first births, particularly in young girls with a poorly developed pelvis. They are a direct consequence of prolonged obstructed labor where the pressure of the impacted fetus leads to the destruction of the vesicovaginal/rectovaginal septum with subsequent loss of urinary and/or fecal control.<sup>127,128</sup> They can also be due to trauma at the time of pelvic surgery or as a result of rape, and in parts of Africa, some 15% of cases are caused by harmful female genital mutilation/cutting (FGM/C) before or during labor by unskilled birth attendants.<sup>129</sup> The tragedy is that obstructed labor and obstetric fistulae are largely avoidable; a summary of the preventive measures, as described by the WHO, is shown in Table 58-4.

**Obstetric fistulae are highly stigmatizing, and affected women who constantly leak urine and fecal matter frequently become social outcasts.** Unlikely to have further children or find employment, they are regarded as worthless to their families and are frequently rejected. Specialist fistula repair centers and

**TABLE 58-4** PREVENTION OF OBSTETRIC FISTULAE

| TYPE                 | WHEN                      | WHAT   |
|----------------------|---------------------------|--|
| Primary prevention   | Before pregnancy          | <ul style="list-style-type: none"> <li>• Eliminate female genital mutilation, early marriage, and early childbearing</li> <li>• Pregnancies are planned</li> </ul>   |
| Secondary prevention | During pregnancy          | <ul style="list-style-type: none"> <li>• Skilled antenatal care</li> <li>• During birth, awareness of signs and symptoms of impending fistula such as prolonged labor and the need to seek care</li> <li>• Manage prolonged labor (“Do not let the sun set twice on a laboring woman”*)</li> </ul>   |
| Tertiary prevention  | During and after delivery | <ul style="list-style-type: none"> <li>• Easy and early access to facilities equipped to manage essential obstetric care including CD</li> <li>• Monitor every labor using partogram to identify women at risk or to monitor those who develop obstructed labor and refer immediately if CD cannot be done in the current facility</li> <li>• Use of indwelling catheters to help enable spontaneous closure of small fistulae in mothers who have survived an obstructed labor</li> <li>• Encourage such women to seek skilled care during next pregnancy and delivery</li> </ul> |

\*Kenyan proverb.

CD, cesarean delivery.

the training of local surgeons to perform simple repairs helps to restore function, fertility, and dignity to these women, but such services are still beyond the reach of most fistula sufferers.

### Cesarean Delivery

Cesarean delivery rates in many resource-poor countries remain much lower than the 10% to 15% cited by the WHO as their target in 1985.<sup>130</sup> In other countries, the rate continues to rise above unacceptably high levels, particularly in private hospitals. **In 2008, the WHO estimated an overall rate of 45.9% for Brazil, 30.3% for the United States, and only 0.7% for Burkina Faso; this equates to 3.18 million CDs that should have been performed, and 6.20 million performed unnecessarily.**<sup>35</sup> The cost of the global “excess” of CD was estimated to be \$2.32 billion, whereas the cost of the global unmet need for CD is a mere \$432 million.<sup>35</sup> This excess of CD is due to maternal request, increasing maternal age, obesity, poor clinical acumen, risk-averse behaviors, and fear of litigation.<sup>131</sup> However, it is not an operation without sequelae, and the rising incidence of PPH due to placenta increta and/or placenta accreta involving a previous CD scar has risen significantly, as demonstrated by research, in the United Kingdom.<sup>132</sup>

As with all surgical procedures, the benefits and risks must be carefully assessed for both mother and baby. A mother can die of hypovolemic shock after a technically successful CD with average blood loss if she is dehydrated, severely anemic, and unable to cope with an operative insult. If the local health care facility is poorly equipped with no access to emergency resuscitation, blood transfusion, or anesthesia, it may be preferable to delay the CD until transfer to a safer facility can be arranged. However, significant delays in the second stage of labor leads to additional complications that include increased likelihood of hemorrhage, extension of the surgical incision into the vagina or uterine arteries, sepsis, and fistula development.

### PRACTICAL ADVICE ON VOLUNTEERING TO WORK OVERSEAS

Many health professionals wish to “give back” to the most vulnerable of the world’s citizens; for some, offering their skills in-country is becoming an increasingly popular option. Some choose to work abroad to add experience to their curriculum vitae or when applying for university or higher training, whereas others wish to undertake research or practice their clinical skills.

A growing trend is also to participate in teaching and/or bilateral sustainable support programs in a needy facility organized by their local institutions. Partnering among universities, hospitals, and medical and midwifery schools is also becoming more popular and is a good way to ensure a constant supply of teachers and clinical staff upon which the host institution may have come to rely. Volunteers also play a key role in “training the trainers”—that is, enabling cadres of local staff to act as ongoing trainers in their own country. However, whatever the reasons, volunteering only benefits the local population if the placement is carefully planned, leads to sustainable improvement, and is undertaken with care and understanding.

**Well-organized trips conducted sensitively with respect for the mothers, health care workers, and local cultures can be life-enriching experiences for all concerned and yield life-long benefits.** However, this is not always the case; at its worst, the arrogant, dismissive, or critical behavior of some volunteers has given so called “volunteerism”<sup>133</sup> a bad reputation locally. Concern exists that such initiatives can lead to exploitation and harm, particularly when projects are only focused on meeting the volunteer’s needs or undertaking research that will not benefit the local community. Indeed, in some parts of Africa, what is now referred to as “extraction tourism”—in which only the temporary visitor seems to benefit, often leaving a worse situation and unpleasant feelings behind—is so bad that volunteers are no longer welcome.

For staff working within already well-established exchange schemes, the knowledge of how to prepare and behave should have already been explained, and initial local difficulties have been overcome. However, for others working alone or with small organizations, knowing what to expect and how to plan and conduct the placement is the subject of this section.

In summary, the **key personal qualities** for working abroad include:

1. Compassion and respect
2. Humility and honesty
3. High ethical and moral standards
4. Acceptance of the community and its values and a willingness to behave in a culturally appropriate manner
5. Commitment to promote the welfare of the community you serve first and putting their needs before your own
6. Ability to practice and teach the highest quality evidence-based medicine using sustainable drugs and equipment appropriate for the local circumstances, which will be

available after your departure and, in the case of machinery, will include a source for spare parts so the equipment can be repaired

7. An openness and willingness to learn from local staff, who will have much to teach and share
8. A dedication to ensuring sustainability
9. The ability to resist being openly critical of the lack of resources and poor infrastructure, saying how much better things are at home (staff and patients are all too aware of this)
10. The integrity to follow the same ethical principles you would adhere to in your own institute or country (for research, this is crucial)

Although these principles may seem glaringly obvious, experience has repeatedly shown that failure to follow such simple guidelines can lead to disappointment and frustration on all sides.

## Respect

**The health staff you will work with and the mothers, babies, and communities you will care for are no different than anywhere else. Even though they may be poor beyond imagination, perhaps have inexplicable customs, and cannot speak your language, each deserves as much respect as you would give all your patients or colleagues at home.** They are generally living lives so hard as to be unfathomable, and this deserves recognition, admiration, and compassion. Try to learn a few words of their language, and treat everyone with dignity and respect. Learn about social customs and taboos so you do not inadvertently offend.

## Realism

Do not have unrealistic expectations about what can be achieved in the time available to you. In most countries, it takes far longer to organize things, and wheels turn very slowly. Often, a lot of bureaucratic red tape and delay intervenes both before leaving and while in-country. Start organizing your trip months beforehand, and obtain the necessary permissions before you leave. Visas, too, can take time.

Remember that you will not be the first or last volunteer. Volunteering is a growing business, and some popular facilities, like the base camps of Mt. Everest, can become very overcrowded. In some areas, numerous NGOs or other organizations have been seen running the same type of program without joint preplanning or teamwork. This lack of coordination is at best ineffective, and at its worst, disastrous, because it leads to confusion among volunteers and staff, duplication of work, and the waste of very scarce resources. If you wish to work in a particular place, always check who is working there already and contact them. Check with the hosts to see if you would really be welcome, and be sure they are not just being polite to a request from someone they do not know. Rather than just trying to do what you think will help, ask the local staff what would help fill service gaps for them.

Also, be aware that health facilities are generally chronically and completely understaffed with only one or two midwives or doctors to care for numerous patients, at best. As such, they will have little time to teach and nurture inexperienced volunteers because they take up crucial time that could be spent with patients. The paradox is that in wishing to please, they will be polite and may spend too much time with you and not their patients. Such volunteers would probably do better by joining

an already well-established program that can accommodate and acclimatize them. Some larger programs hold predeparture training workshops. In these sessions, be honest about your skills and abilities, and consider how much supervision you would need; then choose your options carefully. You may be welcome, but you will need to be able to step in immediately and pull your own weight rather than becoming an additional burden on an already overstretched staff.

## Health Care Staff

The staff you will work with invariably will work longer hours, in far worse conditions, and for far less pay than you. Sometimes they work with no pay at all if money in the health center is limited for a while. In addition, they are rightly proud of what they can achieve with so very little. Although everyone is almost always polite, talking about your own salary or showing large amounts of money is insensitive. However initially surprised or shocked you may be, do not be critical of the facility, lack of resources, or age or type of equipment available. The staff will already be acutely aware of the limitations and will be proud of the innovative local solutions they may have devised to the best of their resources and ability. Although they will have been trained in a variety of institutions, with different knowledge and skills, they will most certainly be more able than you to undertake more complex operations under challenging conditions until you, too, have become expert in their art. Examples of this could include complex fistula repair or even the simple repairs done by the trained former patients of the Addis Ababa Fistula Hospital.

**Midwives are the backbone of most maternity services around the world and are widely respected and generally highly competent. Do not underestimate their abilities.** They are specialists in “normal” deliveries, and in many places, including the United Kingdom, they teach medical students and junior residents crucial obstetric skills. In European countries, some work as independent autonomous practitioners. In the United Kingdom, midwives are present at every birth, and over 65% of women are delivered with their assistance alone. Either independently or working within a multidisciplinary team for higher risk pregnancies, their skills help improve maternal health care; the latest direct-cause maternal mortality ratio for the United Kingdom, 5.4 per 100,000 live births, is one of the lowest in the world.<sup>30</sup> Other countries with very low death rates are also characterized by the inclusion of their own midwives. They are highly skilled in managing the normal and knowing when to refer for help; the maternal mortality rates in these countries are the lowest in the world. Experienced midwives who work in resource-poor countries will have seen and managed more sick women than most obstetricians in a lifetime. They work without the resources taken for granted elsewhere. A number have a wide variety of other skills, and in certain places—with training, for example—they even undertake cesarean delivery, symphysiotomy, and simple fistulae repair. However, there are far too few midwives, and they are often vastly overworked with intolerably high caseloads and very long shifts. One midwife in a labor ward with 50 or more women is not unusual. Some adopt the babies of mothers who have died, and most are pillars of their community. All will have much to teach you.

In many low-income countries, only a few specialists in obstetrics and gynecology work in the public sector; other health care professionals such as family doctors, medical or clinical officers, or operating theater assistants are trained to perform

many routine procedures. In obstetrics, this involves training staff in the competencies to undertake some work traditionally done by maternity health care professionals, doctors, midwives, and nurses—so-called task shifting.<sup>134</sup> **To meet the crisis in human resources all across the developing world, low- and mid-level workers are expanding their skills and taking on new roles according to the competencies in which they have been trained and are able to master.**

## Research

Visitors who plan research activities in a foreign country must only undertake these having first obtained national and local ethics committee approval. This can take months, and the process will vary according to local laws. Additionally, the rules in their own institution and country must be followed. If required, consent forms should be obtained from all study participants, having first clearly explained the process in their own language. If a research project is performed in a country with no ethics committee or institutional review board or similar body, researchers should ensure their proposed study adheres to the World Medical Association Declaration of Helsinki.<sup>135</sup>

Research projects should also only focus on interventions that could benefit the women, babies, or communities under consideration. It is not moral or ethical to test drugs, equipment, supplements, vaccines, and so on that will be so expensive as to be unavailable to the women who were the research subjects.

Because of their punishing workload, health care staff in low-income countries have little or no time to prepare papers for publication. However, local researchers should be encouraged and helped to write and author papers, be first author where appropriate, and present their findings at local and international conferences. This not only recognizes their contribution and benefits their careers, it also adds to their knowledge base; such local experience is invaluable when planning appropriate and effective interventions. This support for local doctors is becoming an increasing requirement of those who fund medical and other research programs.

## Predeparture Preparation

The following list, although not exhaustive by any means, should help you to start your preparation. Although some general pointers are always helpful, issues specific to the location may apply that you will need to identify and understand. Your hosts can help you in this, but remember: you are ultimately responsible for your health and well-being while in a volunteering program.

Thoroughly research the country and institutions you are planning to visit well in advance of leaving. **Apart from general background, read any WHO, UN, World Bank, and other institutions' in-country fact sheets on the general health of the population as well as in your specific area. Talk with ex-volunteers and find out their practical tips.**

Try to arrange an orientation session about your placement. If it is with a large organization, they may invite you to attend a predeparture meeting to discuss practicalities and your responsibilities. If they are abroad, social media such as Skype are extremely helpful.

Learn about requirements for local medical registration and arrangements for medical indemnity. Ask for their safety briefing packs, and obtain key contact numbers.

Ensure that your passport is valid for at least 6 months beyond the intended length of your entire stay, including any vacation

time at the end. Check visa requirements well in advance of your departure by contacting the Embassy or High Commission for the country you are visiting. This may take a long time to complete.

Evaluate your budget. If not provided for you, the cost of subsistence is usually very low, but the cost of accommodation may vary widely. Ask your hosts for their recommendations. Factor in costs for a comprehensive package of personal insurance for health, travel, and loss of possessions.

Consult an established travel center concerning vaccinations and malaria prophylaxis at least 6 months before you travel. Some vaccines, such as against yellow fever, are compulsory to enter many sub-Saharan African countries. The availability of postexposure prophylaxis for HIV is essential in many countries, and you may need to take these supplies with you. Also arrange to take supplies of any essential drugs you personally need because they are unlikely to be widely available elsewhere. You may need to bring these into the country with a letter or confirmatory prescription from your physician.

Contact your licensing body for advice on maintaining your medical licensure and indemnity at home during your placement. Allow yourself maximum time to gain medical registration within the country you are visiting because this can be time consuming.

You will need to protect your pension and take precautions for every eventuality. Research the best options for life insurance.

You will also wish to consider whether you will be taking any drugs or equipment with you and, if so, be sure that you are not at risk of contravening local customs and excise regulations and such. You should check this with your sponsor and on the relevant Web sites.

It is beneficial to arrange for two mentors, one in-country and one at home, to support you. Ask your sponsors to arrange an in-country mentor. Your hospital, professional association, or medical school may be able to put you in touch with colleagues who have experience working in the country and who may be prepared to mentor to you while you are away.

As soon as you arrive, it is essential that you register with the embassy or foreign office of your home country so that they are aware that you are there should there be any emergencies. Many of these organizations use Twitter or other social media to give regular updates of the current political and security climate. Maintain regular contact with your organizing institution and with your mentors.

Keep a diary, take photographs (with permission), and also relax, have fun, make new friends, and enjoy your new environment.

## KEY POINTS

- ◆ Every day, 800 women die as a result of pregnancy or childbirth, and an additional 16,000 develop severe and long-lasting complications.
- ◆ Every day, 8000 newborn babies die and 7000 are still-born, and more than half of these deaths are from maternal complications.
- ◆ Adolescent pregnancies account for 11% of all births worldwide, and these young girls and their babies are at far higher risk of death and complications than other mothers.

- ◆ Of all the maternal and neonatal deaths worldwide, 99% take place in developing countries.
- ◆ The leading obstetric causes of maternal death in developing countries are hemorrhage, puerperal sepsis, preeclampsia, unsafe abortion, obstructed labor, and embolism. HIV causes a growing number of deaths in countries where it is endemic.
- ◆ If all pregnant women and their babies could access the maternity care recommended by the WHO, the annual number of maternal deaths would fall by two thirds—from 290,000 to 96,000—and newborn deaths would fall by more than three quarters to 660,000 each year.
- ◆ If all women had control over their fertility and could access effective contraception, unintended pregnancies would drop by 70%, and unsafe abortions would drop by 74%.
- ◆ Apart from a lack of skilled health care and other resources, the quality of the care provided also varies widely. The clinical guidelines and protocols set forth by the WHO and professional organizations need to be urgently implemented, and their uptake audited, in developed as well as in developing countries.
- ◆ Safe motherhood for all women is enshrined as a basic human right by the United Nations, yet many societies have yet to recognize and address this, and they fail to provide the necessary resources to provide adequate reproductive health, maternity, and newborn care or to enact and enforce laws to support equality for women in all aspects of their life, which includes abolition of child marriage and other harmful traditional practices.
- ◆ A woman's life is always worth saving.

## Acknowledgment

The section on the United States was written with assistance by William Callaghan, MD, MPH, chief of Maternal and Infant Health Branch, Division of Reproductive Health, Centers for Disease Control and Prevention, and in collaboration with the American College of Obstetricians and Gynecologists.

## INVASIVE CARDIAC MONITORING

| MEASURE                                   | VALUE (36-38 WEEKS) | UNITS                     |
|---|---------------------|---------------------------|
| Cardiac output*                           | 6.2 ± 1.0           | L/min                     |
| Systemic vascular resistance              | 1210 ± 266          | Dyne/cm/sec <sup>-5</sup> |
| Heart rate                                | 83 ± 10             | Beats/min                 |
| Pulmonary vascular resistance             | 78 ± 22             | Dyne/cm/sec <sup>-5</sup> |
| Colloid oncotic pressure                  | 18.0 ± 1.5          | mm Hg                     |
| Mean arterial pressure (MAP)              | 90.3 ± 5.8          | mm Hg                     |
| Pulmonary capillary wedge pressure (PCWP) | 7.5 ± 1.8           | mm Hg                     |
| Central venous pressure (CVP)             | 3.6 ± 2.5           | mm Hg                     |
| Left ventricular stroke work index        | 48 ± 6              | g/mm <sup>-2</sup>        |

Data from Clark SL, Cotton DB, Lee W, et al. Central hemodynamic assessment of normal term pregnancy. *Am J Obstet Gynecol.* 1989;161:1439; Spatling L, Fallenstein F, Huch A, et al. The variability of cardiopulmonary adaptation to pregnancy at rest and during exercise. *Br J Obstet Gynaecol.* 1992;99(Suppl 8):1.

\*Cardiac output increases during the first trimester of pregnancy but thereafter is essentially unchanged over the course of pregnancy; heart rate gradually rises 5 to 10 beats/min over the course of pregnancy.

## NONINVASIVE CARDIAC MONITORING

| MEASURE  | 10-18 WEEKS | 18-26 WEEKS | 26-34 WEEKS | 34-42 WEEKS |
|--|-------------|-------------|-------------|-------------|
| Cardiac output (L/min)   | 7.26 ± 1.56 | 7.60 ± 1.63 | 7.38 ± 1.63 | 6.37 ± 1.48 |
| Stroke volume (mL)   | 85 ± 21     | 85 ± 21     | 82 ± 21     | 70 ± 14     |
| Systemic vascular resistance (SVR) (dyne/cm/second <sup>-5</sup> ) | 966 ± 226   | 901 ± 224   | 932 ± 240   | 1118 ± 325  |
| Heart rate (beats/min)   | 87 ± 14     | 90 ± 14     | 92 ± 14     | 92 ± 7      |
| Mean arterial pressure (mm Hg)                                     | 87 ± 7      | 84 ± 7      | 84 ± 7      | 86 ± 7      |

Data from Van Oppen CA, Van Der Tweel I, Alsbach JGP, et al. A longitudinal study of maternal hemodynamics during normal pregnancy. *Obstet Gynecol.* 1996;88:40.

## ARTERIAL BLOOD GAS VALUES (THIRD TRIMESTER)

|                                   | NORMAL ALTITUDE | MODERATE ALTITUDE* (1388 M) |
|-----------------------------------|-----------------|-----------------------------|
| Arterial pH                       | 7.40-7.48       | 7.44-7.48                   |
| Arterial PO <sub>2</sub> (mm Hg)  | 80-90           | 78.9-93.5                   |
| Arterial PCO <sub>2</sub> (mm Hg) | 26.9-32.5       | 23.9-29.3                   |
| Sodium bicarbonate (mEq/L)        | 19.9-24.1       | 16.7-20.5                   |

Data from Hankins GD, Clark SL, Harvey CJ, et al. Third trimester arterial blood gas and acid base values in normal pregnancy at moderate altitude. *Obstet Gynecol.* 1996;88:347; and Eng M, Butler J, Bonica JJ. Respiratory function in pregnant obese women. *Am J Obstet Gynecol.* 1975;123:241.

\*Provo, Utah.

## PULMONARY FUNCTION TESTS

|                                | 8-11 WEEKS    | 20-23 WEEKS   | 28-31 WEEKS   | 36-40 WEEKS   |
|--------------------------------|---------------|---------------|---------------|---------------|
| Respiratory rate (breaths/min) | 15 (14-20)    | 16 (15-18)    | 18 (15-20)    | 17 (16-18)    |
| Tidal volume (mL)              | 640 (550-710) | 650 (625-725) | 650 (575-720) | 700 (660-755) |

Data from Spatling L, Fallenstein F, Huch A, et al. The variability of cardiopulmonary adaptation to pregnancy at rest and during exercise. *Br J Obstet Gynaecol.* 1992;99:1. Values expressed as median (25th to 75th percentiles).

## PULMONARY FUNCTION TESTS, MEAN VALUES

|                                    | FIRST TRIMESTER | SECOND TRIMESTER | THIRD TRIMESTER |
|------------------------------------|-----------------|------------------|-----------------|
| Mean vital capacity (L)            | 3.8             | 3.9              | 4.1             |
| Mean inspiratory capacity (L)      | 2.6             | 2.7              | 2.9             |
| Mean expiratory reserve volume (L) | 1.2             | 1.2              | 1.2             |
| Mean residual volume (L)           | 1.2             | 1.1              | 1.0             |

Data from Gazioglu K, Kaltreider NL, Rosen M, Yu PN. Pulmonary function during pregnancy in normal women and in patients with cardiopulmonary disease. *Thorax.* 1920;25:445; and Puranik BM, Kaore SB, Kurhade GA, et al. A longitudinal study of pulmonary function tests during pregnancy. *Indian J Physiol Pharmacol.* 1994;38:129.

## PEAK FLOWS STABLE OVER GESTATION

|          | PEAK FLOW (L/MIN) |
|----------|-------------------|
| Standing | >320              |
| Sitting  | >310              |
| Supine   | >300              |

Data from Harirah HM, Donia SE, Nasrallah FK, et al. Effect of gestational age and position on peak expiratory flow rate: a longitudinal study. *Obstet Gynecol.* 2005;105:372.

## LIVER/PANCREATIC FUNCTION TESTS

|                                    | FIRST TRIMESTER | SECOND TRIMESTER | THIRD TRIMESTER | TERM    |
|------------------------------------|-----------------|------------------|-----------------|---------|
| Total alkaline phosphatase (IU/L)  | 17-88           | 39-105           | 46-228          | 48-249  |
| Gamma glutamyl transferase (IU/L)  | 2-37            | 2-43             | 4-41            | 5-79    |
| Aspartate transaminase (AST, IU/L) | 4-40            | 10-33            | 4-32            | 5-103   |
| Alanine transaminase (ALT, IU/L)   | 1-32            | 2-34             | 2-32            | 5-115   |
| Total bilirubin (mg/dL)            | 0.05-1.3        | 0.1-1.0          | 0.1-1.2         | 0.1-1.1 |
| Unconjugated bilirubin (mg/dL)     | 0.1-0.5         | 0.1-0.4          | 0.1-0.5         | 0.2-0.6 |
| Conjugated bilirubin (mg/dL)       | 0-0.1           | 0-0.1            | 0-0.1           | —       |
| Total bile acids (μM/L)            | 1.7-9.1         | 1.3-6.7          | 1.3-8.7         | 1.8-8.2 |
| Elevated total bile acids (μM/L)   | >10             | >10              | >10             | >10     |
| Lactate dehydrogenase (U/L)        | 78-433          | 80-447           | 82-524          | —       |
| Amylase (IU/L)                     | 11-97           | 14-92            | 14-97           | 10-82   |
| Lipase (IU/L)                      | 5-109           | 8-157            | 21-169          | —       |

Data from Bacq Y, Zarka O, Brechot JF, et al. Liver function tests in normal pregnancy: a prospective study of 103 pregnant women and 103 matched controls. *J Hepatol.* 1996;23:1030; Karesenti D, Bacq Y, Brechot JF, Mariotte N, Vol S, Tichet J. Task Force on Hypertension in Pregnancy, 2013.

## CHOLESTEROL AND LIPIDS

|                           | FIRST TRIMESTER | SECOND TRIMESTER | THIRD TRIMESTER | TERM    |
|---------------------------|-----------------|------------------|-----------------|---------|
| Total cholesterol (mg/dL) | 117-229         | 136-299          | 161-349         | 198-341 |
| HDL (mg/dL)               | 40-86           | 48-95            | 43-92           | 44-98   |
| LDL (mg/dL)               | 39-153          | 41-184           | 42-224          | 86-227  |
| VLDL (mg/dL)              | 10-18           | 13-23            | 15-36           | 25-51   |
| Triglycerides (mg/dL)     | 11-209          | 20-293           | 65-464          | 103-440 |

Data from Belo L, Caslake M, Gaffney D, et al. Changes in LDL size and HDL concentration in normal and preeclamptic pregnancies. *Atherosclerosis.* 2002;162:425; Desoye G, Schweditsch MO, Pfeiffer KP, Zechner R, Kostner GM. Correlation of hormones with lipid and lipoprotein levels during normal pregnancy and postpartum. *J Clin Endocrinol Metab.* 1987;64:704; Jimenez DM, Pocovi M, Ramon-Cajal J, Romero MA, Martinez H, Grande H. Longitudinal study of plasma lipids and lipoprotein cholesterol in normal pregnancy and puerperium. *Gynecol Obstet Invest.* 1988;25:158; Lain KY, Markovic N, Ness RB, Roberts JM. Effect of smoking on uric acid and other metabolic markers throughout normal pregnancy. *J Clin Endocrinol Metab.* 2005;90:5743; Lockitch G. *Handbook of diagnostic biochemistry and hematology in normal pregnancy.* Boca Raton, FL: CRC Press; 1993. HDL, high-density lipoprotein; LDL, low-density lipoprotein; TRI, trimester; VLDL, very-low-density lipoprotein.

HEMATOLOGIC INDICES, IRON, AND B<sub>12</sub>

|   | FIRST TRIMESTER | SECOND TRIMESTER | THIRD TRIMESTER | TERM      |
|---|-----------------|------------------|-----------------|-----------|
| White blood cells (10 <sup>3</sup> /mm <sup>3</sup> ) | 3.9-13.8        | 4.5-14.8         | 5.3-16.9        | 4.2-22.2  |
| Neutrophils (10 <sup>3</sup> /mm <sup>3</sup> )       | 2.2-8.8         | 2.9-10.1         | 3.8-13.1        | 4.8-12.9  |
| Lymphocytes (10 <sup>3</sup> /mm <sup>3</sup> )       | 0.4-3.5         | 0.7-3.9          | 0.7-3.6         | 0.9-2.5   |
| Monocytes (10 <sup>3</sup> /mm <sup>3</sup> )         | 0-1.1           | 0-1.1            | 0-1.4           | 0-0.8     |
| Eosinophils (10 <sup>3</sup> /mm <sup>3</sup> )       | 0-0.6           | 0-0.6            | 0-0.6           | —         |
| Basophils (10 <sup>3</sup> /mm <sup>3</sup> )         | 0-0.1           | 0-0.1            | 0-0.1           | —         |
| Platelet count (10 <sup>9</sup> /L)                   | 149-433         | 135-391          | 121-429         | 121-397   |
| Hemoglobin (g/dL)                                     | 11.0-14.3       | 10.5-13.7        | 11.0-13.8       | 11.0-14.6 |

- E-Fig. A2-29 Changes in the uterus caused by pregnancy and parturition

## KEY POINTS

- ◆ To facilitate childbearing, the female pelvis—as opposed to the male pelvis—is characterized by a wider subpubic angle, increased width of the sciatic notch, and greater distance from the symphysis pubis to the anterior edge of the acetabulum.
- ◆ The levator ani, the major supporting structure for the pelvic viscera, is a tripartite muscle mass composed of the iliococcygeus, pubococcygeus, and puborectalis; the iliococcygeus is the broadest and most posterior portion.
- ◆ Innervation of the levator ani is through the third and fourth sacral nerves.
- ◆ The major nerve supply of the perineum is derived from the pudendal nerve. However, the ilioinguinal, genitofemoral, perineal branch of the posterior femoral cutaneous, coccygeal, and last sacral nerve also contribute; thus a pudendal nerve block anesthetizes only a portion of the perineum.
- ◆ The internal iliac (hypogastric) artery arises at the level of lumbosacral articulation. It can be distinguished from the external iliac by its smaller size and by its more medial and more posterior position.
- ◆ The ureter lies more superficially and is either medial or slightly anterior to the internal iliac artery.
- ◆ The cardinal ligaments are located at the base of the broad ligament and are continuous with the connective tissue of the parametrium; they are attached to the pelvic diaphragm through continuity with the superficial superior fascia of the levator ani.
- ◆ Because the origin of the uterine artery is variable, its isolation and ligation for control of postpartum bleeding are often fruitless. The uterine artery usually arises as an independent vessel from the internal iliac artery, but it may also arise from the inferior gluteal, internal pudendal, umbilical, or obturator arteries.
- ◆ Afferent pain fibers for the uterus, tubes, and ovary enter the cord at T10, T11, and T12; thus spinal or epidural anesthesia must extend to these levels. Fortunately, efferent fibers to the uterus enter above these levels and thus do not interfere with contractions.
- ◆ The body of the nonpregnant uterus weighs approximately 70 g, whereas at term it weighs approximately 1100 g.

## SUGGESTED READING

1. Moore KL, Dalley AF 2nd. Pelvis and perineum. In: *Clinically Oriented Anatomy*. 6th ed. Baltimore: Lippincott Williams & Wilkins; 2009:326.

\*Figures for Appendix II are available at [ExpertConsult.com](http://ExpertConsult.com).

**E-FIG A2-1** Major components of the bony pelvis, frontal superior view of the female pelvis. The plane of the pelvic brim faces forward and forms an angle of about 60 degrees to the horizontal. Features that most clearly distinguish the female from the male pelvis include a wider subpubic angle, wider sciatic notch, and greater distance from pubic symphysis and anterior edge of the acetabulum.

**E-FIG A2-2** Major ligaments and notches of the female pelvis, posterior view. During pregnancy, temporary changes take place in the ligaments that permit both movement of the joints and enlargement of the pelvic cavity. This becomes important during parturition.

**E-FIG A2-3** Muscles of the pelvic diaphragm, oblique view. The pelvic diaphragm forms a muscular floor for the support of the pelvic organs. Note the location of the urethra, uterus, and rectum as they pierce the floor of the pelvic diaphragm.

**E-FIG A2-4** Muscles of the pelvic diaphragm, superior view. As seen from above, the pelvic diaphragm consists of a number of different muscles and ligaments. The spaces between these muscles transmit a number of vessels and nerves as they leave the pelvis. Note the relationship of the central tendon of the perineum to the rectum and uterus.

**E-FIG A2-5** Muscles of the pelvic diaphragm, inferior view. The pelvic diaphragm is bilaterally symmetric, with the perineal body (central tendon) and the anococcygeal ligament forming a strong median raphe. *lig.*, Ligament.

**E-FIG A2-6** Fascial and peritoneal relationships of the pelvic diaphragm. In this frontal view of the pelvis, the levator ani can be seen to slope downward and medially, surrounding the vagina. The loose connective tissue beneath the pelvic peritoneum is variable in thickness, depending on the general adiposity of the individual. Note also the continuity of the different fascias as they merge to form the neurovascular sheaths.

**E-FIG A2-7** Muscles of the deep perineal space, inferior view. As viewed with the patient in dorsal lithotomy position, the deep perineal space consists of smaller muscles than those of the superficial perineal space. Note that the vestibular bulb lies within the superficial perineal space. *Inset:* Division of the perineum into a urogenital (anterior) triangle and an anal (posterior) triangle.

**E-FIG A2-8** Muscles of the superficial perineal space, from below. As viewed with the patient in dorsal lithotomy position, the muscles of the superficial perineal space of the urogenital triangle and the muscles of the anal triangle all converge in the midline. *m.*, Muscle.

**E-FIG A2-9** Ischiorectal fossa, frontal section. The ischiorectal fossa surrounds the rectum and vagina and forms most of the potential space within the posterior triangle of the perineum. The fascia of the levator ani merges with the visceral sheath of the rectum and vagina to lend support.

**E-FIG A2-10** Ischioanal fossa and urogenital diaphragm, sagittal section. The ischioanal fossa extends both forward and backward from the anal triangle. The urogenital diaphragm subdivides the urogenital triangle, with the anterior recess of the ischioanal fossa superior to it. The subcutaneous fat between the inferior aspect of the superficial perineal space and the skin varies among individuals.

**E-FIG A2-11** External anal sphincter as viewed in dorsal lithotomy position. The external anal sphincter is composed of three muscles that arise from the coccyx and converge into the central tendon of the perineum. Midline or mediolateral episiotomy may damage this sphincter; proper reapproximation is essential for fecal continence.

**E-FIG A2-12** Cutaneous nerve supply to the perineum. Most cutaneous innervation to the perineum comes from the pudendal nerve, but important regions are supplied by other sources. Pudendal block thus only anesthetizes a portion of the perineal surface. The exact limits of each specific nerve supply are variable. *N.*, Nerve; *nn.*, nerves.

**E-FIG A2-13** Superficial perineal blood supply and nerves as viewed in dorsal lithotomy position. The vessels and nerves to the superficial perineal space follow each other. The vasculature is markedly engorged during pregnancy, and bleeding from these vessels may be significant because of laceration, trauma, or episiotomy. Note the transverse branch of the perineal artery, a vessel often encountered during routine midline or mediolateral episiotomy. *a.*, Artery; *br.*, branch; *n.*, nerve.

**E-FIG A2-14** Vessels and nerves of the deep perineal space. The vasculature and innervation to the deep perineal space enters the anterior triangle from superior to inferior, in contrast to the superficial perineal space vessels and nerves. Note that the blood supply and innervation to the vestibular bulb and greater vestibular gland (Bartholin gland) are derived from the deep perineal vessels and nerves. *a.*, Artery; *n.*, nerve.

**E-FIG A2-15** Major organs of the pelvis, sagittal section. The internal organs of the pelvis are supported by the levator ani. Note how the anteverted, anteflexed uterus gains further support from both the urinary bladder and rectum. The ureter crosses the lateral aspect of the uterus at the level of the internal os on its way to the bladder. The actual position of the ovary and fimbriated end of the tube is quite variable.

**E-FIG A2-16** Anatomy of the fallopian tube and ovary, posterior view. The ovary and tube are suspended by mesenteries derived as specialized portions of the broad ligament. The vasculature and nerves enter through the mesovarium and mesosalpinx.

**E-FIG A2-17** Anatomic regions of the uterus, lateral view. The uterus is composed of cervix, isthmus, corpus, and fundus. Because the regions of the uterus grow at different rates during pregnancy, the distance between cornual fallopian tube and fundus increases markedly with increasing gestation. Note that the peritoneal reflection of the bladder occurs at the level of the uterine isthmus.

**E-FIG A2-18** Anatomic relationships of the uterus, lateral view. The broad ligament contains the uterus and forms an anterior and posterior covering. The triangular space along the lateral uterine wall lies between the leaves of the broad ligament. Note the relationship of the ureter to the uterine artery. *lig.*, Ligament.

**E-FIG A2-19** Broad ligament and contained organs, frontal view. The round ligament runs within the anterior leaf of the broad ligament and inserts through the inguinal canal to the labium majus. *Inset:* The relationships as seen from an anterosuperior perspective. Note the rectovaginal pouch as seen from above and anteriorly. *lig.*, Ligament.

**E-FIG A2-20** Organs of the pelvis, posterior view. The rectouterine pouch is demarcated by the uterosacral ligaments. This pouch is often termed the *posterior cul-de-sac*. In this diagram, a section of the posterior leaf of the broad ligament has been removed to show the relationship of the uterine artery to the ureter. Intraligamentous tumors, infection, endometriosis, or previous surgery can often alter this relationship. *lig.*, Ligament.

**E-FIG A2-21** Major vessels of the pelvis, frontal view. The major vasculature of the pelvis is shown in relationship to the pelvic diaphragm. The proximity of the ureter to the internal iliac (hypogastric) artery is noteworthy. Ligation of the hypogastric artery may thus jeopardize the ureter unless care is taken. Note the anterior and posterior trunks of the internal iliac artery. *a.*, Artery; *v.*, vein.

**E-FIG A2-22** Major vessels of the pelvis, lateral view. The major subdivisions of the anterior and posterior trunks are highly variable, and no singular branching pattern accounts for most patients. Note the relationship of the vessels to the sacral plexus. The uterus has been amputated at the level of the isthmus to permit a better view of the branching patterns of the anterior trunk. *a.*, Artery; *aa.*, arteries.

**E-FIG A2-23** Blood supply to the uterus, fallopian tube, and ovary. The vasculature supply to the major pelvic organs is derived from the internal iliac (uterine) artery and the ovarian artery. Note the anastomotic plexi of vessels along the lateral aspect of the uterus at the region of the cornu. Descending branches from the uterine artery supply the cervix and vagina. *a.*, Artery; *br.*, branch.

**E-FIG A2-24** Blood supply to the vagina. Like the uterus, the vagina derives its blood supply from two major sources: the uterine and pudendal arteries. The internal pudendal artery supplies the vagina from inferior to superior. The vaginal artery, often a branch from the uterine artery, and the uterine artery supply the superior position of the vagina. *a.*, Artery; *br.*, branch; *U-G*, urogenital.

**E-FIG A2-25** Major lymphatics of the pelvis. The major lymph nodes of the pelvis follow the major vessels. Each group of nodes receives contributions from multiple organs. The groupings are somewhat arbitrary, because no distinct separation of individual node groups exists.

**E-FIG A2-26** Major nerves of the pelvis, lateral view. Few branches of the sacral plexus are evident because these nerves leave the pelvis even as the branches are forming. Most of the pelvic plexus lies medial to the vasculature. *n.*, Nerve.

**E-FIG A2-27** Afferent innervation of the female genital tract. The left side of this diagram demonstrates the sympathetic nervous system. Fibers entering the spinal cord are illustrated on the right. The major afferent pain fibers for the uterus, tubes, and ovaries enter the cord at T10, T11, and T12. The afferent innervation of the vagina and external genitalia enter at S2, S3, and S4. *n.*, nerve; *nn.*, nerves; *sup.*, superior.

**E-FIG A2-28** Changes in the uterus with age and parity. At puberty, growth occurs primarily in the corpus and the fundus, although the cervix also continues to grow. After menopause, the uterus regresses to a state more closely allied to that of the premenarcheal anatomy. During pregnancy, the cervical portion is relatively greater than in the nonpregnant state.

**E-FIG A2-29** Changes in the uterus caused by pregnancy and parturition. The hormonal changes of pregnancy, as well as dynamic forces of labor, cause the development of the lower uterine segment from the vestigial uterine isthmus. After parturition, these changes regress dramatically. Low transverse cesarean delivery incisions are performed through this thinned isthmic region, known as the *lower uterine segment*.

**ITP** Idiopathic thrombocytopenic purpura; immune thrombocytopenic purpura  
**IU** International unit  
**IUD** Intrauterine device  
**IUFD** Intrauterine fetal death/demise  
**IUGR** Intrauterine growth restriction  
**IUPC** Intrauterine pressure catheter  
**IUT** Intrauterine transfusion  
**IV** Intravenous  
**IVC** Inferior vena cava  
**IVF** In vitro fertilization  
**IVH** Intraventricular hemorrhage  
**IVIG** Intravenous immunoglobulin  
**IVP** Intravenous pyelogram  
**IVS** Intervillous space  
**IVT** Intravascular transfusion  
**KB** Kleihauer-Betke test  
**kDa** Kilodalton  
**kHz** Kilohertz (1000 cycles per second)  
**KIR** Killer cell immunoglobulin-like receptor  
**KMC** Kangaroo maternal care  
**KOH** Potassium chloride  
**LABA** Long-acting  $\beta$ -agonist  
**LAC** Lupus anticoagulant  
**LAM** Lactational amenorrhea method  
**LARC** Long-acting reversible contraception  
**LBC** Lamellar body count  
**LBP** Lipopolysaccharide binding protein  
**LBW** Low birthweight  
**LCHAD** Long-chain 3-hydroxyacyl coenzyme A dehydrogenase  
**LCPUFA** Long-chain polyunsaturated fatty acid  
**LDA** Low-dose aspirin  
**LDH** Lactate dehydrogenase  
**LDL** Low-density lipoprotein  
**LEEP** Loop electrosurgical excision procedure  
**LES** Lower esophageal sphincter  
**LGA** Large for gestational age  
**LH** Luteinizing hormone  
**LIC** Low-income country  
**LLETZ** Large loop excision of the transformation zone  
**LM** *Listeria monocytogenes*  
**LMA** Laryngeal mask airway  
**LMNG** Liverpool and Manchester Neurodevelopmental Group  
**LMP** Last menstrual period  
**LMWH** Low-molecular-weight heparin  
**LN** Lupus nephritis  
**LNG** Levonorgestrel  
**LOA** Left occiput anterior  
**LOP** Left occiput posterior  
**LPD** Luteal phase defect  
**LPS** Lipopolysaccharide  
**LRD** Limb reduction defect  
**L/S ratio** Lecithin/sphingomyelin ratio  
**LTBI** Latent tuberculosis infection  
**LTG** Lamotrigine  
**L-thyroxine** Levothyroxine  
**LTR** Long terminal repeat  
**LTRA** Leukotriene receptor agonist  
**LUS** Lower uterine segment  
**LVOT** Left ventricular outflow tract  
**LVP** Largest vertical pocket  
 **$\mu$ g** Microgram  
**MA** Microarray  
**MAC** Membrane attack complex; *Mycobacterium avium* complex  
**MAP** Mean arterial pressure  
**MAS** Meconium aspiration syndrome  
**mBPP** Modified biophysical profile  
**Mc** Microchimerism  
**MC** Monochorionic  
**MCA** Middle cerebral artery  
**MCH** Maternal, infant, and child health  
**MCP-1** Monocyte chemotactic protein 1 (CCL2)  
**MCV** Mean corpuscular volume  
**MDE** Major depressive episode  
**MDG** Millennium development goal  
**MDI** Metered-dose inhaler  
**MDQ** Mood disorders questionnaire  
**MF** Maternal-fetal  
**MFMU** Maternal-Fetal Medicine Units  
**MHA-TP** Microhemagglutination *Treponema pallidum*  
**MHC** Major histocompatibility complex  
**MHz** Megahertz (1 million cycles per second)  
**MI** Mechanical index; myocardial infarction  
**MIC** Middle-income country  
**MLCK** Myosin light-chain kinase  
**MM** Malignant melanoma  
**MMF** Mycophenolate mofetil  
**mm Hg** Millimeters of mercury  
**MMI** Methimazole  
**MMP** Matrix metalloproteinase  
**MMP-1** Interstitial collagenase  
**MMP-8** Neutrophil collagenase  
**MMP-9** Gelatinase B  
**MMR** Maternal mortality ratio; measles, mumps, rubella  
**MMWR** *Morbidity and Mortality Weekly Report*  
**MODY** Maturity-onset diabetes of youth  
**MoM** Multiples of the median  
**MOMP** Major outer membrane protein  
**MPR** Multifetal pregnancy reduction

- MPSS** Massively parallel DNA shotgun sequencing
- MRA** Magnetic resonance angiography
- MRCF** Magnetic resonance cholangiopancreatography
- MRI** Magnetic resonance imaging
- mRNA** Messenger RNA
- MRSA** Methicillin-resistant *Staphylococcus aureus*
- MRV** Magnetic resonance venogram
- MS** Multiple sclerosis
- MSAFP** Maternal serum alpha-fetoprotein
- MTCT** Mother-to-child transmission
- MTX** Methotrexate
- mV** millivolts
- MVC** Motor vehicle crash
- MVP** Maximum vertical pocket
- MVU** Montevideo unit
- MZ** Monozygotic
- N, NA** Neuraminidase
- NAAPR** North American AED Pregnancy Registry
- NAAT** Nucleic acid amplification test
- NAEPP** National Asthma Education and Prevention Program
- NAFLD** Nonalcoholic fatty liver disease
- NAFTNet** North American Fetal Therapy Network
- NAS** Neonatal abstinence syndrome
- NASBA** Nucleic acid sequence-based amplification
- NAT** Nucleic acid test
- NB** Nasal bone
- NCHS** National Center for Health Statistics
- NCCP** National Collaborative Perinatal Project
- ncRNA** Noncoding RNA
- NDD** Neurodevelopmental disorder
- NEAD** Neurodevelopmental effect of an antiepileptic drug
- NEC** Necrotizing enterocolitis
- NGO** Nongovernmental organization
- NHANES** National Health and Nutrition Examination Survey
- NHL** Non-Hodgkin lymphoma
- NICHD** National Institute for Child Health and Human Development
- NICU** Neonatal intensive care unit
- NIH** National Institutes of Health
- NIPT** Noninvasive prenatal testing
- NK** Natural killer
- NLE** Neonatal lupus erythematosus
- NLR** Nod-like receptor
- NMDA** N-methyl-D-aspartate
- NNRTI** Nonnucleoside reverse transcriptase inhibitor
- NNT** Number needed to treat
- NO** Nitric oxide
- NPWT** Negative pressure wound therapy
- NPY** Neuropeptide Y
- NRBC** Nucleated red blood cell
- NRP** Neonatal resuscitation program
- NRT** Nicotine replacement therapy
- NRTI** Nucleotide/nucleoside reverse transcriptase inhibitor
- NS** Normal saline
- NSAID** Nonsteroidal antiinflammatory drug
- NSPHPT** Neonatal severe primary hyperparathyroidism
- NSR** Normal sinus rhythm
- NST** Nonstress test
- NT** Nuchal translucency
- NTD** Neural tube defect
- NTP** Nortriptyline
- NTSV** Nulliparous term singleton vertex
- NVP** Nausea and vomiting of pregnancy; nevirapine
- NYHA** New York Heart Association
- O<sub>2</sub>** Oxygen
- OA** Occiput anterior
- OAE** Otoacoustic emission
- OAT** Opioid agonist therapy
- OC** Oral contraceptive
- OFD** Occipitofrontal diameter
- OI** Opportunistic infections
- OP** Occiput posterior
- OR** Odds ratio
- OT** Occiput transverse
- P450arom** P450 cytochrome aromatase
- P450scc** Cytochrome P450scc
- PA** Placenta accreta
- PABA** Para-aminobenzoic acid
- PACU** Postanesthesia care unit
- PAI** Plasminogen activator inhibitor
- PAI-1** Type 1 plasminogen activator inhibitor
- PAMG-1** Placental  $\alpha$ -microglobulin 1
- PAMP** Pathogen-associated molecular pattern
- Pap smear** Papanicolaou smear
- PAPP-A** Pregnancy-associated plasma protein A
- PAWP** Pulmonary artery wedge pressure
- PAX2** Paired box gene 2
- P/C** Protein/creatinine (ratio)
- PCA** Patient-controlled analgesia
- PCB** Polychlorinated biphenyl
- PCEA** Patient-controlled epidural analgesia
- PCOS** Polycystic ovary syndrome
- PCR** Polymerase chain reaction
- PCWP** Pulmonary capillary wedge pressure
- PD** Potential difference
- PD-1** Programmed death 1 receptor
- PDA** Patent ductus arteriosus
- PDPH** Postdural puncture headache
- PDX1** Pancreatic duodenal homeobox 1
- PE** Preeclampsia; pulmonary embolus
- PEEP** Positive end-expiratory pressure
- PEF** Peak expiratory flow
- PEFR** Peak expiratory flow rate
- PEP** Polymorphic eruption of pregnancy
- PFMT** Pelvic floor muscle training
- PFP** Pruritic folliculitis of pregnancy
- PG** Pemphigoid gestationis; phosphatidylglycerol
- PGC-1 $\alpha$**  Peroxisome proliferator-activated receptor gamma coactivator
- PGD** Preimplantation genetic diagnosis
- PGE<sub>1</sub>** Prostaglandin E1 (misoprostol)
- PGE<sub>2</sub>** Prostaglandin E2 (dinoprostone)
- PGH** Placental growth hormone
- PGI<sub>2</sub>** Prostaglandin I<sub>2</sub>
- PGS** Personal genome service; preimplantation genetic screening
- PHPT** Primary hyperparathyroidism
- PICC** Peripherally inserted central catheter
- PID** Pelvic inflammatory disease
- PI** Protease inhibitor
- PJP** *Pneumocystis jiroveci* pneumonia
- PK** Pharmacokinetic
- PLGF** Placental-like growth factor
- PLO** Pregnancy and lactation-associated osteoporosis
- PMR** Perinatal mortality rate
- PO** Per os (by mouth)
- POP** Progestin-only oral contraception
- PP** Prurigo of pregnancy
- PPAR** Peroxisome proliferator-activated receptor
- PPCM** Peripartum cardiomyopathy
- PPD** Postpartum depression; purified protein derivative
- PPH** Postpartum hemorrhage
- PPHN** Persistent pulmonary hypertension of the newborn
- PPROM** Preterm premature rupture of the membranes
- PPT** Postpartum thyroiditis
- PPV** Positive predictive value
- PR** Progesterone receptor
- pRBCs** Packed red blood cells
- PrEP** Preexposure prophylaxis
- PRES** Posterior reversible encephalopathy syndrome
- PRIMS** Pregnancy and multiple sclerosis
- PRL** Prolactin
- PROM** Premature rupture of the membranes
- PRR** Pattern-recognition receptor
- PSV** Peak systolic velocity
- PTB** Preterm birth
- PTH** Parathyroid hormone
- PTHrP** Parathyroid hormone-related protein
- PTNA** Percutaneous needle aspiration
- pTREG** Peripheral T-regulatory cells
- PTSD** Posttraumatic stress disorder
- PTU** Propylthiouracil
- PUBS** Percutaneous umbilical blood sampling
- PUD** Peptic ulcer disease
- PUFA** Polyunsaturated fatty acid
- PUVA** Psoralen with ultraviolet light A
- PVC** Premature ventricular contraction
- PVH/IVH** Periventricular/intraventricular hemorrhage
- PVL** Periventricular leukomalacia
- PVNH** Periventricular modular heterotopia
- PVR** Pulmonary vascular resistance
- Qp** Pulmonary flow
- QPCR** Qualitative polymerase chain reaction
- Qs** Systemic flow
- RA** Rheumatoid arthritis
- RAAS** Renin-angiotensin-aldosterone system
- RAD** Radiation absorbed dose
- RANTES (CCL5)** Regulated on activation, normal T-cell expressed and secreted
- RB** Reticulate body
- RBC** Red blood cell
- RCOG** Royal College of Obstetricians and Gynaecologists
- RCT** Randomized controlled trial
- RCVS** Reversible cerebral vasoconstriction syndrome
- RDA** Recommended daily allowance
- RDS** Respiratory distress syndrome
- REDV** Reversed end-diastolic velocity

- REM** Rapid eye movement; recurrent early miscarriage
- REPL** Recurrent early pregnancy loss
- RF** Rheumatoid factor
- RFRA** Religious Freedom Restoration Act
- Rh(D)** Rhesus (D antigen)
- RhIG** Rhesus immune globulin
- RIBA** Recombinant immunoblot assay
- RIDT** Rapid influenza diagnostic test
- RIF** Rifampin
- RLS** Restless legs syndrome
- RM** Recurrent miscarriage
- RMR** Resting metabolic rate
- RNA** Ribonucleic acid
- ROA** Right occiput anterior
- ROC** Receiver operator characteristic
- ROP** Retinopathy of prematurity
- RPR** Rapid plasma reagin
- RR** Relative risk
- RT** Reverse transcriptase
- RT3U** Resin triiodothyronine uptake
- RUQ** Right upper quadrant
- RV** Right ventricle
- RXR** Retinoid X receptor
- SAGES** Society of American Gastrointestinal and Endoscopic Surgeons
- SAH** Subarachnoid hemorrhage
- SBAR** Situation, background, assessment, recommendation
- SBO** Small bowel obstruction
- SCH** Subclinical hypothyroidism
- SCN1A** Sodium channel, voltage-gated, type 1 alpha subunit
- SD** Standard deviation
- S/D** Systolic/diastolic (ratio)
- SEFW** Sonographically estimated fetal weight
- sFit-1** Soluble fms-like tyrosine kinase 1
- SGA** Small for gestational age
- SIDS** Sudden infant death syndrome
- slgA** Secretory immunoglobulin A
- SIRS** Systemic immune response syndrome
- SIRT1** NAD-dependent deacetylase sirtuin 1
- slUGR** Selective intrauterine growth restriction
- SLE** Systemic lupus erythematosus
- SMA** Spinal muscular atrophy
- SMFM** Society for Maternal-Fetal Medicine
- SNP** Single nucleotide polymorphism
- SOAP** Society of Obstetric Anesthesia and Perinatology
- SP** Surfactant protein
- SPTA** Spatial-peak temporal-average
- sPTB** Spontaneous preterm birth
- SROM** Spontaneous rupture of membranes
- SS** Sjögren syndrome
- SSc** Systemic sclerosis
- SSC** Skin-to-skin contact
- SSI** Surgical site infection
- SSKI** Saturated solution of potassium iodide
- SNRI** Serotonin-norepinephrine reuptake inhibitor
- SSPE** Subacute sclerosing panencephalitis
- SSRI** Selective serotonin reuptake inhibitor
- ST** Selective termination
- STD** Sexually transmitted disease
- STI** Sexually transmitted infection
- SUD** Substance use disorder
- SUDEP** Sudden unexpected death in epilepsy
- SV** Stroke volume
- SVR** Systemic vascular resistance
- SYS** Secondary yolk sac
- T<sub>3</sub>** Triiodothyronine
- T<sub>4</sub>** Thyroxine
- T-ACE** Tolerance-annoyance, cut down, eye opener
- TA-CVS** Transabdominal chorionic villus sampling
- TAFI** Thrombin-activatable fibrinolysis inhibitor
- TAPS** Twin anemia-polycythemia sequence
- TAU** Transabdominal ultrasound
- TB** Tuberculosis
- TBA** Traditional birth attendant
- TBG** Thyroxine-binding globulin
- TBII** Thyroid-binding inhibitor immunoglobulin
- TBT** Term Breech Trial
- TC-CVS** Transcervical chorionic villus sampling
- TCD** Transcerebellar diameter
- TCR** T-cell receptor
- TEE** Thermic effect of energy
- TEF** Thermic effect of food
- TF** Tissue factor
- TFPI** Tissue factor pathway inhibitor
- TFT** Thyroid function test
- TGA** Transposition of the great arteries
- TgAb** Antithyroglobulin antibodies
- TGC** Time gain compensation
- TGF- $\beta$**  Transforming growth factor beta
- Th** Thymus helper
- Th1** Helper T-cell type 1
- Th2** Helper T-cell type 2
- THBR** Thyroid hormone-binding ratio
- Th cell** Helper T cell
- TI** Thermal index
- TIMP** Tissue inhibitor of matrix metalloproteinase
- TIPS** Transjugular intrahepatic portosystemic shunt
- TLC** Total lung capacity
- TLR** Toll-like receptor
- TLU** Translabial ultrasound
- TNF- $\alpha$**  Tumor necrosis factor alpha
- TOLAC** Trial of labor after cesarean delivery
- TORCH** Toxoplasmosis, other infections, rubella, cytomegalovirus, herpes
- tPA** Tissue plasminogen activator
- TPE** Total urinary protein excretion
- TPN** Total parenteral nutrition
- TPO** Thyroid peroxidase
- TPOAb** Thyroid peroxidase antibody
- TPR** Total peripheral resistance
- TR- $\beta$**  Thyroid receptor beta
- TRAb** Thyroid-stimulating hormone receptor antibody
- TRAb** Thyroid-blocking antibody
- TRAIL** TNF-related apoptosis-inducing ligand/Apo-2L
- TRAP** Twin reversed arterial perfusion
- TREG** Regulatory T cells
- TRH** Thyroid-releasing hormone; thyrotropin-releasing hormone
- TSH** Thyroid-stimulating hormone
- TSHRAb** Thyroid-stimulating hormone receptor antibody
- TSI** Thyroid-stimulating immunoglobulin
- TST** Tuberculin skin testing
- TT<sub>3</sub>** Total triiodothyronine
- TT<sub>4</sub>** Total thyroxine
- TTP** Thrombotic thrombocytopenic purpura
- tTREG** Thymic T-regulatory cells
- TTTS** Twin-twin transfusion syndrome
- TVCL** Transvaginal cervical length
- TVU** Transvaginal ultrasound
- TXA<sub>2</sub>** Thromboxane A<sub>2</sub>
- UAE** Urinary albumin excretion
- UC** Ulcerative colitis
- U-D** Uterine incision-delivery interval
- UDPGT** Uridine diphosphoglucuronosyl transferase
- uE<sub>3</sub>** Unconjugated estriol
- UFH** Unfractionated heparin
- UK** United Kingdom
- ULvWF** Unusually large multimers of von Willebrand factor
- UN** United Nations
- UNICEF** United Nations Children's Fund
- uPA** Urokinase-type plasminogen activator
- UPD** Uniparental disomy
- USDA** U.S. Department of Agriculture
- USPSTF** U.S. Preventive Services Task Force
- UTI** Urinary tract infection
- UVB** Ultraviolet light B
- V/Q** Ventilation-perfusion scan
- VAS** Vibroacoustic stimulation
- VBAC** Vaginal birth after cesarean delivery
- VDRL** Venereal disease research laboratories
- VEGF** Vascular endothelial growth factor
- VKA** Vitamin K antagonist
- VLBW** Very low birthweight
- VLDL** Very-low-density lipoprotein
- VOUS** Variants of unknown significance
- VPA** Valproic acid
- VPTD** Very preterm delivery
- VSD** Ventricular septal defect
- VTE** Venous thromboembolism
- VUS** Venous ultrasonography
- vWD** von Willebrand disease
- vWF** von Willebrand factor
- VZIG** Varicella zoster immune globulin
- VZV** Varicella zoster virus
- WBC** White blood cell
- WGA** Whole genomic amplification
- WHO** World Health Organization
- ZDV** Zidovudine
- ZPI** Protein Z-dependent protease inhibitor

# Index

Page numbers followed by “f” indicate figures, “t” indicate tables, “b” indicate boxes, and “e” indicate online-only material.

## A

“ABCDE” criteria for pigmented lesions, 1081

Abdomen, ultrasound screening for anomalies in, 187

Abdominal cerclage, 602, 603f-604f

Abdominal circumference (AC)

for fetal growth assessment, 746  
normal values in pregnancy, 1219t  
for ultrasound gestational age determination, 177, 178f-179f

Abdominal closure, in cesarean delivery, 435-436, 436f

Abdominal diameter-biparietal diameter difference (AD-BPD), 388

Abdominal disorders, physiologic effects of pregnancy to, 1012-1013

Abdominal entry, in cesarean delivery, 431-432, 431f

Abdominal fetal electrocardiogram, and fetal status evaluation, 335

Abdominal imaging, during pregnancy, 1000-1001

Abdominal pain, 1013-1015, 1014t  
right lower quadrant, 1013, 1013b  
right upper quadrant, 999-1000

Abdominal (heterotopic) pregnancy, 1014

Abdominal skin incision, in cesarean delivery, 431-432, 431f

Abdominal wall abscess, 438-439

Abdominal wall defects, 483

Abortion

partial-birth, 1183-1184  
politics, 1186-1188  
reproductive liberty, 1183  
septic, as coagulopathy risk factor, 418  
smoking and, 149

Abruptio placenta, 396-400

in chronic hypertension, 697  
clinical manifestations, 397  
in cocaine use, 151  
definition of, 396-397  
diagnosis of, 398-399, 399f-400f  
in eclampsia, 692  
in gestational hypertension, 664  
in HELLP syndrome, 675, 675t, 678  
incidence of, 397  
locations for, 398, 399f  
management of, 399-400  
neonatal outcome, 400  
pathogenesis of, 396-397

Abruptio placenta (*Continued*)

and perinatal morbidity and mortality, 400  
in preeclampsia, 683, 688  
in premature rupture of the membranes, 649-650, 656  
risk factors, 397-398  
smoking and, 149  
thrombocytopenia and, 671  
with trauma, in pregnancy, 565-567, 569-571

Abruptio, prior, as abruptio placenta risk factor, 398

Abscess

abdominal wall, 438-439, 438f  
breast, 539-540  
epidural, 354  
hepatic, 1005  
pelvic, 1139t

Absorption, of iron, 44

Abuse

fetal, 1194  
maternal maltreatment, 529-530  
trauma, in pregnancy, 567

Abuse Assessment Score, 109

AC. *See* Abdominal circumference (AC)

Acardiac twinning, 721-722, 721f

Accelerations, in fetal heart rate monitoring, 322-323

absence of, 322-323, 323t  
definition of, 322, 322f  
physiology of, 322-323  
uniform, 328

Accutane, fetal effects of, 141-142, 141f

ACE. *See* Angiotensin-converting enzyme

(ACE) inhibitors

Acetabulum, 1224.e1f

Acetaminophen

fetal effects of, 149

for hyperthermia, 358

Acetylation, of histone tails, 85

Achondroplasia, 189

Acid-base status, fetal, biophysical profile correlation with, 235

Acidemia, 315-316

and hypoxia, 315-316  
metabolic, 335-336  
mixed, 335-336  
respiratory, 335-336

Acidosis

in acute renal failure, 854-855  
fetal, 235

Acid-suppressing drugs, fetal effects of, 146

ACMG. *See* American College of Medical Genetics and Genomics (ACMG)

Acne

conglobata, 1076t  
vulgaris, 1079

ACOG. *See* American College of Obstetricians and Gynecologists (ACOG)

Acoustic neuroma, 1069

Acquired immunodeficiency syndrome (AIDS)

as cause of death, 1199

*Pneumocystis jiroveci* pneumonia (PJP) and, 833-834

Acrodermatitis enteropathica, 1081

Acromegaly, 939-940

ACTH. *See* Adrenocorticotrophic hormone (ACTH)

Activated partial thromboplastin time, 46

Activated protein C (APC)/sensitivity (S) ratio, 46

Active phase of labor

cervical dilation in, 273  
defined, 271-272  
disorders of, 273-274  
arrest of labor, 273  
electromechanical classification of, 274  
protraction disorders, 273

Active smoking, in preconception health counseling, 108

Active transporters, 15-16

Activity

fetal

maternal assessment of, 227-228, 228f, 885  
maternal monitoring of, 755  
prenatal care and, 114

Acupuncture

in breech presentation, 387  
for nausea and vomiting during pregnancy, 132

Acute fatty liver of pregnancy (AFLP), 1008-1009, 1008t

abdominal pain, 1014  
as coagulopathy risk factor, 418

Acute intermittent porphyria, 1006

Acute lymphoblastic leukemia (ALL), 1063

Acute myeloid leukemia (AML), 1063

Acute nonlymphocytic leukemia (ANLL), 1063-1064

Acute normovolemic hemodilution, for postpartum hemorrhage, 421

Acute pancreatitis, 1002-1003

hyperparathyroidism and, 912

Acute pyelonephritis, abdominal pain and, 1015

- Acute renal disease, in pregnancy, 853-855
- Acute renal failure, 854-855
- in eclampsia, 692
  - in HELLP syndrome, 675, 675<sup>t</sup>
- Acute respiratory distress syndrome (ARDS), in HELLP syndrome, 675
- Acute urethral syndrome, 1133
- Acyclovir
- in breast milk, 154
  - for eczema herpeticum, 1078
  - fetal effects of, 148
  - for herpesvirus, 1119
  - for varicella pneumonia, 832
- ADAMTS13, 949
- Adaptive immune system, 71-72
- antibody isotypes in, 71-72, 72<sup>f</sup>
  - humoral immune response in, 71
  - major histocompatibility complex (MHC) in, 71
  - overview of, 65, 67<sup>f</sup>
- Adaptive thermogenesis, 125-126
- Addiction, narcotic, 151
- Adenomas
- clinically nonfunctioning, 940
  - gonadotroph, 940
  - hepatic, 1006
  - parathyroid, 911-912
  - pituitary, 938
- Adipogenesis, 89, 89<sup>f</sup>
- Adnexa, ultrasound of, 175-176, 176<sup>f</sup>
- Adnexal masses
- aspiration of, 560
  - corpus luteum cyst, 556, 557<sup>f</sup>
  - cystadenomas, 556-558, 558<sup>f</sup>
  - dermoids, 556-558, 558<sup>f</sup>
  - endometriomas, 556-558, 558<sup>f</sup>
  - follicular cysts, 556, 557<sup>f</sup>
  - imaging, 557<sup>f</sup>; 558-559
  - malignant, 556-558
  - ovarian cancer and, 1067
  - ovarian torsion of, as complication, 559, 560<sup>f</sup>
  - in pregnancy, 556-560
  - prevalence of, 556
  - Rokitansky tubercle, 556-558, 558<sup>f</sup>
  - theca lutein cysts, 556, 557<sup>f</sup>
- Adnexal torsion, in abdominal pain, 1015
- Adolescent
- girls and lifetime risk of maternal death, 1197-1198
  - weight gain recommendations for pregnant, 124-125
- Adrenal glands, fetal, 35
- Adrenal insufficiency, 942-943
- Adrenals, 941-944
- adrenal insufficiency and, 942-943
  - Cushing syndrome and, 941-942
  - maternal, 55-56
  - pheochromocytoma in, 943-944
  - primary hyperaldosteronism in, 943
- β-Adrenergic blocking agents, for hyperthyroidism, 924
- Adrenocorticotrophic hormone (ACTH)
- fetal, 35
  - fetal endocrine manifestations of placental insufficiency, 742
  - maternal, 55
- Adult health and disease
- developmental origins of, 83-99
  - programming in

- in United States in 2013, 123*f*

Oblique lie, 249, 250*f*

Obsessive-compulsive disorder, 1160

Obstetric complications, prevention and management in resource-poor countries, 1205-1207

Obstetric conjugate, 253

Obstetric deaths, indirect, 1198

Obstetric fistulae, 1198, 1206-1207

- prevention of, 1207*t*

Obstetric history, integrating nutrition into, 122-123

Obstetric newborn care, 1199*b*

Obstetric preventable adverse events, frequency of, 1174-1175

Obstetric risk, in prenatal care, 112

Obstetric safety, approaches to improve, 1175-1178

- checklist and protocols of, 1175-1176

- communication enhancement of, 1177

- multifaceted of, 1177-1178

- simulation of, 1176-1177

Obstetric syndromes, features of, 625

Obstetric ultrasound, for imaging, dating, growth and anomaly, 160-192

Obstetrician, in breastfeeding, 531-533, 531*t*

Obstructed labor, 1206-1207

Obstructive sleep apnea (OSA), 48-49

Obturator artery, 1224.*e11f*

Obturator canal, 1224.*e2f*

Obturator fascia, 1224.*e3f*

Obturator foramen, 1224.*e1f*

Obturator internus, 1224.*e2f*-1224.*e3f*, 1224.*e5f*

Obturator nodes, 1224.*e13f*

Occipitofrontal diameter, 250*f*

Occiput anterior (OA) position, 251, 251*f*

- operative vaginal delivery, 294-297, 296*f*

Occiput posterior (OP) position, 251, 251*f*, 274

- forceps rotation, 297-298

- operative vaginal delivery, 294-297, 296*f*

- spontaneous anterior rotation, 274

Occiput transverse (OT) position, 251, 251*f*

- operative vaginal delivery, 297

Occupational and environmental hazards

- ionizing radiation in, 155-156

- lead in, 156

- mercury in fish in, 156-157

- obstetrician's role in evaluating

- reproductive risks with, 157

- in preconception health counseling, 109-110

- video display terminals in, 156

Octreotide

- for acromegaly, 939-940

- for thyrotropin-secreting tumors, 940

Ogilvie syndrome, 1023

Ohm's law, 804

Olanzapine, for schizophrenia, 1164

Oligodendrogliomas, 1069-1070

Oligohydramnios, 172-173, 790-792

- amniotic fluid index for diagnosis, 237, 787-788, 790

- from angiotensin-converting enzyme (ACE) inhibitors, 144

- causes of, 790*b*

- evaluation of, 791

- with hypertension-preeclampsia, 685

Oligohydramnios (*Continued*)

- from indomethacin tocolysis, 635-636

- in labor, 791-792

- perinatal outcome of, 790

- in postterm pregnancy, 798-799

- with premature rupture of the membranes, 647-648, 650, 790

- pulmonary hypoplasia with, 650

- trauma and, in pregnancy, 566

- treatment of, 791, 791*t*

Oligosaccharides, in breast milk, 528

Omalizumab, for asthma, 841

Omega-3 fatty acids, 1154

- maternal needs for, 126-127

Omega-3 polyunsaturated fatty acids (PUFAs), for preterm birth prevention, 640

Omeprazole, fetal effects of, 146

OmniCup vacuum extraction device, 294, 295*f*

Omphalocele, 188, 483, 188.*e3f*

Ondansetron

- for bulimia, 1163

- fetal effects of, 146

Onycholysis, 1076*t*, 1079

Oophoropexy, 559-560

Operating tables, for obese women, 906

Opiates, in preconception health counseling, 109

## Opioids

- agonist therapy, 1169

- acute pain management for, 1170

- for labor, 348-349

- fentanyl, 349

- meperidine, 348

- nalbuphine (Nubain), 348-349

- patient-controlled analgesia, 348

- remifentanyl, 349

- substance use/abuse, 1168-1170

Opioidization, 71

Optimizing care, in preconception health counseling, 110

Oral acyclovir, for varicella zoster virus, 1121

Oral contraception

- in breast milk, 154-155

- progestin-only, 511

Organs, contained, 1224.*e10f*

Orthostatic hypotension, in hemorrhage, 396

Osmolality, normal values in pregnancy for, 1216*t*

Osmoregulation, maternal, 51, 51*f*

Osmotic pressures, in placenta, 15, 19

Osteocalcin, 911

- fetal manifestations of placental

- insufficiency, 742

Osteogenesis imperfecta, 189, 189.*e2f*-189.*e3f*

Osteomyelitis, in sickle cell disease, 957

Osteoporosis, 915-916

- in pregnancy, 58

- programming, 92

Ototoxicity, from aminoglycosides, 147

Outcome measures, 1178-1179

Outflow tracts, ultrasound screening for anomalies in, 187

Output display standard, in ultrasound, 182

 vitamin D, 127-129  
 vitamin K, 129
- Vitamin A  
 deficiency of, 127  
 fetal effects of, 142  
 role in body, 127  
 supplementation guidelines for, 127

- Vitamin B6 (pyridoxine), 1019  
     fetal effects of, 145  
     for nausea and vomiting of pregnancy, 54, 132  
     supplementation guidelines for, 129
- Vitamin B12 deficiency  
     causes of, 955-956, 956*b*  
     megaloblastic anemia and, 955
- Vitamin C  
     for preeclampsia prevention, 670  
     for premature rupture of the membrane prevention, 649  
     role in body, 129  
     supplementation guidelines for, 129
- Vitamin D  
     deficiency, 58, 915  
     and epilepsy, 1040  
     fetal effects of low maternal, 127  
     in fetal endocrine manifestations of placental insufficiency, 742  
     maternal, 58  
     serum levels of, 129  
     supplementation  
         guidelines for, 127-129  
         in hyperparathyroidism, 914  
         in hypoparathyroidism, 914  
         randomized controlled trials (RCTs), 915  
     in undernourished fetus, 92
- Vitamin E, for preeclampsia prevention, 670
- Vitamin K  
     for coagulopathy, 419  
     supplementation, for epilepsy, 1040  
     supplementation guidelines for, 129
- Vitamin K-deficiency bleeding, of neonates, 486-487
- Vitelline circulation, 29
- VLBW. *See* Very low birthweight (VLBW)
- Volatile halogenated agent, in general anesthesia, 364
- Volume expansion, maternal for intrauterine growth restriction, 754
- Volume resuscitation, for postpartum hemorrhage, 419-420  
     colloid solutions, 420
- Vomiting  
     of pregnancy, 54, 132, 1000, 1019  
     prenatal care and, 114-115  
     as upper gastrointestinal symptoms, 1015, 1015*b*
- von Willebrand cleaving enzyme, 949
- von Willebrand disease, 46, 507, 960-962
- VSD. *See* Ventricular septal defect (VSD)
- VSGA. *See* Very small for gestational age (VSGA)
- Vulvar cancer, 1068-1069
- Vulvar edema, in severe preeclampsia, 665*f*
- Vulvar hematoma, 413-414, 414*f*
- Vulvar melanosis, 1076*t*
- ## W
- Wandering baseline, 328
- Wandering blade, 297
- Wandering method, 297
- Warfarin  
     in breast milk, 154  
     fetal effects of, 143, 143*f*  
     for prosthetic valves, 813
- Warmer, radiant, 480-481
- Water  
     amniotic fluid index changes with hydration, 791, 791*t*  
     channels, 19  
     delivery in, 347-348  
     intoxication, with oxytocin use, 276  
     in neonatal nutrition, 481  
     placental transport of, 19
- Weaning, 545-546
- Weight gain  
     gestational, 39  
     in obese women, 901-903, 902*t*  
     recommendations in, 39*t*  
     maternal  
         in diabetes mellitus, 871  
         excessive, during pregnancy, 122  
         in multifetal pregnancy, 723-724, 724*t*  
         prolonged second stage of labor and, 261  
         recommendations for, 123-124, 124*t*  
         for adolescents, 124-125  
         with low or underweight preconception BMI, 124  
         for multiple gestations, 124, 125*t*  
         with overweight and obese prepregnancy BMI, 124, 125*t*  
     in preconception health counseling, 106
- Weight loss  
     obesity and, 560-561  
     postpartum, 501-502
- Weiner, Alexander, 773
- Well-woman visits, components of, 103-105, 104*f*, 117-118
- Western blot, for human immunodeficiency virus (HIV), 1101
- White, Priscilla, 875
- White blood cell (WBC) count  
     in acute leukemia, 1063-1064  
     maternal, 45
- Whole blood, for postpartum hemorrhage, 420
- Whole-genome amplification (WGA), 215
- Wilson disease, 1005
- Women's rights, 1200-1201
- Woods corkscrew maneuver, for shoulder dystocia, 390-391
- Work overseas, practical advice on  
     volunteering to, 1207-1209  
     health care staff, 1208-1209  
     predeparture preparation of, 1209  
     realism, 1208  
     research, 1209  
     respect, 1208
- World Health Organization (WHO)  
     in preterm birth frequency data, 616  
     sexually transmitted disease data, 1089-1090
- Wound infection  
     after cesarean delivery, 1139-1140  
     as complication, of cesarean delivery, 438-439, 438*f*  
     endometritis, 1139
- ## X
- X-ray pelvimetry, average and critical limit values for pelvic measures by, 252*t*
- ## Y
- Yale-New Haven Hospital, 1178
- Yolk sac  
     absorptive role of, 12  
     development of, 5  
     secondary, 5  
     physiology of, 12-13  
     secretion of alpha-fetoprotein (AFP), 12  
     transfer proteins of, 12-13  
     ultrasound of, 168-169, 168*f*
- ## Z
- Zatuchni-Andros score, 381, 381*t*
- Zavanelli maneuver, for shoulder dystocia, 391-392
- Zidovudine (ZDV), fetal effects of, 148
- Zinc  
     deficiency, acrodermatitis enteropathica from, 1081  
     supplementation guidelines for, 131
- Ziprasidone, for schizophrenia, 1164-1165
- Zolpidem, for sleep problems, 49
- Zoom, in ultrasound, 163, 163*f*
- Zygosity, in multiple gestations, 707-708

**CLINICAL KEY™**

Smarter search. Faster answers.

# Smarter, Faster Search for Better Patient Care

**Unlike a conventional search engine, ClinicalKey  
is specifically designed to serve doctors by providing  
three core components:**

**1 Comprehensive  
Content**

The most current, evidence-based answers available for every medical and surgical specialty.

**2 Trusted  
Answers**

Content supplied by Elsevier, the world's leading provider of health and science information.

**3 Unrivalled Speed  
to Answer**

Faster, more relevant clinical answers, so you can spend less time searching and more time caring for patients.

**Start searching with ClinicalKey today!**

Visit **ClinicalKey.com** for more information and subscription options.
