
### Vacuum Delivery and the Preterm Fetus

No quality data support firm recommendations in regard to a gestational age limit below which the vacuum extractor should not be used. Two studies have reported the use of soft cups without adverse outcomes in preterm fetuses; however, these studies were small and lacked power to demonstrate significance. No RCTs have compared forceps with vacuums or different vacuum types to pass judgment on a gestational age cutoff. **ACOG reports that most experts in operative vaginal delivery limit the vacuum procedure to fetuses beyond 34 weeks' gestation.**<sup>71</sup> This is a reasonable cutoff given that the premature head is likely at greater risk for compression-decompression injuries simply because of the pliability of the preterm skull and the more fragile soft tissues of the scalp.

### COUNSELING: FORCEPS, VACUUM, OR CESAREAN DELIVERY

The increasing use of vacuum extraction over forceps has resulted in numerous publications that have compared efficacy and morbidity between methods. Table 14-3 provides a summary of the disadvantages associated with both methods. In a Cochrane meta-analysis<sup>97</sup> that included 10 RCTs of vacuum and forceps use, **vacuum extraction had a greater failure rate than that of forceps but was associated with less maternal trauma,**

**TABLE 14-3** COMPARATIVE MORBIDITIES ASSOCIATED WITH FORCEPS DELIVERY AND VACUUM EXTRACTION

| FORCEPS  | VACUUM EXTRACTION                                    |
|--|--|
| Greater third- and fourth-degree and vaginal lacerations | Higher failure rate than forceps                     |
| Greater maternal discomfort postpartum                   | Increased risk of neonatal injury                    |
| Greater duration of training needed                      | Minor: cephalohematoma, retinal hemorrhage           |
| Increased risk of neonatal facial nerve injury           | Major: subarachnoid hemorrhage, subgaleal hemorrhage |
|  | Less need for maternal anesthesia                    |

Modified from Johanson RB, Menon BK. Vacuum extraction versus forceps for assisted vaginal delivery. *Cochrane Database Syst Rev.* 2000;(2):CD000224.

**including third- and fourth-degree extensions and vaginal lacerations, than forceps use. Less maternal regional and general anesthesia was used for vacuum extractions, and no differences were found in significant neonatal injury between the two groups. Despite small sample sizes, vacuum extraction was associated with an increased risk of cephalohematoma and retinal hemorrhage when compared with forceps use.** Cephalohematoma formation with vacuum extraction was reported to have a mean incidence of 6%, with no difference between soft or rigid vacuum cups, and it is considered to be a finding of little significance.<sup>29,97</sup> More information on the long-term effects of retinal hemorrhage related to vacuum delivery is needed.

Unless a patient is willing to undergo cesarean delivery before the onset of advanced labor, there does not appear to be any advantage to avoiding operative vaginal delivery in an attempt to reduce the long-term risks of incontinence. **The effects of both forceps and vacuum delivery on the risk of developing urinary incontinence appear to be the same as those of spontaneous vaginal delivery:** between 5% and 20% of women develop long-term persistent urinary incontinence regardless of vaginal delivery method. In addition, despite evidence that the anal sphincter injury rate in women who deliver by forceps is higher, **it is not clear whether the long-term rates of fecal incontinence in these women is any different than in those who deliver spontaneously.** Approximately 10% to 30% of women develop some degree of altered fecal continence following vaginal delivery, and cesarean delivery before the onset of labor is the only reliable means of reducing this risk.

**The greatest risk for urinary incontinence appears to be the total number of vaginal deliveries, and the greatest risk for subsequent development of fecal incontinence appears to be related to the effect of the largest neonate delivered vaginally, irrespective of mode of delivery.** Regarding fetal risks, vacuum deliveries appear to increase the incidence of cephalohematoma and subgaleal and retinal hemorrhages compared with forceps or spontaneous vaginal deliveries. Forceps deliveries increase the risk of facial bruising and transient facial nerve palsies compared with vacuum or spontaneous vaginal deliveries. However, no evidence suggests that these immediate neonatal morbidities result in any long-term visual, neurologic, or cognitive developmental abnormalities. Finally, patients delivered by cesarean delivery in the second stage have a higher risk of intraoperative and postoperative complications, higher rates of blood loss, and longer hospital stays than those delivered by operative vaginal delivery.

**Patients should also be informed that substantially more women who have an operative vaginal delivery achieve**

**subsequent vaginal delivery in the next pregnancy compared with those who have a cesarean delivery (78% vs. 31%).** Therefore it is reasonable to counsel patients that the options for second-stage assisted delivery include both forceps and vacuum when appropriate, because the proper application of these instruments and execution of these deliveries can avoid the maternal morbidity associated with cesarean delivery and increase the likelihood of a subsequent vaginal delivery for the next pregnancy without additional long-term maternal or neonatal risk.

In a Cochrane review<sup>64</sup> of 10 randomized studies that compared the use of forceps to vacuum extraction for assisted vaginal delivery, vacuum devices were found to be more likely to fail than forceps, as noted above. However, vacuum use was also more likely to result in vaginal delivery, probably because failed vacuum extraction led to the use of forceps and subsequent vaginal delivery due to a lower forceps failure rate. A lower failure rate is not the only reason to consider forceps. **Forceps may be the only acceptable instrument to effect an operative vaginal delivery in some circumstances.** Some examples of these clinical situations include delivery of the head at assisted breech delivery, assisted delivery of a preterm infant younger than 34 weeks' gestation, delivery with a face presentation with mentum anterior, suspected coagulopathy or thrombocytopenia in the fetus, and instrumental delivery for maternal medical conditions that preclude pushing.<sup>14</sup> Because the specific clinical situation and operator experience are the key factors that contribute to the choice of instrument, it is critical that students of obstetrics be thoroughly familiar with the use of both instruments. Finally, **an attempt at counseling patients on the risks, benefits, and alternatives of operative vaginal delivery should take place during prenatal visits.** This is because it is not ideal to counsel patients in the second stage of labor when they are generally experiencing pain and exhaustion and may be under the influence of narcotics. This counseling should also be documented in the medical record.

## SIMULATION AND RESIDENCY TRAINING IN OPERATIVE VAGINAL DELIVERY

**The overall incidence of operative vaginal delivery has remained stable over the past 15 years. Interestingly, over this same time span, vacuum extraction procedures have overtaken forceps procedures as the method of choice (Fig. 14-8).** In a review of operative vaginal delivery, Yeomans<sup>98</sup> strongly advocates that residency training programs incorporate detailed instructions in forceps techniques and that simulation training precede clinical work to enhance understanding of the mechanics. Bahl and colleagues<sup>99</sup> reviewed video recordings to establish critical components of nonrotational vacuum deliveries, and they defined key technical skills required for the evaluation of clinical competence of trainees in this technique. Further detailed studies are needed to ensure that both vacuum and forceps techniques can be taught and evaluated first with the use of simulation and then in the clinical setting.

A 1992 report of a survey conducted by Ramin and colleagues<sup>100</sup> of U.S. residency training programs reported that most programs use the 1988 classification scheme and that 86% taught midforceps delivery. It should be noted that even though a large percentage of programs teach the complex forceps procedures, the number of such procedures to reach proficiency has not been elucidated. In short, the overall decline in forceps

**FIG 14-8** The overall incidence of operative vaginal delivery (OVD) has remained stable over the last 15 years. Interestingly, over this same time span, vacuum extraction procedures have overtaken forceps procedures as the method of choice. (Modified from Mikovsky P, Watson WJ. Obstetric vacuum extraction: state of the art in the new millennium. *Obstet Gynecol Surv.* 2001;56:736.)

**TABLE 14-4** MODES OF DELIVERY AND BIRTH OUTCOMES BEFORE AND AFTER INITIATION OF DEDICATED OBSTETRICS STAFF LOCATED ON LABOR AND DELIVERY

|                                     | BEFORE    | AFTER      | P VALUE |

| Apgar score <7 at 5 min             | 67 (2%)   | 104 (2%)   | NS      |

NS, not significant.

procedures performed, the complexity of midpelvic cavity deliveries, and the shift from complex rotational deliveries to vacuum extraction and cesarean deliveries by younger faculty—as shown by Tan and colleagues<sup>86</sup> and Jain and colleagues<sup>101</sup>—may make the midforceps procedure obsolete in the near future.<sup>100</sup> In response to these types of concerns, Solt and associates<sup>102</sup> conducted a unique study to determine whether the rates of vacuum extraction and forceps procedures could be reversed without an increase in morbidity in a residency program. This retrospective study compared outcomes 2 years before and 2 years after an obstetrics faculty member was dedicated to the labor floor from Monday through Thursday, 7 AM to 5 PM. **Table 14-4 depicts how such a dedicated instructor can increase the number of forceps deliveries relative to vacuum extractions without increasing third- or fourth-degree lacerations or adverse neonatal outcomes. In fact, the number of events of fetal pH less than 7.1 was reduced during the teaching period.**<sup>99</sup>

Although the early 1990s report by Ramin and colleagues<sup>100</sup> provided encouraging information regarding the use of the 1988 classification scheme, a 2004 study by Carollo and others<sup>103</sup> is unsettling. This study conducted a survey of several teaching hospitals in the Denver area and asked the following important questions: (1) How do you define fetal station? (2) How do you think a majority of your colleagues define fetal station? (3) How do you think ACOG defines fetal station? and (4) How important do you think these distinctions are? What makes this study

additionally unique is that these questions were asked of both attendings and residents in obstetrics and gynecology as well as nurses. **Approximately 35% of attending physicians still defined station by dividing the pelvis into thirds, as set forth in the old 1965 ACOG classification scheme, rather than using centimeters.** In addition, nearly 15% used the BPD, rather than the presenting part, as the landmark on the fetus to define station. These percentage numbers were higher for nurses and residents. The percent of correctly used techniques for defining station was highest at the university teaching hospital. These data suggest that although we do fairly well at teaching proper technique for determining station, we do poorly in disseminating information into practice. **Operative vaginal deliveries will be more difficult and dangerous if misunderstandings in defining fetal station persist.**

### KEY POINTS

- ◆ Obstetric forceps are the one instrument that makes the practice of obstetric care unique to obstetricians. The proper use of these instruments has afforded safe and timely vaginal delivery to those whose abnormal labor course and urgent need for delivery require their use.
- ◆ Rates of cesarean delivery have risen in the United States, reaching a rate of approximately 25% of all deliveries, whereas rates of forceps deliveries have declined from 17.7% in 1980 to 4% in 2000.
- ◆ Resident work hour restrictions have resulted in a decline in resident experience with both primary cesarean delivery and vacuum-assisted vaginal delivery.
- ◆ Treat the vacuum extractor with the same respect as the forceps. The prerequisites for application of forceps or vacuum extractor are identical.
- ◆ When using vacuum extraction, descent of the fetal head should occur with each pull. If no descent occurs after three pulls, the operative attempt should be stopped.
- ◆ It appears that forceps delivery has little if any effect on the subsequent development of urinary incontinence.
- ◆ The rate of anal sphincter injury in women who deliver by forceps may be higher; however, long-term rates of fetal incontinence appear to be no different than those in women who deliver spontaneously.
- ◆ The risks of fetal injury associated with operative vaginal delivery are generally instrument specific: vacuum deliveries account for higher rates of cephalohematoma and subgaleal and retinal hemorrhages, and forceps deliveries account for a nonsignificantly higher rate of scalp and facial injuries.
- ◆ Numerous retrospective studies that have compared midcavity and rotation forceps delivery with cesarean delivery demonstrate no increased risk of fetal or neonatal adverse outcomes, including Apgar score, umbilical cord blood gas values, trauma, and NICU admission.
- ◆ When properly applied and used, forceps deliveries that require greater than 45 degrees rotation may be safely accomplished without increased risk of maternal or neonatal morbidity and therefore should remain a

management option for women with second-stage labor abnormalities.

- ◆ The sequential use of vacuum extraction and forceps increases the likelihood of adverse maternal and neonatal outcomes more than the sum of the relative risks of each instrument.

## OVERVIEW

Normal human labor is characterized by rhythmic uterine contractions that intermittently interrupt the transplacental passage of oxygen from the mother to the fetus. These brief episodes of transient interruption of oxygenation are tolerated without consequence by almost all fetuses. In a very small subset, however, severe fetal oxygen deficiency can lead to hypoxic injury or even death. Many possible causes of fetal or neonatal injury are not directly related to fetal oxygenation, including conditions such as infection, congenital anomalies, and meconium aspiration. However, intrapartum interruption of fetal oxygenation is the condition for which conservative and/or operative interventions have the greatest potential to prevent injury or death. To that end, intrapartum fetal monitoring is intended to assess the adequacy of fetal oxygenation during labor. Evidence of interrupted fetal oxygenation demonstrated by the monitor can alert the clinician to the need for further evaluation and possible conservative interventions to ameliorate oxygen deficiency, such as administration of supplemental oxygen or maternal position changes. If conservative measures are not successful, the monitor can help determine the frequency, duration, and severity of interrupted oxygenation so that appropriately informed decisions can be made regarding the optimal timing and method of delivery to avoid the potential consequences of fetal hypoxia.

## BRIEF HISTORY OF FETAL MONITORING

Auscultation of the fetal heart was described in the medical literature as early as the eighteenth century.<sup>1,2</sup> In 1822, Le Jumeau de Kergardec proposed that auscultation of the fetal heart could be useful in confirming pregnancy, diagnosing multiple gestations, determining fetal position, and judging the state of fetal health or disease by changes in strength and frequency of the heart tones.<sup>2</sup> Later, others described fetal heart rate (FHR) changes associated with changes in fetal oxygenation, umbilical cord compression, fetal head compression, “fetal distress,” and “asphyxic intoxication.”<sup>1,2</sup> These observations were made using the stethoscope (*mediate auscultation*) or with the ear of the examiner placed directly upon the maternal abdomen (*immediate auscultation*). In 1917, Hillis described the modified stethoscope known today as the *DeLee-Hillis fetoscope*.

In 1906, Cremer recorded the first fetal electrocardiogram (ECG). By placing one electrode on the maternal abdomen and another in the vagina, he observed small fetal electrical impulses among the higher-voltage maternal signals. For decades, the clinical usefulness of the abdominal fetal ECG was limited by unreliable signal quality. Recent technological advances that have improved the accuracy and reliability of abdominal fetal ECG will be discussed later in this chapter.

The concept of direct application of the ECG electrode to the fetus in utero was introduced in the 1950s. During the 1960s, Hon<sup>3</sup> in the United States, Caldeyro-Barcia and colleagues<sup>4</sup> in Uruguay, and Hammacher<sup>5</sup> in Germany pioneered the development of electronic fetal monitoring (EFM). The first practical clinical FHR monitor became available in the United States in 1968, and throughout the 1970s, FHR monitoring became increasingly incorporated into obstetric practice. The introduction of Doppler ultrasound technology permitted FHR monitoring in patients with intact membranes. By 2002, EFM was used in approximately 85% of all births in the United States.<sup>6</sup> Today, most women who give birth in the United States have EFM during labor.

## INSTRUMENTATION

The fetal monitor tracing is a continuous paper strip comprising two Cartesian graphs. The upper graph displays an instantaneous recording of the FHR; time is shown on the *x*-axis, and heart rate is shown on the *y*-axis. On the *x*-axis, fine vertical lines represent intervals of 10 seconds, and heavy vertical lines represent 1-minute intervals. Fine horizontal lines on the *y*-axis represent intervals of 10 beats/min with a range of 30 to 240 beats/min. Uterine activity is displayed on the lower graph, time is on the *x*-axis, and pressure is on the *y*-axis. Fine vertical lines represent intervals of 10 seconds, and heavy vertical lines represent 1-minute intervals. On the *y*-axis, fine horizontal lines represent intervals of 5 mm Hg with a range of 0 to 100 mm Hg. Heart rate and uterine activity are plotted separately on the heat-sensitive paper by thermal pens. Standard paper speed is 3 cm/min in the United States and 1 cm/min in most other countries.

## Direct Fetal Heart Rate and Uterine Activity Monitoring

Direct FHR monitoring involves transcervical application of an ECG electrode to the fetus, dilation of the cervix, rupture of the membranes, and access to the fetal presenting part. These requirements limit the use of direct monitoring to the intrapartum period. The bipolar fetal ECG electrode is attached directly to the fetal presenting part by gently screwing a small spiral metal wire into the skin. When one pole of the electrode is applied to the fetal presenting part and the other pole is bathed in vaginal fluid to complete the electrical circuit, the ECG electrode detects electrical impulses that originate in the fetal heart; amplified signals are processed by a cardiometer (Fig. 15-1). Computer logic compares each incoming fetal QRS complex with the one immediately preceding it. The time interval between the two complexes is measured electronically and is

**FIG 15-1** Techniques used for direct monitoring of fetal heart rate (FHR) and uterine contractions (UC). The fetal electrocardiogram is obtained by direct application of the scalp electrode, which is then attached to a leg plate on the mother's thigh. The signal is transmitted to the monitor, where it is amplified, counted by the cardiotachometer, and then recorded. Uterine contractions are assessed with an intrauterine pressure catheter connected to a pressure transducer. This signal is then amplified and recorded.

used to calculate a heart rate, which is plotted as a point on the FHR graph located on the upper channel of the paper chart. This process is repeated with each cardiac cycle to produce a series of closely spaced individual points that appear on the paper chart as an irregular line that represents a graphic instantaneous display of the FHR.

Direct assessment of uterine activity uses a thin, flexible intrauterine pressure catheter (IUPC) placed transcervically into the amniotic cavity. Intrauterine pressure is transmitted from the amniotic fluid through the fluid-filled catheter to an external pressure transducer. The transducer converts pressure measurements into electrical signals to permit the continuous display of pressure readings on the uterine activity graph located on the lower channel of the paper chart. Newer catheters use closed systems with a strain gauge or sensors in the catheter tip that relay signals to a strain gauge located at the base of the catheter. A second port can be used to infuse saline into the amniotic cavity (*amnioinfusion*) to relieve variable FHR decelerations caused by umbilical cord compression. **An appropriately calibrated IUPC permits accurate assessment of the frequency, duration, and intensity of uterine contractions as well as the baseline uterine tone between contractions.**

### Indirect Fetal Heart Rate and Uterine Activity Monitoring

Indirect (external) monitoring does not require the transcervical placement of electrodes or catheters. Consequently, external FHR monitoring uses an ultrasound transducer applied with straps to the maternal abdomen and can be performed prior to labor. Ultrasound waves produced by the transducer are transmitted to the maternal skin through coupling gel; these waves penetrate maternal and fetal tissues and are reflected by moving tissue interfaces. Waves reflected from moving structures of the fetal heart return to the transducer for processing. Fetal heart structures moving *toward* the transducer reflect ultrasound waves at a *higher* frequency than the outgoing signal, whereas structures moving *away* from the transducer reflect ultrasound waves at a *lower* frequency. These changes in frequency, known as *Doppler shift* or *Doppler effect*, produce phasic signals that are

converted into a graphic display of the FHR in a process similar to that used in direct monitoring (Fig. 15-2). The raw signals produced by an external ultrasound transducer are more prone to artifact than those produced by a direct fetal ECG electrode. However, with improved computer processing and application of the autocorrelation technique, FHR tracings produced by modern external monitors are comparable to those produced by a direct fetal ECG electrode.

Indirect assessment of uterine activity is performed with a pressure transducer (tocodynamometer) applied tightly to the maternal abdomen over the uterine fundus. Uterine contractions change the shape and rigidity of the uterus and anterior abdominal wall, which generates pressure changes that are transmitted to the sensor located in the tocodynamometer transducer. Changes in pressure are converted into electrical signals and are plotted on the lower channel of the paper chart as a continuous display of uterine activity. **When properly positioned on the maternal abdomen, the external tocodynamometer permits assessment of the relative frequency and duration of uterine contractions. However, it does not directly measure intrauterine pressure and therefore does not provide a reliable assessment of uterine contraction intensity or resting tone between contractions.** When external uterine activity monitoring is used, contraction intensity and baseline uterine tone usually are assessed by palpation. Contraction strength is graded as *mild*, *moderate*, or *strong* depending upon the degree to which the uterine fundus can be indented by palpation with the fingertips during the peak of a uterine contraction. During mild contractions, the fundus is easily indented by the fingertips; during strong contractions, the fundus cannot be indented. If the fundus can be indented by intermediate pressure, the contraction strength is moderate.

### PHYSIOLOGIC BASIS FOR ELECTRONIC FETAL HEART RATE MONITORING

The objective of intrapartum FHR monitoring is to prevent fetal injury that might result from interruption of normal fetal oxygenation during labor. The underlying assumption is that

**FIG 15-2** Instrumentation for external monitoring. Fetal heart rate (FHR) is monitored using the Doppler ultrasound transducer, which both emits and receives the reflected ultrasound signal that is then counted and recorded. Uterine contractions (UC) are detected by the pressure-sensitive tocodynamometer and are then amplified and recorded.

interruption of fetal oxygenation leads to characteristic physiologic changes that can be detected by changes in the FHR. The role of intrapartum FHR monitoring in assessing the fetal physiologic changes caused by interrupted oxygenation can be summarized in two key points. Fetal oxygenation involves (1) the transfer of oxygen from the environment to the fetus, and (2) the fetal response to interruption of oxygen transfer. Specific FHR patterns provide reliable information regarding these two aspects of fetal oxygenation.

### TRANSFER OF OXYGEN FROM THE ENVIRONMENT TO THE FETUS

Oxygen is transferred from the environment to the fetus by maternal and fetal blood along a pathway that includes the maternal lungs, heart, vasculature, uterus, placenta, and umbilical cord. The “oxygen pathway” is illustrated in Figure 15-3. Interruption of oxygen transfer can occur at any or all of the points along this pathway.

#### External Environment

Oxygen comprises approximately 21% of inspired air. Therefore in inspired air, the partial pressure exerted by oxygen gas ( $PO_2$ ) is approximately 21% of total atmospheric pressure (760 mm Hg) minus the pressure exerted by water vapor (47 mm Hg). At sea level, this translates to approximately 150 mm Hg. As oxygen is transferred from the external atmosphere to maternal blood and then to fetal blood, the partial pressure progressively declines. **By the time oxygen reaches fetal umbilical venous blood, the partial pressure may be as low as 30 mm Hg. After oxygen is delivered to fetal tissues, the  $PO_2$  of deoxygenated blood in the umbilical arteries returning to the placenta is approximately 15 to 25 mm Hg.**<sup>7-9</sup> The sequential transfer of oxygen from the environment to the fetus and potential causes of interruption at each step are described below.

#### Maternal Lungs

Inspiration carries oxygenated air from the external environment to the distal air spaces of the lungs, the alveoli. On the way to the alveoli, inspired air mixes with less oxygenated air leaving

**FIG 15-3** The oxygen pathway.

the lungs. As a result, the  $PO_2$  of air within the alveoli is lower than that in inspired air. At sea level, alveolar  $PO_2$  is approximately 100 to 105 mm Hg. From the alveoli, oxygen diffuses across a thin blood-gas barrier into the pulmonary capillary blood. This pulmonary blood-gas barrier consists of three layers: a single-cell layer of alveolar epithelium and basement membrane, a layer of extracellular matrix (interstitium), and a single-cell layer of pulmonary capillary endothelium and basement membrane. Interruption of oxygen transfer from the

**FIG 15-4** Maternal oxygen dissociation curve. The tendency for hemoglobin to release oxygen is increased by factors that signal an increased requirement for oxygen. Specifically, oxygen release is enhanced by factors that indicate active cellular metabolism. These factors shift the oxyhemoglobin saturation curve to the right and include anaerobic metabolism (reflected by increased 2,3-diphosphoglycerate concentration), production of lactic acid (reflected by decreased pH), aerobic metabolism (reflected by increased partial pressure of carbon dioxide [ $\text{PCO}_2$ ]), and heat.

environment to the alveoli can result from airway obstruction or depression of central respiratory control caused by medications (narcotics, magnesium) or convulsions (apnea). Interruption of oxygen transfer from the alveoli to the pulmonary capillary blood can be caused by a number of factors that include ventilation-perfusion mismatch and diffusion defects due to conditions such as pulmonary embolus, pneumonia, asthma, atelectasis, or acute respiratory distress syndrome (ARDS).

### Maternal Blood

After diffusing from the pulmonary alveoli into maternal blood, more than 98% of oxygen combines with hemoglobin in maternal red blood cells. The remaining 1% to 2% is dissolved in the blood and is measured by the partial pressure of oxygen in arterial blood ( $\text{PaO}_2$ ). The amount of oxygen bound to hemoglobin depends directly upon the  $\text{PaO}_2$ . Hemoglobin saturations at various  $\text{PaO}_2$  levels are illustrated by the oxyhemoglobin dissociation curve (Fig. 15-4).

A normal adult  $\text{PaO}_2$  value of 95 to 100 mm Hg results in a hemoglobin saturation of approximately 95% to 100%, indicating that hemoglobin is carrying 95% to 100% of the total amount of oxygen it is capable of carrying. A number of factors affect the affinity of hemoglobin for oxygen and can shift the oxyhemoglobin dissociation curve to the left or right. **In general, the tendency for hemoglobin to release oxygen is increased by factors that signal an increased requirement for oxygen.** Specifically, oxygen release is enhanced by factors that indicate active cellular metabolism. These factors shift the oxyhemoglobin saturation curve to the right and include by-products of anaerobic metabolism (reflected by increased 2,3-diphosphoglycerate [DPG] concentration), production of lactic acid (reflected by decreased pH), by-products of aerobic metabolism (reflected by increased partial pressure of carbon dioxide [ $\text{PCO}_2$ ]), and heat. Interruption of oxygen transfer from

the environment to the fetus due to abnormal maternal oxygen-carrying capacity can result from severe anemia or from hereditary or acquired abnormalities that affect oxygen binding, such as hemoglobinopathies or methemoglobinemia. In an obstetric population, reduced maternal oxygen-carrying capacity is an uncommon cause of interrupted fetal oxygenation.

### Maternal Heart

From the lungs, pulmonary veins carry oxygenated maternal blood to the heart. Pulmonary venous blood enters the left atrium with a  $\text{PaO}_2$  of approximately 95 to 100 mm Hg. Oxygenated blood passes from the left atrium through the mitral valve into the left ventricle and out the aorta for systemic distribution. Normal transfer of oxygen from the environment to the fetus is dependent upon normal cardiac function, reflected by cardiac output—the product of heart rate and stroke volume. Heart rate is determined by intrinsic cardiac pacemakers (sinoatrial node, atrioventricular node), the cardiac conduction system, autonomic regulation (sympathetic, parasympathetic), intrinsic humoral factors (catecholamines), extrinsic factors (medications), and local factors (calcium, potassium). Stroke volume is determined by preload, contractility, and afterload. *Preload* is the amount of stretch on myocardial fibers at the end of diastole when the ventricles are full of blood, and it is dependent on the volume of venous blood returning to the heart. *Contractility* is the force and speed with which myocardial fibers shorten during systole to expel blood from the heart. *Afterload* is the pressure that opposes the shortening of myocardial fibers during systole and is estimated by the systemic vascular resistance or systemic blood pressure.

Interruption of oxygen transfer from the environment to the fetus at the level of the maternal heart can be caused by any condition that reduces cardiac output, including altered heart rate (arrhythmia), reduced preload (hypovolemia, compression of the inferior vena cava), impaired contractility (ischemic heart disease, diabetes, cardiomyopathy, congestive heart failure), or increased afterload (hypertension). In addition, structural abnormalities of the heart and great vessels (valvular stenosis, valvular insufficiency, pulmonary hypertension, coarctation of the aorta) may impede its ability to pump blood. **In a healthy obstetric patient, the most common cause of reduced cardiac output is reduced preload resulting from hypovolemia or compression of the inferior vena cava by the gravid uterus.**

### Maternal Vasculature

Oxygenated blood leaving the heart is carried by the systemic vasculature to the uterus. The vascular path includes the aorta, common iliac artery, internal iliac (hypogastric) artery, anterior division of the internal iliac artery, and the uterine artery. From the uterine artery, oxygenated blood travels through the arcuate, radial, and finally the spiral arteries before exiting the maternal vasculature and entering the intervillous space of the placenta. **Interruption of oxygen transfer from the environment to the fetus at the level of the maternal vasculature commonly results from hypotension caused by regional anesthesia, hypovolemia, impaired venous return, impaired cardiac output, or medication.** Alternatively, it may result from vasoconstriction of distal arterioles in response to endogenous vasoconstrictors or medications. Conditions associated with chronic vasculopathy—such as chronic hypertension, long-standing diabetes, collagen vascular disease, thyroid disease, or renal disease—may result in chronic suboptimal transfer of

FIG 15-5 Placental blood flow.

oxygen and nutrients to the fetus at the level of the maternal vasculature. Preeclampsia is associated with abnormal vascular remodeling at the level of the spiral arteries and can impede perfusion of the intervillous space. Acute vascular injuries (trauma, aortic dissection) are rare. In a healthy obstetric patient, transient hypotension is the most common cause of interrupted oxygen transfer at the level of the maternal vasculature. Chronic vascular conditions can exacerbate this interruption and should be considered in the course of thorough evaluation.

### Uterus

Between the maternal uterine arteries and the intervillous space of the placenta, the arcuate, radial, and spiral arteries and their corresponding veins traverse the muscular wall of the uterus. **Interruption of oxygen transfer from the environment to the fetus at the level of the uterus commonly results from uterine contractions that compress intramural blood vessels and impede the flow of blood.** Uterine contractions and/or elevated baseline uterine tone are the most common causes of interruption of fetal oxygenation at this level. Uterine rupture is less common but must be considered in the appropriate clinical context.

### Placenta

The placenta facilitates the exchange of gases, nutrients, wastes, and other molecules—for example antibodies, hormones, and

medications—between maternal blood in the intervillous space and fetal blood in the villous capillaries. On the maternal side of the placenta, oxygenated blood exits the spiral arteries and enters the intervillous space to surround and bathe the chorionic villi. On the fetal side of the placenta, paired umbilical arteries carry blood from the fetus through the umbilical cord to the placenta. **At term, the umbilical arteries receive 40% of fetal cardiac output.** Upon reaching the placental cord insertion site, the umbilical arteries divide into multiple branches that fan out across the surface of the placenta. As illustrated in Figure 15-5, at each cotyledon, placental arteries dive beneath the surface en route to the chorionic villi.

The chorionic villi are microscopic branches of trophoblast that protrude into the intervillous space. Each villus is perfused by a fetal capillary bed that represents the terminal distribution of an umbilical artery. At term, fetal villous capillary blood is separated from maternal blood in the intervillous space by a thin blood-blood barrier similar to the blood-gas barrier in the maternal lung. The placental blood-blood barrier is comprised of a layer of placental trophoblast and a layer of fetal capillary endothelium with intervening basement membranes separated by a layer of villous stroma. Substances are exchanged between maternal and fetal blood by a number of mechanisms, including simple diffusion, facilitated diffusion, active transport, bulk flow, pinocytosis, and leakage. Examples of these mechanisms are summarized in Table 15-1. **Oxygen is transferred from the**

**TABLE 15-1** MECHANISMS OF PLACENTAL TRANSFER

| MECHANISM             | DESCRIPTION  | SUBSTANCES   |
|-----------------------|--|--|
| Simple diffusion      | Passage of substances along a concentration gradient from a region of higher concentration to one of lower concentration that is passive and does not require energy | Oxygen, carbon dioxide, small ions (sodium chloride), lipids, fat-soluble vitamins, many drugs |
| Facilitated diffusion | Passage of substances along a concentration gradient with the assistance of a carrier molecule without energy requirement  | Glucose, carbohydrates   |
| Active transport      | Passage of substances against a concentration gradient with the assistance of a carrier molecule and energy  | Amino acids, water-soluble vitamins, large ions  |
| Bulk flow             | Transfer of substances by a hydrostatic or osmotic gradient  | Water, dissolved electrolytes  |
| Pinocytosis           | Transfer of engulfed particles across a cell membrane  | Immunoglobulins, proteins  |
| Breaks and leakage    | Small breaks in the placental membrane that allow passage of plasma and substances   | Maternal or fetal blood cells  |

**FIG 15-6** Uterine and umbilical blood gas values. (From Miller LA, Miller DA, Martin Tucker S. *Mosby's Pocket Guide to Fetal Monitoring: A Multidisciplinary Approach*. St. Louis: Elsevier; 2012.)

intervillous space to the fetal blood by a process that depends upon the PaO<sub>2</sub> of maternal blood perfusing the intervillous space, the flow of oxygenated maternal blood into and out of the intervillous space, the chorionic villous surface area, and the rate of oxygen diffusion across the placental blood-blood barrier.

### Intervillous Space PaO<sub>2</sub>

Oxygenated maternal blood leaves the maternal heart with a partial pressure of oxygen dissolved in arterial blood (PaO<sub>2</sub>) of approximately 95 to 100 mm Hg. Exiting the spiral arteries to perfuse the intervillous space of the placenta, oxygenated maternal blood has a PaO<sub>2</sub> of approximately 95 to 100 mm Hg. Oxygen is released from maternal hemoglobin and diffuses across the placental blood-blood barrier into fetal blood, where it combines with fetal hemoglobin. As a result, maternal blood in the intervillous space becomes relatively oxygen depleted and exits the intervillous space via uterine veins with a PaO<sub>2</sub> of approximately 40 mm Hg (Fig. 15-6).

The average PaO<sub>2</sub> of maternal blood in the intervillous space is between the PaO<sub>2</sub> of blood entering the intervillous space (95 to 100 mm Hg) and the PaO<sub>2</sub> of blood exiting the intervillous space (40 mm Hg). **The average intervillous space PaO<sub>2</sub> is in the range of 45 mm Hg.** Interruption of fetal oxygenation can result from conditions that reduce the PaO<sub>2</sub> of maternal blood entering the intervillous space. These conditions have been discussed previously.

### Intervillous Space Blood Flow

At term, uterine perfusion accounts for 10% to 15% of maternal cardiac output, or approximately 700 to 800 mL/min. Much of this blood is located in the intervillous space of the placenta surrounding the chorionic villi. Conditions that can reduce the volume of the intervillous space include collapse or destruction

of the intervillous space because of placental abruption, infarction, thrombosis, or infection.

### Chorionic Villous Surface Area

Optimal oxygen exchange is dependent upon normal chorionic villous surface area. Normal transfer of oxygen from the environment to the fetus at the level of the placenta can be interrupted by conditions that limit or reduce the chorionic villous surface area available for gas exchange. These conditions can be acute or chronic and include primary abnormalities in the development of the villous vascular tree or secondary distortion of normal chorionic villous architecture by infarction, thrombosis, hemorrhage, inflammation, infection, or abnormal vascular growth.

### Diffusion Across the Blood-Blood Barrier

Diffusion of a substance across the placental blood-blood barrier is dependent upon concentration gradient, molecular weight, lipid solubility, protein binding, and ionization. In addition, the diffusion rate is inversely proportional to the diffusion distance. **At term, the placental blood-blood barrier is very thin, and the diffusion distance is short.** Under normal circumstances, oxygen and carbon dioxide diffuse readily across this thin barrier; however, normal diffusion can be impeded by conditions that increase the distance between maternal and fetal blood. These conditions can be acute, subacute, or chronic and include villous hemorrhage, inflammation, thrombosis, infarction, edema, fibrosis, and excessive cellular proliferation characterized by the presence of syncytial knots.<sup>10</sup>

### Interruption of Placental Blood Vessels

For the sake of completeness, fetal blood loss caused by injury to blood vessels at the level of the placenta warrants discussion. Damaged chorionic vessels can allow fetal blood to leak into the intervillous space, leading to fetal-maternal hemorrhage. This may be a consequence of abdominal trauma but can also occur in association with placental abruption or invasive procedures, and a specific cause is not always identified. Ruptured vasa previa is a rare cause of fetal hemorrhage. Vasa previa is a placental vessel traversing the chorioamniotic membrane in close proximity to the cervical os. Such a vessel may be damaged by normal cervical change during labor, or it can be injured inadvertently during membrane rupture or digital exam.

### Summary of Placental Causes of Interrupted Oxygenation

Many conditions can interfere with the transfer of oxygen across the placenta. Those that involve the microvasculature frequently are diagnosed by histopathologic examination after delivery. Clinically detectable causes, such as placental abruption or

bleeding placenta previa or vasa previa, should be considered but may not be amenable to conservative corrective measures.

### Fetal Blood

After oxygen has diffused from the intervillous space across the placental blood-blood barrier and into fetal blood, the venous PO<sub>2</sub> is in the range of 30 mm Hg, and fetal hemoglobin saturation is between 50% and 70%. **Although fetal PO<sub>2</sub> and hemoglobin saturation values are low in comparison to adult values, adequate delivery of oxygen to the fetal tissues is maintained by a number of compensatory mechanisms.** For example, fetal cardiac output per unit weight is greater than that of the adult. Hemoglobin concentration and affinity for oxygen are greater in the fetus as well, resulting in increased oxygen-carrying capacity. Finally, oxygenated blood is directed preferentially toward vital organs by way of laminar blood flow and anatomic shunts at the level of the ductus venosus and foramen ovale. Conditions that can interrupt the transfer of oxygen from the environment to the fetus at the level of the fetal blood are uncommon but may include fetal anemia and reduced oxygen-carrying capacity secondary to alloimmunization, hemoglobinopathy, glucose-6-phosphate dehydrogenase (G6PD) deficiency, viral infections, fetomaternal hemorrhage, methemoglobinemia, or bleeding vasa previa.

### Umbilical Cord

After oxygen binds to fetal hemoglobin in the villous capillaries, oxygenated blood returns to the fetus by way of villous veins that coalesce to form placental veins on the surface of the placenta. Placental surface veins unite to form a single umbilical vein within the umbilical cord. **Interruption of the transfer of oxygen from the environment to the fetus at the level of the umbilical cord can result from simple mechanical compression.** Other uncommon causes may include vasospasm, thrombosis, atherosclerosis, hypertrophy, hemorrhage, inflammation, or a true “knot.” From the environment to the fetus, maternal and fetal blood carries oxygen along the oxygen pathway illustrated in Figure 15-3. Examples of causes of interrupted oxygen transfer at each step along the pathway are summarized in Table 15-2.

Gas exchange also involves the transfer of carbon dioxide in the opposite direction, from the fetus to the environment. Any condition that interrupts the transfer of oxygen from the environment to the fetus has the potential to interrupt the transfer of carbon dioxide from the fetus to the environment. However, carbon dioxide diffuses across the placental blood-blood barrier more rapidly than does oxygen; therefore any interruption of the pathway is likely to impact oxygen transfer to a greater extent than it does carbon dioxide transfer.

### FETAL RESPONSE TO INTERRUPTED OXYGEN TRANSFER

Depending upon frequency, degree, and duration, interruption of oxygen transfer at any point along the oxygen pathway may result in progressive deterioration of fetal oxygenation. The cascade begins with hypoxemia, defined as decreased oxygen content in the blood. At term, hypoxemia is characterized by an umbilical artery PaO<sub>2</sub> below the normal fetal range of approximately 15 to 25 mm Hg. Recurrent or sustained hypoxemia can lead to decreased delivery of oxygen to the tissues and reduced tissue oxygen content, termed *hypoxia*.

**TABLE 15-2** EXAMPLES OF CAUSES OF INTERRUPTED OXYGEN TRANSFER AT EACH STEP IN THE OXYGEN PATHWAY

| OXYGEN PATHWAY | CAUSES OF INTERRUPTED OXYGEN TRANSFER   |
|----------------|---|
| Lungs          | Respiratory depression (narcotics, magnesium)<br>Seizure (eclampsia)<br>Pulmonary embolus<br>Pulmonary edema<br>Pneumonia/acute respiratory distress syndrome<br>Asthma<br>Atelectasis<br>Pulmonary hypertension (rarely)<br>Chronic lung disease (rarely)                      |
| Heart          | Reduced cardiac output<br>Hypovolemia<br>Compression of the inferior vena cava<br>Regional anesthesia (sympathetic blockade)<br>Cardiac arrhythmia<br>Congestive heart failure (rarely)<br>Structural cardiac disease (rarely)  |
| Vasculature    | Hypotension<br>Hypovolemia<br>Compression of the inferior vena cava<br>Regional anesthesia (sympathetic blockade)<br>Medications (hydralazine, labetalol, nifedipine)<br>Vasculopathy (chronic hypertension, SLE, preeclampsia)<br>Vasoconstriction (cocaine, methylergonovine) |
| Uterus         | Excessive uterine activity<br>Uterine stimulants (prostaglandins, oxytocin)<br>Uterine rupture  |
| Placenta       | Placental abruption<br>Vasa previa (rarely)<br>Fetal-maternal hemorrhage (rarely)<br>Placental infarction, infection (usually confirmed retrospectively)  |
| Umbilical cord | Cord compression<br>Cord prolapse<br>True “knot”  |

SLE, systemic lupus erythematosus.

Normal homeostasis requires an adequate supply of oxygen and fuel in order to generate the energy required by basic cellular activities. When oxygen is readily available, aerobic metabolism efficiently generates energy in the form of adenosine triphosphate (ATP). By-products of aerobic metabolism include carbon dioxide and water. **When oxygen is in short supply, tissues may be forced to switch from aerobic to anaerobic metabolism, which generates energy less efficiently and results in the production of lactic acid. Accumulation of lactic acid in the tissues results in metabolic acidosis.** Lactic acid accumulation can lead to utilization of buffer bases, primarily bicarbonate, to help stabilize tissue pH. If the buffering capacity is exceeded, tissue pH and eventually blood pH may begin to fall, leading to metabolic acidemia.

*Acidemia* is defined as increased hydrogen ion content (decreased pH) in the blood. Recurrent or sustained hypoxia and acidosis in the peripheral tissues can lead to loss of peripheral vascular smooth muscle contraction, reduced peripheral vascular resistance, hypotension, and potential hypoxic-ischemic injury to critical tissues and organs, including the brain and heart. With respect to fetal physiology, **it is critical to distinguish between respiratory acidemia, caused by accumulation of CO<sub>2</sub>, and metabolic acidemia, caused by accumulation of lactic acid in excess of buffering capacity. Respiratory acidemia is relatively common and clinically benign.**<sup>9</sup> Conversely,

metabolic acidemia is uncommon and may be a marker of clinically significant interruption of fetal oxygenation.<sup>11</sup>

### Mechanisms of Injury

If interruption of fetal oxygenation progresses to the stage of metabolic acidemia and hypotension, as described above, multiple organs and systems—including the brain and heart—can suffer hypoperfusion, reduced oxygenation, lowered pH, and reduced delivery of fuel for metabolism. These changes can contribute to a cascade of cellular events that include altered enzyme function, protease activation, ion shifts, altered water regulation, abnormal neurotransmitter metabolism, free radical production, and phospholipid degradation. Disruption of normal cellular metabolism can lead to cellular and tissue dysfunction, injury, and even death.

### Injury Threshold

The relationship between fetal oxygen deprivation and neurologic injury is complex. Electronic FHR monitoring was introduced with the hope that it would reduce the incidence of neurologic injury in the form of cerebral palsy (CP) caused by intrapartum interruption of fetal oxygenation. Subsequently, **it has become apparent that most cases of CP are unrelated to intrapartum events and therefore cannot be prevented by modification of intrapartum management, including FHR monitoring.** Nevertheless, some cases of CP may be linked to events during labor and delivery; therefore it is important to understand, to the extent possible, the relationship between intrapartum fetal oxygenation and the subsequent development of CP. In 1999, the International Cerebral Palsy Task Force published a consensus statement<sup>12</sup> identifying essential criteria to establish intrapartum interruption of fetal oxygenation as a possible cause of CP. In January of 2003, The American College of Obstetricians and Gynecologists (ACOG) and the American Academy of Pediatrics (AAP) Cerebral Palsy Task Force published a monograph<sup>11</sup> entitled “Neonatal Encephalopathy and Cerebral Palsy: Defining the Pathogenesis and Pathophysiology,” which summarized the literature regarding the relationship between intrapartum events and neurologic injury. Agencies and professional organizations that endorsed the ACOG-AAP task force report include the Centers for Disease Control and Prevention (CDC), the Child Neurology Society, the March of Dimes Birth Defects Foundation, the National Institute of Child Health and Human Development (NICHD), the Royal Australian and New Zealand College of Obstetricians and Gynecologists, the Society for Maternal-Fetal Medicine (SMFM), and the Society of Obstetricians and Gynaecologists of Canada.

The consensus report established four essential criteria to define an acute intrapartum hypoxic event sufficient to cause CP (Box 15-1). The first criterion identified significant umbilical artery metabolic acidemia at birth (pH <7.0 and base deficit  $\geq 12$  mmol/L) as an essential prerequisite to establish a possible link between intrapartum interruption of fetal oxygenation and the later diagnosis of CP. **It is important to recognize that even when significant metabolic acidemia is present, neonatal encephalopathy and fetal neurologic injury are uncommon.** Respiratory acidemia without a metabolic component is not a significant risk factor for fetal neurologic injury.<sup>9</sup>

The second criterion emphasized that in the absence of moderate to severe neonatal encephalopathy, intrapartum interruption of fetal oxygenation is very unlikely to result in CP. Neonatal encephalopathy has many possible causes. Hypoxic-ischemic

#### BOX 15-1 ESSENTIAL CRITERIA TO DEFINE AN ACUTE INTRAPARTUM EVENT SUFFICIENT TO CAUSE CEREBRAL PALSY

1. Umbilical cord arterial blood pH <7 and base deficit  $\geq 12$  mmol/L
2. Early onset of severe or moderate neonatal encephalopathy in infants born at 34 or more weeks of gestation
3. Cerebral palsy of the spastic quadriplegic or dyskinetic type
4. Exclusion of other identifiable etiologies such as trauma,\* coagulation disorders, infectious conditions, or genetic disorders

\*Does not refer to fetal injury potentially related to the mechanical forces of labor or maternal expulsive efforts.

#### BOX 15-2 CRITERIA THAT COLLECTIVELY SUGGEST THE EVENT OCCURRED WITHIN 48 HOURS OF BIRTH

1. A sentinel hypoxic event immediately before or during labor
2. A sudden and sustained fetal bradycardia, or the absence of fetal heart rate variability in the presence of persistent late or variable decelerations, usually after a hypoxic sentinel event when the pattern was previously normal
3. Apgar scores of 0 to 3 beyond 5 min
4. Onset of multisystem involvement within 72 hr of birth
5. Early imaging study showing evidence of acute nonfocal cerebral abnormality

encephalopathy (HIE) resulting from intrapartum interruption of fetal oxygenation represents only a small subset of neonatal encephalopathy, and most cases of HIE do not result in permanent neurologic injury.

The third criterion acknowledged that different subtypes of CP have different potential origins. The spastic quadriplegic subtype of CP caused by injury to the parasagittal cortex is characterized by abnormal motor control of all four extremities. The dyskinetic subtype of CP associated with injury to the basal ganglia involves disorganized, choreoathetoid movements. Although the presence of these CP subtypes does not constitute conclusive evidence of intrapartum hypoxic injury, they are the only subtypes that have been linked to hypoxic-ischemic neurologic injury at term. Other CP subtypes such as spastic diplegia, hemiplegia, ataxia, and hemiparetic CP are unlikely to result from acute intrapartum hypoxia. **Conditions such as epilepsy, mental retardation, and attention-deficit/hyperactivity disorder do not result from intrapartum fetal hypoxia in the absence of CP.**<sup>11</sup>

The fourth criterion highlighted the fact that hypoxic-ischemic injury due to intrapartum interruption of fetal oxygenation is a potential cause of a relatively small subset of all cases of CP. Other identifiable etiologies include trauma, coagulation disorders, vascular accidents, infectious conditions, and genetic disorders. The 2003 ACOG-AAP Cerebral Palsy Task Force report<sup>11</sup> further identified five criteria to help establish the timing of injury, emphasizing that these criteria are not specific to hypoxic-ischemic injury. These criteria are summarized in Box 15-2.

In 2014, the ACOG-AAP Neonatal Encephalopathy Task Force revisited the scientific evidence linking intrapartum events,

neonatal encephalopathy and subsequent neurologic outcome. The resulting monograph, *Neonatal Encephalopathy and Neurologic Outcome* (Second Edition), reaffirmed the concept that the pathway from intrapartum hypoxic-ischemic injury to subsequent CP must progress through neonatal encephalopathy.<sup>13</sup> The report also reaffirmed the conclusion that spastic quadriplegia and dyskinetic CP are the subtypes most likely to be associated with hypoxic intrapartum injury at term. These conditions were *not* identified as absolute requirements for the diagnosis of intrapartum hypoxic neurologic injury. **The 2014 report further concluded that “unless the newborn has accumulated significant metabolic acidemia, the likelihood of subsequent neurologic and cardiovascular morbidities attributable to perinatal events is low,” and “in a fetus exhibiting either moderate variability or accelerations of the FHR, damaging degrees of hypoxia-induced metabolic acidemia can reliably be excluded.”** Unlike its predecessor, the 2014 task force report did not identify metabolic acidemia as an absolute requirement to diagnose intrapartum hypoxic neurologic injury.

## PATTERN RECOGNITION AND INTERPRETATION

The clinical application of electronic FHR monitoring (EFM) consists of three interdependent elements: (1) *definition*, that is, the words used to describe the FHR observations; (2) *interpretation*, or the physiologic significance of the FHR observations; and (3) *management*, or the clinical response to the FHR observations.

## EVOLUTION OF STANDARDIZED FETAL HEART RATE DEFINITIONS

Electronic FHR monitoring was introduced into clinical practice before consensus was reached regarding standardized definitions of FHR patterns. This resulted in wide variations in the descriptions and interpretations of common FHR observations, and this lack of standardization was a major impediment to effective communication. In 1995 and 1996, the NICHD convened a workshop to develop “standardized and unambiguous definitions for fetal heart rate tracings.”<sup>14</sup> However, the NICHD recommendations were not incorporated rapidly into clinical practice, and wide variations persisted. In May, 2005, ACOG endorsed the 1997 NICHD recommendations in Practice Bulletin #62 (subsequently updated in December 2005 in Practice Bulletin #70).<sup>15</sup> Shortly thereafter, the NICHD definitions were endorsed by the Association of Women’s Health, Obstetric and Neonatal Nurses (AWHONN) and the American College of Nurse Midwives (ACNM).

## 2008 NATIONAL INSTITUTE OF CHILD HEALTH AND HUMAN DEVELOPMENT CONSENSUS REPORT

A second NICHD consensus panel was convened in 2008 to review and update the standardized definitions published in 1997 and to seek consensus regarding basic principles of FHR interpretation.<sup>16</sup> The standardized NICHD definitions published in 2008 are summarized in Table 15-3.

In addition to clarifying and reiterating the standardized FHR definitions proposed by the 1997 NICHD consensus statement, the 2008 report recommended a simplified, objective system

**TABLE 15-3** STANDARD FETAL HEART RATE DEFINITIONS

| PATTERN            | DEFINITION   |
|--------------------|--|
| Baseline           | Mean FHR rounded to increments of 5 beats/min in a 10-min window, excluding accelerations, decelerations, and periods of marked FHR variability (>25 beats/min). There must be at least 2 min of identifiable baseline segments (not necessarily contiguous) in any 10-min window or the baseline for that period is indeterminate. <ul style="list-style-type: none"> <li>• Normal baseline FHR range 110 to 160 beats/min</li> <li>• <i>Tachycardia</i> is defined as an FHR baseline &gt;160 beats/min</li> <li>• <i>Bradycardia</i> is defined as an FHR baseline &lt;110 beats/min</li> </ul> |
| Variability        | Fluctuations in the FHR baseline are irregular in amplitude and frequency and are visually quantitated as the amplitude of the peak to the trough in beats per minute. <ul style="list-style-type: none"> <li>• Absent—amplitude range undetectable</li> <li>• Minimal—amplitude range detectable but ≤5 beats/min</li> <li>• Moderate (normal)—amplitude range 6 to 25 beats/min</li> <li>• Marked—amplitude range &gt;25 beats/min</li> </ul>  |
| Accelerations      | Abrupt increase (onset to peak <30 sec) in the FHR from the most recently calculated baseline. At ≥32 weeks, an acceleration peaks ≥15 beats/min above baseline and lasts ≥15 sec but <2 min. At <32 weeks, acceleration peaks ≥10 beats/min above baseline and lasts ≥10 sec but <2 min. Prolonged acceleration lasts ≥2 min but <10 min. Acceleration ≥10 min is a baseline change.  |
| Early              | Gradual (onset to nadir ≥30 sec) decrease in FHR during a uterine contraction. Onset, nadir, and recovery of the deceleration occur at the same time as the beginning, peak, and end of the contraction, respectively.   |
| Late               | Decrease in FHR is gradual (onset to nadir ≥30 sec) during a uterine contraction. Onset, nadir, and recovery of the deceleration occur after the beginning, peak, and end of the contraction, respectively.  |
| Variable           | Decrease in the FHR is abrupt (onset to nadir <30 sec) and ≥15 beats/min below the baseline and lasting ≥15 sec but less than 2 min.   |
| Prolonged          | Deceleration is ≥15 beats/min below baseline and lasts ≥2 min or more but <10 min. Deceleration ≥10 min is a baseline change.  |
| Sinusoidal pattern | Pattern in FHR baseline is smooth, sine wave–like, and undulating with a cycle frequency of 3 to 5/min that persists for at least 20 min.  |

FHR, fetal heart rate.

for classifying FHR tracings. The 2008 NICHD classification system replaced subjective terms such as *fetal distress*, *fetal stress*, *reassuring fetal status*, *nonreassuring fetal status*, and *fetal intolerance to labor*—all of which are defined inconsistently in the literature.

As summarized in Box 15-3, the three-tier system groups FHR tracings into one of three categories. *Category I* includes tracings with a normal baseline rate (110 to 160 beats/min); moderate variability; and no variable, late, or prolonged decelerations. *Category III* includes tracings with at least one of the following four traits: (1) absent variability with recurrent late decelerations, (2) absent variability with recurrent variable decelerations, (3) absent variability with bradycardia for at least 10 minutes, or (4) a sinusoidal pattern for at least 20 minutes. *Category II* includes all tracings that do not meet criteria for

**BOX 15-3 FETAL HEART RATE CATEGORIES**

Category I requires *all* of the following:

- Baseline rate: 110 to 160 beats/min
- Variability: Moderate
- Accelerations: Present or absent
- Decelerations: No late, variable, or prolonged decelerations

Category II

- Any fetal heart rate tracing that does not meet criteria for classification in category I or III

Category III requires at least *one* of the following:

- Absent variability with recurrent late decelerations
- Absent variability with recurrent variable decelerations
- Absent variability with bradycardia for at least 10 min
- Sinusoidal pattern for at least 20 min

classification as category I or category III. The proposed FHR categories provide a summary method of defining FHR tracings, but they do not replace complete description of baseline rate, variability, accelerations, decelerations, sinusoidal pattern, and changes or trends over time.

The 2008 NICHD consensus report also addressed uterine activity. *Normal uterine contraction frequency* was defined as five or fewer contractions in a 10-minute window averaged over 30 minutes. Contraction frequency of more than 5 in 10 minutes averaged over 30 minutes was defined as *tachysystole*,<sup>16</sup> a term that applies to both spontaneous and stimulated labor.<sup>16,17</sup> Equally important aspects of uterine activity include contraction intensity, contraction duration, resting time between contractions, and resting uterine tone between contractions. The terms *hyperstimulation* and *hypercontractility* are defined inconsistently in the literature; therefore the consensus report recommended they be abandoned. The recommendations of the 2008 NICHD consensus report were subsequently published in ACOG Practice Bulletins 106 and 116.<sup>17,18</sup>

The physiology underlying common FHR patterns has been the subject of scientific investigation for decades; however, most theories regarding the physiologic significance of specific FHR patterns have not been substantiated by appropriately controlled scientific research. In an area as critical as intrapartum FHR monitoring, it is imperative to distinguish between concepts based on scientific evidence and those based on unsubstantiated theories. Scientific evidence can be stratified according to the method outlined by the U.S. Preventive Services Task Force as summarized in [Box 15-4](#).<sup>19</sup>

Level I evidence is considered the most robust, and level III is the least so. Only level I and level II analytic evidence is capable of establishing statistically significant relationships. Level III descriptive evidence can be used to generate theories, but is not capable of proving them.

### Definitions and General Considerations

The standardized definitions proposed by the NICHD in 1997 and reiterated in 2008 apply to the interpretation of FHR patterns, produced either by a direct fetal electrode that detects the fetal ECG or by an external Doppler device that detects fetal cardiac motion using the autocorrelation technique, a computerized method of minimizing the artifact associated with Doppler ultrasound calculation of the FHR, a feature incorporated in all modern FHR monitors. **Other important general considerations are as follows:**

### BOX 15-4 STRATIFICATION OF SCIENTIFIC EVIDENCE ACCORDING TO THE METHOD OUTLINED BY THE U.S. PREVENTIVE SERVICES TASK FORCE

Level I: Evidence obtained from at least one properly designed randomized controlled trial

Level II-1: Evidence obtained from well-designed controlled trials without randomization

Level II-2: Evidence obtained from well-designed cohort or case-control analytic studies, preferably from more than one center or research group

Level II-3: Evidence obtained from multiple time series with or without the intervention; dramatic results in uncontrolled experiments also could be regarded as this type of evidence.

Level III: Opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees

- Patterns are categorized as *baseline*, *periodic*, or *episodic*.
- Baseline patterns include baseline rate and variability.
- Periodic and episodic patterns include FHR accelerations and decelerations.
- *Periodic* patterns are those associated with uterine contractions.
- *Episodic* patterns are those *not* associated with uterine contractions.
- *Deceleration onset* is defined as abrupt if the onset to nadir (lowest point) is less than 30 seconds and gradual if the onset to nadir is 30 seconds or greater.
- Although terms such as *beat-to-beat variability*, *short-term variability*, and *long-term variability* are used frequently in clinical practice, the NICHD panel recommended that no distinction be made between short-term or beat-to-beat variability and long-term variability because in actual practice, they are visually determined as a unit.
- A number of FHR characteristics are dependent upon gestational age, so gestational age must be considered in the full evaluation of the pattern.
- In addition, the FHR tracing should be evaluated in the context of maternal medical condition, prior results of fetal assessment, medications, and other factors.
- FHR patterns do not occur alone and generally evolve over time. Therefore a full description requires a qualitative and quantitative assessment of baseline rate, variability, accelerations, decelerations, sinusoidal pattern, and changes or trends over time.

### Specific Fetal Heart Rate Patterns

Understanding the common FHR patterns and characteristics is fundamental to the interpretation of these as they relate to intrapartum care. As described above, intrapartum FHR monitoring is critical to ensuring fetal and maternal well-being.

#### **BASELINE RATE**

##### *DEFINITION*

*Baseline FHR* is defined as the approximate mean FHR rounded to increments of 5 beats/min during a 10-minute segment excluding accelerations, decelerations, and periods of marked variability. In any 10-minute window, the minimum baseline duration must be at least 2 minutes—not necessarily contiguous—or the baseline for that period is deemed

**FIG 15-7** Baseline fetal heart rate (FHR) is the mean FHR rounded to increments of 5 beats/min in a 10-minute window excluding accelerations, decelerations, and periods of marked FHR variability ( $>25$  beats/min). At least 2 minutes of identifiable baseline segments, not necessarily contiguous, must be present in any 10-minute window or the baseline for that period is indeterminate. In this tracing, the baseline heart rate is 120 beats/min with accelerations.

indeterminate. If the baseline during any 10-minute segment is deemed indeterminate, it may be necessary to refer to any previous 10-minute segments for determination of the baseline (Fig. 15-7).

#### PHYSIOLOGY

Baseline FHR is regulated by intrinsic cardiac pacemakers (sinoatrial node, atrioventricular node), cardiac conduction pathways, autonomic innervation (sympathetic, parasympathetic), intrinsic humoral factors (catecholamines), extrinsic factors (medications), and local factors (calcium, potassium). Sympathetic innervation and plasma catecholamines increase baseline FHR, whereas parasympathetic innervation reduces the baseline rate. Autonomic input regulates the FHR in response to fluctuations in the partial pressure of oxygen ( $PO_2$ ), partial pressure of carbon dioxide ( $PCO_2$ ), and blood pressure detected by chemoreceptors and baroreceptors located in the aortic arch and carotid arteries. **A normal FHR baseline of 110 to 160 beats/min is consistent with normal neurologic regulation of the FHR. Fetal tachycardia is defined as a baseline rate above 160 beats/min for at least 10 minutes.** Conditions potentially associated with fetal tachycardia are summarized in Box 15-5.

**Fetal bradycardia is defined as a baseline rate below 110 beats/min for at least 10 minutes.** Box 15-6 summarizes conditions associated with fetal bradycardia.

#### VARIABILITY

##### DEFINITION

*Variability* is defined as fluctuations in the baseline FHR that are irregular in amplitude and frequency. Variability is measured from the peak to the trough of the fluctuations and is quantitated in beats per minute. No distinction is made between short-term (beat-to-beat) variability and long-term variability

FIG 15-9 Minimal variability.

because in actual practice, they are visually determined as a unit. In addition, there is no consensus that beat-to-beat differences in rate can be quantitated accurately with the unaided eye. Standardized NICHD nomenclature classifies variability as absent, minimal, moderate, or marked. As depicted in Figure 15-8, variability is defined as *absent* when the amplitude range of the FHR fluctuations is undetectable to the unaided eye. Variability is defined as *minimal* when the amplitude range is visually detectable but is less than or equal to 5 beats/min, as illustrated in Figure 15-9. When the amplitude range of the

FHR fluctuations is 6 to 25 beats/min, variability is defined as *moderate*, as illustrated in Figure 15-10. Variability is defined as *marked* when the amplitude range of the FHR fluctuations is greater than 25 beats/min (Fig. 15-11).

#### PHYSIOLOGY

Many factors interact to regulate FHR variability, including intrinsic cardiac pacemakers (sinoatrial node, atrioventricular node), cardiac conduction pathways, autonomic innervation (sympathetic, parasympathetic), intrinsic humoral factors

FIG 15-10 Moderate variability.

FIG 15-11 Marked variability.

(catecholamines), extrinsic factors (medications), and local factors (calcium, potassium). Fluctuations in  $PO_2$ ,  $PCO_2$ , and blood pressure are detected by chemoreceptors and baroreceptors located in the aortic arch and carotid arteries. Signals from these receptors are processed in the medullary vasomotor center, likely with regulatory input from higher centers in the hypothalamus and cerebral cortex. Sympathetic and parasympathetic signals from the medullary vasomotor center modulate the FHR in response to moment-to-moment changes in fetal  $PO_2$ ,  $PCO_2$ , and blood pressure. With every heartbeat, slight fluctuations in

heart rate help to optimize fetal cardiac output and distribution of oxygenated blood to the fetal tissues. These fluctuations are referred to as *fetal heart rate variability* and are displayed graphically on the FHR tracing as an irregular horizontal line. The 2008 NICHD consensus report concluded that moderate variability reliably predicts the absence of fetal metabolic acidemia at the time it is observed.<sup>16</sup> **However, the converse is not true; minimal or absent variability does not confirm the presence of fetal metabolic acidemia or ongoing hypoxic injury.**<sup>16</sup> Other conditions potentially associated with minimal

**FIG 15-12** Accelerations. (From Clark SL, Nageotte MP, Garite TJ, et al. Intrapartum management of category II fetal heart rate tracings: towards standardization of care. *Am J Obstet Gynecol.* 2013;209[2]:89-97.)

#### BOX 15-7 CONDITIONS POTENTIALLY ASSOCIATED WITH MINIMAL TO ABSENT FETAL HEART RATE VARIABILITY AND ABSENT ACCELERATIONS

Fetal metabolic acidemia

or absent variability are summarized in [Box 15-7](#). The 2014 Neonatal Encephalopathy Task Force consensus report<sup>13</sup> identified moderate variability as one of the features of the FHR tracing that reliably excludes “damaging degrees of hypoxia-induced metabolic acidemia.” Most of the literature regarding “decreased” FHR variability does not differentiate between *absent variability*, when the amplitude range is undetectable, and *minimal variability*, when the amplitude range is detectable but is 5 beats/min or less. Therefore it is not possible to draw valid conclusions regarding the relative clinical significance of these two categories; the significance of marked variability has not been established.<sup>16</sup> Possible explanations include a normal variant or an exaggerated autonomic response to early

stages of interrupted fetal oxygenation. [Box 15-7](#) summarizes some conditions potentially associated with minimal or absent variability.

#### ACCELERATION

##### DEFINITION

An *acceleration* is as an abrupt increase (onset to peak <30 seconds) in FHR above the baseline. The peak is at least 15 beats/min above the baseline, and the acceleration lasts at least 15 seconds from the onset to return to baseline, as illustrated in [Figure 15-12](#). Before 32 weeks of gestation, an *acceleration* is defined as having a peak at least 10 beats/min above the baseline and a duration of at least 10 seconds. An acceleration that lasts at least 2 minutes but less than 10 minutes is defined as a *prolonged acceleration*. An acceleration that lasts 10 minutes or longer is defined as a *baseline change*.

##### PHYSIOLOGY

Accelerations in FHR frequently occur in association with fetal movement, possibly as a result of stimulation of peripheral proprioceptors, increased catecholamine release, and autonomic stimulation of the heart. Another possible mechanism of FHR acceleration is transient compression of the umbilical vein, which results in decreased fetal venous return and a reflex rise in heart rate. The 2008 NICHD consensus report concluded that accelerations reliably predict the absence of fetal metabolic acidemia at the time they are observed.<sup>16</sup> However, the converse is not true. The absence of accelerations does not confirm the presence of fetal metabolic acidemia or ongoing hypoxic injury.<sup>16</sup> Other conditions potentially associated with the absence of accelerations are summarized in [Table 15-4](#).<sup>17</sup> The 2014 Neonatal Encephalopathy Task Force concluded that the presence of FHR accelerations reliably excludes “damaging degrees of hypoxia-induced metabolic acidemia.”<sup>16</sup> In the absence of spontaneous accelerations, fetal stimulation can provoke fetal movement and FHR accelerations. Accelerations can be provoked with a variety of methods that

FIG 15-13 Early decelerations.

**TABLE 15-4** MATERNAL AND FETAL FACTORS THAT CAN INFLUENCE THE FETAL HEART RATE TRACING BY MECHANISMS NOT SPECIFICALLY RELATED TO FETAL OXYGENATION

| FACTOR             | REPORTED FETAL HEART RATE ASSOCIATIONS   |
|--------------------|--|
| Fever/infection    | Increased baseline rate, decreased variability   |
| Medications        | Effects depend upon specific medication and may include changes in baseline rate, frequency and amplitude of accelerations, variability and sinusoidal pattern <sup>17</sup> |
| Hyperthyroidism    | Tachycardia, decreased variability   |
| Prematurity        | Increased baseline rate, decreased variability, reduced frequency and amplitude of accelerations   |
| Fetal anemia       | Sinusoidal pattern, tachycardia  |
| Heart block        | Bradycardia, decreased variability   |
| Tachyarrhythmia    | Variable degrees of tachycardia, decreased variability   |
| Congenital anomaly | Decreased variability, decelerations   |
| Preexisting injury | Decreased variability, absent accelerations  |
| Sleep cycle        | Decreased variability, reduced frequency and amplitude of accelerations  |

include vibroacoustic stimulation (VAS), transabdominal halogen light stimulation, and direct fetal scalp stimulation. Accelerations provoked by external stimuli have the same clinical significance as spontaneous accelerations.<sup>16</sup>

### DECELERATIONS

Decelerations in the FHR are categorized as early, late, variable, or prolonged and are quantitated by depth in beats per minute below the baseline and duration in minutes and seconds. An abrupt deceleration reaches its nadir within 30 seconds from the time it starts. A gradual deceleration will reach its nadir in 30 seconds or more. Decelerations that occur with at least 50% of uterine contractions in a 20-minute window are defined as *recurrent*. Decelerations that occur with fewer than 50% of contractions in a 20-minute period are defined as *intermittent*. Classification of decelerations as mild, moderate, or severe has not been shown to correlate with metabolic acidemia or newborn outcome independent of other FHR characteristics such as moderate variability, accelerations, frequency of decelerations, duration of decelerations, or total number of decelerations. Therefore

such classification is not included in standardized NICHD terminology.<sup>16</sup>

### EARLY DECELERATION

#### DEFINITION

*Early deceleration* is defined as a gradual decrease (onset to nadir <30 seconds) in FHR from the baseline and a subsequent return to baseline associated with a uterine contraction (Fig. 15-13). In most cases the onset, nadir, and recovery of the deceleration occur at the same time as the beginning, peak, and end of the contraction, respectively.

#### PHYSIOLOGY

Although the precise physiologic mechanism is not known, early decelerations are considered to represent a fetal autonomic response to changes in intracranial pressure and/or cerebral blood flow caused by intrapartum compression of the fetal head during uterine contractions. ***Early decelerations are not associated with interruption of fetal oxygenation or adverse neonatal outcome and are considered clinically benign.*** No level I or level II analytic evidence in the literature supports the notion that mechanical compression of the fetal head by uterine contractions and/or maternal expulsive efforts can cause local cerebral ischemia and neurologic injury in the absence of global hypoxia and neonatal encephalopathy. Furthermore, no scientific evidence suggests that mechanical compression of the fetal head by the forces of labor is a predictable or preventable cause of perinatal stroke. On the contrary, a consensus report from the National Institute of Neurologic Disorders and Stroke and the NICHD in 2007 concluded “there are no reliable predictors of perinatal ischemic stroke upon which to base prevention or treatment strategies.”<sup>20</sup> Despite the absence of scientific merit, these theories have become increasingly popular in the legal arena. Unless such theories can be validated and replicated by appropriately controlled analytic studies, they play no meaningful role in intrapartum management decisions.

### LATE DECELERATION

#### DEFINITION

*Late deceleration* of the FHR is defined as a gradual decrease (onset to nadir  $\geq 30$  seconds) of the FHR from the baseline and subsequent return to the baseline associated with a uterine contraction, as illustrated in Figure 15-14. In most cases the onset,

FIG 15-14 Late decelerations.

nadir, and recovery of the deceleration occur after the beginning, peak, and ending of the contraction, respectively.

#### PHYSIOLOGY

**A late deceleration is a reflex fetal response to transient hypoxemia during a uterine contraction.** Myometrial contractions can compress maternal blood vessels that traverse the uterine wall and reduce maternal perfusion of the intervillous space of the placenta. Reduced delivery of oxygenated blood to the intervillous space can reduce the diffusion of oxygen into the fetal capillary blood in the chorionic villi, leading to a decline in fetal  $PO_2$ . If the fetal  $PO_2$  falls below the normal range (approximately 15 to 25 mm Hg in the umbilical artery), chemoreceptors detect the change and signal the medullary vasomotor center in the brainstem to initiate a protective autonomic reflex response. Initially, sympathetic outflow causes peripheral vasoconstriction and shunts oxygenated blood flow away from nonvital vascular beds and toward vital organs such as the brain, heart, and adrenal glands. The resulting increase in fetal blood pressure is detected by baroreceptors that trigger a parasympathetic reflex slowing of the heart rate to reduce cardiac output and return the blood pressure to normal. After the contraction, fetal oxygenation is restored, autonomic reflexes subside, and the FHR gradually returns to baseline. This combined sympathetic-parasympathetic reflex response to transient interruption of fetal oxygenation, summarized in Figure 15-15, has been confirmed in animal studies.<sup>21</sup> **If interruption of fetal oxygenation is sufficient to result in metabolic acidemia, a late deceleration may result from direct hypoxic myocardial depression during a contraction,** as illustrated in Figure 15-15.<sup>21</sup> Because the latter mechanism requires metabolic acidemia, it is virtually excluded by the observation of moderate variability or accelerations. Late decelerations classically have been attributed to “uteroplacental insufficiency.” However, this term is potentially misleading because it can be interpreted to indicate that interruption of fetal oxygenation is limited to the uterus and placenta. In reality,

interruption of the oxygen pathway at any point can contribute to a late deceleration. For example, conditions such as maternal hypoxemia, decreased cardiac output, or hypotension can result in late decelerations even with mild uterine contractions and a normally functioning placenta. **Regardless of the underlying mechanism, all late decelerations reflect interruption of oxygen transfer from the environment to the fetus at one or more points along the oxygen pathway.** Supporting evidence is level II-1 and II-2.

As illustrated in Figure 15-16, common causes of late deceleration include a relative increase in uterine contraction intensity or baseline tone and/or a relative lowering of maternal blood pressure.

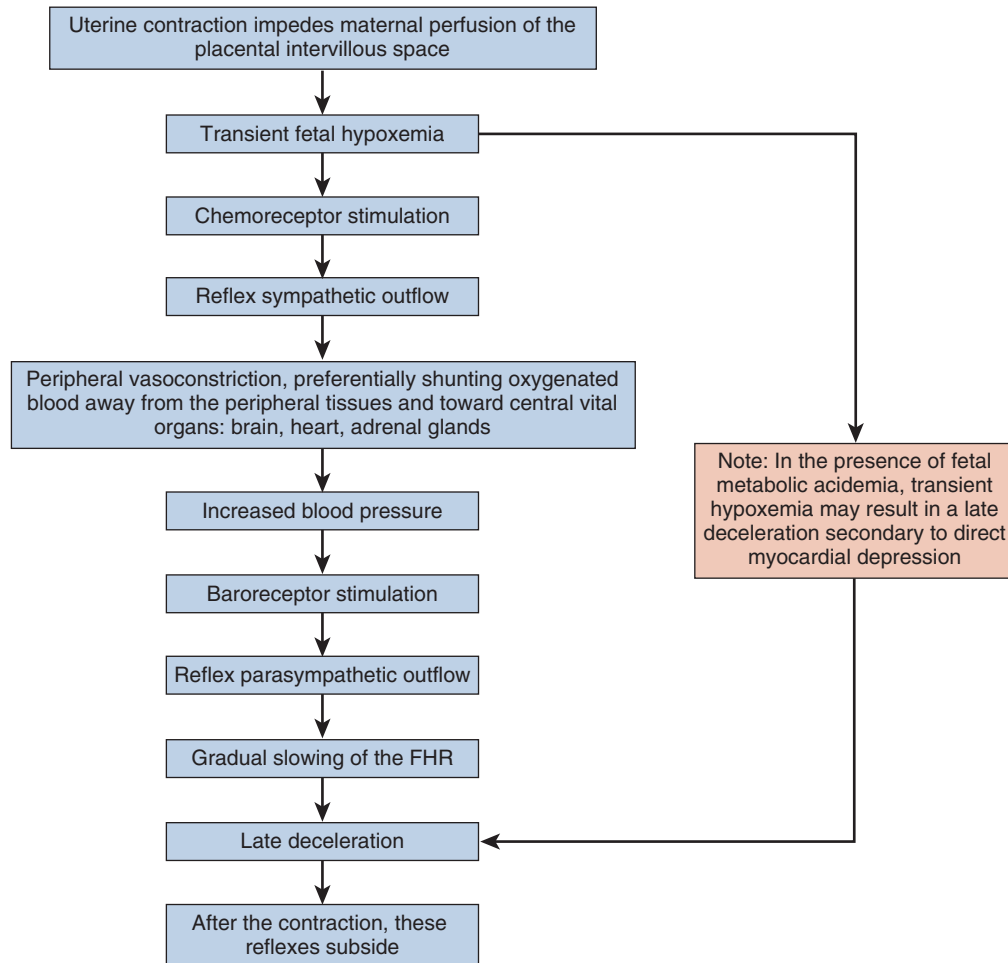

#### VARIABLE DECELERATION

##### DEFINITION

*Variable deceleration* of the FHR is defined as an abrupt decrease (onset to nadir <30 seconds) in FHR below the baseline (Fig. 15-17). The decrease is at least 15 beats/min below the baseline, the deceleration lasts at least 15 seconds, and fewer than 2 minutes pass from onset to return to baseline. Variable decelerations can occur with or without uterine contractions.

#### PHYSIOLOGY

A variable deceleration represents a fetal autonomic reflex response to transient mechanical compression or stretch of the umbilical cord.<sup>22</sup> Initially, compression of the umbilical cord occludes the thin-walled, compliant umbilical vein; decreases fetal venous return; and triggers a baroreceptor-mediated reflex rise in FHR, sometimes described as a “shoulder.” Further compression occludes the umbilical arteries and causes an abrupt increase in fetal peripheral resistance and blood pressure. Baroreceptors detect the abrupt rise in blood pressure and signal the medullary vasomotor center in the brainstem, which in turn triggers an increase in parasympathetic outflow and an abrupt decrease in heart rate. As the cord is decompressed, this sequence

**FIG 15-15** Mechanism of late deceleration. FHR, fetal heart rate.

#### EFFECTS OF HYPERTONUS AND MATERNAL HYPOTENSION

**FIG 15-16** Common causes of late deceleration. UA, uterine activity.

of events occurs in reverse; this mechanism is summarized in Figure 15-18. Umbilical cord compression can coincide with interruption at any or all of the other points along the oxygen pathway; therefore the observation of a variable deceleration does not preclude interruption of the oxygen pathway at the level of the maternal lungs, heart, vasculature, uterus or placenta. *For the purposes of standardized FHR interpretation, a variable deceleration reflects interruption of oxygen transfer from the environment*

*to the fetus at one or more points along the oxygen pathway.* Supporting evidence is level II and III. The 2008 NICHD Consensus Report identified several additional features of variable decelerations, the clinical significance of which requires further research investigation.<sup>16</sup> Examples include a slow return of the FHR after the end of the contraction, sometimes called *variable with a late component*; biphasic or *W-shaped decelerations*; tachycardia following variable decelerations; accelerations

FIG 15-17 Variable decelerations.

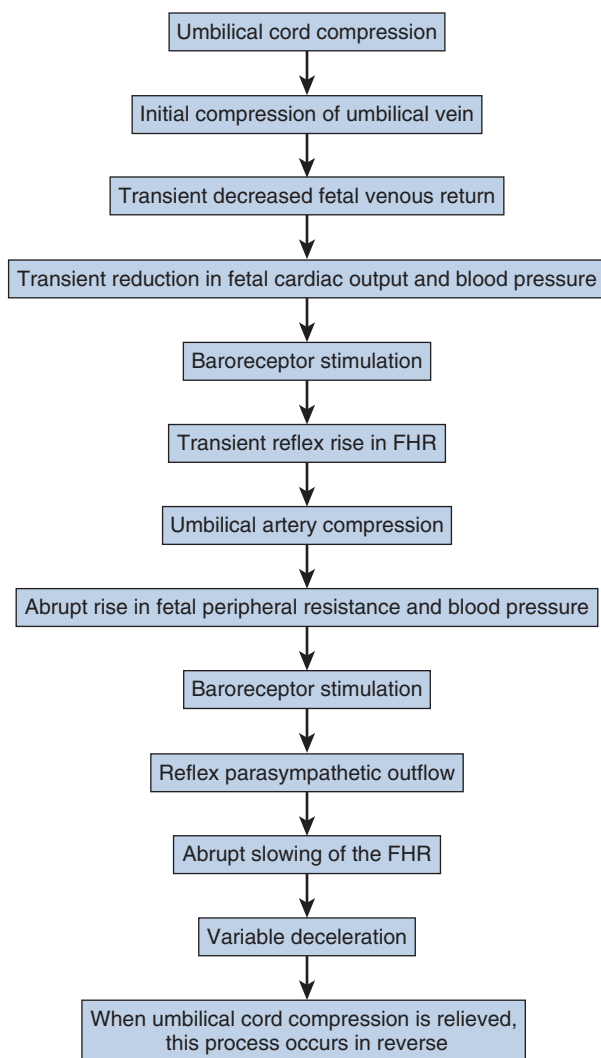

FIG 15-18 Mechanism of a variable deceleration. FHR, fetal heart rate.

that precede and/or follow decelerations, sometimes called *shoulders* or *overshoots*; and fluctuations in the FHR in the trough of the deceleration, sometimes termed *variability within a deceleration*. The predictive value of grading decelerations as mild, moderate, or severe has not been established independent of other FHR characteristics such as baseline rate, variability, and accelerations or frequency, duration, or number of decelerations.

### PROLONGED DECELERATION

#### DEFINITION

*Prolonged deceleration* of the FHR is defined as a decrease, either gradual or abrupt, in FHR at least 15 beats/min below the baseline that lasts at least 2 minutes from onset to return to baseline (Fig. 15-19). A prolonged deceleration that lasts 10 minutes or longer is defined as a *baseline change*.

#### PHYSIOLOGY

If the physiologic mechanisms responsible for late or variable decelerations persist, a deceleration can last long enough to be defined as a *prolonged deceleration*. **For the purposes of standardized FHR interpretation, a prolonged deceleration reflects interruption of oxygen transfer from the environment to the fetus at one or more points along the oxygen pathway.** At the level of the maternal lungs, for example, a prolonged deceleration can result from maternal apnea during a convulsion. At the level of the maternal heart, a cardiac arrhythmia can compromise cardiac output and cause a prolonged FHR deceleration. At the level of the vasculature, the oxygen pathway can be interrupted by maternal hypotension associated with regional anesthesia or compression of the great vessels by the gravid uterus. Examples of interruption of the oxygen pathway at the level of the uterus include excessive uterine activity or uterine rupture; at the level of the placenta, they include abruption or bleeding placenta previa; finally, at the level of the umbilical cord, examples include cord compression, stretch, or prolapse.

FIG 15-19 Prolonged deceleration.

FIG 15-20 Sinusoidal pattern.

## SINUSOIDAL PATTERN

### DEFINITION

The sinusoidal pattern, illustrated in Figure 15-20, is a smooth, sine wave–like undulating pattern in FHR baseline with a frequency of 3 to 5 cycles/min that persists for at least 20 minutes. The sinusoidal pattern is excluded from the definition of variability and can be distinguished from variability because it is characterized by fluctuations in the baseline that are regular in amplitude in frequency.

### PHYSIOLOGY

**Although the pathophysiologic mechanism is not known, this pattern is classically associated with severe fetal anemia.** Variations of the pattern have been described in association with chorioamnionitis, fetal sepsis, or administration of narcotic analgesics. Scientific evidence regarding associated factors is

level II-2 to level III, and evidence regarding pathophysiology is level III.

## STANDARDIZED FETAL HEART RATE INTERPRETATION

Intrapartum FHR interpretation can be summarized in two evidence-based central principles that reflect consensus in the medical literature. These two principles can be applied to an FHR tracing to produce a factually accurate, logical, and consistent interpretation that can help guide management.

1. Variable, late, and prolonged decelerations signal interruption of oxygen transfer from the environment to the fetus at one or more points along the oxygen pathway.
2. Moderate variability and/or accelerations reliably exclude ongoing hypoxic injury at the time they are observed.

Several maternal and fetal factors can influence the appearance of an FHR tracing by mechanisms not directly related to oxygenation. These are summarized in Table 15-4.

## FETAL CARDIAC ARRHYTHMIAS

Precise characterization of fetal cardiac arrhythmias can challenge the clinical skill of the most experienced specialist, even with the benefit of direct, magnified visualization of the fetal heart using advanced sonography equipment with color, pulse-wave, and M-mode Doppler capabilities; therefore any attempt to classify fetal cardiac rhythm abnormalities using EFM alone will yield a tentative diagnosis at best. This imprecision is compounded by the fact that rates above 240 beats/min (the upper limit of the FHR graph on standard paper) may be halved or not printed at all by the monitor. This critically limits the ability of the FHR monitor to distinguish between conditions such as fetal supraventricular tachycardia, atrial fibrillation, and atrial flutter, all of which can result in heart rates above 240 beats/min. EFM cannot determine whether a fetal heartbeat is initiated by an electrical impulse that originates in the atrium or in the ventricle. In other words, the electronic monitor cannot reliably distinguish an atrial arrhythmia from a ventricular arrhythmia. Nevertheless, EFM can offer some clues to the presence of an abnormal fetal heart rhythm. For example, dropped beats might appear on the FHR monitor as sharp downward spikes with a nadir at approximately half of the baseline rate. A premature beat with a compensatory pause might appear as a sharp upward spike followed immediately by a downward spike. Bradycardia as a result of 2:1 (atrioventricular) heart block can appear persistently or intermittently as a baseline rate that is approximately half of the normal rate. Sinus bradycardia should be suspected if the baseline rate is lower than 110 beats/min but higher than half of the normal rate. Any FHR less than 110 beats/min requires thorough evaluation before it can be attributed to a benign condition. If the fetal heart is not generating electrical activity, as in the case of fetal demise, a fetal scalp electrode may detect the electrical impulses from the maternal heart and record the maternal heart rate. If any question exists as to the clinical significance of any unusual fetal heart rhythm seen on the fetal monitor or detected audibly, further evaluation with other modalities, such as ultrasound, is necessary to establish an accurate diagnosis.

## PATTERNS NOT DEFINED BY THE NATIONAL INSTITUTE OF CHILD HEALTH AND HUMAN DEVELOPMENT

Several terms and concepts that are not defined by the NICHD may be encountered in clinical practice. The 2008 NICHD consensus report<sup>16</sup> states that FHR characteristics such as overshoot, shoulders, FHR fluctuations within a deceleration, variable deceleration with a slow return to baseline, and biphasic decelerations require further research investigation to determine clinical significance. These and other undefined terms are discussed below.

### Wandering Baseline

An FHR baseline that is within the normal range (110 to 160 beats/min) but that is not stable at a single rate long enough to define a mean has been described as a “wandering baseline.” Absent variability and absent accelerations are characteristic

features of the pattern, and decelerations may be present or absent. This combination of FHR findings has been suggested to indicate preexisting neurologic injury and impending fetal death. The physiologic mechanism is not known, and published data are limited to descriptive reports (level III).

### Lambda Pattern

The lambda FHR pattern is characterized by a brief acceleration followed by a small deceleration. Although the underlying physiologic mechanism is not known, this pattern is common during early labor and has no specific clinical significance.<sup>23</sup>

### Shoulder

As discussed previously, variable decelerations result from transient mechanical compression of umbilical blood vessels within the umbilical cord. Initial compression of the umbilical vein reduces fetal venous return and triggers a baroreceptor-mediated reflex rise in FHR that commonly is described as a “shoulder.”<sup>22</sup> As the cord is decompressed, a second shoulder frequently follows the deceleration and likely reflects the same underlying mechanism. This observation has no known association with adverse newborn outcome. On the other hand, no evidence suggests conclusively that such shoulders imply the same ability to exclude ongoing hypoxic injury as do spontaneous or stimulated FHR accelerations. The clinical significance of a shoulder requires further research investigation.<sup>16</sup> Supporting evidence is level II and III.

### Uniform Accelerations

Various terms have been used to describe FHR accelerations. Examples include *uniform sporadic accelerations*, *variable sporadic accelerations*, *uniform periodic accelerations*, *variable periodic accelerations*, and *crown accelerations*. These terms are not included in standardized NICHD definitions, and no basis for such subclassification has been established. Available evidence is level III.

### Atypical Variable Decelerations

#### Variable Deceleration With a Late Component

Variable deceleration with a “late component” describes a deceleration with an abrupt onset and a gradual return to baseline. The abrupt onset suggests that the deceleration begins as a reflex autonomic response to an abrupt rise in blood pressure caused by umbilical cord compression (the variable component of the pattern). The gradual return to baseline suggests a gradual reduction of autonomic outflow upon resolution of transient hypoxemia, as occurs in a late deceleration (the late component of the pattern). A plausible explanation of the pattern is initial umbilical cord compression that causes an abrupt reflex fall in FHR and a transient decline in fetal PO<sub>2</sub>. A drop in fetal PO<sub>2</sub> below the normal range may trigger the reflex sympathetic outflow, peripheral vasoconstriction, elevation of blood pressure, and reflex parasympathetic slowing of the fetal heart that is characteristic of a late deceleration. Decompression of the umbilical cord results in rapid resolution of the parasympathetic outflow that accompanies a variable deceleration. However, the physiologic mechanism responsible for late deceleration resolves more gradually, which causes the FHR to return gradually to the previous baseline. Although this explanation is plausible, the specific physiologic mechanism has not been studied systematically. In regard to neonatal outcome, no level I or level II evidence has demonstrated that a variable deceleration with a late component

confers a different prognosis than a variable deceleration without a late component. Scientific evidence regarding the underlying physiologic mechanism is limited to level III evidence. Second-stage variable decelerations with slow recovery have been reported to increase the likelihood of operative delivery; however, no consistent impact on newborn outcome has been described.

### Overshoot

The term *overshoot* has been used to describe an FHR pattern that consists of a variable deceleration followed by a smooth, prolonged rise in the FHR above the previous baseline with gradual return.<sup>24-27</sup> The essential elements of this uncommon pattern include the persistent absence of variability and the absence of accelerations. The overshoot pattern has been attributed to a range of conditions that include preexisting neurologic injury, “chronic fetal distress,” “repetitive transient central nervous system ischemia,” and “mild fetal hypoxia above the deceleration threshold.”<sup>25-28</sup> These claims have not been substantiated by level I or level II evidence, and the physiologic mechanism responsible for the overshoot pattern is unknown. Because of the wide variation in reported associations and the absence of agreement in the literature regarding the definition, visual appearance, or clinical significance of overshoot, it is advisable to avoid the term in favor of standard NICHD nomenclature. All evidence regarding the overshoot pattern in humans is descriptive (level III), and this pattern is not included in standardized NICHD terminology.

### V- and W-Shaped Variable Decelerations

The visual appearance of a variable deceleration has been suggested to predict the underlying cause. For example, a V-shaped variable deceleration has been suggested to indicate umbilical cord compression due to oligohydramnios, whereas a W-shaped variable deceleration has been suggested to reflect umbilical cord compression due to a nuchal cord. Such atypical features have not been demonstrated to predict outcome independent of known confounding factors such as baseline rate, variability, and accelerations or frequency, duration, or number of decelerations. These terms are not included in standardized NICHD terminology.

### Variability Within a Deceleration

At the nadir of a variable or late deceleration, the FHR frequently appears irregular, similar to the appearance of moderate variability. The visual similarity has led some to suggest that FHR fluctuations during a deceleration have the same clinical significance as baseline variability. Whereas the notion is not implausible, it has not been confirmed. In addition, it is inconsistent with standard NICHD terminology. Variability is a characteristic of the FHR baseline; it is not a characteristic of periodic or episodic decelerations that interrupt the baseline. In the absence of supporting evidence, the most appropriate approach is to avoid assigning undue significance to this observation. Evidence regarding these patterns is limited to level III.

### Mild, Moderate, and Severe Variable Decelerations

The depth and duration of variable decelerations have been suggested to predict newborn outcome. Kubli and colleagues<sup>28</sup> proposed three categories of variable decelerations based upon these characteristics. According to this classification system, a *mild variable deceleration* was defined by a duration of less than 30 seconds regardless of depth, a depth no lower than 80 beats/min,

or a depth of 70 to 80 beats/min that lasts less than 60 seconds. A *moderate variable deceleration* was defined by a depth of less than 70 beats/min that lasts 30 to 60 seconds or a depth of 70 to 80 beats/min that lasts more than 60 seconds. A *severe deceleration* was defined as a deceleration below 70 beats/min that lasts more than 60 seconds. No level I or level II evidence in the literature confirms that the depth of any type of deceleration—early, variable, late, or prolonged—is predictive of fetal metabolic acidemia, fetal hypoxia, or newborn outcome independent of other important FHR characteristics such as baseline rate, variability, accelerations and frequency, duration, and number of decelerations. Therefore mild, moderate, and severe categories are not included in standard NICHD definitions of FHR decelerations. The 2008 NICHD report<sup>16</sup> states that such classification requires further research investigation to determine clinical significance. Consistent with NICHD terminology, decelerations are quantitated by depth in beats per minute and duration in minutes and seconds.

## STANDARDIZED MANAGEMENT DECISION MODEL

Evolving consensus regarding FHR definitions and interpretation facilitates the development of a standardized, evidence-based approach to intrapartum FHR management. Standardized FHR management does not replace individual clinical judgment. On the contrary, standardized management encourages the timely application of individual clinical judgment. By serving as a forcing function, standardized intrapartum FHR management helps to identify and avoid potential sources of preventable error in an organized, systematic fashion. A *forcing function* is a critical step in an algorithm that prevents the user from taking a subsequent action without consciously considering information relevant to that action. By forcing conscious attention upon the action, it helps to reduce the risk of error and increase the likelihood that the action will be reasonable. The management decision support model described in this chapter uses the standardized FHR definitions and categories proposed by the NICHD in 1997 and 2008.<sup>14,16</sup> It does not include adjunctive tests of fetal status such as fetal scalp blood sampling, fetal pulse oximetry, and fetal ECG analysis, which currently are unavailable for general clinical use in the United States. These techniques are reviewed later in the chapter.

### Standard of Care

Standard of care is a legal concept that typically is defined as the level of care expected of a reasonable, competent clinician under similar circumstances. In order for care to be deemed reasonable, the underlying rationale must be credible. **Credibility requires factual accuracy and the ability to articulate clearly and understandably. Standard FHR definitions and interpretation facilitate factual accuracy. A standardized, simplified approach to FHR management provides an organized, evidence-based framework that can be articulated clearly and understandably.**

### Initiation of Monitoring

Intrapartum monitoring is intended to assess the adequacy of fetal oxygenation and uterine activity during labor so that appropriate measures can be taken to avoid hypoxic fetal injury, ensure appropriate labor progress, and optimize the likelihood of safe vaginal delivery. **Effective intrapartum monitoring requires**

reliable information; therefore it is essential to confirm that the monitor is recording the FHR and uterine activity adequately to permit appropriately informed management decisions (Fig. 15-21). If external monitoring does not provide adequate information for accurate definition and interpretation, internal monitoring with a fetal scalp electrode and/or IUPC should be considered. Under certain circumstances, the FHR monitor can inadvertently record the maternal heart rate. If the fetus is not alive, an internal fetal scalp electrode can detect the maternal ECG and record the maternal heart rate. An external Doppler device can record the maternal heart rate even if the fetus is alive. Particularly in the setting of maternal tachycardia, the maternal heart rate can appear deceptively similar to a normal FHR pattern, including normal-appearing baseline rate and variability. A widely recognized pattern that warrants particular attention is the observation of maternal heart rate accelerations during uterine contractions that can be mistaken for FHR accelerations. Heart rate accelerations that coincide with uterine contractions should prompt further evaluation to exclude this phenomenon. At times, the external Doppler monitor can alternate between the fetus and the mother. When switching from one to the other, the tracing will not necessarily demonstrate visual discontinuity; therefore visual continuity of the tracing alone cannot be relied upon to exclude this phenomenon. Some newer systems will alert the user to the

presence of "signal coincidence" or "signal ambiguity" when the monitor's computer logic determines that the maternal heart rate derived from a maternal ECG or pulse oximetry transducer is the same as the presumed FHR derived from the Doppler transducer or scalp electrode. Suspected signal coincidence or ambiguity should prompt further evaluation to confirm the source of the heart rate signal. Unless the monitor is recording the FHR, it cannot be used to assess fetal oxygenation; therefore it is essential to distinguish between maternal and fetal heart rates. If any question exists, other methods should be used as needed, including ultrasound, palpation of the maternal pulse, fetal scalp electrode, or maternal pulse oximetry.

### Evaluation of Fetal Heart Rate Components

Thorough, systematic evaluation of the FHR tracing includes assessment of uterine activity along with the FHR components defined by the NICHD: baseline rate, variability, accelerations, decelerations, sinusoidal pattern, and changes or trends in the tracing over time. After assessing all components, the tracing can be placed into one of the three FHR categories introduced in the 2008 NICHD consensus report (see Fig. 15-21).

If all FHR components are normal (category I), the FHR tracing reliably predicts the absence of interruption of oxygenation by the absence of variable, late, or prolonged decelerations and reliably predicts the absence of ongoing hypoxic neurologic

**TABLE 15-5** NORMAL UMBILICAL CORD BLOOD VALUES

| VESSEL | pH      | PCO <sub>2</sub> | PO <sub>2</sub> | BASE DEFICIT |
|--------|---------|------------------|-----------------|--------------|
| Artery | 7.2-7.3 | 45-55            | 15-25           | <12          |
| Vein   | 7.3-7.4 | 35-45            | 25-35           | <12          |

injury by the presence of moderate variability with or without accelerations. In low-risk patients, ACOG Practice Bulletin 116 and ACOG-AAP *Guidelines for Perinatal Care* recommend that the FHR tracing should be reviewed at least every 30 minutes during the active phase of the first stage of labor and at least every 15 minutes during the second stage.<sup>18,29</sup> In patients who are not deemed to be low risk, the FHR tracing should be reviewed at least every 15 minutes during the active phase of the first stage of labor and at least every 5 minutes during the second stage (see Fig. 15-21). Documentation should be performed periodically at reasonable intervals in accordance with institutional policies and procedures.

### A Standardized “ABCD” Approach to Fetal Heart Rate Management

If assessment of the FHR indicates that the tracing is not in category I, further evaluation is warranted. A practical, systematic “ABCD” approach to management begins with “A”—*assess* the oxygen pathway (see Fig. 15-21).

#### Assess the Oxygen Pathway

Rapid, systematic assessment of the pathway of oxygen transfer from the environment to the fetus can identify potential sources of interrupted oxygenation (Table 15-5). **Initial assessment of the maternal lungs, heart, and vasculature usually is accomplished by reviewing the vital signs, including respiratory rate, heart rate, and blood pressure. Uterine activity is assessed by palpation or by review of the information provided by a tocodynamometer or IUPC. Suspected uterine rupture or placental abruption requires immediate attention and targeted evaluation. Finally, umbilical cord prolapse usually can be excluded by visualization or examination. If rapid evaluation of these steps suggests that further investigation is warranted, it should be undertaken as necessary. As summarized in Figure 15-21, several maternal and fetal factors can influence the appearance of the FHR tracing by mechanisms other than direct interruption of fetal oxygenation. If FHR changes are thought to be due to any of these conditions, individualized assessment and management should be directed at the specific cause. Some examples include a sinusoidal pattern in the setting of severe fetal anemia, bradycardia due to fetal heart block, or tachycardia due to fever, infection, or medications or cardiac arrhythmia.**

#### Begin Corrective Measures as Indicated

If assessment of the oxygen pathway suggests interruption at one or more points, corrective measures are initiated as indicated. Specific measures are summarized in Figure 15-21. **The choice of appropriate corrective measures is based on interpretation of the FHR tracing as a whole. Interpretation of individual components out of context provides an incomplete clinical picture and is discouraged. Selection of the most appropriate corrective measures can be refined by acknowledging some specific associations. For example, in the setting of variable**

**decelerations, initial attention may focus on umbilical cord compression or prolapse. In the setting of late decelerations, initial attention may focus on maternal cardiac output, blood pressure, and uterine activity.**

### CONSERVATIVE CORRECTIVE MEASURES

#### SUPPLEMENTAL OXYGEN

Fetal oxygenation is dependent upon the oxygen content of maternal blood perfusing the intervillous space of the placenta. Administration of supplemental oxygen can increase the PO<sub>2</sub> of inspired air, increasing both the partial pressure of oxygen dissolved in maternal blood and the amount of oxygen bound to hemoglobin. This can increase the oxygen concentration gradient across the placental blood-blood barrier and can lead to increased fetal PO<sub>2</sub> and oxygen content. Several studies have reported resolution of FHR decelerations and improvement of variability after administration of supplemental oxygen to the mother, providing indirect evidence of improved fetal oxygenation.<sup>30,32</sup> Direct evidence is provided by fetal pulse oximetry studies that demonstrate increased fetal hemoglobin saturation following maternal administration of oxygen.<sup>30,32</sup> Higher saturation values may persist for 30 minutes after oxygen is discontinued. Evidence regarding the optimal duration of oxygen administration is inconsistent. The potential for fetal free radical production argues in favor of the use of supplemental oxygen in clinical settings in which there is a reasonable expectation of benefit.<sup>32</sup> Although the optimal method and duration of oxygen administration have not been established, available data support the use of a nonrebreather face mask to administer oxygen at a rate of 10 L/min for approximately 15 to 30 minutes.<sup>30</sup>

#### MATERNAL POSITION CHANGES

There are sound physiologic reasons to avoid the supine position during labor. In the supine position, the pressure of the gravid uterus on the inferior vena cava can impair venous return, cardiac output, and perfusion of the uterus and placenta. Pressure on the aorta and/or iliac arteries may impede the delivery of oxygenated blood to the uterus and placenta. Lateral maternal positioning (right or left) appears to have a more beneficial impact on fetal oxygen status than does the supine position.<sup>30,33</sup> In the setting of suspected umbilical cord compression, maternal position changes may result in fetal position changes and relief of pressure on the umbilical cord.

#### INTRAVENOUS FLUID ADMINISTRATION

Uteroplacental perfusion is dependent upon cardiac output and intravascular volume. Normal blood pressure does not necessarily reflect optimal intravascular volume, venous return, preload, or cardiac output. An intravascular bolus of isotonic fluid can improve cardiac output by increasing circulating volume, venous return, left ventricular end diastolic pressure, ventricular preload, and ultimately stroke volume in accordance with the Frank-Starling mechanism. Consequently, an increase in intravascular volume may have a significant impact on cardiac output and uteroplacental perfusion.<sup>34</sup> An intravenous (IV) fluid bolus of 500 to 1000 mL can result in improved fetal oxygenation even in an apparently euvoletic patient.<sup>30,31</sup> Caution must be exercised in patients at risk for volume overload and pulmonary edema. The optimal rate of IV fluid administration during labor is not known. Potential maternal and fetal complications argue against administering large-volume IV boluses of glucose-containing fluids.

### CORRECT MATERNAL HYPOTENSION

A number of factors predispose laboring women to transient episodes of hypotension, including inadequate hydration, supine position resulting in compression of the inferior vena cava, decreased venous return and reduced cardiac output, and peripheral vasodilation due to sympathetic blockade during regional anesthesia. Maternal hypotension can reduce uteroplacental perfusion and fetal oxygenation. Maternal position changes and IV hydration usually correct the blood pressure. However, if these measures do not achieve the desired result, medication may be necessary. Ephedrine is a sympathomimetic amine with weak  $\alpha$ - and  $\beta$ -agonist activity. The primary mechanism of action is the release of norepinephrine from presynaptic vesicles, which results in stimulation of postsynaptic adrenergic receptors.<sup>34</sup>

### REDUCE UTERINE ACTIVITY

Excessive uterine activity is a common cause of interrupted fetal oxygenation. A number of terms used to describe excessive uterine activity—including *hyperstimulation*, *hypercontractility*, and *tetanic contraction*—are defined inconsistently in the literature. The 2008 NICHD consensus statement<sup>16</sup> recommended using the term *tachysystole* to describe uterine contraction frequency in excess of five contractions in 10 minutes averaged over 30 minutes. Normal contraction frequency is defined as five or fewer contractions in 10 minutes averaged over 30 minutes. Other important features of uterine activity include contraction intensity, duration, resting tone, and time between contractions. If an abnormal FHR pattern is thought to be related to excessive uterine activity, options include discontinuing uterine stimulants, reducing the dose of uterine stimulants, and/or administering uterine relaxants such as terbutaline.

### AMNIOINFUSION

Intrapartum amnioinfusion involves the instillation of isotonic fluid through an intrauterine catheter into the amniotic cavity to restore the amniotic fluid volume to normal or near-normal levels. The procedure is intended to relieve intermittent umbilical cord compression, variable FHR decelerations, and transient episodes of interrupted fetal oxygenation. The impact of amnioinfusion on late decelerations is not known. Routine amnioinfusion for meconium-stained amniotic fluid without variable decelerations is not recommended.<sup>35</sup>

### ALTER SECOND-STAGE PUSHING AND BREATHING TECHNIQUE

During the second stage of labor, maternal expulsive efforts can be associated with FHR decelerations. Suggested corrective approaches include open-glottis, rather than Valsalva-style, pushing; fewer pushing efforts per contraction; shorter individual pushing efforts; pushing with every other or every third contraction; and pushing only with perceived urge.<sup>30,31</sup> A systematic approach to FHR management does not require the use of all of these measures in every situation. It simply helps to ensure that important considerations are not overlooked and that decisions are made in a timely manner. In addition, it provides a framework to help clinicians articulate an organized, clear, and understandable plan of management—a key element of credibility, reasonableness, and the standard of care.

### REEVALUATE THE FETAL HEART RATE TRACING

After assessing the oxygen pathway and beginning corrective measures deemed appropriate, the tracing is reevaluated. The

time frame for reevaluation is based on clinical judgment and usually ranges from 5 to 30 minutes in accordance with ACOG-AAP guidelines and applicable institutional policies.<sup>29</sup> If the FHR tracing returns to category I and labor progress is adequate, continued surveillance is appropriate. The decision to perform routine or heightened surveillance is based on clinical judgment, taking into account the entire clinical situation. If the FHR tracing progresses to category III despite appropriate conservative corrective measures, delivery usually is expedited as rapidly as safely and reasonably feasible. Tracings that remain in category II warrant additional evaluation.

Category II is extremely broad and includes FHR tracings for which continued surveillance is appropriate. However, it also includes tracings that warrant preparation for rapid delivery. If a category II FHR tracing demonstrates moderate variability or accelerations and does not demonstrate clinically significant decelerations, continued surveillance is reasonable (Fig. 15-22). Category II tracings that do not meet these criteria require additional attention. If any question remains regarding the presence of moderate variability or accelerations or the clinical significance of any decelerations, a reasonable approach is to take the next step in the ABCD management model.

### Clear Obstacles to Rapid Delivery

If conservative corrective measures do not correct the FHR tracing to the satisfaction of the clinician, it is reasonable to plan ahead by clearing common obstacles to rapid delivery. **This does not constitute a commitment to a particular time or method of delivery. Instead, this step serves as a forcing function to systematically address common sources of unnecessary delay so that important factors are not overlooked and decisions are made in a timely manner. This is accomplished by considering information relevant to the next action and communicating proactively with other members of the team. Potential sources of unnecessary delay can be grouped into major categories. Organized in nonrandom order from largest to smallest, these categories include the facility, staff, mother, fetus, and labor. Standardized intrapartum FHR management does not mandate that every possible corrective measure should be carried out. It simply provides a practical checklist of common factors that should be considered in order to optimize team communication, encourage timely decision making, and minimize preventable errors.**

### Determine Decision-to-Delivery Time

When weighing the risks and benefits of continued expectant management versus expeditious delivery, the anticipated decision-to-delivery time must be taken into consideration. **After appropriate conservative measures have been implemented, it is reasonable to make a good-faith estimate of the time needed to accomplish delivery in the event of a sudden deterioration of the FHR. This step can be facilitated by systematically considering individual characteristics of the facility, staff, mother, fetus, and labor.**

Management steps in the ABCD model are amenable to standardization and represent the majority of decisions that must be made during labor. However, once they are exhausted, further management decisions require the individual judgment of the clinician, who ultimately will assume responsibility for the safety of the mother and the fetus in the event that operative delivery becomes necessary.

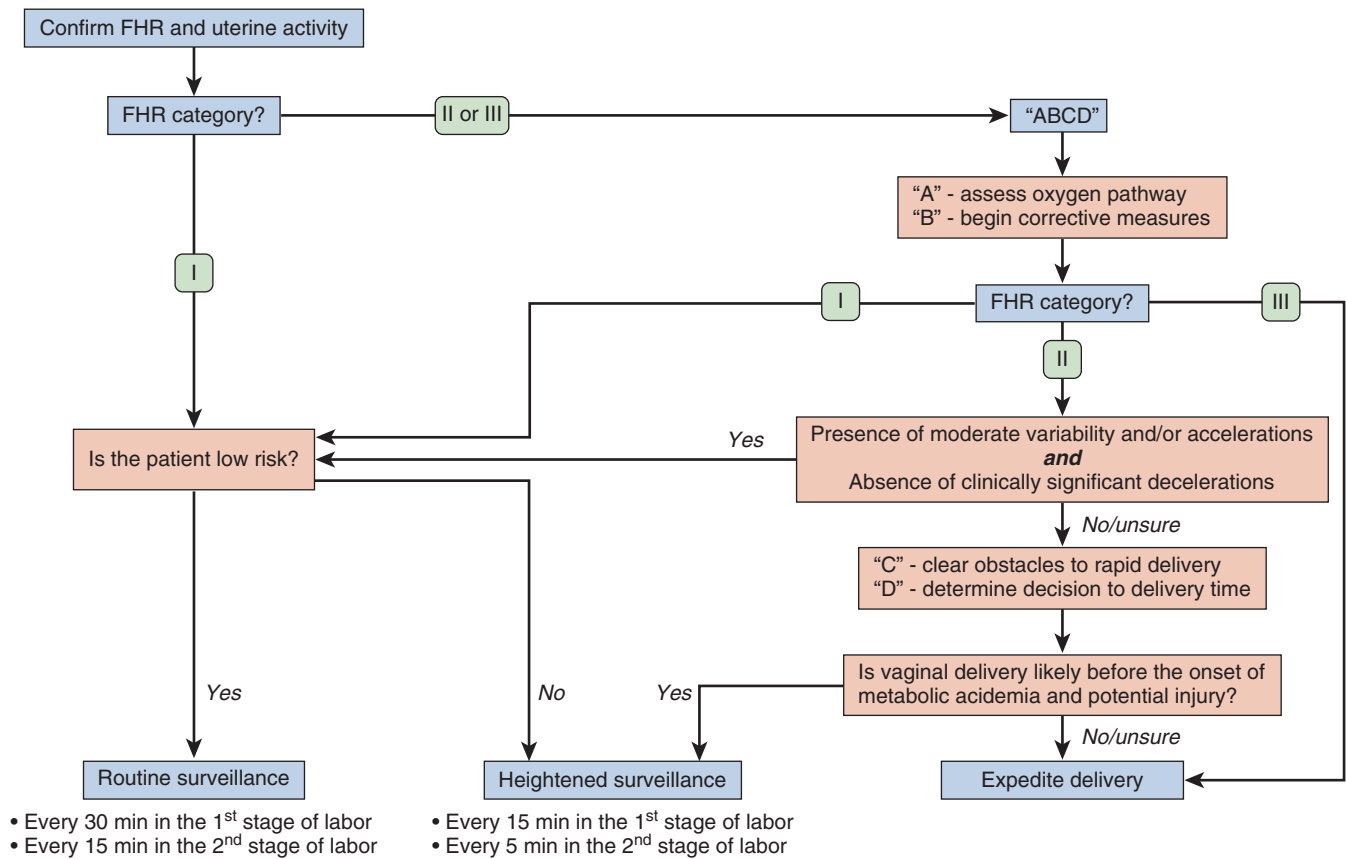

FIG 15-22 Intrapartum fetal heart rate (FHR) management decision model.

### Expectant Management Versus Delivery

If conservative measures do not correct a persistent category II FHR tracing, the clinician must decide whether to continue to await spontaneous vaginal delivery or to proceed with operative delivery. The decision balances the likelihood of safe vaginal delivery against the potential for fetal hypoxic injury. In 2013, Clark and colleagues<sup>36</sup> proposed a standardized approach to the management of persistent category II FHR tracings. As illustrated in Figure 15-23, the algorithm emphasizes the reliability of moderate variability or accelerations to exclude ongoing hypoxic injury.<sup>36</sup>

For the purposes of this algorithm, *significant decelerations* are defined as late decelerations or variable decelerations that last more than 60 seconds. Recommended management of prolonged decelerations includes discontinuation of the algorithm and initiation of appropriate corrective measures. In the setting of moderate variability or accelerations and normal progress in the active phase or second stage of labor, the algorithm permits continued expectant management with close observation in most cases, regardless of the presence of decelerations. One exception is the scenario in which conservative measures fail to correct recurrent significant decelerations remote from delivery. Another is the setting in which vaginal bleeding and/or previous cesarean section introduce the risks of placental abruption or uterine rupture. In such situations, further evaluation may be necessary, and adherence to the algorithm should be individualized. On the other side of the algorithm, if moderate variability and accelerations are absent, and recurrent significant decelerations fail to respond to corrective measures for 30 minutes,

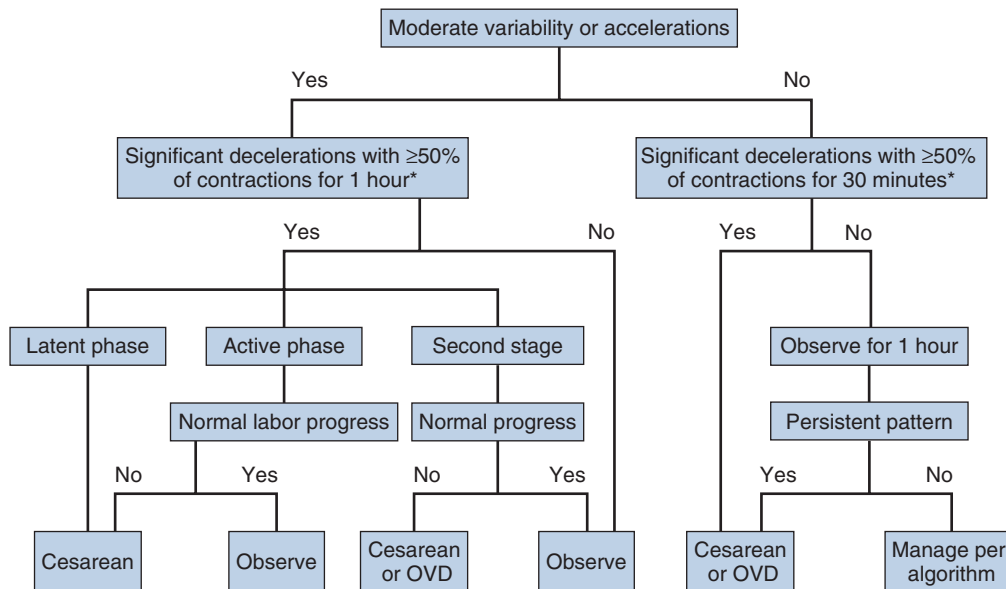

delivery should be considered regardless of the stage of labor. If moderate variability and accelerations are absent for 30 minutes *without* recurrent decelerations, the algorithm permits observation for an hour, beyond which time persistence of the pattern warrants consideration of delivery. This algorithm reflects the consensus of 18 authors regarding one reasonable approach to persistent category II FHR patterns. No single approach to such patterns has been demonstrated to be superior to all others. However, a growing body of evidence supports the concept that the adoption of one appropriate management plan, by virtue of standardization alone, will yield results superior to those achieved by random application of several individually equivalent approaches.<sup>36,37</sup>

### Other Methods of Evaluating Fetal Status

One of the primary shortcomings of electronic FHR monitoring is the high rate of false-positive results. Even the most abnormal FHR patterns are poorly predictive of neonatal morbidity. Consequently, alternative methods of evaluating fetal status have been explored and include fetal scalp pH and lactate determination, fetal stimulation, computer analysis of FHR, fetal pulse oximetry, and ST-segment analysis. In assessing the immediate condition of the newborn, umbilical cord acid-base determination can serve as an adjunct to the Apgar score.

### Intrapartum Fetal Scalp pH and Lactate Determination

Intermittent sampling of fetal scalp blood for pH determination was described in the 1960s and was studied extensively in the 1970s. However, its use has been limited by many factors, including the requirements for cervical dilation and membrane

**FIG 15-23** Algorithm for management of category II fetal heart rate tracings. \*Have not resolved with appropriate conservative corrective measures, which may include supplemental oxygen, maternal position changes, intravenous fluid administration, correction of hypotension, reduction or discontinuation of uterine stimulation, administration of uterine relaxant, amnioinfusion, and/or changes in second-stage breathing and pushing techniques. OVD, operative vaginal delivery. (Clark SL, Nageotte MP, Garite TJ, et al. Intrapartum management of category II fetal heart rate tracings: towards standardization of care. *Am J Obstet Gynecol.* 2013;209[2]:89-97.)

rupture, the technical difficulty of the procedure, the need for serial pH determinations, and uncertainty regarding interpretation and application of results. It is used infrequently in the United States but remains a common practice in many other countries. A recent meta-analysis<sup>38</sup> compared fetal scalp pH determination to fetal scalp lactate determination and found no differences in maternal, fetal, neonatal, or infant outcomes. Goodwin and colleagues<sup>39</sup> reported that the elimination of fetal scalp pH determination in a large clinical service resulted in no increase in the rates of cesarean delivery for fetal distress, low Apgar scores requiring neonatal intensive care unit (NICU) admission, or the clinical diagnosis of perinatal asphyxia.

### Fetal Scalp Stimulation and Vibroacoustic Stimulation

A number of studies have reported that FHR accelerations in response to fetal scalp stimulation or vibroacoustic stimulation (VAS) are highly predictive of normal scalp blood pH.<sup>40,41</sup> A literature review and meta-analysis by Skupski and colleagues<sup>42</sup> confirmed the utility of various methods of intrapartum fetal stimulation, including scalp puncture, atraumatic stimulation with an Allis clamp, VAS, and digital stimulation. Fetal scalp stimulation, VAS, and halogen light stimulation can be used to provoke FHR accelerations in order to exclude the presence of fetal metabolic acidemia.<sup>42</sup> Accelerations provoked by fetal stimulation have the same prognostic significance as spontaneous FHR accelerations.<sup>16</sup> Fetal stimulation should be performed at times when the FHR is at baseline. The utility of fetal stimulation during FHR decelerations or bradycardia has not been established.

### Computer Analysis of Fetal Heart Rate

Visual analysis of the FHR has been plagued by reports of poor interobserver and intraobserver reliability. In an attempt to overcome these limitations, Dawes and others<sup>43,44</sup> derived an objective system of numeric FHR analysis. Computer analysis of intrapartum FHR records has been reported to be more precise than visual assessment but has not been shown to improve

prediction of neonatal outcome.<sup>45</sup> Keith and colleagues<sup>46</sup> reported the results of a multicenter trial of an intelligent computer system that used clinical data in addition to FHR data. In 50 cases analyzed, the system's performance was indistinguishable from that of 17 expert clinicians. The authors reported that the system was highly consistent, recommended no unnecessary intervention, and performed better than all but two of the experts.

### Fetal Pulse Oximetry

Intrapartum reflectance fetal pulse oximetry is a modification of transmission pulse oximetry that indirectly measures the oxygen saturation of hemoglobin in fetal blood. An intrauterine sensor placed in contact with fetal skin uses the differential absorption of red and infrared light by oxygenated and deoxygenated fetal hemoglobin to provide a continuous estimation of fetal oxygen saturation. Several studies have examined the utility of intrapartum fetal pulse oximetry.<sup>47-52</sup> Although the studies reported a reduction in the incidence of cesarean delivery for fetal indications, no consistent impact on overall cesarean rates or newborn outcomes has been demonstrated. The results of a number of randomized trials led the manufacturer to announce that it would no longer distribute the sensors in the United States, effectively withdrawing the product from the market.

### P-R and ST-Segment Analysis

P-R and ST-segment analysis study of the fetal ECG has produced varying results. In animal studies, FHR decelerations that accompany hypoxemia have been observed in association with characteristic changes in the fetal P-R interval. Strachan and colleagues<sup>53</sup> compared standard EFM to EFM plus P-R interval analysis in 1038 women. The groups demonstrated statistically similar rates of operative intervention for presumed fetal distress and the authors reported no differences in newborn outcomes. The ST segment of the fetal ECG reflects myocardial repolarization. Myocardial hypoxia can lead to elevation of the ST segment and T wave secondary to catecholamine release,  $\beta$ -adrenoceptor

activation, glycogenolysis, and tissue metabolic acidosis.<sup>54-58</sup> These observations have led to the development of technology to analyze the fetal ECG plus the ST waveform (STAN; Neoventa Medical). One randomized trial<sup>59</sup> in 2434 patients demonstrated a 46% reduction in operative intervention for fetal distress when ST-segment analysis was added to standard EFM. Operative interventions for dystocia and other indications were not increased. Fewer cases of metabolic acidemia and low 5-minute Apgar scores were observed in the group with EFM plus ST-segment analysis; however, these differences did not reach statistical significance. Another trial<sup>60</sup> that used newer technology included 4966 women randomized to EFM alone versus EFM plus ST-segment analysis. When analyzed according to intention to treat, the incidence of umbilical artery acidemia was 53% lower in the group who had EFM plus ST-segment analysis, but cesarean delivery rates were not different. A large multicenter trial<sup>61</sup> randomized 5681 women to intrapartum EFM alone versus EFM plus ST-segment analysis. No significant difference was observed in the primary outcome of *metabolic acidosis*, defined as an umbilical artery pH below 7.05 with a base deficit of more than 12 mmol/L in the extracellular fluid. In the group with EFM plus ST analysis, statistically fewer cases were reported of fetal blood sampling during labor (10.6% vs. 20.4%), umbilical artery pH below 7.05 and base deficit greater than 12 mmol/L in the blood (1.6% vs. 2.6%), and umbilical artery pH below 7.05 (1.9% vs. 2.7%). Cesarean deliveries, instrumented vaginal deliveries, and total operative deliveries occurred with statistically similar frequency in both groups, with no differences in operative deliveries for fetal distress. No other statistically significant differences were reported in newborn outcome. A 2013 meta-analysis<sup>62</sup> of five studies that included 15,338 women concluded that adjunctive ST-segment analysis resulted in fewer fetal scalp samples, fewer operative vaginal deliveries, and fewer NICU admissions. However, no significant differences were found in the rate of cesarean births, low Apgar scores, metabolic acidemia at birth, neonatal intubation, or neonatal encephalopathy.

The Eunice Kennedy Shriver NICHD Maternal Fetal Medicine Units Network recently completed analysis of data from a Phase III trial (NCT01131260) of the safety and efficacy of fetal ECG ST-segment and T-wave analysis (STAN) as an adjunct to electronic FHR monitoring. The study<sup>63</sup> randomized 11,108 women to undergo standard intrapartum FHR monitoring alone or standard FHR monitoring plus STAN. No significant differences were found between the groups in the primary outcome—a composite of one or more of intrapartum fetal death, neonatal death, Apgar score of 3 or lower at 5 minutes, neonatal seizure, umbilical cord artery pH of 7.05 or lower plus base deficit of at least 12 mmol/L, intubation for ventilation at delivery, and neonatal encephalopathy. Moreover, no differences were reported between the groups in operative vaginal deliveries, cesarean deliveries, NICU stay, meconium aspiration, or shoulder dystocia. The authors concluded that the use of STAN as an adjunct to conventional intrapartum electronic FHR monitoring did not improve perinatal outcomes, nor did it decrease operative deliveries in hospitals in the United States.<sup>63</sup>

### Abdominal Fetal Electrocardiogram

A noninvasive abdominal fetal ECG (fECG) monitoring system, the Monica AN24 (Monica Healthcare, Nottingham, UK) has been approved for clinical practice.<sup>64</sup> The system uses five ECG electrodes placed around the maternal abdomen. The electrodes detect the fetal ECG, as well as the uterine electromyogram, to

provide a continuous display of FHR and uterine activity. Prospective observational studies have demonstrated that FHR detection using abdominal fECG was more reliable and accurate than Doppler ultrasound during the first stage of labor and was equivalent to Doppler during the second stage.<sup>64</sup> Abdominal fECG was less likely than Doppler ultrasound to display the maternal heart rate in place of the fetal heart rate. Another study demonstrated that Doppler ultrasound detection of FHR degraded with increasing maternal body mass index (BMI); however, maternal habitus did not affect the accuracy and reliability of the abdominal fECG.<sup>65</sup>

### Umbilical Cord Blood Gas Determination

Umbilical cord blood gas and pH assessment is a useful adjunct to the Apgar score in assessing the immediate condition of the newborn. **No contraindications exist to obtaining cord gases. The ACOG Committee on Obstetric Practice recommends that physicians should attempt to obtain umbilical venous and arterial blood samples in the following situations<sup>66</sup>:**

- Cesarean delivery for fetal compromise
- Low 5-minute Apgar score
- Severe growth restriction
- Abnormal fetal heart rate tracing
- Maternal thyroid disease
- Intrapartum fever
- Multifetal gestations

Immediately after delivery of the neonate, a segment of umbilical cord should be double-clamped and divided. A clamped segment of cord will remain stable for pH, PO<sub>2</sub>, and PCO<sub>2</sub> analysis for at least 60 minutes.<sup>65</sup> A cord blood sample in a heparin-flushed syringe is stable for up to 60 minutes.<sup>64</sup> Base-deficit values may increase by 1.2 mmol/L in 20 minutes and by 4.5 mmol/L in 60 minutes.<sup>13,65</sup> Lactate values can increase by 40% within 20 minutes and by 245% in 60 minutes, therefore if warranted by the condition of the neonate, blood should be drawn from an artery and a vein in the clamped cord segment and should be sent to the laboratory for blood gas analysis, including pH, PO<sub>2</sub>, PCO<sub>2</sub>, and base deficit, preferably within 20 minutes. If blood gas analysis is expected to take longer than 20 minutes, the syringe should be stored on ice. In all such cases, base deficit and lactate values should be interpreted with caution.<sup>13</sup> Umbilical arterial values reflect the metabolic status of fetal tissues before placental gas exchange, whereas umbilical venous values reflect metabolic status after gas and acid transfer in the placenta. Normal umbilical arterial results preclude significant fetal hypoxia or acidemia around the time of delivery. An attempt should be made to obtain paired arterial and venous specimens to help ensure that at least one artery is sampled and to minimize debate over whether a true arterial specimen was obtained. If it is not possible to draw blood from the umbilical cord, blood may be obtained from the surface of the placenta, where umbilical arteries cross over veins. Blood gas values can change significantly over time when the sample is obtained from the placenta via an unclamped vessel. Therefore such samples should be analyzed as promptly as possible and interpreted with appropriate caution. Exposure of arterial or venous samples to air tends to increase the PO<sub>2</sub> and decrease the PCO<sub>2</sub> toward atmospheric values.<sup>13</sup> Approximate normal values for cord blood are summarized in Table 15-5.<sup>7,8,13</sup>

The base deficit reflects utilization of buffer bases (primarily bicarbonate) to help stabilize pH, usually in the setting of peripheral tissue hypoxia, anaerobic metabolism, and production and accumulation of lactic acid. An umbilical artery pH

less than 7.20 usually is considered to define acidemia. **A much lower pH (7.0) has been defined as the threshold of potential injury.** Acidemia is categorized as respiratory, metabolic, or mixed. Isolated *respiratory acidemia* is diagnosed when the umbilical artery pH is less than 7.20, the PCO<sub>2</sub> is elevated, and the base deficit is less than 12 mmol/L. This reflects interrupted exchange of blood gases, usually as a transient phenomenon related to umbilical cord compression. Isolated *respiratory acidemia* is not associated with fetal neurologic injury.<sup>9</sup> Isolated *metabolic acidemia* is diagnosed when the pH is less than 7.20, the PCO<sub>2</sub> is normal, and the base deficit is at least 12 mmol/L. Metabolic acidemia can result from recurrent or prolonged interruption of fetal oxygenation that has progressed to the stage of peripheral tissue hypoxia, anaerobic metabolism, and lactic acid production in excess of buffering capacity. Although most cases of fetal metabolic acidemia do not result in injury, the risk is increased in the setting of significant metabolic acidemia (umbilical artery pH <7.0 and base deficit ≥12 mmol/L).<sup>11,12</sup> *Mixed acidemia* (respiratory and metabolic) is diagnosed when the pH is below 7.20, the PCO<sub>2</sub> is elevated, and the base deficit is 12 mmol/L or greater. The clinical significance of mixed acidemia is similar to that of isolated metabolic acidemia. The categories of acidemia are summarized in Table 15-6.

## ALTERNATIVES TO ELECTRONIC FETAL MONITORING

### Electronic Fetal Monitoring Versus Traditional Auscultation

As early as the nineteenth century, certain audible FHR patterns were observed to be associated with poor newborn outcome. In the 1960s, the introduction of EFM and fetal scalp blood sampling provided additional tools to evaluate the fetus. In 1967, Hon and Quilligan<sup>67</sup> proposed a system for classifying FHR decelerations. In 1969, Kubli and Hon<sup>28</sup> explored the relationship between the type and severity of FHR deceleration and the

fetal scalp blood pH. They reported that fetuses with no decelerations, early decelerations, or mild variable decelerations had average scalp pH values greater than 7.29, whereas those with severe variable or late decelerations had pH values below 7.15. Investigators have demonstrated the importance of FHR variability and FHR accelerations as indicators of the absence of metabolic acidemia and ongoing hypoxic injury.<sup>40,41</sup> When intrapartum EFM replaced the traditional practice of intermittent auscultation (IA) in the 1970s, a series of studies reported significantly lower perinatal mortality rates in electronically monitored patients. These studies were nonrandomized and used nonconcurrent controls. Critics have cited rapidly improving neonatal care and falling perinatal mortality rates as possible sources of bias. During the time of these studies, hospitals that were not using EFM experienced improvements in perinatal outcome similar to those seen in hospitals that were using EFM.<sup>68</sup> Nevertheless, these studies had the effect of validating the use of EFM. In 1976, the first of a series of randomized controlled trials was published that compared EFM to IA during labor. To date, 12 such studies have been published.<sup>69-80</sup> These trials are summarized in Table 15-7.

### Randomized Controlled Trials of Electronic Fetal Monitoring Versus Auscultation

In 1976, Haverkamp and associates<sup>69</sup> reported the first prospective randomized study of 483 high-risk obstetric patients to compare EFM to IA in labor. In the EFM group, a scalp electrode was placed as soon as possible. Auscultation in the control (IA) group was performed every 15 minutes in the first stage of labor and every 5 minutes in the second stage, for 30 seconds after uterine contractions. Electronic monitoring was used in both groups but was blinded in the IA group. In the EFM group, FHR patterns were evaluated using the criteria of Kubli and Hon.<sup>28</sup> In patients with late decelerations or severe variable decelerations that persisted after 15 minutes of corrective measures (oxygen, positional changes, correction of hypotension), delivery was accomplished. "Fetal distress" in the IA group was diagnosed by the presence of bradycardia to 100 beats/min after three or more consecutive contractions. Delivery was accomplished if the pattern was not relieved within 15 minutes. No significant differences were reported between the EFM and control groups in the outcomes of perinatal mortality, Apgar scores, cord blood pH values, neurologic signs in the neonate, or neonatal nursery morbidity. The monitored group, however, had significantly higher rates of cesarean delivery overall (16.5%

**TABLE 15-6** CATEGORIES OF UMBILICAL ARTERY ACIDEMIA

\*Fewer neonatal seizures were reported in the electronic fetal monitoring (EFM) group, but no difference was found at 4 years of age.

†The cesarean rate for fetal indications was higher in the EFM group, but overall cesarean rates were not reported.

‡The study ended after the third quarterly review because of a statistically significant fivefold decrease in perinatal mortality in the EFM group.

vs. 6.8%) and higher rates of cesarean delivery for “fetal distress” (7.4% vs. 1.2%).

The second study, by Renou and colleagues<sup>70</sup> in 1976, randomized 350 patients to undergo intrapartum fetal monitoring with EFM or IA. Continuous EFM was performed in the study group, and scalp pH was measured if the FHR tracing was judged to be abnormal. The protocol for auscultation in the IA group was not reported. No significant differences were found between the groups with respect to perinatal mortality, Apgar scores, or maternal or neonatal infection; however, patients in the monitored group had significantly higher cord blood pH values and significantly lower rates of NICU admission, neonatal neurologic signs and symptoms, and neonatally diagnosed brain damage (not further defined). The cesarean section rate was significantly higher in the monitored group than in the control group (22.3% vs. 13.7%), but the rates of cesarean delivery for suspected fetal compromise were not reported.

In 1978, Kelso and colleagues published the third randomized controlled trial (RCT) to compare EFM and IA in 504 patients.<sup>71</sup> Continuous EFM was used in study patients, and a fetal scalp electrode was placed as early as possible. Auscultation in the IA group was performed at least every 15 minutes for 1 minute during and immediately following a contraction. Crossover was not permitted, and scalp pH determination was not utilized. No significant differences were reported between the groups with respect to perinatal mortality, low Apgar scores, cord blood pH values, NICU admissions or lengths of stay, neonatal or maternal infections, or abnormal neonatal neurologic findings. The only significant difference between the groups was an increase in the incidence of cesarean birth in the monitored group (9.5% vs. 4.4%); however, no significant difference was found in the incidence of cesarean delivery for fetal distress (EFM 1.6%, control 1.2%).

In 1979, Haverkamp and associates<sup>72</sup> published another RCT that included additional measures of infant status and the option to perform fetal scalp pH determination during labor. A total of 690 high-risk patients were randomized into three groups: in the first group, fetal assessment during labor was accomplished by IA; the second group had continuous EFM alone; and the third group had continuous EFM with the option to measure scalp blood pH as needed. Among the three groups, no significant differences were seen in perinatal mortality, Apgar scores, cord blood pH values, maternal or neonatal infectious morbidity, NICU admissions, or neonatal neurologic abnormalities. A significant increase in the incidence of cesarean birth was demonstrated in the group monitored with EFM alone (EFM alone, 18%; EFM with the option to scalp sample, 11%; IA, 6%). The option to perform scalp sampling resulted in an intermediate cesarean delivery rate that was not significantly different from either of the other groups. Analyzed together, electronically monitored patients had a significantly higher incidence of cesarean delivery for fetal distress than did controls (5.2% vs. 0.43%).

The fifth trial was published in 1981 by Wood and colleagues,<sup>73</sup> wherein a total of 989 patients were randomized to undergo EFM or IA during labor. Monitored patients had placement of a fetal scalp electrode as early as possible. The protocol for auscultated patients was not described. Scalp pH measurements were performed as needed, and no significant differences were found between the groups in perinatal mortality, Apgar scores, cord blood pH values, NICU admissions, or neonatal neurologic abnormalities. In this study, the overall rate of operative intervention (including forceps) was significantly higher in

the monitored group, but the cesarean delivery rates were not significantly different (4% in the EFM group and 2% in the IA group). Rates of cesarean delivery for fetal distress were not reported.

In 1985, MacDonald and colleagues<sup>74</sup> published a randomized controlled trial that compared EFM to IA in 12,964 pregnancies. It was the first study to calculate prospectively the sample size needed to demonstrate statistically significant differences between the groups. Prior to initiation of the study, estimates were made of the anticipated frequencies of intrapartum stillbirths, neonatal deaths, neonatal seizures in survivors, and other severe abnormal neurologic characteristics. The authors calculated that 13,000 patients would be needed to demonstrate a 50% reduction in the combined incidence of intrapartum stillbirths, neonatal deaths, and neonatal seizures in survivors (power 75%,  $P = .05$ ). A trial of that size would have a 50% chance of detecting a 50% reduction in the rate of seizures alone. In the EFM group, a fetal scalp electrode was applied as early as possible, and scalp pH measurements were performed as needed. Criteria for evaluation of the FHR tracings were similar to those of Kubli and Hon.<sup>28</sup> Suspicious or ominous tracings were those with marked tachycardia or bradycardia, moderate tachycardia or bradycardia with decreased variability, absent to minimal variability, late decelerations, moderate to severe variable decelerations, and other difficult-to-interpret patterns. In the first stage of labor, a scalp pH evaluation was performed if such patterns persisted for at least 10 minutes. A scalp pH below 7.20 was an indication for delivery. If the fetal scalp pH was between 7.20 and 7.25 with persistent suspicious or ominous FHR patterns, or if it was less than 7.20 regardless of the FHR pattern, delivery was accomplished. If the scalp pH was greater than 7.25 but the tracing remained suspicious or ominous, the scalp pH was repeated within 30 to 60 minutes. In the second stage of labor, delivery was accomplished if FHR abnormalities persisted for at least 10 minutes. In the control group, IA was performed every 15 minutes for 60 seconds in the first stage of labor and between each contraction during the second stage. If the FHR was less than 100 beats/min or greater than 160 beats/min during three contractions and could not be corrected with conservative measures, a scalp pH was measured and managed as above, or delivery was expedited, depending on the stage of labor. Blood sampling also was performed at unspecified intervals in the control group when labor exceeded 8 hours, and no significant differences were found between the groups in perinatal mortality, low Apgar scores, neonatal trauma, resuscitation requirement, NICU admissions, or infectious morbidity. Among the 28 perinatal deaths, asphyxia was considered to be the primary cause in seven patients in each group. Significantly more cases of neonatal seizures and persistent neurologic abnormalities (>1 week) were present in the control group. However, follow-up at 4 years of age revealed three cases of CP in each group.<sup>81</sup> Labor was significantly shorter in the EFM group, and analgesia was required less often. Twice as many fetuses with low scalp pH (<7.20) were identified in the EFM group, and scalp sampling was used more frequently (EFM 4.4%, control 3.5%). The cesarean delivery rate in the EFM group (2.4%) was not significantly different from that in the auscultated group (2.2%). Overall rates of operative delivery were higher in the EFM group (10.6% vs. 8.5%) because of an increased use of forceps (8.2% vs. 6.3%). Rates of cesarean delivery for fetal distress were not significantly different (EFM 0.4%, IA 0.2%). In this study, the largest to date, EFM was associated with no increase in maternal morbidity.

In 1986, Neldam and colleagues<sup>75</sup> reported a randomized controlled trial of EFM versus IA in 969 patients. In the EFM group, monitoring was initiated when patients no longer desired to ambulate. A scalp electrode was placed as soon as possible thereafter. In the IA group, fetal heart tones were auscultated twice an hour for at least 15 seconds at cervical dilation less than 5 cm, every 15 minutes from 5 cm until the second stage of labor, and for 30 seconds after each contraction or at least every 5 minutes during the second stage. Scalp pH sampling was optional and was performed only five times (EFM three, control two). No statistical differences were detected between the groups with respect to perinatal mortality, low Apgar scores, seizures, NICU admissions, or lengths of stay. Significantly more abnormal FHR patterns were detected in the EFM group, however, no difference was reported in the incidence of cesarean delivery.

In 1986, Leveno and colleagues<sup>76</sup> published a prospective trial that included 14,618 patients randomized to EFM or IA during alternate months. Perinatal mortality, 5-minute Apgar scores, NICU admissions, ventilator requirement, and neonatal seizures were similar in the two groups. More abnormal FHR patterns were observed in the monitored group, which led to significantly more cesarean sections for “fetal distress” (9% vs. 4%). However, overall cesarean rates were not reported.

The ninth study, by Luthy and colleagues<sup>77</sup> in 1987, compared EFM and IA in 246 patients with preterm labor. In the EFM group, external monitoring was used until advanced cervical dilation (7 cm) had been attained, at which time amniotomy was performed and a scalp electrode was placed. In those with ruptured membranes, a scalp electrode was placed once delivery was inevitable. Fetal scalp blood sampling was used as clinically indicated in both groups. The groups did not differ with respect to the use of tocolytics, corticosteroids, oxytocin, or regional anesthesia. No differences were found in perinatal mortality, low Apgar scores, cord pH values, neonatal seizures, respiratory distress syndrome, or intracranial hemorrhage. Cesarean section rates were not statistically different (EFM 15.6%, controls 15.2%), and no difference was found in the incidence of cesarean delivery for “fetal distress” (EFM 8.2%, controls 5.6%).

In 1993, Vintzileos and colleagues<sup>78</sup> published a randomized trial that was conducted in Greece to compare EFM and IA in 1428 patients in a population with high baseline perinatal mortality rates (20.4 to 22.6 per 1000). The relatively high incidence of perinatal death markedly improved the likelihood of detecting a statistically significant effect of EFM. The authors prospectively calculated that in a sample of 2210 patients, they would have an 80% chance of detecting a 67% reduction in perinatal mortality at a 0.05 level of significance. Reviews were conducted every 3 months, and the study was ended after the third review in light of a statistically significant fivefold decrease in perinatal mortality in the EFM group, in which external monitoring was used as long as satisfactory tracings were obtained. Scalp electrodes were placed as needed. In the control group, IA was performed every 15 minutes during the first stage of labor and every 5 minutes during the second stage. Fetal scalp blood sampling was not used in either group, and crossover was not permitted. Significantly fewer perinatal deaths occurred in the EFM group than in the controls (2.6 vs. 13 per 1000), and no hypoxia-related perinatal deaths were reported in the EFM group, whereas 6 such deaths occurred in the auscultation group (0.9%). This difference was statistically significant. The groups did not differ significantly with respect to low Apgar scores, NICU admissions or lengths of stay, ventilator requirements,

neonatal HIE, intraventricular hemorrhage, seizures, hypotonia, necrotizing enterocolitis, or respiratory distress syndrome. The incidence of cesarean delivery for fetal distress was significantly higher in the EFM group (5.3% vs. 2.3%), but the overall incidence of cesarean birth was not significantly different between the EFM and IA groups (9.5% vs. 8.6%).

In Sweden in 1994, Herbst and Ingemarsson<sup>79</sup> randomized 4044 patients to receive continuous EFM or intermittent EFM with IA during labor. In the latter group, EFM was used for 10 to 30 minutes every 2 to 2.5 hours during the first stage of labor with intermittent auscultation every 15 to 30 minutes between recording periods. No statistically significant differences were found between the groups in the rates of cesarean delivery, cesarean delivery for fetal distress, low umbilical artery pH values, low Apgar scores, or admissions to the NICU.

In India in 2006, Madaan and Trivedi<sup>80</sup> randomized 100 patients with one previous low transverse cesarean delivery to either continuous EFM or IA during labor and found no differences between the groups in maternal or neonatal morbidity or in rates of vaginal, forceps, or cesarean delivery.

### Summary of Randomized Trials of Electronic Fetal Monitoring Versus Intermittent Auscultation

Randomized trials have demonstrated, with some caveats, that IA and EFM can perform similarly with respect to perinatal morbidity and mortality without contemporary evidence of a significant impact on cesarean delivery rates. It is important to note that the randomized trials compared EFM with IA combined with one-on-one nursing and frequent auscultation of fetal heart sounds. This level of individualized nursing care may be available in some settings, however, most obstetric units will find the personnel requirements to be impractical and cost prohibitive. Although FHR decelerations and accelerations can be detected with IA, no evidence suggests that IA can confirm the presence of moderate variability—an FHR characteristic that has emerged as one of the most reliable measures of adequate fetal oxygenation, and one that is used by clinicians on a daily basis to ensure that it is safe to continue labor. Thus in most of the randomized trials, an abnormal FHR observed during IA warranted a change to EFM. The safety of managing an abnormal FHR pattern with IA alone has not been established. The AGOC-AAP *Guidelines for Perinatal Care*<sup>29</sup> indicate that EFM or IA may be used to determine fetal status during labor. When IA is used, obstetric unit guidelines should clearly delineate the procedures to be followed, including the consistent use of standard NICHD definitions of FHR. In the absence of risk factors, a standard approach is to determine, evaluate, and record the FHR every 30 minutes in the active phase of the first stage of labor and at least every 15 minutes in the second stage.<sup>29</sup> If risk factors are present, the FHR should be determined, evaluated, and recorded at least every 15 minutes during the active phase of the first stage of labor, preferably before, during, and after a uterine contraction. During the second stage, the FHR should be determined, evaluated, and recorded at least every 5 minutes.<sup>29</sup>

### POTENTIAL RISKS OF ELECTRONIC FETAL MONITORING

#### Infection

Early concerns regarding the potential for maternal or neonatal bacterial infections in electronically monitored patients appear to have been unfounded. One randomized trial demonstrated

an increased risk of maternal infectious morbidity in patients randomized to EFM.<sup>69</sup> However, these results are difficult to interpret in light of the fact that fetal scalp electrodes were used in both the EFM and IA groups (FHR tracings were recorded in the IA group, but clinicians were blinded to them). The largest randomized trial to date revealed no increased infectious morbidity in electronically monitored patients.<sup>74</sup> Nevertheless, **disruption of the integrity of fetal skin with a fetal scalp electrode should be avoided in patients at risk for vertical perinatal transmission of viral infections, including human immunodeficiency virus (HIV), herpes simplex virus (HSV), and hepatitis.**

### Operative Intervention

Meta-analyses of the randomized trials of EFM versus IA have reported higher rates of operative intervention in monitored patients compared with controls.<sup>82,83</sup> A Cochrane review<sup>84</sup> that spanned three decades reported a 15% higher rate of instrumental vaginal delivery in electronically monitored patients (risk ratio [RR], 1.15; 95% confidence interval [CI], 1.01 to 1.33). The same review reported a 63% higher rate of cesarean delivery in electronically monitored patients (RR, 1.63; 95% CI, 1.29 to 2.07).<sup>84</sup> However, published data from the most contemporary randomized trials suggest that the effect of EFM on cesarean delivery rates is minimal. Four randomized trials that included a total of 2027 subjects were published before 1980, during the first decade of clinical use of EFM.<sup>69-72</sup> All of these studies reported significantly higher rates of cesarean delivery in electronically monitored patients. However, as summarized in [Table 15-7](#), seven of the eight randomized trials published after 1980, which included more than 10 times the number of subjects (20,740), failed to replicate this observation.<sup>73-75,77-80</sup> The eighth trial<sup>76</sup> did not report overall cesarean delivery rates. **Although historically EFM has been considered to contribute to higher cesarean rates, an alternative explanation of the most contemporary data is that the early impact of EFM on cesarean delivery rates has been mitigated by refinements in FHR interpretation and management that have accompanied decades of clinical experience with the technology.**

### BENEFITS OF ELECTRONIC FETAL MONITORING

Nonrandomized studies in the 1970s reported significantly lower perinatal mortality rates in electronically monitored patients. In subsequent years, only one randomized trial was able to replicate these observations.<sup>78</sup> Despite a lack of consensus on many points, EFM has been demonstrated to be at least as effective in preventing perinatal morbidity and mortality as the previous practice of IA.

### LIMITATIONS OF ELECTRONIC FETAL MONITORING

#### Prediction and Prevention of Hypoxic Injury

Despite early hopes, EFM has not proven to be a reliable predictor of fetal or neonatal metabolic acidemia, neonatal encephalopathy, or long-term neurologic impairment in the form of CP. The reported false-positive rate of EFM for detecting CP is 99.8%, yielding a positive predictive value of 1 in 500.<sup>17,85</sup> To provide context for this figure, the prevalence of CP in the general population is approximately 1 in 500.<sup>85</sup> The failure of EFM to predict hypoxic neurologic injury is largely due to the

fact that EFM is *not a diagnostic test for hypoxic neurologic injury*. Instead, it is a *screening test* that detects transient intrapartum interruption of fetal oxygenation as an early precursor to hypoxic neurologic injury. When used as a screening test, the negative predictive value of EFM is excellent. Normal EFM results virtually preclude intrapartum interruption of fetal oxygenation sufficient to cause hypoxic injury; however, the converse is not true. Abnormal EFM results rarely predict the presence of hypoxic injury. Instead, abnormal EFM results usually reflect transient interruption of fetal oxygenation, a common feature of normal labor that rarely leads to hypoxic injury. This is particularly true when abnormal EFM results trigger conservative measures that alter the natural progression of oxygen deficiency. After decades of research, it is clear that EFM is a reliable screening test with exceptional negative predictive value. Normal screening results confirm the safety of continued expectant management. Abnormal screening results should prompt additional investigation, heightened surveillance, and initiation of conservative measures as needed to improve fetal oxygenation. Definitive intervention in the form of operative delivery is ideally reserved for cases in which conservative measures are unsuccessful and ongoing hypoxic injury cannot be excluded. No single EFM finding or combination of findings has been found to be a reliable predictor of long-term neurodevelopmental impairment in the form of CP. Consequently, any attempt to use EFM for its positive predictive value as a diagnostic test for CP is destined to yield unsatisfactory results. When EFM replaced the traditional practice of IA in the 1970s, nonrandomized trials reported significantly lower perinatal mortality rates in electronically monitored patients. In subsequent years, only one randomized trial—conducted in a setting with high baseline perinatal mortality rates of 20.4 to 22.6 per 1000—was able to replicate this observation. A recent meta-analysis<sup>84</sup> of published randomized trials that included more than 33,000 patients demonstrated no significant reduction in perinatal mortality in electronically monitored patients compared with those monitored with IA. In fact, data derived from all of the randomized trials combined have failed to demonstrate the ability of EFM to reduce the risk of fetal metabolic acidemia, neonatal HIE, CP, or perinatal death compared with IA conducted with one-on-one nursing under strict research protocols.<sup>84</sup> This has led some to conclude that EFM has failed as a public health screening program.<sup>86</sup> An alternative interpretation is that in appropriately selected patients, EFM and IA conducted with vigilance commensurate with that applied in the randomized trials can be expected to perform similarly with respect to maternal and perinatal morbidity and mortality.

#### Prediction and Prevention of Fetal Stroke

As old EFM polemics gradually give way to evidence-based consensus, new controversies are arising. For example, a recent meta-analysis of four studies reported a possible relationship between abnormal intrapartum FHR patterns and the later diagnosis of perinatal arterial ischemic stroke (PAIS).<sup>87</sup> One of the four studies included only preterm deliveries and did not report the specific FHR abnormalities observed in the control and study groups.<sup>88</sup> The other three studies included only term deliveries, and none of these demonstrated an independent link between FHR abnormalities and PAIS.<sup>89-91</sup> No published evidence supports a causal relationship between FHR abnormalities and PAIS at any gestational age. Moreover, no published evidence suggests that intrapartum EFM is capable of detecting or predicting PAIS or that any form of obstetric intervention is

capable of preventing PAIS. No level I or II evidence exists that links PAIS independently with any measure of uterine activity or labor duration.<sup>13</sup> This is consistent with the 2007 consensus report of the National Institute of Neurologic Disorders and Stroke and the NICHD, which concluded that “there are no reliable predictors of perinatal ischemic stroke upon which to base prevention or treatment strategies.”<sup>20</sup>

### Fetal Head Compression

Early deceleration of the FHR has long been recognized as a benign reflex response to transient compression of the fetal head during a uterine contraction. The innocuous nature of this phenomenon is underscored by the fact that early decelerations are included in NICHD category I, indicating normal fetal oxygenation.<sup>16</sup> However, some have suggested that intrapartum fetal head compression can cause hypoxic-ischemic brain injury, even in a normally oxygenated fetus.<sup>92</sup> This theory suggests that uterine contractions compress the fetal head against the maternal pelvis with such force that fetal intracranial pressure exceeds cerebral perfusion pressure, reducing intracranial blood flow to the point of regional cerebral ischemia and focal hypoxic-ischemic injury. Descriptive studies have reported that fetal head pressures during uterine contractions can be more than twice as high as intraamniotic pressures.<sup>93</sup> Other studies have demonstrated changes in fetal cerebral perfusion pressure, cerebral blood flow, and cerebral oxygen consumption during fetal head pressure.<sup>94-96</sup> However, no published level I or level II evidence has demonstrated that these changes translate to histologic neuropathology or clinical neurologic impairment. On the contrary, observations in fetal sheep suggest that the reflex Cushing response to head compression could be protective against such injury.<sup>97,98</sup> Level II evidence in the form of case-control studies has identified several perinatal risk factors for CP that include prematurity, infection, maternal thyroid disease, and congenital malformations.<sup>99</sup> However, no level I or II evidence has demonstrated a link between any measure of uterine activity and the later development of CP. The notion that fetal brain injury can be caused by the mechanical forces of labor is further challenged by level II evidence from a large cohort study that included more than 380,000 spontaneous vaginal deliveries and more than 33,000 cesarean deliveries without labor.<sup>100</sup> Neonates exposed to uterine contractions of sufficient frequency, intensity, and duration to result in spontaneous vaginal delivery had no higher rates of mechanical brain injury in the form of intracranial hemorrhage than did neonates who were exposed to no uterine contractions at all. This theory is not supported by analytic evidence in the literature. Consequently, it should not be used as a foundation for intrapartum management decisions.

### SUMMARY

Evolving standardization and evidence-based consensus regarding EFM definitions, interpretation, and management are gradually supplanting the controversy and confusion that characterized EFM for decades. **Intrapartum FHR decelerations—variable, late, and prolonged—reliably identify transient episodes of interruption of fetal oxygenation. Moderate variability or accelerations confirm the absence of ongoing hypoxic neurologic**

**injury with an extremely high degree of reliability, and the negative predictive value of EFM is near 100%. A test that is virtually always right is the ideal foundation for rational decision making. Conversely, if EFM is relied upon for its positive predictive value to detect hypoxic neurologic injury, it will be wrong approximately 499 times out of 500.**<sup>85</sup> Reasonable management decisions cannot be based on the results of a test that is virtually always wrong. The standardized EFM definitions proposed by the NICHD and endorsed by ACOG, AWHONN, and ACNM should be used consistently. Standardized interpretation should eschew unproven theories in favor of evidence-based principles derived from appropriately controlled scientific research. Together, standardized definitions and evidence-based principles of interpretation help ensure factual accuracy. A standardized, simplified approach to EFM management provides a framework to help clinicians formulate a thoughtful, systematic plan of action that can be articulated clearly and understandably.

### KEY POINTS

- ◆ The goal of intrapartum FHR monitoring is to assess the adequacy of fetal oxygenation during labor so that timely and appropriate steps can be taken when necessary to avoid fetal hypoxic injury.
- ◆ Fetal oxygenation involves the transfer of oxygen from the environment to the fetus. Oxygen is transported by maternal and fetal blood along the oxygen pathway, which includes the maternal lungs, heart, vasculature, uterus, placenta, and umbilical cord.
- ◆ The consequences of interruption of fetal oxygenation can lead sequentially to fetal hypoxemia (low oxygen content in the blood), fetal hypoxia (low oxygen content in the tissues), metabolic acidosis (accumulation of lactic acid in the tissues), metabolic acidemia (accumulation of lactic acid in the blood), and eventually injury or death.
- ◆ The FHR monitor provides reliable information regarding interruption of the oxygen pathway. The observation of an FHR deceleration that reaches its nadir in less than 30 seconds (variable deceleration) suggests compression of the umbilical cord. However, the mere fact that a deceleration reaches its nadir in less than 30 seconds does not exclude interruption of the oxygen pathway at other points, such as the lungs (hypoxemia), heart (poor cardiac output), vasculature (acute hypotension), uterus (uterine rupture, uterine contraction), or placenta (placental abruption). A late deceleration, by definition, reaches its nadir in 30 seconds or more. Historically, late decelerations have been attributed to uteroplacental insufficiency, which suggests interruption of the oxygen pathway at the level of the uterus or placenta. However, the fact that a deceleration takes 30 seconds to reach its nadir does not exclude the possibility of interruption of the oxygen pathway at other points, such as the maternal lungs (hypoxemia), heart

(poor cardiac output), or vasculature (hypotension). A prolonged deceleration can result from interruption of the oxygen pathway at any point. For the purposes of practical FHR interpretation, all clinically significant FHR decelerations that have any potential impact on fetal oxygenation (variable, late, or prolonged decelerations) have the same common trigger: interruption of the oxygen pathway **at one or more points**. This unifying concept helps reduce conflict and controversy and offers the additional benefits of standardization, simplicity, factual accuracy, and ease of articulation.

- ◆ In addition to providing practical information regarding interruption of the oxygen pathway, the FHR monitor provides useful information regarding the adequacy of fetal oxygenation. Moderate FHR variability or accelerations reliably exclude fetal hypoxic injury at the time they are observed; however, the converse is not true. The absence of moderate variability and/or accelerations does not indicate the presence of hypoxic injury.
- ◆ The negative predictive value of electronic FHR monitoring is excellent. A normal test virtually precludes fetal hypoxic injury at the time it is observed.
- ◆ The positive predictive value of electronic FHR monitoring is poor. Abnormal FHR monitoring accurately predicts CP approximately one time out of 500, yielding a false-positive rate above 99%. Except in extreme cases, no FHR pattern or combination of patterns has been demonstrated to predict hypoxic neurologic injury with a meaningful degree of accuracy.
- ◆ Even in the setting of abnormal FHR monitoring, the pathway from intrapartum hypoxic-ischemic injury to subsequent CP must progress through neonatal encephalopathy. The absence of neonatal encephalopathy is inconsistent with hypoxic-ischemic neurologic injury near the time of delivery.
- ◆ No randomized controlled trials, cohort studies, case-control studies, or other peer-reviewed studies in the literature support the hypothesis that fetal head compression caused by uterine contractions or maternal pushing efforts can cause local cerebral ischemia and hypoxic-ischemic injury in the absence of the established mechanism of global hypoxia. Similarly, no predictors of perinatal ischemic stroke are known upon which to base prevention strategies, and no known relationship exists between FHR monitoring and local cerebral hypoxic injury or stroke that can be used to identify, predict, or prevent such injuries.
- ◆ In the United States, standard FHR terminology has been proposed by the NICHD and is endorsed by virtually all major organizations that represent providers of obstetric care. Consistent use of standard terminology helps to ensure effective communication and optimize outcomes.

Obstetric anesthesia encompasses all techniques used by anesthesiologists and obstetricians to alleviate the pain associated with labor and delivery: this includes general anesthesia, neuraxial anesthesia (spinal or epidural), local anesthesia (local infiltration, paracervical block, pudendal block), and parenteral analgesia. **Pain relief during labor and delivery is an essential part of good obstetric care.** Unique clinical considerations guide anesthesia provided for obstetric patients; physiologic

changes of pregnancy and increases in certain complications must be considered. This chapter reviews the various methods that can be used for obstetric analgesia and anesthesia as well as their indications and complications.

## PERSONNEL

In larger hospitals in the United States, anesthesiologists—working either independently or supervising a team of residents—along with anesthesiologist assistants and certified nurse anesthetists provide anesthesia for 98% of obstetric procedures.<sup>1</sup> Nurse anesthetists working independent of anesthesiologists rarely provide anesthesia for obstetric cases in larger hospitals but provide anesthesia for 34% of obstetric procedures in hospitals with fewer than 500 births per year.<sup>1</sup> The American Society of Anesthesiologists (ASA) partnered with the American College of Obstetricians and Gynecologists (ACOG) to issue a Joint Statement on the Optimal Goals for Anesthesia Care in Obstetrics,<sup>2</sup> which recommends that a qualified anesthesiologist assume responsibility for anesthetics in every hospital that provides obstetric care. The statement notes: “There are many obstetric units where obstetricians or obstetrician-supervised nurse anesthetists administer labor anesthetics. **The administration of general or neuraxial anesthesia requires both medical judgment and technical skills.** Thus a physician with privileges in anesthesiology should be readily available.”<sup>2</sup> To provide optimal care for the parturient, the ASA also states in their Practice Guidelines for Obstetric Anesthesia that “**A communication system should be in place to encourage early and ongoing contact between obstetric providers, anesthesiologists, and other members of the multidisciplinary team.**”<sup>3</sup>

## PAIN PATHWAYS

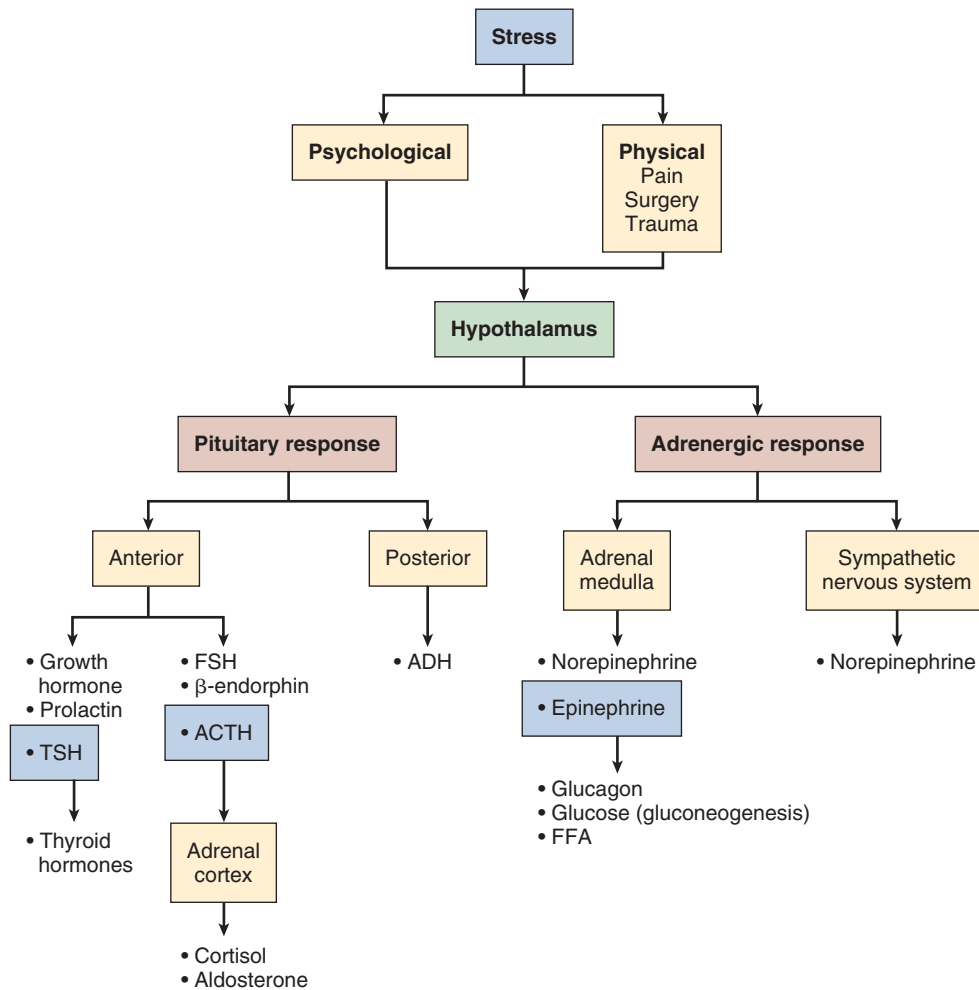

Pain during the first stage of labor results from a combination of uterine contractions and cervical dilation. Painful sensations travel from the uterus through visceral afferent (sympathetic)

**FIG 16-1** Pain pathways of labor and delivery and nerves blocked by various anesthetic techniques.

nerves that enter the spinal cord through the posterior segments of thoracic spinal nerves 10, 11, and 12 (Fig. 16-1). During the second stage of labor, additional painful stimuli are added as the fetal head distends the pelvic floor, vagina, and perineum. The sensory fibers of sacral nerves 2, 3, and 4 (i.e., the pudendal nerves) transmit painful impulses from the perineum to the spinal cord during the second stage and during any perineal

repair (see Fig. 16-1). During cesarean delivery, although the incision is usually around the thoracic spinal nerve 12 (T-12) dermatome, anesthesia is required to the level of thoracic spinal nerve 4 (T-4) to completely block peritoneal discomfort, especially during uterine exteriorization. Pain after cesarean delivery is due to both incisional pain and uterine involution.

**FIG 16-2** The stress response. ACTH, adrenocorticotrophic hormone; ADH, antidiuretic hormone; FFA, free fatty acid; FSH, follicle-stimulating hormone; TSH, thyroid-stimulating hormone.

## EFFECTS OF PAIN AND STRESS

The process of labor involves significant pain and stress for most women. Using the McGill Pain Questionnaire, which measures intensity and quality of pain, Melzack<sup>4</sup> found that 59% of nulliparous and 43% of parous women described their labor pain in terms more severe than did those suffering from cancer pain. **The most substantial predictors of pain intensity were ultimately low socioeconomic status and prior menstrual difficulties.**

The maternal and fetal stress response to the pain of labor has been difficult to assess. Most investigators have described and quantified stress in terms of the release of the adrenocorticotrophic hormone (ACTH) cortisol, catecholamines, and β-endorphins (Fig. 16-2). Furthermore, **animal studies indicate that both epinephrine and norepinephrine can decrease uterine blood flow in the absence of maternal heart rate and blood pressure changes, which contributes to occult fetal asphyxia.** As demonstrated in baboons and monkeys, maternal psychological stress (induced by bright lights or toe clamping) can detrimentally affect uterine blood flow and fetal acid-base status.<sup>5</sup> In pregnant sheep, catecholamines increase and uterine blood flow decreases after painful stimuli and after nonpainful stimuli such as loud noises induce fear and anxiety, as evidenced by struggling (Fig. 16-3).

**FIG 16-3** Effects of electrically induced stress (30 to 60 seconds) on maternal mean arterial blood pressure, plasma norepinephrine levels, and uterine blood flow. (Modified from Shnider SM, Wright RG, Levinson G, et al. Uterine blood flow and plasma norepinephrine changes during maternal stress in the pregnant ewe. *Anesthesiology*. 1979;50:524.)

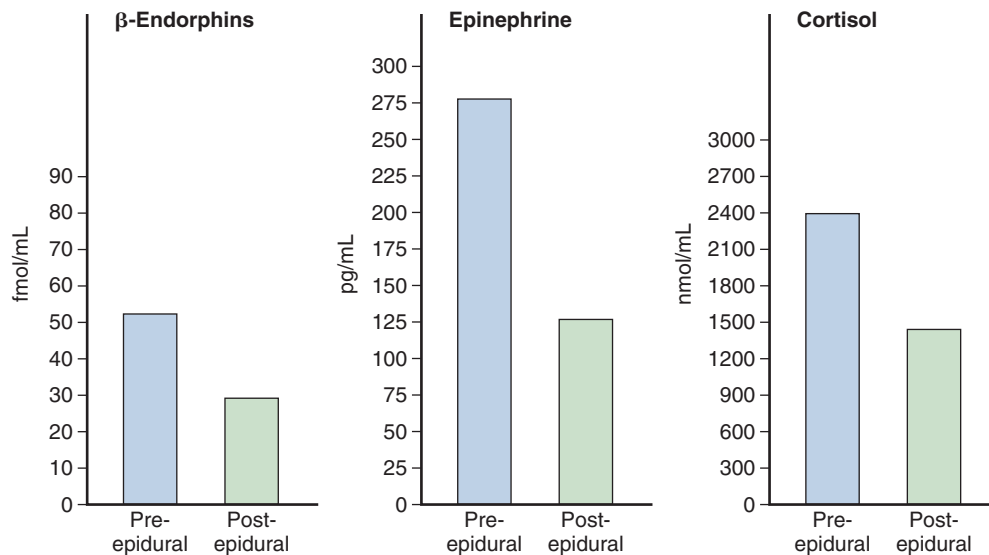

FIG 16-4 Effects of epidural analgesia on the response to stress.

Modified from Bucklin BA, Hawkins JL, Anderson JR, Ullrich FA. Obstetric anesthesia workforce survey. *Anesthesiology*. 2005;103:645.

Although some of the physiologic stress of labor is unavoidable, analgesia and anesthesia may reduce stress responses secondary to pain. Postpartum women suffer objective deficits in cognitive and memory function when compared with nonpregnant women, and intrapartum analgesia does not exacerbate but rather *lessens* the cognitive defect compared with unmedicated parturients.<sup>6</sup> Epidural analgesia is associated with a decreased risk of postpartum depression. In one study, depression occurred in 14% of parturients who received epidural labor analgesia and in 34.6% of those who did not.<sup>7</sup> Analgesia also reduces paternal anxiety and stress, increases fathers' feelings of helpfulness, and enhances their involvement and satisfaction with the childbirth experience.<sup>8</sup> Epidural analgesia prevents increases in both cortisol and 11-hydroxycorticosteroid levels during labor, but systemically administered opioids do not. Epidural analgesia also attenuates elevations of epinephrine and norepinephrine and endorphin levels (Fig. 16-4).<sup>9</sup> **Assuming any hypotension is rapidly treated and that perfusion is preserved by preventing aortocaval compression with uterine displacement, fetal acid-base status (as measured by base deficit) of human infants whose mothers receive epidural anesthesia during the first stage of labor is altered less than that of infants of mothers who receive systemic opioid analgesia.**

## ANALGESIA FOR LABOR

Table 16-1 presents the frequency with which the various forms of analgesia are used during labor. The data are from a large survey of hospitals in the United States, stratified by the size of their delivery service.<sup>1</sup>

## Psychoprophylaxis and Nonpharmacologic Analgesia Techniques

Psychoprophylaxis is any nonpharmacologic method that minimizes the perception of painful uterine contractions. Relaxation, concentration on breathing, gentle massage, and partner or doula participation contribute to effectiveness. One of the method's most valuable contributions is that it is often taught in prepared childbirth classes, where parents tour the labor and delivery suite and learn about the normal processes of labor and delivery, which in many instances mitigates their fear of the unknown.<sup>10</sup>

Although psychoprophylactic techniques can be empowering, the majority of women will still ultimately blend them with pharmacologic methods.<sup>1</sup> Because the majority of first-time mothers choose epidural analgesia, teaching that use of drug-induced pain relief represents failure or will harm the child are counterproductive and can heighten fear and anxiety during labor.

Nonpharmacologic techniques for labor analgesia may be used alone or in conjunction with parenteral or neuraxial techniques. Table 16-2 shows frequently used techniques and the evidence that supports their use. A systematic review of acupuncture concluded that the evidence for efficacy is promising but few data are available.<sup>11</sup> From the three randomized controlled trials (RCTs) they reviewed, the authors suggest that acupuncture alleviates labor pain and reduces use of both epidural analgesia and parenteral opioids. Acupuncture may be helpful for patients who feel strongly about avoiding epidural analgesia in labor, although arranging to have a qualified and credentialed acupuncturist available at the time of delivery may

be challenging. An RCT of laboring in water found no advantage in labor outcome or in reducing the need for analgesia, but the request for epidural analgesia was delayed by about 30 minutes.<sup>12</sup> The ACOG has expressed concerns about *delivering* in water because of the lack of trials to demonstrate safety and the rare but reported unusual complications, such as infection or asphyxia.<sup>13</sup> They state that “the safety and efficacy of immersion in water during the second stage of labor have not been established, and immersion in water during the second stage of labor has not been associated with maternal or fetal benefit. Given these facts and case reports of rare but serious adverse effects in the newborn, the practice of immersion in the second stage of labor (underwater delivery) should be considered an experimental procedure that should only be performed within the context of an appropriately designed clinical trial with informed consent.”

Intradermal sterile water injections at four sites in the lower back were once thought to have a similar gating mechanism as acupuncture and are simple to perform, but little evidence exists for their efficacy (see Table 16-2). A number of studies have examined transcutaneous electrical nerve stimulation (TENS) during labor. Patients tend to rate the device as helpful despite the fact that it does not decrease pain scores or the use of additional analgesics. As one study noted, TENS units do not appear to change the degree of pain but may have somehow made the pain less disturbing (see Table 16-2). **Although the efficacy of these techniques is largely unproven because of a lack of RCTs, no serious safety concerns exist with any of these techniques, which is attractive to patients and their caregivers.** Women expect to have choices and a degree of control during childbirth, and their caregivers should provide analgesic options for them to choose from, including nonpharmacologic methods.

**Systemic Opioid Analgesia**

Opioids can be given in intermittent doses by intramuscular (IM) or intravenous (IV) routes at the patient’s request, or the patient can self-administer with patient-controlled analgesia (PCA). **All opioids provide sedation and a sense of euphoria, but their analgesic effect in labor is limited, and their primary mechanism of action is sedation.**<sup>14</sup> Opioids can also produce nausea and respiratory depression in the mother, the degree of which is usually comparable for equipotent analgesic doses. Also, **all opioids freely cross the placenta to the newborn and decrease beat-to-beat variability in the fetal heart rate (FHR). They can increase the likelihood of significant respiratory depression in the newborn at birth and can increase**

**the subsequent need for treatment.** A meta-analysis aggregated the results of several randomized trials and revealed that opioid treatment is associated with an increased risk of Apgar scores below 7 at 5 minutes (odds ratio [OR], 2.6; 95% confidence interval [CI], 1.2 to 5.6), and increased need for neonatal naloxone (OR, 4.17; 95% CI, 1.3 to 14.3), although the overall incidence of both was low.<sup>15</sup> **An important and significant disadvantage of opioid analgesia is the prolonged effect of these agents on maternal gastric emptying.** When parenteral or epidural opioids are used, gastric emptying is prolonged, and if general anesthesia becomes necessary, the risk of aspiration is increased.<sup>16</sup>

The opioids in common use today are meperidine, nalbuphine, fentanyl, and remifentanyl. Morphine fell out of favor in the 1960s to 1970s because of a single study that reported increased respiratory depression in the newborn compared with meperidine, but no recent study has compared the relative safety of opioids for the newborn in the setting of modern practice.

**Patient-Controlled Analgesia**

IV patient-controlled analgesia (PCA) is often used for women who have a contraindication to neuraxial analgesia (e.g., severe thrombocytopenia). The infusion pump is programmed to give a predetermined dose of drug upon patient demand. The physician will program the pump to include a lockout interval to limit the total dose administered per hour. Advantages of this method include the sense of autonomy, which patients appreciate, and elimination of delays in treatment while the patient’s nurse obtains and administers the dose. In general, PCA results in a decreased total dose of opioid during labor.<sup>17</sup> Fentanyl, remifentanyl,<sup>18</sup> and meperidine are the opioids most commonly used with this technique.

**Meperidine (Demerol)**

Meperidine is a synthetic opioid, and 100 mg is roughly equianalgesic to morphine 10 mg but has been reported to have a somewhat less depressive effect on respiration. Usually, 25 to 50 mg are administered intravenously; it may also be used intramuscularly or in a PCA pump to deliver 15 mg of meperidine every 10 minutes as needed until delivery.<sup>19</sup> Intravenously, the onset of analgesia begins almost immediately and lasts approximately 1.5 to 2 hours. Side effects may include tachycardia, nausea and vomiting, and delayed gastric emptying.

**Normeperidine is an active metabolite of meperidine and potentiates meperidine’s depressant effects in the newborn.** Normeperidine concentrations increase slowly; therefore it exerts its effect on the newborn during the second hour after administration. Multiple doses of meperidine result in greater accumulation of both meperidine and normeperidine in fetal tissues<sup>20</sup>; thus administration of large doses of meperidine in the first stage of labor, rather than during the second stage, leads to high doses accumulated in the fetus. A randomized controlled study using intravenous PCA with meperidine for labor analgesia found that 3.4% of infants required naloxone at delivery (vs. 0.8% with epidural analgesia).<sup>21</sup> Normeperidine accumulation in the fetus can result in prolonged neonatal sedation and neurobehavioral changes.<sup>22</sup> These neurobehavioral changes are evident into day 2 and day 3 of life.

**Nalbuphine (Nubain)**

Nalbuphine is a synthetic agonist-antagonist opioid, meaning it has opioid-blocking properties as well as analgesic properties. Its

analgesic potency is similar to that of morphine when compared on a milligram-per-milligram basis, and usual doses are 5 to 10 mg intravenously every 3 hours. A reported advantage of nalbuphine is its ceiling effect for respiratory depression,<sup>25</sup> that is, respiratory depression from multiple doses appears to plateau. One limitation of nalbuphine is that its antagonist activity may also limit the analgesia it can produce, and it may interfere with spinal and epidural opioids given as part of a neuraxial technique. Nalbuphine causes less maternal nausea and vomiting than meperidine, but it tends to produce more maternal sedation, dizziness, and dysphoria and increases the risk of opioid withdrawal in susceptible patients.

### Fentanyl

Fentanyl is a fast-onset, short-acting synthetic opioid with no active metabolites. In a randomized comparison with meperidine, fentanyl 50 to 100 µg every hour provided equivalent analgesia with fewer neonatal effects and less maternal sedation and nausea. The main drawback of fentanyl is its short duration of action, which requires frequent redosing or the use of a patient-controlled IV infusion pump. A sample PCA setting for fentanyl is a 50 µg incremental dose with a 10-minute lockout and no basal rate.<sup>17</sup>

### Remifentanyl

Remifentanyl is an even faster-onset, shorter-acting synthetic opioid with no active metabolites; it is metabolized by plasma esterases and is not affected by impaired renal or hepatic function.<sup>18</sup> It should be administered as PCA because of its half-life of only 3 minutes. The ideal dosing regimen has not been determined, but a sample PCA setting might be 0.5 µg/kg boluses every 2 to 3 minutes with no basal rate. Sedation and hypoventilation with oxygen desaturations are more common than with other opioids; therefore respiratory monitoring is required. Placental transfer occurs, but in the neonate it appears to be rapidly metabolized or redistributed.

### Sedatives

**Sedatives such as barbiturates, phenothiazines, and benzodiazepines do not possess analgesic qualities. All sedatives and hypnotics cross the placenta freely, and except for the benzodiazepines, they have no known antagonists. Sedation is rarely desirable during the childbirth experience.**

Promethazine may actually impair the analgesic efficacy of opioids. In a randomized double-blind trial, women received placebo, metoclopramide, or promethazine as an antiemetic with meperidine analgesia.<sup>24</sup> Analgesia after placebo or metoclopramide was significantly better than that after promethazine as measured by pain scores and need for supplemental analgesics. Metoclopramide 10 mg has also been shown to improve PCA analgesia during second-trimester termination of pregnancy.<sup>25</sup> In two randomized double-blind studies, the group that received metoclopramide (vs. saline) used 54% and 66% less IV morphine.

**Two major disadvantages of benzodiazepines are that they cause undesirable maternal amnesia<sup>26</sup> and may disrupt thermoregulation in newborns, which renders them less able to maintain an appropriate body temperature.<sup>27</sup>** Presumably this can occur with any of the benzodiazepines. As with many drugs, beat-to-beat variability of the FHR can be reduced even with a single IV dose, although these changes do not reflect alterations in the acid-base status of the newborn. Flumazenil, a specific

### BOX 16-1 FACTORS THAT INFLUENCE PLACENTAL TRANSFER FROM MOTHER TO FETUS

#### Drug

- Molecular weight
- Lipid solubility
- Ionization, pH of blood
- Spatial configuration

#### Maternal

- Uptake into bloodstream
- Distribution via circulation

- Lipid membrane: Fick's law of simple diffusion

#### Fetal

- Circulation: ductus venosus, foramen ovale, ductus arteriosus

benzodiazepine antagonist, can reliably reverse benzodiazepine-induced sedation and ventilatory depression.

### Inhaled Nitrous Oxide (N<sub>2</sub>O)

Nitrous oxide, an inhaled anesthetic gas commonly used during general anesthesia and dental care, has been used in many parts of the world for labor analgesia.<sup>28</sup> It is administered in a 50:50 mix with oxygen using a blender device and a mask held by the mother. A one-way valve allows her to inhale nitrous oxide before and during contractions. Patients report that nitrous oxide does not completely relieve pain, but in many women, it diminishes the perception of pain. Nitrous oxide is safe for the mother and the fetus and does not diminish uterine contractility; the main side effects are nausea and dizziness. It can also be used for short painful procedures such as perineal repair or manual removal of the placenta.<sup>29</sup>

### Placental Transfer

**Essentially, all analgesic and anesthetic agents except highly ionized muscle relaxants cross the placenta freely (Box 16-1).**<sup>30</sup> The limited transfer of muscle relaxants such as succinylcholine enables anesthesiologists to use general anesthesia for cesarean delivery without causing fetal paralysis.

**Because the placenta has the properties of a lipid membrane, most drugs and all anesthetic agents cross by simple diffusion.** Thus the amount of drug that crosses the placenta increases as concentrations in the maternal circulation and total area of the placenta increase. **Diffusion is also affected by the properties of the drug itself, including molecular weight, spatial configuration, degree of ionization, lipid solubility, and protein binding.** For example, bupivacaine is highly protein bound, a characteristic that some believe explains why fetal blood concentrations are so much lower than with other local anesthetics. On the other hand, bupivacaine is also highly lipid soluble. The more lipid soluble a drug is, the more freely it passes through a lipid membrane. Furthermore, once in the fetal system, lipid solubility enables the drug to be taken up by fetal tissues rapidly (i.e., redistribution), which again contributes to the lower blood concentration of the agent.

**The degree of ionization of a drug is also important.** Most drugs exist in both an ionized and nonionized state, and the nonionized form more freely crosses lipid membranes. The degree of ionization is influenced by the pH; this may become relevant when there is a significant pH gradient between the mother (normal pH of 7.40) and an acidotic infant (pH <7.2). For example, local anesthetics are more ionized at a lower pH, so the nonionized portion of the drug in the maternal circulation (normal pH) crosses to the acidotic fetus, becomes ionized, and thus remains in the fetus, potentially leading to higher local anesthetic concentrations in the fetus/newborn. Whether this has relevant adverse clinical effects on the fetus is unknown.

## Neuraxial Analgesic and Anesthetic Techniques

**Neuraxial analgesic and anesthetic techniques—spinal, epidural, or a combination—use local anesthetics to provide sensory blockade, as well as various degrees of motor blockade, over a specific region of the body.** In obstetrics, neuraxial and other regional analgesic techniques include major blocks, such as lumbar epidural and spinal, and minor blocks, such as paracervical, pudendal, and local infiltration (see Fig. 16-1).

### Lumbar Epidural Analgesia/Anesthesia

**Epidural blockade is a neuraxial anesthetic used to provide analgesia during labor or surgical anesthesia for vaginal or cesarean delivery.**<sup>31</sup> Epidural analgesia offers the most effective form of pain relief<sup>32</sup> and is used by the majority of women in the United States.<sup>1</sup> In most obstetric patients, the primary indication for epidural analgesia is the patient's desire for pain relief. Medical indications for epidural analgesia during labor may include anticipated difficult intubation due to morbid obesity or other causes, a history of malignant hyperthermia, selected forms of cardiovascular and respiratory disease, and prevention or treatment of autonomic hyperreflexia in parturients with a high spinal cord lesion. The technique uses a large-bore needle (16, 17, or 18 gauge) to locate the epidural space. Next, a catheter is inserted through the needle, and the needle is removed over the catheter. After aspirating the catheter, a test dose of local anesthetic with a "marker" such as epinephrine may be given first to be certain the catheter has not been unintentionally placed in the subarachnoid (spinal) space or in a blood vessel. Intravascular placement will lead to maternal tachycardia because of the epinephrine, and rapid onset of sensory and motor block will occur if the local anesthetic is injected into the spinal fluid. Once intravascular and intrathecal placement have been ruled out, local anesthetic is injected through the catheter, which remains taped in place to the mother's back to enable subsequent injections throughout labor (Fig. 16-5; see also Fig. 16-1). Thus it is often called *continuous epidural analgesia*. Anesthesiologists also use a technique described as *segmental epidural analgesia* (Fig. 16-6), in which low concentrations of local anesthetic<sup>3</sup> (<0.25% bupivacaine) are injected at L2 to L5 and affect the small, easily blocked sympathetic nerves that mediate early labor pain but spare the sensation of pressure and motor function of the perineum and lower extremities. The patient should be able to move about in bed and perceive the impact of the presenting part on the perineum.

A dilute local anesthetic combined with an opioid such as fentanyl is administered for maintenance of epidural analgesia. Although the administration may be by continuous infusion at a rate of 5 to 15 mL/hr, patient-controlled epidural analgesia

(PCEA) allows for patient-controlled epidural boluses combined with a continuous infusion. More recently, programmed epidural boluses have been combined with patient-controlled boluses as supplements.<sup>33</sup> Patients vary in their responses to local anesthetics, and infusions may need to be adjusted to a lower rate or concentration if the patient develops excessive motor block. If perineal anesthesia is needed for delivery, a larger volume of local anesthetic can be administered at that time through the catheter (see Fig. 16-6). Alternatively, for perineal anesthesia, the obstetrician can perform a pudendal block or provide local infiltration of the perineum.

A variant of the epidural technique involves passing a small-gauge pencil-point spinal needle through the epidural needle before catheter placement. This combined spinal-epidural (CSE) technique provides more rapid onset of analgesia using a very small dose of opioid or a local anesthetic and opioid combination. An RCT in a private practice setting compared CSE and traditional epidural analgesia in 800 term parturients.<sup>34</sup> They found that patients who received CSE had better pain scores during the first stage of labor and required fewer top-ups by the anesthesiologist, an important consideration when anesthesia manpower is limited. Some practitioners have used this technique to allow parturients to ambulate during labor (the "walking epidural") because there is little or no interference with motor function. Because the dose of drug used in the subarachnoid space is much smaller than that used for epidural analgesia, the risks of local anesthetic toxicity or high spinal block are avoided. Side effects of spinal opioids are usually mild and easily treated and include pruritus and nausea.

Nonreassuring fetal heart rate changes may occur more often in patients who receive combined spinal-epidural analgesia than in those who receive epidural analgesia alone.<sup>35</sup> Although the incidence of hypotension is similar between the two techniques, the etiology of fetal bradycardia after spinal analgesia may relate more to uterine hypertonus than to hypotension. Maternal endogenous catecholamines, specifically the  $\beta$ -agonist epinephrine, decrease rapidly with the onset of spinal analgesia. Loss of  $\beta$ -agonist activity may result in uterine hypertonus, especially in the presence of exogenous oxytocin infusions. Fortunately, these nonreassuring FHR changes do not seem to affect labor outcome. In a review of 2380 deliveries in a community hospital, no increase was found in emergency cesarean delivery in the 1240 patients who received neuraxial analgesia for labor (98% of which were CSE) compared with the 1140 patients who received systemic or no medication.<sup>36</sup> A systematic review of randomized comparisons of intrathecal opioid analgesia versus epidural or parenteral opioids in labor found that the use of intrathecal opioids significantly increased the risk of fetal bradycardia (OR, 1.8; 95% CI, 1.0 to 3.1).<sup>37</sup> However, the risk of cesarean delivery for FHR abnormalities was similar in the two groups (6.0% vs. 7.8%). FHR should be monitored during and after the administration of either epidural or intrathecal medications to allow for timely intrauterine resuscitation.<sup>3</sup>

### Complications of Neuraxial Blocks

The Serious Complication Repository Project of the Society of Obstetric Anesthesia and Perinatology (SOAP) reported that high neuraxial block, respiratory arrest in labor and delivery, and unrecognized spinal catheters were the most frequently reported serious complications in more than 257,000 anesthesia procedures over a 5-year study period (Table 16-3).<sup>38</sup> Other side effects of epidural or CSE analgesia include hypotension, local

**FIG 16-5** Technique of lumbar epidural puncture by the midline approach. **A**, This side view shows the left hand held against the patient's back with the thumb and index finger grasping the hub. Attempts to inject solution while the point of the needle is in the interspinous ligament meet resistance. **B**, The point of the needle is in the ligamentum flavum, which offers marked resistance and makes it almost impossible to inject solution. **C**, Entrance of the needle's point into the epidural space is discerned by sudden lack of resistance to injection of saline. Force of injected solution pushes dura-arachnoid away from the point of the needle. **D**, Catheter is introduced through needle. Note that the hub of the needle is pulled caudad toward the patient, increasing the angle between the shaft of the needle and the epidural space. Also note the technique of holding the tubing, which is wound around the right hand. **E**, Needle is withdrawn over the tubing and is held steady with the right hand. **F**, Catheter is immobilized with adhesive tape. Note the large loop made by the catheter to decrease risk of kinking at the point where the tube exits from the skin. (From Bonica JJ. *Obstetric Analgesia and Anesthesia*. Amsterdam: World Federation of Societies of Anesthesiologists; 1980.)

anesthetic toxicity, allergic reaction, neurologic injury, and post-dural puncture headache. In addition, epidural analgesia use may increase the rate of intrapartum fever and can lengthen the second stage of labor. The effect of epidural analgesia on labor progression is discussed in detail below.

Because epidural anesthesia is associated with side effects and complications, some of which are dangerous, those who administer it must be thoroughly familiar not only with the technical

aspects of its administration but also with the signs and symptoms of complications and their treatment. Specifically, the ASA and ACOG have stated: "Persons administering or supervising obstetric anesthesia should be qualified to manage the infrequent but occasionally life-threatening complications of major regional anesthesia such as respiratory and cardiovascular failure, toxic local anesthetic convulsions, or vomiting and aspiration. Mastering and retaining the skills and knowledge necessary to manage

**FIG 16-6** Segmental epidural analgesia for labor and delivery. A single catheter is introduced into the epidural space and is advanced so that its tip is at L2. Initially, small volumes of low concentrations of local anesthetic are used to produce segmental analgesia. For the second stage, the analgesia is extended to the sacral segments by injecting a larger amount of the same concentration of local anesthetic with the patient in the semirecumbent position. After internal rotation, a higher concentration of local anesthetic is injected to produce motor block of the sacral segments and thus achieve perineal relaxation and anesthesia. The wedge under the right buttocks causes the uterus to displace to the left. (From Bonica JJ. *Obstetric Analgesia and Anesthesia*. Amsterdam: World Federation of Societies of Anesthesiologists; 1980.)

these complications requires adequate training and frequent application.”<sup>2</sup> The ASA practice guidelines also state that “When a neuraxial technique is chosen, appropriate resources for the treatment of complications (e.g., hypotension, systemic toxicity, high spinal anesthesia) should be available.”<sup>3</sup>

**HYPOTENSION**

*Hypotension* is defined variably but most often as a systolic blood pressure less than 100 mm Hg or a 20% decrease from baseline. It occurs after approximately 10% of spinal or epidural blocks given during labor.<sup>39</sup> Hypotension occurs primarily as a result of the effects of local anesthetic agents on sympathetic fibers, which normally maintain blood vessel tone. Vasodilation results in decreased venous return of blood to the right side of the heart, with subsequent decreased cardiac output and hypotension. A secondary mechanism may be decreased maternal endogenous catecholamines following pain relief. Hypotension threatens the fetus by decreasing uterine blood flow. However, when recognized promptly and treated effectively, few if any untoward effects result in either mother or fetus. Special care should be taken to avoid or promptly treat hypotension, especially when acute or chronic fetal compromise is suspected.

**Treatment of hypotension begins with prophylaxis, which includes IV access for volume expansion and administration of pressors and left uterine displacement to prevent aorto-caval compression by the gravid uterus and to maintain cardiac preload and cardiac output.** Isotonic crystalloid boluses should not contain dextrose because of the association with subsequent neonatal hypoglycemia. Proper treatment of hypotension depends on immediate diagnosis; therefore the individual administering the anesthesia must be present and attentive. **Once diagnosed, hypotension is corrected by increasing the rate of IV fluid infusion and exaggerating left uterine displacement. If these simple measures do not suffice, a vasopressor is indicated.**

The vasopressor of choice has evolved from ephedrine given in 5- to 10-mg doses to phenylephrine in 50- to 100-μg increments. Ephedrine is a mixed α- and β-agonist and was thought to be less likely to compromise uteroplacental perfusion than the pure α-agonists, but ephedrine has been associated with fetal tachycardia. **Recent clinical studies have suggested that phenylephrine may be given to safely treat hypotension during neuraxial anesthesia for cesarean delivery and that it leads to higher umbilical artery pH values in the fetus and results in**

**less maternal nausea and vomiting.** When compared with phenylephrine for treatment of hypotension following neuraxial analgesia in multiple randomized trials, ephedrine was associated with higher degrees of fetal acidosis.<sup>40</sup> The  $\beta$ -agonist action of ephedrine may increase fetal oxygen requirements and can lead to hypoxia in cases of uteroplacental insufficiency. Phenylephrine corrects maternal hypotension, apparently without causing clinically significant uterine artery vasoconstriction or decreased placental perfusion even in extremely high doses. Rather than causing abnormal increases in systemic vascular resistance, these doses may simply return vascular tone to normal after spinal anesthesia. It is also possible that constricting peripheral arteries may preferentially shunt blood to the uterine arteries. The parturient has decreased sensitivity to all vasopressors, and that may also protect the fetus from excessive vasoconstriction. The  $\alpha$ -adrenergic agents, such as methoxamine and phenylephrine, cause reflex bradycardia that may be useful when a parturient is excessively tachycardic in association with hypotension, or if tachycardia associated with ephedrine would be detrimental. Ephedrine may be preferable if the patient's heart rate is below 70 at baseline.

### LOCAL ANESTHETIC TOXICITY

The incidence of systemic local anesthetic toxicity (high blood concentrations of local anesthetic) after obstetric lumbar epidural analgesia is less than 1 in 250,000.<sup>38</sup> Cases of local anesthetic toxicity were absent from the most recent review of the ASA Closed Claims Project database.<sup>41</sup> Toxicity occurs when the local anesthetic is injected into a blood vessel, rather than into the epidural space, or when too much is administered even though injected properly. **These reactions can also occur during placement of pudendal or paracervical blocks. All local anesthetics have maximal recommended doses, and these should not be exceeded.** For example, the maximum recommended dose of lidocaine is 4 mg/kg when used without epinephrine and 7 mg/kg when used with epinephrine. Epinephrine delays and decreases the uptake of local anesthetic into the bloodstream. Package inserts for all local anesthetics contain appropriate dosing information (Table 16-4).

**Local anesthetic reactions have two components, central nervous system (CNS) and cardiovascular.** Usually, the CNS component precedes the cardiovascular component. Prodromal symptoms of the CNS reaction include excitation, bizarre behavior, ringing in the ears, and disorientation. These symptoms may culminate in convulsions, which are usually brief. After the convulsions, cognitive depression follows, manifested by the postictal state. The *cardiovascular component* of the local anesthetic reaction usually begins with hypertension and tachycardia but is soon followed by hypotension, arrhythmias, and in some instances, cardiac arrest. Thus the cardiovascular

component also has excitant and depressant characteristics. Often the CNS component occurs without the more serious cardiovascular component, although bupivacaine may represent an exception to this principle. **Resuscitation of patients who receive an intravascular injection of bupivacaine is extremely challenging, likely owing to the prolonged blocking effect on sodium channels.** Laboratory evidence supports bupivacaine's increased cardiotoxicity over equianalgesic doses of other amide local anesthetics such as ropivacaine and lidocaine.<sup>42</sup> The manufacturers of bupivacaine have recommended that the 0.75% concentration not be used in obstetric patients or for paracervical block. However, use of a more dilute concentration does not guarantee safety; **bupivacaine and all local anesthetics should be administered by slow, incremental injection.**

Adverse events due to local anesthetic toxicity have decreased because of greater emphasis on incremental dosing and use of a test dose, typically one containing 15  $\mu$ g of epinephrine, to exclude unintentional IV or subarachnoid catheter placement. Others have questioned the lack of specificity of test doses during labor and the potential harm to the fetus or hypertensive mother.<sup>43</sup> Intravascular injection of 15  $\mu$ g epinephrine produces maternal tachycardia, which may be difficult to differentiate from that seen during a contraction. Nonreassuring fetal heart tones due to decreased uterine blood flow may also occur after administration of intravascular epinephrine, especially when the fetus is already compromised.

Treatment of a local anesthetic reaction depends on recognizing the signs and symptoms. Prodromal symptoms should trigger the immediate cessation of the injection of local anesthetic. If convulsions have already occurred, treatment is aimed at maintaining proper oxygenation and preventing the patient from harming herself. Convulsions use considerable amounts of oxygen, which results in hypoxia and acidosis. Should the convulsions continue for more than a brief period, small IV doses of propofol (30 to 50 mg) or a benzodiazepine (2 to 5 mg midazolam) are useful. The cardiac and respiratory depressant effects of these agents add to the depressant phase of the local anesthetic reaction; therefore appropriate equipment and personnel must be available to maintain oxygenation and a patent airway and to provide cardiovascular support. Rarely, succinylcholine is needed for paralysis to prevent the muscular activity and to facilitate ventilation and perhaps intubation. In cases of complete cardiac collapse, delivery of the infant may facilitate maternal resuscitation. **IV lipid emulsion may be an effective therapy for cardiotoxic effects of lipid-soluble local anesthetics such as bupivacaine or ropivacaine.**<sup>44</sup> **Intralipid should be available wherever regional anesthesia is provided.**

The SOAP developed a consensus statement on the management of cardiac arrest in pregnancy that aims to improve maternal resuscitation by providing health care providers critical

**TABLE 16-4** MAXIMAL RECOMMENDED DOSES OF COMMON LOCAL ANESTHETICS

| LOCAL ANESTHETIC | WITH EPINEPHRINE* |                 | WITHOUT EPINEPHRINE |                 |
|------------------|-------------------|-----------------|---------------------|-----------------|
|                  | mg/kg             | DOSE (mg/70 kg) | mg/kg               | DOSE (mg/70 kg) |
| Bupivacaine      | 3.0               | 210             | 2.5                 | 175             |
| Chloroprocaine   | 14.0              | 980             | 11.0                | 770             |
| Etidocaine       | 5.5               | 385             | 4.0                 | 300             |
| Lidocaine        | 7.0               | 490             | 4.0                 | 300             |
| Mepivacaine      | —                 | —               | 5.0                 | 350             |
| Tetracaine       | —                 | —               | 1.5                 | 105             |

\*All epinephrine concentrations are 1:200,000.

information relevant to maternal cardiac arrest.<sup>45</sup> The document includes key cognitive and technical interventions to be undertaken that include immediate basic life support (BLS) and calls for help, chest compressions monitored by capnography if possible, manual left uterine displacement while supine on a backboard, defibrillation, airway management and ventilation, IV access to administer drugs per current advanced cardiovascular life support (ACLS) guidelines, and perimortem cesarean or operative vaginal delivery. Delivery should be performed as soon as possible, striving to make the skin incision for cesarean delivery at 4 minutes after the start of cardiac arrest.

### ALLERGY TO LOCAL ANESTHETICS

The two classes of local anesthetics are *amides* and *esters*. **A true allergic reaction to an amide-type local anesthetic (e.g., lidocaine, bupivacaine, ropivacaine) is extremely rare. Allergic reactions to the esters (2-chloroprocaine, procaine, tetracaine) are also uncommon but can occur** and are often associated with a reaction to para-aminobenzoic acid (PABA) in skin creams or suntan lotions. When a patient reports that she is “allergic” to local anesthetics, she is frequently referring to a normal reaction to the epinephrine that is occasionally added to local anesthetics, particularly by dentists. Epinephrine can cause increased heart rate, pounding in the ears, and nausea—symptoms that may be interpreted as an allergic reaction. Therefore it is important to document the situation in which the reaction occurred.

### HIGH SPINAL OR “TOTAL SPINAL” ANESTHESIA

**This complication occurs when the level of anesthesia rises dangerously high and results in paralysis of the respiratory muscles, including the diaphragm (C3-C5).** The incidence of total spinal anesthesia after neuraxial blocks is 1 in 4336 (see Table 16-3).<sup>38</sup> This is the most frequent complication encountered secondary to spinal or epidural anesthesia. Total spinal anesthesia can result from a miscalculated dose of drug or unintentional subarachnoid injection during an epidural block. The ASA Closed Claims Project analysis of obstetric anesthesia liability claims found that the most common cause of maternal death or brain damage in neuraxial anesthesia claims was high block; 80% were associated with dosing epidural anesthesia and 20% involved spinal anesthesia.<sup>41</sup> The accessory muscles of respiration are paralyzed earlier, and their paralysis may result in apprehension and anxiety and a feeling of dyspnea. The patient usually can breathe adequately as long as the diaphragm is not paralyzed, but treatment must be individualized. Dyspnea, real or imagined, should always be considered an effect of paralysis until proved otherwise. Cardiovascular effects, including hypotension and even cardiovascular collapse, may accompany total spinal anesthesia.

Treatment of total spinal anesthesia includes rapidly assessing the true level of anesthesia; therefore individuals who administer major regional anesthesia should be thoroughly familiar with dermatome charts (Fig. 16-7) and should also be able to recognize what a certain sensory level of anesthesia means with regard to innervation of other organs or systems. For example, a T4 sensory level may represent total sympathetic nervous system blockade. **Numbness and weakness of the fingers and hands indicates that the anesthesia has reached the cervical level (C6-C8), which is dangerously close to the innervation of the diaphragm.** If the diaphragm is not paralyzed, the patient is breathing adequately, and cardiovascular stability is maintained,

administration of oxygen and reassurance may suffice. If the patient remains anxious or if the level of anesthesia seems to involve the diaphragm, assisted ventilation is indicated, and endotracheal intubation will be necessary to protect the airway. In addition, cardiovascular support is provided as necessary. Delay in treatment due to inadequate monitoring, absence of the anesthesia provider, lack of airway equipment or emergency drugs in the labor room, or delay in resuscitation during transfer of the patient to the operating room for delivery will worsen outcome.<sup>46</sup> With prompt and adequate treatment, serious sequelae should be extremely rare.

### NERVE INJURY

Paralysis after either epidural or spinal anesthesia is extremely rare; even minor injuries such as foot-drop and segmental loss of sensation are uncommon. **However, the ASA Closed Claim Project analysis of liability claims notes that the incidence of claims for nerve injury has increased in their most recent review and is now the most common cause of liability in obstetric anesthesia.**<sup>41</sup> Serious neurologic injury occurs with an incidence of 1 in 35,923 (see Table 16-3).<sup>38</sup> Most postpartum neurologic complications are caused by nerve compression during delivery, and both anesthesiologists and obstetricians should be able to recognize common manifestations of these neuropathies.<sup>47</sup> With commercially prepared drugs, ampules, and disposable needles, infection and caustic injury rarely occur. **When nerve damage follows neuraxial analgesia during obstetric or surgical procedures, the anesthetic technique must be suspected, although causation is rare. Other potential etiologies include incorrectly positioned stirrups, difficult forceps applications, or abnormal fetal presentations.** During abdominal procedures, overzealous or prolonged application of pressure with retractors on sensitive nerve tissues may also result in injury. Fortunately, most neurologic deficits after labor and delivery are minor and transient; however, if they are prolonged or worsen, consultation with a neurologist or neurosurgeon should be considered.

**A systematic review of serious adverse events among 1.37 million women who received epidural analgesia during labor found the risks of epidural hematoma and epidural abscess were 1 case per 168,000 women and 1 per 145,000 respectively.**<sup>48</sup> The risk of persistent neurologic injury was one case per 240,000 women, and the risk of transient neurologic injury was one per 6700. In contrast, the SOAP Serious Complication Registry found the incidence of anesthesia-related epidural hematoma was 1 in 251,463 and the incidence of epidural abscess or meningitis was 1 in 62,866 (see Table 16-3).<sup>38</sup> One of the more dramatic and correctable forms of nerve damage follows compression of the spinal cord by a hematoma that has formed during the administration of spinal or epidural anesthesia, presumably from accidental puncture of an epidural vessel. If the condition is diagnosed early, usually with the aid of a neurologist or neurosurgeon, the hematoma can be removed by laminectomy and the problem will resolve without permanent damage. Fortunately, this is a rare complication. Nonetheless, spinal and epidural blocks are contraindicated if the patient has a coagulopathy or is pharmacologically anticoagulated. Hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome may be a particularly strong risk factor because of multifactorial sources for coagulation defects.<sup>49</sup> Any significant motor or sensory deficit after neuraxial anesthesia should be investigated immediately and thoroughly (see Fig. 16-7).

FIG 16-7 Dermatome chart. (Modified from Haymaker L, Woodhall B. *Peripheral Nerve Injuries*. Philadelphia: WB Saunders; 1945.)

Although the incidence of neuraxial infection such as spinal meningitis or epidural abscess is rare, when it occurs it is an important cause of significant maternal morbidity and mortality. In 2009, the Centers for Disease Control and Prevention (CDC) reviewed five cases of bacterial meningitis linked to intrapartum spinal anesthesia in which one woman died.<sup>50</sup> A common denominator in these cases was that either the anesthesiologist who performed the block or visitors in the room were not wearing masks. **Both the American Society of Regional Anesthesia (ASRA) and the ASA have published guidelines on prevention of infection during neuraxial anesthesia that include recommendations to remove jewelry, wash hands, wear a fresh face mask, and disinfect the patient's back using 2% chlorhexadine in alcohol.**<sup>51,52</sup>

### SPINAL HEADACHE

**Spinal headache rarely follows uncomplicated spinal anesthesia but usually occurs when, during the process of administering an epidural block, the dura is punctured with a large-bore needle ("wet tap").** The incidence of this complication varies between 1% and 3%, and its occurrence depends on the experience of the person performing the epidural block.<sup>53</sup> The risk of postdural puncture headache following CSE is

no different than that with epidural analgesia alone, approximately 1.5%.

Once a wet tap occurs, a spinal headache results in as many as 70% of patients. The incidence is much less following spinal anesthesia, because smaller atraumatic (pencil-point) needles are used. **Characteristically, a spinal headache is more severe in the upright position and is relieved by the supine position. A differential diagnosis should include migraine, pneumocephalus from the loss of resistance to air technique, infection, cortical vein thrombosis, preeclampsia, and intracerebral or subarachnoid hemorrhage.**<sup>54</sup> All epidurals are placed using a loss of resistance technique. The loss of resistance can be discerned with either air or saline in the syringe (see Fig. 16-8, A). A spinal headache is thought to be caused by loss of cerebrospinal fluid, which causes the brain to settle and thus causes the meninges and vessels to stretch. Hydration, bed rest, abdominal binders, and the prone position have all been advocated as prophylactic measures after known dural puncture. However, most anesthesiologists now agree that these actions are of little value.<sup>55</sup>

When a patient develops a postdural puncture headache (PDPH), she should be counseled about the cause and potential treatment options, which range from conservative to aggressive. Close follow-up, reassurance, and treatment if required is

important, because although not dangerous, headache is a common cause of a lawsuit in obstetric anesthesia.<sup>41</sup> If the headache is mild and interferes minimally with activity, treatment may be initiated with oral analgesics and caffeine, which is a cerebral vasoconstrictor that may provide symptomatic relief.<sup>55</sup> If simple measures prove ineffective, an epidural blood patch should be considered. Approximately 20 mL of the patient's own blood is placed aseptically into the epidural space to provide a tamponade effect that may result in immediate relief. It may also coagulate over the dural hole and prevent further cerebrospinal fluid leakage. Patients can be released within an hour and should be instructed to avoid coughing or straining for the first day after insertion of the blood patch. **The epidural blood patch has been found to be remarkably effective and nearly complication free, despite the fact that it is an iatrogenic epidural hematoma.** Prophylactic epidural blood patches inserted through the epidural catheter immediately after delivery are not effective in preventing headaches. A preventive measure that may be effective is passing the epidural catheter through the dural hole at the time of the wet tap to provide continuous spinal anesthesia, with removal of the catheter 24 hours after delivery.<sup>56</sup>

### BACK PAIN

Back pain is a common peripartum complaint and is a common concern for women considering neuraxial anesthesia for their delivery. An antepartum survey of pregnant patients before their delivery and before any use of neuraxial anesthesia found that 69% of patients reported back pain, 58% reported sleep disturbances due to back pain, 57% said the pain impaired activities of daily living, and 30% had stopped at least one daily activity because of pain.<sup>57</sup> Only 32% informed their obstetric providers they had back pain, and only 25% of those providers recommended treatment. **Despite concerns that using neuraxial anesthesia contributes to back pain, postpartum surveys indicate that the incidence of back pain after childbirth is the same whether women had neuraxial analgesia for their delivery or not, approximately 40% to 50% at 2 and 6 months postpartum.**<sup>58,59</sup> Despite these reassuring findings, liability for back pain claims is increasing for obstetric anesthesiologists.<sup>41</sup>

### BREASTFEEDING ISSUES

Breastfeeding has been recognized as an important public health initiative because of the short- and long-term advantages for mothers and newborns. The Joint Commission has introduced obstetric quality indicators (e.g., breastfeeding) that set expectations for minimum performance on accountability measures for delivery of perinatal care.<sup>60</sup> Some patients and providers are concerned that neuraxial analgesia may hinder the newborn's ability to breastfeed effectively.<sup>61</sup> Observational studies that show an association between difficult breastfeeding and anesthetic use during labor do not account for obstetric events such as prolonged labor or operative delivery, factors that can cause difficulty with early breastfeeding. **Factors that contribute to successful breastfeeding include lactation consultation services, maternal motivation, and support from obstetricians and pediatricians.**<sup>62</sup>

No randomized trials have compared breastfeeding outcomes in patients who received epidural analgesia to those who received no medication.<sup>62</sup> Large doses of epidural fentanyl (>150 µg) given during the course of labor may interfere with early breastfeeding success; thus high concentrations and boluses should

be avoided.<sup>63</sup> Not surprisingly, women treated with epidural analgesia for postoperative pain control after cesarean delivery are more successful at breastfeeding than those treated with systemic opioids.<sup>64</sup> Infants of women treated with intravenous PCA after cesarean delivery were less alert and had more neonatal neurobehavioral depression after meperidine than after morphine, probably because of meperidine's active metabolites; presumably, IV opioids administered during labor would have the same effect.

### Effects on Labor and Method of Delivery

In the past, significant controversy surrounded how to appropriately counsel patients regarding the effect of neuraxial analgesia on their labor course and risk of cesarean delivery. **The most recent opinion on this subject from the ACOG states that "Neuraxial techniques are the most effective and least depressant treatments for labor pain. [We] previously recommended that practitioners delay initiating epidural analgesia in nulliparous women until the cervical dilatation reached 4-5 cm. However, more recent studies have shown that epidural analgesia does not increase the risks of cesarean delivery. The fear of unnecessary cesarean delivery should not influence the method of pain relief that women can choose during labor."**<sup>65</sup>

The impact of neuraxial analgesia on cesarean delivery rates has been one of the most important labor and delivery outcomes studied over the last several decades. Multiple studies have evaluated this outcome in an attempt to identify factors associated with cesarean delivery. **Although older observational studies suggested an increased risk of cesarean delivery associated with neuraxial analgesia, evidence from recent RCTs now supports the use of neuraxial analgesia without a significant increase in cesarean delivery rates.** A Cochrane Review<sup>66</sup> assessed the effects of all modalities of neuraxial analgesia, including CSE, on obstetric outcome when compared with non-epidural or no pain relief during labor. Twenty-one RCTs that involved 6664 women were included, and all the studies except one compared epidural analgesia with opiates. The authors concluded that epidural analgesia was effective in reducing pain during labor without evidence of a significant difference in the risk of cesarean delivery (relative risk [RR], 1.07; 95% CI, 0.93 to 1.23; 20 trials, 6534 women).<sup>66</sup>

Other studies<sup>67-69</sup> of early labor versus late initiation of neuraxial analgesia further support the ACOG committee opinion that states no increase in cesarean delivery rate results when epidural analgesia is initiated early in labor (<4 cm dilated). A Cochrane Review on early versus late initiation of epidural analgesia for labor concluded that quality evidence suggests early and late initiation of epidural analgesia for labor have similar effects on all measured outcomes.<sup>70</sup>

### STUDY DESIGN

Multiple prospective randomized studies of epidural analgesia have been performed both in nulliparous populations and in mixed populations. However, the poor quality of analgesia provided by systemic opioids typically leads to high rates of crossover of control patients into the epidural analgesia arm. Neither intent-to-treat analysis nor actual-use analysis are entirely satisfactory in this situation. Studies with the lowest crossover rates have accomplished their goal through the use of substantial doses of parenteral opioids, which has resulted in higher than expected rates of neonatal resuscitation in the opioid groups.<sup>19,21</sup> Nonrandomized studies provide interesting observational data;

however, careful analysis of potential confounders is critical because patients who self-select epidural analgesia are clearly different from patients who avoid it. Of concern, randomized studies are often conducted in academic centers where operative delivery rates in low-risk patients may be significantly different than in community hospitals. Finally, neuraxial analgesia techniques vary, and modifications in technique occur continuously. More modern techniques use lower concentrations of local anesthetic and titrate the dose to the specific needs of the patient, potentially lowering the risk of operative delivery.<sup>3</sup>

### PROGRESS OF LABOR AND CESAREAN DELIVERY RATE

**Management of epidural analgesia and timing of administration should be individualized to the patient's needs and level of pain.** Attention should be focused on minimizing local anesthetic concentrations while still providing adequate pain control and avoiding administration of epidural analgesia until the obstetrician is committed to delivery. A concern has been a possible dose-response effect—that is, more dense analgesia could result in an increased cesarean delivery rate. Several RCTs have evaluated traditional epidural analgesia with 0.25% bupivacaine compared with low-dose bupivacaine/fentanyl epidural techniques and have found no differences in the rate of cesarean delivery.<sup>71</sup> **Although epidural analgesia does not increase the risk of cesarean delivery, management of neuraxial analgesia should be individualized to the patient's needs and level of pain with a focus on minimizing local anesthetic concentrations and motor block while still providing adequate pain control.**

The potential for prolonged labor, increased oxytocin use, and increased risk of instrumental delivery have been additional considerations for clinicians and their patients who receive neuraxial analgesia. Although the relative risk of oxytocin treatment after initiation of epidural analgesia varies considerably depending on obstetric practice (i.e., rates of induction and active management of labor), systematic reviews<sup>66,72</sup> that have evaluated this outcome demonstrate that **epidural analgesia is associated with a significant increase in the use of oxytocin after the initiation of epidural analgesia.** Epidural analgesia also exerts some effect on the length of active labor. **Although neuraxial analgesia may shorten first-stage labor in some women and lengthen it in others, there is little doubt that effective neuraxial analgesia prolongs the second stage of labor by 15 to 30 minutes.**<sup>72</sup> However, when asked their preferences, women prefer a lower intensity and longer duration of pain during labor to higher intensity, shorter duration labor pain.<sup>73</sup> Although few obstetricians in the past would allow the second stage to continue for more than 2 hours, most agree that a delay in the second stage does not adversely affect maternal or neonatal outcome provided (1) electronic fetal monitoring confirms reassuring fetal status, (2) maternal hydration and analgesia are adequate, and (3) progress is ongoing in the descent of the fetal head. A retrospective study of 42,268 women, half of whom had epidural analgesia, found that both nulliparous and multiparous women who had epidural analgesia had longer second stages of labor.<sup>74</sup> However the 95<sup>th</sup> percentile threshold for second-stage labor was more than 2 hours longer in women with epidural analgesia compared with women who did not receive epidural analgesia. Adopting this longer time period might prevent some unnecessary interventions. ACOG has stated that if progress is being made, the duration of the second stage alone does not mandate intervention. In such cases, **potential strategies for decreasing the risk of instrument-assisted delivery include**

**reduced density of neuraxial analgesia during the second stage, delayed pushing, and avoiding arbitrary definitions of a prolonged second stage.**

Any analysis of the relationship between neuraxial analgesia and instrument-assisted vaginal delivery is complicated by the strong influence of obstetric practice and the obstetrician's attitude toward operative vaginal delivery. Also, obstetricians may be more likely to perform elective instrument-assisted delivery in patients with effective analgesia. Three systematic reviews have evaluated the effect of neuraxial analgesia on mode of vaginal delivery.<sup>71,72,75</sup> These trials included nearly 10,000 patients, and the results suggested that epidural analgesia was associated with an increased risk of instrumented vaginal delivery. However, operator bias is an important consideration. In clinical practice, indications vary widely among obstetricians, and it is often difficult to distinguish between *indicated* and *elective* instrumented deliveries. Although most obstetricians are more likely to perform such deliveries in women with adequate pain relief, another factor that affects the rate of instrumented vaginal deliveries is whether these deliveries are conducted in teaching institutions. Such deliveries are more likely to be performed in patients with adequate analgesia for the purposes of teaching; residents in obstetrics need to perform a minimum number of instrumented vaginal deliveries to graduate from training. Minimizing the risk of instrumented vaginal delivery while maximizing analgesia requires attention by the anesthesiologist to the individual needs of the patient. Modern neuraxial techniques use lower concentrations of local anesthetic and a titrated dose, factors that likely contribute to lowering the risk of operative delivery in such patients.

**In a given population, the risk of cesarean delivery may vary depending on the patient population, obstetric management, protocols for oxytocin augmentation, the obstetric provider, patient attitudes toward cesarean delivery, and provider comfort with instrument-assisted vaginal delivery as well as additional risk factors. Neuraxial analgesia alone does not increase the risk of cesarean delivery.**

### FEVER

**Epidural analgesia during labor is associated with an increase in maternal temperature compared with women who receive no analgesia or systemic opioids alone.**<sup>76</sup> In a well-designed study with a low crossover rate (6%), Sharma and colleagues<sup>75</sup> reported a 33% rate of intrapartum fever greater than 37.5°C in nulliparous patients randomized to epidural analgesia compared with 7% in those who received parenteral opioids. The more than fourfold increased risk of fever occurred despite relatively minor prolongations in the mean duration of labor (50 minutes). Similarly, Yancey and colleagues<sup>77</sup> also described an eighteenfold increase in the rate of intrapartum fever in nulliparous patients (from 0.6% to 11%) in a single year following the introduction of an epidural analgesia service in their hospital.

**The etiology of this febrile response is not well understood; possible mechanisms include noninfectious inflammatory activation, changes in thermoregulation, and acquired intrapartum infection.** Intrapartum fever after epidural analgesia is associated with increased serum levels of inflammatory cytokines in the mother and fetus, but no mechanism in which epidural blockade might cause inflammation has been elucidated. Thermoregulation may be altered because epidural analgesia leads to decreased sweating (by providing sympathetic blockade) and less hyperventilation after relief of pain in labor. Both sweating and hyperventilation would otherwise provide

heat dissipation. **No study has found an increased rate of infection associated with epidural analgesia for labor.**

Acetaminophen, the standard therapy used to ameliorate hyperthermia, is not effective in preventing fever secondary to epidural analgesia. High-dose maternal corticosteroids given to parturients with epidural analgesia blocks the febrile response but also substantially increases the risk of bacteremia in exposed babies.<sup>78</sup> A randomized trial of prophylactic cefoxitin versus placebo did not prevent fever in nulliparous women who requested epidural analgesia.<sup>79</sup>

Despite the lack of infectious morbidity, intrapartum exposure to hyperthermia may not be benign for the neonate. A retrospective review of low-risk women who received epidural analgesia found maternal temperature greater than 99.5°F was associated with adverse neonatal outcomes such as hypotonia, assisted ventilation, low Apgar scores, and early-onset seizures.<sup>80</sup> Without temperature elevation, epidural use was not associated with adverse neonatal outcomes, but the rate of adverse outcomes increased directly with maximum maternal temperature. An animal study indicates that the presence of hyperthermia during an ischemic event increases susceptibility to hypoxic-ischemic insult.<sup>81</sup> Although the absolute risk is low, maternal temperature greater than 38°C is associated with 9.3-fold increased risk of cerebral palsy in term infants (95% CI, 2.7 to 31). **It is important to clarify that no evidence suggests that epidural analgesia is associated with infection, encephalopathy, or cerebral palsy.** Active cooling measures such as decreasing room temperature, removing blankets from the mother, and use of cool IV fluids should be used for all febrile parturients.

### Paracervical Block

Paracervical block analgesia is a simple and effective procedure when performed properly (see Table 16-1). Commonly, 5 to 6 mL of a dilute solution of local anesthetic without epinephrine (e.g., 1% lidocaine or 1% or 2% 2-chloroprocaine) is injected into the mucosa of the cervix at the 3 and 9 o'clock positions (Fig. 16-8). The duration of analgesia depends on the local anesthetic used. This technique has fallen out of favor owing to its association with the fetal bradycardia that follows in 2% to 70% of applications. Occurring within 2 to 10 minutes and persisting from 3 to 30 minutes, these bradycardias are usually benign; however, cases of fetal acidosis and death have been reported. A significant decrease in pH and a rise in base deficit occur only in those fetuses with bradycardia that persists more than 10 minutes.<sup>82</sup> **Although no consensus has been reached regarding the mechanism of paracervical block bradycardia, this block should be used cautiously at all times and should not be used at all in the presence of nonreassuring fetal heart rate monitoring or suspected uteroplacental insufficiency.**

### ANESTHESIA FOR INSTRUMENTED VAGINAL DELIVERY OR PERINEAL REPAIR

The goal of pain relief for vaginal delivery is to match the patient's wishes with the requirements of the delivery without subjecting either mother or fetus to unnecessary risk.

#### Local Anesthesia

**In the form of perineal infiltration, local anesthesia is widely used and very safe. Spontaneous vaginal delivery, episiotomy, and perhaps outlet vacuum deliveries can be accomplished**

**FIG 16-8** Technique of paracervical block. Schematic coronal section (enlarged) of lower portion of cervix and upper portion of vagina shows relation of needle to paracervical region. (Modified from Bonica JJ. *Principles and Practice of Obstetric Analgesia and Anesthesia*. Philadelphia: FA Davis; 1967:234.)

**TABLE 16-5**

**LIDOCAINE CONCENTRATIONS IN MATERNAL PLASMA AND UMBILICAL CORD VEIN AT DELIVERY AFTER PERINEAL INFILTRATION**

| SAMPLE (N = 15)       | CONCENTRATION (ng/mL) |           |
|-----------------------|-----------------------|-----------|
|                       | MEAN ± SD             | RANGE     |
| Maternal plasma       |                       |           |
| Peak concentration    | 648 ± 666             | 60-2400   |
| At delivery           | 548 ± 468             | 33-1474   |
| Umbilical cord vein   | 420 ± 406             | 45-1380   |
| Fetal/maternal ratio* | 1.32 ± 1.46           | 0.05-4.66 |

From Philipson EH, Kuhnert BR, Syracuse CD. Maternal, fetal, and neonatal lidocaine levels following local perineal infiltration. *Am J Obstet Gynecol*. 1984;149:403.

\*Ratio of level in cord vein to level in maternal vein at delivery (mean of individual ratios, not ratio of means).

SD, standard deviation.

**with this simple technique.** Local anesthetic toxicity may occur if large amounts of local anesthetic are used or if an inadvertent intravascular injection occurs. Usually, 5 to 15 mL of 1% lidocaine suffices. Rapid and significant transfer of lidocaine to the fetus occurs after perineal infiltration. The concentration of lidocaine at delivery was greater in the umbilical vein than in the mother in 5 of 15 infants (Table 16-5).

#### Pudendal Nerve Block

Pudendal nerve block is a minor regional block that is also reasonably effective and very safe. Using an Iowa trumpet and a 20-gauge needle, the obstetrician injects 5 to 10 mL of local

anesthetic just below the ischial spine. Because the hemorrhoidal nerve may be aberrant in 50% of patients, some physicians prefer to inject a portion of the local anesthetic somewhat posterior to the spine (Fig. 16-9). Although a transperineal approach to the ischial spine is possible, most prefer the transvaginal approach, for which 1% lidocaine or 2% 2-chloroprocaine can be used.

Pudendal block is generally satisfactory for all spontaneous vaginal deliveries and episiotomies and for some outlet or low operative vaginal deliveries, but it may not be sufficient for deliveries that require additional manipulation. **The potential for local anesthetic toxicity is higher with pudendal block, compared with perineal infiltration, because of large vessels proximal to the injection site** (see Fig. 16-9). Therefore aspiration of the needle before injection is particularly important. When perineal and labial infiltration are required in addition to pudendal block, it is critically important to closely monitor the total amount of local anesthetic given.

### Monitored Anesthesia Care With Sedation

**For urgent or unanticipated instrumented deliveries, an anesthesiologist, anesthesiologist assistant, or nurse anesthetist may administer nitrous oxide or IV analgesia while maintaining protective laryngeal and cough reflexes. The obstetrician should add local infiltration or a pudendal block.** The combined effects are additive and are satisfactory for most operative vaginal deliveries, shoulder dystocias, and head entrapments. The anesthesiologist frequently questions the patient to determine the level of anesthesia and to ensure that deeper planes of anesthesia are avoided. Such precautions are important because if the patient becomes unconscious, all of the hazards associated with general anesthesia are possible, including airway obstruction, hypoxia, and aspiration. Because continual assessment of the patient's state of consciousness is required and is sometimes difficult, only anesthesiologists, anesthesiologist assistants, or nurse anesthetists should administer inhalation analgesia. Furthermore, in the United States, this technique may require use of the anesthesia machine, misuse of which can prove disastrous. The anesthesiologist may use 50% nitrous oxide or, for IV analgesia, ketamine 0.25 to 0.5 mg/kg. This latter agent may be particularly effective in the labor room when an anesthesia machine is not available or for the patient who cannot or will not tolerate an anesthetic face mask. Inhalation or IV analgesia renders some patients amnesic of the event, which may be undesirable for the mother.

### Spinal (Subarachnoid) Block

**A saddle block is a spinal block in which the level of anesthesia is limited to little more than the perineum.** Spinal anesthesia is reasonably easy to perform and usually provides total pain relief in the blocked area; therefore spontaneous

and forceps deliveries, perineal repairs, and more complicated deliveries can all be accomplished without pain for the mother. The patient's ability to push may be compromised somewhat by diminished motor strength and significant sensory block. Left uterine displacement should be maintained after the local anesthetic has been injected to maintain venous return and prevent excess hypotension.

Other techniques such as initiation of epidural anesthesia (assuming it is not already in place for labor analgesia) or general anesthesia are rarely if ever used in modern practice.

## ANESTHESIA FOR CESAREAN DELIVERY

**In the United States, general anesthesia is used for about 10% of cesarean births (depending on the size of the hospital), and spinal, epidural, or CSE anesthetics are used for approximately 90% of these deliveries** (Table 16-6).<sup>1</sup> Local anesthesia for cesarean delivery is possible but is rarely used or taught anymore. Although neuraxial anesthesia may have benefits for the mother, neuraxial or general anesthesia results in similar fetal outcomes as ascertained by Apgar scores and blood gas measurements (Table 16-7).

### Premedication

Premedication using sedative or opioid agents is usually omitted because these agents cross the placenta and can depress the newborn. Sedation should be unnecessary if the procedure is explained well and the patient is reassured.

### Aspiration and Aspiration Prophylaxis

Aspiration is a serious and potentially fatal complication of general anesthesia and therefore deserves specific attention. When aspiration does occur, the consequences are worse if gastric volume is high and if the acidity of the aspirate is low. Pregnant patients are at higher risk for aspiration because the enlarged uterus increases intraabdominal pressure and thus intragastric pressure; the gastroesophageal sphincter is distorted by the enlarged uterus, making it less competent and possibly explaining the high incidence of heartburn that occurs during pregnancy. Increased progesterone levels affect smooth muscle, which delays gastric emptying and relaxes the gastroesophageal sphincter. Labor itself delays gastric emptying, primarily when patients have received opioids.<sup>16</sup>

The severity of lung damage and rates of morbidity after aspiration vary and depend on the type of material aspirated. Less acidic aspirates (pH >2.5) fill the alveoli and decrease PaO<sub>2</sub> without a significant destructive or inflammatory effect. Aspirates with a pH of less than 2.5 cause hemorrhage, inflammatory exudates, and edema and result in lower PaO<sub>2</sub>. **Aspiration of partially digested food produces the most severe physiologic and histologic alterations.** PaO<sub>2</sub> decreases more than with any

other type of aspiration, and lung damage is considerably more destructive (Table 16-8).

Although acidic stomach contents can be neutralized safely and effectively with clear antacids or an H<sub>2</sub>-receptor antagonist, antacids cannot ameliorate the risks of aspiration after food intake. Aspiration of partially digested food causes significant hypoxia and lung damage, even at a pH level as high as 5.9. To decrease aspiration risk in cases of unplanned cesarean delivery, oral intake during labor should be limited to modest amounts of clear liquids or ice chips.<sup>3</sup>

**Use of a clear antacid is considered routine for all parturients prior to surgery. Additional aspiration prophylaxis using an H<sub>2</sub>-receptor blocking agent and metoclopramide may be given to parturients with risk factors such as morbid obesity, diabetes mellitus, or a difficult airway or for those who have previously received opioids.** As soon as it is known that the patient requires cesarean delivery, be it with neuraxial or general anesthesia, 30 mL of a clear, nonparticulate antacid—such as 0.3 M sodium citrate, Bicitra (citric acid and sodium citrate), or Alka Seltzer, 2 tablets in 30 mL water—is administered to decrease gastric acidity and ameliorate the consequences of aspiration, should it occur. The chalky white particulate antacids are avoided because they can produce lung damage if aspirated (Fig. 16-10).<sup>83</sup>

### Left Uterine Displacement

As during labor, the uterus may compress the inferior vena cava and the aorta during cesarean delivery, leading to reduced venous return to the heart, reduced cardiac output, and reduced

### BOX 16-2 ADVANTAGES AND DISADVANTAGES OF GENERAL ANESTHESIA FOR CESAREAN DELIVERY

#### Advantages

- Patient does not have to be awake during a major operation.
- General anesthesia provides total pain relief.
- Operating conditions are optimal.
- The mother can be given 100% oxygen if needed.

#### Disadvantages

- Patients will not be awake during cesarean delivery, but there is a small risk of undesirable awareness.
- A slight risk of fetal depression exists immediately after birth.
- Intubation causes hypertension and tachycardia, which may be particularly dangerous in severely preeclamptic patients.
- Intubation can be difficult or impossible.
- Aspiration of stomach contents is possible.

uteroplacental perfusion. **Aortocaval compression is detrimental to both mother and fetus.** The duration of anesthesia has little effect on neonatal acid-base status when left uterine displacement is practiced; however, when patients remain supine, Apgar scores decrease as time of anesthesia increases.<sup>84</sup>

### General Anesthesia

The term *balanced general anesthesia* refers to a combination of various agents—including hypnotic agents to induce sleep, inhalation agents, opioids, and muscle relaxants—as opposed to high concentrations of potent inhalation agents alone. It is preferred for obstetric applications (Box 16-2).

Failure to intubate and aspiration continue to cause anesthesia-related maternal mortality, and as a result, many anesthesiologists, obstetricians, and patients now prefer neuraxial anesthesia over general anesthesia.<sup>1</sup> To understand how these complications may arise, the obstetrician should be aware of the sequence of events during general anesthesia.

### Preoxygenation

**Preoxygenation is especially important in pregnant patients, who have decreased functional residual capacity and are more likely than nonpregnant patients to rapidly become**

**FIG 16-10** Lung after aspiration of particulate antacid. Note marked extensive inflammatory reaction. The alveoli are filled with polymorphonuclear leukocytes and macrophages in approximately equal numbers. Insets at right show large and small intraalveolar particles surrounded by inflammatory cells (48 hours). Later, the reaction changed to an intraalveolar cellular collection of clusters of large macrophages with abundant granular cytoplasm, some of which contained small amphophilic particles similar to those seen in the insets. No fibrosis or other inflammatory reaction was seen (28 days). (From Gibbs CP, Schwartz DJ, Wynne JW, et al. Antacid pulmonary aspiration in the dog. *Anesthesiology*. 1979;51:380.)

**hypoxemic if difficult intubation accompanied by apnea occurs.** Before starting induction, 100% oxygen should be administered through a face mask for 2 to 3 minutes. In situations of dire emergency, four vital-capacity breaths of 100% oxygen through a tight-circle system will provide similar benefit.<sup>85</sup>

### Induction

The anesthesiologist administers a short-acting induction agent to render the patient unconscious. An appropriate dose of any of these agents has little effect on the fetus. **Induction agents that may be used are propofol,<sup>86</sup> etomidate,<sup>87</sup> and ketamine,<sup>88</sup> all of which are rapidly redistributed in both mother and fetus.** Women who receive ketamine for induction require less analgesic medications in the first 24 hours after their cesarean delivery compared with those who received thiopental.<sup>89</sup> Ketamine antagonism of N-methyl-D-aspartate (NMDA) receptors may prevent central hypersensitization and provide preemptive analgesia.

Although obstetricians are often concerned about the *induction-to-delivery interval* (I-D) during general anesthesia, the *uterine incision-to-delivery interval* (U-D) is more predictive of neonatal status.<sup>84,90</sup> With a prolonged I-D interval, there is fetal uptake of the inhaled anesthetic and depressed Apgar scores (i.e., sleepy babies), but fetal acid-base status is normal, and effective ventilation is all that is needed. A prolonged U-D interval greater than 3 minutes leads to depressed Apgar scores with neuraxial or general anesthesia and is associated with elevated fetal umbilical artery norepinephrine concentrations and associated fetal acidosis.<sup>90</sup>

Immediately after the induction agent, the anesthesiologist gives a muscle relaxant to facilitate intubation. Succinylcholine—a rapid-onset, short-acting muscle relaxant—remains the agent of choice in most patients.

During rapid-sequence induction, as the induction agent begins to take effect and the patient approaches unconsciousness, an assistant applies pressure to the cricoid cartilage just below the thyroid cartilage and does not release the pressure until an endotracheal tube is placed, the cuff is inflated, and its position is verified by end-tidal carbon dioxide measurement and bilateral breath sounds. **Pressure on the cricoid compresses the esophagus and is extremely important in preventing aspiration should regurgitation or vomiting occur.** In most instances, aspiration can be prevented by using cricoid pressure at induction of anesthesia.

### Intubation

**In most cases, intubation proceeds smoothly. However, in approximately 1 in 533 obstetric patients, it is difficult, delayed, or impossible.<sup>38</sup>** The incidence of failed intubation in obstetric patients is more common than in patients in the general operating room (1 in 533 in obstetric patients vs. 1 in 2230 in surgical patients).<sup>38,91</sup> When the delay is prolonged or the intubation is impossible, **the critical factors include delivering oxygen to the now unconscious and paralyzed patient and preventing aspiration.** Delay in intubation is associated with escalating aspiration risk; therefore it is particularly important during a difficult intubation that the person applying cricoid pressure not release that pressure until told to do so by the anesthesiologist.

The patient at risk for a difficult or impossible intubation can often be identified before surgery. Examination of the airway is a critical part of the preanesthetic evaluation (Fig. 16-11). The anesthesiologist will assess four factors: (1) the ability to visualize oropharyngeal structures (Mallampati classification<sup>92</sup>); (2) range of motion of the neck; (3) presence of a receding mandible, which indicates the depth of the submandibular space; and (4) whether protruding maxillary incisors are present. It is important to know that airway patency can worsen significantly over the course of labor. One study found significant increases in the Mallampati score and the incidence of class III and class IV airways along with a decrease in oral volume and pharyngeal areas when they compared prelabor and postlabor airway examinations.<sup>93</sup> The worsening airways were unrelated to labor duration or fluid intake. These changes would make endotracheal intubation more difficult; thus a careful airway examination is essential just before administering anesthesia rather than relying on prelabor information. **Obstetricians should be alert to the**

**presence of obesity, severe edema, and anatomic abnormalities of the face, neck, or spine that include those from trauma or surgery, abnormal dentition, difficulty opening the mouth, extremely short stature, short neck or arthritis of the neck, or goiter. When the obstetrician recognizes airway abnormalities, patients should be referred for an early preoperative evaluation by the anesthesiologist.**

Before surgery begins, the anesthesiologist must ensure that the endotracheal tube is properly positioned using capnography and auscultation. The operation should not proceed until the airway is secure because the patient cannot be allowed to awaken after the abdomen is opened.

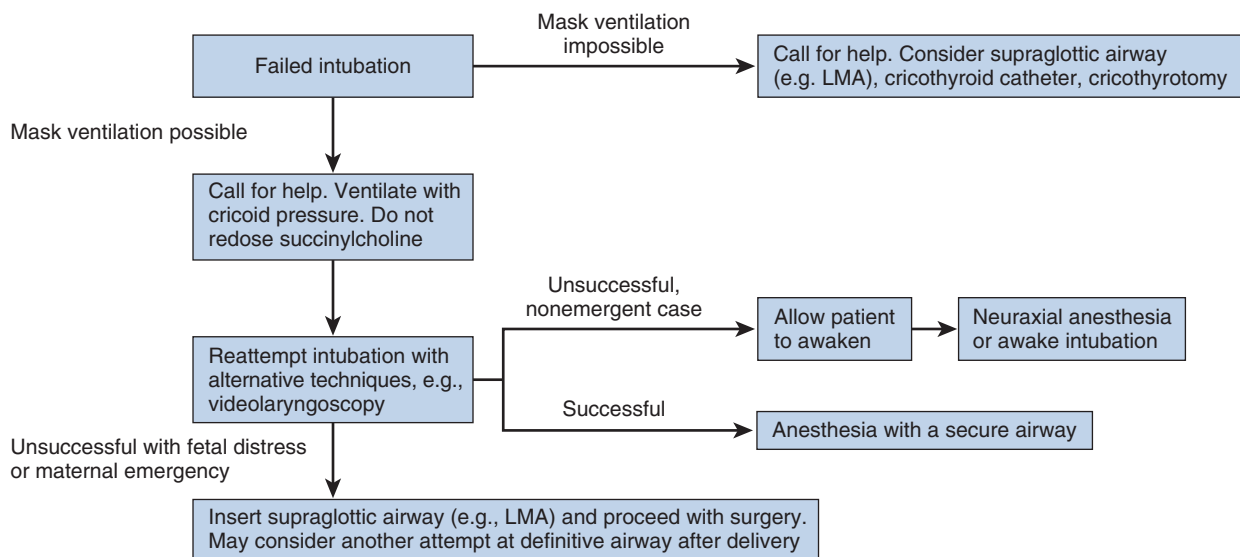

### FAILED INTUBATION

**When intubation cannot be accomplished and cesarean delivery is not urgent, the decision to delay the operation and allow the mother to awaken is easy. However, if the operation is being done because of rapidly worsening fetal condition or maternal hemorrhage, allowing the mother to awaken may further jeopardize the fetus or mother. Rarely, in situations of dire fetal compromise, the anesthesiologist and obstetrician may jointly decide to proceed with cesarean delivery while the anesthesiologist provides oxygenation, ventilation, and anesthesia by face mask ventilation or laryngeal mask airway (LMA), with an additional person maintaining continuous cricoid pressure. In these emergent situations, it may be necessary to have additional trained personnel to provide assistance. After delivery, the obstetrician may need to obtain temporary hemostasis and then halt surgery while the anesthesiologist secures the airway by fiberoptics or other methods.**

An algorithm for management of failed intubation in the obstetric patient is shown in Figure 16-12. Nursing staff should also be familiar with the difficult airway algorithm in case they are called upon to assist during an airway emergency.<sup>94</sup> Videolaryngoscopy is a valuable tool in the emergency setting,<sup>95</sup> and supraglottic devices such as the LMA should always be immediately available for rescue in the case of difficult or failed intubation.<sup>94</sup>

**FIG 16-11** Mallampati airway classifications with corresponding laryngoscopic view of the vocal cords. (Modified from Hughes SC, Levinson G, Rosen MA, eds. *Shnider and Levinson's Anesthesia for Obstetrics*, 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2002.)

**FIG 16-12** An algorithm for the management of failed intubation in the obstetric patient. LMA, laryngeal mask airway.

## Agents

### NITROUS OXIDE AND OXYGEN

Once the endotracheal tube is in place, a 50:50 mixture of nitrous oxide and oxygen—which is safe for both mother and fetus—is usually added to provide analgesia and amnesia.

### VOLATILE HALOGENATED AGENT

In addition to nitrous oxide, a low concentration of a volatile halogenated agent (e.g., isoflurane, sevoflurane, or desflurane) is added to provide maternal amnesia and additional analgesia. In low concentrations, these agents are not harmful to mother or fetus. **Uterine relaxation does not result from low concentrations of these agents, and bleeding should not be increased secondary to their addition. Proceeding without a potent inhalation agent results in an unacceptably high incidence of maternal awareness and recall.** Even with the use of one of these agents, maternal awareness and recall occasionally occur.<sup>96</sup> Therefore it is important that all operating room personnel use discretion in conversation and conduct themselves as if the patient were awake.

### Post Delivery

The concentration of nitrous oxide can be increased after delivery if the mother tolerates a lower inspired concentration of oxygen. In addition, the volatile halogenated agent is continued at a low concentration, and pain relief is supplemented with an opioid such as fentanyl or morphine. Other IV agents such as benzodiazepines may be added to ensure maternal amnesia. Oxytocin is infused intravenously to improve uterine tone; however, large bolus injections are avoided because they can cause a drop in systemic vascular resistance, hypotension, and tachycardia. **Maternal deaths have been reported following IV bolus oxytocin in the setting of hypovolemia or pulmonary hypertension.**<sup>97</sup>

### Extubation

Because the patient can aspirate while awakening and during emergence, extubation is not done until the patient is awake and can respond appropriately to commands. Coughing and bucking do not necessarily indicate that the patient is awake, merely that she is in the second stage—the excitement stage—of anesthesia. It is during this period of anesthesia that laryngospasm is most likely to occur should any foreign body, including the endotracheal tube or bits of stomach contents, stimulate the larynx. **To prevent aspiration, the patient must therefore be awake and conscious, not merely active, before extubation.**

## Neuraxial Anesthesia

**If the fetal status permits and no maternal contraindications exist, neuraxial anesthesia is preferred for cesarean delivery (Box 16-3).**<sup>1</sup> Contraindications to neuraxial anesthesia include hemodynamically significant hemorrhage or sepsis, infection at the site of needle insertion, coagulopathy, increased intracranial pressure caused by a mass lesion, patient refusal, and perhaps some forms of heart disease. Significant ongoing hemorrhage is a firm contraindication to neuraxial anesthesia because the sympathetic blockade overrides compensatory vasoconstriction and potentially precipitates cardiovascular decompensation.

The use of neuraxial anesthesia in patients with fetal compromise depends on the severity of the fetal condition. **If the situation is severe and acute, do not delay delivery to perform a neuraxial technique de novo. Ongoing acute fetal**

### BOX 16-3 ADVANTAGES AND DISADVANTAGES OF NEURAXIAL ANESTHESIA

#### Advantages

- The patient is awake and can participate in the birth of her child.
- There is little risk of drug depression or aspiration and no intubation difficulties.
- Newborns generally have good neurobehavioral scores.
- The father is more likely to be allowed in the operating room.
- Postoperative pain control using neuraxial opioids may be superior to intravenous patient-controlled anesthesia.

#### Disadvantages

- Patients may prefer not to be awake during major surgery.
- A block that provides inadequate anesthesia may result.
- Hypotension, perhaps the most common complication of neuraxial anesthesia, occurs during 25% to 85% of spinal or epidural anesthetics.
- Total spinal anesthesia may occur, which necessitates airway management.
- Local anesthetic toxicity may occur.
- Although extremely rare, permanent neurologic sequelae may occur.
- Several contraindications exist.

**deterioration is usually an indication for general anesthesia.**

However, a history or suspicion of difficult intubation should prompt either awake intubation or neuraxial anesthesia, despite the presence of fetal compromise, because of the risk of maternal death from unsuccessful intubation. Lesser degrees of fetal compromise may permit neuraxial anesthesia. For example, if an epidural catheter has been placed earlier, a partial level of anesthesia already exists, and the patient is hemodynamically stable, extension of epidural anesthesia may be appropriate for cesarean delivery. The anesthesiologist can give additional local anesthetic while the urethral catheter is inserted and the abdomen is prepared and draped. Often, anesthesia will be satisfactory when the surgeon is ready to make the skin incision. If not, the FHR pattern will dictate whether a delay is acceptable. When partial but inadequate epidural anesthesia results, the clinician may consider supplemental infiltration of local anesthetic, but most often general anesthesia will be indicated.

In cases in which the FHR tracing is not critical, de novo spinal or CSE anesthesia may be performed for cesarean delivery. In cases in which extension of existing epidural anesthesia is unsuccessful, spinal anesthesia should be placed with caution because the risk of high spinal anesthesia is increased.<sup>38</sup>

In healthy patients, the choice between epidural, spinal, and CSE anesthesia primarily rests with the anesthesiologist. With the recent availability of small-gauge spinal needles with a pencil-point tip design, the risk of headache is no different after spinal or epidural anesthesia. Most consider spinal block to be easier and quicker to perform, and most believe that the resulting anesthesia will be more solid and complete. Perhaps the most significant advantage of spinal anesthesia is that it requires considerably less local anesthetic, and therefore, the potential for local anesthetic toxicity is reduced. A CSE technique provides the benefits of spinal anesthesia plus the ability to prolong the

anesthetic if needed by dosing the epidural catheter; however, any of these techniques is satisfactory and should provide safe, effective anesthesia for the mother and the fetus.

### Postoperative Care

If spinal or epidural anesthesia was used for cesarean delivery, excellent postoperative analgesia can be obtained by addition of preservative-free morphine to the local anesthetic solution. The more lipid-soluble opioids such as fentanyl or sufentanil are used to improve the quality of intraoperative anesthesia but have a short duration of 2 to 4 hours. They may be used postoperatively in combination with a local anesthetic in a continuous or patient-controlled epidural infusion. In contrast, morphine is hydrophilic, which gives it a prolonged duration of up to 24 hours, and it can be given as a single dose at the time of cesarean delivery. Unfortunately, its water solubility also gives morphine a long onset time and a higher incidence of side effects. The most common side effects of spinal and epidural opioids are itching and nausea; respiratory depression is a rare but serious complication. **Several studies have shown that spinal or epidural opioids provide superior pain relief when compared with parenteral (intramuscular or intravenous PCA) opioids with a trend toward earlier hospital discharge and lower cost.**<sup>3</sup>

If general anesthesia was used, or neuraxial opioids provide inadequate pain control, an intravenous PCA can be used for postoperative pain management. Morphine, hydromorphone, and fentanyl have all been used successfully. When intravenous PCA is used, the pump settings include an incremental dose of 1 to 2 mg morphine, 0.2 to 0.4 mg hydromorphone, or 25 µg fentanyl and a lockout interval of 6 to 10 minutes. Basal rates are rarely necessary for pain control and only increase maternal sedation and side effects. Using PCA provides better patient satisfaction by allowing the patient to control her pain medication.

**The addition of nonsteroidal antiinflammatory drugs (NSAIDs) significantly improves pain scores with neuraxial morphine and reduces use of PCA opioids.**<sup>98</sup> IV ketorolac, rectal indomethacin, or oral ibuprofen can be used depending on the patient's ability to tolerate oral intake. Contraindications for NSAID use include renal insufficiency or low urine output, use of gentamicin or similar drugs with renal toxicity, coagulopathy, and uterine atony. Although the package insert for ketorolac states that it is contraindicated for use in breastfeeding mothers, the American Academy of Pediatrics approves its use while women are breastfeeding. IV or oral acetaminophen should also be used as part of a multimodal analgesic regimen.

In most cases, postoperative care is uneventful in obstetric patients. However, **recent reports suggest that the postoperative period can be an important time for anesthetic-related maternal mortality.** In a state review of maternal deaths in Michigan from 1985 through 2003, 8 of 855 maternal deaths were found to be anesthesia related and occurred during emergence or recovery from general anesthesia.<sup>99</sup> Hypoventilation or airway obstruction occurred in these cases, and obesity and black race were factors associated with these deaths. These cases raise important questions about appropriate postanesthesia care unit (PACU) management after general anesthesia for cesarean delivery and point out the need for additional monitoring in obese patients at risk for obstructive sleep apnea. A recent survey of obstetric anesthesiology directors of North American academic institutions found that 45% of institutions (28 of 62) had no

specific postanesthesia recovery training for nursing staff who provide postcesarean care for patients recovering from neuraxial or general anesthesia.<sup>100</sup> In addition, 43% of respondents (29 of 67) rated the recovery care provided to cesarean delivery patients as lower quality than care given to general surgical patients. Results from this survey suggest that in many cases, the level of care provided for postanesthesia recovery from cesarean delivery may not meet guidelines established by the ASA Task Force on Postanesthetic Care and the American Society of Perianesthesia Nurses. However, the ASA Practice Guidelines for Obstetric Anesthesia<sup>3</sup> emphasize that labor and delivery units should have the same staffing and equipment as surgical operating and recovery rooms to reduce risks associated with emergence after general anesthesia for cesarean delivery and to reduce the risk associated with obesity and obstructive sleep apnea.

### KEY POINTS

- ◆ Analgesia during labor can reduce or prevent potentially adverse stress responses to the pain of labor, including postpartum depression.
- ◆ Parenteral opioids for labor analgesia work primarily by sedation and, except at high doses, result in minimal reduction of maternal pain. Side effects include maternal nausea and respiratory depression in both the mother and newborn. The routine use of promethazine in conjunction with opioids should be avoided.
- ◆ Placental transfer of a drug between mother and fetus is governed by the characteristics of the drug, including its size, lipid solubility, and ionization; maternal blood levels and uterine blood flow; placental circulation; and the fetal circulation.
- ◆ Continuous neuraxial (epidural or spinal) analgesia is the most effective form of intrapartum pain relief currently available and has the flexibility to provide additional anesthesia for spontaneous or instrumented delivery, cesarean delivery, and postoperative pain control.
- ◆ Spinal opioids as part of a CSE technique provide excellent analgesia during much of the first stage of labor, and they decrease or avoid the risks of local anesthetic toxicity, high spinal anesthesia, and motor block. Most patients need additional analgesia with epidural local anesthetics later in labor and during the second stage.
- ◆ Side effects and complications of neuraxial anesthesia include hypotension, local anesthetic toxicity, total spinal anesthesia, neurologic injury, and spinal headache. Personnel who provide anesthesia must be competent and available to treat these problems.
- ◆ Epidural analgesia does not increase the rate of cesarean delivery but may increase oxytocin use and the rate of instrument-assisted vaginal deliveries. The duration of the second stage is increased by 15 to 30 minutes. Maternal-fetal factors and obstetric management are the most important determinants of the cesarean delivery rate.
- ◆ Epidural analgesia is associated with an increased rate of maternal fever during labor, although the mechanism is unknown. This does not alter the rate of documented neonatal sepsis. Other neonatal implications are unclear.

- ◆ General anesthesia is used for less than 5% of elective and roughly 25% of emergent cesarean deliveries. Although safe for the newborn, general anesthesia can be associated with failed intubation and aspiration, causes of anesthesia-related maternal mortality.
- ◆ Aspiration of gastric contents is most detrimental when food particles are present or the pH is less than 2.5; therefore patients should be encouraged not to eat during labor, and acid-neutralizing medications should be used before operative deliveries.
- ◆ The use of neuraxial anesthesia is not absolutely contraindicated in cases of nonreassuring fetal testing; the method of anesthesia should be chosen based on the degree of fetal compromise and maternal safety.

Near term or during labor, the fetus normally assumes a vertical orientation, or *lie*, and a cephalic presentation, with the flexed fetal vertex presenting to the pelvis (Fig. 17-1). However, in about 3% to 5% of singleton gestations at term, an abnormal lie, presentation, or flexed attitude occurs; such deviations constitute fetal malpresentations. **The word *malpresentation* suggests the possibility of adverse consequences, and malpresentation is often associated with increased risk to both the**

**mother and the fetus.** In the early twentieth century, malpresentation often led to a variety of maneuvers intended to facilitate vaginal delivery, including destructive operations leading, predictably, to fetal death. Later, manual or instrumented attempts to convert the malpresenting fetus to a more favorable orientation were devised. Internal podalic version (IPV) followed by a complete breech extraction was once advocated as a solution to many malpresentation situations. However, like with most manipulative efforts to achieve vaginal delivery, IPV was associated with high fetal and maternal morbidity and mortality rates and has been largely abandoned. **In contemporary practice, cesarean delivery has become the recommended mode of delivery in the malpresenting fetus.**

## CLINICAL CIRCUMSTANCES ASSOCIATED WITH MALPRESENTATION

Generally, factors associated with malpresentation include (1) **diminished vertical polarity of the uterine cavity**, (2) **increased or decreased fetal mobility**, (3) **obstructed pelvic inlet**, (4) **fetal malformation**, and (5) **prematurity**. The association of great parity with malpresentation is presumably related to laxity of maternal abdominal musculature and resultant loss of the normal vertical orientation of the uterine cavity. Placentation either high in the fundus or low in the pelvis (Fig. 17-2) is another factor that diminishes the likelihood of a fetus assuming a longitudinal axis. Uterine myomata, intrauterine synechiae, and müllerian duct fusion abnormalities such as a septate uterus or uterine didelphys are similarly associated with a higher than expected rate of malpresentation. Because both prematurity and polyhydramnios permit increased fetal mobility, the probability of a noncephalic presentation is greater if preterm labor or rupture of the membranes occurs. Furthermore, preterm birth involves a fetus that is small relative to the maternal pelvis; therefore engagement and descent with labor or rupture of the membranes can occur despite a malpresentation. In contrast, conditions such as chromosomal aneuploidies, congenital myotonic dystrophy, joint contractures from various

**FIG 17-1** Frontal view of a fetus in a longitudinal lie with fetal vertex flexed on the neck.

**FIG 17-2** Either the high fundal or low implantation of the placenta, as illustrated here, would normally be in the vertical orientation of the intrauterine cavity and increase the probability of a malpresentation.

etiologies, arthrogryposis, oligohydramnios, and fetal neurologic dysfunction that result in decreased fetal muscle tone, strength, or activity are also associated with an increased incidence of fetal malpresentation. Finally, the cephalopelvic disproportion associated with severe fetal hydrocephalus or with a contracted maternal pelvis may be implicated as an etiology of malpresentation because normal engagement of the fetal head is prevented.

### ABNORMAL AXIAL LIE

The fetal *lie* indicates the orientation of the fetal spine relative to the spine of the mother. The normal fetal lie is longitudinal and by itself does not indicate whether the presentation is cephalic or breech. If the fetal spine or long axis crosses that of the mother, the fetus may be said to occupy a *transverse* or *oblique* lie (Fig. 17-3), which may cause an arm, foot, or shoulder to be the presenting part (Fig. 17-4). The lie may be termed *unstable* if the fetal membranes are intact and fetal mobility is increased, which results in frequent changes of lie and/or presentation.

Abnormal fetal lie is diagnosed in approximately 1 in 300 cases, or 0.33% of pregnancies at term. Prematurity is often a factor, with abnormal lie reported to occur in about 2% of pregnancies at 32 weeks' gestation—six times the rate found at term. Persistence of a transverse, oblique, or unstable lie beyond 37 weeks' gestation requires a systematic clinical assessment and a plan for management; this is because rupture of the membranes without a fetal part filling the inlet of the pelvis poses an increased risk of cord prolapse, fetal compromise, and maternal morbidity if neglected.

As noted, great parity, prematurity, contraction or deformity of the maternal pelvis, and abnormal placentation are

**FIG 17-3** A fetus may lie on a longitudinal, oblique, or transverse axis, as illustrated. The lie does not indicate whether the vertex or the breech is closest to the cervix.

**FIG 17-4** This fetus lies in an oblique axis with an arm prolapsing.

the most commonly reported clinical factors associated with abnormal lie; however, it often happens that none of these factors are present. In fact, any condition that alters the normal vertical polarity of the intrauterine cavity will predispose to abnormal lie.

Diagnosis of the abnormal lie may be made by palpation using Leopold maneuvers or by vaginal examination verified by ultrasound. Whereas routine use of Leopold maneuvers may be helpful, Thorp and colleagues<sup>1</sup> found **the sensitivity of Leopold maneuvers for the detection of malpresentation to be only 28%, and the positive predictive value was only 24% compared with immediate ultrasound verification.** Others have observed prenatal detection in as few as 41% of cases before labor. Adaptations have been made to the Leopold maneuvers that may improve detection of an abnormal lie or presentation. The Sharma modified Leopold maneuver and the Sharma right and left lateral maneuvers in the original report<sup>2</sup> demonstrated improved diagnostic accuracy; they detected vertex presenting occipitoanterior (95% vs. 84.4%,  $P = .04$ ), posterior presentations (96.3% vs. 66.6%,  $P = .00012$ ), and breech presentations correctly more often than with traditional Leopold maneuvers. These maneuvers use the forearms in addition to the hands and fingers. As with any abdominal palpation technique, limitations on accuracy are to be expected in the obese patient and in a patient with uterine myomata. **The ready availability of ultrasound in most clinical settings is of benefit, and its use can obviate the vagaries of the abdominal palpation techniques. In all situations, early diagnosis of malpresentation is of benefit.** A reported fetal loss rate of 9.2% with an early diagnosis, versus a loss rate of 27.5% with a delayed diagnosis, indicates that early diagnosis improves fetal outcome.

Reported perinatal mortality rates for unstable or transverse lie (corrected for lethal malformations and extreme prematurity) vary from 3.9% to 24%, with maternal mortality as high as 10%. Maternal deaths are usually related to infection after premature rupture of membranes (PROM), hemorrhage secondary to abnormal placentation, complications of operative

intervention for cephalopelvic disproportion, or traumatic delivery. Fetal loss of phenotypically and chromosomally normal gestations at ages considered to be viable is primarily associated with delayed interventions, prolapsed cord, or traumatic delivery. **Cord prolapse occurs 20 times as often with abnormal lie as it does with a cephalic presentation.**

## MANAGEMENT OF A SINGLETON GESTATION

Safe vaginal delivery of a fetus from an abnormal axial lie is not generally possible. A search for the etiology of the malpresentation is always indicated. A transverse/oblique or unstable lie late in the third trimester necessitates ultrasound examination to exclude a major fetal malformation and abnormal placentation. Fortunately, most cases of major fetal anomalies or abnormal placentation can now be diagnosed long before the third trimester. Phelan and colleagues<sup>3</sup> reported 29 patients with transverse lie diagnosed at or beyond 37 weeks' gestation and managed expectantly, and 83% (24 of 29) spontaneously converted to breech (9 of 24) or vertex (15 of 24) before labor; however, the overall cesarean delivery rate was 45%, with two cases of cord prolapse, one uterine rupture, and one neonatal death. **External cephalic version (ECV) is recommended at 36 to 37 weeks to help diminish the risk of adverse outcome.**

In cases of an abnormal lie, the risk of fetal death varies with the obstetric intervention. Fetal mortality should approach zero for cesarean birth but has been reported to be as high as 10% in older reports and between 25% and 90% when IPV and breech extraction are performed. **ECV has been found to be safe and relatively efficacious<sup>4</sup>** and is further discussed later in this chapter. If external version is unsuccessful or unavailable, if spontaneous rupture of the membranes occurs, or if active labor has begun with an abnormal lie, cesarean delivery is the treatment of choice for the potentially viable infant. There is no place for IPV and breech extraction in the management of transverse or oblique lie or in an unstable presentation in a singleton pregnancy because of the unacceptably high rate of fetal and maternal complications.

A persistent abnormal axial lie, particularly if accompanied by ruptured membranes, also alters the choice of uterine incision at cesarean delivery. **A low transverse (Kerr) uterine incision has many surgical advantages and is generally the preferred approach for cesarean delivery for an abnormal lie** (see Chapter 19). Because up to 25% of transverse incisions may require vertical extension for delivery of an infant from an abnormal lie, and the lower uterine segment is often poorly developed and insufficiently broad such that a traumatic delivery of the presenting part is made more difficult, other uterine incisions may be considered. A "J" or "T" extension of the low transverse incision results in a uterine scar that is more susceptible to subsequent rupture due to poor vascularization. **Therefore in the uncommon case of a transverse or oblique lie with a poorly developed lower uterine segment, when a transverse incision is deemed unfeasible or inadequate, a vertical incision (low vertical or classical) may be a reasonable alternative.** Intraoperative cephalic version may allow the use of a low transverse incision, but ruptured membranes or oligohydramnios may make this difficult. Uterine relaxing agents such as inhalational anesthetics or intravenous (IV) nitroglycerin may improve success of these maneuvers if the difficulty is attributable to a contracted uterine fundus.

## DEFLECTION ATTITUDES

**Attitude** refers to the position of the fetal head in relation to the neck. The normal attitude of the fetal head during labor is one of full flexion with the fetal chin against the upper chest. Deflexed attitudes include various degrees of deflection or even extension of the fetal neck and head (Fig. 17-5), leading to, for example, face or brow presentations. Spontaneous conversion to a more normal, flexed attitude or further extension of an intermediate deflection to a fully extended position commonly occurs as labor progresses owing to resistance exerted by the bony pelvis and soft tissues. **Although safe vaginal delivery is possible in many cases, experience indicates that cesarean**

**FIG 17-5** The normal “attitude” (top) shows the fetal vertex flexed on the neck. Partial deflexion (middle) shows the fetal vertex intermediate between flexion and extension. Full deflexion (lower) shows the fetal vertex completely extended with the face presenting.

delivery may be the most appropriate alternative when arrest of progress is observed.

## FACE PRESENTATION

A face presentation is characterized by a longitudinal lie and full extension of the fetal neck and head with the occiput against the upper back (Fig. 17-6). The fetal chin (mentum) is chosen as the point of designation during vaginal examination. For example, a fetus presenting by the face whose chin is in the right posterior quadrant of the maternal pelvis would be called a *right mentum posterior* (Fig. 17-7). The reported incidence of face presentation ranges from 0.14% to 0.54% and averages about 0.2%, or 1 in 500 live births overall.<sup>5,6</sup> The reported perinatal mortality rate, corrected for nonviable malformations and extreme prematurity, varies from 0.6% to 5% and averages about 2% to 3%.

All clinical factors known to increase the general rate of malpresentation have been implicated in face presentation; many infants with a face presentation have malformations. Anencephaly, for instance, is found in about one third of cases of face presentation. Fetal goiter and tumors of the soft tissues of the head and neck may also cause deflexion of the head. Frequently observed maternal factors include a contracted pelvis or cephalopelvic disproportion in 10% to 40% of cases. In a review of face presentation, Duff<sup>6</sup> found that one of these etiologic factors was found in up to 90% of cases.

Early recognition of the face presentation is important, and the diagnosis can be suspected when abdominal palpation finds the fetal cephalic prominence on the same side of the maternal abdomen as the fetal back (Fig. 17-8); however, **face presentation is more often discovered by vaginal examination.** In practice, fewer than 1 in 20 infants with face presentation is diagnosed by abdominal examination. In fact, only half of these infants are found by any means to have a face presentation before the second stage of labor, and half of the remaining cases are

**FIG 17-6** This fetus with the vertex completely extended on the neck enters the maternal pelvis in a face presentation. The cephalic prominence would be palpable on the same side of the maternal abdomen as the fetal spine.

**FIG 17-7** The point of designation from digital examination in the case of a face presentation is the fetal chin relative to the maternal pelvis. *Left*, right mentum posterior (RMP); *middle*, mentum anterior (MA); *right*, left mentum transverse (LMT).

**FIG 17-8** Palpation of the maternal abdomen in the case of a face presentation should find the fetal cephalic prominence on the side away from the fetal small parts, instead of on the same side, as in the case of a normally flexed fetal neck and head.

undiagnosed until delivery. However, perinatal mortality may be higher with late diagnosis.

### Mechanism of Labor

Knowledge of the early mechanism of labor for face presentation is incomplete. Many infants with a face presentation probably begin labor in the less extended brow position. With descent into the pelvis, the forces of labor press the fetus against maternal tissues; subsequent flexion (to a vertex presentation) or full extension of the head on the spine (to a face presentation) then occurs. **The labor of a face presentation must include engagement, descent, internal rotation generally to a mentum anterior position, and delivery by flexion as the chin passes under the symphysis (Fig. 17-9).** However, flexion of the occiput may not always occur, and delivery in the fully extended attitude may be common.

**The prognosis for labor with a face presentation depends on the orientation of the fetal chin.** At diagnosis, 60% to 80% of infants with a face presentation are mentum anterior,<sup>6</sup> 10% to 12% are mentum transverse,<sup>7</sup> and 20% to 25% are mentum posterior.<sup>7</sup> Almost all average-sized infants presenting mentum

anterior with adequate maternal pelvic dimensions will achieve spontaneous or assisted vaginal delivery. Furthermore, most mentum transverse infants will rotate to the mentum anterior position and will deliver vaginally, and even 25% to 33% of mentum posterior infants will rotate and deliver vaginally in the mentum anterior position. In a review of 51 cases of persistent face presentation, Schwartz and colleagues<sup>7</sup> found that the mean birthweight of those infants in a mentum posterior position who did rotate and deliver vaginally was 3425 g, compared with 3792 g for those infants who did not rotate and deliver vaginally. **Persistence of the mentum posterior position with an infant of normal size, however, makes safe vaginal delivery less likely. Overall, 70% to 80% of infants with a face presenting can be delivered vaginally, either spontaneously or by low forceps in the hands of a skilled operator, whereas 12% to 30% require cesarean delivery.** Manual attempts to convert the face to a flexed attitude or to rotate a posterior position to a more favorable mentum anterior position are rarely successful and increase both maternal and fetal risks.<sup>5</sup> Again, IPV and breech extraction for face presentation historically are associated with unacceptably high fetal loss rates. Maternal deaths from

**FIG 17-9** Engagement, descent, and internal rotation remain cardinal elements of vaginal delivery in the case of a face presentation, but successful vaginal delivery of a term-size fetus presenting a face generally requires delivery by flexion under the symphysis from a mentum anterior position, as illustrated here.

uterine rupture and trauma have also been documented. Thus contemporary management through spontaneous delivery and cesarean delivery for other obstetric indications as necessary are the preferred routes for both maternal and fetal safety.<sup>5</sup>

**Prolonged labor is a common feature of face presentation and has been associated with an increased number of intrapartum deaths;** therefore prompt attention to an arrested labor pattern is recommended. In the case of an average or small fetus, an adequate pelvis, and hypotonic labor, oxytocin may be considered. No absolute contraindication to oxytocin augmentation of hypotonic labor in face presentations exists, but an arrest of progress despite adequate labor should call for cesarean delivery.

Worsening of the fetal condition in labor is common. Salzmänn and colleagues observed a **tenfold increase in fetal compromise with face presentation.** Several other observers have also found that abnormal fetal heart rate (FHR) patterns occur more often with face presentation.<sup>5,6</sup> Continuous intrapartum electronic FHR monitoring of a fetus with face presentation is considered mandatory, but extreme care must be exercised in the placement of an electrode because ocular or cosmetic damage is possible. **If external Doppler heart rate monitoring is inadequate and an internal electrode is recommended, placement of the electrode on the fetal chin is often preferred.**

**FIG 17-10** This fetus is in a brow presentation in a frontum anterior position. The head is in an intermediate deflexion attitude.

Contraindications to vaginal delivery of a face presentation include macrosomia, nonreassurance of FHR monitoring even without arrested or protracted labor, or an inadequate maternal pelvis; cesarean delivery has been reported in as many as 60% of cases of face presentation for these reasons.<sup>6</sup> If cesarean delivery is warranted, care should be taken to flex the head gently, both to accomplish elevation of the head through the hysterotomy incision as well as to avoid potential cervical nerve damage to the neonate. Forced flexion may also result in fetal injury, especially with fetal goiter or neck tumors.

**Fetal laryngeal and tracheal edema that results from the pressure of the birth process might require immediate naso-tracheal intubation.** Nuchal tumors or simple goiters, fetal anomalies that might have caused the malpresentation, require expert neonatal management, including the possibility of an ex utero intrapartum treatment (EXIT) procedure, which establishes a fetal/neonatal airway before the umbilical cord is clamped. Identification of and planning for these particular circumstances in the prelabor setting are ideal.

## BROW PRESENTATION

**A fetus in a brow presentation occupies a longitudinal axis with a partially deflexed cephalic attitude midway between full flexion and full extension (Fig. 17-10).** The frontal bones are the point of designation. If the anterior fontanel is on the mother's left side, with the sagittal suture in the transverse pelvic axis, the fetus would be in a left frontum transverse position (Fig. 17-11). The reported incidence of brow presentation varies widely, from 1 in 670 to 1 in 3433, averaging about 1 in 1500 deliveries. Brow presentation is detected more often in early labor before flexion occurs to a normal attitude. Less frequently, further extension results in a face presentation.

In 1976, the perinatal mortality rate corrected for lethal anomalies and very low birthweight varied from 1% to 8%.<sup>8</sup> In a study of 88,988 deliveries, corrected perinatal mortality rates for brow presentations depended on the mode of delivery; a loss rate of 16%, the highest in this study, was associated with manipulative vaginal birth.

**FIG 17-11** In brow presentation, the anterior fontanel (frontum) relative to the maternal pelvis is the point of designation. *Left*, fetus in left frontum transverse (LFT); *middle*, frontum anterior (FA); *right*, left frontum anterior (LFA).

In general, factors that delay engagement are associated with persistent brow presentation. Cephalopelvic disproportion, prematurity, and high parity are often found and have been implicated in more than 60% of cases of persistent brow presentation.

Detection of a brow presentation by abdominal palpation is unusual in practice. More often, a brow presentation is detected on vaginal examination. As in the case of a face presentation, diagnosis in labor is more likely. Fewer than 50% of brow presentations are detected before the second stage of labor, and most of the remainder are undiagnosed until delivery. Frontum anterior is reportedly the most common position at diagnosis, occurring about twice as often as either transverse or posterior positions. Although the initial position at diagnosis may be of limited prognostic value, the cesarean delivery rate is higher with frontum transverse or frontum posterior than with frontum anterior positioning.

A persistent brow presentation requires engagement and descent of the largest (mento-occipital) diameter of the fetal head. This process is possible only with a large pelvis or a small infant, or both. However, most brow presentations convert spontaneously by flexion or further extension to either a vertex or a face presentation and are then managed accordingly. The earlier the diagnosis is made, the more likely conversion will occur spontaneously. Fewer than half of fetuses with persistent brow presentations undergo spontaneous vaginal delivery, but in most cases, a trial of labor is not contraindicated.<sup>8</sup>

Prolonged labors have been observed in 33% to 50% of brow presentations, and secondary arrest is not uncommon. Forced conversion of the brow to a more favorable position with forceps is contraindicated, as are attempts at manual conversion. One unexpected cause of persistent brow presentation may be an open fetal mouth pressed against the vaginal wall, splinting the head and preventing either flexion or extension (Fig. 17-12). Although this is rare in phenotypically normal fetuses, it needs to be considered in anomalous conditions of the fetus such as epignathus, a rare oropharyngeal teratoma.

Similar to face presentations, minimal manipulation yields the best results if the FHR pattern remains reassuring. Expectant management may be justified, preferably with a relatively large pelvis in relation to fetal size and adequate labor progress, according to one large study.<sup>9</sup> If a brow presentation persists with

a large baby, successful vaginal delivery is unlikely, and cesarean delivery may be most prudent.

Radiographic or computed tomographic (CT) pelvimetry is not used clinically, and one report states that although 91% of cases with adequate pelvimetry converted to a vertex or a face presentation and delivered vaginally, 20% with some form of pelvic contracture did also. **Therefore regardless of pelvic dimensions, consideration of a trial of labor with careful monitoring of maternal and fetal condition may be appropriate.** As in the case of a face presentation, oxytocin may be used cautiously to correct hypotonic contractions, but prompt resumption of progress toward delivery should follow.

## COMPOUND PRESENTATION

Whenever an extremity, most commonly an upper extremity, is found prolapsed beside the main presenting fetal part, the situation is referred to as a *compound presentation* (Fig. 17-13). The reported incidence ranges from 1 in 377 to 1 in 1213 deliveries.<sup>8</sup> The combination of an upper extremity and the vertex is the most common.

This diagnosis should be suspected with any arrest of labor in the active phase or failure to engage during active labor. Diagnosis is made on vaginal examination by discovery of an irregular mobile tissue mass adjacent to the larger presenting part. Recognition late in labor is common, and as many as 50% of persisting compound presentations are not detected until the second stage. Delay in diagnosis may not be detrimental because it is likely that only the persistent cases require intervention.

**Although maternal age, race, parity, and pelvic size have been associated with compound presentation, prematurity is the most consistent clinical finding.** The very small premature fetus is at great risk of persistent compound presentation. In late pregnancy, ECV of a fetus in breech position increases the risk of a compound presentation.

Older, uncontrolled studies report elevated perinatal mortality rates with a compound presentation, with an overall rate of 93 per 1000. Higher loss rates of 17% to 19% have been reported when the foot prolapses. As with other malpresentations, fetal risk is directly related to the method of management. A fetal mortality rate of 4.8% has been noted if no intervention is required compared with 14.4% with intervention other than cesarean delivery. A 30% fetal mortality rate has been observed

**FIG 17-12** The open fetal mouth against the vaginal sidewall may brace the head in the intermediate deflexion attitude as shown here.

**FIG 17-13** The compound presentation of an upper extremity and the vertex illustrated here most often spontaneously resolves with further labor and descent.

with IPV and breech extraction. These figures may demonstrate selection bias because it is possible that more often, the difficult cases were chosen for manipulative intervention. **When intervention is necessary, cesarean delivery appears to be the only safe choice.**

Fetal risk in compound presentation is specifically associated with birth trauma and cord prolapse. **Cord prolapse occurs in**

**11% to 20% of cases, and it is the most frequent complication of this malpresentation.** Cord prolapse probably occurs because the compound extremity splints the larger presenting part and results in an irregular fetal aggregate that incompletely fills the pelvic inlet. In addition to the hypoxic risk of cord prolapse, common fetal morbidity includes neurologic and musculoskeletal damage to the involved extremity. Maternal risks include soft tissue damage and obstetric laceration. Again, although laboring is not proscribed, **the prolapsed extremity should not be manipulated. However, it may spontaneously retract as the major presenting part descends.** Seventy-five percent of vertex/upper extremity combinations deliver spontaneously. Occult or obscured cord prolapse is possible, and therefore continuous electronic FHR monitoring is recommended.

The primary indications for surgical intervention (i.e., cesarean delivery) are cord prolapse, nonreassuring FHR patterns, and arrest of labor. **Cesarean delivery is the only appropriate clinical intervention for cord prolapse and nonreassuring FHR patterns because both version extraction and repositioning the prolapsed extremity are associated with adverse outcome and should be avoided.** From 2% to 25% of compound presentations require cesarean delivery. Protraction of the second stage of labor and dysfunctional labor patterns have been noted to occur more frequently with persistent compound presentations. As in other malpresentations, spontaneous resolution occurs more often, and surgical intervention is less frequently necessary in those cases diagnosed early in labor. Small or premature fetuses are more likely to have persistent compound presentations but are also more likely to have a successful vaginal delivery. **Persistent compound presentation with parts other than the vertex and hand in combination in a term-sized infant has a poor prognosis for safe vaginal delivery, and cesarean delivery is usually necessary.** However, a simple

compound presentation (e.g., hand) may be allowed to labor, if labor is progressing normally with reassuring fetal status.

BREECH PRESENTATION

The infant presenting as a breech occupies a longitudinal axis with the cephalic pole in the uterine fundus. This presentation occurs in 3% to 4% of labors overall, although it is found in 7% of pregnancies at 32 weeks and in 25% of pregnancies of less than 28 weeks' duration.<sup>10</sup> The three types of breech are noted in Table 17-1. The infant in the *frank breech* position is flexed at the hips with extended knees (pike position). The *complete breech* is flexed at both joints (tuck position), and the *footling* or *incomplete breech* has one or both hips partially or fully extended (Fig. 17-14).

The diagnosis of breech presentation may be made by abdominal palpation or vaginal examination and confirmed by ultrasound. **Prematurity, fetal malformation, müllerian anomalies, and polar placentation are commonly observed causative factors.** High rates of breech presentation are noted in certain fetal genetic disorders, including trisomies 13, 18, and 21; Potter syndrome; and myotonic dystrophy. Conditions that alter fetal muscular tone and mobility—such as increased and decreased amniotic fluid, for example—also increase the frequency of breech presentation. The breech head appears dolichocephalic on ultrasound, and for that reason, the biparietal diameter (BPD) appears small. However, the head circumference remains

unaffected. This difference may be as much as 16+ days (95% confidence interval [CI], 14.3 to 18.1;  $P = .001$ ).<sup>11</sup> Whereas the contracted BPD may affect ultrasound-determined weight estimates of the fetus, an occipitofrontal diameter (OFD) to BPD ratio of greater than 1.3 in the absence of other indicators of growth delay signals the deformation characteristic of the breech-presenting fetus. Approximately 80% of breech fetuses will have a dolichocephalic contour, previously termed the “breech head.”<sup>12</sup> The fundus of the uterus assumes a more elongated contour than the bowl-like developed lower uterine segment. Thus it is believed that forces external to the fetus are responsible for this head shape. Because both dolichocephaly and breech may be associated with a genetically and phenotypically anomalous fetus, it behooves the sonologist to perform a detailed survey of the fetal anatomy prior to assuming the presence of the “breech head.”

Mechanism and Conduct of Labor and Vaginal Delivery

The two most important elements for the safe conduct of vaginal breech delivery are continuous electronic FHR monitoring and noninterference until spontaneous delivery of the breech to the umbilicus has occurred. Early in labor, the capability for immediate cesarean delivery should be established. Anesthesia should be available, the operating room readied, and appropriate informed consent obtained (discussed later). Two obstetricians should be in attendance in addition to a pediatric team. Appropriate training and experience with vaginal breech delivery are fundamental to success. Although experience is becoming infinitely less common, simulation of breech deliveries will help to maintain these skills. The instrument table should be prepared in the customary manner, with the addition of Piper forceps and extra towels. No contraindication exists to epidural analgesia in labor, and many believe epidural anesthesia to be an asset in the control and conduct of the second stage.

The infant presenting in the frank breech position usually enters the pelvic inlet in one of the diagonal pelvic diameters (Fig. 17-15). Engagement has occurred when the bitrochanteric diameter of the fetus has progressed beyond the plane of the pelvic inlet, although by vaginal examination, the

FIG 17-14 The *complete breech* is flexed at the hips and flexed at the knees. The *incomplete breech* shows incomplete deflexion of one or both knees or hips. The *frank breech* is flexed at the hips and extended at the knees.

**FIG 17-15** The breech typically enters the inlet with the bitrochanteric diameter aligned with one of the diagonal diameters, with the sacrum as the point of designation in the other diagonal diameter. This illustrates a left sacrum posterior alignment.

**FIG 17-16** With labor and descent, the bitrochanteric diameter generally rotates toward the anteroposterior axis, and the sacrum rotates toward the transverse axis.

presenting part may be palpated only at a station of  $-2$  to  $-4$  (out of 5). As the breech descends and encounters the levator ani muscular sling, internal rotation usually occurs to bring the bitrochanteric diameter into the anteroposterior (AP) axis of the pelvis. **The point of designation in a breech labor is the fetal sacrum;** therefore when the bitrochanteric diameter is in the AP axis of the pelvis, the fetal sacrum will lie in the transverse pelvic diameter (Fig. 17-16).

If normal descent occurs, the breech will present at the outlet and will begin to emerge, first as sacrum transverse, then rotating to sacrum anterior. This direction of rotation may reflect the greater capacity of the hollow of the posterior pelvis to accept the fetal chest and small parts. Crowning occurs when the bitrochanteric diameter passes under the pubic symphysis. It is important to emphasize that operator intervention is not yet needed or helpful, other than possibly to perform the episiotomy if indicated and to encourage maternal expulsive efforts.

**Premature or aggressive intervention may adversely affect the delivery in at least two ways. First, complete cervical dilation must be sustained for sufficient duration to retard**

retraction of the cervix and entrapment of the aftercoming fetal head. Rushing the delivery of the trunk may result in cervical retraction. Second, the safe descent and delivery of the breech infant must be the result of uterine and maternal expulsive forces only in order to maintain neck flexion. Any traction by the provider in an effort to speed delivery would encourage deflexion of the neck and result in the presentation of the larger occipitofrontal fetal cranial profile to the pelvic inlet (Fig. 17-17). Such an event could be catastrophic. Rushed delivery also increases the risk of a nuchal arm, with one or both arms trapped behind the head above the pelvic inlet. Entrapment of a nuchal arm makes safe vaginal delivery much more difficult because it dramatically increases the aggregate size of delivering fetal parts that must egress vaginally. Safe breech delivery of an average-sized infant, therefore, depends predominantly on maternal expulsive forces and patience, *not* traction, from the provider.

As the frank breech emerges further, the fetal thighs are typically flexed firmly against the fetal abdomen, often splinting and protecting the umbilicus and cord. **The Pinard maneuver**

A Spontaneous expulsion

B Undesired deflexion

**FIG 17-17** The fetus emerges spontaneously (**A**), whereas uterine contractions maintain cephalic flexion. Premature aggressive traction (**B**) encourages deflexion of the fetal vertex and increases the risk of head entrapment or nuchal arm entrapment.

A

B

**FIG 17-18** After spontaneous expulsion to the umbilicus, external rotation of each thigh (**A**) combined with opposite rotation of the fetal pelvis results in flexion of the knee and delivery of each leg (**B**).

may be needed to facilitate delivery of the legs in a frank breech presentation. After delivery to the umbilicus has occurred, pressure is applied to the medial aspect of the knee, which causes flexion and subsequent delivery of the lower leg. Simultaneous to this, the fetal pelvis is rotated away from that side (Fig. 17-18). This results in external rotation of the thigh at the hip, flexion of the knee, and delivery of one leg at a time. The dual movement of counterclockwise rotation of the fetal pelvis as the operator externally rotates the right thigh and clockwise rotation of the fetal pelvis as the operator externally rotates the fetal left thigh is most effective in facilitating delivery. The fetal trunk is then wrapped with a towel to provide secure support of the body while further descent results from expulsive forces from the mother. The operator primarily facilitates the delivery of the fetus by providing support and guiding the body through the introitus. The operator is not applying outward

traction on the fetus, which might result in deflexion of the fetal head or nuchal arm.

When the scapulae appear at the introitus, the operator may slip a hand over the fetal shoulder from the back (Fig. 17-19); follow the humerus; and, with movement from medial to lateral, sweep first one and then the other arm across the chest and out over the perineum. Gentle rotation of the fetal trunk counterclockwise assists delivery of the right arm, and clockwise rotation assists delivery of the left arm (turning the body “into” the arm). This accomplishes delivery of the arms by drawing them across the fetal chest in a fashion similar to that used for delivery of the legs (Fig. 17-20). These movements cause the fetal elbow to emerge first, followed by the forearm and hand. Once both arms have been delivered, if the vertex has remained flexed on the neck, the chin and face will appear at the outlet, and the airway may be cleared and suctioned (Fig. 17-21).

A

B

**FIG 17-19** When the scapulae appear under the symphysis, the operator reaches over the left shoulder, sweeps the arm across the chest (A), and delivers the arm (B).

**FIG 17-20** Gentle rotation of the shoulder girdle facilitates delivery of the right arm.

With further maternal expulsive forces alone, spontaneous controlled delivery of the fetal head often occurs. If not, delivery may be accomplished with a simple manual effort to maximize flexion of the vertex using pressure on the fetal maxilla (not the mandible), the Mauriceau-Smellie-Veit maneuver, using gentle

**FIG 17-21** Following delivery of the arms, the fetus is wrapped in a towel for control and is slightly elevated. The fetal face and airway may be visible over the perineum. Excessive elevation of the trunk is avoided.

**FIG 17-22** Cephalic flexion is maintained by pressure (black arrow) on the fetal maxilla, not the mandible. Often, delivery of the head is easily accomplished with continued expulsive forces from above and gentle downward traction.

downward traction along with suprapubic pressure (Credé maneuver; Fig. 17-22). Although maxillary pressure facilitates flexion, the main force effecting delivery remains the mother.

Alternatively, the operator may apply Piper forceps to the aftercoming head. The application requires *very slight* elevation of the fetal trunk by the assistant, while the operator kneels and applies the Piper forceps from beneath the fetus directly to the fetal head in the pelvis. Delivery of the breech presenting fetus, therefore, should occur on a table/bed capable of allowing the operators to correctly position themselves for the application of forceps. Direct access to the perineum is required. If a delivery bed is used, merely dropping the foot of the bed will be inadequate. The position of the operator for applying the forceps is depicted in Figure 17-23, which also demonstrates how *excessive* elevation by the assistant may potentially cause harm to the neonate. Hyperextension of the fetal neck from excessive elevation of the fetal trunk, shown in Figure 17-23, should be avoided because of the potential for spinal cord injury.

Piper forceps are characterized by absence of pelvic curvature. This modification allows *direct* application to the fetal head and

**FIG 17-23** Demonstration of *incorrect* assistance during the application of Piper forceps. The assistant hyperextends the fetal neck, a position that increases the risk for neurologic injury.

**FIG 17-24** The fetus may be laid on the forceps and delivered with gentle downward traction, as illustrated here.

avoids conflict with the fetal body that would occur with the application of standard instruments from below. The assistant maintains control of the fetal body while the forceps are inserted into the vagina from beneath the fetus by the primary operator. The blade to be placed on the maternal left is held by the handle in the operator's left hand; the blade is inserted with the operator's right hand in the vagina along the left maternal sidewall and is placed against the right fetal parietal bone. The handle of the right blade is then held in the operator's right hand and is inserted by the left hand along the right maternal sidewall and placed against the left fetal parietal bone. At this point, the

assistant allows the fetal body to rest on the shank and handles of the forceps. Gentle downward traction on the forceps with the fetal trunk supported on the forceps shanks results in controlled delivery of the vertex (Fig. 17-24). Forceps application controls the fetal head and prevents extension of the head on the neck. Application of Piper forceps to the aftercoming head may be advisable both to ensure control of the delivery and to maintain optimal operator proficiency in anticipation of deliveries that may require their use.

**Arrest of spontaneous progress in labor with adequate uterine contractions necessitates consideration of cesarean**

**delivery.** Any evidence of fetal compromise or sustained cord compression on the basis of continuous electronic FHR monitoring also requires consideration of cesarean delivery. Vaginal interventions directed at facilitating delivery of the breech complicated by an arrest of spontaneous progress are discouraged because fetal and maternal morbidity and mortality are both greatly increased. However, if labor is deemed to be hypotonic by internally monitored uterine pressures, oxytocin is not contraindicated.<sup>13,14</sup>

Mechanisms of descent and delivery of the incomplete and the complete breech are not unlike those used for the frank breech described earlier; at least one leg may not require attention. The risk of cord prolapse or entanglement is greater, and hence the possibility of emergency cesarean delivery is increased. Furthermore, incomplete and complete breeches may not be as effective as cervical dilators as either the vertex or the larger aggregate profile of the thighs and buttocks of the frank breech. Thus the risk of entrapment of the aftercoming head is increased, and as a result, **primary cesarean delivery is often advocated for nonfrank breech presentations.** However, the randomized trial of Gimovsky and colleagues<sup>15</sup> found vaginal delivery of the nonfrank breech to be reasonably safe.

### Contemporary Management of the Term Breech

Debate has largely diminished about the proper management of the term breech. Much of the older data were derived from relatively few studies of varied methodologies, patient populations, and multiple retrospective cohort analyses, which are subject to bias. These reports indicated that the perinatal mortality rate for the vaginally delivered breech appears to be greater than for its cephalic counterpart, but much of the reported perinatal mortality rate associated with breech presentation was largely due to lethal anomalies and complications of prematurity, both of which are found more frequently among breech infants. Excluding anomalies and extreme prematurity, the corrected perinatal mortality reported by some investigators approached zero regardless of the method of delivery, whereas others found that even with exclusion of these factors, the term breech infant has been found to be at higher risk for birth trauma and asphyxia.<sup>16</sup> To date, only three randomized trials have been reported.<sup>13,15</sup> Although conclusions regarding the safety of breech vaginal delivery from a fetal standpoint may continue to vary, **the practical reality today is that intentional vaginal breech delivery is rare.** A summary of some of the reported complications is listed in Table 17-2. **Overall, consideration of a potential breech vaginal delivery must be mutually agreed on by the patient and the physician after complete informed consent is obtained.**

### Further Discussion of Delivery for the Term Frank or Complete Breech

The cesarean delivery rate for breech presentation approached 90% in some centers in the mid-1970s without a consequent proportionate drop in the perinatal mortality rate. Maternal mortality is clearly higher with cesarean delivery and ranges from 0.2% to 0.43%.<sup>10</sup> With an older, more obese, sicker maternal population who have more chronic medical problems and have sustained more cesarean deliveries, we can expect this rate to further increase. Maternal morbidity is also higher with cesarean delivery. Some institutions reported a 50% incidence of post-cesarean maternal morbidity compared with as little as 5% with

**TABLE 17-2** INCIDENCE OF COMPLICATIONS SEEN WITH BREECH PRESENTATION

| COMPLICATION                            | INCIDENCE                                |

vaginal delivery.<sup>10,15</sup> **In an attempt to balance both maternal and fetal risks, plans were proposed to select appropriate candidates for a trial of labor.**

In 1965, **Zatuchni and Andros<sup>17</sup>** retrospectively analyzed 182 breech births, of which 25 infants had poor outcomes. These investigators devised a score based on six clinical variables at the time of admission (Table 17-3) that identified those patients destined to manifest difficulties in labor, for whom prompt and appropriate interventions could be made. **The score used parity, gestational age, estimated weight, prior successful breech vaginal delivery, dilation, and station to ascertain likelihood of successful vaginal delivery.** However, the parturient could increase the score by presenting later in labor; other factors that affect the score are less modifiable. At least three subsequent prospective studies applied the Zatuchni-Andros system and found it to be both sensitive and accurate in selecting candidates for successful vaginal delivery.<sup>18</sup> **A Zatuchni-Andros score of less than 4 in these studies accurately predicted poor outcomes in patients with infants presenting as a breech.** Furthermore, in applying the scoring system, only 21% to 27% of patients failed to qualify for a trial of labor.<sup>18</sup> Previous breech delivery, one of the items scored in the Zatuchni-Andros system, has a significant odds ratio (OR) for recurrence of breech (4.32; 95% CI, 4.08 to 4.59) after one breech delivery, and the OR jumps up to 28.1 after three (95% CI, 12.2 to 64.8). However, this study did not control for recurrent causes of breech presentation such as uterine malformations and abnormal placentation.<sup>19</sup>

Because most reports of breech delivery are level II to III evidence, their validity and, most importantly, their universal applicability may be questioned. Many data were gathered before electronic FHR monitoring became commonplace. Until the year 2000, only one randomized trial (level I evidence) had examined term frank breech and method of delivery.<sup>13</sup> Improved

perinatal survival had been reported for breeches delivered by cesarean section, and some evidence, although inconsistent, suggests that the method of delivery may also have an impact on the quality of survival.<sup>16</sup> Functional neurologic defects were found by 2 years of age in 24% of breech infants born vaginally but only in 2.5% of those breech weight- and age-matched infants born by cesarean delivery.<sup>20</sup> However, in comparing 175 breech infants with a 94% cesarean delivery rate with 595 historic controls with a 22% rate of abdominal delivery, Green and colleagues<sup>21</sup> found no significant differences in outcome. Neurologic outcomes were reviewed for 239 of 348 infants delivered from breech position.<sup>22</sup> Examinations performed at 3 to 10 years of age showed no statistically significant neurologic differences between neonates delivered by vaginal breech versus matched vertex controls. Thus, **these authors concluded that breech outcomes relate to degree of prematurity, maternal pregnancy complications, and fetal malformations as well as to birth trauma or asphyxia.** A 2009 Norwegian study<sup>23</sup> demonstrated that breech presentation *and* breech delivery are significant risk factors for cerebral palsy and represent a trend toward increasing risk for cerebral palsy among singletons born at term in breech by vaginal delivery (nearly fourfold). This adds to the body of literature that demonstrates that **breech-presenting fetuses are already at increased risk for neurologic adversity, even when controlled for birth order, prematurity, smallness for gestational age, assisted reproduction, sex, and route of delivery.**

Pelvimetry is frequently used when deciding whether to allow a trial of labor in a breech presenting fetus. Clinical pelvimetry is an acceptable technique that can be used to determine the dimensions of the mid pelvis, the outlet, and the inlet by way of surrogate measurement (the obstetric conjugate). The reader is referred to the Intrapartum Care section and [Chapter 12](#), on normal labor and delivery, for discussion and demonstration of clinical pelvimetry. **Radiographic pelvimetry has been included in the management of the breech presentation with little objective validation.** Regardless, it is expected to predict successful vaginal delivery when adequate pelvic dimensions are present. At least four techniques for pelvimetry are commonly used worldwide: these include (1) conventional plain-film radiography, using up to three films; (2) CT with up to three views that include lateral, AP, and axial slice; (3) magnetic resonance imaging (MRI); and (4) digital fluorography, which is not presently used in the United States. MRI is the only technique not associated with radiation exposure, and CT pelvimetry using a single lateral view results in the lowest exposure dose; air-gap technique with conventional radiography will lower the radiation dosage, and current trends show a move toward the lower-dose CT techniques of up to three images.

The clinician must possess the necessary training and experience to offer a patient with a persistent breech presentation a trial of labor. Furthermore, the relationship between the patient and the clinician should be well established, and the discussions of risks and benefits must be objective and nondirective with accurate documentation of the discussion. If any of these factors are lacking, cesarean delivery becomes the safer choice. However, even if a clinician has made the choice that he or she will *never* prospectively offer a patient with breech presentation a trial of labor, the burden of responsibility to know and understand the mechanism and management of a breech delivery is not relieved. No one active in obstetrics will avoid the occasional emergency breech delivery. Regular review of principles and practice with

### BOX 17-1 MANAGEMENT OF BREECH PRESENTATION

A trial of labor may be considered if the following conditions are met:

- EFW is between 2000 and 3800 g
- Presentation is a frank breech
- Maternal pelvis is adequate
- Fetal neck and head are flexed
- Fetal monitoring is used
- Zatuchni-Andros score is  $\geq 4$
- Rapid cesarean delivery is possible
- Good progress is maintained in labor
- Experience and training are available
- Informed consent is possible
- Cesarean delivery may be prudent if:
  - EFW is  $<1500$  g or  $>4000$  g
  - Fetus is in a footling presentation
  - Parturient has a small pelvis
  - Fetal neck and head are hyperextended
  - Zatuchni-Andros score is  $<4$
  - Expertise in breech delivery is absent
  - A nonreassuring FHR pattern is present
  - Arrest of progress has occurred

EFW, estimated fetal weight; FHR, fetal heart rate.

simulations using a mannequin and model pelvis with an experienced colleague can increase the skills and improve the performance of anyone facing such an emergency. A 2006 study<sup>24</sup> of resident skill before and after simulation training showed universal improvement in technique and performance of key maneuvers required for vaginal delivery of a breech fetus when such maneuvers were performed in mock emergency settings using a Noelle pelvic trainer (Gaumard Scientific). Maintenance of skill is particularly important as breech vaginal delivery becomes less frequently encountered in routine obstetric practice (this is discussed in greater detail below, in regard to the Term Breech Trial).

Factors that affect the decision to deliver a breech vaginally or by cesarean delivery are listed in [Box 17-1](#). The obvious implication of the dramatically diminished experience in training programs with vaginal breech delivery is that inexperience will constitute an indication for cesarean delivery. Certainly, **in no case should a woman with an infant presenting as a breech be allowed to labor unless (1) anesthesia coverage is immediately available, (2) cesarean delivery can be undertaken promptly, (3) continuous FHR monitoring is used, and (4) the delivery is attended by a pediatrician and two obstetricians, of whom at least one is experienced with vaginal breech birth.**

### TERM BREECH TRIAL

**One of the most influential publications was the multicenter prospective study known as the Term Breech Trial (TBT).** The impetus for this investigation was a series of retrospective studies that demonstrated increased morbidity and mortality of neonates after vaginal breech delivery, which included neonatal intensive care unit admissions, hyperbilirubinemia, bone fractures, intracranial hemorrhage, neonatal depression,<sup>25</sup> convulsions, and death.<sup>26</sup> Other studies, however, found that emergent cesarean delivery was also associated with poor neonatal outcomes. Irion and colleagues<sup>27</sup> reported similarly poor neonatal

outcomes from cesarean deliveries of 705 singleton breeches and concluded that as a result of the increased *maternal* morbidity associated with cesarean birth, delivery of the breech by cesarean section was not firmly indicated. This opinion was supported by Brown and colleagues<sup>14</sup> in their prospective case series, noting that the corrected perinatal mortality rate did not differ for neonates who weighed 1500 g or more.

In October 2000, the first results from the TBT were published.<sup>16</sup> Overall, 2088 patients from 121 centers in 26 countries with varied national perinatal mortality statistics, according to the World Health Organization (WHO), were enrolled in the study. Assignment was random, with 1041 to the planned cesarean delivery group and 1042 to the planned vaginal delivery group. The data were analyzed by the intention-to-treat method, and 941 of 1041 (90.4%) and 591 of 1042 (56.7%) delivered by their intended route of delivery, cesarean delivery and vaginal birth, respectively. Intrapartum events, including cord prolapse and FHR abnormalities, occurred at rates similar to prior studies. Maternal and fetal/neonatal short-term (immediate, 6 weeks, and 3 months) and long-term (2 year) outcome data were presented in this and subsequent reports. **For countries with both low and high perinatal mortality rates (PMRs), the occurrence of perinatal mortality or serious neonatal morbidity (defined within the report) was significantly lower in the planned cesarean delivery group than in the planned vaginal delivery group (relative risk [RR], 0.33; 95% CI, 0.19 to 0.56;  $P < .0001$ ). In countries with an already low PMR, a proportionately greater risk reduction in PMR was found in the planned cesarean delivery. The effects of operator experience and prolonged labor did not affect the direction of the risk reduction and only marginally affected the amplitude. No differences existed in maternal mortality or serious maternal morbidity between the groups.**<sup>16</sup>

The effects on the correlation between labor and delivery factors were assessed in a separate regression analysis that used only delivery mode in one regression and only labor factors—including all other variables such as fetal monitoring, length of labor, and medications—in the other. **Mode of delivery and birth weight were both significantly associated with adverse fetal outcome without a significant degree of interaction of these variables. Essentially, smaller infants (less than 2800 g) were at greatest risk (OR, 2.13; 95% CI, 1.2 to 3.8;  $P = .01$ ). Neonates with birthweights greater than 3500 g showed a trend toward more adverse outcomes, but the trend did not reach significance. The analysis of the labor data shows a “dose-response relationship between the progression of labor and the risk of adverse perinatal outcome,” such that a **prelabor cesarean delivery is associated with the lowest rates of adverse outcome compared with vaginal breech delivery.**<sup>28</sup> Maternal outcomes at 3 months showed a reduced rate of urinary incontinence (RR, 0.62; 95% CI, 0.41 to 0.93) in the planned cesarean delivery group,<sup>29</sup> but 2 years after delivery, no differences were found in urinary incontinence or breastfeeding, medical, sexual, social, pain, or reproductive issues.<sup>30</sup> Neonatal outcomes at 2 years showed no difference in mortality rates or neurodevelopmental delay between the planned cesarean delivery and planned vaginal delivery groups.<sup>31</sup> **To summarize the TBT, if a trial of labor is attempted and is successful, babies born by planned vaginal delivery have a small but significant risk of dying or sustaining a debilitating insult in the short term compared with a planned cesarean delivery. If they survive, no difference is seen in the mortality rate or in the presence****

**of developmental delay when compared with children born by planned cesarean delivery.**

The worldwide repercussions of the TBT are still being realized. Eighty of the collaborating centers in 23 of 26 countries responded to a follow-up questionnaire regarding change in practice patterns after the results of the TBT were published. A plurality stated that practice had changed (92.5%), and 85% of respondents reported that an analysis of relative costs would not affect the continued implementation of a policy of planned cesarean delivery for the breech at term.<sup>32</sup>

A Dutch study examined the effects on delivery statistics and outcomes following the TBT and showed an increase in the cesarean delivery rate for the term breech from 50% to 80%, which was associated with a concomitant reduction in perinatal mortality rate from 0.35% to 0.18%.<sup>33</sup>

The total U.S. cesarean delivery rate peaked in 2009 at 32.9% of all births, rising from a low of 20.7% in 1996. A modest decline to 32.8% occurred in 2010, and this rate has been maintained through 2012. The 1981 National Institutes of Health Consensus Report found that 12% of cesarean deliveries in 1978 were performed for breech presentation and that this indication contributed 10% to 15% to the overall rise in the rate of cesarean births. At least a portion of the increase in cesarean delivery rates is a response to the perceived risk of morbidity and mortality associated with the breech presentation.<sup>16,21</sup> **Currently, 17% of cesarean deliveries are performed for breech.**<sup>34</sup> **In the United States, the cesarean delivery rate for breech presentation increased from 11.6% to 86.9% in 2002 and stood at 85% as of 2003.**<sup>21,35,36</sup> **Comparing the U.S. cesarean delivery rates from 1998 and 2011, before and after the TBT's publication, a marked increase is apparent in the rates for cesarean delivery: 21.2% of all live births in 1998, compared with 26.1% in 2002, and up to 32.8% currently.** Rates of both primary and repeat cesarean deliveries increased. This may be in part because of the staggering number of multiple births and their related degree of prematurity, the relative reduction in vaginal birth after cesarean delivery,<sup>35</sup> and the self-fulfilling prophecy of lack of experience owing to increasing trends toward cesarean delivery for breech, which leaves a void of experienced operators to perform breech vaginal deliveries (see Chapter 20). Currently, the American College of Obstetricians and Gynecologists (ACOG) has released statements that place emphasis on reducing the cesarean delivery rate; one of the recommendations is to offer ECV for the persistent breech at term and for a trial of labor with twins when the first twin is in a cephalic presentation. Both of these bear continued consideration with each pregnancy. The implications for future pregnancies have been studied: maternal morbidity and mortality rates are significantly increased with cesarean birth compared with vaginal delivery (8.6% vs. 9.2%),<sup>37</sup> in particular repeat cesarean delivery, for which breech presentation has become an inarguable cause, perhaps unnecessarily.

Even though greater risks appear to face the breech infant, many still believe that complete abandonment of vaginal delivery for the breech is not yet justified. The TBT also has its detractors, who state that inclusion of fetuses with estimated weights up to 4 kg and less than 2500 g, procedural aberrations in labor assessment and adequacy (length of time permitted for first and second stage of labor, liberal use of induction and augmentation of labor), and worldwide differences in standards of obstetric care and its providers make the trial's results not generalizable. No study is perfect in its methodology or results;

this trial has been criticized for its statistical methodology, the ascertainment of expertise, inclusion of both fetal deaths and anomalous fetuses, and the absence of ultrasound from some participating centers, among other transgressions.<sup>38</sup> However flawed it may, the TBT adds to the body of literature on breech vaginal delivery but as such may not be the final answer to the question of the safety of vaginal breech delivery.

Since that time, a large prospective cohort analysis was performed at 174 centers in France and Belgium, two countries where the TBT has had only a modest effect on vaginal breech delivery rates. Termed the PREMODA trial (*Presentation et Mode d'Accouchement*, [Presentation and Mode of Delivery]), it evaluated pregnancy and delivery data—a composite of morbidities, similar to the TBT—from women who gave birth to a fetus, alive or not, from 37 or more weeks. An expert committee not blinded to the mode of delivery evaluated each birth outcome as to whether an elective cesarean delivery at 39 weeks would have prevented the particular outcome. They found that 6 of the 22 fetal deaths and 17 of the 18 neonatal or postneonatal deaths before discharge were due to lethal anomalies; only one death occurred among phenotypically normal fetuses, and this was deemed sudden and unexpected at 15 days of life. In sum, this study noted a global fetal or neonatal mortality risk of 1.59% (95% CI, 1.33 to 1.89); this was not significantly different from the population delivered by planned cesarean. The mortality and serious morbidity rate was significantly less than that of countries with a low PMR rate in the TBT (1.59% vs. 5.7%). Thus in these countries with an already low PMR, excess neonatal morbidity and mortality are not attributed to breech vaginal delivery. However, these results may not be applicable to the United States because the expertise for performing breech vaginal delivery is unfortunately not as available in this country.<sup>39</sup>

### Special Clinical Circumstances and Risks: Preterm Breech, Hyperextended Head, and Footling Breech

The various categories of breech presentation clearly demonstrate dissimilar risks, and management plans might vary among these situations. **The premature breech, the breech with a hyperextended head, and the footling breech are categories that have high rates of fetal morbidity or mortality. Complications associated with incomplete dilation and cephalic entrapment may be more frequent. For these three breech situations, in general, cesarean delivery appears to optimize fetal outcome and is therefore recommended.**

Low birthweight (<2500 g) is a confounding factor in about one third of all breech presentations.<sup>17</sup> Whereas the benefit of cesarean delivery for the breech infant weighing 1500 to 2500 g remains controversial,<sup>13</sup> some studies have shown improved survival with cesarean delivery in the 1000- to 1500-g weight group.<sup>40,41</sup> A multicenter study of long-term outcomes of vaginally delivered infants at 26 to 31 weeks' gestation found no differences in rates of death or developmental disability within 2 years of follow-up.<sup>42</sup> Traumatic morbidity is reportedly decreased in both weight groups by the use of cesarean delivery, including a lower rate of both intraventricular and periventricular hemorrhage. Although some advocate a trial of labor in the frank breech infant weighing over 1500 g, others recommend labor only when the infant exceeds 2000 grams. Proportionately fewer frank breech presentations occur in the low-birthweight group. **In fact, most infants who weigh less than 1500 g and present as a breech are footling breeches.** Although

most deaths in those with a very low birthweight are due to prematurity or lethal anomalies, cesarean delivery has been shown by some to decrease corrected perinatal mortality in this weight group compared with that in similar-sized vertex presentations.<sup>43</sup> Other authors suggest that improved survival in these studies relates to improved neonatal care of the premature infant when compared with the outcomes of historic controls. However, when vaginal delivery of the preterm breech is chosen or is unavoidable, older studies have demonstrated reduced fetal morbidity and mortality when conduction anesthesia and forceps for the delivery of the aftercoming head are used; neither are commonplace in modern obstetrics. A study of neonates at 26 to 29 weeks 6 days gestational age born by planned breech versus planned cesarean delivery showed no difference in mortality rate.<sup>44</sup> Although in this study, premature rupture of the membranes (PROM) at a gestational age less than 24 weeks, head entrapment, and a gestational age between 26 to 27 weeks 6 days were all independently associated with neonatal death.

Preterm premature rupture of the fetal membranes (PPROM) is associated with prematurity and chorioamnionitis, both of which have been found to be independent risk factors for the development of cerebral palsy (CP). PPRM is associated with a high rate of malpresentation because of prematurity and decreased amniotic fluid. Knowing the association of chorioamnionitis with periventricular leukomalacia (PVL), a lesion found to precede development of CP in the premature neonate, Baud and colleagues<sup>45</sup> correlated the mode of delivery with PVL and subsequent CP in breech preterm deliveries. **The authors found that in the presence of chorioamnionitis, delivery by planned cesarean section was associated with a dramatic decrease in the incidence of PVL.**

**Hyperextension of the fetal head during vaginal breech delivery has been consistently associated with a high (21%) risk of spinal cord injury.** It is important to differentiate simple deflexion of the head from clear hyperextension, given that Ballas and colleagues demonstrated that simple deflexion carries no excess risk. Deflexion of the fetal vertex, as opposed to hyperextension, is similar to the relationship between the occipitofrontal cranial plane and the axis of the fetal cervical spine illustrated in Figure 17-5. Often, as labor progresses, spontaneous flexion will occur in response to fundal forces.

**Finally, the footling breech carries a prohibitively high (16% to 19%) risk of cord prolapse during labor.** In many cases, cord prolapse manifests only late in labor, after commitment to vaginal delivery may have been made. Cord prolapse necessitates prompt cesarean delivery. Furthermore, the footling breech is a poor cervical dilator, and cephalic entrapment becomes more likely.

### Breech Second Twin

**Approximately one third of all twin gestations present as cephalic/breech—that is, first twin is a cephalic presentation and the second is a breech** (see also Chapter 32, Multiple Gestations). **The management alternatives in the case of the cephalic/breech twin pregnancy in labor include cesarean delivery, vaginal delivery of the first twin, and either attempted ECV or IPV and breech extraction of the second twin.** Blickstein and colleagues compared the obstetric outcomes of 39 cases of vertex/breech twins with the outcomes of 48 vertex/vertex twins. Although the breech second twin had a higher incidence of low birthweight and a longer hospital stay, the authors found no basis for elective cesarean delivery in this

clinical circumstance. **The outcomes of another study<sup>46</sup> of 136 pairs of cephalic/noncephalic twins weighing more than 1500 g allows us to conclude that breech extraction of the second twin appears to be a safe alternative to cesarean delivery.** Laros and Dattel<sup>47</sup> studied 206 twin pairs and similarly found no clear advantage to arbitrary cesarean delivery because of a specific presentation. When comparing outcomes of 390 vaginally delivered second twins (207 delivered vertex, 183 delivered breech), with 95% of the breech deliveries being total breech extractions, it is noted that no significant differences existed between the cephalic and breech infants even when stratified by birthweight.<sup>48</sup> These outcomes assume the skills and experience required to perform a successful breech extraction. A recent Danish retrospective evaluation<sup>49</sup> of IPV for a noncephalic second twin demonstrated that although it occurs only rarely, IPV is associated with fewer asphyxiated neonates than second twins delivered by cesarean delivery after a vaginal delivery of the first twin; in addition, a trend was seen toward higher cord pH and higher Apgar scores in the IPV group. The disturbing trend highlighted by this study is the very high chance of the vaginal and cesarean combination delivery.

**The Twin Birth Study,<sup>50</sup> a multicenter randomized trial, showed that cesarean delivery of twins demonstrated neither a decrease nor an increase in the rate of fetal or neonatal death or morbidity compared with vaginal delivery. The authors of this study advocate that patients seek out providers who are skilled in the vaginal birth of the second twin.** For any clinician uncomfortable with the prospective vaginal delivery of a singleton breech, however, cesarean delivery may be a safer option for the pregnancy with a noncephalic-presenting second twin.

Vaginal delivery of the first twin followed by external version of the second is a viable alternative, using ultrasound in the delivery room to directly visualize the fetus. Often a transient decrease in uterine activity occurs after the delivery of the first infant, which can be used to advantage in the performance of a cephalic version. Description of experience with 30 noncephalic second twins (12 transverse and 18 breech) shows that version after birth of the first twin was successful in 11 of the 12 infants in a transverse lie and in 16 of the 18 breech infants.<sup>51</sup> These twins were all older than 35 weeks' gestation, with intact membranes of the second twin after delivery of the first, no evidence of anomalies, and normal amniotic fluid volume.

**If IPV/extraction of the second twin is to be performed, it can be facilitated by ultrasonic guidance.** A hand is inserted into the uterus, both fetal feet are identified and grasped with the membranes intact, and traction is applied to bring the feet into the pelvis and out the introitus, with maternal expulsive efforts remaining the major force in effecting descent of the fetus. The membranes are left intact until both feet are at the introitus. Once the membranes are ruptured, the delivery is subsequently managed as a footling breech delivery. If the operator has difficulty identifying the fetal feet, intrapartum ultrasound may be of assistance.

During breech extraction, and perhaps more often with a breech extraction of a smaller twin, the fetal head can become entrapped in the cervix. In such cases, the operator's entire hand is placed in the uterus, the fetal head is cradled, and as the hand is withdrawn, the head is protected.<sup>52</sup> This splinting technique has also been used for the safe extraction of the breech head at the time of cesarean delivery. Head entrapment may also occur

because of increased uterine tone or contractions. In this case, a **uterine relaxing agent may be used, with nitroglycerin 50 to 200 µg intravenously being one of the fastest acting, safest agents in appropriately selected patients.** Terbutaline, ritodrine, or inhalational anesthesia may also be used.

### External Cephalic Version

**External cephalic version (ECV) is recommended for the breech fetus at 36 to 37 weeks' gestation.<sup>4,53</sup>** Many have found that ECV significantly reduces the incidence of breech presentation in labor and is associated with few complications such as cord compression or placental abruption.<sup>4</sup> **Reported success with ECV varies from 60% to 75%, and a similar percentage of these remain vertex at the time of labor.<sup>4</sup>** Although many infants in breech presentation before 34 weeks' gestation will convert spontaneously to a cephalic presentation, the percentage that spontaneously convert decreases as term approaches. Repetitive external version applied weekly after 34 weeks' gestation in one report was successful in converting more than two thirds of cases and reducing their breech presentation rate by 50%. In another randomized trial<sup>53</sup> of ECV in low-risk pregnancies between 37 and 39 weeks' gestation, success was achieved in 68% of 25 cases in the version group, whereas only 4 of the 23 controls converted to a vertex spontaneously before labor. All of those in whom external version was successful presented in labor as a vertex. In another prospective, controlled study of ECV performed weekly between 33 weeks' gestation and term, 48% of the study group was vertex in labor compared with only 26% of controls. Another experience with 112 patients demonstrated a 49% success rate with ECV. The cesarean delivery rate was 17% among those patients with successful ECV compared with 78% among those with an unsuccessful version attempt.

The timing of ECV has been evaluated in the early ECV2 trial,<sup>54</sup> published in 2011. Whereas a greater percentage of ECVs performed early (34 weeks to 35 weeks 6 days gestational age), as opposed to those performed late (at or beyond 37 weeks' gestation), were cephalic at the time of delivery, no difference was found in the rate of cesarean delivery between the two groups. The additional detractor from doing an early ECV is that the rate of late preterm births did increase. The study noted that the success rate of early versus late ECV was greater, but the authors did not comment on the significance of this difference.

**Outcomes of pregnancies after ECV prove that it is a safe and effective intervention.<sup>4</sup>** Successful version was reported more often in parous than in nulliparous women and more often between 37 and 39 weeks' gestation than after 40 weeks. Fetal complications include abruption, a nonreassuring FHR pattern, rupture of the membranes, cord prolapse, spontaneous conversion back to breech, and fetomaternal hemorrhage. Maternal complications include a high rate of cesarean delivery—up to 64% in one study, and a twofold to fourfold risk in another—primarily for dystocia, despite successful conversion.<sup>55</sup>

**Gentle, constant pressure applied in a relaxed patient with frequent FHR assessments are elements of success stressed by all investigators.<sup>53</sup>** Methodology varies, although the "forward roll" is more widely supported than the "back flip" (Fig. 17-25).<sup>53</sup> The mechanical goal is to squeeze the fetal vertex gently out of the fundal area to the transverse and finally the lower segment of the uterus.

**A number of factors predict success of ECV with reliability.** A study in 2010 by Burgos and colleagues<sup>56</sup> demonstrated

**FIG 17-25** External cephalic version is accomplished by gently “squeezing” the fetus out of one area of the uterus and into another. Illustrated here is the popular “forward roll.”

increased rates of successful ECV at approximately 37 weeks’ gestation with parity greater than two (OR, 3.74; 95% CI, 2.37 to 5.9), posterior placental location (OR, 2.85; 95% CI, 1.87 to 4.36), and double footling breech as opposed to frank breech (OR, 2.77; 95% CI, 1.16 to 6.62). Complete breech also showed increased odds of success, but not to the extent that the double-footling breech did. Relative assessment of amniotic fluid volume was also made, and both “normal” and “abundant” fluid volumes showed improved successes. Two studies<sup>57,58</sup> demonstrated better results when the amniotic fluid index (AFI) exceeded 7 cm.

Tocolysis, regional anesthesia, and ultrasound during ECV may also be helpful. Use of a number of tocolytics has been reported; however, considerable experience has been reported using IV ritodrine, which has been voluntarily withdrawn from the U.S. market by the manufacturer. Other agents that have been used include hexoprenaline, salbutamol (albuterol), nitroglycerin, and terbutaline, which now carries a Food and Drug Administration (FDA) black-box warning. A randomized trial<sup>59</sup> of 103 nulliparous patients found that the success rate with subcutaneous terbutaline was 52%, compared with 27% in the control group, and no adverse maternal effects resulting from the drug were found. A randomized trial of 58 patients at 37 to 41 weeks’ gestation with breech presentation found no benefit from  $\beta$ -mimetic tocolysis, with success rates of approximately two thirds in each group.

**The use of regional anesthesia for ECV has also been controversial.** Many believe that operators might apply excessive pressure to the maternal abdomen when epidural anesthesia is used, which might make fetal compromise more likely, as indicated by FHR decelerations and possibly related to placental abruption. However, a randomized trial<sup>60</sup> of ECV in 69 women using epidural anesthesia demonstrated a better than twofold increase in the success of the procedure when an epidural was used. Disparate results are demonstrated when combined spinal-epidural (CSE) analgesia or spinal anesthesia is used. A randomized study<sup>61</sup> of nulliparas undergoing ECV showed a fourfold improvement in the success of ECV and a reduced visual analog pain score with spinal anesthesia compared with no anesthetic. Another randomized trial<sup>62</sup> of CSE anesthesia at analgesic doses versus systemic opioids showed no difference in the rates of successful ECV. This trial had an overall low rate of successful ECV (39%) and a low rate in each arm (47% in the CSE and 31% in the opioid arms, respectively), and the participation of 47 physicians suggests the possibility of highly varied skill levels across the providers. This trial specifically aimed to determine whether analgesia, as opposed to anesthesia, improves success. It appears that **the relationship of ECV success may be dose dependent as far as neuraxial anesthetic use is concerned because other trials that have used large anesthetic doses favor improved ECV success rates.**

A Cochrane database study<sup>63</sup> of the effects of tocolysis, regional anesthesia, vibroacoustic stimulation (VAS), and trans-abdominal amnioinfusion for ECV was performed and reported in 2012. It reviewed 25 studies with data on 2548 women. Tocolytics, in particular  $\beta$ -mimetics, increased the rate of cephalic presentation at term (RR, 1.38; 95% CI, 1.03 to 1.85) and reduced the cesarean delivery rate (RR, 0.82; 95% CI, 0.71 to 0.94). No difference was noted between success rates in nulliparas and multiparas with a cephalic presentation in labor or cesarean delivery; **therefore terbutaline before ECV is recommended.**

**Regional anesthesia in combination with tocolysis demonstrated more successful ECVs than the tocolytic drug alone (RR, 0.67; 95% CI, 0.51 to 0.89), but no difference was noted in either the rate of cesarean delivery or cephalic presentation in labor, and no difference in the occurrence of fetal bradycardia was observed. Data were insufficient to determine the efficacy of VAS, amnioinfusion, opioids, nitric oxide donors, or calcium channel blockers for improving ECV success rate.**<sup>14</sup>

On the adverse side, factors associated with failure of ECV included obesity, deep pelvic engagement of the breech, oligohydramnios, and posterior positioning of the fetal back. Fetomaternal transfusion has been reported to occur in up to 6% of patients undergoing external version<sup>64</sup>; thus **Rh-negative unsensitized women should receive RhD immune globulin.** Quantitation of fetomaternal hemorrhage with the Kleihauer-Betke (acid elution) or flow cytometry test will determine the number of vials of Rh0D immune globulin to be administered.

In the case of the gravida with a previous cesarean delivery, ECV has also been controversial. Studies of limited sample size have concluded that ECV is safe for mother and fetus and that it results in increased rates of vaginal delivery. Success rates of up to 82% in patients with a previous cesarean delivery have been reported.<sup>65</sup> Use of IV ritodrine tocolysis in 11 patients with a history of a previous low cervical transverse cesarean delivery

resulted in no uterine dehiscences found clinically or at the time of cesarean delivery.<sup>66</sup>

A 2009 study by Sela and colleagues<sup>67</sup> that included a review of the world literature (of singleton fetuses without anomalies at 36 or more weeks' gestation, all retrospective studies) found ECV success rates in multiparas that ranged between 65.8% and 100% (mean 76.6%) in patients with a single prior cesarean delivery. Prior successful vaginal delivery was predictive of higher success rates for ECV overall, and no excess morbidity/mortality or asymptomatic scar dehiscence was noted in these patients. The largest study of complication rates from ECV included patients with a prior cesarean delivery, but neither the success nor complication rates for this subgroup were reported; descriptions of overall complications included no case of overt uterine rupture or scar dehiscence.<sup>68</sup> Although these are now limited recommendations for patients with two prior cesarean deliveries to attempt a trial of labor after cesarean (TOLAC; see Chapter 20), data are not available regarding success rates and complications of ECV in this population.

Acupuncture and moxibustion of acupoint BL 67 (Zhiyin, which lies beside the outer corner of the fifth toenail) have been studied in relation to converting the noncephalic presenting fetus, and a Cochrane review<sup>69</sup> on this topic was recently published. Although early studies demonstrated benefit of these therapies, this review of eight studies with data on 1346 women showed that moxibustion alone did not reduce noncephalic presentation compared with no treatment. In comparison to acupuncture, however, moxibustion proved to be superior (RR, 0.25; 95% CI, 0.09 to 0.72), but in *combination* with acupuncture, a reduction was noted in both noncephalic presentations (RR, 0.73; 95% CI, 0.57 to 0.94) and cesarean deliveries (RR, 0.79; 95% CI, 0.64 to 0.98). The increasing role of complementary and alternative medicine and traditional techniques in modern medicine remain to be further examined.

## SHOULDER DYSTOCIA

In a normal delivery, after expulsion of the fetal head, external rotation occurs and returns the head to a right-angle position in relation to the shoulder girdle. The fetal shoulder during descent is in an oblique pelvic diameter; however, after expulsion and restitution, the anterior fetal shoulder should emerge from the oblique axis under the pubic ramus. **Shoulder dystocia occurs when the fetal shoulders are obstructed at the level of the pelvic inlet. Shoulder dystocia results from a size discrepancy between the fetal shoulders and the pelvic inlet, which may be absolute or relative, because of malposition.** A persistent anterior-posterior location of the fetal shoulders at the pelvic brim occurs when increased resistance is present between the fetal skin and the vaginal walls, such as with accelerated fetal growth; a large fetal chest relative to the biparietal diameter, seen in infants of diabetic gravidas; and when truncal rotation does not occur, as with precipitous labor. Shoulder dystocia typically occurs when the descent of the anterior shoulder is obstructed by the symphysis pubis. It can also result from impaction of the posterior shoulder on the maternal sacral promontory.<sup>70</sup>

Unfortunately, the ultimate diagnosis of this obstetric emergency will not occur until after the fetal head has emerged from the vagina (Fig. 17-26). The *turtle sign*, in which there is retraction of the fetal head against the maternal perineum, is suggestive but not diagnostic of the presence of shoulder dystocia. Shoulder dystocia is therefore most commonly diagnosed upon

**FIG 17-26** When delivery of the fetal head is not followed by delivery of the shoulders, the anterior shoulder often becomes caught behind the symphysis, as illustrated. The head may retract toward the perineum, and desperate traction on the fetal head is not likely to facilitate delivery and may lead to trauma.

failure of delivery of the fetal shoulder(s) after initial attempts at extraction-oriented manual traction and when ancillary obstetric maneuvers are required. Although other definitions have been reported in the literature, these are not commonly used in daily clinical practice. Two studies have proposed defining *shoulder dystocia* as a prolonged head-to-body delivery interval of 60 seconds (the mean plus two standard deviations) and/or use of ancillary obstetric maneuvers.<sup>71,72</sup> In Hoffman's multicenter study,<sup>73</sup> however, only two (0.01%) among the 2018 reported shoulder dystocias documented such a head-to-body time in the delivery notes.

**Shoulder dystocia has been reported to complicate 0.2% to 3% of all vaginal deliveries.**<sup>73</sup> This wide range has been attributed to the inherent subjectivity of the clinician's definition of *shoulder dystocia*, the degree of reporting, and differences in defining the study population. The risk of shoulder dystocia rises with increasing fetal birthweight; in these instances, the trunk—and in particular, the chest—grow larger relative to the head. **The percentage of deliveries complicated by shoulder dystocia for unassisted births not complicated by diabetes was 5.2% for infants weighing 4000 to 4250 g, 9.1% for those between 4250 and 4500 g, 14.3% for those 4500 and 4750 g, and 21.1% for those 4750 to 5000 g.**<sup>74</sup> It must be remembered that approximately 50% to 60% of shoulder dystocias occur in infants who weigh less than 4000 g. **Moreover, even if the birthweight of the infant is over 4000 g, shoulder dystocia will complicate only 3.3% of the deliveries.**<sup>70</sup>

In addition to being generally poor predictors for shoulder dystocia, historic clinical risk factors such as maternal obesity, prolonged second stage, previous birth of an infant weighing more than 4000 g, gestational diabetes mellitus, prolonged second stage of labor, prolonged deceleration phase (8 to 10 cm), prolonged and postterm pregnancy, increased maternal age, excess maternal weight gain, male fetus, and epidural analgesia/anesthesia are also not readily amenable to interventions that can alter fetal outcome. A triivariate analysis of labor induction, oxytocin use, and a birthweight greater than 4500 g only showed a sensitivity of 12.4% and a positive predictive value of 3.4% for the prediction of shoulder dystocia.<sup>75</sup>

**Recurrence risks for shoulder dystocia have been reported to range from approximately 10% to 25%.<sup>76</sup>** Among patients with recurrent shoulder dystocia, statistically significant risk factors have included maternal prepregnancy weight, maternal weight at delivery, duration of the second stage of labor, birthweight greater than the index pregnancy, and birthweight more than 4000 g.<sup>70</sup> Nearly 40% of providers surveyed in one study would allow a trial of labor in a patient with a documented history of a prior vaginal delivery complicated by shoulder dystocia.<sup>77</sup>

Antepartum and intrapartum efforts to predict postnatal birthweight—performed using either Leopold maneuvers, maternal assessment of birthweight, or with ultrasound-derived estimated fetal weight—are commonly used in clinical practice, although such efforts have been generally disappointing in the prediction and prevention of shoulder dystocia. **The American College of Obstetricians and Gynecologists recommends that planned cesarean delivery may be considered with estimated fetal weights that exceed 5000 g in women without diabetes and 4500 g in women with diabetes.<sup>78</sup>** Mean error rates for late third trimester ultrasound, however, have been reported to approximate 10% to 15%.<sup>79</sup> The fetal vertex is often too deeply engaged in the pelvis to allow accurate measurement of head circumference. Maternal body habitus and the presence of oligohydramnios are also contributing factors to this inability to accurately estimate fetal weight.

**The concept of prophylactic cesarean delivery as a means to prevent shoulder dystocia and therefore avoid brachial plexus injury has not been supported by either clinical or theoretic data.** The model of Rouse and associates<sup>80</sup> compared policies of management 1) without ultrasound; 2) with ultrasound and elective cesarean delivery for an estimated fetal weight over 4000 g; and 3) with ultrasound and elective cesarean delivery for an estimated fetal weight over 5000 g. It was found that 2345 to 3695 cesarean deliveries would need to be performed to prevent one permanent brachial plexus injury among nondiabetic women, with additional costs of \$4.9 to \$8.7 million. Using decision analysis techniques, Herbst<sup>81</sup> compared three strategies for an infant with an estimated fetal weight of 4500 g. She similarly found that expectant treatment was the preferred strategy at a cost of \$4104.33 per injury-free child, compared with planned cesarean delivery at a cost of \$5212.06 and an induction cost of \$5165.08.

A few authors have retrospectively evaluated the fetal abdominal diameter–biparietal diameter difference (AD-BPD) as a predictor for shoulder dystocia. These studies have been limited by their retrospective nature, difficulty in measuring the fetal abdominal outline at advanced gestational ages, small sample size, and lack of applicability to the general population. Among infants of diabetic mothers whose estimated fetal weights were 3800 to 4200 grams, Cohen and colleagues<sup>82</sup> found that shoulder dystocia occurred in 6 of 20 patients (30%) in whom the AD-BPD difference was at least 2.6 cm but in none of 11 patients in whom it was less than 2.6 cm ( $P = .05$ ). In nondiabetic women with suspected *macrosomia*, defined as an estimated fetal weight above 4000 g, the adjusted odds ratio of shoulder dystocia in the group with an AD-BPD difference of 2.6 cm or more was 3.67 (95% CI, 1.44 to 9.36).<sup>83</sup> In a study by Miller and colleagues,<sup>84</sup> those patients with shoulder dystocia had an increased AD-BPD difference (2.9 vs. 1.97,  $P = .0002$ ), and when the difference was 2.6 cm or more, the risk of dystocia was 25% for unselected patients and 38.5% for patients with

diabetes. Overall, an OR of 5.88 (95% CI, 1.18 to 19.09) for presence of dystocia was noted in all patients and carried a sensitivity of 35.7% and a specificity of 91.4%. For patients with diabetes, an OR of 7.19 for shoulder dystocia (95% CI, 1.58 to 32.67) was found.

**Postpartum hemorrhage and the unintentional extension of the episiotomy or laceration into the rectum are the most common maternal complications associated with shoulder dystocia.** In a study by Gherman and associates,<sup>85</sup> these occurred in 11% and 3.8%, respectively, of the described shoulder dystocias.

A large multicenter study that evaluated 2018 cases of shoulder dystocia included 60 cases of Erb-Duchenne paralysis, four with Klumpke paralysis, 41 clavicular or humeral fractures, and six episodes of hypoxic-ischemic encephalopathy (HIE).<sup>73</sup> **Unilateral brachial plexus palsies are the most common neurologic injury sustained by the neonate.** The right arm is typically affected owing to the fact that the left occiput anterior presentation is more common. Most (80%) of the brachial plexus palsies have been located within the C5-C6 nerve roots (Erb-Duchenne paralysis). Other types of brachial plexus palsies that have been described include Klumpke paralysis (C8-T1), an intermediate palsy, and complete palsy of the entire brachial plexus. Diaphragmatic paralysis, Horner syndrome, and facial nerve injuries have occasionally been reported to accompany brachial plexus paralysis. **Approximately one third of brachial plexus palsies will be associated with a concomitant bone fracture, most commonly of the clavicle (94%).<sup>86</sup>**

Using computer modeling, the forces applied to the fetal brachial plexus during shoulder dystocia—and also with the addition of release maneuvers—were estimated by Grimm and colleagues.<sup>87</sup> All maneuvers resulted in less stretch to the brachial plexus than with standard lithotomy delivery alone. Delivery of the posterior arm showed a 71% reduction in stretch applied to the anterior nerve plexus and was the maneuver that required the least force to deliver the anterior shoulder. In the past, it had been empirically deduced that brachial plexus injury resulted exclusively from operator-induced excess traction in the setting of shoulder dystocia. **In addition to research within the obstetric community, the pediatric, orthopedic, and neurologic literature now stresses that the existence of brachial plexus paralysis does not constitute a priori proof that exogenous forces were the cause of the injury.<sup>88</sup>** Maternal endogenous forces have been shown to exceed clinician-applied exogenous forces. It has been consistently reported that approximately 50% of brachial plexus paralysis occurs in the absence of clinically recognized shoulder dystocia. Gherman and colleagues<sup>89</sup> showed that neonates who experienced brachial plexus palsy without shoulder dystocia were of lower birthweight and had an increased rate of clavicular fractures, and these paralyzes were more likely to be persistent at 1 year of life.

The use of an exogenous force (traction) by the delivering provider is inherent in the management of the majority of vaginal deliveries and in the management of shoulder dystocia cases. **Clinical diagnosis of shoulder dystocia results from failure of delivery of the fetal shoulder(s) after an initial traction attempt.** A few authors have empirically advocated proceeding directly to maneuvers for attempted delivery of the fetal shoulders (i.e., avoidance of initial diagnostic traction) in order to maintain the forward momentum of the fetus. Others support a short delay in the delivery of the shoulders and advocate observation alone, arguing that the endogenous rotational

**FIG 17-27** After delivery of the head, *restitution* results in the long axis of the head reassuming its normal orientation to the shoulders as seen here.

**FIG 17-28** Gentle, symmetric pressure on the head will move the posterior shoulder into the hollow of the sacrum and will encourage delivery of the anterior shoulder. Care should be taken not to “pry” the anterior shoulder out asymmetrically because this might lead to trauma to the anterior brachial plexus.

mechanics of the second stage may spontaneously alleviate the obstruction.

**When shoulder dystocia is clinically diagnosed, the first order of business should be to stop all endogenous and exogenous forces until an attempt is made to alleviate the obstruction.** The patient should be instructed to stop pushing, although it must be recognized that most likely, the gravida will continue to involuntarily exert endogenous expulsive forces because uterine contractions do not spontaneously abate once the head emerges from the vagina. Maternal expulsive efforts will need to be restarted after the fetal shoulders have been converted to the oblique diameter—that is, as a diagnostic step to prove that a maneuver has been successful—in order to complete the delivery (Fig. 17-27).

**Whenever extraction (exogenous) forces are applied by the delivering clinician, the fetal head should be maintained in an axial position, and rotation of the head should be avoided.** By following the natural curve of the maternal pelvis, axially derived traction does by definition have a downward component (Fig. 17-28). Axial traction is traction applied in alignment with

**TABLE 17-4** MANEUVERS FOR THE ALLEVIATION OF SHOULDER DYSTOCIA

|                                 |
|---------------------------------|
| McRoberts maneuver              |
| Suprapubic pressure             |
| Rubin maneuver                  |
| Woods corkscrew maneuver        |
| Extraction of the posterior arm |
| Gaskin maneuver                 |
| Zavanelli maneuver              |
| Symphysiotomy                   |

the fetal cervicothoracic spine. Traction applied in the plane of the fetal cervicothoracic spine is typically along a vector estimated to be 20 to 25 degrees below the horizontal plane when the woman in labor is in a lithotomy position.<sup>88</sup> Thus while axial traction is also downward, it is applied without lateral bending of the fetal neck (i.e., bending the neck toward the floor or the ceiling). Laterally derived traction should not be used as the sole maneuver to effect delivery in the absence of ancillary obstetric maneuvers. Among the four cases in which this occurred in the series by Leung and associates,<sup>90</sup> three (75%) brachial plexus injuries and one (25%) clavicular fracture were reported.

No randomized clinical trials have been undertaken to guide physicians as to the order of the maneuvers that are to be performed (Table 17-4). The most effective preventive measure is to be familiar with the normal mechanism of labor and to be prepared to deal with the potential for shoulder dystocia in any vaginal delivery. Attendants should refrain from applying fundal pressure as a maneuver for the alleviation of shoulder dystocia, because pushing on the fundus serves only to further impact the anterior shoulder behind the symphysis pubis. Fundal pressure can be used to assist with delivery of the fetal body, but only if the shoulder dystocia has already been alleviated.

**The McRoberts maneuver is a simple, logical, and effective measure and is typically considered as the first-line treatment for shoulder dystocia.** The McRoberts maneuver and suprapubic pressure are appropriate first-line techniques because they are noninvasive, easy to learn, and can be performed quickly. In a retrospective review, Gherman and colleagues<sup>85</sup> found that the McRoberts maneuver was the only step required in 42% of 236 cases. The McRoberts maneuver involves hyperflexion of the maternal legs onto the abdomen, which results in flattening of the lumbar spine and ventral rotation of the maternal pelvis and symphysis (Fig. 17-29). Care should be taken to avoid prolonged or overly aggressive application of the McRoberts maneuver because the fibrocartilaginous articular surfaces of the symphysis pubis and surrounding ligaments may be unduly stretched.<sup>91</sup>

**It is reasonable to consider performing delivery of the posterior shoulder/arm as the next maneuver in this sequence** (Fig. 17-30). The ultimate decision for this, however, should be based on provider experience and the clinical situation. Several techniques to deliver the posterior shoulder have been described, but the most widely used method is extraction of the posterior fetal arm. To approach the posterior arm, the delivering clinician's hand is placed in the vagina, and the humerus of the posterior fetal arm is traced from the shoulder to the elbow. Once the forearm is grasped, it is swept across the fetal chest, and the arm is pulled out of the vagina. If the forearm is not accessible, pressure can be placed on the antecubital fossa to flex the elbow. If this allows access to the forearm, delivery of the posterior arm is accomplished as described above. If the forearm

**FIG 17-29** The least invasive maneuver to disimpact the shoulders is the McRoberts maneuver. Sharp ventral flexion of the maternal hips results in ventral rotation of the maternal pelvis and an increase in the useful size of the outlet.

is still not accessible, attempts are then made to deliver the posterior shoulder or to make the posterior arm accessible using posterior axillary traction methods. Menticoglou<sup>92</sup> described a technique of using the fingers to accomplish axillary traction. The technique starts by having an assistant hold the fetal head up, avoiding traction. Then, the operator's two middle fingers are positioned from each side of the posterior fetal shoulder and into the axilla. Downward and outward traction is then placed on the posterior shoulder to follow the curve of the sacrum. As the shoulder comes into view, the posterior arm is delivered as previously described. Another method of performing axillary traction is with the use of a sling. Hofmeyr and Cluver<sup>93</sup> described a technique of applying axillary traction using a sling fashioned from a 12- to 14-French suction catheter. In this technique, the suction catheter is passed over the shoulder and around the axilla. The two free ends of the catheter are clamped, and downward traction is used until the shoulder descends enough to allow for delivery of the posterior arm.

In the computer modeling evaluation of Grimm and colleagues,<sup>87</sup> **posterior arm delivery required the least exogenous force to effect delivery and resulted in the lowest brachial plexus stretch.** This decreases the impacted diameter from the bisacromial diameter to the axilloacromial diameter. The end point of posterior arm extraction is to substitute the axilloacromial diameter for the bisacromial diameter, with the former being approximately 3 cm shorter than the latter. Geometric analysis<sup>94</sup> has revealed that posterior arm delivery reduces shoulder dystocia more than twice as often relative to the McRoberts maneuver. Hoffman and associates<sup>73</sup> completed a cohort study

in which 2018 patients delivered with a shoulder dystocia had their records analyzed by trained abstractors for the maneuvers performed. **Delivery of the posterior shoulder was the most successful maneuver (84.4%) to alleviate shoulder dystocia, and the Woods maneuver (72%), Rubin maneuver (66%), and suprapubic pressure (62.2%) also showed high rates of delivery.** Multiple logistic regression analysis revealed a higher risk of neonatal injury with the Rubin (OR 1.54) and Woods (OR 2.22) maneuvers than with delivery of the posterior shoulder (OR 1.36). Leung and colleagues<sup>90</sup> found that among cases in which the McRoberts maneuver was unsuccessful, subsequent rotational methods and posterior arm delivery were similarly successful (72% vs. 63.6%) without a statistically significant increase in the rate of brachial plexus injury.

**Suprapubic pressure** is applied either directly downward onto the anterior presenting shoulder or by using a rocking motion from the fetal back toward the front. The aim of this maneuver is to decrease the bisacromial diameter by adducting the anterior shoulder and to deflect the bisacromial diameter to an oblique plane.

**Rotational maneuvers routinely performed include the Rubin or Woods corkscrew maneuvers.** The *Rubin maneuver* is performed by placing a hand into the vagina and applying pressure to the posterior aspect of the most accessible fetal shoulder (Fig. 17-31). The shoulder is then pushed toward the anterior surface of the fetal chest. The proposed mechanism of this maneuver is via adduction of the fetal shoulder, which reduces the bisacromial diameter and allows for the anterior shoulder to be rotated and dislodged from behind the pubic symphysis. The

Alternative method

**FIG 17-30** Rotation of the anterior shoulder forward through a small arc or of the posterior shoulder forward through a larger one will often lead to descent and delivery of the shoulders. Forward rotation is preferred, because it tends to compress and diminish the size of the shoulder girdle, whereas backward rotation would open the shoulder girdle and increase its size.

*Woods corkscrew maneuver* is performed by placing the fingers on the anterior aspect of the posterior fetal shoulder and rotating the shoulder toward the fetal back. The suggested mechanism for this maneuver relates to an attempt at rotation of the fetal torso in a 180-degree fashion to allow descent with rotation, much like the movement of a threaded screw when rotated.

Change of maternal position into an “all fours” position (*Gaskin maneuver*) may help to disimpact the fetal shoulder(s) to allow gravitational forces to push the posterior shoulder anteriorly. This maneuver has not been tested prospectively nor has it been compared with the traditional shoulder dystocia-relieving maneuvers, and it may be impractical for some patients. Fetal monitors and IV lines may hinder the patient’s mobility, and neuraxial anesthesia with concomitant motor blockade may reduce strength, making this maneuver difficult. A series of 82 consecutive cases of shoulder dystocia managed with the all-fours maneuver showed no increased maternal or neonatal morbidity or mortality and only one case of humerus fracture, noted in a fetus whose weight exceeded 4500 g.<sup>95</sup>

The use of routine episiotomy in the management of all shoulder dystocia cases has been advocated in the past but with little scientific evidence in support of this practice. From a

**FIG 17-31** The operator here inserts a hand and sweeps the posterior arm across the chest and over the perineum. Care should be taken to distribute the pressure evenly across the humerus to avoid unnecessary fracture.

theoretic standpoint, it does not seem probable that an incision into the soft tissue of the vagina and perineum would be helpful in resolving an impaction of the bony structures of the fetal shoulders in the bony construct of the maternal pelvis. **The need for cutting a generous episiotomy must be based on clinical circumstances, such as a narrow vaginal fourchette in a nulliparous patient.** Episiotomy can allow for greater access to the vagina for the performance of the internal manipulations necessary for the rotational maneuvers or for delivery of the posterior shoulder.<sup>96</sup>

Two techniques rarely used in the United States for the management of shoulder dystocia are vaginal replacement of the fetal head with subsequent cesarean delivery (*Zavanelli maneuver*) and subcutaneous symphysiotomy. These should be considered as heroic, last resort maneuvers to be performed after consideration of potentially significant maternal and fetal risks. **In the Zavanelli maneuver, the fetal head is rotated back to a direct occiput anterior position and then subsequently flexed. Constant, firm pressure is used to push the head back into the vagina.** Tocolytic agents or uterine-relaxing general anesthesia may be administered during the maneuver and in preparation for cesarean delivery. Use of the Zavanelli maneuver may be considered when impaction of the fetal shoulder on the sacral promontory has occurred, for bilateral shoulder dystocia,

or when the posterior shoulder is not in the pelvis.<sup>97</sup> Sandberg<sup>98</sup> reviewed the Zavanelli maneuver for both vertex- and breech-presenting undeliverable fetuses. Cephalic replacement was successful in 84 of 92 vertex-presenting fetuses; in 11 of 11 breech-presenting fetuses, podalic replacement was successful. Maternal risks included soft tissue trauma and sepsis, but the fetal risks were described as “minimal,” with no fetal injuries attributed to the maneuver; this may be misleading because of the presence of a multitude of etiologies for permanent injury or death, likely from attempts at disimpaction, prolonged delivery time, and hypoxia. O’Leary<sup>99</sup> described 35 cases, 31 of which were considered successful and one of which needed a hysterotomy incision to allow manual disimpaction of the fetal shoulders to facilitate vaginal delivery when the fetal head could not be replaced into the vagina from below.

Subcutaneous symphysiotomy has been practiced in underdeveloped regions of the world for many years as an expedient alternative to cesarean delivery with very good results. However, in a case series of three symphysiotomies,<sup>100</sup> the procedure was used as a last resort and was associated with the death of all three neonates because of hypoxic complications. Symphysiotomy was concluded to be safe and effective as long as attention is paid to the three main points in the procedure: 1) lateral support of the legs, 2) partial sharp dissection of the symphysis, and 3) displacement of the urethra to the side with an indwelling urinary catheter.

**Although patients are commonly placed in position for the McRoberts maneuver before delivery, currently available studies do not show clear benefit to these prophylactic measures to prevent shoulder dystocia.** In a study by Beall and colleagues,<sup>101</sup> patients with estimated fetal weights in excess of 3800 g were randomized to undergo a prophylactic McRoberts maneuver and suprapubic pressure before delivery of the fetal head or to undergo maneuvers only after delivery of the head, if necessary. No differences were reported between the two groups in the average head-to-body time, the proportion of patients with head-to-body time greater than 60 seconds, and the proportion of identified shoulder dystocias. Patients in the prophylactic group had a significant increase in the risk of cesarean delivery (31/90 [34%] vs. 11/95 [12%],  $P < .001$ ). In a study by Poggi and associates,<sup>102</sup> multiparous patients were randomized to delivery in the lithotomy position or were positioned for the McRoberts maneuver after the fetal head was delivered. The peak force for delivery of the anterior shoulder, the peak force rate, and head-to-body delivery interval were not statistically different between the two groups. Similar numbers of clinical shoulder dystocias (one per group) were encountered in each study group.

Shoulder dystocia should be viewed as an obstetric emergency because of the short period of time required to relieve the obstruction prior to the onset of hypoxic brain injury. **Contemporaneous documentation of the management of shoulder dystocia is recommended to record significant facts, findings, and observations about the shoulder dystocia event and its sequelae. Although no standard has been defined as to what exactly should be documented, a useful guideline is the ACOG Patient Safety Checklist (e-Fig. 17-1).**<sup>103</sup> Many electronic health records also allow easy documentation of the following suggested items:

1. Type of delivery; if instrumented, document station and indication
2. Time interval between delivery of the fetal head and body

3. Which shoulder was anterior or posterior
4. Timing and sequence of maneuvers performed
5. Medical and nursing personnel in attendance
6. Neonatal assessment of the baby
7. Presence or absence of episiotomy
8. Timing, duration, and angle of traction applied
9. Condition of the infant: Apgar scores, umbilical cord blood gases, evidence of fractures, and/or reduced movement of either arm
10. Information given to the patient or family

Not all fetuses have the same baseline reserve during second-stage labor, so it is difficult to state an exact length of time in which HIE will occur if delivery is not completed. Given the considerable overlap in delivery timing for neonates with and without injuries or depression, it is difficult to pinpoint an exact time within which delivery should ideally occur. **Based on the current literature, it seems reasonable to consider extraordinary measures to effect delivery once 4 to 5 minutes have elapsed and the fetus is still undelivered.**<sup>70</sup>

### KEY POINTS

- ◆ *Fetal lie* refers to the orientation of the fetal spine relative to that of the mother. Normal fetal lie is longitudinal and by itself does not connote whether the presentation is cephalic or breech.
- ◆ Cord prolapse occurs 20 times as often with an abnormal axial lie as it does with a cephalic presentation.
- ◆ Fetal malformations are observed in more than half of infants with a face presentation.
- ◆ Fetal malpresentation requires timely diagnostic exclusion of major fetal or uterine malformations and/or abnormal placentation.
- ◆ A closely monitored labor and vaginal delivery is a safe possibility with face or brow malpresentations. However, cesarean delivery is the only acceptable alternative if normal progress toward spontaneous vaginal delivery is not observed.
- ◆ External cephalic version of the infant in breech presentation near term is a safe and often successful management option. Use of tocolytics and epidural anesthesia may improve success.
- ◆ Appropriate training and experience is a prerequisite to the safe vaginal delivery of selected infants in breech presentation.
- ◆ In experienced hands, women with twins presenting vertex/nonvertex can undergo a trial of labor because this management has similar maternal and perinatal outcomes to a planned cesarean delivery.
- ◆ A simple compound presentation may be permitted a trial of labor as long as labor progresses normally with reassuring fetal status. However, compression or reduction of the fetal part may result in injury.

## DOCUMENTING SHOULDER DYSTOCIA

Date \_\_\_\_\_ Patient \_\_\_\_\_ Date of birth \_\_\_\_\_ MR # \_\_\_\_\_

Physician or certified nurse–midwife \_\_\_\_\_ Gravidity/Parity \_\_\_\_\_

Timing:

Onset of active labor \_\_\_\_\_

Start of second stage \_\_\_\_\_

Delivery of head \_\_\_\_\_

Time shoulder dystocia recognized and help called \_\_\_\_\_

Delivery of posterior shoulder \_\_\_\_\_

Delivery of infant \_\_\_\_\_

Antepartum documentation:

- ☐ Assessment of pelvis
- ☐ History of prior cesarean delivery: Indication for cesarean delivery: \_\_\_\_\_
- ☐ History of prior shoulder dystocia ☐ History of gestational diabetes
- ☐ Largest prior newborn birth weight \_\_\_\_\_ ☐ Estimated fetal weight \_\_\_\_\_
- ☐ Cesarean delivery offered if estimated fetal weight greater than 4,500 g (if the patient has diabetes mellitus) or greater than 5,000 g (if patient does not have diabetes mellitus)

Intrapartum documentation:

- ☐ Mode of delivery of vertex:
  - ☐ Spontaneous ☐ Operative delivery: Indication: \_\_\_\_\_
  - ☐ Vacuum ☐ Forceps
- ☐ Anterior shoulder:
  - ☐ Right ☐ Left
- ☐ Traction on vertex:
  - ☐ None ☐ Standard
- ☐ No fundal pressure applied
- ☐ Maneuvers utilized (1):
  - ☐ Hip flexion (McRoberts maneuver) ☐ Suprapubic pressure (stand on the side of the occiput)
  - ☐ Delivery of posterior arm ☐ All fours (Gaskin maneuver)
  - ☐ Posterior scapula (Woods maneuver) ☐ Anterior scapula (Rubin maneuver)
  - ☐ Abdominal delivery ☐ Zavanelli maneuver
- ☐ Episiotomy:
  - ☐ None ☐ Median ☐ Mediolateral ☐ Proctoepisiotomy
- ☐ Extension of episiotomy:
  - ☐ None ☐ Third degree ☐ Fourth degree
- ☐ Laceration:
  - ☐ Third degree ☐ Fourth degree
- ☐ Cord blood gases sent to the laboratory:
  - ☐ Yes: Results: \_\_\_\_\_
  - ☐ No

(continued)

*(continued)*

- ☐ Status of neonate prior to leaving delivery room or operating room:
  - Apgar scores \_\_\_\_\_
  - Evidence of injury \_\_\_\_\_
  - Birth weight (if available) \_\_\_\_\_
- ☐ Staff present \_\_\_\_\_
- ☐ Family members present \_\_\_\_\_
- ☐ Patient and family counseled ☐ Debriefing with appropriate personnel
- Postpartum/neonatal documentation:
  - ☐ Delivery discussed with family ☐ Perineal assessment if third or fourth degree laceration
  - ☐ Monitored for postpartum hemorrhage:
    - ☐ Yes: Results: \_\_\_\_\_
    - ☐ No
  - ☐ Communication with pediatrics department if there is evidence of injury or asphyxia
  - ☐ Coordination of follow-up care for mother and baby
  - ☐ Monitored for postpartum depression:
    - ☐ Yes: Results: \_\_\_\_\_
    - ☐ No

**Procedural Elements for Shoulder Dystocia**

The following steps should be taken when managing shoulder dystocia:

1. Call for help from pediatrics, anesthesia, and neonatal intensive care unit staff, and assign a timekeeper
2. Initiate maneuver (eg, McRoberts maneuver)
3. Re-evaluate course of actions, including using other maneuvers or repeating maneuvers if unsuccessful
4. Consider abdominal delivery
5. Document event—move to documentation checklist

*Standardization of health care processes and reduced variation has been shown to improve outcomes and quality of care. The American College of Obstetricians and Gynecologists has developed a series of Patient Safety Checklists to help facilitate the standardization process. This checklist reflects emerging clinical, scientific and patient safety advances as of the date issued and is subject to change. The information should not be construed as dictating an exclusive course of treatment or procedure to be followed. Although the components of a particular checklist may be adapted to local resources, standardization of checklists within an institution is strongly encouraged.*

**How to Use This Checklist**

The Patient Safety Checklist on Documenting Shoulder Dystocia should be used to guide the documentation process if a patient has experienced shoulder dystocia.

| Continuous positive airway pressure | CPAP  |
| Fresh frozen plasma                 | FFP   |
| Packed red blood cells              | pRBCs |

**Obstetric hemorrhage is one of the leading causes of maternal morbidity and mortality throughout the world.** Hemorrhage following delivery is the leading reason for an obstetric admission to the intensive care unit (ICU), and it is responsible for one third of all pregnancy-related deaths in both high- and low-income countries.<sup>1</sup> Therefore it is critical for the obstetrician to have a thorough understanding of the hemodynamic changes that accompany pregnancy, the maternal adaptations that occur with excessive blood loss, and the management principles for obstetric hemorrhage.

## PREGNANCY-RELATED HEMODYNAMIC CHANGES

**Pregnancy is associated with five significant hemodynamic changes** (see Chapter 3). The first of these changes is **plasma volume expansion**. The average singleton pregnancy is accompanied by a 40% to 50% increase in plasma volume by the thirtieth week of gestation. This increase in plasma volume occurs along with the second change, an **increase in red blood cell (RBC) mass**. With appropriate substrate availability, RBC mass can be expected to increase 20% to 30% by the end of pregnancy. Third, **maternal cardiac output rises** with normal pregnancy owing to both increased stroke volume and increased heart rate. According to consensus, the average rise in cardiac output is 30% to 50% above nonpregnant levels, and the peak occurs in the early third trimester. Fourth, **systemic vascular resistance falls** in parallel with this rise in cardiac output and blood volume expansion. Fifth, **fibrinogen and the majority of**

**procoagulant blood factors (II, VII, VIII, IX, and X) increase** during pregnancy. These five changes are protective of maternal hemodynamic status and thus allow for certain physiologic adaptations that accompany obstetric hemorrhage.

## PHYSIOLOGIC ADAPTATION TO HEMORRHAGE

During pregnancy and the puerperium, a **defined sequence of physiologic adaptations occurs with hemorrhage** (Fig. 18-1). When 10% of the circulatory blood volume is lost, vasoconstriction occurs in both the arterial and venous compartments in order to maintain blood pressure and to preserve blood flow to essential organs. As blood loss reaches 20% or more of the total blood volume, increases in systemic vascular resistance can no longer compensate for the lost intravascular volume, and blood pressure decreases with a commensurate rise in heart rate. Cardiac output falls in parallel because of a loss in preload that results in poor end-organ perfusion. If the intravascular volume is not appropriately replaced, shock will ensue.

In severe preeclampsia (PE), these physiologic adaptations are altered. Unlike in most pregnant women, the protective mechanism of blood volume expansion is diminished with severe PE. It is estimated that plasma volume expansion is 9% lower in the setting of PE. In addition, because of the significant vasoconstriction that accompanies PE, blood loss in these patients may be underestimated because blood pressure is often maintained in the normotensive range. Finally, oliguria may not be as reliable an indicator of poor end-organ perfusion secondary to hemorrhage because reduced urine output is often a manifestation of the severity of PE.

## CLASSIFICATION OF HEMORRHAGE

A standard classification for acute blood loss is illustrated in Table 18-1. **Understanding the physiologic responses that accompany varying degrees of volume deficit can assist the clinician when caring for hemorrhaging patients.**

**FIG 18-1** Relationships among systemic vascular resistance, blood pressure, and cardiac output in the face of progressive blood volume deficit.

**TABLE 18-1** HEMORRHAGE CLASSIFICATION AND PHYSIOLOGIC RESPONSE

| CLASS | ACUTE BLOOD LOSS (mL) | % LOST | PHYSIOLOGIC RESPONSE  |
|-------|-----------------------|--------|---|
| 1     | 1000                  | 15     | Dizziness, palpitations, minimal blood pressure change                        |
| 2     | 1500                  | 20-25  | Tachycardia, tachypnea, sweating, weakness, narrowed pulse pressure           |
| 3     | 2000                  | 30-35  | Significant tachycardia and tachypnea, restlessness, pallor, cool extremities |
| 4     | ≥2500                 | 40     | Shock, air hunger, oliguria or anuria   |

Modified from Baker RJ. Evaluation and management of critically ill patients. *Obstet Gynecol Annu.* 1977;6:295; and Bonnar J. Massive obstetric haemorrhage. *Baillieres Best Pract Res Clin Obstet Gynaecol.* 2000;14:1.

Determination of the hemorrhage class reflects the volume deficit, which may not be the same as the volume loss. The average 70-kg pregnant woman maintains a blood volume of 6000 mL by 30 weeks of gestation (85 mL/kg).

**Class 1 hemorrhage** corresponds to approximately 1000 mL of blood loss. This blood loss correlates to a 15% volume deficit. Women with this amount of volume deficit exhibit mild physiologic changes such as dizziness and palpitations owing to the hemodynamic adaptations that accompany normal pregnancy.

**Class 2 hemorrhage** is characterized by 1500 mL of blood loss, or a 20% to 25% volume deficit. Early physical changes that occur during a hemorrhage of this class include **tachycardia** and **tachypnea**. Although tachycardia is usually recognized as a compensatory mechanism to increase cardiac output, the significance of tachypnea is unclear and is often unappreciated clinically. Tachypnea can represent a sign of impending clinical decompensation. **Narrowing of the pulse pressure** is another

sign of a class 2 hemorrhage. The pulse pressure represents the difference between the systolic and diastolic blood pressures. Systolic blood pressure is a good representation of stroke volume and  $\beta_1$  stimulation. Diastolic blood pressure is a reflection of systemic vasoconstriction; therefore the pulse pressure represents the interrelationship between these entities. With a class 2 volume deficit, the sympathoadrenal system is activated, which results in a diversion of blood away from nonvital organs (skin, muscle, and kidney) and a redistribution of the circulation to vital body organs, including the brain and heart. The end result is increased vasoconstriction, increased diastolic blood pressure, maintenance of systolic blood pressure, and a narrowing of the pulse pressure. With greater narrowing of the pulse pressure, more compensatory vasoconstriction occurs to accommodate for a loss in stroke volume. A final physiologic response of class 2 hemorrhage is **orthostatic hypotension**. Although blood pressure comparisons can be made in the supine, sitting, and standing positions to document this response, a practical approach is to assess the time needed to refill a blanched hypothenar area on the patient's hand. Typically, a patient with normal volume status can reperfuse this area within 1 to 2 seconds after pressure is applied. A patient with a class 2 hemorrhage and orthostatic hypotension will have significant reperfusion delay.

**Class 3 hemorrhage** is defined as a blood loss of 2000 mL and corresponds to a volume deficit of 30% to 35%. Within this hemorrhage class, the physiologic responses noted in class 2 hemorrhage are exaggerated. Patients demonstrate significant **tachycardia** (120 to 160 beats/min), **tachypnea** (30 to 50 breaths/min), **overt hypotension**, **restlessness**, **pallor**, and **cool extremities**.

**Class 4 hemorrhage** is characterized by more than 2500 mL of blood loss. This amount of blood loss exceeds 40% of the patient's total blood volume. The clinical manifestations of this volume deficit include **absent distal pulses**, **shock**, **air hunger**, and **oliguria or anuria**. When significant hemorrhage occurs, renal blood flow is reduced and is redirected from the outer renal cortex to the juxtamedullary region. In this region, increased water and sodium absorption occur and result in decreased urine volume, lower urinary sodium concentration, and increased urine osmolality. A urine sodium concentration less than 10 to 20 mEq/L or a urine/serum osmolar ratio greater than 2 indicates significantly reduced renal perfusion in the face of hemorrhage.

## ANTEPARTUM HEMORRHAGE

### Placental Abruptio

#### Definition and Pathogenesis

**Placental abruptio**, or **abruptio placentae**, refers to the premature separation of a normally implanted placenta from the uterus prior to delivery of the fetus. The diagnosis is typically reserved for pregnancies at greater than 20 weeks of gestation. Abruptio is characterized by defective maternal vessels in the decidua basalis, which rupture and cause the separation. On rare occasions, the separation may be caused by a disruption of the fetal-placental vessels. These damaged vessels cause bleeding, which results in a decidual hematoma that may promote placental separation, destruction of placental tissue, and a loss of maternal-fetal surface area for nutrient and gas exchange.

Whereas some placental abruptions may occur acutely after a sudden mechanical event (e.g., blunt trauma, sudden uterine decompression, or motor vehicle accident), most

**cases result from more chronic processes.**<sup>2</sup> Abnormal development of the spiral arteries can lead to decidual necrosis, inflammation, infarction, and bleeding due to vascular disruption.<sup>3-6</sup> Thrombin, which is released in response to decidual hemorrhage or hypoxia, appears to play an active role in the pathogenesis of placental abruption. Thrombin acts as a direct uterotonic, enhances the action of matrix metalloproteinases, upregulates apoptosis genes, increases the expression of inflammatory cytokines, triggers the coagulation cascade, and initiates functional progesterone withdrawal.<sup>7-9</sup> These thrombin-mediated events initiate a cyclic pathway of vascular disruption, hemorrhage, inflammation, contractions, and rupture of membranes.<sup>5</sup>

### Incidence

**The overall incidence of placental abruption is approximately 1 in 100 births;** however, a range of 1 in 80 to 1 in 250 deliveries has been reported.<sup>10,11</sup> The range in incidence likely reflects variable criteria for diagnosis as well as an increased recognition in recent years of milder forms of abruption. **About one third of all antepartum bleeding can be attributed to placental abruption, which peaks in the third trimester; 40% to 60% of abruptions occur prior to 37 weeks of gestation.**<sup>10</sup>

### Clinical Manifestations

**Several factors determine the clinical manifestations of placental abruption.** These factors include (1) the **temporal nature of the abruption** (acute vs. chronic), (2) **clinical presentation** (overt vs. concealed), and (3) **severity**. An acute, overt abruption typically presents with vaginal bleeding, abdominal pain, and uterine contractions. As the placental separation worsens, uterine tenderness, tachysystole, fetal heart rate (FHR) patterns consistent with hypoxia, and fetal death may occur. **The amount of vaginal bleeding correlates poorly with the extent of placental separation and its potential for fetal compromise. In fact, concealed abruption occurs in 10% to 20% of cases.**<sup>12</sup> With severe abruptions, more than 50% of the placental surface area separates. With extensive abruption, a significant risk for fetal death exists, and maternal compromise in the form of consumptive coagulopathy may result from the triggering of the clotting cascade by hemorrhage and extensive thrombin deposition.

**Chronic abruption may be insidious in its presentation and is often associated with ischemic placental disease.**<sup>13</sup> Typically, these cases present with intermittent, light vaginal bleeding and evidence of chronic placental inflammation and dysfunction, such as oligohydramnios, fetal growth restriction, preterm labor, premature preterm rupture of membranes (PPROM), and PE.

### Risk Factors

Although the exact etiology of placental abruption is unclear, a variety of risk factors have been identified (Box 18-1).

#### INCREASING PARITY AND MATERNAL AGE

Several studies have noted a **higher incidence of placental abruption with increasing parity**. Among primigravid women, the frequency of placental abruption is less than 1%; however, 2.5% of grand multiparas experience placental abruption. Theories suggest that damaged endometrium, impaired decidualization, and aberrant vasculature may have causal roles with increasing parity or age.

**Maternal age is often cited as an associated risk factor for placental abruption.** Although a 15-year population-based

#### BOX 18-1 RISK FACTORS FOR PLACENTAL ABRUPTION

Increasing parity and maternal age

Maternal substance use

- Cigarette smoking
- Cocaine abuse

Trauma

Maternal diseases

- Hypertension
- Hypothyroidism
- Asthma

Preterm premature rupture of membranes

Rapid uterine decompression associated with multiple gestation and polyhydramnios

Uterine and placental factors

- Anomalies
- Synechiae
- Fibroids
- Cesarean scar
- Abnormal placental formation
- Chronic ischemia

Prior abruption

Hyperhomocysteinemia

study in Norway was able to demonstrate a strong relationship between maternal age and placental abruption for all levels of parity, others studies suggest that there is no increased risk for placental abruption among older women when parity and hypertensive disease are excluded.

#### MATERNAL SUBSTANCE ABUSE

**Cigarette smoking is associated with a significantly increased incidence of placental abruption and fetal death.** There appears to be a dose-response relationship with the number of cigarettes smoked and the risks for placental abruption and fetal loss. Compared with nonsmokers, smokers have a 40% increased risk for fetal death from placental abruption with each pack of cigarettes smoked. In addition, smoking and hypertensive disease appear to have an additive effect on the likelihood of placental abruption. Proposed etiologies include placental hypoperfusion with resulting decidual ischemia and necrosis.

**Cocaine abuse in the third trimester has been associated with as high as a 10% placental abruption rate.** The pathogenesis appears to be related to cocaine-induced vasospasm with subsequent decidual ischemia, reflex vasodilation, and vascular disruption within the placental bed.

#### TRAUMA

**Blunt or penetrating trauma to the gravid abdomen has been associated with placental abruption.** After a **minor trauma**, the risk for placental abruption is **between 7% and 9%**, whereas the risk may be **as high as 13%** after severe injury.<sup>14</sup> The two most common causes of maternal trauma are motor vehicle crashes and domestic abuse. With motor vehicle crashes, uterine stretch, direct penetration, and placental shearing from acceleration-deceleration forces are the primary etiologies of trauma-related placental abruption (see Chapter 26).

#### MATERNAL DISEASES

**Maternal hypertension has been the most consistently identified risk factor for placental abruption.**<sup>13</sup> This relationship has been observed with both chronic and pregnancy-related hypertensive disease. Compared with normotensive women, hypertensive women have a fivefold increased risk for placental

abruption. Unfortunately, antihypertensive therapy has not been shown to reduce the risk for placental abruption in women with chronic hypertension.

Maternal subclinical hypothyroidism and asthma have also been associated with placental abruption in some studies.<sup>15,16</sup>

### PRETERM PREMATURE RUPTURE OF MEMBRANES

**Placental abruption occurs in 2% to 5% of pregnancies with PPROM.** Intrauterine infection and oligohydramnios significantly increase the risk for placental abruption, and nonreassuring FHR patterns occur in nearly half of these pregnancies.

It is unclear whether placental abruption is the cause or consequence of PPROM. Hemorrhage and associated thrombin generation may stimulate cytokine and protease production, which results in membrane rupture. Alternatively, the cytokine-protease cascade that follows ruptured membranes may cause damage to the decidual vasculature, which predisposes the placenta to separation.

### RAPID UTERINE DECOMPRESSION ASSOCIATED WITH MULTIPLE GESTATIONS AND POLYHYDRAMNIOS

**Rapid decompression of an overdistended uterus can precipitate an acute placental abruption. This may occur in the setting of multiple gestations or with polyhydramnios.** Compared with singletons, twins have been reported to have nearly a threefold increased risk for placental abruption. Although the exact timing of placental abruption in multiple gestations is difficult to ascertain, it has been attributed to rapid decompression of the uterus after the delivery of the first twin. Likewise, rapid loss of amniotic fluid in pregnancies complicated by polyhydramnios has been implicated in placental abruption. This can occur with spontaneous rupture of membranes or may follow therapeutic amniocentesis. For this reason, controlled artificial rupture of membranes with induction of labor may be advisable if significant polyhydramnios complicates pregnancy.

### UTERINE AND PLACENTAL FACTORS

**Suboptimal placental implantation in patients with uterine anomalies, synechiae, fibroids, and cesarean scars is associated with abruption.**<sup>17</sup> In addition, abnormal placental formation (e.g., circumvallate placenta) or chronic ischemia associated with PE and fetal growth restriction have been implicated in placental abruption.<sup>18</sup>

### PRIOR ABRUPTION

Women who have had a previous abruption are at significant risk for recurrent abruption. **After one abruption, the recurrence risk is 5% to 15%, whereas the risk increases to 20% to 25% after two abruptions.**<sup>19</sup> The risk of recurrence is greater after a severe abruption. **When an abruption is associated with fetal demise, there is a 7% incidence of the same outcome in a future gestation.**

### THROMBOPHILIA

Inconsistent data exist regarding an association among thrombophilias and placental abruptions.<sup>20,21</sup> Hyperhomocysteinemia (a fasting homocysteine level >15  $\mu\text{mol/L}$ ) may be associated with recurrent abruption.

### Diagnosis

**Placental abruption is primarily a clinical diagnosis that is supported by radiographic, laboratory, and pathologic**

**studies.** Any findings of vaginal bleeding, uterine contractions, abdominal and/or back pain, or trauma should prompt an investigation for potential placental abruption. Vaginal bleeding may range from mild to severe. Unfortunately, bleeding may be underestimated because it can be retained behind the placenta. The typical abruption contraction pattern is high frequency and low amplitude; however, it may simulate labor in some circumstances.

### RADIOLOGY

Although early studies that evaluated the use of **ultrasound** for the diagnosis of placental abruption identified less than 2% of cases, recent advances in imaging and its interpretation have improved detection rates. Early hemorrhage is typically hyperechoic or isoechoic, whereas resolving hematomas are hypoechoic within 1 week and sonolucent within 2 weeks of the abruption. Acute hemorrhage may be misinterpreted as a homogeneous thickened placenta or fibroid.

Ultrasound can identify **three predominant locations for placental abruption.** These are **subchorionic** (between the placenta and the membranes), **retroplacental** (between the placenta and the myometrium), and **preplacental** (between the placenta and the amniotic fluid). **Figure 18-2** illustrates the classification of hematomas in relation to the placenta. **Figure 18-3** demonstrates a sonographic representation of a subchorionic abruption.

The location and extent of the placental abruption identified on ultrasound examination is of clinical significance. **Retroplacental hematomas are associated with a worse prognosis for fetal survival than subchorionic hemorrhage.** The size of the hemorrhage is also predictive of fetal survival. Large retroplacental hemorrhages (>60 mL) have been associated with a 50% or greater fetal mortality, whereas similarly sized subchorionic hemorrhages are associated with a 10% mortality risk.<sup>22</sup>

Magnetic resonance imaging (MRI) has been used occasionally for the diagnosis of placental abruption when sonography is equivocal.<sup>23,24</sup>

### LABORATORY FINDINGS

Few laboratory studies assist in the diagnosis of placental abruption. **Hypofibrinogenemia and evidence of consumptive coagulopathy may accompany severe abruption;** however, clinical correlation is necessary. Moreover, most abruptions are not accompanied by maternal coagulopathy.

Abnormal serum markers early in pregnancy, such as an unexplained elevated maternal serum  $\alpha$ -fetoprotein (MSAFP) or human chorionic gonadotropin (hCG) and decreased pregnancy-associated plasma protein A (PAPP-A) or estriol, have been associated with an increased risk for subsequent placental abruption.<sup>18,25</sup>

### PATHOLOGIC STUDIES

**Macroscopic inspection of the placenta may demonstrate adherent clot and depression of the placental surface.** Fresh or acute placental abruptions may not have any identifiable evidence on gross pathologic examination, but histologic analysis may show preservation of the villous stroma, eosinophilic degeneration of the syncytiotrophoblast, and scattered neutrophils with villous agglutination.<sup>5</sup> Chronic abruptions may demonstrate histologic signs of chronic deciduitis, maternal floor decidual necrosis, villitis, decidual vasculopathy, infarction,

**FIG 18-2** The classification system of placental abruption. **A**, Retroplacental abruption. The bright red area represents a blood collection behind the placenta (*dark red*). **B**, Subchorionic abruption. The bright red area represents subchorionic bleeding, which is observed to dissect along the chorion. **C**, Preplacental abruption. The bright red area represents a blood collection anterior to the placenta within the amnion and chorion (subamniotic). (From Trop I, Levine D. Hemorrhage during pregnancy: sonography and MR imaging. *AJR Am J Roentgenol*. 2001;176:607.)

intervillous thrombosis, villous maldevelopment, and hemosiderin deposition.<sup>9</sup>

### Management

Both maternal and fetal complications may occur with placental abruption. Maternal complications include blood loss, consumptive coagulopathy, need for transfusion, end-organ damage, cesarean delivery, and death. Fetal complications include intrauterine growth restriction (IUGR),

oligohydramnios, prematurity, hypoxemia, and stillbirth. Although maternal complications are related to the severity of the abruption, fetal complications are related to both the severity and timing of the hemorrhage.<sup>12</sup>

Despite its relative frequency, no randomized trials and few studies have examined management approaches for placental abruption.<sup>26</sup> Typically, management of placental abruption depends on the severity, gestational age, and maternal-fetal status. Once the diagnosis of placental abruption has been

**FIG 18-3** Ultrasonic image of a subchorionic abruption. (Courtesy K. Francois.)

made, precautions should be taken to anticipate the possible life-threatening consequences for both mother and fetus. These precautions include baseline **laboratory assessment** (hemoglobin, hematocrit, platelet count, type and screen, fibrinogen, and coagulation studies), **appropriate intravenous (IV) access** (large-bore catheter), **availability of blood products**, **continuous FHR and contraction monitoring**, and **communication with operating room (OR) and neonatal personnel**.

**Small placental abruptions remote from term (<34 weeks) may be managed expectantly.** With cases of chronic abruption, clinical circumstances that include gestational age and the extent of the abruption influence the need for prolonged hospitalization until delivery. In many cases, a cyclic event of bleeding, thrombin generation, contractions, and further placental separation occurs. Tocolysis may help prevent contractions and thus may break the abruption cycle. If the maternal-fetal status is stable, a trial of tocolysis for documented preterm labor and administration of antenatal corticosteroid therapy can be considered. Whereas the choice of tocolysis should be individualized, magnesium sulfate administration may confer an added benefit of fetal neuroprotection. Reported series of expectant management in preterm gestations with placental abruption have shown a significant prolongation of the pregnancy (>1 week) in more than 50% of patients without adverse maternal or fetal outcomes. In a large series of preterm patients who presented with placental abruption and received tocolysis, about one third delivered within 48 hours of admission, one third delivered within 7 days, and one third delivered more than 1 week from initial presentation. No cases of intrauterine demise were reported in women who presented with a live fetus. Although these results are encouraging, the clinician must always keep in mind that placental abruption can result in both maternal and fetal morbidity. Any attempt to arrest preterm labor in a known or suspected placental abruption must be weighed against the likelihood of neonatal survival and morbidity, the severity of the abruption, and the safety of the mother.

**Women who present at or near term with a placental abruption should undergo delivery.** Induction or augmentation of labor is not contraindicated in the setting of an abruption; however, close surveillance for any evidence of maternal or fetal compromise is advised. Continuous FHR monitoring is recommended because 60% of fetuses may exhibit intrapartum heart rate patterns consistent with hypoxia.

Intrauterine pressure catheter (IUPC) placement and internal FHR monitoring can assist the clinician during the intrapartum course. IUPC monitoring may demonstrate elevated uterine resting tone, which can be associated with fetal hypoxia. Maternal hemodynamic and clotting parameters must be followed closely to detect signs of evolving coagulopathy. **Although vaginal delivery is generally preferable, operative delivery is often necessary owing to fetal or maternal decompensation.** When cesarean delivery is required, a rapid decision-to-delivery time is optimal because an interval of less than 20 minutes from the onset of fetal bradycardia is associated with improved outcomes. A *Couvellaire uterus*, also known as *uteroplacental apoplexy*, is characterized by extravasation of blood into the myometrium; it may be noted in some cases and is often associated with significant uterine atony. Administration of uterotonic therapy usually improves the condition. Hysterectomy should be reserved for cases of atony and hemorrhage unresponsive to conventional uterotonic therapies and replacement of blood products.

**The management of women with consumptive coagulopathy and fetal demise requires a thorough knowledge of the natural history of severe placental abruption.** Nearly five decades ago, Pritchard and Brekken noted several clinically important observations: (1) about 40% of patients with placental abruption and fetal demise will demonstrate signs of consumptive coagulopathy; (2) within 8 hours of initial symptoms, hypofibrinogenemia will be present; (3) severe hypofibrinogenemia will not recover without blood product replacement; and (4) the time course for recovery from hypofibrinogenemia is roughly 10 mg/dL per hour after delivery of the fetus and placenta.

When managing women with severe placental abruptions and fetal demise, maintenance of maternal volume status and replacement of blood products is essential. Although operative delivery may appear to lead to the most rapid resolution of the problem, it may pose significant risks to the patient. Unless the consumptive coagulopathy is corrected, surgery can result in uncontrollable bleeding and an increased need for hysterectomy. The uterus does not need to be evacuated before coagulation status can be restored. Blood product replacement and delayed delivery until hematologic parameters have improved are generally associated with good maternal outcomes.

### Neonatal Outcome

**Placental abruption is associated with increased perinatal morbidity and mortality.** When compared with normal pregnancies, pregnancies complicated by abruption have a **tenfold increased risk for perinatal death**. A case-control study has also shown a **greater risk for adverse long-term neurobehavioral outcomes** in infants delivered after placental abruption. Neonates at risk for abnormal outcomes had higher incidences of abnormal FHR tracings (45%) and emergency cesarean deliveries (53%) compared with controls (10% and 10%, respectively). **Finally, hypoxia-associated periventricular leukomalacia and sudden infant death syndrome (SIDS) are more common in newborns delivered after placental abruptions.**

### Placenta Previa

#### Definition and Pathogenesis

**Placenta previa** is defined as the presence of placental tissue over or adjacent to the cervical os. Traditionally, four variations of placenta previa were recognized: 1) complete, 2) partial,

3) marginal, and 4) low lying.<sup>27</sup> Although *complete placenta previa* has been the term used to refer to the total coverage of the internal cervical os by placental tissue, the differences among the terms *partial* (placental edge partially covering the internal cervical os), *marginal* (placental edge at the margin of the internal cervical os), and *low lying* (placental edge within 2 cm of the internal cervical os) were often subtle and varied by the timing and method of diagnosis. Improved ultrasound technology and precision have allowed for more accurate assessments of the placental location in relation to the cervical os. **Recent revised classification of placenta previa consists of two variations: true *placenta previa*, in which the internal cervical os is covered by placental tissue, and *low-lying placenta*, in which the placenta lies within 2 cm of the cervical os but does not cover it.**<sup>27</sup> Although not a true placenta previa, low-lying placentas are associated with increased risks for bleeding and other adverse pregnancy events.<sup>28</sup>

### Incidence

The overall reported incidence of placenta previa at delivery is 1 in 200 births. In the second trimester, placenta previa may occur in up to 6% of pregnancies.<sup>29</sup> The term *placental migration* has been used to explain this “resolution” of placenta previa that is noted near term. Three theories have been suggested to account for this phenomenon. The first hypothesis proposes that as the pregnancy advances, the stationary lower placental edge relocates away from the cervical os with the development of the lower uterine segment. Indeed, the lower uterine segment has been noted to increase from 0.5 cm at 20 weeks to more than 5 cm at term. Secondly, the placenta-free uterine wall has been proposed to grow at a faster rate than the uterine wall covered by the placenta. A final hypothesis suggests that *trophotropism*, the growth of trophoblastic tissue away from the cervical os toward the fundus, results in resolution of the placenta previa.<sup>30</sup>

### Clinical Manifestations

Placenta previa typically presents as **painless vaginal bleeding in the second or third trimester**. The bleeding is believed to occur from disruption of placental blood vessels in association with the development and thinning out of the lower uterine segment. **Between 70% and 80% of patients with placenta previa will have at least one bleeding episode.** About 10% to 20% of patients present with uterine contractions before bleeding, and fewer than 10% remain asymptomatic until term. Of those with bleeding, **one third of women will present before 30 weeks of gestation, one third between 30 and 36 weeks, and one third after 36 weeks.** Early-onset bleeding (<30 weeks) carries with it the greatest risk for blood transfusion and associated perinatal morbidity and mortality.

### Risk Factors

Several risk factors for placenta previa have been noted (Box 18-2). Additionally, some reports have documented a higher association of fetal malpresentation, preterm labor, PPRM, IUGR, congenital anomalies, and amniotic fluid embolism with placenta previa.<sup>31</sup>

#### INTRINSIC MATERNAL FACTORS

Studies have reported **more cases of placenta previa with increasing parity**. Grand multiparas have been reported to have a 5% risk for placenta previa compared with 0.2% among

#### BOX 18-2 RISK FACTORS FOR PLACENTA PREVIA

- Intrinsic maternal factors
  - Increasing parity
  - Advanced maternal age
  - Maternal race
- Extrinsic maternal factors
  - Cigarette smoking
  - Cocaine use
  - Residence at higher elevation
  - Infertility treatments
- Fetal factors
  - Multiple gestations
  - Male fetus
- Prior placenta previa
- Prior uterine surgery and cesarean delivery

nulliparous women. **Maternal age also seems to influence the occurrence of placenta previa.** Women older than 35 years of age have more than a fourfold increased risk for placenta previa, and women older than 40 years of age have a ninefold greater risk. Finally, **maternal race has been associated with placenta previa.** In a large population-based cohort,<sup>32</sup> the rate of placenta previa among white, black, and other races was 3.3, 3, and 4.5 per 1000 births, respectively. Asian women appear to have the highest rates of placenta previa.

#### EXTRINSIC MATERNAL FACTORS

**Cigarette smoking has been associated with as high as a threefold increased risk for previa formation.** Likewise, a case-control study has demonstrated that **maternal cocaine use increases the risk of placenta previa fourfold.** Residence at higher elevations may also contribute to previa development. The need for increased placental surface area secondary to decreased uteroplacental oxygenation may play a role in this association. Finally, **prior infertility treatment is statistically associated with higher rates of placenta previa.**<sup>33</sup>

#### FETAL FACTORS

**Controversy exists regarding an increased risk for placenta previa with multiple gestations.** Although some studies have shown a higher incidence of placenta previa among twins, others have not documented a significantly increased risk.<sup>34</sup> A consistently **higher proportion of offspring in women with placenta previa are male.** This association is unexplained; however, two theories suggest larger placental sizes among male fetuses and delayed implantation of the male blastocyst in the lower uterine segment.

#### PRIOR PLACENTA PREVIA

**Having had a prior placenta previa increases the risk for the development of another previa in a subsequent pregnancy.** This association has been reported to be as high as an eightfold relative risk. The exact etiology for this increased risk is unclear.

#### PRIOR UTERINE SURGERY AND PRIOR CESAREAN DELIVERY

**Prior uterine surgery has been associated with placenta previa formation.** Although a history of curettage and/or myomectomy attends a slightly elevated previa risk, prior cesarean delivery has been the most consistent risk factor. **In the pregnancy following a cesarean delivery, the risk for placenta previa has been reported to range from 1% to 4%.**<sup>35,36</sup> A linear increase is seen in placenta previa risk with the number

**of prior cesarean deliveries.** Placenta previa occurs in 0.9% of women with one prior cesarean delivery, in 1.7% of women with two prior cesarean deliveries, and in 3% of those with three or more cesarean deliveries.<sup>37</sup> In patients with four or more cesarean deliveries, the risk for placenta previa has been reported to be as high as 10%.<sup>35</sup> Endometrial scarring is thought to be the etiologic factor for this increased risk.

**Diagnosis**

The timing of the diagnosis of placenta previa has undergone significant change in the past four decades. Painless third-trimester bleeding was a common presentation for placenta previa in the past, whereas **most cases of placenta previa are now detected antenatally with ultrasound** prior to the onset of significant bleeding.

**RADIOLOGY**

**Transabdominal and transvaginal ultrasound provide the best means for diagnosing placenta previa.** Although transabdominal ultrasound can detect at least 95% of placenta previa cases, transvaginal ultrasound has a reported diagnostic accuracy that approaches 100%. Typically, a combined approach can be used in which transabdominal ultrasound is the initial diagnostic modality, followed by transvaginal ultrasound for uncertain cases. Transvaginal ultrasound is safe and is not contraindicated in these circumstances. Of note, quality images can be obtained using transvaginal ultrasound without the probe contacting the cervix (Fig. 18-4).

**If a placenta previa or low-lying placenta is diagnosed in the second trimester, repeat sonography should be obtained in the early third trimester at 32 weeks.**<sup>27</sup> More than 90% of the cases of placenta previa diagnosed in the second trimester resolve by term. The potential for placenta previa resolution is dependent on the timing of the diagnosis, extension over the cervical os, and placental location. For example, one study of 714 women with an ultrasound diagnosis of placenta previa noted that the earlier the diagnosis, the more likely the previa would resolve by term (Table 18-2). In addition, complete placenta previa diagnosed in the second trimester will persist into the third trimester in 26% of cases, whereas a low-lying placenta will persist in only 2.5% of cases. Finally, anterior placenta previa is less likely to migrate away from the cervical os than posterior placement.

Occasionally, MRI may be used to diagnose placenta previa. MRI is particularly helpful with posterior placenta previa identification and assessment of invasive placentation (see below).

**Management**

**General management principles for patients with placenta previa in the third trimester include serial ultrasounds to assess placental location and fetal growth, avoidance of cervical examinations and intercourse, activity restrictions, counseling regarding labor symptoms and vaginal bleeding, dietary and nutrient supplementation to avoid maternal anemia, and early medical attention if any vaginal bleeding occurs.**

**ASYMPTOMATIC PLACENTA PREVIA**

A recent working group has given specific recommendations for management of asymptomatic placenta previa at varying gestational ages.<sup>27</sup> For pregnancies at greater than 16 weeks of gestation with a low-lying placenta (placental edge within 2 cm from

**FIG 18-4** Transabdominal and transvaginal ultrasounds of low-lying placenta. Arrows identify the placental edge. (Courtesy K. Francois.)

**TABLE 18-2**      **POTENTIAL FOR PLACENTA PREVIA AT TERM BY GESTATIONAL AGE AT DIAGNOSIS**

| GESTATIONAL AGE AT DIAGNOSIS (WK) | PREVIA AT TERM (%) |
|-----------------------------------|--------------------|
| 15-19                             | 12                 |
| 20-23                             | 34                 |
| 24-27                             | 49                 |
| 28-31                             | 62                 |
| 32-35                             | 73                 |

From Dashe JS, McIntire DD, Ramus RM, et al. Persistence of placenta previa according to gestational age at ultrasound detection. *Obstet Gynecol.* 2002;99:692.

the internal cervical os) or a placenta previa, repeat ultrasound to assess placental location is recommended at 32 weeks. If a low-lying placenta or placenta previa persists at 32 weeks, repeat sonography is again obtained at 36 weeks.

**Asymptomatic women with placenta previa may be managed expectantly as outpatients.** Although some sonographic features have been associated with a higher likelihood of bleeding—such as complete placental coverage of the cervical os, a thickened placental edge, echo-free placental space over the cervical os, and cervical length less than 3 cm—it is not possible to predict all cases of bleeding that result from placenta previa.<sup>30</sup> With this in mind, asymptomatic patients should be instructed

to avoid activities that may stimulate uterine contractions and/or cervical irritation, such as strenuous exercise, intercourse, and digital cervical examinations. Several studies have documented the safety, efficacy, and cost savings of outpatient management for asymptomatic placenta previa. **Candidates for outpatient management must (1) be compliant, (2) live within a short commute from the hospital, (3) have 24-hour emergency transportation to the hospital, and (4) verbalize a thorough understanding of the risks associated with placenta previa.**

#### BLEEDING PLACENTA PREVIA

**Women with placenta previa who present with acute vaginal bleeding require hospitalization and immediate evaluation to assess maternal-fetal stability. They should initially be managed in a labor and delivery unit with hemodynamic surveillance of the mother and continuous FHR monitoring. Large-bore IV access and baseline laboratory studies** (hemoglobin, hematocrit, platelet count, blood type and screen, and coagulation studies) should be obtained. **If the pregnancy is less than 34 weeks of gestation, administration of antenatal corticosteroids should be undertaken** as well as an assessment of the facility's emergency resources for both the mother and the neonate. In some cases, maternal transport and consultation with a maternal-fetal medicine specialist and a neonatologist may be warranted. **Finally, tocolysis may be used if the vaginal bleeding is preceded by or associated with uterine contractions.** Whereas various agents have been used, magnesium sulfate is often preferred as a first-line agent because of its limited potential for hemodynamic-related maternal side effects and its added benefit for fetal neuroprotection.<sup>30</sup>

**Once stabilized, most women with symptomatic placenta previa can be maintained on hospitalized bed rest and expectantly managed.** In several observational studies, 50% of women with bleeding placenta previa were undelivered in 4 weeks, including those with initial bleeding episodes of more than 500 mL. Minimizing maternal anemia by using blood conservation techniques is recommended. Although some patients may require transfusion, many patients can be supplemented with iron replacement (oral or IV), vitamin C to enhance oral iron absorption, and B vitamins. Erythropoietin may be used in selected cases to hasten red cell formation. Lastly, autologous donation may be considered in patients with hemoglobin concentrations greater than 11 g/dL.<sup>38,39</sup>

Although maternal hemorrhage is of the utmost concern, **fetal blood can also be lost during the process of placental separation with a bleeding placenta previa. Rh0(D) immune globulin should be given to all Rh-negative unsensitized women with third-trimester bleeding from placenta previa.** A Kleihauer-Betke preparation of maternal blood should be considered. Occasionally, a fetomaternal hemorrhage of greater than 30 mL occurs that necessitates additional doses of Rh0(D) immune globulin. One study noted that 35% of infants whose mothers received an antepartum transfusion were also anemic and required a transfusion following delivery.

#### DELIVERY

**Cesarean delivery is indicated for all women with sonographic evidence of placenta previa and most women with low-lying placenta.** When the placental distance is between 1 and 20 mm from the internal cervical os, the rate of cesarean delivery ranges from 40% to 90%.<sup>40</sup> If a vaginal trial of labor is attempted for a low-lying placenta, precautions should be taken

for the possibility of an emergent cesarean delivery and need for blood transfusion.

A consensus panel has given delivery-timing guidelines for uncomplicated placenta previa,<sup>22</sup> which includes cases with normal fetal growth and no other pregnancy-associated complications. **Cesarean delivery of asymptomatic placenta previa should occur between 36<sup>0/7</sup> and 37<sup>0/7</sup> weeks of gestation. In cases of complicated placenta previa, delivery should occur immediately regardless of gestational age. Complicated placenta previa includes bleeding associated with a nonreassuring fetal heart pattern despite resuscitative measures, life-threatening maternal hemorrhage, and/or refractory labor.**<sup>30</sup>

**When performing a cesarean delivery for placenta previa, the surgeon should be aware of the potential for rapid blood loss during the delivery process.** Blood products that are cross-matched should be readily available for delivery. In addition, before incising the lower uterine segment, the surgeon should assess the vascularity of this region. Although a low transverse incision is not contraindicated in patients with placenta previa, performing a vertical uterine incision may be preferable in some cases. This is particularly true with an anterior placenta previa. Ideally, the placenta should not be disrupted when entering the uterus. If disruption occurs, expedited delivery is essential. Given the potential for invasive placentation, the physician should allow the placenta to spontaneously deliver. If it does not separate easily, precautions should be taken for placenta accreta management (see below). Once the placenta separates, bleeding is controlled by the contraction of uterine myometrial fibers around the spiral arterioles. Because the lower uterine segment often contracts poorly, significant bleeding may occur from the placental implantation site. Aggressive uterotonic therapy, surgical intervention, and/or tamponade techniques should be undertaken to rapidly control bleeding. Finally, some studies have shown reduced bleeding at the placental site with the injection of subendometrial vasopressin after delivery of the fetus.<sup>41</sup>

### Associated Conditions

#### Placenta Accreta

##### DEFINITION AND PATHOGENESIS

**Placenta accreta represents the abnormal attachment of the placenta to the uterine lining due to an absence of the decidua basalis and an incomplete development of the fibrinoid layer.**

Variations of placenta accreta include placenta increta and placenta percreta, in which the placenta extends to or through the uterine myometrium, respectively (Fig. 18-5).

##### INCIDENCE AND RISK FACTORS

**The overall incidence of placenta accreta or one of its variations is 3 per 1000 deliveries.** Based on histologic diagnosis, placenta accreta is the most common form of invasive placentation (79%) followed by placenta increta (14%) and placenta percreta (7%), respectively. **The two most significant risk factors for placenta accreta are placenta previa and prior cesarean delivery.** The risk for placenta accreta in patients with placenta previa and an unscarred uterus is approximately 3%.<sup>35</sup> This risk dramatically increases with one or more cesarean deliveries (Table 18-3). Even without a coexisting placenta previa, placenta accreta is more common in women with a prior cesarean delivery.<sup>37</sup>

**Other reported risk factors include increasing parity and maternal age, submucosal uterine fibroids, prior uterine surgery, cesarean scar, and endometrial defects.**<sup>42,43</sup> Unlike

**FIG 18-5** Uteroplacental relationships found with invasive placentation.

**TABLE 18-3** RISK OF PLACENTA ACCRETA WITH PLACENTA PREVIA AND PRIOR CESAREAN DELIVERY

| NO. OF PRIOR CESAREAN DELIVERIES | PLACENTA ACCRETA RISK (%) |
|----------------------------------|---------------------------|
| 0                                | 3                         |
| 1                                | 11                        |
| 2                                | 40                        |
| 3                                | 61                        |
| ≥4                               | 67                        |

placenta previa, a **female fetus is more common with invasive placentation.**

### CLINICAL MANIFESTATIONS

The clinical manifestations of placenta accreta are often similar to those of placenta previa; however, **profuse bleeding usually follows attempted manual placental separation. Hematuria can be a feature of placenta percreta with bladder invasion.**

### DIAGNOSIS

**Most cases of placenta accreta are now diagnosed antenatally by advanced radiographic techniques.** Prenatal diagnosis has been shown to improve maternal outcomes, resulting in less blood loss and decreased transfusion requirements.<sup>44</sup>

### RADIOGRAPHIC TECHNIQUES

**Ultrasound is the preferred radiographic modality for the diagnosis of placenta accreta.** Findings suggestive of placenta accreta include a loss of the normal hypoechoic retroplacental-myometrial zone, thinning and disruption of the uterine serosa-bladder wall interface, focal exophytic masses within the placenta, and numerous intraplacental vascular lacunae (Fig. 18-6).<sup>45</sup> A recent systemic review and meta-analysis of 23 studies that used prenatal sonographic identification of placenta accreta demonstrated a sensitivity of 90%, a specificity of 97%, a positive likelihood ratio of 11, and a negative likelihood ratio of 0.16.<sup>46</sup>

Color Doppler ultrasound is also useful as an adjunctive tool in diagnosing placenta accreta. Specific color Doppler findings that differentiate placenta accreta from normal placentation

**FIG 18-6** Ultrasonic image of focal placenta accreta (arrow). An area at the uterine-placental interface demonstrates loss of the normal hypoechoic zone, thinning and disruption of the uterine serosa-bladder interface, and a focal exophytic mass within the placenta.

include diffuse and focal intraparenchymal placental lacunar blood flow, hypervascularity of the bladder and uterine serosa, prominent subplacental venous complexes, and loss of subplacental Doppler vascular signals.<sup>47</sup> Some color-flow mapping studies suggest that a myometrial thickness less than 1 mm with large intraplacental venous lakes is highly predictive of invasive placentation (sensitivity, 100%; specificity, 72%; positive predictive value, 72%; and negative predictive value, 100%).

In addition to the above ultrasound modalities, three-dimensional ultrasound has been used successfully to identify invasive placentation.<sup>48,49</sup> Diagnostic criteria include irregular intraplacental vascularization and hypervascularity of the uterine serosa-bladder wall interface.

Finally, **MRI can be used in conjunction with sonography to assess abnormal placental invasion.** MRI is particularly helpful when ultrasound findings are equivocal, the placenta is in a posterior location, and for determination of the extent of placental invasion within surrounding tissue, such as the parametrium and bladder. In a review and meta-analysis<sup>50</sup> of 1010 pregnancies at risk for placenta accreta, MRI had a diagnostic sensitivity of 94% and a specificity of 84%.

### LABORATORY FINDINGS

Placenta accreta has been associated with unexplained elevations in maternal serum  $\alpha$ -fetoprotein (MSAFP).

### PATHOLOGIC STUDIES

**Placenta accreta is confirmed by the pathologic examination of a hysterectomy specimen.** Histologic evaluation demonstrates placental villi within the uterine myometrium and absence of a decidual plate. In focal accreta cases in which the uterus is not removed, curettage specimens may show myometrial cells adherent to the placenta.<sup>51</sup>

### MANAGEMENT

Because of its associated risk for massive postpartum hemorrhage, **placenta accreta accounts for a large percentage of peripartum hysterectomies.**<sup>52</sup> **A multidisciplinary team approach is the ideal way to manage these cases.** Preoperative

assessments by **maternal-fetal medicine specialists, neonatologists, blood conservation teams, anesthesiologists, advanced pelvic surgeons, and urologists**—especially for a suspected placenta percreta—are recommended. Timing of delivery depends upon clinical circumstances; however, **most authorities favor delivery at 34<sup>0/7</sup> to 35<sup>6/7</sup> weeks** with or without antenatal corticosteroid administration.<sup>38</sup> Ideally, the delivery should be scheduled at a time with optimal personnel availability at a facility prepared to manage significant obstetric hemorrhage. **Adequate IV access with two large-bore catheters and ample blood product availability are mandatory.** Cell-saver technology, donor-directed or autologous blood donation, and recombinant VIIa should be considered. Placement of ureteral stents preoperatively or intraoperatively can assist in maintaining urinary tract integrity. When performing the surgery, **it is recommended that the uterus be incised above the placental attachment site and that the placenta be left in situ after clamping the cord because disruption of the implantation site may result in rapid blood loss.** Finally, adjuvant use of aortic and/or internal iliac artery balloon occlusion catheters with postsurgical embolization has been shown to reduce blood loss, transfusion requirements, and duration of surgery in some studies.<sup>53</sup>

In specific circumstances, uterine conservation may be attempted. These situations include focal accreta, desired future fertility, and fundal or posterior placenta accreta. Uterine conservation techniques typically include leaving the placenta in situ at the delivery with subsequent expectant management, delayed manual placental removal, wedge resection or oversewing of the placental implantation site, tamponade of the lower uterine segment, curettage, uterine artery embolization, hemostatic sutures, arterial ligation, and/or administration of methotrexate.<sup>54</sup> Although each of these techniques has reported success, each is also associated with potential complications, including delayed hemorrhage, infection, fistula formation, subsequent surgery and/or hysterectomy, uterine necrosis, and even death.<sup>55</sup> Data are limited regarding long-term reproductive outcomes in women treated conservatively for invasive placentation. Although most women are able to conceive after conservative management, they remain at risk for spontaneous abortion, uterine synechiae and rupture, preterm delivery, recurrent placenta accreta, and peripartum hysterectomy.<sup>54,56-58</sup>

## Vasa Previa

### DEFINITION AND PATHOGENESIS

**Vasa previa is defined as the presence of fetal vessels over the cervical os.** Typically, these fetal vessels lack protection from Wharton jelly (velamentous cord insertion) and are prone to rupture and compression. When the vessels rupture, the fetus is at high risk for exsanguination. **Velamentous cord insertion may occur without vasa previa and can occasionally exist as fetal vessels that run between a bilobed or succenturiate-lobed placenta.**

### INCIDENCE AND RISK FACTORS

**The overall incidence of vasa previa is 1 in 2500 deliveries;** however, data have shown a range from 1 in 2000 to 1 in 5000 deliveries.<sup>59</sup> **Reported risk factors for vasa previa include bilobed and succenturiate-lobed placentas; pregnancies that result from assisted reproductive technology (ART); multiple gestations; and history of second-trimester placenta previa or low-lying placenta.**<sup>59-61</sup>

### CLINICAL MANIFESTATIONS

**In the past, most cases of vasa previa presented after rupture of membranes with acute onset of vaginal bleeding from a lacerated fetal vessel.** If immediate intervention was not provided, fetal bradycardia and subsequent fetal death occurred. Today, many cases of vasa previa are diagnosed antenatally by ultrasound. In rare cases, **pulsating fetal vessels may be palpable in the membranes that overlie the cervical os.**

### DIAGNOSIS

Vasa previa is often diagnosed antenatally by **ultrasound with color and pulsed Doppler mapping.** Transabdominal and transvaginal approaches are most often used. **The diagnosis is confirmed by documenting umbilical vessels over the cervical os using color and pulsed Doppler imaging (Fig. 18-7).**

### MANAGEMENT

**When diagnosed antenatally, vasa previa should be managed similarly to placenta previa.** Some authorities have recommended twice-weekly nonstress testing at 28 to 30 weeks of gestation to assess for cord compression; others have favored

**FIG 18-7** Transvaginal ultrasound images showing vasa previa and velamentous cord. The placenta is posterior with an anterior succenturiate lobe. (From Lockwood CJ, Russo-Steiglitz K. *Velamentous umbilical cord insertion and vasa previa*, [www.uptodate.com](http://www.uptodate.com), July 17, 2015.)

hospitalization in the third trimester with administration of antenatal corticosteroids, serial antepartum testing, and **cesarean delivery between 34<sup>0/7</sup> to 36<sup>0/7</sup> weeks of gestation.**<sup>62,63</sup> If an intrapartum diagnosis of vasa previa is made, expeditious delivery is needed. Immediate neonatal blood transfusion is often required in these circumstances.

## POSTPARTUM HEMORRHAGE

**Postpartum hemorrhage is an obstetric emergency that complicates between 1 in 20 and 1 in 100 deliveries.** In the past decade, reported postpartum hemorrhage has increased 26% within the United States.<sup>64</sup> Because it is a major cause of maternal morbidity and mortality, obstetricians need to have a clear understanding of normal delivery-related blood loss so that postpartum hemorrhage can be efficiently recognized and managed.

### Normal Blood Loss and Postpartum Hemorrhage

Normal delivery-related blood loss depends on the type of delivery. Based on objective data, the mean blood losses for a vaginal delivery, cesarean delivery, and cesarean hysterectomy are 500, 1000, and 1500 mL, respectively.<sup>65</sup> These values are often underestimated and unappreciated clinically owing to the significant blood volume expansion that accompanies normal pregnancy.

Postpartum hemorrhage has been variably defined in the literature. Definitions have included subjective assessments greater than the standard norms, a 10% decline in hemoglobin concentration, and the need for blood transfusion. A more practical definition is excessive delivery-related blood loss that causes the patient to be hemodynamically symptomatic and/or hypovolemic.

### Postpartum Hemorrhage Etiologies

The etiologies of postpartum hemorrhage can be categorized as **primary (early) or secondary (late).** *Primary postpartum hemorrhage* refers to excessive bleeding that occurs within 24 hours of delivery, whereas *secondary postpartum hemorrhage* refers to bleeding that occurs from 24 hours until 12 weeks after delivery. Box 18-3 lists the most common causes of primary and secondary postpartum hemorrhage. Because primary postpartum hemorrhage is more common than the

secondary kind, the remainder of this discussion focuses on its etiology and management (Fig. 18-8).

## Uterine Atony

### DEFINITION AND PATHOGENESIS

**Uterine atony, or the inability of the uterine myometrium to contract effectively, is the most common cause of primary postpartum hemorrhage.** At term, blood flow through the placental site averages 500 to 700 mL per minute. After placental delivery, the uterus controls bleeding by contracting its myometrial fibers in a tourniquet fashion around the spiral arterioles. If inadequate uterine contraction occurs, rapid blood loss can ensue.

### INCIDENCE AND RISK FACTORS

**Uterine atony complicates 1 in 20 deliveries and is responsible for 80% of postpartum hemorrhage cases.** Risk factors for uterine atony include **uterine overdistention** (multiple gestation, polyhydramnios, fetal macrosomia), **labor induction, rapid or prolonged labor, grand multiparity, uterine infection, uterine inversion, retained products of conception, abnormal placentation, and use of uterine-relaxing agents** (tocolytic therapy, halogenated anesthetics, nitroglycerin).

### CLINICAL MANIFESTATIONS AND DIAGNOSIS

**Uterine atony is diagnosed clinically by rapid uterine bleeding associated with a lack of myometrial tone and an absence of other etiologies for postpartum hemorrhage.** Typically, bimanual palpation of the uterus confirms the diagnosis.

### PREVENTION AND MANAGEMENT

By recognizing risk factors for uterine atony and quickly initiating a treatment cascade, the clinician can minimize blood loss. Three preventive methods for atonic postpartum hemorrhage are 1) **active management of the third stage of labor**, 2) **spontaneous placental separation during cesarean delivery**, and 3) **prolonged postpartum oxytocin infusion.** Active management of the third stage of labor includes early cord clamping, controlled cord traction, uterine massage, and administration of uterotonic therapy before placental separation. A systematic review<sup>66</sup> of seven studies that compared active to expectant management of the third stage of labor showed significant reductions in maternal blood loss, postpartum hemorrhage, prolonged third stage of labor, and the need for additional uterotonic therapies. Whereas controversy exists regarding the timing of uterotonic administration, a recent systematic review<sup>67</sup> suggested that giving uterotonic therapy before delivery of the placenta results in less blood loss and fewer postpartum transfusions.

A second strategy to minimize uterine atony is to allow spontaneous placental separation during cesarean delivery. In one controlled study, spontaneous placental separation reduced blood loss by 30% and reduced postpartum endometritis sevenfold compared with manual removal.

A final preventive approach for atonic postpartum hemorrhage is prolonged postpartum oxytocin infusion. A recent clinical trial<sup>68</sup> assessed two postpartum oxytocin regimens following delivery: a bolus of oxytocin after delivery versus a bolus of oxytocin followed by a 4-hour IV infusion of oxytocin. A significant reduction was seen in uterine atony and need for additional uterotonic therapy in the women who received the prolonged oxytocin infusion. Additional evidence-based review

#### BOX 18-3 ETIOLOGIES OF POSTPARTUM HEMORRHAGE

##### Early

Uterine atony  
Lower genital tract lacerations (perineal, vaginal, cervical, periclitoral, periurethral, rectum)  
Upper genital tract lacerations (broad ligament)  
Lower urinary tract lacerations (bladder, urethra)  
Retained products of conception (placenta, membranes)  
Invasive placentation (placenta accreta, placenta increta, placenta percreta)  
Uterine rupture  
Uterine inversion  
Coagulopathy

##### Late

Infection

data support prolonged (4 to 8 hours) oxytocin administration after delivery.<sup>69</sup>

If preventive measures are unsuccessful, medical management for uterine atony should be initiated. This treatment includes bimanual uterine massage and uterotonic therapy.

#### BIMANUAL UTERINE MASSAGE

To provide effective bimanual uterine massage, **the uterus should be compressed between the external, fundally placed hand and the internal, intravaginal hand** (Fig. 18-9). Care must be taken to avoid aggressive massage that can injure the large vessels of the broad ligament.

#### UTEROTONIC THERAPY

**Uterotonic medications represent the mainstay of drug therapy for postpartum hemorrhage secondary to uterine atony.** Table 18-4 lists available uterotonic agents with their dosages, side effects, and contraindications. **Oxytocin** is usually given as a first-line agent. IV therapy is the preferred route of administration, but intramuscular and intrauterine dosing is possible. Initial treatment starts with 10 to 30 units of oxytocin in 500 to 1000 mL of crystalloid solution. Higher doses (80 units in 500 to 1000 mL) have proved safe and efficacious, with a 20% reduction in the need for additional uterotonic therapy and reduced composite hemorrhage treatment (uterotonic drugs, transfusion, tamponade, embolization, surgery).<sup>70</sup>

When oxytocin fails to produce adequate uterine tone, second-line therapy must be initiated. Currently, a variety of additional uterotonic agents are available. The choice of a second-line agent depends on its side-effect profile as well as its

FIG 18-9 Bimanual uterine massage.

**TABLE 18-4** UTEROTONIC THERAPIES

| AGENT                                       | DOSE   | ROUTE                                   | DOSING INTERVAL                      | SIDE EFFECTS                                      | CONTRAINDICATIONS                                      |

contraindications. **Misoprostol, a synthetic prostaglandin E<sub>1</sub> analogue**, is a safe, inexpensive, and efficacious uterotonic medication that does not require refrigeration. It has been used for both the prevention and treatment of postpartum hemorrhage.<sup>71-73</sup> Misoprostol is attractive as a second-line agent in that it has multiple administration routes that can be combined. Although higher doses (600 to 1000 µg) have traditionally been used rectally, the sublingual route allows for lower dosing (400 µg) with higher bioavailability.<sup>71</sup> Although helpful in some settings, **methylergonovine** has limited usefulness for acute postpartum hemorrhage because of its relatively long half-life and potential for worsening hypertension in patients with preexisting disease.

**Prostaglandins** are highly effective uterotonic agents. Both natural and synthetic prostaglandin formulations are available. Intramuscular and intrauterine administration of **prostaglandin F<sub>2α</sub>** can be used for control of atony. Recurrent doses (0.25 mg) may be administered as often as every 15 minutes to a maximum of eight doses (2 mg total dose). It is important to note that asthma is a *strong contraindication* to the use of prostaglandin F<sub>2α</sub> because of its bronchoconstrictive properties. **Prostaglandin E<sub>2</sub> (dinoprostone)** is a naturally occurring oxytocic that can dramatically improve uterine tone; however, it has an unfavorable side-effect profile often precludes its use (fever, chills, nausea, emesis, diarrhea, and headaches). Lastly, oxytocin analogues and combined ergometrine-oxytocin preparations are available outside of the United States for control of uterine atony.

When atony is due to tocolytic drugs that have impaired calcium entry into the cell (magnesium sulfate, nifedipine), calcium gluconate should be considered as an adjuvant therapy. Given as an IV push, one ampule (1 g in 10 mL) of calcium gluconate can effectively improve uterine tone and resolve bleeding due to atony.

If pharmacologic methods fail to control atony-related hemorrhage, alternative measures must be undertaken. **The genital tract should be carefully inspected for lacerations before proceeding with these measures, which include uterine tamponade, selective arterial embolization, and surgical intervention.**

#### UTERINE TAMPONADE

**Uterine packing is a safe, simple, and effective way to control postpartum hemorrhage by providing tamponade to the bleeding uterine surface.** Although packing techniques vary, a few basic principles should be followed. The pack should be made of long, continuous gauze (e.g., Kerlix) rather than multiple small sponges. Some authorities have had success with

**FIG 18-10** The Bakri tamponade balloon. (From Bakri YN, Arulkumaran S. Intrauterine balloon tamponade for control of postpartum hemorrhage, [www.uptodate.com](http://www.uptodate.com), July 7, 2015.)

the use of thrombin-impregnated or chitosan-covered gauze.<sup>74</sup> When packing the uterus, placement should begin at the fundus and progress downward in a side-to-side fashion to avoid dead space for blood accumulation. Transurethral Foley catheter placement and prophylactic antibiotic use should be considered to prevent urinary retention and infection, respectively. Finally, prolonged packing should be avoided (not more than 12 to 24 hours), and close attention should be paid to the patient's vital signs and blood indices while the pack is in place in order to minimize unrecognized ongoing bleeding.

In recent years, **intrauterine tamponade balloons** have largely replaced traditional uterine packing. Multiple balloon types have been used and include the Bakri tamponade balloon, the BT-Cath, the Belfort-Dildy Obstetrical Tamponade System, the Sengstaken-Blakemore tube, and the #24 Foley catheter with 30 mL balloon. The **Bakri tamponade balloon**, the **BT-Cath**, and the **Belfort-Dildy Obstetrical Tamponade System** were all developed specifically for postpartum hemorrhage management. The Bakri tamponade balloon (Cook Women's Health; <http://www.cookmedical.com>) consists of a silicone balloon attached to a catheter. The catheter is inserted into the uterus either manually or under

**FIG 18-11** Proper placement of the Bakri tamponade balloon. (Courtesy Cook Women's Health.)

**FIG 18-12** The Belfort-Dildy obstetrical tamponade system. (Courtesy Glenveigh Medical.)

ultrasound guidance, and the silicone balloon is subsequently inflated with sterile saline (maximum of 500 mL). Once inflated, the balloon should adapt to the uterine configuration to provide tamponade to the endometrial surface. The intraluminal catheter allows drainage from within the uterus so that ongoing assessment of blood loss can occur. Proper placement of the balloon is essential to provide adequate tamponade (Fig. 18-11). Like the Bakri tamponade balloon, the BT-Cath (Utah Medical Products) is a silicone balloon; however, it is shaped like an inverted pear. This tamponade balloon also has a double-lumen catheter that allows saline filling of the balloon as well as drainage of blood from within the uterus. Finally, the Belfort-Dildy Obstetrical Tamponade System (Glenveigh Medical) incorporates both intrauterine and intravaginal polyurethane balloons that conform to these cavities, respectively (Fig. 18-12).<sup>75</sup> The uterine balloon can be rapidly inflated from a saline bag to a

larger volume of 750 mL when the smaller balloons are inadequate (e.g., with multiple gestations). Like the other balloons, this system has a drainage port to assess for ongoing bleeding; however, unlike the others, it also has an infusion port to irrigate the uterus.

#### SELECTIVE ARTERIAL EMBOLIZATION

**Selective arterial embolization is an increasingly common therapeutic option for hemodynamically stable patients with postpartum hemorrhage.** The procedure can be performed alone or after failed surgical intervention.<sup>76</sup> Diagnostic pelvic angiography is used to visualize bleeding vessels, and gelatin (e.g., Gelfoam) pledgets are placed into the vessels for occlusion. **Cumulative success rates of 90% to 97% have been reported.**<sup>76</sup>

Selective arterial embolization has several advantages over surgical intervention. First, it allows for selective occlusion of bleeding vessels. This can be extremely valuable in circumstances of aberrant pelvic vasculature, such as uterine arteriovenous malformations. Second, the uterus and potential future fertility are preserved. Case series<sup>76</sup> have reported successful pregnancies after pelvic embolization. Finally, the procedure has minimal morbidity, enables the physician to forego or delay surgical intervention, and can be performed in coagulopathic patients, which allows more time for blood and clotting factor replacement. Procedure-related complications occur in 3% to 6% of cases.<sup>76</sup> Reported complications include postembolization fever, infection, ischemic pain, vascular perforation, and tissue necrosis. A relative disadvantage of the procedure is its limited availability. Timely coordination of services between the obstetric team and interventional radiology personnel, as well as a hemodynamically stable patient, are necessary to provide this treatment option.

#### SURGICAL INTERVENTION

When uterine atony is unresponsive to conservative management, surgical intervention by laparotomy is necessary. Possible interventions include arterial ligation, uterine compression sutures, and hysterectomy.

**The goal of arterial ligation is to decrease uterine perfusion and subsequent bleeding.** Success rates have varied from 40% to 95% in the literature depending on which vessels are ligated. Arterial ligation may be performed on the ascending uterine arteries, the uteroovarian arteries, the infundibulopelvic ligament vessels, and the internal iliac (hypogastric) arteries. Because internal iliac arterial ligation can be technically challenging and time consuming, it is not advised as a first-line technique unless the surgeon is extremely skilled in performing the procedure. Instead, a stepwise progression of uterine vessel ligation is recommended.

Nearly five decades ago, O'Leary described a technique of bilateral uterine artery ligation for control of postpartum hemorrhage. Today, it is still considered the initial ligation technique given its ease in performance and the accessibility of the uterine artery. To perform the procedure, the ascending uterine artery should be located at the border of the upper and lower uterine segment. Absorbable suture is passed through the uterine myometrium at the level of the lower uterine segment and laterally around the uterine vessels through a clear space in the broad ligament. The suture is then tied to compress the vessels against the uterine wall (Fig. 18-13). Because the suture is placed fairly high in the lower uterine segment, ureteral injury is avoided;

**FIG 18-13** Uterine artery ligation.

**FIG 18-14** Bilateral looped uterine vessel sutures. (From Bakri YN, Arulkumaran S. *Intrauterine balloon tamponade for control of postpartum hemorrhage*, [www.uptodate.com](http://www.uptodate.com), July 7, 2015.)

therefore the bladder does not need to be mobilized. Unilateral artery ligation will control hemorrhage in 10% to 15% of cases, whereas bilateral ligation will control hemorrhage in over 90% of cases.

If bleeding persists, the uteroovarian and infundibulopelvic vessels should be ligated. The uteroovarian arteries can be ligated similarly to what has been described for the ascending uterine vessels. If this measure is unsuccessful, interruption of the infundibulopelvic vessels can be undertaken. Although the ovarian blood supply may be decreased with an infundibulopelvic vessel ligation, successful pregnancy has been reported following this procedure.

**Bakri has described a newer technique for bilateral uterine artery ligation in combination with tamponade balloon placement (Fig. 18-14).** The procedure, termed **Bilateral Looped Uterine Vessel Sutures (B-LUVS)**, incorporates absorbable sutures looped bilaterally through the myometrium around the uterine vessels from the lower segment up to the cornual region. Once the sutures are tied, a Bakri tamponade balloon is placed within the uterine cavity to provide internal tamponade. A small series has had high success with this combined ligation-tamponade approach.

In addition to arterial ligation, **uterine compression sutures** have been described for atony control. Several techniques have evolved over the past two decades, including the **B-Lynch suture, Hayman vertical sutures, Pereira transverse and vertical sutures, and multiple square sutures.**<sup>77,78</sup> To place a compression suture, the patient should lie in the dorsal lithotomy position to facilitate assessment of vaginal bleeding. Large absorbable suture is typically anchored within the uterine myometrium both anteriorly and posteriorly. It is passed in a continuous or intermittent fashion around or through the external surface of the uterus and tied firmly so that adequate uterine compression occurs. **Figures 18-15 to 18-18** demonstrate proper placements of these sutures. Like arterial ligation, uterine compression sutures can be combined with tamponade balloons for refractory bleeding. The “uterine sandwich” technique refers to placement of a B-Lynch suture followed by a Bakri tamponade balloon within the uterine cavity.<sup>79</sup> Typically, the tamponade balloon is inflated to a lesser volume (median of 100 mL) in these cases. Small series<sup>79</sup> have demonstrated high success rates for this combined approach.

**The final surgical intervention for refractory bleeding due to atony is hysterectomy, which provides definitive therapy.**

**FIG 18-15** B-Lynch compression suture. (From Belfort MA. Management of postpartum hemorrhage at cesarean delivery, [www.uptodate.com](http://www.uptodate.com), June 26, 2015.)

**FIG 18-16** Hayman vertical sutures. (From Belfort MA. Management of postpartum hemorrhage at cesarean delivery, [www.uptodate.com](http://www.uptodate.com), June 26, 2015.)

Because blood loss may be severe, it is often prudent to modify the surgical approach by using the “clamp-cut-drop” technique (Fig. 18-19), performing a supracervical hysterectomy, or both.<sup>80</sup> These considerations are especially important when the patient is hemodynamically unstable (Video 18-1).

### Genital Tract Lacerations

#### DEFINITION AND PATHOGENESIS

Genital tract lacerations may occur with both vaginal and cesarean deliveries. These lacerations involve the maternal soft tissue structures and can be associated with large hematomas and rapid blood loss if unrecognized. The most common lower genital tract lacerations are perineal, vulvar, vaginal, and

**FIG 18-17** Pereira transverse and vertical sutures (From Belfort MA. Management of postpartum hemorrhage at cesarean delivery, [www.uptodate.com](http://www.uptodate.com), June 26, 2015.)

**FIG 18-18** Multiple square sutures. (From Belfort MA. Management of postpartum hemorrhage at cesarean delivery, [www.uptodate.com](http://www.uptodate.com), June 26, 2015.)

**FIG 18-19** Clamp-cut-drop technique for hysterectomy. (From Wright JD, Bonanno C, Shah M, et al. Peripartum hysterectomy. *Obstet Gynecol.* 2010;116:429-434.)

cervical. Upper genital tract lacerations are typically associated with broad ligament and retroperitoneal hematomas.

#### INCIDENCE AND RISK FACTORS

Although it is difficult to ascertain their exact incidence, **genital tract lacerations are the second leading cause of postpartum hemorrhage.** Risk factors include instrumented vaginal delivery, fetal malpresentation or macrosomia, episiotomy, precipitous delivery, prior cerclage placement, Dührssen incisions, and shoulder dystocia.

#### CLINICAL MANIFESTATIONS AND DIAGNOSIS

A genitourinary tract laceration should be suspected if bleeding persists after delivery despite adequate uterine tone. Occasionally, the bleeding may be masked because of its location, such as with the broad ligament. In these circumstances, large amounts of blood loss may occur in an unrecognized hematoma. Pain and hemodynamic instability are often the primary presenting symptoms.

For diagnosis, it is best to evaluate the lower genital tract superiorly from the cervix and to progress inferiorly to the vagina, perineum, and vulva. Adequate exposure and retraction are essential for identification of many of these lacerations.

#### MANAGEMENT

Once a genital tract laceration is identified, **management depends on its severity and location.** Lacerations of the cervix and vaginal fornices are often difficult to repair owing to their position. In these circumstances, relocation to an OR with anesthesia assistance for better pain relief, pelvic relaxation, and visualization are recommended. For cervical lacerations, it is important to secure the apex of the tear because this is often a major source of bleeding. Unfortunately, exposure of this angle can be difficult. A helpful technique for these scenarios is to start suturing the laceration at its proximal end, thereby using the

suture for traction to expose the more distal portion of the cervix until the apex is in view (Fig. 18-20).

**Perineal repairs are the most common types of genital tract lacerations.** Figures 18-21 to 18-23 illustrate second-, third-, and fourth-degree perineal lacerations and techniques for their repair. If the laceration is adjacent to the urethra, the use of a

**FIG 18-20** Repair of a cervical laceration, beginning at the proximal part of the laceration and using traction on the previous sutures to aid in exposure of the distal defect.

**FIG 18-21** Repair of a second-degree laceration. A first-degree laceration involves the fourchette, the perineal skin, and the vaginal mucous membrane. A second-degree laceration also includes the muscles of the perineal body. The rectal sphincter remains intact.

**FIG 18-22** Repair of the sphincter after a third-degree laceration. A third-degree laceration extends not only through the skin, mucous membrane, and perineal body but includes the anal sphincter. Interrupted figure-of-eight sutures should be placed in the capsule of the sphincter muscle.

**FIG 18-23** Repair of a fourth-degree laceration. This laceration extends through the rectal mucosa. **A**, The extent of this laceration is shown with a segment of the rectum exposed. **B**, Approximation of the rectal submucosa. This is the most commonly recommended method for repair. **C**, Alternative method of approximating the rectal mucosa in which the knots are actually buried inside the rectal lumen. **D**, After closure of the rectal submucosa, an additional layer of running sutures may be placed. The rectal sphincter is then repaired.

transurethral catheter can aid in a more efficient repair and can protect uninjured organs. Digital rectal exam is recommended after repair of third- and fourth-degree lacerations in order to ensure proper integrity of the rectum.

On occasion, a blood vessel laceration may lead to the formation of a pelvic hematoma in the lower or upper genital tract.

The three most common locations for a pelvic hematoma are vulvar, vaginal, and retroperitoneal.

#### VULVAR HEMATOMA

**Vulvar hematomas usually result from lacerated vessels in the superficial fascia of the anterior or posterior pelvic triangle.**

FIG 18-24 Vulvar hematoma fascial boundaries.

FIG 18-25 Large vulvar hematoma.

Blood loss is tamponaded by Colles fascia, the urogenital diaphragm, and anal fascia (Fig. 18-24). Because of these fascial boundaries, the mass will extend to the skin, and a visible hematoma results (Fig. 18-25).

**Surgical drainage is the primary treatment for vulvar hematomas.** A wide linear incision through the skin is recommended. Typically, the bleeding is due to multiple small vessels; hence, vessel ligation is not possible. Once the hematoma is evacuated, the dead space should be closed in layers with absorbable suture, and a sterile pressure dressing should be applied. A

transurethral catheter should be placed until significant tissue edema subsides.

#### VAGINAL HEMATOMA

**Vaginal hematomas result from delivery-related soft tissue damage.** These hematomas accumulate above the pelvic diaphragm (Fig. 18-26), and occasionally, they protrude into the vaginal-rectal area. Like vulvar hematomas, vaginal hematomas are due to multiple small vessel lacerations. Depending on the extent of the hemorrhage, **vaginal hematomas may or may not require surgical drainage.** Small, nonexpanding hematomas are often best managed expectantly. Larger, expanding hematomas require surgical intervention. Unlike vulvar hematomas, the incision of a vaginal hematoma does not require closing, rather a vaginal pack or tamponade device should be placed on the raw edges. If bleeding persists, **selective arterial embolization may be considered.**

#### RETROPERITONEAL HEMATOMA

Although infrequent, **retroperitoneal hematomas are the most serious and life threatening.** The early symptoms of a retroperitoneal hematoma are often subtle, with the hematoma being unrecognized until the patient is hemodynamically unstable from massive hemorrhage. **These hematomas usually occur after a vessel laceration from the internal iliac (hypogastric) arterial tree (Fig. 18-27).** Such lacerations may result from instrumented vaginal delivery, inadequate hemostasis of the uterine arteries at the time of cesarean delivery, or uterine rupture during a trial of labor after cesarean delivery (TOLAC). **Treatment of a retroperitoneal hematoma typically involves laparotomy, hematoma evacuation, and arterial ligation. In some situations, selective arterial embolization may be used as a primary or adjunctive treatment.**

**FIG 18-26** Vaginal hematoma.

**FIG 18-27** Retroperitoneal hematoma.

### Retained Products of Conception DEFINITION AND PATHOGENESIS

Retained products of conception, namely placental tissue and amniotic membranes, can inhibit the uterus from adequate contraction and can result in hemorrhage. The diagnosis is made when spontaneous expulsion of the tissue has not occurred within 30 to 60 minutes of delivery.

### INCIDENCE AND RISK FACTORS

Retained products of conception complicate 0.5% to 1% of deliveries. Risk factors include midtrimester delivery, chorioamnionitis, and accessory placental lobes.

### CLINICAL MANIFESTATIONS AND DIAGNOSIS

Retained products of conception typically present with uterine bleeding and associated atony. To assess the uterus for retained products of conception, the uterine cavity needs to be explored. Manual exploration is not only diagnostic but is also often therapeutic (Fig. 18-28). By wrapping the examination hand with moist gauze, removal of retained placental fragments and amniotic membranes can be facilitated. If manual access to the uterine cavity is difficult or limited owing to maternal body habitus or inadequate pain relief, transabdominal or transvaginal ultrasound may be used to determine whether retained placental fragments are present.<sup>81</sup>

FIG 18-28 Manual uterine exploration.

### MANAGEMENT

Once a diagnosis of retained products of conception is established, removal must be undertaken. Therapeutic options include **manual extraction**, as noted previously, or **uterine curettage**. Nitroglycerin (50 to 200 µg IV) has been used effectively to assist with manual placental extraction. Nitroglycerin provides rapid uterine relaxation to assist with removal of the retained tissue. Uterine curettage may be performed in a delivery room; however, excessive bleeding mandates that an OR be used for the procedure. Either a large blunt (Banjo or Hunter) curette or vacuum suction curette can be used. Transabdominal ultrasound guidance is helpful in determining when tissue evacuation is complete.

### Uterine Rupture

#### DEFINITION AND PATHOGENESIS

**Uterine rupture** refers to the complete nonsurgical disruption of all uterine layers—endometrium, myometrium, and serosa. The severity of hemorrhage and maternal-fetal morbidity depends on the extent of the rupture. A large rupture may be associated with massive hemorrhage and extrusion of the fetus and/or placenta into the maternal abdomen; whereas a small rupture may have minimal bleeding and insignificant maternal-fetal consequences. *Uterine dehiscence* refers to an incomplete or occult uterine scar separation, in which the uterine serosa remains intact. Typically, no adverse obstetric outcomes are associated with a dehiscence.

#### INCIDENCE AND RISK FACTORS

The overall incidence of uterine rupture (scarred and unscarred uteri) is 1 in 2000 deliveries. Uterine rupture is most common in women with a scarred uterus, including those with prior cesarean delivery and myomectomy. The incidence of uterine rupture in women with prior cesarean delivery varies from 0.3% to 1%.<sup>82</sup> The location of the previous hysterotomy affects the uterine rupture risk. For prior cesarean deliveries, the risk of uterine rupture is illustrated in Table 18-5.

TABLE 18-5 RISK OF UTERINE RUPTURE BASED ON INCISION OF PRIOR CESAREAN DELIVERY

| INCISION OF PRIOR CESAREAN DELIVERY | UTERINE RUPTURE RISK (%) |
|-------------------------------------|--------------------------|
| Classical                           | 2-6                      |
| T or J shaped                       | 2-6                      |
| Low vertical                        | 2                        |
| Low transverse                      | 0.5-1                    |

From Landon MB, Hauth JC, Leveno KJ, et al. Maternal and perinatal outcomes associated with a trial of labor after prior cesarean delivery. *N Engl J Med*. 2004;351(25):2581.

Although **multiple risk factors** have been associated with uterine rupture, no single factor or combination of factors can reliably predict all cases.<sup>83</sup> Despite this, consistent data demonstrate strong associations for TOLAC and one or more of the following: **multiple prior cesarean deliveries**, **no previous vaginal delivery**, **induced or augmented labor**, **term gestation**, **thin uterine scar identified by ultrasound**, **multiple gestation**, **fetal macrosomia**, **postcesarean delivery infection**, **single-layer closure of hysterotomy incision**, and **short interpregnancy interval**.<sup>84</sup> Uterine rupture associated with TOLAC is discussed in Chapter 20. Other reported risk factors for uterine rupture include **increasing maternal age**, **multiparity**, **fetal malpresentation**, **uterine manipulation** (e.g., internal podalic version), **mid- to high-operative vaginal delivery**, **congenital uterine malformations**, **Ehlers-Danlos syndrome**, **invasive placentation**, and **trauma**.<sup>85</sup>

#### CLINICAL MANIFESTATIONS AND DIAGNOSIS

Uterine rupture is associated with both fetal and maternal clinical manifestations. **Fetal bradycardia with or without preceding variable or late decelerations** is the most common clinical manifestation of symptomatic uterine rupture and occurs in 33% to 70% of cases.<sup>86</sup> In some circumstances, a **loss of fetal station in labor** may occur. **Maternal clinical manifestations** are variable and may include **acute vaginal bleeding**, **constant abdominal pain or uterine tenderness**, **change in uterine shape**, **cessation of contractions**, **hematuria** (if extension into the bladder has occurred), and **signs of hemodynamic instability**.

Uterine rupture is suspected clinically but confirmed surgically. Laparotomy will demonstrate complete disruption of the uterine wall with hemoperitoneum and partial or complete extravasation of the fetus into the maternal abdomen.

#### MANAGEMENT

Once the fetus and placenta are delivered, the **site of rupture should be assessed to determine whether it can be repaired**. **If feasible, the defect should be repaired in multiple layers with absorbable suture**. Adjacent structures (e.g., bladder and adnexa) should be assessed for damage and repaired accordingly. Hysterectomy is reserved for cases of massive hemorrhage, irreparable uterine defects, and/or maternal hemodynamic instability.

### Uterine Inversion

#### DEFINITION AND PATHOGENESIS

**Uterine inversion** refers to the collapse of the fundus into the uterine cavity, and it is classified by degree and timing. With regard to degree, uterine inversion may be first degree (incomplete), second degree (complete), third degree

**FIG 18-29** Classification of uterine inversion. (From Repke JT. *Puerperal uterine inversion*, [www.uptodate.com](http://www.uptodate.com), Dec 8, 2004.)

(prolapsed), or fourth degree (total; Fig. 18-29). *First-degree uterine inversion* represents a partial extrusion of the fundus into the uterine cavity. In *second-degree uterine inversion*, the internal lining of the fundus crosses through the cervical os, forming a rounded mass in the vagina with no palpable fundus abdominally. *Third-degree uterine inversion* refers to the entire uterus prolapsing through the cervix with the fundus passing out of the vaginal introitus. *Fourth-degree uterine inversion* represents both total uterine and vaginal prolapse through the vaginal introitus. Uterine inversion timing is classified as *acute* (within 24 hours of delivery), *subacute* (>24 hours postpartum but <4 weeks), or *chronic* (>1 month postpartum).

The two most commonly proposed etiologies for uterine inversion include excessive umbilical cord traction with a fundally attached placenta and fundal pressure in the setting of a relaxed uterus. However, a causal relationship between active management of the third stage of labor and uterine inversion remains unproven.

#### INCIDENCE AND RISK FACTORS

Uterine inversion is a rare event that complicates about 1 in 1200 to 1 in 57,000 deliveries.<sup>87</sup> Proposed risk factors include uterine overdistention, fetal macrosomia, rapid labor and delivery, congenital uterine malformations, uterine fibroids, invasive placentation, retained placenta, short umbilical cord, use of uterine-relaxing agents, nulliparity, manual placental extraction, and Ehlers-Danlos syndrome.<sup>87</sup>

#### CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical presentation of uterine inversion varies by its degree and timing. Whereas incomplete uterine inversion may be subtle in its clinical findings, complete uterine inversion often presents with brisk vaginal bleeding, inability to palpate the fundus abdominally, and maternal hemodynamic instability. It may

occur before or after placental detachment. The diagnosis is made clinically with bimanual examination, during which the uterine fundus is palpated in the lower uterine segment or within the vagina. Sonography can be used to confirm the diagnosis if the clinical examination is unclear.<sup>88</sup>

#### MANAGEMENT

Once diagnosed, uterine inversion requires rapid intervention in order to restore maternal hemodynamic stability and control hemorrhage. Maternal fluid resuscitation through a large-bore IV catheter is recommended. The uterus must be replaced to its proper orientation to resolve the hemorrhage, which is best accomplished in an OR with the assistance of an anesthesiologist. The uterus and cervix should initially be relaxed with nitroglycerin (50 to 500 µg), a tocolytic agent (magnesium sulfate or β-mimetic), or an inhaled anesthetic. Once relaxed, gentle manual pressure is applied to the uterine fundus to return it to its proper abdominal location (Fig. 18-30). Uterotonic therapy should then be given to assist with uterine contraction and to prevent recurrence of the inversion.

If manual repositioning is unsuccessful, other options include hydrostatic reduction and surgical correction. With hydrostatic reduction, warmed sterile saline is infused into the vagina. The physician's hand or a Silastic ventouse cup is used as a fluid retainer to generate intravaginal hydrostatic pressure and resultant correction of the inversion (Fig. 18-31). Surgical options include the Huntington and Haultain procedures, laparoscopic-assisted repositioning, and cervical incisions with manual uterine repositioning.<sup>89</sup> The Huntington procedure involves a laparotomy with serial clamping and upward traction of the round ligaments to restore the uterus to its proper position. If this technique fails, the Haultain procedure can be attempted, which includes a vertical incision within the inversion and subsequent repositioning of the fundus. As with manual repositioning, uterotonic

**FIG 18-30** Manual replacement of uterine inversion. (From Repke JT. *Puerperal uterine inversion*, [www.uptodate.com](http://www.uptodate.com), Dec 8, 2004.)

therapy should be administered immediately after uterine replacement in order to prevent reinversion.

## Coagulopathy

### DEFINITION AND PATHOGENESIS

Coagulopathy represents an imbalance between the clotting and fibrinolytic systems. This imbalance may be hereditary or acquired in origin. *Hereditary coagulopathies* are relatively rare and have variable etiologies. Although *acquired coagulopathy* can be iatrogenic, such as that associated with anti-coagulant administration, it is **usually the result of clotting factor consumption**. Figure 18-32 demonstrates the pathophysiology of consumptive coagulopathy and its association with hemorrhage.

### INCIDENCE AND RISK FACTORS

The overall incidence of coagulopathy in the obstetric population has not been reported; however, several **associated clinical**

**FIG 18-31** Hydrostatic reduction for uterine inversion. (From Repke JT. *Puerperal uterine inversion*, [www.uptodate.com](http://www.uptodate.com), Dec 8, 2004.)

**conditions** have been documented. These include **massive antepartum or postpartum hemorrhage; sepsis; severe PE; hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome; amniotic fluid embolism; fetal demise; placental abruption; septic abortion; and acute fatty liver of pregnancy.**

### CLINICAL MANIFESTATIONS AND DIAGNOSIS

The primary clinical manifestations of consumptive coagulopathy include **bleeding, hypotension out of proportion to blood loss, microangiopathic hemolytic anemia, acute lung injury, acute renal failure, and ischemic end-organ tissue damage.**

Consumptive coagulopathy is a clinical diagnosis that is confirmed with laboratory data, such as evidence of thrombocytopenia, hemolytic changes on the peripheral blood smear, decreased fibrinogen, elevated fibrin degradation products, and prolonged prothrombin time (PT) and activated partial thromboplastin time (aPTT). When timely laboratory assessment is unavailable, drawing 5 mL of maternal blood into an empty red-topped tube and watching for clot formation will provide the clinician with a rough estimate of the degree of existing coagulopathy. If a clot is not visible within 6 minutes or forms and lyses within 30 minutes, the fibrinogen level is usually less than 150 mg/dL.

### MANAGEMENT

The most important factor in the successful treatment of coagulopathy is identifying and correcting the underlying etiology. For most obstetric causes, **delivery of the fetus initiates resolution of the coagulopathy.** In addition, rapid replacement of blood products and clotting factors should occur simultaneously. The patient should **have two large-bore IV catheters for fluid and blood component therapy, and laboratory studies should be drawn serially every 4 hours until resolution** of the coagulopathy is evident. The obstetrician should attempt to achieve a hematocrit greater than 21%, a platelet count greater than 50,000/mm<sup>3</sup>, a fibrinogen level greater than 100 mg/dL, and PT and aPTT less than 1.5 times control. It also is important **to maintain adequate oxygenation and normothermia.** Finally, adjuvant therapies should be

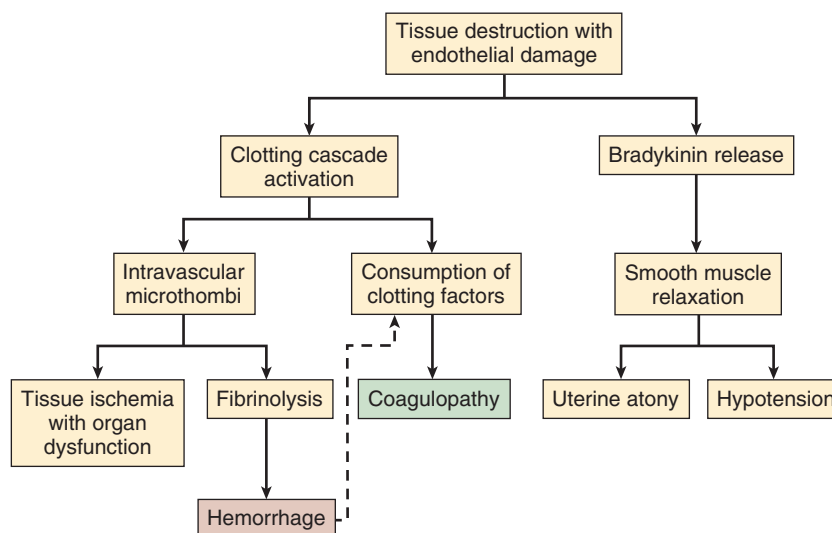

FIG 18-32 Pathophysiology and clinical manifestations of consumptive coagulopathy.

considered such as vitamin K, recombinant activated factor VII, fibrinogen concentrate, prothrombin complex concentrate, tranexamic acid, and hemostatic agents.

#### VITAMIN K

Factors II, VII, IX, and X are vitamin K–dependent clotting factors. In consumptive coagulopathy, these clotting factors are consumed. Administration of vitamin K (5 to 10 mg) by subcutaneous, intramuscular, or IV routes can assist with endogenous replenishment of these procoagulants.

#### RECOMBINANT ACTIVATED FACTOR VII

Factor VII is a precursor for the extrinsic clotting cascade. When massive procoagulant factor consumption occurs, replacement is necessary. **Human recombinant factor VIIa has been used successfully in cases of consumptive coagulopathy attributed to postpartum hemorrhage.**<sup>90</sup> The dosage of this IV therapy has ranged from 16.7 to 120 µg/kg.<sup>90</sup> An important advantage of this therapy is its rapid bioavailability (10 to 40 minutes) for reversal of coagulopathy; however, disadvantages include a relatively short half-life (2 hours), cost (approximately \$1 per microgram), and thromboembolism risk. Recombinant activated factor VIIa should be considered in cases of refractory coagulopathy or when blood component replacement is delayed.

#### FIBRINOGEN CONCENTRATE

A human fibrinogen concentrate (RiaStap [CSL Behring]) has been approved by the U.S. Food and Drug Administration (FDA). Each vial of fibrinogen concentrate contains 900 to 1300 mg fibrinogen and 400 to 700 mg human albumin. Fibrinogen concentrate can be used alone or in combination with cryoprecipitate. It has been used successfully in Europe for the treatment of massive obstetric hemorrhage due to consumptive coagulopathy.<sup>91</sup>

#### PROTHROMBIN COMPLEX CONCENTRATE

Prothrombin complex concentrate (Kcentra [CSL Behring]) contains factors II, VII, IX, and X and proteins C and S. It can be used as an alternative to fresh frozen plasma (FFP).

Advantages to its use include no need for thawing or blood group typing and decreased risks of volume overload, transfusion-related acute lung injury (TRALI), and allergic reactions.

#### TRANEXAMIC ACID

Tranexamic acid is an IV antifibrinolytic drug that may be used for the prevention and treatment of hemorrhage. In a small multicenter trial, tranexamic acid reduced postpartum hemorrhage and transfusion requirements.<sup>92</sup>

#### HEMOSTATIC AGENTS

**A variety of topical hemostatic agents are available for control of coagulopathic surface bleeding.** These agents have different clotting factors and mechanisms of action. Examples include oxidized regenerated cellulose (e.g., Surgicel [Ethicon]), fibrin sealants (e.g., Tisseal [Baxter]), microporous polysaccharide spheres (e.g., Arista [Bard Davol]), microfibrillar collagen (e.g., Avitene [Bard Davol]), hemostatic matrices (e.g., Floseal [Baxter]), gelatin matrices (e.g., Gelfoam), and topical thrombin. These agents may be used alone or in combination.

#### Fluid Resuscitation and Transfusion

All obstetricians will encounter antepartum and postpartum hemorrhage. In most instances, **fluid resuscitation and blood component therapy are life-saving.** Therefore every physician should have a thorough understanding of appropriate volume resuscitation, transfusion therapy, and alternative treatment options and their risks.

#### Volume Resuscitation

Initial management of a hemorrhaging patient requires appropriate volume resuscitation. Two large-bore IV catheters are recommended. **Warmed crystalloid solution in a 3:1 ratio to the estimated blood loss should be rapidly infused.** Goals of therapy are to maintain an adequate maternal blood pressure (systolic blood pressure >90 mm Hg) and urine output (at least 30 mL/hr). If the hemorrhage is easily controlled, this may be the only therapy needed. The patient should have serial assessments of her vital signs and hematologic profiles to confirm hemodynamic stability.

**TABLE 18-6** BLOOD COMPONENT THERAPY

| PRODUCT                         | CONTENTS                               | VOLUME       | ANTICIPATED EFFECT (PER UNIT)                               |
|---------------------------------|--|--------------|---|
| Whole blood                     | All components                         | 500 mL       | Used only in emergencies*                                   |
| Packed red blood cells          | Red blood cells                        | 300 mL       | Increase hemoglobin by 1 g/dL<br>Increase hematocrit by 3%  |
| Platelets (single donor pooled) | Platelets                              | 300 mL (6 U) | Increase platelet count by 30,000 to 60,000/mm <sup>3</sup> |
| Fresh frozen plasma             | All clotting factors                   | 250 mL       | Increase fibrinogen by 5-10 mg/dL                           |

vWF, von Willebrand factor.

## COLLOID SOLUTIONS

Colloid solutions contain larger particles, *colloids*, which are less permeable across vascular membranes. These solutions provide a greater increase in colloid oncotic pressure and plasma volume; however, they are more expensive than crystalloids and may be associated with anaphylactoid reactions. Examples of colloid solutions include albumin, hetastarch, and dextran.

## Blood Component Therapy

### WHOLE BLOOD

Whole blood contains red blood cells (RBCs), clotting factors, and platelets. Whole blood is rarely used in modern obstetrics because of its many disadvantages, including a short storage life (24 hr), large volume (500 mL per unit), and potential for hypercalcemia.

### PACKED RED BLOOD CELLS

Packed red blood cells (pRBCs) are the most appropriate therapy for patients who require RBC replacement because of hemorrhage. They are the only blood product to provide oxygen-carrying capacity. **Each pRBC unit contains approximately 300 mL of volume (250 mL RBCs and 50 mL of plasma). In a 70-kg patient, one unit of pRBCs will raise the hemoglobin by 1 g/dL and the hematocrit by 3%.** Transfusion of pRBCs should be considered in any gravida with hemoglobin less than 8 g/dL or with active hemorrhage and associated coagulopathy.

### PLATELET CONCENTRATES

Platelets are separated from whole blood and are stored in plasma. **Because 1 unit of platelets provides an increase of only approximately 7500/mm<sup>3</sup>, platelet concentrates of 6 to 10 units need to be transfused.** Platelet concentrates can be derived from multiple donors or single donors. The single-donor concentrates are preferred because they expose the patient to fewer potential antigenic and immunologic risks. Transfusion of a single-donor platelet concentrate will increase the circulating platelet count by 30,000 to 60,000/mm<sup>3</sup>. Because sensitization can occur, it is important for platelets to be ABO and Rh specific. **Transfusion of platelets should be considered when the platelet count is less than 20,000/mm<sup>3</sup> after a vaginal delivery or less than 50,000/mm<sup>3</sup> after a cesarean delivery, or when coagulopathy is evident.**

### FRESH FROZEN PLASMA

**FFP is plasma that is extracted from whole blood.** FFP primarily contains fibrinogen, antithrombin, and clotting factors V, XI, and XII. Transfusing FFP not only assists with coagulation but also provides the patient with volume resuscitation because

**each unit contains approximately 250 mL.** Typically, fibrinogen levels are used to monitor a patient's response to FFP. Each unit of FFP **should raise the fibrinogen level by 5 to 10 mg/dL**, and FFP does not need to be ABO or Rh compatible. FFP should be considered for hemorrhaging patients with evidence of consumptive coagulopathy, coagulopathic liver disease, and for warfarin reversal.

### CRYOPRECIPITATE

**Cryoprecipitate is the precipitate that results from thawed FFP.** It is rich in fibrinogen, von Willebrand factor, and factors VIII and XIII. Like FFP, **cryoprecipitate can be measured clinically by the fibrinogen response, which should increase by 5 to 10 mg/dL per unit.** Unlike FFP, **each unit of cryoprecipitate provides minimal volume (10 to 15 mL)**, so it is an ineffective agent for volume resuscitation. Cryoprecipitate is indicated for patients with coagulopathy and concerns of volume overload, hypofibrinogenemia, factor VIII deficiency, and von Willebrand disease.

Table 18-6 contains a summary of the available blood component therapies.

### MASSIVE TRANSFUSION PROTOCOLS

Although no universally accepted guidelines exist for blood product replacement, expert opinion derived from trauma and military experience suggests that more aggressive replacement of coagulation factors with pRBCs improves outcomes and survival.<sup>93-95</sup> A variety of protocols have been recommended, most of which aim for an equal ratio of pRBCs, FFP, and platelets. **A commonly adopted massive transfusion protocol is 6 units of pRBCs to 4 units of FFP to 1 unit of platelet concentrate (6:4:1).**<sup>93</sup> Some centers have added **6 to 10 units of cryoprecipitate** to this regimen.

### TRANSFUSION RISKS AND REACTIONS

#### METABOLIC ABNORMALITIES AND HYPOTHERMIA

When pRBCs are stored, leakage of potassium and ammonia can occur into the plasma. This may result in hyperkalemia and high ammonia concentrations in patients who require massive transfusion. In addition, because most pRBC units are stored in a citrate solution, hypocalcemia may occur. Serial assessments of metabolic profiles with ionized calcium levels can assist the clinician in managing these changes.

In addition to metabolic abnormalities, hypothermia may complicate the clinical course of massive transfusion and result in cardiac arrhythmias. Hypothermia can be prevented by warming pRBC units before transfusion and by providing alternative heating devices to the patient (e.g., Bair Hugger anesthesia warmer [3M]).

**TABLE 18-7** TRANSFUSION-RELATED INFECTION RISKS

| INFECTION                | TRANSMISSION RISK         |
|--------------------------|---------------------------|
| HIV-1, HIV-2             | 1 in 1.4–4.7 million      |
| Hepatitis B              | 1 in 100,000–400,000      |
| Hepatitis C              | 1 in 1.6 to 3.1 million   |
| HTLV-I and -II           | 1 in 500,000 to 3 million |
| Bacterial contamination: |                           |
| Red blood cells          | 1 in 28,000–143,000       |
| Platelets                | 1 in 2000–8000            |

HIV, human immunodeficiency virus; HTLV, human T-cell lymphotropic virus.

### IMMUNOLOGIC REACTIONS

Transfusions introduce interactions between inherited or acquired antibodies and the foreign antigens of the transfused blood products; the most common immunologic reactions are febrile nonhemolytic transfusion reactions. Cytokines are believed to be the primary cause of these reactions. Retrospective cohort studies suggest that transfusion of leukoreduced blood products may decrease the frequency of these reactions; however, randomized controlled trial (RCT) data are limited. Less common immunologic complications include acute or delayed hemolytic transfusion reactions, anaphylaxis, urticarial reactions, posttransfusion purpura, and graft-versus-host disease.

### INFECTION RISKS

All blood products have the potential to transmit viral and bacterial infections. Although transmission rates have substantially decreased in the past two decades, they are still a potential risk that must be disclosed when a transfusion is needed. [Table 18-7](#) lists current transfusion-associated infection risks.<sup>96</sup>

### TRANSFUSION-ASSOCIATED VOLUME/CIRCULATORY OVERLOAD AND TRANSFUSION-RELATED ACUTE LUNG INJURY

*Transfusion-associated volume/circulatory overload* (TACO) refers to pulmonary edema that results from excessively large infusions of fluids and blood products. Symptoms include dyspnea, orthopnea, tachycardia, wide pulse pressure, hypertension, and hypoxemia. TACO typically is associated with elevated brain natriuretic peptide (BNP), central venous pressure, and pulmonary artery wedge pressure. TACO is usually treated with diuretics and supplemental oxygen.

*Transfusion-related acute lung injury* (TRALI) refers to a rare but potentially life-threatening form of acute lung injury that can result from blood product administration. TRALI is thought to result from a “two-hit” mechanism that involves neutrophil sequestration/priming and activation.<sup>97</sup> TRALI is characterized by sudden onset of hypoxemic respiratory insufficiency during or within 6 hours of blood product administration. Additional findings include noncardiogenic pulmonary edema, hypotension, fever, tachypnea, tachycardia, and cyanosis. Treatment is twofold and includes transfusion discontinuation and supportive care with oxygen administration, ventilatory support (continuous positive airway pressure [CPAP], bilevel positive airway pressure [BiPAP], or mechanical ventilation), hemodynamic stabilization (fluid resuscitation and/or vasoactive agents), and possible steroid administration.

## Blood Conservation Approaches

### Preoperative Autologous Blood Donation and Transfusion

*Preoperative autologous blood donation and transfusion* refers to the collection of the patient's own RBCs prior to surgery and reinfusion of those cells intraoperatively or postoperatively. Although it is unreasonable to have all pregnant individuals consider autologous blood donation, patients at high risk for transfusion (e.g., those with placenta previa or placenta accreta) may be good candidates. Guidelines for autologous blood donation include a minimum predonation hemoglobin of 11 g/dL, first donation within 6 weeks of anticipated delivery (because of the pRBC storage life of 42 days), a week-long interval between donations, and no donation within 2 weeks of anticipated delivery.<sup>96</sup>

**Autologous transfusion should be used selectively.** Not only is it significantly more expensive than homologous transfusion, but also the risks for bacterial contamination and subsequent homologous transfusion are not completely eliminated.

### Acute Normovolemic Hemodilution

*Acute normovolemic hemodilution* refers to a blood conservation technique in which blood is removed from the patient preoperatively and is replaced by a crystalloid or colloid solution to maintain normovolemia. During surgery, the blood loss is diluted. The patient is reinfused with her more concentrated blood postoperatively. Acute normovolemic hemodilution can be considered for patients with good initial hemoglobin concentrations who are expected to have a blood loss of at least 1000 mL during surgery (e.g., placenta accreta).

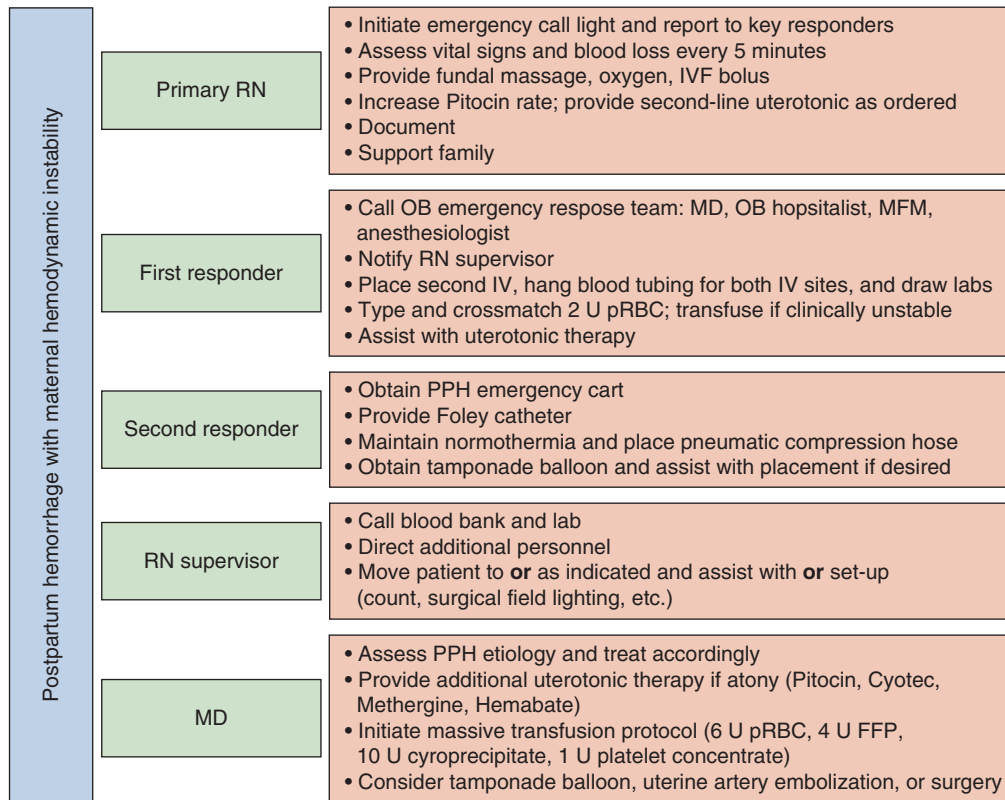

### Intraoperative Blood Salvage

*Intraoperative blood salvage* refers to collecting the patient's blood during surgery, filtering the blood, and then reinfusing the red cells back to the patient. Cell-Saver technology is the most widely used blood-salvage system. In the past, theoretic concerns regarding the risks for infection and amniotic fluid embolism limited the use of blood-salvage technology in obstetrics; however, **several studies have documented its safety and effectiveness.**<sup>98</sup> Intraoperative blood salvage has many advantages over homologous transfusion. It eliminates the risk for infectious disease transmission, alloimmunization, and immunologic transfusion reactions. It is a cost-effective procedure that avoids wastage of blood and thereby reduces the need for homologous transfusion. In addition, it can rapidly provide the patient with RBCs (1 unit of pRBCs per 3-minute interval). Finally, many Jehovah's Witnesses will accept intraoperative blood salvage because the blood remains in a continuous circuit and does not leave the OR.

### Alternative Oxygen Carriers

Because some patients refuse to accept blood products (e.g., Jehovah's Witnesses) or are unable to be transfused owing to a lack of blood compatibility, oxygen carriers have been developed as alternatives to transfusion therapy. The two primary products are hemoglobin-based oxygen carriers and perfluorocarbons. Hemoglobin-based oxygen carriers use hemoglobin derived from animals or outdated human blood. The hemoglobin is separated from the red cell stroma and undergoes multiple filtration and polymerization processes before use. Perfluorocarbons are inert compounds that can dissolve gases, including oxygen.

**FIG 18-33** Postpartum hemorrhage treatment protocol. FFP, fresh frozen plasma; IV, intravenous; IVF, intravenous fluids; MD, physician; MFM, maternal-fetal medicine; OB, obstetric; PPH, postpartum hemorrhage; pRBC, packed red blood cells; RN, registered nurse. (Courtesy K. Francois.)

Both products have high oxygen-carrying capacities. Unfortunately, cost, supply problems, lack of FDA approval, and poor side-effect profiles have limited the usefulness of these agents.

### Hemorrhage Prevention and Protocols

Because obstetric hemorrhage is such a widespread problem, it is important for institutions to develop standardized management protocols and to conduct hemorrhage drills. Multiple organizations have developed guidelines for the diagnosis, management, and prevention of postpartum hemorrhage. The use of obstetric rapid response teams, massive transfusion protocols, and prescriptive checklists is vital to program success. In addition, simulation-based teaching models have been helpful to identify knowledge deficits, improve accuracy of blood loss estimation, and instill provider confidence in the clinical management of postpartum hemorrhage.<sup>99-102</sup> Figure 18-33 provides a modified postpartum hemorrhage treatment protocol from the author's institution.

#### KEY POINTS

- ◆ Hemorrhage is a major cause of obstetric morbidity and mortality throughout the world. It is responsible for one third of all pregnancy-related deaths in both high- and low-income countries.
- ◆ Understanding the hemodynamic changes of pregnancy and the physiologic responses that occur with hemorrhage assists in appropriate management. Clinicians should recognize the four classes of hemorrhage to allow for rapid intervention.

- ◆ Placental abruption is diagnosed primarily by clinical findings and is confirmed by radiographic, laboratory, and pathologic studies. Management of placental abruption is dependent on the severity, gestational age, and maternal-fetal status.
- ◆ Placenta previa is typically diagnosed with sonography. Placenta previa remote from term can be expectantly managed, and outpatient management is possible in selected cases.
- ◆ Placenta previa in association with a prior cesarean delivery is a major risk factor for placenta accreta. Additional radiographic surveillance should be attempted in these cases to provide antenatal diagnosis of placenta accreta.
- ◆ Placenta accreta is best managed with a multidisciplinary approach that includes maternal-fetal medicine specialists, neonatologists, blood-conservation teams, anesthesiologists, advanced pelvic surgeons, and urologists. Scheduled preterm delivery at 34 to 35 weeks of gestation is recommended.
- ◆ Antenatal detection of vasa previa is possible with sonography and significantly improves perinatal outcomes.
- ◆ Postpartum hemorrhage complicates 1 in 20 to 1 in 100 deliveries. Every obstetrician and birth attendant needs to have a thorough understanding of normal delivery-related blood loss in order to recognize postpartum hemorrhage.
- ◆ Management of uterine atony should follow a rapidly initiated sequenced protocol that may include bimanual

massage, uterotonic therapy, uterine tamponade, selective arterial embolization, or surgical intervention.

- ◆ Coagulopathy mandates treatment of the initiating event and rapid replacement of consumed blood products. Transfusion of blood components should not be delayed, and replacement protocols should be followed.
- ◆ Blood conservation approaches should be considered if clinically appropriate.
- ◆ Standardized obstetric hemorrhage management protocols, checklists, and drills have been shown to improve outcomes.

## DEFINITIONS

*Cesarean delivery* (CD) is defined as birth of a fetus from the uterus through an abdominal incision.<sup>1</sup> The terms *cesarean delivery* or *cesarean birth* are preferred as opposed to *cesarean section*. *Primary cesarean* refers to a CD done in a woman without a prior cesarean birth, whereas *repeat cesarean* refers to a CD done in a woman who had a cesarean birth in a previous pregnancy.<sup>1</sup> This chapter reviews the history, incidence, indications, techniques, and complications of CD as well as tubal sterilization.

## HISTORY OF CESAREAN DELIVERY

CD has been described since ancient times, and evidence exists from both early Western and non-Western societies of this surgical procedure being performed.<sup>2</sup> The evolution of the term *cesarean* has been debated over time. Although originally believed to have been derived from the birth of Julius Caesar, it is unlikely that his mother, Aurelia, would have survived the operation; her knowledge of her son's invasion of Europe many years later indicates that she survived childbirth. In Caesar's time, surgical delivery was reserved for when the mother was dead or dying. Roman law under Numa Pompilius the first ("Lex Regia"), then renamed after Caesar ("Lex Cesarea"), specified surgical removal of the fetus before burial of the deceased pregnant woman; religious edicts required separate burial for the infant and mother. The term *cesarean* may also refer to patients being cut open, because the Latin verb *caedere* means to cut. *Cesarean operation* was the preferred term before the 1598 publication of Guillemeau, who introduced the term *section*.

Although sporadic reports of heroic life-saving efforts through cesarean childbirth existed for hundreds of years, it was not until the latter part of the nineteenth century that the operation became established as part of obstetric practice. This coincided with the gradual transition of childbirth as primarily a midwife-attended event, often in rural settings, to an urban hospital experience. The wide emergence of hospitals laid the foundation for establishing obstetrics as a hospital-based specialty. As new methods for anesthesia emerged, CD for obstructed labor gained popularity over destructive procedures, such as craniotomy, that accompanied difficult vaginal births. Despite the dangers that still existed with CD, the operation was viewed as preferable to a difficult high forceps delivery, which was associated with fetal injury and deep pelvic lacerations. Although refinements in anesthesia techniques allowed the operation to be performed,

mortality rates remained very high, with sepsis and peritonitis as leading causes of postoperative deaths. Primitive surgical techniques and lack of antisepsis clearly contributed to morbidity. Surgeons attempted to complete the operation without closing the uterus, fearing that the suture material itself would promote infection and that the uterus would best heal by secondary intention. As a result, women were placed at risk for both hemorrhage and infection.

Lebas first advocated suturing the uterus after CD in 1769. Traditionally, sutures were not used inside the abdomen or pelvis because they were considered impossible to remove once the cavity was closed. In 1876, Eduardo Porro advocated for supracervical hysterectomy and bilateral salpingo-oophorectomy during CD to control bleeding and to prevent postoperative infection. Shortly thereafter, surgeons gained experience with internal suturing because silver-wire stitches were developed by the gynecologist J. Marion Sims, who had perfected the use of these sutures in the treatment of vesicovaginal fistulae resulting from obstructed labors. In the early 1880s, two German obstetricians, Ferdinand Adolf Kehrer (1837-1914) and Max Sänger (1853-1903), both independently proposed a transverse incision of the lower segment of the uterus, at the level of the internal cervical os, and developed two-layer uterine closure methods with the sutures used by J. Marion Sims. Another pivotal contribution was made in 1900 by Hermann Johannes Pfannenstiel (1862-1909), a German gynecologist who described a transverse suprapubic incision, or pelvic skin incision.

As gynecologic surgeons performed more CDs and the outcomes improved, greater attention was placed on technique, including the site of the uterine incision. Between 1890 and 1925, more and more surgeons began using transverse incisions of the uterus. John Martin Munro Kerr (1868-1960), a professor of Obstetrics Midwifery at the University of Glasgow, popularized the Pfannenstiel skin incision and lower segment uterine incision and is considered the “father” of the modern CD. It was noted that such incisions reduced the rate of infection and the risks of incisional hernia and rupture with subsequent pregnancies compared with the vertical incisions. However, before the advent of antibiotics, owing to the risk for peritonitis, extraperitoneal cesarean was advocated by Frank (1907), Veit and Fromme (1907), and Latzko (1909) and was popularized by Beck (1919) in the United States. Interestingly, the vertical opening of the abdomen was still the main technique used in the 1970s, although it was known from the beginning of the twentieth century to be associated with higher rates of long-term postoperative complications, such as wound dehiscence and abdominal incision hernia, and it is also cosmetically less pleasing.

**The introduction of penicillin in 1940 dramatically reduced the risk for peripartum infections. As antibiotic therapy emerged, the need for extraperitoneal dissection diminished.** As technology developed, including improved anesthesia, and the medical management of pregnancy and childbirth accelerated, CD became more commonplace in obstetrics. Given its current safety and effectiveness, a liberalized approach to using cesarean childbirth has emerged in developed countries over the past 40 years.

## INCIDENCE

The CD *rate* describes the proportion of women undergoing CD of all women giving birth during a specific time period. The CD rate may be further subdivided into primary and repeat CD

### BOX 19-1 SELECTED FACTORS RESPONSIBLE FOR INCREASED CESAREAN DELIVERY RATES

#### Obstetric Factors

- Increased primary CD rate
  - Failed induction, increased use of induction
  - Decreased use of operative vaginal delivery
  - Increased macrosomia, CD for macrosomia
  - Decline in vaginal breech delivery
- Increased repeat CD rate
  - Decreased use of vaginal birth after CD

#### Maternal Factors

- Increased proportion of women >35 yr
- Increased proportion of NP women
- Increased primary CDs on maternal request

#### Physician Factors

- Malpractice litigation concerns

CD, cesarean delivery; NP, nulliparous.

rates, both as a proportion of the entire obstetric population. **CD rates have risen in the United States in a dramatic fashion from less than 5% in the 1960s to 32.7% by 2013, with stable rates around 32% to 33% in the last 5 years or so.<sup>3</sup>** CD accounts for more than 1 million major operations performed annually in the United States. It is the most common major surgical procedure undertaken today in the United States and around the world. **Among the reasons for this increase are (1) a continued increase in primary CDs for dystocia, failed induction, and malpresentation; (2) an increase in the proportion of women with obesity, diabetes mellitus, and multiple gestation, which predispose to CD; (3) increased practice of CD on maternal request; and (4) limited use of a trial of labor after cesarean (TOLAC) delivery due to both safety and medicolegal concerns.** Factors responsible for increased cesarean rates are shown in Box 19-1.

A recent increase in international CD rates has also been documented. Rates of about 25% to 30% are reported in some European countries, such as the United Kingdom; they are over 40% in Italy, over 50% in China, and even higher in places like Brazil and Egypt. The rise in CD rates has prompted increased interest in the indications, complications, and techniques involved with this procedure.

**The World Health Organization (WHO) has proposed an incidence of CD between 10% and 15% as a target to optimize maternal and perinatal health.** However, it is not possible to determine an optimal CD rate because any ideal rate must be a function of multiple clinical factors that vary in each population and are influenced by the level of obstetric care provided. Further complicating this issue is the absence of complete and accurate data that focus on both maternal and infant outcomes. Hence, although **CD rates** can be considered a measure of a specific health care process (mode of delivery), these rates **are not appropriate outcome measures** because they do not indicate whether cesarean or vaginal birth results in optimal perinatal outcomes. **Maternal and perinatal morbidity and mortality should be the outcomes monitored to ensure best quality of care.** Higher CD rates (e.g., 15% to 20% compared with <5% to 10%) have been associated with better perinatal outcomes in several studies.<sup>4</sup> So **instead of setting goals or limits for overall CD rates, it is most important to monitor maternal**

**and perinatal health outcomes.** We would all agree with a 0% or 100% CD rate if either of these were associated with the lowest incidences of complications for mother or baby. The optimal CD rate in the early twenty-first century is in between these extremes and depends on the population. For example, Robson<sup>5</sup> has suggested a helpful classification of different populations to compare cesarean rates. Class I is the most common class in most centers and includes singleton term vertex gestations admitted in spontaneous labor. Only by comparing data for similar Robson classes, or at least a similar case mix, can data regarding CD rates really be objectively evaluated. Moreover, institutions involved in tertiary obstetric care that manage a large number of preterm deliveries and maternal complications of pregnancy should have higher cesarean rates than primary care facilities. Two populations often targeted for comparison include **nulliparous women with a singleton vertex gestation at 37 weeks or greater without other complications and women with one prior low transverse CD delivering a single vertex fetus at 37 weeks or greater without other complications.**<sup>6</sup> The use of these simple case-mix adjusted rates should make comparative evaluation of CD rates and their comparison to maternal and perinatal outcomes more meaningful. As data become more unified and methodologically sound, the quality of obstetric care can be better assessed.

In 2014, the American College of Obstetricians and Gynecologists (ACOG) and the Society for Maternal-Fetal Medicine (SMFM) published an obstetric care consensus document on the safe prevention of primary CD in which several interventions were suggested to prevent unnecessary CDs (Box 19-2).<sup>7</sup> Institutions can indeed safely reduce cesarean birth rates through quality-improvement initiatives.<sup>8</sup>

## INDICATIONS FOR CESAREAN DELIVERY

CD can be performed for maternal-fetal, fetal, and maternal indications. The most common current indications are, in order of frequency, (1) failure to progress, also called *cephalopelvic disproportion* (CPD) or *dystocia* (about 30%); (2) prior cesarean (30%); (3) nonreassuring fetal heart rate (FHR) patterns (10%); and (4) fetal malpresentation (10%). Indications are listed by category in Box 19-3. Looking at just the first CD, the common indications are shown in percentages in Figure 19-1.

### Maternal-Fetal Indications

Most CDs are performed for conditions that might pose a threat to both mother and fetus if vaginal delivery occurred. Complete placenta previa and placental abruption with the potential for hemorrhage are clear examples. Dystocia presents a risk for both direct fetal and maternal trauma, and it may also compromise fetal oxygenation and metabolic status. **The suggestions for definitions of arrest of labor in the first and second stage and failed induction, shown in Box 19-2, should be followed for management as long as maternal and fetal conditions are reassuring.**

### Fetal Indications

**Fetal indications are primarily recognized by nonreassuring FHR testing with the potential for long-term consequences of metabolic acidosis.** Continuous FHR monitoring is associated with a significant reduction in neonatal seizures and remains the most commonly used modality for fetal monitoring in labor. Scalp stimulation can be used to ameliorate the high

**FIG 19-1** Indications for primary cesarean delivery. (Data from Barber EL, Lundsberg LS, Belanger K, Pettker CM, Funai EF, Illuzzi JL. Indications contributing to the increasing cesarean delivery rate. *Obstet Gynecol.* 2011;118:29-38.)

false-positive rate of continuous FHR monitoring (see Box 19-2). Unfortunately, pulse oximetry, ST-segment monitoring, and other modalities have not been shown to affect neonatal outcomes or CD rates (see Chapter 15).

Other fetal indications for CD include malpresentation, such as a breech orientation, and more than 90% of these babies in singleton gestations are delivered by cesarean.<sup>9</sup> Active maternal herpes infection would be an indication for CD to reduce the risk for transmission of infection. Suspected macrosomia or the potential for fetal trauma are indications for CD only in rare circumstances (see Box 19-2). Fetuses with certain birth defects, such as hydrocephalus with macrocephaly and neural tube defects, have traditionally undergone CD; however, insufficient data exist to make this an absolute indication. Babies with fetal abdominal wall defects, such as omphalocele and gastroschisis, can be delivered safely vaginally, if there are no obstetric indications for cesarean.

### Maternal Indications

**Maternal indications for CD are relatively few and can be considered as medical or mechanical in nature** (see Box 19-3). Most of these indications are not based on evidence from randomized controlled trials (RCTs). Certain maternal cardiac conditions, such as a dilated aortic root with Marfan syndrome, are indications for CD. Central nervous system abnormalities in which increased intracranial pressure would be undesirable, such as accompanies the second stage of labor, have also led to recommendations for CD.

Alterations in the capacity of the maternal pelvis can be indications for CD. Mechanical vaginal obstruction as a result of pelvic masses such as lower segment myomata are examples. Finally, women with massive condylomata may also require CD, but this is rare.

### Cesarean Delivery on Maternal Request

As CD has become safer, women have occasionally voiced their wish for a cesarean *without* a medical indication. This clinical scenario has been recently called “cesarean delivery on maternal

**BOX 19-2 SAFE PREVENTION OF CESAREAN DELIVERY****First Stage of Labor**

- A prolonged latent phase (>20 hr in NP women and >14 hr in MP women) should not be an indication for CD. (Grade 1B)
- Slow but progressive labor in the first stage rarely should be an indication for CD. (Grade 1B)
- As long as fetal and maternal status are reassuring, cervical dilation of 6 cm should be considered the threshold for the active phase in most laboring women. Thus before 6 cm of dilation is achieved, standards of active-phase progress should not be applied. (Grade 1B)
- CD for active-phase arrest in the first stage of labor should be reserved for women at or beyond 6 cm of dilation with ruptured membranes who fail to progress despite 4 hr of adequate uterine activity or at least 6 hr of oxytocin administration with inadequate uterine activity and no cervical change. (Grade 1B)

**Second Stage of Labor**

- A specific absolute maximum length of the second stage of labor above which all women should be delivered operatively has not been identified. (Grade 1C)
- Before diagnosing arrest of labor in the second stage, if the maternal and fetal conditions permit, allow for the following:
  - At least 2 hr of pushing in MP women (Grade 1B)
  - At least 3 hr of pushing in NP women (Grade 1B)
 Longer durations may be appropriate on an individualized basis (e.g., with the use of epidural analgesia or with fetal malposition) as long as progress is being documented. (Grade 1B)
- Operative vaginal delivery in the second stage of labor should be considered an acceptable alternative to CD. Training in, and ongoing maintenance of, practical skills related to operative vaginal delivery should be encouraged. (Grade 1B)
- Manual rotation of the fetal occiput in the setting of fetal malposition in the second stage of labor is a reasonable alternative to operative vaginal delivery or CD. To safely prevent CD in the setting of malposition, it is important to assess fetal position throughout the second stage of labor. (Grade 1B)

**Fetal Heart Rate Monitoring**

- Amnioinfusion for repetitive variable fetal heart rate decelerations may safely reduce the CD rate. (Grade 1A)
- Scalp stimulation can be used as a means of assessing fetal acid-base status when abnormal or indeterminate (*nonreassuring*) fetal heart patterns (e.g., minimal

variability) are present, and it is a safe alternative to CD in this setting. (Grade 1C)

**Induction of Labor**

- Induction of labor generally should be performed based on maternal and fetal medical indications and after informed consent is obtained and documented. Inductions at 41 0/7 weeks of gestation and beyond should be performed to reduce the risk of CD and the risk of perinatal morbidity and mortality. (Grade 1A)
- Cervical ripening methods should be used when labor is induced in women with an unfavorable cervix. (Grade 1B)
- If the maternal and fetal status allow, CDs for failed induction of labor in the latent phase can be avoided by allowing longer durations of the latent phase (up to 24 hr or longer) and requiring that oxytocin be administered for at least 18 hr after membrane rupture before deeming the induction a failure. (Grade 1B)

**Fetal Malpresentation**

- Fetal presentation should be assessed and documented beginning at 36 0/7 weeks of gestation to allow for external cephalic version to be offered. (Grade 1C)

**Suspected Fetal Macrosomia**

- CD to avoid potential birth trauma should be limited to estimated fetal weights of at least 5000 g in women without diabetes and at least 4500 g in women with diabetes. The prevalence of birthweight of 5000 g or more is rare, and patients should be counseled that estimates of fetal weight, particularly late in gestation, are imprecise. (Grade 2C)
- Women should be counseled about the IOM maternal weight guidelines in an attempt to avoid excessive weight gain. (Grade 1B)

**Twin Gestations**

- Perinatal outcomes for twin gestations in which the first twin is in cephalic presentation are not improved by CD. Thus women with either cephalic/cephalic-presenting twins or cephalic/noncephalic-presenting twins should be counseled to attempt vaginal delivery. (Grade 1B)

**Other**

- Individuals, organizations, and governing bodies should work to ensure that research is conducted to provide a better knowledge base to guide decisions regarding CD and to encourage policy changes that safely lower the rate of primary CD. (Grade 1C)

Cephalopelvic disproportion  
 Placental abruption  
 Placenta previa  
 Repeat cesarean delivery  
 Cesarean delivery on maternal request

**Maternal**

Specific cardiac disease (e.g., Marfan syndrome with dilated aortic root)

**Fetal**

Nonreassuring fetal status  
 Breech or transverse lie  
 Maternal herpes

**BOX 19-4 RISKS AND BENEFITS OF CESAREAN DELIVERY WITHOUT MEDICAL INDICATIONS****Potential Benefits**

Reduction in perinatal morbidity and mortality:  
 Elimination of intrapartum events associated with perinatal asphyxia  
 Reduction in traumatic birth injuries  
 Reduction in stillbirth beyond 39 weeks' gestation  
 Possible protective effect against pelvic floor dysfunction  
 Less postpartum hemorrhage

**Potential Risks**

Increased short-term maternal morbidity  
 Increased endometritis, transfusion, and venous thrombosis rates  
 Increased length of stay and longer recovery time  
 Increased short-term neonatal morbidity  
 Increased mild neonatal respiratory morbidity  
 Increased long-term maternal and neonatal morbidity  
 Increased risk for placenta accreta and hysterectomy with subsequent cesarean deliveries

request.” **The lack of specificity of the term “elective” suggests the most reasonable and prudent course of action is to not use it, but rather to document the specific indication—whether medical or nonmedical—for the intervention or procedure (i.e., CD on maternal request).**<sup>10</sup> At times, physicians have also advocated cesarean as the preferred mode of delivery, even in the absence of accepted indications as described previously. We would term this scenario “cesarean delivery on physician request.”

The decision to plan a cesarean or a vaginal birth should be based on the best literature available with which to compare these choices. Cases in which cesarean (or vaginal) delivery is for accepted indications as described previously should be excluded from this comparison. The National Institutes of Health (NIH) and ACOG have carefully reviewed the literature on this topic.<sup>11,12</sup> Both have reported that no quality evidence has compared planned cesarean to planned vaginal delivery because no randomized studies exist for the majority of women—those with a singleton gestation in vertex presentation at term. Moderate-quality evidence shows that planned cesarean is associated with less postpartum hemorrhage, more mild neonatal respiratory morbidity, longer maternal hospital stay, and possibly greater complications in subsequent pregnancies (Box 19-4).<sup>11,12</sup>

**Women who desire several children should be advised against non-medically indicated CD because of the direct association with an increasing number of CDs and increasing life-threatening complications such as placenta previa, placenta accreta, and the need for cesarean hysterectomy.**<sup>12</sup> Unfortunately, at times CD is performed on maternal request because of a fear of excessive pain and fear of damage to the vagina and perineum. Fear of childbirth is present in about 3% to 8% of women, who should be reassured of adequate maternal pain relief in labor and counseled regarding TOLAC. Increased maternal risks attributed to vaginal delivery also include urinary and fecal incontinence, pelvic prolapse, and sexual dysfunction. The precise contribution of vaginal delivery versus pregnancy and labor to these complications remains difficult to ascertain, and many epidemiologic studies do stratify data according to variables such as gestational age, maternal age, parity, and fetal weight.

All remaining comparisons, which will be discussed later, are based on weak evidence and should not decisively sway clinical decisions. **Perinatal mortality has been reported to be several times lower with a planned CD compared with labor and vaginal birth.** Additionally, hypoxic-ischemic encephalopathy (HIE) of the newborn related to intrapartum events—including abruption, cord prolapse, and progressive asphyxia—occurs in approximately 1 in 3000 to 5000 births. Many of these cases presumably would be prevented by planned CD, as would unexplained stillbirths that occur beyond 39 weeks' gestation. Traumatic birth injuries such as intracranial hemorrhage, fractures, and brachial plexus injury are also reduced with CD.

Overall, the maternal risks of CD have been considered marginal compared with those of vaginal delivery. Excluding indicated cesarean deliveries, rates of maternal mortality are comparable with those of vaginal delivery. Sachs and colleagues<sup>13</sup> reported a CD-associated mortality rate of 22.3 per 100,000 compared with 10.9 per 100,000 for vaginal delivery; however, the rates were comparable excluding medical complications.

CD does increase maternal morbidity. Compared with vaginal birth, the rate of endometritis is increased (3.0% vs. 0.4%), yet rates of postpartum hemorrhage, transfusion, and deep venous thrombosis (DVT) are comparable. Other reports confirm increased risks for these morbidities with CD, including major complication rates as high as 4.5%. **CD also presents a risk for future placental abnormalities, including placenta previa and placenta accreta. These risks increase with the increasing number of CDs performed for each woman and are substantial with more than three operations. Thus the decision to undergo CD on request must include thoughtful consideration of future childbearing plans.**

When a planned CD is performed without accepted indications, at the request of either the patient or the physician, it should be performed at 39 weeks.<sup>11,12,14</sup> After appropriate counseling, if the woman still insists on a CD, implementing her request is ethically permissible. Less than 10% of women prefer a CD based solely on their own desires.

**TECHNIQUE OF CESAREAN DELIVERY**

Because more than 1.3 million CDs are performed in the United States every year,<sup>15</sup> and about 20 million are done worldwide, it is extremely important to adhere to the safest, most effective technique associated with the lowest perinatal and maternal complications. Each aspect of CD should be evaluated individually, optimally by RCT, because it is impossible to evaluate the benefit of a specific technical aspect if multiple aspects are studied together. Proper universal surgical precautions aimed at preventing blood loss and infection should be used. Preferred technical aspects of CD are shown in Table 19-1.

**Precesarean Antibiotics**

**Prophylactic preoperative antibiotics are of clear benefit in reducing the frequency of postcesarean endomyometritis and wound infection in both laboring and nonlaboring CDs.**<sup>5</sup>

The timing, agents, and dosages of prophylactic antibiotics have been extensively studied.<sup>16,17</sup> Prophylactic antibiotics should be given approximately 30 to 60 minutes before the skin incision to allow for adequate tissue concentrations; pharmacokinetic studies of cefazolin demonstrate that adequate concentration in maternal and amniotic fluid samples are attained 30 minutes after administration.<sup>17-19</sup> The preferred agent for prophylaxis

**TABLE 19-1** EVIDENCE-BASED RECOMMENDATIONS FOR CESAREAN DELIVERY TECHNIQUES

| STEP  | EVIDENCE SUPPORTS IT: DO THIS  | EVIDENCE REFUTES IT: DO NOT DO THIS                                   | CAN BE CONSIDERED  |
|---|--|---|--|
| Antibiotic prophylaxis with IV first-generation cephalosporin or ampicillin | Administer 30 to 60 min before cesarean incision.  | Administer at neonatal cord clamp.                                    |  |
| Thromboprophylaxis  | Use mechanical prophylaxis with graduated compression stockings or a pneumatic compression device during and after CD.   |   |  |
| Lateral tilt  | Consider a lateral tilt.   |   |  |
| Bladder catheterization   |  |   | Intraoperative catheterization is not mandatory; consider removal immediately after operation. |
| Vaginal povidone-iodine preparation   |  |   | This can be considered.  |
| Hair removal  | Hair does not need to be removed, but if it is, use hair clippers the morning of the surgery.  | Shave preoperatively.   |  |
| Site preparation  | Use chlorhexidine-alcohol.   |   |  |
| Drapes  | Use nonadhesive drapes.  | Use adhesive drapes.  |  |
| Prevent needle sticks   | Consider blunt needles.  | Consider not using sharp needles.                                     |  |
| Skin incision   | Use a transverse skin incision.  |   |  |
| Bladder flap  | Do not develop a bladder flap.   |   |  |
| Uterine incision  | Make a low transverse uterine incision unless a vertical incision is indicated (see Box 19-5).   | Make a vertical uterine incision.                                     |  |
| Uterine expansion   | Use blunt uterine incision expansion with cephalad-caudad traction.  | Use sharp uterine extension; use transverse traction.                 |  |
| Cord clamping   | Delay cord clamping for 30 to 120 sec for infants younger than 37 wk.  |   |  |
| Prevention of postpartum hemorrhage   | Use oxytocin 10 to 80 IU in 1 L crystalloid.   | Use misoprostol in lieu of oxytocin.                                  | Tranexamic acid and carbetocin may be considered.  |
| Placental delivery  | Deliver the placenta spontaneously with gentle cord traction.  | Deliver the placenta manually.  |  |
| Abdominal irrigation  |  | Use intraabdominal irrigation with NS to decrease maternal morbidity. |  |
| Uterine exteriorization   |  |   | This is suggested to facilitate better visualization.  |
| Cervical dilation   | Do <i>not</i> manually or surgically dilate the cervix.  | Manually or surgically dilate the cervix.                             |  |
| Uterine repair  | Use a single layer if the patient has completed childbearing (e.g., bilateral tubal ligation performed concurrently with CD). Consider a double layer otherwise. |   |  |
| Subcutaneous space closure  | Close subcutaneous space if 2 cm or larger.  | Routinely use subcutaneous drains.                                    |  |
| Skin closure  | Close the transverse skin incision with suture.  | Close the transverse skin incision with staples.                      |  |

CD, cesarean delivery; IV, intravenous; NS, normal saline.

is either a first-generation cephalosporin (e.g., cefazolin) or ampicillin.<sup>20-23</sup> For women who have an anaphylactic allergic reaction to penicillin, either metronidazole or clindamycin and gentamicin can be used. No apparent advantage has been shown with more broad-spectrum antibiotic prophylaxis (e.g., azithromycin or metronidazole), except perhaps for women who do not get antibiotic prophylaxis for CD.<sup>20-25</sup> Single-dose therapy is as effective as multidose therapy<sup>26</sup> and is therefore preferred.

**For women with clinical chorioamnionitis, treatment with combination antibiotic therapy** (e.g., ampicillin sodium/sulbactam sodium) **supplants the need for prophylaxis if given within the appropriate time frame of cesarean skin incision.** This therapy should be instituted promptly upon diagnosis of chorioamnionitis, and it should be continued until the patient exhibits a clinical response.

### Precesarean Thromboprophylaxis

**Because venous thromboembolism (VTE) is the leading cause of maternal mortality in developed countries, and CD increases this risk, thromboprophylaxis should be considered**

**in all CDs.** Because the incidence of clinically significant thrombosis is 0.9%,<sup>27</sup> an insufficient number of women have been randomized to mechanical prophylaxis, heparin, low-molecular-weight heparin, or no anticoagulation to assess safety and efficacy of these treatment regimens in comparison to one another.<sup>16,28-31</sup> We recommend mechanical prophylaxis with graduated compression stockings or a pneumatic compression device<sup>32,33</sup> during and after every CD until ambulation resumes.<sup>34</sup> Women with additional risk factors such as morbid obesity, prior VTE, or immobility may benefit from medical thromboprophylaxis after cesarean (e.g., with prophylactic heparin).

### Other Prophylactic Precesarean Interventions

A lateral tilt of about 15 degrees is suggested to elevate the mother's right side to avoid vena caval compression and supine hypotension syndrome. However, left lateral tilt, head-up or head-down position, the use of wedges and cushions, flexion of the table, and use of a mechanical displacer have been insufficiently studied to provide any strong recommendation for routine clinical use.<sup>35</sup>

Vaginal preparation immediately before CD with povidone-iodine solution significantly reduces the incidence of postcesarean endometritis (from 8.3% in those who received placebo preparations to 4.3%), especially in women with ruptured membranes (17.9% reduced to 4.3%) and those in labor (13.0% reduced to 7.4%).<sup>36</sup> Although antibiotics were administered prophylactically for CD in these trials, at least one trial administered antibiotics at cord clamping, and two trials did not specify the timing of antibiotic administration. Therefore it is unclear whether vaginal preparation reduces morbidity in women who receive antibiotic prophylaxis for CD preoperatively as is currently recommended.

Fixing an indwelling urethral catheter (e.g., Foley) is routinely performed for planned and emergency CD in most countries around the world. The drainage tube is inserted when analgesia is established and is then left in situ for 12 to 24 hours until the patient is able to mobilize. This tube is connected to a closed collection system to evacuate urine and decompress the urinary bladder. This may improve visualization of the lower uterine segment, which could minimize bladder injury. However, one RCT has shown that the incidence of urinary tract infection, time to patient ambulation, time to first postoperative voiding, requirement for oral rehydration, intestinal movement, and duration of hospital stay are all significantly reduced in the uncatheterized group with no increase in intraoperative complications or urinary retention.<sup>37</sup> It should be noted that the study was not powered to assess for differences in bladder or ureteral injury.<sup>37</sup> Alternatively, immediate postoperative removal of a urethral catheter after planned CD may be associated with a lower risk of urinary infection, although the difference was nonsignificant.<sup>38</sup> **Urinary bladder catheterization for CD is prudent until evidence can delineate that eliminating this practice will not result in an increase in bladder or ureteral injury.** For those who choose not to place an indwelling catheter for CD, the patient should void immediately prior to the operation.<sup>39</sup> Indwelling catheter placement in hemodynamically unstable women is recommended to monitor urine output and evaluate fluid balance.

## Site Preparation

Preparation of the skin is performed to reduce the risk for wound infection by decreasing the amount of skin flora and contaminants at the incision site. **Hair does not have to be removed from the operative site.** Removal with a razor may actually increase the risk for infection by breaks in the skin that allow entry of bacteria.<sup>40</sup> For this reason, some advocate clipping of the hair on the morning of surgery.<sup>40</sup> Only enough hair should be removed to allow good approximation of skin edges.

**Incision-site preparation is accomplished in the operating room through application of a surgical scrub. CD wounds are considered to be clean contaminated. Chlorhexidine-alcohol scrub has been associated with a lower incidence of wound infection compared with povidone-iodine scrub.**<sup>41</sup> In addition, **drapes should not be adhesive** because such drapes have been associated with a higher rate of wound infection compared with nonadhesive drapes.<sup>42-44</sup>

## Abdominal Skin Incision and Abdominal Entry

In general, universally accepted good surgical techniques aimed at avoiding excessive blood loss and tissue trauma should be used. Compared with sharp needles, the use of blunt needles during CD is associated with a decrease in the rate of

**FIG 19-2** The Pfannenstiel abdominal incision is the most common for cesarean delivery (A). The midline (B) and Maylard (C) incisions are much less common. Hatched lines indicate possible extension. (Modified from Baker C, Shingleton HM. Incisions. *Clin Obstet Gynecol.* 1988;31:701.)

surgeon glove perforation but also with a decrease in surgeon satisfaction.<sup>45</sup>

**The surgeon has a choice of a transverse or vertical skin incision, with the transverse Pfannenstiel being the most common incision type in the United States (Fig. 19-2).** Factors that influence the type of incision include the urgency of the delivery, placental disorders such as anterior complete placenta previa and placenta accreta, prior incision type, and the potential need to explore the upper abdomen for nonobstetric pathology. Although some still prefer a vertical incision in emergency situations, a Pfannenstiel incision actually adds only 1 minute of extra operative time in primary and 2 minutes in repeat cesareans, differences that are not associated with improved neonatal outcome compared with that of a vertical incision.<sup>46</sup> Vertical incisions have been performed very rarely in the United States and Europe for routine CDs since the 1980s. A survey of obstetricians in the United Kingdom found that more than 80% use the Pfannenstiel abdominal entry.<sup>47</sup> The remaining 20% use the incision and abdominal entry described by Joel-Cohen.<sup>48</sup> A survey of obstetric residents in the United States found that 77% use a horizontal skin incision for urgent or emergency CD.<sup>49</sup> Overall, the Pfannenstiel incision is currently the preferred technique around the world and is used for more than 90% of CDs in the United States. The Joel-Cohen incision was described for gynecologic surgical procedures such as abdominal hysterectomy, and it allows similar access to the pelvis and lower abdomen as a vertical incision but is more cosmetic and less painful postoperatively. In the early 1990s, the Joel-Cohen incision (Video 19-1) was integrated by Stark and colleagues<sup>50,51</sup> into a minimalist cesarean technique now called the *Misgav Ladach method*. Thus far, studies reporting the benefits of the Joel-Cohen incision include multiple aspects of the CD technique, not just the skin incision<sup>16</sup>; therefore they are not clinically helpful in determining the benefit of the individual CD steps.<sup>52</sup> **Given this, we do not recommend the**

**Joel-Cohen incision over the Pfannenstiel cesarean technique.** For most repeat CDs, the prior skin incision is used. Transverse skin incisions are preferable to vertical incisions (see Table 19-1).

When a transverse Pfannenstiel skin incision is used, it is made about two fingerbreadths (1 inch or 2.5 cm) above the symphysis in the midline and is extended laterally in a slightly curvilinear manner. The length of the incision should be based on the estimated fetal size; at term, it usually should be about 15 cm, or the length of an Allis clamp. The site of the incision, either below or above the pannus or either vertical or transverse, has not been sufficiently studied in obese individuals to provide an evidence-based recommendation.

Occasionally, a transverse incision of the rectus sheath and muscles (Maylard incision) is necessary for proper exposure and room to deliver the fetus (e.g., with massive fetal hydrocephaly). In these cases, only the medial half of the muscle is incised to avoid lacerating the deep epigastric vessels. Complete transection of the rectus muscles is referred to as the *Cherney incision*, which requires identification of the epigastric vessels and ligation bilaterally.

Following the skin incision, the subcutaneous tissue is then bluntly pushed away to identify the underlying fascia. In repeat operations, sharp dissection of the subcutaneous adipose tissue may be required. The fascia is incised and dissected or is bluntly extended in a mild curvilinear manner bilaterally. It should be tented with the surgeon's forceps to separate it from the underlying muscle and to identify perforating vessels, which may require ligation or coagulation. Curvilinear extension is essential because direct transverse extension often leads to inadvertent muscle incisions and bleeding.

Once the fascial incision is completed, the fascia is then grasped in the midline bilaterally and is separated from the underlying rectus muscles superiorly and inferiorly by blunt and sharp dissection from the median raphe. The rectus muscles can be separated bluntly in the midline to reveal the posterior rectus sheath and peritoneum, which can also be entered bluntly with the fingers to avoid trauma to the underlying bowel. The point of entry should be as superior as possible to avoid bladder injury, particularly in repeat operations in which the bladder may be adherent superiorly.

## Bladder Flap

**Creation of a bladder flap versus a direct uterine incision above the bladder fold has been compared in four randomized trials of 581 women.<sup>53</sup> Bladder flap development was associated with a longer incision-to-delivery interval of 1.27 minutes without any differences in bladder injury, total operating time, blood loss, or hospital length of stay.<sup>53</sup> It is important to note that emergency CDs were excluded from the studies, and the majority of pregnancies were over 32 weeks' gestation. Overall, the populations were heterogeneous: two of the four trials were of poor methodologic quality, and one was unpublished.<sup>53</sup> Because there does not appear to be any direct advantage gained from creating a bladder flap, we do not develop a bladder flap.**

Should the obstetrician elect to create a bladder flap, the vesicouterine serosa is picked up with smooth forceps and is incised in the midline with Metzenbaum scissors. The incision is carried out laterally in a curvilinear manner. The vesicouterine fold is then tented with forceps or a pair of hemostats, which allows direct visualization as the bladder flap is bluntly created using

the index and middle fingers. Sharp dissection may be necessary, particularly in repeat operations. The surgeon then bluntly sweeps out laterally on each side to allow just enough room for insertion of the bladder blade. A Richardson retractor is then inserted laterally, and continuous suction is made available in preparation for the uterine incision.

## Uterine Incision

Following full entry into the peritoneal cavity, the surgeon should palpate the uterus for fetal presentation and alignment and then place a bladder retractor to expose the lower uterine segment. The uterus is often dextrorotated, and its position must be appreciated to plan the incision site. The safety and efficacy of using special retractors, especially in obese women, has been insufficiently studied.

**The low transverse uterine incision replaced the vertical uterine incision at the beginning of the twentieth century. The low transverse incision is preferred to a vertical incision because it is associated with less blood loss, is easier to perform and repair, and provides for the option of subsequent TOLAC because the rate of subsequent rupture is lower than with incisions that incorporate the upper uterine segment.<sup>54</sup>**

In cases of a low transverse incision, the incision is begun at least 2 cm above the bladder margin (Fig. 19-3) and suction is applied. Tamponade with sponges superiorly and inferiorly can be performed if considerable bleeding is encountered. This technique allows better visualization and minimizes the chance of fetal laceration. Once the uterine cavity is confirmed, typically by visualization of the amniotic membranes or fetus, the incision is extended laterally and superiorly at the angles by blunt spreading using the index fingers. Randomized trials have compared blunt versus sharp extension of the uterine incision. Sharp extension is associated with increased blood loss and the need for transfusion compared with blunt extension.<sup>55</sup> Blunt uterine incision extension can be done preferably with cephalad-caudad traction because transverse expansion is associated with more unintended extension and more blood loss.<sup>56</sup> As for the skin and the fascial incisions, adequate exposure for an easy extraction of the fetus should be obtained. At term, this is usually more than 15 cm.

Vertical uterine incisions are now rarely performed (Box 19-5). When a vertical incision is used, it is either *low* (involving mostly the low uterine segment) or *classical* (involving the upper uterine segment) and should have clear indications. **A vertical uterine incision may need to be performed if the lower uterine segment is poorly developed (e.g., at 23 to 25 weeks' gestation); if the fetus is in a back-down transverse lie; in cases of an anterior placenta previa or accreta, often in combination with a hysterectomy (Chapter 21); or if leiomyomas obstruct the lower segment.** Other, even less common

### BOX 19-5 POTENTIAL INDICATIONS FOR VERTICAL UTERINE INCISION

- Lower uterine segment is poorly developed (e.g., at 23 to 25 weeks gestation).
- Fetus is in a back-down transverse lie.
- An anterior leiomyoma obstructs the lower uterine segment.
- Complete anterior placenta previa or placenta accreta is present.

**FIG 19-3** Uterine incisions for cesarean delivery. **A**, In the *low transverse incision* (performed in >90% of cesarean deliveries) the incision is made in the lower uterine segment, curving gently upward. If the lower segment is poorly developed, the incision can also curve sharply upward at each end to avoid extending into the ascending branches of the uterine arteries. **B**, The *low vertical incision* is made vertically in the lower uterine segment, avoiding extension into the bladder below. If more room is needed, the incision can be extended upward into the upper uterine segment. **C**, The *classical incision* is entirely within the upper uterine segment and can be at the level shown or in the fundus. **D**, With the *J incision*, if more room is needed when an initial transverse incision has been made, either end of the incision can be extended upward into the upper uterine segment and parallel to the ascending branch of the uterine artery. **E**, With the *T incision*, more room can be obtained in a transverse incision by an upward midline extension into the upper uterine segment.

**FIG 19-4** Low vertical incision. **A**, Ideally, a vertical incision is contained entirely in the lower uterine segment. **B**, Extension into the upper uterine segment, either inadvertently or by choice, is common.

indications may include certain fetal abnormalities such as massive hydrocephalus, a very large sacroccygeal teratoma, or to deliver conjoined twins. The disadvantages of a classical incision are its tendency for greater adhesion formation and greater risk for uterine rupture with subsequent pregnancy. The low

vertical incision depends on the downward displacement of the bladder to confine the incision to the true lower segment (Fig. 19-4). The incision is begun as inferiorly as possible and is extended cephalad with the fingers or bandage scissors. If the thick myometrium of the upper segment is incised, the incision

becomes a classical one and should be described as such in the operative report.

### Delivery of the Fetus

Once an adequate uterine incision has been completed, the fetal head is extracted by elevation and flexion using the operator's hand as a fulcrum. Adequate fundal pressure by the assistant is often critical to obtain delivery. If the head is not easily delivered, the uterine incision (or skin or abdominal incisions) may be extended. Rarely, a tee incision will be made to facilitate delivery; for example, when the fetus is in a back-down transverse lie and cannot be rotated. The use of forceps and/or vacuum will be needed in few cases and should generally be avoided.

**When the vertex is wedged in the maternal pelvis, usually in advanced second-stage arrest, reverse breech extraction (the "pull" method) has been associated with shorter operating time, less extension of the uterine incision, and postpartum endometritis compared with vaginal displacement of the presenting part upward,**<sup>57</sup> but the evidence is insufficient to make a strong recommendation. As noted above, vacuum extraction or short Simpson forceps should in general be avoided because they are rarely necessary if the previously mentioned steps are taken.

Following delivery, the cord is clamped and cut, and the infant is passed from the field to the pediatric team. Delayed cord clamping (DCC) for 30 to 120 seconds and/or umbilical cord milking has been shown to increase placental transfusion, which leads to an increase in neonatal blood volume at birth of approximately 30%. In preterm neonates, increasing evidence suggests that DCC significantly decreases the need for blood transfusions, the incidence of necrotizing enterocolitis, and the risks of intraventricular hemorrhage and late-onset sepsis.<sup>58,59</sup> Therefore **DCC is recommended for all CDs done before 37 weeks.** No such strong evidence exists for term newborns: DCC increases early hemoglobin concentrations and iron stores, but it may also adversely increase the risk of jaundice and the need for phototherapy in term neonates.<sup>60</sup>

### Prevention of Postpartum Hemorrhage

Following delivery of the infant, intravenous (IV) oxytocin is started as a drip. **Studies suggest that 10 to 80 IU of oxytocin in 1 L crystalloid infused over 4 to 8 hours significantly prevents uterine atony and postpartum hemorrhage.**<sup>16</sup> One study that randomized 1798 women to postcesarean IV administration of oxytocin at doses of 80 IU, 40 IU, and 10 IU showed no differences in the composite outcome of treatment for hemorrhage and atony; however, 80 IU did decrease the need for treatment with additional oxytocin compared with the 10 IU dose.<sup>61</sup> One study of 110 women that compared an oxytocin 5-IU bolus with the same bolus followed by 30-IU infusion revealed no significant differences in mean blood loss or in the percentage of patients that required additional uterotonics.<sup>61,62</sup> Misoprostol should not be used in lieu of oxytocin.<sup>16</sup>

Preincision administration of tranexamic acid (10 mg/kg IV) has been shown to decrease blood loss and the need for uterotonics.<sup>16,63</sup> Postdelivery administration of carbetocin (100 µg) resulted in a decrease in the need for uterotonics and uterine massage.<sup>64</sup>

### Placental Extraction

**Removal of the placenta by spontaneous expulsion with gentle cord traction has been shown by several RCTs to be**

**associated with less blood loss and a lower rate of endometritis than manual extraction.**<sup>65-67</sup> Therefore spontaneous expulsion with gentle cord traction and uterine massage should be performed for delivery of the placenta. Intraoperative glove change has not been shown to decrease the risk of endometritis after CD.<sup>66</sup>

### Uterine Repair

Uterine repair may be greatly facilitated by lifting the fundus and delivering the uterus through the abdominal incision. Uterine exteriorization can facilitate better visualization of the extent of the incision to be repaired and can provide a view of the adnexa. No significant increased risk for blood loss, infection, hypotension, or nausea and vomiting with exteriorization of the uterus has been reported compared with intraabdominal repair, as shown by a meta-analysis of 11 trials.<sup>68</sup> The decision regarding uterine exteriorization can be based on the surgeon's preference.

Bleeding along the incision line is temporarily controlled using ring clamps because they are less traumatic than other instruments. The uterus is then manually curetted with a moistened sponge, and all placental fragments or membranes are teased away from the uterine wall. Manual or surgical dilation of the cervix following placental removal is not associated with any benefit.<sup>16,69</sup>

The uterine incision should be well inspected before closure. Any inferior extensions of the incision should be visualized and repaired separately before closure.

**The first layer of uterine closure is performed using continuous suturing. This technique is associated with less operating time and reduced blood loss compared with interrupted sutures.**<sup>70</sup> The locking of the primary layer of closure facilitates hemostasis but may not be necessary if the incision is fairly hemostatic before closure. Size 1-0 or 0-0 synthetic suture is used. Full-thickness repair that includes the endometrial layer is associated with improved healing as evidenced by ultrasound 6 weeks after CD.<sup>55,71</sup>

The lower uterine incision may be closed with either a single or double layer of sutures (Fig. 19-5). Single-layer closure is associated with a statistically significant but clinically small reduction in mean blood loss, duration of the operative

**FIG 19-5** Closure of low transverse incision. **A**, The first layer can be either continuous (recommended) or interrupted. Despite its reputed hemostatic abilities, a continuous locking suture is less desirable because it may interfere with incision vasculature and, hence, with healing and scar formation. **B**, A second inverted layer is created using a continuous Lembert or Cushing stitch. Inclusion of too much tissue produces a bulky mass that may delay involution and can interfere with healing.

**FIG 19-6** Repair of a classical incision. Three-layer closure of a classical incision, including inversion of the serosal layer to discourage adhesion formation. The knot at the superior end of the incision of the second layer can be buried by medial-to-lateral placement of the suture from within the depth of the incision and subsequent lateral-to-medial reentry on the opposing side with resultant knot placement within the incision.

procedure, and presence of postoperative pain compared with a double-layer closure.<sup>72</sup> Controversy surrounds whether an increased risk for subsequent uterine rupture or placenta accreta accompanies the single-layer closure technique (Chapter 20). In women who receive a tubal ligation at the time of CD, we usually perform a single-layer closure if excellent hemostasis is achieved. Otherwise, we prefer a double-layer closure; however, randomized trials that have assessed one- versus two-layer uterine closure have reported mostly short-term outcomes with insufficient evidence to assess long-term outcomes, in particular, uterine rupture with a TOLAC in a future pregnancy.<sup>16</sup>

A vertical uterine incision generally requires at least a double-layer, but more often a triple-layer, closure technique (Fig. 19-6) with a baseball stitch used on the uterine serosa.

The uterine incision is carefully inspected for hemostasis before returning the uterus to the peritoneal cavity. Individual bleeding points are cauterized or ligated using as little suture material as possible. The adnexa are inspected, and tubal ligation is performed if so desired. Following return of the uterus inside the pelvis, sponge and needle counts are then performed before abdominal closure. Intraabdominal irrigation does not reduce intrapartum or postpartum maternal morbidity.<sup>73</sup>

### Abdominal Closure

The parietal and visceral peritoneum are not reapproximated because spontaneous closure will occur within days, and non-closure has been associated in several RCTs with less operative time, less fever, reduced hospital stay, and less need for analgesia compared with closure.<sup>74</sup> Some limited non-level 1 data suggest that closure of the parietal peritoneum may decrease the risk of future adhesions,<sup>75</sup> but this has not been confirmed by better data.

No trials have evaluated the technical aspects of fascial closure at CD. The rectus fascia is usually closed with a continuous nonlocking technique, but some prefer interrupted sutures. Because the fascia is not as vascular, this layer is not locked so as not to cause strangulation of the fascia, which could

increase the risk of fascial dehiscence. A suture with good tensile strength and relatively delayed absorption is preferred. Synthetic braided or monofilament sutures are best to use. In most instances, a running continuous monofilament propylene suture will suffice for a transverse incision. In closing the fascia, placement of the sutures should be at a minimum 1 cm from the margin of the incision; sutures are placed at about 1-cm intervals. In most cases of wound disruption, the suture remains intact but has cut through the fascia as a result of placement too close to the cut margin. Patients at risk for wound disruption may benefit from either the Smead-Jones technique or interrupted figure-of-eight suturing, both using delayed-absorption suture material such as monofilament polyglycolic acid. The Smead-Jones closure technique is preferred for vertical incisions in high-risk cases (Fig. 19-7). To accomplish this technique, a suture is made with either far-near or near-far placement that passes through the lateral side of the anterior rectus fascia and adjacent subcutaneous adipose tissue; then, it crosses the midline of the incision to pick up the medial edge of the rectus fascia, then catches the near side of the opposite rectus sheath before returning to the far margin of the opposite rectus sheath and subcutaneous fat.

**The subcutaneous tissue is closed if it will facilitate skin closure or if the fat thickness is at least 2 cm. Closure of the subcutaneous tissue of at least 2 cm with sutures is associated with fewer wound complications—such as a hematoma, seroma, wound infection, or wound separation—compared with no closure.**<sup>76</sup> Prophylactic wound drainage is not associated with benefits and should therefore not be performed routinely.<sup>77-79</sup> Occasionally, when hemostasis is not adequate either intraabdominally or subcutaneously, drains can be used, but there are no level 1 data that prove their effectiveness.

**The transverse cesarean skin incision should be closed with subcuticular suture, rather than staples, because suture closure significantly decreases by 57% the risks of wound complications (from 10.6% to 4.9%) and specifically wound separation (from 7.4% to 1.6%).**<sup>80,81</sup> Staple closure

**FIG 19-7** Modification of far-near, near-far Smead-Jones suture. Suture passes deeply through the lateral side of the anterior rectus fascia and adjacent fat, crosses the midline of the incision to pick up the medial edge of the rectus fascia, then catches the near side of the opposite rectus sheath; finally, it returns to the far margin of the opposite rectus sheath and subcutaneous fat. (Modified from American College of Obstetricians and Gynecologists. Prologue. In: *Gynecologic Oncology and Surgery*. Washington, DC: American College of Obstetricians and Gynecologists; 1991, p 187.)

is approximately 7 minutes faster than suture closure.<sup>82</sup> Evidence is insufficient to make a recommendation for closure method for CDs performed using vertical skin incisions.<sup>80,81</sup>

## COMPLICATIONS OF CESAREAN DELIVERY

### Intraoperative Complications

Women undergoing CD are at risk for several intraoperative complications, including hemorrhage and injury to adjacent organs. Injury to the bowel, bladder, and ureters is uncommon; however, the obstetrician must be familiar with management of these problems. The key element is to recognize and define the extent of these injuries and to promptly institute repair. Consultation with a urologist, general surgeon, or gynecologic oncologist may be necessary depending on the skill level of the obstetrician and the complexity of the injury encountered.

### Uterine Lacerations

Lacerations of the uterine incision most commonly involve extension of a low transverse incision following arrest of descent in the second stage or with delivery of a large fetus. **Most lacerations are myometrial extensions that can be closed with a running locking suture independently or in conjunction with closure of the primary uterine incision. High lateral extensions may require unilateral ascending uterine artery branch ligation.** In cases that extend laterally and inferiorly, care must be taken to avoid ureteral injury. On occasion, if the extension involves bleeding into the broad ligament, opening this space and identifying the ureters before suture placement may be helpful. On rare occasions, retrograde ureteral stent placement may be necessary. Opening the dome of the bladder is the preferred technique for retrograde stent placement.

### Bladder Injury

Minor injury to the bladder from vigorous retraction and bruising with resultant hematuria is common. More significant

injury, such as a bladder dome laceration, is infrequent but can occur on entering the peritoneum, particularly with multiple repeat operations. Bladder injury is also encountered with development of the bladder flap in cases in which scarring increases adherence to the lower anterior uterine wall. This is another reason that we do not routinely perform a bladder flap. If the bladder is very adherent and is tacked high, it may be advisable to proceed with a vertical uterine incision to avoid bladder disruption.

**Bladder dome lacerations are generally repaired with a double-layer closure technique using 2-0 or 3-0 Vicryl suture. The mucosa may be avoided with closure, although this is not imperative.** If any question exists regarding possible trigone or ureteral injury before repair, IV indigo carmine is administered, and the ureteral orifices are visualized for dye spillage. Retrograde filling of the bladder with sterile milk may be useful following closure to ensure its integrity. Continuous Foley drainage should be accomplished for several days following repair of a bladder injury.

### Ureteral Injury

Ureteral injury has been reported to occur in about 1 in 1000 CDs. The frequency of injury increases with cesarean hysterectomy. **Most ureteral injuries follow attempts to control bleeding from lateral extensions into the broad ligament. As described previously, opening the broad ligament before suture placement may reduce the risk for this complication.** If the integrity of the ureter is in doubt, IV indigo carmine can be administered, with visualization of spillage in the bladder by cystoscope (usually performed by a urologic consultant). The ureteral orifices are visualized for dye spillage, which signifies ureteral patency. If ureteral injury is recognized postoperatively, cystoscopy with stent placement or nephrostomy with radiologic imaging may define the extent of injury and can help in planning appropriate management.

### Gastrointestinal Tract Injury

Bowel injury during CD is rare. Most cases involve incidental enterotomy on entering the abdomen for a repeat laparotomy, especially if scissors or a scalpel are used. This is another reason why we use blunt dissection with fingers for peritoneal entry. Defects in the bowel serosa are closed with interrupted suture of fine silk using an atraumatic needle. If the lumen of the small bowel is lacerated, closure is accomplished in two layers. A 3-0 absorbable suture is preferred for the mucosa, followed by interrupted silk sutures for the serosa.

Large defects of the small bowel or injuries of the colon generally require consultation with a general surgeon or gynecologic oncologist. Small defects may be closed primarily; however, large defects with fecal contamination may require a temporary colostomy. Broad-spectrum antibiotic coverage is recommended for such cases, which must include administration of an aminoglycoside in addition to metronidazole or clindamycin.

### Uterine Atony

A more complete review of the management of uterine atony is found in [Chapter 18](#). Uterine atony can be controlled in most cases by a combination of uterine massage and uterotonic agents. IV oxytocin in dosages up to 80 IU/L running wide open is attempted initially. If this fails to result in uterine contraction, either 0.2 mg of methergonovine maleate is administered intramuscularly or 0.25 mg of 15-methylprostaglandin F<sub>2</sub>-alpha is

**FIG 19-8** Hypogastric artery ligation. Approach to the hypogastric artery through the peritoneum, parallel and just lateral to the ovarian vessels, exposing the interior surface of the posterior layer of the broad ligament. The ureter will be found attached to the medial leaf of the broad ligament. The bifurcation of the common iliac artery into its external and internal (hypogastric) branches is exposed by blunt dissection of the loose overlying areolar tissues. Identification of these structures is essential. **A** and **B**, To avoid traumatizing the underlying hypogastric vein, the hypogastric artery is elevated by means of a Babcock clamp before passing an angled clamp to catch a free tie. (Modified from Breen J, Gregori CA, Kindierski JA. *Hemorrhage in Gynecologic Surgery*. Hagerstown, MD: Harper & Row; 1981; 438.)

administered intramuscularly or directly into the myometrium. Several successive doses of 15-methylprostaglandin F<sub>2</sub>-alpha every 10 to 15 minutes may be tried (up to 1 mg) if necessary. Most individuals respond to one or two doses. Misoprostol, up to 1000 µg per rectum, can be administered. Packing or use of a uterine balloon is also beneficial in these cases if medical management is not fully effective. In most cases of uterine atony, medical management is successful if used promptly and correctly.

In the rare cases in which nonsurgical management does not control bleeding, a surgical approach should be used. The initial surgical approach is bilateral ascending uterine artery branch ligation, especially if future fertility is desired. If this fails, hypogastric artery ligation or hysterectomy may be undertaken (Fig. 19-8). Hypogastric artery ligation is effective in less than 50% of cases.

### Placenta Previa and Placenta Accreta

**The incidence of placenta previa and placenta accreta has increased in frequency with rising CD rates, and in some series of cesarean hysterectomy, placenta accreta is the most common indication.** The risk for placenta accreta increases with each repeat CD and is substantially increased by the presence of placenta previa. The management of placenta accreta is presented in Chapter 21. Specific surgical and additional procedures have also been described for CD for placenta previa (not accreta). A recent study that compared transecting to avoiding incision of the anterior placenta previa during CD has found that avoiding incision by circumventing the placenta and passing a hand around its margin reduces the frequency of maternal

blood transfusion during and after CD.<sup>83</sup> Another technique had been described that uses insertion of interrupted circular suture at the placental separation site via the lower segment uterine incision.<sup>84</sup> The vessels are ligated using interrupted 2- to 3-cm sutures at 1-cm intervals in a circle around the bleeding area on the external (serosal) surface of the uterus. The sutures are placed as deeply as possible in order to reach the endometrium, which leads to a marked decrease in intraoperative bleeding. Similarly, anteroposterior compressive suture of the lower uterine segment has been shown to successfully control the bleeding in CD for placenta previa.<sup>85,86</sup> The local injection of vasopressin into the placental implantation site<sup>87</sup> or the use of a Bakri balloon<sup>88</sup> can also reduce the blood loss without increasing the morbidity.

### Maternal Mortality

The attributable maternal death rate has ranged from 6 to 22 per 100,000. In a study of 250,000 deliveries, Lilford and colleagues<sup>89</sup> reported the relative risk (RR) for maternal death from CD, compared with vaginal birth, to be about sevenfold higher when preexisting medical conditions were excluded. In contrast, Lydon-Rochelle and associates<sup>90</sup> noted **similar rates of maternal death among women delivered by CD versus those delivered vaginally when adjusting for maternal age and the presence of severe preeclampsia.**

Anesthesia-related morbidity and mortality have been substantially reduced through the expanded use of regional anesthesia and awake intubation for patients who require general anesthesia who may have a difficult airway for standard intubation.

## Maternal Postoperative Morbidity

### Endomyometritis

Postcesarean endomyometritis remains the most common complication of CD. With the use of appropriate prophylactic antibiotics as described previously, its frequency is usually less than 5%,<sup>25,91</sup> much reduced from preantibiotic times. Prolonged labor, rupture of membranes, and lower socioeconomic status appear to be the factors that most influence the rate of this complication.

Most cases of endomyometritis arise from ascending infection from cervicovaginal flora. Infections past the deepest part of the uterine incision may extend to the uterine musculature and, if not adequately treated, may produce peritonitis, abscess, and septic phlebitis. Using antibiotic prophylaxis, pelvic abscesses are rare and develop in 0.47% of cases following the diagnosis of chorioamnionitis compared with only 0.1% if fever was not observed during labor.

**The diagnosis of postpartum endomyometritis is based on fever (100.4° F or more) with either fundal tenderness or foul-smelling discharge in the absence of any other source.** The presence of chorioamnionitis, prolonged labor, and ruptured membranes should prompt early treatment in suspected cases. The utility of endometrial cultures is limited owing to contamination with vaginal flora and the fact that therapy is rarely guided by these results. Treatment is primarily based on clinical findings, including uterine tenderness and fever.

Parenteral antibiotics that use a regimen directed against possible anaerobic infection are the preferred therapeutic agents. **A regimen of clindamycin and an aminoglycoside such as gentamicin is associated with better safety and efficacy compared with other regimens.** An alternative is a single-agent penicillin-based regimen using  $\beta$ -lactamase inhibition to allow for anaerobic coverage (e.g., ampicillin and sulbactam). These antibiotics should be continued for at least 24 hours after the patient has defervesced. Once uncomplicated endometritis has clinically improved with IV therapy, oral therapy is not needed.

For women who fail to respond to antibiotic therapy over 2 to 3 days, an alternative source for the fever such as a wound infection, deep abscess, hematoma (Fig. 19-9), or septic pelvic

thrombophlebitis should be considered. On occasion, mastitis may produce significant temperature elevations.

### Wound Infection

Wound infection complicates about 1% to 5% of cesarean deliveries.<sup>92</sup> Most CD wounds are considered clean contaminated owing to the interface with the lower reproductive tract. **Emergent CDs and those associated with chorioamnionitis are considered contaminated and have higher wound infection rates.** Morbidly obese women have a twofold to fourfold increase in wound infections.<sup>93</sup>

The diagnosis of wound infection is usually straightforward in patients who present with tenderness, erythema, or discharge. Early wound infection (first two postoperative days) is often a result of streptococcal infection, whereas later wound infection is generally caused by overgrowth of *Staphylococcus* or a mixed aerobic-anaerobic infection.

Wound discharge may be sent for culture before instituting therapy. The infected portion of the wound should be opened, inspected, irrigated, and debrided as necessary. In most cases, this alone will suffice for therapy. A wound abscess may require drainage (Fig. 19-10). Antibiotic coverage, which is rarely necessary for simple wound infections, should be instituted promptly for advanced serious wound disruptions. Wound closure once the infection has resolved can be accomplished either surgically or by secondary intention. Reclosure of disrupted laparotomy wounds is safe and is successful in more than 80% of patients,

**FIG 19-9** Computed tomographic scan of pelvis 6 days after a cesarean section showing left-sided broad ligament hematoma (H). The uterus (U) is displaced to the right. The patient responded to antibiotics. (Courtesy Dr. Michael Blumenfeld, Department of Obstetrics and Gynecology, Ohio State University–Columbus.)

**FIG 19-10** Magnetic resonance image of abdominal wall abscess. This patient presented 1 week after a cesarean delivery with fever and an abdominal mass. The differential diagnosis included an intraperitoneal infection with extension or a wound abscess. This image shows a wound abscess (A) above fascia that extended to the abdominal wall (arrow). The abscess responded to drainage and antibiotics.

and it decreases healing times compared with healing by secondary intention.

**Extreme wound discoloration, extensive infection, gangrene, bullae, or anesthesia of the surrounding tissue should prompt consideration of necrotizing fasciitis, a life-threatening surgical emergency that has been reported to develop in 1 in 2500 women undergoing primary CD.** In these cases, the wound should be debrided under general anesthesia. Examination of histologic specimens may aid in the diagnosis of necrotizing infection. In such cases, all nonviable tissue should be removed, and consultation with an experienced surgeon is recommended. Antibiotic coverage should be instituted promptly.

### Thromboembolic Disease

Venous thromboembolism (VTE) occurs more commonly during pregnancy secondary to higher levels of clotting factors and venous stasis (see Chapter 45), and it is the leading cause of maternal death in developed countries. Risk factors are also the puerperal period, CD, immobility, obesity, advanced age, and parity. **The incidence of DVT was reported at 0.17%, and that of pulmonary embolism (PE) at 0.12%, in women undergoing CD.**

The diagnosis of DVT is suggested by the presence of unilateral leg pain and swelling. A significant difference in the calf or thigh diameter may be present; however, error with this measurement is possible. The presence of Homans sign, pain with foot dorsiflexion, is often observed if the calf is involved. Many cases of DVT present as PE, particularly in the postoperative patient. Tachypnea, dyspnea, tachycardia, and pleuritic pain are the classic symptoms, with cough and specific pulmonary auscultatory findings less common.

If DVT is suggested, Doppler studies may be useful for proximal disease but are less sensitive for calf thrombosis. Impedance plethysmography is also helpful in detecting proximal disease but it is of limited value in the diagnosis of pelvic thrombosis. If DVT is highly suspected and previous studies were inconclusive, a venogram should be obtained.

The workup for suspected PE includes an arterial blood gas and chest film followed by a ventilation-perfusion study or spiral computed tomography (CT) study. Oxygen should be administered and heparin begun if a clinical PE appears likely. An indeterminate perfusion scan requires pulmonary angiography to establish or rule out the diagnosis of PE.

### Septic Pelvic Thrombophlebitis

Probably less than 1% of women with endomyometritis develop septic pelvic thrombophlebitis; however, accurate figures for the frequency of this condition in current practice are lacking.

**Septic pelvic thrombophlebitis is most often a diagnosis of exclusion established in refractory cases of women being treated for endomyometritis. A pelvic CT scan may aid in the diagnosis, although the sensitivity and specificity of this technique are clearly difficult to establish.** In practice, a febrile patient who has undergone CD and fails to respond to appropriate broad-coverage antibiotic therapy for suspected uterine infection for several days, usually more than 5 to 7 days, may be started on full-dose heparin therapy. The evidence for this practice is very limited. Long-term anticoagulation is not prescribed. Patients with septic pelvic phlebitis may present with spiking nocturnal fever and chills. However, these findings

may be absent, and a persistent febrile state may be all that is present. When anticoagulation therapy elicits no response, imaging studies that include pelvic CT are indicated to rule out an abscess or hematoma.

## TUBAL STERILIZATION

The surgical approach to tubal sterilization is influenced by whether the procedure is being performed on a postpartum or interval basis. Advantages to the postpartum approach include the use of one anesthesia for labor, delivery, and sterilization and only one hospitalization. Tubal ligations after vaginal delivery are performed through a minilaparotomy incision at the level of the uterine fundus, usually subumbilically. The same surgical techniques are applied if tubal ligation is performed at the time of CD.

### Modified Pomeroy

The method of tubal occlusion used by Pomeroy was described in 1930, and it is the most popular means of postpartum tubal ligation because of its simplicity. **The Pomeroy technique as originally described included grasping the fallopian tube at its midportion, creating a small knuckle, and then ligating the loop of tube with a double strand of catgut suture.** It is critical that the fallopian tube be conclusively identified. Visualizing the fimbriated portion of the tube and identifying the round ligament as a separate structure can accomplish this. Absorbable sutures are used so that the tubal ends will separate quickly after surgery, leaving a gap between the proximal and distal ends. In performing the procedure, care should be taken to make the loop of fallopian tube sufficient in size to ensure that complete transection of the tubal lumen will occur. After the loop of fallopian tube is ligated, the mesosalpinx of the ligated loop should be perforated using scissors, and then the knuckle of the tube is transected (Fig. 19-11). It is important not to resect the fallopian tube so close to the suture that the remaining portion of the fallopian tube slips out of the ligature and causes delayed bleeding.

### Parkland Procedure

**The Parkland procedure was designed to avoid close approximation of the cut ends of the fallopian tube accompanying the Pomeroy procedure.** An avascular segment of midposition

**FIG 19-11** Pomeroy sterilization. A knuckle of tube is ligated with absorbable suture, and a small segment is excised. Note that the ligation is performed at a site that will favor reanastomosis, should that become desirable. Some surgeons place an extra tie of nonabsorbable suture around the proximal stump as added protection against recanalization.

**FIG 19-12** Parkland tubal ligation. The avascular mesosalpinx is opened by blunt dissection. A 2-cm midsegment of tube is ligated with 0-0 chromic suture and is divided between the sutures. (Modified from Cunningham FG, Leveno KJ, Bloom SL, et al [eds]. *Williams Obstetrics*, 22nd ed. New York: McGraw-Hill; 2005.)

mesosalpinx is identified, and a hemostat or coagulation can be used to create an opening. The freed fallopian tube is then ligated proximally and distally, and the intervening segment is excised and submitted for pathologic examination. The proximal ligated end of the tube may be left free or can be buried in the mesosalpinx (Fig. 19-12).

### Irving Procedure

Irving first reported his sterilization technique in 1924 with a modification in 1950. In the modified procedure, a window is created in the mesosalpinx and the fallopian tube is doubly ligated, as in the Parkland procedure. The fallopian tube is then transected about 4 cm from the uterotubal portion; the two free ends of the ligation stitch on the proximal tubal segment are held long. The proximal portion of the fallopian tube is dissected free from the mesosalpinx and is then buried into an incision in the myometrium of the posterior uterine wall, near the uterotubal junction. This is accomplished by first creating a tunnel

**FIG 19-13** Irving sterilization. The tube is transected 3 to 4 cm from its insertion, and a short tunnel is created by means of a sharp-nosed hemostat in either the anterior or posterior uterine wall. The cut end of the tube can then be buried in the tunnel, and if necessary, it can be further secured by an interrupted suture at the opening of the tunnel. The distal cut end is buried between the leaves of the broad ligament.

about 2 cm in length with a mosquito clamp in the uterine wall. The two free ends of the ligation stitch on the proximal tubal segment are then brought deep into the myometrial tunnel and are brought out through the uterine serosa. Traction is then placed on the sutures to draw the proximal tubal stump into the myometrial tunnel; tying the free sutures fixes the tube in that location. No treatment of the distal tubal stump is necessary, but some choose to bury the segment in the mesosalpinx (Fig. 19-13). **Although this technique is slightly more complicated than the others, it has the lowest failure rate.**

### Uchida Procedure

In the Uchida sterilization procedure, the muscular portion of the fallopian tube is separated from its serosal cover and is grasped about 6 to 7 cm from the uterotubal junction. Saline solution is injected subserosally, and the serosa is then incised. The muscular portion of the fallopian tube is grasped with a clamp and divided. The serosa over the proximal tubal segment is bluntly dissected toward the uterus, exposing about 5 cm of the proximal tubal segment. The tube is then ligated with chromic suture near the uterotubal junction, and about 5 cm of the tube is resected. The shortened proximal tubal stump is allowed to retract into the mesosalpinx. The serosa around the opening in the mesosalpinx is sutured in a purse-string fashion with a fine absorbable stitch; when the suture is tied, the mesosalpinx is gathered around the distal tubal segment (Fig. 19-14). **Some surgeons choose to excise only 1 cm of fallopian tube, rather than the recommended 5 cm, in case the patient wishes to have a tubal reanastomosis in the future.**

**FIG 19-14** Uchida sterilization. The leaves of the broad ligament and peritubal peritoneum are infiltrated with saline so that the tube can be easily isolated from these structures, divided (**A**), and ligated (**B**). The broad ligament is then closed, and the proximal stump is buried between the leaves and includes the distal stump in the line of closure.

### KEY POINTS

- ◆ In 1970, the CD rate was about 5%. By 2008, it had reached 32.8%, the highest rate ever recorded in the United States. Vaginal birth after cesarean (VBAC) rates have plummeted, from a peak of 28.3% in 1996 to 8.5% in 2008, contributing to the rise in CD. Most recently, CD rates have stabilized around 31% to 32% in the United States.
- ◆ Factors that have contributed to the rise in CD during the past decades include (1) continued increase in primary CDs for dystocia, failed induction, and abnormal presentation; (2) an increase in the proportion of women with obesity, diabetes mellitus, and multiple gestations; (3) increased use of planned CD; and (4) limited use of TOLAC after CD because of both safety and medicolegal concerns.
- ◆ Single-dose, preoperative prophylactic antibiotics are of clear benefit in reducing the frequency of postcesarean endomyometritis and wound infection.
- ◆ Mechanical prophylaxis with graduated compression stockings or a pneumatic compression device during and after all cesarean deliveries should be considered.
- ◆ Horizontal skin incision is preferred because vertical skin incision is associated with long-term postoperative complications, such as wound dehiscence and abdominal incisional hernia, and it is also cosmetically less pleasing.
- ◆ A low transverse uterine incision is preferred for almost all CDs.
- ◆ Blunt uterine extension is associated with decreased blood loss and is therefore preferred.

- ◆ Delayed cord clamping should be done for 30 to 120 seconds for all infants delivered at less than 37 weeks' gestation.
- ◆ IV oxytocin, 10 to 80 IU in 1 L crystalloid, should be given prophylactically after the baby is delivered in all CDs.
- ◆ Several RCTs have demonstrated greater blood loss and a higher rate of endometritis with manual extraction of the placenta at CD. Thus spontaneous expulsion of the placenta with gentle cord traction is preferred.
- ◆ The uterine incision can be repaired in a single layer if the patient has completed child-bearing, such as a bilateral tubal ligation performed concurrently with CD. Consider double-layer closure otherwise.
- ◆ When closing the abdomen after a CD, the subcutaneous tissue is closed if its thickness exceeds 2 cm. This approach significantly reduces the risk for wound disruption.
- ◆ The skin should be closed with sutures, not staples.
- ◆ Postcesarean endomyometritis remains the most common complication of CD. With the use of appropriate prophylactic antibiotics as described previously, its frequency is usually less than 5%.

## VAGINAL BIRTH AFTER CESAREAN DELIVERY

### Trends

In a review of contemporary cesarean delivery practice, Zhang and colleagues<sup>1</sup> concluded that one of the most important contributors to the rising cesarean delivery rate in the United States was the decline in vaginal birth after cesarean delivery (VBAC). Specifically, after a steady increase in the overall U.S. cesarean delivery rate beginning in the early 1960s, a modest decline in this rate was observed that reached a nadir of 21% in 1996, largely because of an increased rate of allowing a trial of labor after cesarean delivery (TOLAC) that was estimated to exceed 50% (Fig. 20-1). However, by 2006 the TOLAC rate had plummeted to approximately 15%, and the rate of successful TOLAC has also had declined. Given that **it has been suggested that about two thirds of women with a prior cesarean delivery are**

**actually candidates for a TOLAC, most planned repeat operations are influenced by physician discretion and patient choice.** A comparison of TOLAC rates between the United States and several European nations, where TOLAC rates vary between 50% and 70%, suggest significant underuse of TOLAC in this country. Given this information and the fact that 10% of the obstetric population has had a previous cesarean delivery, more widespread use of TOLAC has the potential to decrease the overall rate of cesarean delivery.

The evolution in management of the woman with a prior cesarean delivery can be traced through several American College of Obstetricians and Gynecologists (ACOG) documents and key studies over the past 25 years. In 1988, ACOG published "Guidelines for Vaginal Delivery after a Previous Cesarean Birth," recommending TOLAC and VBAC as it became clear that this procedure was safe and did not appear to be associated with excess perinatal morbidity compared with repeat cesarean delivery. They recommended that each hospital develop its own protocol for the management of VBAC patients and that in the absence of a contraindication such as a prior classical incision, women who had undergone one prior low transverse cesarean section should be counseled and encouraged to attempt labor. This recommendation was supported by several large case series that attested to the safety and effectiveness of TOLAC. With this information, TOLAC rates exceeded 50% in many institutions. Some third-party payers and managed care organizations began to mandate a TOLAC for women with a prior cesarean delivery. Feeling institutional pressure to lower cesarean rates, physicians began to offer a TOLAC liberally and likely included less-than-optimal candidates. With the rise in VBAC experience, a number of reports appeared in the literature suggesting a possible increase in uterine rupture and its maternal and fetal consequences. Descriptions of uterine rupture with hysterectomy and adverse perinatal outcomes, including fetal death and neonatal brain injury, set the stage for the precipitous decline in VBAC rates during the past 20 years.<sup>2,3</sup>

**FIG 20-1** United States total cesarean delivery rate from 1990 through 2008 and the primary cesarean delivery and vaginal birth after cesarean (VBAC) rates from 1990 through 2004. (Modified from MacDorman M, DeClercq E, Menacker F. Recent trends and patterns in cesarean and vaginal birth after cesarean deliveries in the United States. *Clin Perinatol*. 2011;38;179-192.)

In 1999, ACOG issued a practice bulletin<sup>5</sup> acknowledging that while the risks of TOLAC were apparently small in magnitude, clinically significant risks of uterine rupture did exist, with poor outcomes for both women and their infants. It was also recognized that such adverse events during a TOLAC could lead to malpractice suits.<sup>4</sup> ACOG thus recommended that TOLAC be conducted in settings in which a physician capable of performing a cesarean delivery was “immediately available” and that institutions be equipped to respond to emergencies such as uterine rupture. The language in the 1999 document also suggested that instead of “encouraging” TOLAC, women with prior low transverse cesarean deliveries should be “offered” TOLAC.<sup>5</sup> A more conservative approach to TOLAC then followed with recognition of the need to reevaluate VBAC recommendations.

In the aftermath of the 1999 document, many hospitals began to no longer offer planned TOLAC. The role of nonclinical factors in the declined utilization of TOLAC has been reviewed by Korst and colleagues.<sup>6</sup> These authors noted five factors that seem to have influenced VBAC rates: (1) recommendations of opinion leaders and professional guidelines, (2) hospital facilities and cesarean delivery availability, (3) reimbursement, (4) medical liability, and (5) patient-level factors. Among patient-level factors is the consideration that patients are becoming more risk averse and are thus more comfortable with choosing planned repeat cesarean delivery. The question remains as to whether women are less convinced on their own that VBAC is a reasonable option or whether they are being dissuaded by the health care system. Nonetheless, the 2010 ACOG practice bulletin—consistent with prior publications—concludes that most women with one previous cesarean delivery via a low transverse incision are candidates for TOLAC and should be counseled about and offered a TOLAC.<sup>7</sup>

In response to a growing body of evidence that indicates restriction of a women’s access to TOLAC-VBAC, despite two recent large-scale contemporary multicenter studies that attest to their relative safety,<sup>8,9</sup> the National Institutes of Health (NIH) held a consensus development conference concerning VBAC in 2010. The panel at that conference concluded that TOLAC is a reasonable birth option for many women with a previous cesarean delivery. The panel also

found that existing practice guidelines and the medical liability climate were restricting access to TOLAC-VBAC and that these factors need to be addressed.<sup>10</sup> A specific concern raised was the low level of evidence for the requirement for “immediately available” surgical and anesthesia personnel in existing guidelines and the need to reassess this recommendation with reference to other obstetric complications of comparable risk given limited physician and nursing resources.

The ACOG 2010 practice bulletin<sup>7</sup> acknowledged a background of limited access to TOLAC-VBAC evolving over time as well as the recommendation by the NIH panel to facilitate access. Although again recommending that TOLAC-VBAC be undertaken in facilities with staff immediately available to provide emergency care, ACOG recognized that resources for immediate cesarean delivery may not be available in smaller institutions. In such cases, the decision to offer and pursue TOLAC should be carefully considered by patients and their health care providers. It was recommended that the best alternative may be to refer patients to a facility with available resources.

### Candidates for a Trial of Labor After Cesarean

The optimal candidates for planned TOLAC are those women in whom the balance of risks (i.e., as low as possible) and chances of success (i.e., as high as possible) are acceptable to the patient and health care provider.<sup>7</sup> Most women who have had a low transverse uterine incision with a prior cesarean delivery and have no contraindications to vaginal birth should be considered candidates for a TOLAC. **The following are selection criteria suggested by ACOG<sup>7</sup> for identifying candidates for TOLAC:**

- One or two previous low transverse cesarean deliveries
- Clinically adequate pelvis
- No other uterine scars or previous rupture
- Physicians immediately available throughout active labor capable of monitoring labor and performing an emergency cesarean delivery

It should be noted that these criteria identify women who are likely to be reasonable candidates and do not exclude women with any other clinical situation from the option of TOLAC. For example, several studies indicate that it may be reasonable to offer a TOLAC to women with macrosomia, gestation beyond 40 weeks, previous low vertical incision, unknown uterine scar type, and twin gestation.<sup>8,11-14</sup>

Conversely, a TOLAC is contraindicated in women at high risk for uterine rupture. **A TOLAC should *not* be attempted in the following circumstances:**

- Previous classical or T-shaped incision or extensive transfundal uterine surgery
- Previous uterine rupture
- Medical or obstetric complications that preclude vaginal delivery

### Success Rates for a Trial of Labor After Cesarean

The overall success rate for a population of women undergoing TOLAC appears to be in the 60% to 80% range,<sup>7</sup> although some data suggest this rate may be lower in contemporary practice. A cross-sectional analysis study<sup>15</sup> that utilized National Hospital Discharge Survey information noted that TOLAC success rates had fallen from nearly 70% in 2000 to 40% to 50% by 2009.

Predictors of successful TOLAC are well described.<sup>16-24</sup> The ability to predict successful TOLAC is important because

maternal morbidity is lowest among women who achieve VBAC and is greatest among women who fail TOLAC and require a repeat operation. The prior indication for cesarean delivery clearly affects the likelihood of successful TOLAC because women with “recurrent” indications (i.e., labor arrest disorders) are less likely to achieve VBAC. Also, a history of prior vaginal birth is associated with the highest success rates for VBAC (Table 20-1). Several authors have developed models for predicting

**TABLE 20-1** SUCCESS RATES FOR TRIAL OF LABOR AFTER CESAREAN DELIVERY

|                               | VBAC SUCCESS (%) |
|-------------------------------|------------------|
| <b>Prior Indication</b>       |                  |
| CPD/FTP                       | 63.5             |
| NRFWB                         | 72.6             |
| Malpresentation               | 83.8             |
| <b>Prior Vaginal Delivery</b> |                  |
| Yes                           | 86.6             |
| No                            | 60.9             |
| <b>Labor Type</b>             |                  |
| Induction                     | 67.4             |
| Augmented                     | 73.9             |
| Spontaneous                   | 80.6             |

Modified from Landon MB, Leindecker S, Spong CY, et al. Factors affecting the success of trial of labor following prior cesarean delivery. *Am J Obstet Gynecol.* 2005;193:1016. CPD, cephalopelvic disproportion; FTP, failure to progress; NRFWB, nonreassuring fetal well-being; VBAC, vaginal birth after cesarean.

VBAC (Fig. 20-2). Grobman and colleagues<sup>25</sup> developed a model based on factors that could be assessed at the first prenatal visit. These included the variables of maternal age, body mass index (BMI), race and ethnicity, prior vaginal delivery, prior VBAC, and a recurrent indication for the cesarean delivery. After development and internal validation of the model, it was found to be accurate and discriminating and subsequently has been validated in populations other than that in which it was developed.<sup>26-29</sup> The calculator is available online at [mfmu.bsc.gwu.edu](http://mfmu.bsc.gwu.edu). Because circumstances at the time of admission for delivery may affect the chance of successful TOLAC, a second calculator was created to take these factors into account and is also available at the maternal-fetal medical units (MFMU) site. The additional factors include maternal BMI at delivery, cervical status, need for induction, and the presence or absence of preeclampsia.<sup>30</sup> A simple admission model and scoring system for the prediction of VBAC success that incorporates cervical status, history of vaginal birth, maternal age, prior indication for cesarean delivery, and maternal BMI has also been investigated by Metz and colleagues.<sup>31</sup>

A summary of factors associated with VBAC in the setting of TOLAC is summarized in the following sections.

### Maternal Demographics

Race, age, BMI, and insurance status have all been demonstrated to be associated with the success of TOLAC.<sup>16</sup> In a multicenter

**FIG 20-2** Graphic nomogram used to predict probability of vaginal birth after cesarean (VBAC). The nomogram is used by locating each patient characteristic and finding the number of points on the uppermost scale to which that characteristic corresponds. The sum of total points predicts the probability of VBAC on the lower scale. BMI, body mass index. (Modified from Grobman WA, Lai Y, Landon MB, et al, for the National Institute of Child Health and Human Development [NICHD] Maternal Fetal Medicine Units Network [MFMU]. Development of a nomogram for prediction of vaginal birth after cesarean delivery. *Obstet Gynecol.* 2007;109:806-812.)

study of 14,529 term pregnancies in which TOLAC was attempted, white women had a 78% success rate, compared with 70% in nonwhite women.<sup>16</sup> Obese women are more likely to fail a TOLAC, as are women older than 40 years.<sup>16</sup> Conflicting data exist with regard to payer status.<sup>32</sup>

### Prior Indication for Cesarean Delivery

Success rates for women whose first cesarean delivery was performed for a nonrecurring indication (breech, nonreassuring fetal well-being) are similar to vaginal delivery rates for nulliparous women. Prior cesarean delivery for a breech presentation is associated with a reported success rate of 89%.<sup>16</sup> In contrast, **prior cesarean delivery for cephalopelvic disproportion (CPD) or failure to progress (FTP) has been associated with success rates that range from 50% to 67%.**

### Prior Vaginal Delivery

Prior vaginal delivery, including prior VBAC, is one of the greatest predictors for successful TOLAC. In one series,<sup>16</sup> **women with a prior vaginal delivery had an 87% TOLAC success rate, compared with a 61% success rate in women without a prior vaginal delivery.** Caughey and colleagues<sup>17</sup> reported that for patients with a prior VBAC, the success rate was 93%, compared with 85% in women with a vaginal delivery before their cesarean birth but who had not had a successful VBAC. Mercer and colleagues<sup>18</sup> noted that the success rate increased from 87.6% with one prior vaginal delivery to 90.0% in those with two prior successful attempts.

### Birthweight

Increased birthweight is associated with a lower likelihood of a successful VBAC.<sup>11,19</sup> **Birthweight greater than 4000 g in particular is associated with a higher risk for failed VBAC.**<sup>33</sup> Although some report success rates below 50%, others have documented that as many as 60% to 70% of women who attempt VBAC with a macrosomic fetus are successful. Peaceman and colleagues<sup>20</sup> reported a 34% success rate when the second pregnancy birthweight exceeded the first by 500 g and the prior indication was dystocia, compared with a 64% success rate with other prior indications. It should be noted that although birthweight has been associated with the success of VBAC, this factor cannot be known with precision prior to undertaking TOLAC, and it has not been demonstrated to what degree estimated fetal weight is associated with VBAC.

### Labor Status and Cervical Examinations

Both labor status and cervical examination on admission influence the success of a TOLAC. Flamm and Geiger<sup>21</sup> reported **an 86% success rate in women who presented in labor with cervical dilation greater than 4 cm. Conversely, the VBAC success rate dropped to 67% if the cervix was dilated less than 4 cm on admission.**

Not surprisingly, women who undergo induction of labor are at higher risk for repeat cesarean delivery compared with those who enter spontaneous labor.<sup>16,22</sup> Data from the National Institute of Child Health and Human Development (NICHD) MFMU Cesarean Registry demonstrated **a 67.4% success rate in women who underwent induction versus 80.5% in those who underwent spontaneous labor.**<sup>22</sup> In a study of 429 women undergoing induction with a prior cesarean delivery, Grinstead and Grobman<sup>23</sup> reported an overall 78% success rate. These authors noted several factors related to the labor induction as

**TABLE 20-2** SUCCESS RATES FOR TRIAL OF LABOR AFTER TWO PRIOR CESAREAN DELIVERIES

| STUDY                       | SUBJECTS (N) | SUCCESS RATE (%) |
|-----------------------------|--------------|------------------|
| Miller et al <sup>42</sup>  | 2936         | 75.3             |
| Caughey et al <sup>43</sup> | 134          | 62.0             |
| Macones et al <sup>34</sup> | 1082         | 74.6             |
| Landon et al <sup>45</sup>  | 876          | 67.0             |

determinants of VBAC success, including indication for induction and the need for cervical ripening. Grobman and colleagues<sup>22</sup> have also reported a VBAC success rate of 83% in 1208 women with a prior cesarean delivery and prior vaginal delivery undergoing induction of labor.

### Previous or Unknown Incision Type

Previous incision type cannot be ascertained in certain patients. Nevertheless, it appears that **women whose previous incision type is unknown have VBAC success rates similar to those of women with documented prior low transverse incisions.**<sup>16</sup> **Similarly, women with previous low vertical incisions do not appear to have lower VBAC success rates.**<sup>24</sup>

### Multiple Prior Cesarean Deliveries

Women with more than one prior cesarean delivery have been demonstrated to have a lower likelihood of achieving VBAC (Table 20-2). Caughey and colleagues<sup>17</sup> reported a 75% success rate for women with one prior cesarean delivery compared with 62% in women with two prior operations. In contrast, a larger multicenter study<sup>34</sup> of 13,617 women undergoing a TOLAC revealed a 75.5% success rate for women with two prior cesarean deliveries, which was not statistically different from the 75% success rate in women with one prior operation.

### Postterm Pregnancy

TOLAC success rates may be lower for women at or beyond 40 weeks of gestation when compared with those who have yet to reach 40 weeks. Nevertheless, the chance of success for women who are at or beyond 40 weeks of gestation has been demonstrated to be approximately 70%,<sup>12</sup> and a gestational age beyond a woman's due date should not preclude TOLAC.

### Twin Gestation

Two large-scale contemporary studies<sup>9,16</sup> of women attempting VBAC indicate that success rates for women undergoing TOLAC with twins are not different than for those with singleton gestations.

## RISKS ASSOCIATED WITH A TRIAL OF LABOR AFTER CESAREAN

### Uterine Rupture

The principal risk associated with TOLAC is uterine rupture. This complication is directly attributable to TOLAC because symptomatic rupture is rarely observed in planned repeat operations.<sup>8,35-39</sup> **It is important to differentiate between uterine rupture and uterine scar dehiscence. This distinction is clinically relevant because dehiscence most often represents an occult scar separation observed at laparotomy in women with a prior cesarean delivery.** With uterine dehiscence, the serosa of the uterus is intact and hemorrhage, with its potential for

**TABLE 20-3**    RISK FOR UTERINE RUPTURE BASED ON INCISION TYPE

| PRIOR INCISION TYPE | RUPTURE RATE (%) |
|---------------------|------------------|
| Low transverse      | 0.5-1.0          |
| Low vertical        | 0.8-1.1          |
| Classic or T shaped | 4-9              |

fetal and maternal sequelae, is absent. In contrast, uterine rupture is a through-and-through disruption of all uterine layers, with potential consequences of nonreassuring fetal status and perinatal mortality along with severe maternal morbidity, hemorrhage, and mortality. Terminology, definitions, and ascertainment for uterine rupture vary significantly in the existing VBAC literature.<sup>37</sup> A review<sup>38</sup> of four observational studies reported the risks of symptomatic uterine rupture in the TOLAC group and elective repeat cesarean group to be 0.47% (95% confidence interval [CI], 0.28% to 0.77%) and 0.026% (95% CI, 0.009% to 0.082%), respectively. **The large multicenter MFMU Network Study<sup>8</sup> reported a 0.69% frequency of uterine rupture, with 124 symptomatic ruptures occurring in 17,898 women undergoing TOLAC.**

The rate of uterine rupture depends both on the type and location of the previous uterine incision (Table 20-3). Uterine rupture rates are highest with a previous classical or T-shaped incision, with a range reported between 4% and 9%. The risk for rupture with a previous low vertical incision has been difficult to estimate owing to imprecision with the diagnosis and the uncommon use of this incision type. Naif and colleagues<sup>40</sup> reported a 1.1% risk for rupture in 174 women with a prior low vertical scar undergoing TOLAC, whereas Shipp and associates<sup>41</sup> reported a 0.8% (3 of 377) risk for rupture with a prior low vertical incision. On the basis of these two studies, the authors concluded that **women with a prior low vertical uterine incision are not at significantly increased risk for rupture compared with women with a prior low transverse incision.**

Women with an unknown incision type do not appear to be at increased risk for uterine rupture. Among 3206 women with an unknown scar in the MFMU Network Cesarean Registry, uterine rupture occurred in 0.5% of women undergoing TOLAC.<sup>13</sup> Nevertheless, this frequency is a reflection of the fact that in a contemporary setting, most women with unknown scars will have had a prior low transverse incision. **In counseling women with an unknown scar, the physician should attempt to understand whether a prior cesarean delivery had been performed under circumstances in which it was more likely that a different type of incision had been used.** For example, a history of preterm cesarean delivery should warrant caution, especially in the setting of malpresentation, because the incision may have involved an undeveloped muscular portion of the uterus, or it may have been a classical incision. For these reasons, if the clinician suspects that the prior delivery occurred under circumstances in which an incision that extended into the muscular portion of the uterus was used, we generally proceed with repeat cesarean delivery.

The most serious sequelae of uterine rupture include perinatal death, hypoxic-ischemic encephalopathy (HIE), and hysterectomy. Citing six perinatal deaths in 74 uterine ruptures among 11 studies, Guise and colleagues<sup>38</sup> calculated 0.14 additional perinatal deaths per 1000 TOLACs. This figure is remarkably similar to that from the NICHD MFMU Network study by Landon and colleagues,<sup>8</sup> in which there were two neonatal

Modified from Landon MB, Hauth JC, Leveno KJ, et al, for the National Institute of Child Health and Human Development Maternal-Fetal Medicine Units Network: Maternal and perinatal outcomes associated with a trial of labor after prior cesarean section. *N Engl J Med* 2004;351:2581.

deaths among 124 ruptures, for **an overall rate of rupture-related perinatal death of 0.11 per 1000 TOLACs.** An all-inclusive review<sup>39</sup> of 880 maternal uterine ruptures in studies of varying quality during a 20-year period showed a rate of 0.4 per 1000 (Table 20-4).

Perinatal hypoxic brain injury is another recognized adverse outcome related to uterine rupture. However, estimates of the frequency of perinatal “asphyxia” have varied in the literature because it has been inconsistently defined in TOLAC studies, and variables such as cord blood gas levels and Apgar scores are reported in only a fraction of cases. Landon and colleagues<sup>8</sup> found a significant increase in the rate of HIE related to uterine rupture among the offspring of women who underwent a TOLAC at term compared with the children of women who underwent a planned repeat cesarean delivery (0.46 per 1000 vs. 0 cases, respectively). **In this study of 114 cases of uterine rupture at term, seven infants (6.1%) sustained HIE, and two of these infants died in the neonatal period (Table 20-5).**

Maternal hysterectomy also may be a complication of uterine rupture if the defect cannot be repaired or is associated with uncontrollable hemorrhage. In five studies<sup>37</sup> that reported on hysterectomies related to rupture, seven cases occurred in 60 symptomatic ruptures (13%; range, 4% to 27%), indicating that 3.4 per 10,000 women electing a TOLAC sustain a rupture that necessitates hysterectomy. Five of 124 women (4%) included in the NICHD MFMU Network study<sup>8</sup> experienced hysterectomy following rupture. However, hysterectomy also can occur in the setting of a planned repeat cesarean, and some evidence suggests that it is no more likely during a TOLAC than during a planned repeat cesarean delivery. Guise and colleagues,<sup>38</sup> for example, reported that the risk for hysterectomy in women attempting TOLAC was not significantly different than that in those undergoing planned repeat cesareans.

**Risk Factors for Uterine Rupture**

**Rates of uterine rupture vary significantly depending on a variety of associated risk factors. In addition to the type of**

**uterine scar, characteristics of the obstetric history that include the number of prior cesarean and vaginal deliveries, the interdelivery interval, and the uterine closure technique have been reported to be associated with the risk for uterine rupture.** Similarly, factors related to labor management, including induction and the use of oxytocin augmentation, have been studied.

### Number of Prior Cesarean Deliveries

In a large single-center study of more than 1000 women with multiple prior cesarean deliveries undergoing TOLAC, Miller and colleagues<sup>42</sup> reported uterine rupture in 1.7% of women with two or more previous cesarean deliveries compared with 0.6% in those with one prior cesarean (odds ratio [OR], 3.06; 95% CI, 1.95 to 4.79). Interestingly, the risk for uterine rupture was not increased further for women with three prior cesarean deliveries. Caughey and colleagues<sup>43</sup> conducted a smaller study of 134 women with two prior cesarean deliveries and controlled for labor characteristics as well as obstetric history. These authors reported a rate of uterine rupture of 3.7% among these 134 women, compared with 0.8% in the 3757 women with one previous scar (OR, 4.5; 95% CI, 1.18 to 11.5). Macones and colleagues<sup>34</sup> reported a rate of uterine rupture of 1.8% (20 of 1082) in women with two prior cesarean deliveries compared with 0.9% (113 of 12,535) in women with one prior operation (adjusted OR, 2.3; 95% CI, 1.37 to 3.85). A meta-analysis also suggested a nearly threefold increased risk for uterine rupture with two previous cesarean deliveries (1.59% vs. 0.72%).<sup>44</sup> In contrast, the analysis of Landon and colleagues<sup>45</sup> from the MFMU Network Cesarean Registry found no significant difference in rupture rates in women with one prior cesarean (115 of 16,916 [0.7%]) versus multiple prior cesareans (9 of 975 [0.9%]). **It thus appears that even if having had more than one prior cesarean section is associated with an increased risk for uterine rupture, the magnitude of any additional risk is fairly small (Table 20-6). ACOG considers it reasonable to offer TOLAC to women with more than one prior cesarean delivery and to counsel such women based on the combination of other factors that affect their probability of achieving a successful VBAC.**<sup>7</sup>

### Prior Vaginal Delivery

**Prior vaginal delivery, either before or after a prior cesarean delivery, appears to be highly protective against uterine rupture in the setting of TOLAC.** In a study of 3783 women undergoing a TOLAC, Zeloff and colleagues<sup>46</sup> noted that the

rate of uterine rupture among women with a prior vaginal birth was 0.2% (2 of 1021), compared with 1.1% (30 of 2762) among women with no prior vaginal deliveries. After controlling for demographic differences and labor characteristics, women who had one or more vaginal deliveries had a rate of uterine rupture that was one fifth that of women who did not have a prior vaginal birth (adjusted OR, 0.2; 95% CI, 0.04 to 0.8). A similar protective effect of prior vaginal birth has been reported in two large multicenter studies.<sup>8,9</sup>

### Uterine Closure Technique

Over the past 20 years, the single-layer closure technique has gained popularity because it has appeared to be associated with shorter operating time and comparable short-term complications compared with the traditional two-layer technique. In a randomized trial, Chapman and colleagues<sup>47</sup> compared the frequency of uterine rupture in 145 women who received either one- or two-layer closure at their primary cesarean delivery. Following TOLAC, no cases of uterine rupture were found in either group; however, the study was underpowered to detect a potential difference. A larger observational study<sup>48</sup> identified an approximately fourfold increased rate (3.1% vs. 0.5%) of rupture following a single-closure technique when compared with a previous double-layer closure. In a 2010 case-control study,<sup>49</sup> the same group suggested an increased risk for uterine rupture in women with a history of a single-layer closure (OR, 2.69; 95% CI, 1.57 to 5.28) compared with a two-layer closure. Further, single-layer uterine closure was the only significant variable associated with adverse neonatal outcome, yet it has been postulated that single-layer closure may have been used in some cases when the lower uterine segment was thin and not amenable to a two-layer closure or that other aspects of the closure, such as suture type or locking technique, may be confounding the apparent association. Indeed, in another study by Durnwald and Mercer,<sup>50</sup> no association between the number of layers closed and uterine rupture was found. Thus it remains unclear whether the single-layer closure technique increases the risk for rupture.

### Interpregnancy Interval

Several studies have addressed whether TOLAC after a short interpregnancy interval may be associated with an increased risk for uterine rupture. Shipp and colleagues<sup>51</sup> reported an incidence of rupture of 2.3% (7 of 311) in women with an interdelivery interval less than 18 months compared with 1.1% (22 of 2098) with a longer interdelivery interval. After controlling for demographic characteristics and oxytocin use, women with a shorter interpregnancy interval were three times more likely to experience uterine rupture. Using a multivariable approach, Bujold and associates<sup>52</sup> reported an interdelivery interval of less than 24 months to be associated with an almost threefold increased risk for uterine rupture. In their study, the rate of rupture was 2.8% in women with a short interval versus 0.9% in women when it had been more than 2 years since the prior cesarean birth. Yet in a study of 1185 women undergoing a TOLAC, Huang and colleagues<sup>53</sup> found no increased risk for uterine rupture with an interdelivery interval of less than 18 months.

### Induction of Labor

Induction of labor may be associated with an increased risk for uterine rupture when compared with spontaneous labor.<sup>54,55</sup>

**In a population-based cohort analysis, Lydon-Rochelle and colleagues<sup>54</sup> reported a rate of uterine rupture of 24 of 2326**

**TABLE 20-6** RISK FOR UTERINE RUPTURE FOLLOWING MULTIPLE PRIOR CESAREAN DELIVERIES

| STUDY                       | N    | RUPTURE RATE     |                    |                |

(1.0%) for women undergoing induction compared with 56 of 10,789 (0.5%) in women who had spontaneous onset of labor. Landon and colleagues<sup>8</sup> noted the risk for uterine rupture to be elevated nearly threefold (OR, 2.86; 95% CI, 1.75 to 4.67), although the attributable risk of rupture related to labor induction was relatively small (1.0% vs. 0.4%). In an analysis<sup>22</sup> from this study of women (*n* = 11,778), those with only one prior low transverse cesarean delivery showed an increase in uterine rupture in those undergoing induction who had no prior vaginal delivery but did not reveal any increased risk of uterine rupture with labor induction among women who had a TOLAC with a history of prior vaginal delivery. In this study, the need for cervical ripening did not appear to affect the frequency of uterine rupture. Conversely, in another investigation,<sup>56</sup> women with a favorable cervix undergoing induction had a similar risk for uterine rupture as women entering labor spontaneously, whereas those being induced with an unfavorable cervix had a fourfold increased risk of uterine rupture. Despite these analyses, it remains unclear whether induction increases the risk for uterine rupture in comparison to expectant management—the clinical alternative for women who desire a TOLAC. Based on the cumulative data, ACOG considers induction of labor for maternal or fetal indications to be an option for women undergoing TOLAC.

Conflicting data have also been reported concerning whether various induction methods increase the risk for uterine rupture (Table 20-7). The study of Lydon-Rochelle and colleagues<sup>54</sup> suggests an increased risk for uterine rupture with the use of prostaglandins for labor induction. Uterine rupture was noted in 15 of 1960 women (0.8%) induced without prostaglandins, compared with 9 of 366 women (2.5%) induced with prostaglandin. Unfortunately, these authors could not determine which specific prostaglandin agent was used. In the study of Dekker and associates,<sup>55</sup> the risk for rupture with oxytocin alone was 0.54% compared with 0.68% with prostaglandins and 0.88% when the combined agents were used.

Neither Landon's group<sup>8</sup> nor that of Macones<sup>9</sup> confirmed the findings of Lydon-Rochelle and colleagues<sup>54</sup> of an increased risk for rupture associated with the use of prostaglandin agents alone for induction. Macones and colleagues<sup>9</sup> did report an increased risk for rupture in women undergoing induction but only if they received both prostaglandins and oxytocin, and the methodology in this study allowed the authors to distinguish between induction methods. Interestingly, in the MFMU Network study of Landon and associates,<sup>8</sup> no cases of uterine rupture were reported when prostaglandin alone was used for induction, including 52 cases in which misoprostol was used. Nevertheless, the safety of this medication, which is popular for cervical

ripening and labor induction (see Chapter 13), has been challenged for women attempting VBAC. Plaut and colleagues<sup>32</sup> reported a uterine rupture rate of 5.6% (5 of 89) in women who received misoprostol for labor induction. However, as in other series, it is unclear whether these women received oxytocin as well. The timing (delay) of uterine rupture in relation to misoprostol administration also calls into question cause and effect. Following several case reports of uterine rupture with misoprostol use, Wing and colleagues<sup>33</sup> conducted a randomized trial of intravaginal misoprostol versus oxytocin in women attempting VBAC in which 17 women received misoprostol and 21 women received oxytocin. The study was stopped prematurely because two emergency cesarean deliveries were performed with uterine disruption in patients who received misoprostol.

Unfortunately, many VBAC studies fail to specify the prostaglandin used for labor induction. In the largest report of women who received prostaglandins for labor induction attempting VBAC, Smith and colleagues<sup>57</sup> reported a 0.87% risk for uterine rupture among 4475 women who received unspecified prostaglandins, compared with 0.29% in 4429 women who did not receive this class of medication. Although the relative risk associated with prostaglandin use was elevated, the absolute risk increase for rupture was low. **At present, based on the limited data that do exist, ACOG suggests that misoprostol (prostaglandin E<sub>1</sub>) not be used for third-trimester cervical ripening or labor induction in women who have had a cesarean delivery and that sequential use of prostaglandin E<sub>2</sub> and oxytocin be avoided in women undergoing TOLAC.** This recommendation has thus limited the induction options for women undergoing TOLAC and in need of cervical ripening, primarily in regard to oxytocin or mechanical methods with or without oxytocin. Small studies<sup>58</sup> of women with prior cesarean delivery undergoing induction with a transcervical Foley catheter suggest that uterine rupture rates are similar to those of women entering spontaneous labor attempting VBAC.

**Labor Augmentation**

**Data conflict as to whether oxytocin used for labor augmentation during TOLAC in contemporary obstetric practice is associated with an increased risk of uterine rupture.** In a case-control study, Leung and colleagues<sup>59</sup> reported an OR of 2.7 for uterine rupture in women who received oxytocin augmentation. However, it is possible that the dysfunctional labor may be the risk factor responsible for rupture. In contrast to the data of Leung and associates, Zelop and others<sup>60</sup> found that labor augmentation with oxytocin did not significantly increase the risk for rupture. Cahill and colleagues<sup>61</sup> reported a dose-response relationship between maximal oxytocin dose and the risk for rupture among women who attempt TOLAC. A limitation of this report is that it includes both women undergoing induction and those receiving oxytocin augmentation. At their maximal dose of oxytocin (>20 mU/min), these authors noted the risk for uterine rupture to be 2.07%. **From these data, it appears that oxytocin may be used in women undergoing TOLAC, although higher infusion rates should be used with caution.**

**Sonographic Evaluation of the Uterine Scar**

To better identify women at risk for uterine rupture undergoing TOLAC, the thickness of the lower uterine segment (LUS) prior to labor has been assessed with ultrasound. Ultrasound measurement of the thickness of residual myometrium in the LUS

\*Thromboembolic disease includes deep venous thrombosis or pulmonary embolism.

†Other adverse events include broad ligament hematoma, cystotomy, bowel injury, and ureteral injury.

CI, confidence interval.

has been assessed, as has the width, depth, and length of the hypochoic interface at the site of the prior cesarean delivery.<sup>62</sup> However, these measurements may change with gestational age, and at present, there appears to be no value for any measurement that performs well enough for use in clinical practice to predict the integrity of the uterine scar during labor. In one systematic review<sup>63</sup> of 21 studies of the use of sonographic LUS thickness to predict the risk of a uterine scar defect during a TOLAC, no ideal cutoff value for use in clinical practice could be found.

### Other Risks Associated With a Trial of Labor After Cesarean Delivery

In the absence of randomized controlled trials, the observational data that exist to inform women and health care providers about the variety of adverse outcomes that may be associated with a TOLAC, compared with a planned repeat cesarean delivery, do not provide certainty with regard to these risks because there may be a lack of comparability between women undergoing a TOLAC and those having a planned repeat cesarean delivery.<sup>36-38</sup>

Based on the data, it has been generally accepted that vaginal delivery is associated with lower morbidity and mortality than cesarean delivery. Landon and colleagues<sup>8</sup> found an increased risk for both postpartum endometritis and blood transfusion in women undergoing a TOLAC compared with those undergoing planned repeat cesarean delivery without labor (Table 20-8). However, the exclusion of women who presented in early labor, who subsequently underwent a repeat operation that had been intended, may have lowered the risk for complications in the

planned repeat cesarean group. Gilbert and colleagues<sup>64</sup> attempted to produce a more minimally biased cohort by performing propensity analysis to determine more precisely the comparative risks of spontaneous labor and planned cesarean delivery. They found that the rates of endometritis and operative injury were lower and the rates of hysterectomy and wound complication were higher among women who underwent a planned repeat cesarean delivery.

It should be noted that these comparisons are for entire populations of women and may not hold for a given individual. It is well accepted that most of the excess adverse events that accompany a TOLAC are attributable to the group of women who require a repeat cesarean operation in labor (Table 20-9).<sup>65</sup> Thus when considering the balance of risks between TOLAC and planned repeat cesarean delivery, it is important to consider the chance that a woman who is undertaking a TOLAC will achieve a vaginal birth. In one analysis, if a woman undergoing a TOLAC had a greater than 60% to 70% chance of VBAC, her chance of having major or minor morbidity was no greater than that of a woman undergoing a planned repeat cesarean delivery.<sup>66</sup>

An increased risk for maternal mortality in the context of cesarean delivery in general has been extrapolated to women undergoing a planned repeat operation versus a planned TOLAC, although the data to support this association are limited. Guise and colleagues<sup>38</sup> evaluated 24 maternal deaths among 402,833 patients with prior a cesarean delivery and noted that the overall risk for maternal death associated with TOLAC was significantly lower (RR, 0.33; 95% CI, 0.13 to 0.88) than with a repeat

operation. Nevertheless, the infrequency of maternal death, confounding variables such as maternal disease, and the classification of a planned or unplanned procedure complicate mortality estimates and comparisons. **Maternal death attributable to uterine rupture is exceedingly rare, and in the population of the MFMU Cesarean Registry, maternal death was not significantly more common with planned repeat cesarean delivery.<sup>8</sup> However, the study was not powered to detect a difference between this group and women attempting a TOLAC.**

### Management of a Trial of Labor after Cesarean

The optimal management of labor in women undergoing a TOLAC is based not on randomized trials but primarily on opinion. Women attempting VBAC should be encouraged to contact their health care provider promptly when labor begins or rupture of the membranes occurs. Continuous electronic fetal monitoring is recommended, although the need for routine internal monitoring with fetal scalp or intrauterine pressure catheters has not been established. **Studies that have examined fetal heart rate (FHR) patterns before uterine rupture consistently report that nonreassuring signs, particularly prolonged decelerations or bradycardia, are the most common finding accompanying uterine rupture.<sup>67,68</sup>**

Uterine rupture can be catastrophic, sudden, and unpredictable.<sup>69</sup> Personnel who care for women undergoing TOLAC should be familiar with electronic FHR patterns that may be associated with uterine rupture as well as the potential need for emergent delivery. Despite the presence of adequate personnel to conduct an emergency cesarean delivery, prompt and appropriate intervention does not always prevent fetal neurologic injury or death (Fig. 20-3).<sup>70</sup> In the study of Leung and colleagues,<sup>67</sup> significant neonatal morbidity occurred when 18 minutes or longer elapsed between the onset of FHR deceleration and delivery. In contrast to Leung's findings, Bujold and Gauthier<sup>70</sup> reported that fewer than 18 minutes elapsed between prolonged decelerations and delivery in two of three neonates diagnosed with HIE in 23 cases of uterine rupture.

Epidural analgesia is not contraindicated in the setting of TOLAC and does not appear to affect success rates.<sup>16</sup> Epidural analgesia also does not mask the signs and symptoms of uterine rupture. In fact, women may manifest evidence of abdominal pain and may respond by attempting to have their epidural dosed more frequently when a uterine rupture occurs.<sup>71</sup> As has been discussed previously, neither oxytocin induction nor augmentation is contraindicated, and it is reasonable when indicated to consider modest doses of oxytocin.

Performance of the vaginal delivery itself is not altered by a history of prior cesarean birth. Most obstetricians do not routinely explore the uterus to detect asymptomatic scar dehiscences. However, excessive vaginal bleeding or maternal hypotension should be promptly evaluated, which includes assessment for possible uterine rupture. Of 124 cases of uterine rupture accompanying 17,898 trials of labor, 14 (11%) were identified following vaginal delivery.<sup>8</sup>

### Counseling for a Trial of Labor After Cesarean

Because uterine rupture may be a catastrophic event, ACOG continues to recommend that it is optimal to attempt TOLAC in institutions equipped to respond to emergencies with physicians immediately available to provide emergency care, and they recognize that referral may be appropriate if a facility has inadequate resources to offer TOLAC.<sup>7</sup> ACOG further recommends

#### BOX 20-1 RISKS ASSOCIATED WITH TRIAL OF LABOR AFTER CESAREAN DELIVERY

##### Uterine Rupture and Related Morbidity

Uterine rupture (0.5-1.0/100)  
Perinatal death and/or encephalopathy (0.5/1000)  
Hysterectomy (0.3/1000)

##### Increased Maternal Morbidity With Failed TOLAC

Transfusion  
Endometritis  
Length of stay

##### Other Risks With TOLAC

Potential risk for perinatal asphyxia with labor (cord prolapse, abruption)  
Potential risk for antepartum stillbirth beyond 39 weeks' gestation

TOLAC, trial of labor after cesarean.

#### BOX 20-2 RISKS ASSOCIATED WITH PLANNED REPEAT CESAREAN DELIVERY

- Increased maternal morbidity compared with successful trial of labor
- Increased length of stay and recovery
- Increased risks for abnormal placentation and hemorrhage with successive cesarean deliveries

that when resources for immediate cesarean delivery are not available, health care providers and patients considering TOLAC should discuss the hospital's resources and the availability of staff. The decision to pursue TOLAC in such a setting should be carefully considered by patients and their health care providers.

**Regardless of the approach to delivery, a pregnant woman with a previous cesarean delivery is at risk for both maternal and perinatal complications. Complications associated with both procedures should be discussed, and an attempt should be made to include an individualized risk assessment for the likelihood of successful VBAC (Box 20-1) and the corresponding comparative risk of maternal and perinatal morbidity.** Such an estimate may be obtained from prior prediction models that have been developed, such as those by Grobman and associates.<sup>25,30</sup> Whereas no prediction model can provide an individual risk of uterine rupture that is as accurate and reliable as that of the prediction of VBAC, a consideration of individual-specific factors associated with uterine rupture should also be considered. Lastly, plans for future childbearing and the risks for multiple cesarean deliveries, including the risks for placenta previa and placenta accreta, should also be considered (Box 20-2).<sup>72,73</sup>

**It is essential to make an effort to obtain records of the prior cesarean delivery to ascertain the previous uterine incision type. This is particularly relevant to cases in which it is more likely that a non-low transverse uterine incision was used.** If previous uterine incision type is unknown, the implications of that missing information should be discussed.

Following informed consent detailing the most relevant risks and benefits for the individual woman, the delivery plan should be formulated using a shared decision-making process by both the patient and physician. There should be clear recognition that this plan may change depending on clinical circumstances, including events during the labor process. It is inappropriate to mandate TOLAC because many women desire a planned repeat

**FIG 20-3** **A**, This 37-year-old patient (gravida 7, para 3, ab 3) presented for induction of labor at 41 weeks' gestation. She had had two prior vaginal deliveries, but her last baby was born at 33 weeks by low transverse cesarean section for nonimmune hydrops caused by a cardiac malformation. The patient's induction was begun with prostaglandin gel. Her cervix changed from fingertip dilated, 50% effaced to 1-cm dilated, 70% effaced with a cephalic presentation at  $-2$  station. Oxytocin was then begun at 1 mU/min. The patient progressed well, and epidural anesthesia was administered at 4 to 5 cm dilation, 90% effaced, and 0 station. The patient was at 6 cm dilation with a tracing that demonstrated normal heart rate variability and variable decelerations. **B**, Thirty minutes after the above tracing was recorded, the fetal heart rate pattern changed to severe variable decelerations. **C**, The tracing then demonstrated prolonged decelerations at 90 beats/min. The patient was taken to the operating room for an emergency cesarean delivery, and it was found that rupture had occurred along the site of the previous uterine incision. A female fetus weighing 3200 g with Apgar scores of 7 and 8 was delivered; umbilical arterial pH was 7.17 and venous pH was 7.22. The uterine incision had not extended and was easily closed, and the baby did well.

operation after thorough counseling. Similarly, patient autonomy requires that practitioners document informed consent regarding TOLAC and attempt to enable women who desire TOLAC to achieve their goal. Korst and colleagues<sup>6</sup> have noted the reported high frequency of lack of informed consent regarding TOLAC-VBAC and have questioned the extent to which women are able to truly choose TOLAC as opposed to being dissuaded by the health care system. Because facilities, resources, and policies vary widely among health care institutions, it has been suggested that health care organizations and physicians consider making public their TOLAC policies and VBAC rates as well as their plans for responding to obstetric emergencies.<sup>10</sup> This transparency in data would no doubt help inform women

with prior cesarean deliveries in choosing both their planned approach to delivery and an appropriate facility for their childbirth.

Based on the available evidence, TOLAC should continue to remain an option for most women with a prior cesarean delivery, particularly when the low absolute risks that accompany TOLAC are considered. The attributable risk for a serious adverse perinatal outcome (perinatal death or HIE) at term appears to be about 1 per 2000 TOLACs. Combining an independent risk for hysterectomy attributable to uterine rupture at term with the risk for newborn HIE indicates the chance of one of these adverse events occurring to be about 1 in 1250 cases.

The decision to elect a TOLAC may also increase the risk for perinatal death and HIE unrelated to uterine rupture. For women awaiting spontaneous labor beyond 39 weeks, a small possibility of unexplained stillbirth exists that might have been avoidable had a scheduled repeat operation been performed at 39 weeks. A risk for fetal hypoxia and its sequelae may also accompany labor events unrelated to the integrity of the uterine scar. In the MFMU Network study,<sup>8</sup> five cases of non-rupture-related HIE occurred in term infants in the TOLAC group compared with none in the planned repeat cesarean population.

### Cost-Effectiveness of a Trial of Labor After Cesarean

Several investigators have assessed whether and under what circumstances TOLAC is a cost-effective strategy. An analysis by Grobman and colleagues<sup>74</sup> suggested that the choice of planned repeat cesarean delivery, instead of TOLAC, at the time of a second pregnancy prevented one major adverse neonatal outcome but required 1591 additional cesarean deliveries and cost an additional \$2.4 million per 100,000 women. Chung and associates<sup>75</sup> incorporated quality-adjusted life-years as the measure of effectiveness in their analysis and determined that TOLAC in a second pregnancy was cost-effective as long as the chance of VBAC exceeded approximately 74%.

The analysis by Chung and colleagues, however, did not account for the consequences in future pregnancies of the choice regarding the approach to delivery. Also, the analyses of both groups, Grobman's and Chung's, used summary point estimates from the observational studies in the literature, which as previously noted, may have been biased as a result of the nonrandom nature of the choice to attempt either TOLAC or planned repeat cesarean delivery. In a more recent analysis, Gilbert and colleagues<sup>76</sup> attempted to rectify both limitations by including probabilities of outcomes throughout a woman's reproductive life that were contingent upon her initial choice regarding TOLAC and by obtaining probability estimates directly from the MFMU Cesarean Registry that were derived from a propensity analysis. In this study, **TOLAC was found to be cost effective over a wide variety of circumstances, even when women had a probability of VBAC as low as 43%.**

### KEY POINTS

- ◆ VBAC rates have plummeted from a peak of approximately 30% in 1996 to 5% in 2010.
- ◆ Most women with a prior low transverse cesarean delivery are candidates for TOLAC and should be counseled about and offered this option.
- ◆ The success rate for TOLAC is influenced by prior indication for cesarean delivery, history of vaginal delivery, demographic characteristics such as maternal age and BMI, the occurrence of spontaneous labor, and cervical status at admission.
- ◆ Oxytocin may be used for induction, as well as augmentation, of labor in women undergoing TOLAC.
- ◆ The use of misoprostol for cervical ripening is contraindicated in women undergoing TOLAC.
- ◆ The most consistent sign associated with uterine rupture is fetal heart rate abnormalities that include prolonged variable decelerations and bradycardia.

*Placenta accreta* (PA) refers to different grades of morbid placental attachment to the uterine wall secondary to invasion of the trophoblast into the myometrium beyond the uteroplacental interface. The term *placenta increta* is used to describe deep myometrial invasion by trophoblast villi, and *placenta percreta* refers to villi perforating through the full thickness of the myometrium and uterine serosa with possible involvement of adjacent organs.<sup>1-3</sup> The difference between placenta accreta, increta, and percreta is related to the extent of invasion, and the umbrella term *disorders of invasive placental* is used to encompass all three (Fig. 21-1).

PA has also been categorized as total, partial, or focal depending on the amount of placental tissue involved. This subclassification has been used less frequently because microscopic examination of the hysterectomy specimen is rarely complete, and attempts at manual removal often distort the placental anatomy.<sup>2</sup> However, with increasing numbers of cases of PA being diagnosed antenatally, and with greater expertise in conservative therapeutic procedures, this classification might become more useful.

The first detailed description of a PA<sup>1</sup> appeared within 20 years of major changes in the surgical techniques for, and more common use of, cesarean delivery (CD). It was not reported by the prominent pathologists of the eighteenth and nineteenth centuries, which may indicate the direct relationship between the increased use of CD and morbid placental adherence.<sup>4</sup> Although PA remains a relatively uncommon

obstetric pathology, it has become a complication that an obstetrician with a practice of average volume is likely to encounter more commonly, compared with the once or twice in a lifetime encounter of two decades ago. PA has also become a major cause of life-threatening obstetric complications worldwide.

**When PA is present, the failure of the entire placenta to separate normally from the uterine wall after delivery is typically accompanied by severe postpartum hemorrhage (PPH; see Chapter 18).** Attempts to remove the adherent tissue may provoke further bleeding and a cascade of ongoing hemorrhage, shock, and coagulation disorders that require complex clinical management (Box 21-1). This chapter reviews the pathogenesis, epidemiology, antenatal diagnosis, and management of this obstetric disease.

## PATHOGENESIS

Unlike many other placental disorders—such as hydatidiform moles, which have been known for centuries—PA was only recently described, in 1937 by Irving and Hertig.<sup>1</sup> Before the nineteenth century, few successful attempts had been made at performing CDs.<sup>5</sup> CD was a surgical procedure of last resort, and the operation was essentially performed to save the baby's life. It is only when surgeons started to remove and subsequently to suture the uterus after delivery that the maternal death rate following CD started to improve. By the 1920s, the combination of surgical improvements by Kehrer (uterine closure), Pfannenstiel (suprapubic transverse entry), and Munro Kerr (lower segment uterine incision) and developments in anesthesia and microbiology had brought down the maternal mortality from 70% in the 1850s to less than 10%. The introduction of uterine agents, blood transfusions, and antibiotics just before and after the Second World War further reduced the complication rate of CD.<sup>5</sup> These changes made the technique safer and allowed mothers not only to survive the surgical procedure but also to have one or more subsequent pregnancies (see Chapter 19).

**Total or partial absence of decidua is the characteristic histologic feature of PA and is relatively clear cut in cases of implantation on a uterine scar.<sup>2</sup> This results in the absence of the normal plane of cleavage above the decidua basalis,**

**BOX 21-1 CRITERIA FOR THE DIAGNOSIS OF CLINICALLY SIGNIFICANT PLACENTA ACCRETA**

1. Placenta does not separate and is expelled spontaneously, fully, or partially after delivery of the baby.
2. Attempt at removal of the placenta leads to brisk hemorrhage.
3. Histopathology confirms myometrial fibers in apposition with trophoblasts at the suspected site of invasive placentation if partial or complete excision of the uterus has been performed.

**FIG 21-1** Uteroplacental relationships found with invasive placentation.

**thus preventing placental separation after delivery.** Myometrium does not actually heal by regenerating muscle fibers, rather it forms “foreign” substances, including collagen. The resulting fibrous tissue is weaker, less elastic, and more prone to injury than the original muscle. Myofiber disarray, tissue edema, inflammation, and elastosis have all been observed in uterine wound healing after surgery.<sup>6</sup> Experiments in mice have indicated that differences in regenerative ability translate into histologic, proliferative, and functional differences in biomechanical properties of the scarred myometrium after CD.<sup>7</sup>

Several concepts have been proposed to explain the abnormal placentation in PA including (1) a primary defect of trophoblast function; (2) a secondary decidua basalis defect as the result of a failure of normal decidualization; and, more recently, (3) abnormal vascularization and tissue oxygenation of the scar area.<sup>4</sup> The strongest risk factor for placenta previa is a prior cesarean delivery, which indicates that a failure of decidualization in the area of a previous uterine scar can have an impact on both implantation and placentation. These findings suggest that the decidual defect following a uterine scar may have an adverse effect on early implantation by creating conditions for preferential attachment of the blastocyst to scar tissue and facilitating abnormally deep invasion of the extravillous trophoblast.

**Comparison of the ultrasound features of the uterine cesarean scar with histologic findings has shown that large and deep myometrial defects are often associated with absence of reepithelialization of the scar area.**<sup>8</sup> These findings support the concept of a primary defect in PA, exposing the deep vasculature of the myometrium below the junctional zone to the migrating trophoblast. The loss of this normal plane of cleavage

**BOX 21-2 PRIMARY AND SECONDARY UTERINE PATHOLOGIES ASSOCIATED WITH PLACENTA ACCRETA****Primary Uterine Pathology**

Major uterine anomalies  
Adenomyosis  
Submucous uterine fibroids  
Myotonic dystrophy

**Secondary Uterine Pathology**

Cesarean delivery  
Uterine curettage  
Manual removal of the placenta  
Cavity-entering myomectomy  
Hysteroscopic surgery (endometrial resection)  
In vitro fertilization procedures  
Uterine artery embolization  
Chemotherapy and radiotherapy

and the excessive vascular remodeling of the radial and arcuate arteries can explain the antenatal findings and the clinical consequences of PA. A recent study<sup>9</sup> of the uterine circulation in women with a previous CD has shown that uterine artery resistance is increased, and the volume of uterine blood flow is decreased, as a fraction of maternal cardiac output compared with women with a previous vaginal birth. These data suggest a possible relationship between a poorly vascularized uterine scar area and an increase in the resistance to uterine blood flow with a secondary impact on reepithelialization of the scar area and subsequent decidualization. Overall, these data support the concept that abnormal decidualization and deep invasion of the placental bed by the trophoblast in PA are often secondary to the presence of a myometrial scar.<sup>4</sup>

Fragments of myometrium are found in the products of conception in approximately one third of uterine curettages after miscarriage.<sup>10</sup> The fact that it does not have a clear correlation with clinical PA in a subsequent pregnancy suggests that the trauma to the myometrium and the surface of the endometrial damage is often limited in a curettage procedure compared with that of a CD or other major uterine surgery. By contrast, severely deficient uterine scars with complete loss of large areas of the myometrium could explain rare reports of placenta percreta leading to uterine rupture in the first half of pregnancy.<sup>11-15</sup> Although this is an extremely rare complication of placentation, the mechanism of uterine rupture due to a placenta percreta is likely to be similar to that of a tubal rupture in an ectopic placentation. These findings emphasize the pivotal role of the superficial myometrium in modulating normal uterine placentation.

**EPIDEMIOLOGY**

Any primary or secondary alterations of the uterine endometrial-myometrial integrity have been associated with the development of PA. **With the rapid increase in the incidence of CD over the last several decades, this procedure has become associated with most cases of PA, whereas other factors are now responsible for a relatively small proportion of PA (Box 21-2).** CD is now the most commonly performed major operation around the world, with more than 1 million procedures performed each year in the United States alone (see Chapter 19). Not surprisingly, a substantial increase has been seen in the occurrence of PA over the last 50 years with as much as a tenfold rise in its

incidence in most Western countries. Studies in the United States have indicated an overall incidence of PA of approximately 1 in 533 deliveries.<sup>16,17</sup> A recent meta-analysis has shown a calculated summary odds ratio (OR) of 1.96 for PA after one CD.<sup>18</sup> A recent case-control study has shown that, compared with primary intrapartum CD, primary prelabor CD significantly increased the risk of PA in a subsequent pregnancy in the presence of placenta previa.<sup>19</sup> **Overall, the data from epidemiologic studies consistently indicate that prior CD is the most important factor associated with subsequent PA and that the risk of PA increases with the number of prior CDs.**

### Placenta Previa With Accreta

Epidemiologic studies have also indicated that **CD is associated with an increased risk of placenta previa** (see Chapter 18) in subsequent pregnancies.<sup>17,18,20,21</sup> A recent meta-analysis of five cohort and 11 case-control studies published between 1990 and 2011 revealed that after a CD, the calculated summary OR is 1.47 for placenta previa.<sup>18</sup> The risk of previa is higher with an increasing number of prior CDs.<sup>16</sup> Following a single CD, a 50% increase is seen in the risk of placenta previa in a subsequent singleton pregnancy. For women with two CDs, there is a twofold increase in the risk of placenta previa compared with women with a history of two vaginal deliveries.<sup>17</sup>

PA complicates about 5% of pregnancies with placenta previa.<sup>22</sup> The risk of PA in the setting of placenta previa increases with the number of prior CDs. Thus among women with placenta previa, 40% of those with two previous CDs and 61% of those with three prior CDs develop a PA.<sup>23</sup> This risk is independent of other maternal characteristics such as parity, body mass index (BMI), tobacco use, and coexisting hypertension or diabetes. It has been recently estimated that if the CD rate continues to rise as it has in recent years, by 2020, there will be an additional 6236 placenta previas, 4504 PAs, and 130 maternal deaths annually.<sup>22</sup>

### Cesarean Delivery Scar Defects

With the increasing use of transvaginal ultrasound, a uterine cesarean delivery defect (CDS), or “niche,” is a condition that has been described recently. Much of the focus has been on identifying ultrasound criteria of CDS during pregnancy that may indicate a higher risk of scar dehiscence and/or uterine rupture during a trial of labor after cesarean (TOLAC) in subsequent pregnancies.<sup>24</sup> Yet ultrasound imaging, including three-dimensional (3-D) imaging and sonohysterography, have been increasingly used to investigate uterine scars in nonpregnant women (Fig. 21-2). CDSs have been seen in between 20% and 65% of women undergoing transvaginal ultrasound with a previous CD.<sup>24-28</sup> A CDS is described as a tethering of the endometrium that can serve as a reservoir for blood and fluid, and it can be associated with clinical gynecologic symptoms such as intermenstrual and postmenstrual spotting and dysmenorrhea. A CDS may range from a small defect of the superficial myometrium to a larger defect with a direct communication between the endometrial cavity and the visceral serosa (Fig. 21-3). Studies have demonstrated that a history of multiple CDs and uterine retroflexion are significantly associated with larger CDSs, and larger CDSs are more likely to be associated with symptoms such as intermenstrual spotting and pelvic pain.<sup>25-27</sup>

A recent retrospective cohort study has shown that a clinically evident uterine scar dehiscence in a previous pregnancy is a potential risk factor for preterm delivery, low birthweight, and peripartum hysterectomy in the following pregnancy.<sup>28</sup>

**FIG 21-2** Transvaginal ultrasound view of the uterus in a 5-week pregnancy after two previous elective cesarean deliveries. Note the two small defects through the uterine wall at the junction between the lower and upper uterine segment corresponding to the scar (S) of the previous cesarean delivery incisions.

**FIG 21-3** Transvaginal ultrasound view of the uterus in a 6-week pregnancy after a previous emergency cesarean delivery. A large cesarean delivery scar defect (CDS) creates a niche at the junction between lower and upper uterine segment (arrow).

Interestingly, in this study, previous uterine scar dehiscence did not increase the risk of uterine rupture, PA, or adverse perinatal outcomes, such as low Apgar scores at 5 minutes and perinatal mortality. A recent series of 14 women (20 pregnancies) with a prior uterine rupture and 30 women (40 pregnancies) with a prior uterine dehiscence has shown that these women can have excellent outcomes in subsequent pregnancies if managed in a standardized manner, including CD before the onset of labor or immediately at the onset of spontaneous preterm labor.<sup>29</sup>

Theoretically, uterine scar surgical repair could prevent recurrent cesarean scar pregnancies and could also prevent PA (Fig. 21-4). A recent systematic review of studies reporting on hysteroscopic and laparoscopic CDS resection has found that abnormal uterine bleeding improved in the vast majority (i.e., 87% to 100%) of patients after these interventions.<sup>30</sup> However, the methodologic quality of the reviewed papers was considered to be moderate to poor, and therefore data were insufficient to make firm conclusions. Until surgical interventions are evaluated in a prospective trial, the benefits and efficacy of surgical repair when a CDS is observed should be considered unknown. A recent

**FIG 21-4** A 28-year-old gravida 4, para 1 patient with a history of prior low transverse cesarean delivery, presented for a routing ultrasound at 5-6 weeks' gestation. She had no complaints. The transvaginal ultrasound revealed a heterotopic pregnancy in the uterine scar (HP) and a normal intrauterine pregnancy (IUP). The bladder (B), endometrium (E), cervix (C), uterine fundus (F), and rectum (R) can be seen. The heterotopic pregnancy was surgically excised at laparotomy, and the pregnancy continued. (Courtesy Christopher Lang, MD, Maternal-Fetal Medicine, Mount Carmel St. Ann's Hospital, Columbus, Ohio.)

small retrospective study<sup>31</sup> found that the use of monofilament suture for hysterotomy closure at the time of CD significantly reduced the chance of having placenta previa in the subsequent pregnancy. However, these data have not been replicated, and there is a need for properly designed, quality randomized controlled trials (RCTs) with larger sample sizes to evaluate the impact of different suture materials on uterine scar defects and risk of uterine rupture during TOLAC and on the development of placenta previa/accreta in subsequent pregnancies.

## PRENATAL DIAGNOSIS

Before the development of newer imaging techniques, it was not possible prenatally to assess the depth of placental invasion or, in many cases, to even assess the existence of a PA. Consequently, many publications on PA report what can be considered a mixture of the conditions of accreta, increta, and percreta as well as antenatally suspected and pathologically diagnosed PA, which makes it difficult to assess the results of management for each individual pathologic entity and clinical situation. At present, however, prenatal diagnosis of PA has become a useful tool for a better understanding of the pathophysiology of an abnormally adherent placenta and its appropriate management.

### Ultrasound Imaging

Ultrasound has become the primary screening tool for women at risk of PA. Gray-scale ultrasound features suggestive of PA include the loss of the myometrial interface or retroplacental clear space, reduced myometrial thickness, and chaotic intraplacental blood flow and intraplacental lacunae (Figs. 21-5 to 21-8). *Placenta increta* may be suggested by an examination of the border between the bladder and myometrium, which is normally echogenic and smooth.<sup>4</sup> In *placenta percreta*, the placenta often is seen bulging into the bladder. In rare cases, frank placental invasion into the bladder, which appears as exophytic masses, can be seen.

Much attention has been focused on the presence of "intraplacental lacunae" as a marker of PA.<sup>15</sup> These sonoluculent spaces

**FIG 21-5** Transabdominal grayscale ultrasound longitudinal view of the lower uterine segment at 10 weeks' gestation in a patient with placenta previa major covering the cervix. The basal plate is missing, over an area of 3 cm in diameter, and the placental tissue above it is distorted by a large intervillous lake or lacuna.

**FIG 21-6** Transvaginal grayscale ultrasound longitudinal view of the lower uterine segment at 22 weeks' gestation in a patient with placenta previa major covering the cervix. The basal plate is missing, and the placental anatomy is distorted by large intervillous lakes, or lacunae, which gives the placenta a "moth-eaten" appearance.

contain slow-moving maternal blood on gray-scale imaging and have been described as intraplacental "lakes."<sup>21</sup> The mere presence of some lacunae, however, does *not* signify the presence of a PA. When they involve a small area of the placenta or are found in an area of low villous tissue density, such as in the center of the cotyledons or under the chorionic plate, these lakes may be normal variants and have no clinical significance. Conversely, when a PA is present, the lacunae are extensive and create a "moth-eaten" appearance of the placenta (see Figs. 21-5 and 21-6).

The most common sonographic finding associated with PA is the loss of myometrial interface with enlargement of the underlying uterine vasculature.<sup>32</sup> The addition of color or power Doppler evaluation has been valuable in improving the screening capacity of ultrasound for PA.<sup>32-40</sup> Doppler features that suggest PA include chaotic intraplacental blood flow, the presence of increased blood flow in the retroplacental space, and aberrant vessels crossing between placental surfaces (see Figs. 21-7 and 21-8). In at-risk women, gray-scale ultrasound is moderately sensitive (70% to 90%), although this sensitivity may be

**FIG 21-7** Transabdominal color mapping ultrasound longitudinal view of the lower uterine segment at 20 weeks' gestation in a patient with anterior placenta previa covering the cervix after previous cesarean delivery and a delivery defect detected before pregnancy showing chaotic intraplacental blood flow, the presence of altered blood flow in the retroplacental space, and aberrant vessels crossing between placental surfaces.

**FIG 21-8** Transabdominal color mapping ultrasound longitudinal view of the lower uterine segment at 38 weeks' gestation in a patient with anterior placenta previa after previous cesarean delivery showing the presence of altered blood flow in the retroplacental space and aberrant vessels crossing between placental surfaces. improved by color flow mapping. A recent meta-analysis<sup>41</sup> of 22 studies that included a total of 3641 pregnancies at risk of invasive placentation indicated that the overall sensitivity of ultrasound in diagnosing PA antenatally is around 90%. Quality assessment of the studies showed that the study quality was generally high. The negative predictive value (NPV) of other recent studies ranged between 95% and 100% (Box 21-3). However, not all studies have yielded sensitivities and specificities that were quite as high. For example, a recent prospective study<sup>40</sup> has shown that the sensitivity, specificity, positive predictive value (PPV), and NPV were 53.5%, 88.0%, 82.1%, and 64.8%, respectively. Moreover, it should be noted that most of these values come from studies of high-risk women, and the predictive values among lower risk women (e.g., those without a placenta previa) would be expected to be lower.

**FIG 21-9** Transabdominal color mapping ultrasound longitudinal view of the lower uterine segment at 12 weeks' gestation in a patient with anterior low-lying placenta after previous cesarean delivery showing dilated uteroplacental vessels but no disruption of the basal plate.

### BOX 21-3 PERFORMANCE OF ULTRASOUND IN THE PRENATAL DETECTION OF PLACENTA ACCRETA IN 3641 PREGNANCIES AT RISK FOR ABNORMALLY INVASIVE PLACENTATION

#### Presence of Lacunae

Sensitivity: 77.8% (95% CI, 70.7-83.6)

Specificity: 96.5% (95% CI, 95.6-97.1)

#### Loss of Hypoechoic Space Between Myometrium and Placenta

Sensitivity: 63.9% (95% CI, 55.1-71.9)

Specificity: 97.3% (95% CI, 96.6-97.9)

#### Color Doppler Imaging

Sensitivity: 91.2% (95% CI, 87.2-96.7)

Specificity: 91.9% (95% CI, 88.8-94.2)

#### Ultrasound Overall

Sensitivity: 90.8% (95% CI, 87.0-93.5)

Specificity: 96.9% (95% CI, 96.2-97.4)

Positive predictive value: 74.8% (95% CI, 70.2-78.8)

Negative predictive value: 99.0% (95% CI, 98.6-99.3)

CI, confidence interval.

Modified from D'Antonio F, Iacovella C, Bhide A. Prenatal identification of invasive placentation using ultrasound: systematic review and meta-analysis. *Ultrasound Obstet Gynecol.* 2013;42:509-517.

Disruption of the normal appearance of continuous color flow that results in a gap in myometrial blood flow can also be seen in cases of PA. This gap represents the site of placental invasion into the myometrium and can be diagnosed as early as the first trimester of pregnancy.<sup>42-46</sup> Within this context, it is possible that the suspicion for PA may even be heightened (see Fig. 21-5) or lessened (Fig. 21-9) at the time of an ultrasound examination at 11 to 14 weeks of gestation.<sup>47</sup>

In cases of a placenta in the lower segment, a transvaginal scan will help evaluate the uteroplacental interface near the internal os of the uterine cervix, and it may assist in assessing the degree of placental invasion.<sup>48,49</sup> For example, the degree of excess vascularity of the lower uterine segment assessed by ultrasound

**FIG 21-10** **A**, Sagittal magnetic resonance image (MRI) with the fetus (F) in vertex position at 25 weeks' gestation. The placenta (P) is anterior and low lying with loss of the normal myometrial dark signal. Prominent vessels (arrow) between the uterus and the bladder (B) are concerning for involvement of the bladder wall by placenta percreta. **B**, Axial MRI demonstrates placental tissue (P) abutting the left posterior aspect of the urinary bladder (B) with loss of the dark myometrial signal, preserved on the right side of the placenta (arrow). Findings are suggestive of invasion of the bladder by placenta percreta. Abnormal placentation was confirmed on pathologic examination. correlates with disease severity.<sup>50</sup> A recent study using logistic regression modeling has shown that the use of formal mathematical modeling to predict PA may have a better PPV than qualitative assessment of ultrasound alone.<sup>51</sup> Therefore **integrating PA screening into the 11- to 14-week and/or midgestation obstetric ultrasound examination of women with a previous cesarean scar who present with a low anterior placenta can be helpful in the management of PA.**

### Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has recently been introduced as a tool that can be used to evaluate the possibility of PA. Controversy exists as to its usefulness, although some authors have suggested that MRI is better than ultrasound in defining areas of abnormal placentation and assessing the depth of myometrial invasion, particularly in cases of posterior placentae (Fig. 21-10).<sup>52-54</sup> A recent meta-analysis of 18 studies that involved

1010 pregnancies at risk for invasive placentation has indicated that the sensitivity and specificity of MRI in diagnosing PA antenatally were 94.4% and 84.0%, respectively.<sup>55</sup> MRI was also useful in assessing both the depth and topography of placental invasion (Table 21-1). Focal interruption of the myometrium and the presence of dark intraplacental bands on T2-weighted sequences showed the best sensitivity (92.0%), whereas tenting of the bladder and uterine bulging had the best specificity (98.6%). The prevalence of PA in the cohort under review was nearly 75%, which suggests that women included in these studies were highly selected and at very high risk. Therefore, the diagnostic accuracy of MRI in a more general population is difficult to ascertain, and it has not yet been shown that the addition of MRI to ultrasound results in improved clinical outcomes.

Studies that have compared MRI and ultrasound have not found a consistent difference in either the sensitivity or the specificity for the diagnosis of PA between the two techniques.

However, in several of these studies, MRI was carried out only on a proportion of women referred for ultrasound, and in most of the studies to assess the diagnostic performance of MRI, the radiologists were not blinded to the ultrasound findings.<sup>55</sup> Thus the value of MRI used alone without knowledge of sonographic findings is uncertain. This issue may not be of great relevance in clinical practice, where MRI images are often read with the knowledge of ultrasound findings.

Large population-based studies are needed to assess what MRI can add to ultrasound in predicting the depth and topography of placental invasion. Even if MRI may be able to add information in some limited instances, the cost and limited access of MRI compared with ultrasound makes it an impractical screening technique for PA in routine clinical practice.

## MANAGEMENT

The majority of women with PA will also present with a placenta previa and are therefore at a substantial risk of bleeding and preterm delivery. Each episode of antenatal vaginal bleeding is associated with an increased risk of unscheduled delivery.<sup>56</sup> Therefore antenatal corticosteroid injections to advance fetal lung maturity should be timed according to the maternal symptoms and need for delivery. A decision analysis suggested that **delivery at approximately 34 weeks of gestation among women with a placenta previa and suspected PA, even without confirmation of fetal lung maturity, was the gestational age associated with optimal overall maternal and perinatal outcomes.**<sup>57</sup>

The worst clinical outcomes arise when PA is unsuspected at the time of delivery and the operator attempts to remove the adherent villous tissue.<sup>58</sup> **Women with placenta accreta, increta, or percreta for whom no attempt is made to remove any part of their placenta have reduced levels of hemorrhage and a reduced need for blood transfusion.**<sup>59,60</sup> When the presence of a PA is suspected, careful preoperative planning can minimize maternal morbidity. Thus attempted prenatal diagnosis of morbidly adherent villous tissue is pivotal in the management of PA. Nevertheless, it should be recognized that sonography and MRI are screening tests, and no diagnostic imaging techniques exist that can always be relied on.

Clear clinical evidence shows that **women with PA managed by a multidisciplinary care team, compared with standard obstetric care, are less likely to require large-volume blood transfusion and reoperation within 7 days of delivery for bleeding complications.** They are also less likely to experience prolonged admission to the intensive care unit, and they have less coagulopathy and fewer urinary tract injuries.<sup>60-63</sup> Referral of all women diagnosed antenatally with PA to a tertiary care center with experience in the management of PA and use of a multidisciplinary care team is therefore recommended by professional organizations, including the American College of Obstetricians and Gynecologists (ACOG), the American Society of Anesthesiologists (ASA), the Royal College of Anesthetists (RCA), and the Royal College of Obstetricians and Gynaecologists (RCOG).

Over the last decade, conservative management has been described in which the placenta is left in situ in the uterus after delivery of the neonate. **The main aim of conservative management of PA is to reduce operative injury and blood loss and to increase the chance that a hysterectomy can be avoided.** Often adjuvant procedures, including uterine artery embolization, are performed by interventional radiology.<sup>64,65</sup> These

**TABLE 21-2 PREPARATION FOR SURGICAL MANAGEMENT OF PLACENTA ACCRETA**

| INTERVENTION                   | COMMENT   |
|--------------------------------|---|
| Treatment at a referral center | Availability of multidisciplinary team that includes pelvic surgeons, anesthesiologist, vascular/trauma surgeons, interventional radiologist, neonatologist |
| Preoperative imaging           | Ultrasound evaluation of placenta   |
| Timing of delivery             | Approximately 34 weeks (with placenta previa)   |
| Delivery location              | Consider main OR or have all available equipment on labor and delivery. OR staff must be trained in advanced pelvic surgical procedures.                    |
| Anesthesia                     | Consider general anesthesia.  |
| Vascular access                | Central line, arterial line   |
| Ureteral stents                | Consider retrograde ureteral stent placement prior to laparotomy.   |
| Cell salvage                   | Cell salvage availability   |
| Rapid infusion                 | Availability of rapid infusion device   |
| Interventional radiology       | Consider catheter placement for uterine artery embolization and/or balloon occlusion catheter placement.  |
| Blood bank preparedness        | Packed red cells (10-20 U), fresh frozen plasma (10-20 U), platelets (12 U)   |
| Uterine incision               | Fundal or posterior hysterotomy as needed to avoid placental disruption   |

OR, operating room.

attempts, however, also have been associated with instances of significant delayed bleeding and infection. Consequently, the role of adjuvant procedures in the management of PA remains uncertain. RCTs and large cohort studies to compare primary surgical management and conservative management of placenta accreta are lacking. Management decisions must account for the hemodynamic status of the patient, the desire to preserve fertility, and the resource availability and expertise (Table 21-2; see also Table 21-1).

## Surgical Management

**Hysterectomy remains the most commonly performed procedure for the control of PPH** (see Chapter 20). When massive bleeding is anticipated, appropriate equipment for major gynecologic surgery should be available in the operating room, including a self-retaining retractor and instrumentation to perform a major laparotomy. In many tertiary care centers, these surgeries are performed in the main operating room, as opposed to in the labor and delivery units, to ensure the availability of appropriate equipment; nursing staff trained in advanced abdominal surgery; a multidisciplinary team of surgeons, obstetric anesthesiologists, and interventional radiologists; and blood bank support.<sup>66</sup>

**Prior to skin incision, blood products should be made available; this includes red blood cells, fresh frozen plasma, and platelets if possible** (see Chapter 18). Early blood product replacement with consideration given to volume, oxygen-carrying capacity, and coagulation factors can reduce perioperative complications. Autologous transfusion of salvaged red cells can be used to minimize transfusion of banked blood in women undergoing cesarean hysterectomy.<sup>67</sup> When transfusion is required, infusion of adequate platelets and fresh-frozen plasma in relation to red blood cells (often a 1:1 ratio) has been associated with improved outcomes in cases of trauma, although this strategy has not been evaluated in cases of PA.<sup>68,69</sup> Regional anesthesia may limit the ability to manipulate the abdominal contents for retractor placement; therefore general anesthesia may be preferable for patients with a high risk of requiring a hysterectomy and in cases of placenta percreta that involves

the bladder or the bowel. Prior to initiation of the surgical procedure, adequate vascular access should be ensured. This often includes central venous access as well as an arterial line. The availability of a rapid infusion device to rapidly reinstall blood products is essential if massive blood loss ensues (see Table 21-2).

**The role of interventional radiology at the time of primary CD and hysterectomy remains uncertain.** As described below, uterine artery embolization catheters can be placed preoperatively, and balloon occlusion catheters in the internal iliac vessels can be considered. Although these techniques may facilitate hemostasis in some women, both interventions carry risks.

Once the abdomen has been entered, the entire pelvis is inspected. The most common site of placental invasion is through the anterior uterine wall, but the placenta may invade laterally and may encroach upon the parametrium. Lateral placental invasion may hinder identification of the ureters and make isolation of the uterine vasculature difficult.<sup>66,70</sup> The myometrium under and around the abnormally implanted villous tissue is typically very thin and friable, and it is surrounded by dilated vascular channels (Fig. 21-11). The placental location may be mapped out with sonography and the uterine incision site chosen, preferably away from the placenta. This approach may require a fundal or even posterior uterine wall incision, which can be technically challenging and may result in a delay in delivery of the fetus, which highlights the importance of an attempt to accurately diagnosis PA to avoid unnecessarily exposing mothers without PA and their newborns to surgical procedures with a high perioperative morbidity.<sup>71</sup>

If a hysterectomy is required, it can be performed after closing the uterine incision. After the hysterotomy has been closed, the

round ligament is divided and the retroperitoneum is opened widely. The ureters are visualized, the uteroovarian ligaments are divided, and the ovaries are packed away. The vesicouterine peritoneum is then gently opened, and the bladder is dissected away from the uterus to the extent possible without placental disruption. The uterine artery and its collateral channels are then ligated, again attempting to avoid disrupting the wall of the uterus if it is thinned and friable.<sup>70</sup>

Placement of clamps along the lateral wall of the uterus can result in disruption of the placenta and can lead to significant bleeding. To limit bleeding, the surgeon can attempt to ligate other vasculature running to the uterus.<sup>66,70</sup> The use of ancillary procedures such as prophylactic ligation of the internal iliac artery is of little benefit because of the extensive collateral circulation. After the major vascular channels are divided, dissection should be continued until below the placental tissue; this typically requires additional dissection of the plane between the bladder and uterus/placenta. It is sometimes necessary to perform a cystotomy to fully separate the bladder from the uterus.

Given that PA often occurs in the context of placenta previa, removal of the entire cervix is often required to obtain hemostasis. Placement of a ring forceps on the cervix has also been described to facilitate the identification of the cervix and to limit vaginal blood loss.<sup>72</sup> After the uterus and placenta have been completely removed, the entire pelvis should be reinspected. Multiple, small vascular channels often run along the posterior wall of the bladder, and these must be cauterized or ligated to limit bleeding.

**The genitourinary tract is at substantial risk for injury during these procedures.**<sup>66</sup> Bladder and ureteral injuries are relatively common. If the villous tissue invades into the parametrium, ureteral identification can be difficult. **Retrograde ureteral stents can be placed via cystoscopy to facilitate ureteral identification.** These can be placed after induction of anesthesia and prior to opening the abdomen. Data are limited on the use of ureteral stents to reduce the risk of ureteral injury; therefore further evaluation is required before considering routine use for all women with PA.

Postoperatively, febrile complications and bowel dysfunction are relatively frequent. Reoperation is required in up to one third of women who undergo peripartum hysterectomy.<sup>66</sup> Among women who require reexploration, approximately three quarters require the procedure to control bleeding. The remainder are mostly done to repair operative injuries, mainly of the genitourinary tract.

### Conservative Management

The surgical approach to management of PA is associated with significant maternal morbidity, even when carried out in a tertiary center by an experienced multidisciplinary team.<sup>73</sup> Within this context, conservative (uterine-sparing) approaches for the management of PA have been described. **The conservative surgical approach often involves the use of a fundal/classical incision to deliver the fetus without disturbing the placenta. The uterine incision is closed after delivery, and the placenta is left in situ.** This approach has been combined with additional procedures such as uterine artery embolization, methotrexate therapy, hemostatic sutures, pelvic devascularization, and balloon tamponade with varying rates of success reported in case reports or series (Table 21-3; see Chapter 18).

Few data are available to help select which patients are best served with conservative management and which form of conservative management, if any, is preferable. Routine use of

**FIG 21-11** Intraoperative view of placenta accreta in the patient from Figure 21-6 shows part of the placentation site. The uterine wall is almost transparent, and an area of the abnormally implanted villous tissue is very thin and friable and surrounded by dilated vascular channels. (Courtesy Dr. Edwin Chandrarahan, St. George's University Hospital Foundation Trust.)

**TABLE 21-3** PREPARATION FOR CONSERVATIVE MANAGEMENT OF PLACENTA ACCRETA

| INTERVENTION                 | COMMENT   |
|------------------------------|---|
| Treatment at referral center | Availability of multidisciplinary team including pelvic surgeons, anesthesiologist, vascular/trauma surgeons, interventional radiologist, neonatologist |
| Preoperative preparation     | Preparation as above for primary surgical management if bleeding ensues   |
| Delivery location            | Consider main OR or have all available equipment on labor and delivery. OR staff must be trained in advanced pelvic surgical procedures.                |
| Interventional radiology     | Preoperative uterine artery catheter placement for uterine artery embolization  |
| Vascular access              | Central line, arterial line   |
| Uterine incision             | Fundal or posterior hysterotomy as needed to avoid placental disruption   |
| Blood bank preparedness      | Packed red cells (10-20 U), fresh frozen plasma (10-20 U), platelets (12 U)   |

OR, operating room.

methotrexate in conservatively managed patients is no longer advocated because it has shown little benefit in enhancing placental reabsorption and can be associated with life-threatening complications.<sup>60,66,74</sup> By contrast, in case series, conservative management combined with pelvic artery embolization has been associated with success rates that range between 85% and 95%.<sup>75</sup> Other more controversial approaches to uterine conservation have also been described. A protocol that consists of preventive radiologic catheterization of the descending aorta, CD, use of Affronti endouterine square hemostatic sutures, and placement of an intrauterine Bakri balloon in conjunction with B-Lynch suture was successfully performed in nine women with placenta previa and PA.<sup>76</sup> More recently, a “Triple-P procedure” was described in four women with placenta percreta.<sup>77</sup> With this technique, the uterine blood supply is reduced with arterial balloon occlusion catheters, the myometrial wall underlying the placental bed is excised, and the defect is closed. A recent review of 119 cases of placenta percreta noted that local resection, compared with hysterectomy or leaving the placenta in situ, was associated with fewer complications within 24 hours postoperatively.<sup>78</sup> Nevertheless, the data about conservative techniques are derived from case reports and series, and the number of women managed with these various conservative techniques is small. In addition, evidence suggests that conservative management is associated with severe long-term complications of hemorrhage and infection, which includes a 58% risk of delayed hysterectomy. Therefore when conservative management is chosen, follow-up should include ultrasound to assess the spontaneous or induced regression of placental tissue as well as careful monitoring of the patient’s signs (e.g., temperature) and symptoms. Human chorionic gonadotropin (hCG) levels have not been shown to correlate with the rate of placental resorption.

Pelvic artery embolization performed using minimally invasive interventional radiology techniques has been demonstrated in some but not all reports to reduce intraoperative blood loss, the need for transfusion, and hysterectomy.<sup>66,79,80</sup> After delivery, embolization can be performed either in the operating room or in an interventional radiology suite.<sup>66,75</sup> Pelvic artery embolization is also useful in women who continue to bleed after hysterectomy. However, complications of embolization include thrombosis and necrosis of embolized tissue.

The second interventional radiologic modality that may be of use in women with PA is the placement of intraarterial balloon occlusion catheters.<sup>66,81,82</sup> Occlusion catheters contain small balloons that can be inflated to occlude the lumen of a vessel. Balloon occlusion catheters can be placed under fluoroscopic guidance prior to hysterectomy, and placement within the internal iliac artery is the most common site. At the time of hysterectomy, the balloons can be inflated either prophylactically or only after heavy bleeding is encountered.

Both embolization and balloon occlusion incur risks that include thrombosis, tissue necrosis, and vascular dissection. Accordingly, **the utility of embolization and balloon occlusion catheters remains controversial, and it has not been demonstrated that the routine use of these interventions has benefits that outweigh the risks.**

### Reproductive Outcomes Following Placenta Accreta

Although data are limited, conservative treatment for PA may be followed by a subsequent pregnancy,<sup>83</sup> although that subsequent pregnancy **is at increased risk for adverse maternal outcomes that include recurrent PA, uterine rupture, PPH, and peripartum hysterectomy.**<sup>84-87</sup> Estimated risks have been reported for recurrent PA (22%<sup>87</sup> to 29%<sup>84</sup>), early PPH (8.6%<sup>85,87</sup>), uterine rupture (3.3%), peripartum hysterectomy (3.3%), and blood transfusions (16.7%).<sup>84</sup> Long-term complications include intrauterine synechiae and secondary amenorrhea.<sup>83</sup>

### SUMMARY

*Placenta accreta* (PA) refers to different grades of morbid placental attachment to the uterine wall secondary to deep invasion of villous tissue into the myometrium. Although any primary or secondary alterations of the uterine endometrial-myometrial integrity have been associated with the development of PA, the rapid increase in the frequency of CD over the last several decades has led to PA becoming an increasingly common obstetric complication. The failure of the entire placenta to separate normally from the uterine wall after delivery in PA is typically accompanied by severe PPH. Therefore accurate prenatal diagnosis is important in the outcome of PA, and along with planned management of the condition through the use of a multidisciplinary team, this has been associated with a reduced rate of maternal morbidity. Women diagnosed antenatally with PA should be referred to a tertiary care center and managed by a multidisciplinary team that includes surgeons, obstetric anesthesiologists, interventional radiologists, and hematologists.

### KEY POINTS

- ◆ Prior CD is the most important factor associated with PA, and the risk of PA increases with the number of prior CDs.
- ◆ All women with placenta previa who have had a previous CD are at risk of PA, and each additional CD is associated with an increased risk of PA.

- ◆ Suspected PA on prenatal imaging allows planned management of the condition and has been associated with a reduced rate of maternal morbidity.
- ◆ Ultrasound imaging is superior to MRI for routine screening of PA in at-risk women, but the degree of invasion to adjacent pelvic tissues and organs may be better ascertained with MRI.
- ◆ The optimum time for planned delivery for a woman with suspected PA and placenta previa is approximately 34 weeks, following a course of corticosteroid injections.
- ◆ When a PA is suspected, it is best to avoid disturbing the placenta and to leave it attached at the time of cesarean delivery.
- ◆ Women diagnosed antenatally with PA should be referred to a tertiary care center and managed by a multidisciplinary team that includes surgeons, obstetric anesthesiologists, interventional radiologists, and hematologists.
- ◆ The role of interventional radiology at the time of primary cesarean delivery and hysterectomy remains uncertain.
- ◆ A pregnancy following a previous PA that was treated with conservative management is at increased risk for adverse maternal outcomes such as recurrent PA, uterine rupture, PPH, and peripartum hysterectomy.

The first 4 weeks of an infant's life, the neonatal period, are marked by the highest mortality rate in all of childhood. The greatest risk occurs during the first several days after birth. Critical to survival during this period is the infant's ability to adapt successfully to extrauterine life. During the early

hours after birth, the newborn must assume responsibility for thermoregulation, metabolic homeostasis, and respiratory gas exchange and must also undergo the conversion from fetal to postnatal circulatory pathways. This chapter reviews the physiology of a successful transition as well as the

implications of circumstances that disrupt this process. Implicit in these considerations is the understanding that the newborn reflects the sum total of its genetic and environmental past, which includes any minor or major insults to which it was subjected during gestation and parturition. The period of neonatal adaptation is then most meaningfully viewed as continuous with fetal life.

## CARDIOPULMONARY TRANSITION

### Pulmonary Development

Lung development and maturation require a carefully regulated interaction of anatomic, physiologic, and biochemical processes. The outcome of these events provides an organ with adequate surface area, sufficient vascularization, and the metabolic capability to sustain oxygenation and ventilation during the neonatal period. **Five stages of morphologic lung development have been identified in the human fetus<sup>1</sup>:** (1) the *embryonic period*, from 0 to 6 weeks postconception; (2) the *pseudoglandular period*, from 6 to 16 weeks; (3) the *canalicular period*, from 16 to 24 weeks; (4) the *saccular period*, from 24 to 38 weeks; and (5) the *alveolar period*, from 36 weeks' gestation to 2 years of age.

The lung arises as a ventral diverticulum from the foregut during the fourth week of gestation, in the *embryonic period*. During the ensuing weeks, in the *pseudoglandular period*, branching of the diverticulum occurs and forms a tree of narrow tubes with thick epithelial walls composed of columnar cells. Molecular mechanisms involved in lung development include expression of transcription factors important for specification of the foregut endoderm, endogenous secretion of polypeptides important for pattern formation, and the production of growth and differentiation factors critical to cell development. By 16 weeks, the conducting portion of the tracheobronchial tree up to and including the terminal bronchioles has been established. The vasculature derived from the pulmonary circulation develops concurrently with the conducting airways, and by 16 weeks, preacinar blood vessels are formed. The *canalicular period* is characterized by differentiation of the airways, with widening of the airways and thinning of epithelium. In addition, primitive respiratory bronchioles begin to form, marking the start of the gas-exchanging portion of the lung. Vascular proliferation continues, along with a relative decrease in mesenchyme, which brings the vessels closer to the airway epithelium. The *saccular period* is marked by the development of the gas-exchanging portion of the tracheobronchial tree (acinus) composed of respiratory bronchioles, alveolar ducts, terminal saccules, and finally, alveoli. During this stage, the pulmonary vessels continue to proliferate with the airways and surround the developing air sacs. The final phase of prenatal lung development, the *alveolar period*, is marked by the formation of thin secondary alveolar septa and the remodeling of the capillary bed.

Throughout these periods, mesenchymal and epithelial cell cross-talk directs the normal processes of lung alveolarization and vascularization.<sup>2</sup> **Several million alveoli will form before birth, which emphasizes the importance of the last few weeks of pregnancy to pulmonary adaptation.** Postnatal lung growth is characterized by generation of alveoli, and over 85% of alveolarization takes place after birth.<sup>1</sup>

**The critical determinants of extrauterine survival are the formation of the thin air-blood barrier and production of surfactant.** By birth, the epithelial lining of the gas-exchanging

surface is thin and continuous with two alveolar cell types: *type I cells* are thin and contain few subcellular organelles, whereas *type II cells* contain subcellular organelles that aid in the production of surfactant (Fig. 22-1). Surfactant lipids and surfactant proteins B and C are secreted by exocytosis as lamellar bodies and unravel into tubular myelin. The other surfactant proteins (SPs), SP-A and SP-D, are secreted independently of the lamellar bodies. Tubular myelin is a loose lattice of phospholipids and surfactant-specific proteins. The surface active component of surfactant then adsorbs at the alveolar interface between air and water in a monolayer. With repetitive expansion and compression of the surface monolayer, material is extruded that is either cleared by alveolar macrophages through endocytic pathways or is taken up by the type II cell for recycling back into lamellar bodies.<sup>3</sup>

**Because of the development of high surface forces along the respiratory epithelium when breathing begins, the availability of surfactants in terminal airspaces is critical to postnatal lung function.** Just as surface tension acts to reduce the size of a bubble in water, it also acts to reduce lung inflation, which promotes atelectasis. This is described by the Laplace law, which states that within a sphere the pressure ( $P$ ) is directly proportional to surface tension ( $T$ ) and is inversely proportional to the radius ( $r$ ) of curvature (Fig. 22-2). **Surfactant has the physical property of variable surface tension dependent on the degree of surface area compression. In other words, as the radius of the alveolus decreases, surfactant serves to reduce surface tension, which prevents collapse of the alveolus.** If this property is extrapolated to the lung, smaller alveoli will remain more stable than larger alveoli because of their lower surface tension. This feature is emphasized in Figure 22-3, which compares pressure-volume curves from surfactant-deficient and surfactant-treated preterm rabbits. **Surfactant deficiency is characterized by high opening pressure, low maximal lung volume, and lack of deflation stability at low pressures.**

**Natural surfactant contains mostly lipids, phospholipids specifically, and some protein (Fig. 22-4).<sup>3</sup> Approximately half of the protein is specific for surfactant.** The principal classes of phospholipids are:

- Saturated phosphatidylcholine compounds, the surface tension-reducing component of surfactant, 45%—more than 80% of which is dipalmitoylphosphatidylcholine (DPPC)
- Unsaturated phosphatidylcholine compounds, 25%
- Phosphatidylglycerol, phosphatidylinositol, and phosphatidylethanolamine, 10%

Saturated phosphatidylcholine is found in lung tissue of the human fetus earlier in gestation than in other species. Surfactant is released from storage pools into fetal lung fluid at a basal rate during late gestation and is stimulated by labor and the initiation of air breathing. Four unique surfactant-associated proteins have been identified, and all are synthesized and secreted by type II alveolar cells. **Surfactant protein A (SP-A)** functions cooperatively with the other surfactant proteins and lipids to enhance the biophysical activity of the surfactant, but its most important role is in the innate host defense of the lung. **SP-B and SP-C** are lipophilic proteins that facilitate the adsorption and spreading of lipid to form the surfactant monolayer. SP-B deficiencies are associated with neonatal pulmonary complications and death, whereas SP-C deficiencies are associated with interstitial lung disease that presents at a more variable age. **SP-D** plays a

**FIG 22-1** Metabolism of surfactant. Surfactant phospholipids are synthesized in the endoplasmic reticulum, transported through the Golgi apparatus to multivesicular bodies, and finally packaged in lamellar bodies. After lamellar body exocytosis, phospholipids are organized into tubular myelin before aligning in a monolayer at the air-fluid interface in the alveolus. Surfactant phospholipids and proteins are taken up by type II cells and are either catabolized or reused. Surfactant proteins are synthesized in polyribosomes and are modified in endoplasmic reticulum, Golgi apparatus, and multivesicular bodies. (Modified from Whitsett JA, Pryhuber GS, Rice WR, et al. Acute respiratory disorders. In Avery GB, Fletcher MA, MacDonald MG [eds]: *Neonatology: Pathophysiology and Management of the Newborn*, 5th ed. Philadelphia: Lippincott, Williams & Wilkins; 1999:485.)

**FIG 22-2** Laplace's law. The pressure ( $P$ ) within a sphere is directly proportional to surface tension ( $T$ ) and is inversely proportional to the radius of curvature ( $r$ ). In the normal lung, as alveolar size decreases, surface tension (*thin arrows*) is reduced because of the presence of surfactant. This serves to decrease the collapsing pressure that must be opposed and maintains equal pressures in the small and large interconnected alveoli. (Modified from Netter FH. *The Ciba Collection of Medical Illustrations. The Respiratory System*, Vol 7. Summit, NJ: Ciba-Geigy; 1979.)

**FIG 22-3** Pressure-volume relationships for the inflation and deflation of surfactant-deficient and surfactant-treated (red line) preterm rabbit lungs. Surfactant deficiency (black line) is indicated by high opening pressure, low maximal volume at a distending pressure of 30 cm of water, and lack of deflation stability at low pressures on deflation. (Modified from Jobe AH. Lung development and maturation. In Fanaroff AA, Martin RJ [eds]: *Neonatal-Perinatal Medicine: Diseases of the Fetus and Infant*, 7th ed. St. Louis: Mosby; 2002:973.)

**FIG 22-4** Composition of pulmonary surfactant. SP, surfactant protein. (Modified from Jobe AH. Lung development and maturation. In Fanaroff AA, Martin RJ [eds]: *Neonatal-Perinatal Medicine: Diseases of the Fetus and Infant*, 7th ed. St. Louis: Mosby; 2002:973.)

role in the regulation of surfactant lipid homeostasis, inflammatory responses, and host defense mechanisms.<sup>3</sup>

Several hormones and growth factors contribute to the regulation of pulmonary phospholipid metabolism and lung maturation: glucocorticoids, thyroid hormone, thyrotropin-releasing hormone, retinoic acid, epidermal growth factor, and others. **Glucocorticoids are the most important and are used clinically to augment the synthesis of surfactant and accelerate morphologic development.**<sup>4</sup> Pregnant women with anticipated preterm delivery have received corticosteroid treatment since 1972. Numerous controlled trials have since been performed. Based on a meta-analysis,<sup>5</sup> **a significant reduction of about**

**50% in the incidence of respiratory distress syndrome (RDS) is seen in infants born to mothers who received antenatal corticosteroids.** In a secondary analysis, a 70% reduction in RDS was seen among babies born between 24 hours and 7 days after corticosteroid administration. In addition, evidence suggests reductions in mortality and RDS even with treatment started less than 24 hours before delivery. Although most babies in the trials were between 30 and 34 weeks' gestation, clear reduction in RDS was evident when the population of babies less than 31 weeks was examined, and given the impact on neonatal morbidity and mortality, **prenatal steroid use can be recommended in pregnancies as early as 23 weeks' gestation.**<sup>6</sup>

Gender and race do not influence the protective effect of corticosteroids. In the population of patients with preterm premature rupture of the membranes (PPROM), antenatal corticosteroids also reduce the frequency of RDS.

**Corticosteroids also accelerate maturation of other organs in the developing fetus, including the cardiovascular, gastrointestinal (GI), and central nervous systems.** Corticosteroid therapy reduces the chances of periventricular hemorrhage (PVH) and intraventricular hemorrhage (IVH) in addition to necrotizing enterocolitis (NEC).<sup>5</sup> The significant reductions in serious neonatal morbidity are also reflected in a reduction in the risk of early neonatal mortality. The short-term beneficial effects of antenatal corticosteroids are enhanced by reassuring reports about long-term outcome. The children of mothers treated with antenatal corticosteroids show no lag in intellectual or motor development, no increase in learning disabilities or behavioral disturbances, and no effect on growth compared with untreated infants.<sup>7,8</sup>

Since the advent of antenatal steroids for the prevention of RDS, other therapies have been introduced that decrease mortality and morbidity. **Surfactant replacement therapy to treat specifically the surfactant deficiency that is the cause of RDS has been shown to decrease mortality and the severity of RDS.**<sup>9</sup> The effects of antenatal corticosteroids and postnatal surfactant appear to be additive in terms of decreasing the severity of RDS and the mortality caused by it.<sup>10</sup>

### First Breaths

**A critical step in the transition from intrauterine to extra-uterine life is the conversion of the lung from a fluid-filled organ to one capable of gas exchange.** This requires aeration of the lungs, establishment of an adequate pulmonary circulation, ventilation of the aerated parenchyma, and diffusion of oxygen and carbon dioxide through the alveolar-capillary membranes. This process has its origins in utero as fetal breathing.

### Fetal Breathing

Fetal respiratory activity is initially detectable at 11 weeks. The most prevalent pattern is rapid, small-amplitude movements (60 to 90 per minute), which are present 60% to 80% of the time. Less commonly, irregular low-amplitude movements interspersed with slower, larger amplitude movements are seen.<sup>11</sup> Initially, fetal breathing was thought to depend on behavioral influences. However, subsequent work has shown responses to chemical stimuli and other agents. Acute hypercapnea stimulates breathing. Hypoxia abolishes fetal breathing, whereas an increase in oxygen tension to levels above 200 mm Hg induces continuous fetal breathing. Although peripheral and central chemoreflexes—as well as vagal afferent reflexes—can be demonstrated in the fetus, their role in spontaneous fetal breathing appears to be minimal. The role of fetal breathing in the continuum from fetal to neonatal life is still not completely understood. **Fetal respiratory activity is probably essential to the development of chest wall muscles, including the diaphragm, and serves as a regulator of lung fluid volume and thus lung growth.**

The mechanism responsible for the transition from intermittent fetal to continuous neonatal breathing is unknown. Prostaglandins may be involved in addition to other factors that surround birth, including blood gas changes and various sensory stimuli. Another possibility is the “release” from a placental inhibitory factor that is removed after cord occlusion.

### Mechanics of the First Breath

**With its first breaths, the neonate must overcome several forces that resist lung expansion: (1) viscosity of fetal lung fluid, (2) resistance provided by lung tissue itself, and (3) the forces of surface tension at the air-liquid interface.**<sup>12-14</sup> Viscosity of fetal lung fluid is a major factor as the neonate attempts to displace fluid present in the large airways. As the passage of air moves toward small airways and alveoli, surface tension becomes more important. Resistance to expansion by the lung tissue itself is less significant. The process begins as the infant passes through the birth canal; the intrathoracic pressure caused by vaginal squeeze is up to 200 cm H<sub>2</sub>O. With delivery of the head, approximately 5 to 28 mL of tracheal fluid is expressed. Subsequent delivery of the thorax causes an elastic recoil of the chest. With this recoil, a small passive inspiration (no more than 2 mL) occurs. This is accompanied by glossopharyngeal forcing of some air into the proximal airways (*frog breathing*) and the introduction of some blood into pulmonary capillaries. This pulmonary vascular pressure may have a role in producing continuous surfaces throughout the small airways of the lung, into which surfactant can deploy.

The initial breath is characteristically a short inspiration, followed by a more prolonged expiration.<sup>13</sup> The initial breath begins with no air volume and no transpulmonary pressure gradient. Considerable negative intrathoracic pressure during inspiration is provided by diaphragmatic contraction and chest wall expansion. An opening pressure of about 25 cm H<sub>2</sub>O usually is necessary to overcome surface tension in the smaller airways and alveoli before air begins to enter. The volume of this first breath varies between 30 and 67 mL and correlates with intrathoracic pressure. The expiratory phase is prolonged, because the infant's expiration is opposed by intermittent closure at the pharyngolaryngeal level with the generation of significant positive intrathoracic pressure. This pressure serves to aid both in maintenance of a functional residual capacity (FRC) and with fluid removal from the air sacs. The residual volume after this first breath ranges between 4 and 30 mL, averaging 16 to 20 mL. No major systematic differences are apparent among the first three breaths, which demonstrate similar pressure patterns of decreasing magnitude. The FRC rapidly increases with the first several breaths and then increases more gradually. By 30 minutes of age, most infants attain a normal FRC with uniform lung expansion. **The presence of functional surfactant is instrumental in the accumulation of an FRC.**

In utero, alveoli are open and stable at a nearly neonatal lung volume because they are filled with fetal lung liquid, probably produced by ultrafiltration of pulmonary capillary blood as well as by secretion by alveolar cells. Transepithelial chloride secretion appears to be a major factor responsible for the production of luminal liquid in the fetal lung. **Normal expansion and aeration of the neonatal lung is dependent on removal of fetal lung liquid. Liquid is removed by a combination of mechanical drainage and absorption across the lung epithelium.**<sup>15</sup> This process begins before a normal term birth because of decreased fluid secretion and increased absorption. Once labor is initiated, a reversal of liquid flow occurs across the lung epithelium. Active transcellular sodium absorption drives liquid from the lumen to the interstitial space, where it is drained through the pulmonary circulation and lymphatics.<sup>16</sup> In normal circumstances, the process is complete within 2 hours of birth. Cesarean-delivered infants without benefit of labor and premature infants have delayed lung fluid clearance. In both

FIG 22-5 The fetal circulation.

groups, the prenatal decrease in lung water does not occur. In addition, in the premature neonate, fluid clearance is diminished by increased alveolar surface tension, increased left atrial pressure, and hypoproteinemia.

### Circulatory Transition

The circulation in the fetus (Fig. 22-5) has been studied in a variety of species using several techniques (see Chapter 2).<sup>17,18</sup> Umbilical venous blood returning from the placenta has a  $PO_2$  of about 30 to 35 mm Hg. Because of the left-shifted fetal hemoglobin-oxyhemoglobin dissociation curve, this corresponds to a saturation of 80% to 90%. About 60% of this blood perfuses the liver, mainly to the middle and left lobes, and it ultimately enters the inferior vena cava (IVC) through the hepatic veins. The remainder (40% in mid-gestation, 20% at term) bypasses the hepatic circulation through the ductus venosus and empties directly into the IVC. Because of streaming in the IVC, the more oxygenated blood from the ductus venosus and left hepatic vein, as it enters the heart, is deflected by the crista dividens through the foramen ovale to the left atrium. The remainder of left atrial blood is the small amount of venous return from the pulmonary circulation. The less oxygenated IVC

blood from the lower body and the renal, mesenteric, and right hepatic veins streams across the tricuspid valve to the right ventricle. Almost all the return from the superior vena cava (SVC) and the coronary sinus passes through the tricuspid valve to the right ventricle, with only 2% to 3% crossing the foramen ovale. In the near-term fetus, the combined ventricular output is about 450 mL/kg/min; two thirds from the right ventricle and one third from the left ventricle. The blood in the left ventricle has a  $PO_2$  of 25 to 28 mm Hg (saturation of 60%) and is distributed to the coronary circulation, brain, head, and upper extremities with the remainder (10% of combined output) passing into the descending aorta. The major portion of the right ventricular output (60% of combined output) is carried by the ductus arteriosus to the descending aorta, with only 7% of combined output going to the lungs. Thus 70% of combined output passes through the descending aorta, with a  $PO_2$  of 20 to 23 mm Hg (saturation of 55%) to supply the abdominal viscera and lower extremities. Forty-five percent of combined output goes through the umbilical arteries to the placenta. **Thus blood of a higher  $PO_2$  supplies the critical coronary and cerebral circulations, and umbilical venous blood is diverted to where oxygenation is critical.**

The diversion of right ventricular output away from the lungs through the ductus arteriosus is caused by the very high pulmonary vascular resistance (PVR) in the fetus. This high PVR is maintained by multiple mechanisms. With advancing gestational age, an increase in the number of small pulmonary vessels occurs that increases the cross-sectional area of the pulmonary vasculature. This contributes to the gradual decline in PVR that begins during later gestation (Fig. 22-6). With delivery, a variety of factors interact to decrease PVR acutely; these include mechanical ventilation, increased oxygen tension, and the production of endothelium-derived relaxing factor or nitric oxide (NO).<sup>19</sup>

With the increase in pulmonary flow, left atrial return increases with a rise in left atrial pressure (Table 22-1). In addition, with the removal of the placenta, IVC return to the right atrium is diminished. The foramen ovale is a flap valve, and when left atrial pressure increases over that on the right side, the opening is functionally closed. It is still possible to demonstrate patency with insignificant right-to-left shunts in the first 12 hours of life in a human neonate, but in a 7- to 12-day newborn, such a shunt is rarely seen. Anatomic closure is not complete for a longer time.

TABLE 22-1 PRESSURES IN THE PERINATAL CIRCULATION

|                  | FETAL (mm Hg) | NEONATAL (mm Hg) |
|------------------|---------------|------------------|
| Right atrium     | 4             | 5                |
| Right ventricle  | 65/10         | 40/5             |
| Pulmonary artery | 65/40         | 40/25            |
| Left atrium      | 3             | 7                |
| Left ventricle   | 60/7          | 70/10            |
| Aorta            | 60/40         | 70/45            |

Modified from Nelson NM. Respiration and circulation after birth. In Smith CA, Nelson NM (eds): *The Physiology of the Newborn Infant*, 4th ed. Springfield, IL: Charles C. Thomas; 1976:117.

FIG 22-6 Representative changes in pulmonary hemodynamics during transition from the late-term fetal circulation to the neonatal circulation. (Modified from Rudolph AM. Fetal circulation and cardiovascular adjustments after birth. In Rudolph CD, Rudolph AM, Hostetter MK, et al [eds]: *Rudolph's Pediatrics*, 21st ed. New York: McGraw-Hill; 2003:1749.)

With occlusion of the umbilical cord, the low-resistance placental circulation is interrupted, which causes an increase in systemic pressure. This coupled with the decrease in PVR serves to reverse the shunt through the ductus arteriosus to a predominantly left-to-right shunt. By 15 hours of age, shunting in either direction is physiologically insignificant. Although functionally closed by 4 days, the ductus arteriosus is not anatomically occluded for 1 month. The role of an increased oxygen environment and prostaglandin metabolism in ductal closure is well established. Ductal closure occurs in two phases: constriction and anatomic occlusion. Initially, the muscular wall constricts, followed by permanent closure achieved by endothelial destruction, subintimal proliferation, and connective tissue formation.<sup>20</sup> The ductus venosus is functionally occluded shortly after the umbilical circulation is interrupted.

ABNORMALITIES OF CARDIOPULMONARY TRANSITION

Birth Asphyxia

Even normal infants may experience some limitation of oxygenation (asphyxia) during the birth process. A variety of circumstances can exaggerate this problem and can result in respiratory depression in the infant, including (1) acute interruption of umbilical blood flow, as occurs during cord compression; (2) premature placental separation; (3) maternal hypotension or hypoxia; (4) any of the above-mentioned problems superimposed on chronic uteroplacental insufficiency; and (5) failure to execute a proper resuscitation. Other contributing factors include anesthetics and analgesics used in the mother, mode and difficulty of delivery, maternal health, and prematurity.

The neonatal response to asphyxia follows a predictable pattern. Dawes<sup>21</sup> investigated the responses of the newborn rhesus monkey (Fig. 22-7). After delivery, the umbilical cord was

FIG 22-7 Schematic depiction of changes in rhesus monkeys during asphyxia and on resuscitation by positive-pressure ventilation. (Modified from Dawes GS. *Foetal and Neonatal Physiology*. Chicago: Year Book; 1968.)

tied, and the monkey's head was placed in a saline-filled plastic bag. Within about 30 seconds, a short series of respiratory efforts began. These were interrupted by a convulsion or a series of clonic movements accompanied by an abrupt fall in heart rate. The animal then lay inert with no muscle tone. Skin color became progressively cyanotic and then blotchy because of vasoconstriction in an effort to maintain systemic blood pressure. This initial period of apnea lasted about 30 to 60 seconds. The monkey then began to gasp at a rate of three to six breaths per minute. The gasping lasted for about 8 minutes, becoming weaker terminally. The time from onset of asphyxia to last gasp could be related to postnatal age and maturity at birth; the more immature the animal, the longer the time. Secondary or terminal apnea followed, and if resuscitation was not quickly initiated, death ensued. As the animal progressed through the phase of gasping and then on to terminal apnea, heart rate and blood pressure continued to fall, which indicated hypoxic depression of myocardial function. As the heart failed, blood flow to critical organs decreased and resulted in organ injury.

The response to resuscitation is qualitatively similar in many species, including humans. During the first period of apnea, almost any physical or chemical stimulus causes the animal to breathe. If gasping has already ceased, the first sign of recovery with initiation of positive-pressure ventilation is an increase in heart rate. The blood pressure then rises, rapidly if the last gasp has only just passed, but more slowly if the duration of asphyxia has been longer. The skin then becomes pink, and gasping ensues. Rhythmic spontaneous respiratory efforts become established after a further interval. For each minute past the last gasp, 2 minutes of positive-pressure breathing is required before gasping begins, and it takes 4 minutes to reach rhythmic breathing. Later, the spinal and corneal reflexes return. Muscle tone gradually improves over the course of several hours.

### Delivery Room Management of the Newborn

A number of situations during pregnancy, labor, and delivery place the infant at increased risk for asphyxia: (1) maternal diseases, such as diabetes mellitus and hypertension, in addition to third-trimester bleeding and prolonged rupture of membranes; (2) fetal conditions, such as prematurity, multiple gestation, growth restriction, fetal anomalies, and rhesus isoimmunization; and (3) conditions related to labor and delivery, including fetal distress, meconium staining, breech presentation, and administration of anesthetics and analgesics.

When an asphyxiated infant is expected, a resuscitation team should be in the delivery room. The team should comprise at least two people, one to manage the airway and one to monitor heart rate and provide whatever assistance is needed. The necessary equipment for an adequate resuscitation is listed in Table 22-2. The equipment should be checked regularly and should be in a continuous state of readiness. **The steps in the resuscitation process<sup>22</sup> are outlined in the algorithm in Figure 22-8. Some key points of the algorithm follow.**

1. Do not allow the infant to become hyperthermic under the warmer.
2. The best criteria to use for assessing the infant's condition are respiratory effort—whether it is apneic, gasping, or regular—and heart rate (>100 or <100; Table 22-3).
3. **Most neonates can be effectively resuscitated with a bag and face mask.** The proper bagging devices are pictured in Figure 22-9. In addition, a T-piece resuscitator can be used.

**TABLE 22-2** EQUIPMENT FOR NEONATAL RESUSCITATION

| CLINICAL NEEDS                 | EQUIPMENT  |
|--------------------------------|--|
| Thermoregulation               | Radiant heat source with platform, mattress covered with warm sterile blankets, servo control heating, temperature probe   |
| Airway management              | Suction: Bulb suction, meconium aspirator, wall vacuum suction with sterile catheters<br>Ventilation: Manual infant resuscitation bag connected to a pressure manometer capable of delivering 100% oxygen, appropriate masks for term and preterm infants, oral airways, stethoscope, gloves, compressed air source with oxygen blender, pulse oximeters, and probe (optional)<br>Intubation: Neonatal laryngoscope with #0 and #1 blades; extra bulbs and batteries; endotracheal tubes 2.5, 3.0, 3.5, and 4.0 mm OD with stylet; scissors and tape; and end-tidal CO <sub>2</sub> detection device |
| Gastric decompression          | Nasogastric tube, 8 Fr with 20-mL syringe  |
| Administration of drugs/volume | Sterile gloves and sterile umbilical catheterization tray with scalpel or scissors, antiseptic prep solution, umbilical tape, three-way stopcock, umbilical catheters (3.5 and 5 Fr), volume expanders (normal saline), drug box with appropriate neonatal vials and dilutions (see Table 22-5), sterile syringes and needles  |
| Transport                      | Warmed transport isolette with an oxygen source  |

Modified from Apgar V. A proposal for a new method of evaluation of the newborn infant. *Anesth Analg.* 1953;32:260.

\*Elicited by suctioning the oropharynx and nose.

For the initial inflations, pressures of 30 to 40 cm H<sub>2</sub>O may be necessary to overcome surface active forces in the lungs. Adequacy of ventilation is assessed by observing expansion of the infant's chest with bagging and watching for a gradual improvement in color, perfusion, and heart rate. Rate of bagging should be 40 to 60 beats/min. If the infant does not initially respond to bag and mask ventilation, try to reposition the head in slight extension, reapply the mask to achieve a good seal, consider suctioning the mouth and oropharynx, and try ventilating with the mouth open. It may be necessary to increase the pressure used. However, if no favorable response is seen in 30 to 40 seconds, proceed to intubation (Fig. 22-10).

4. Failure to respond to intubation and ventilation can result from mechanical causes or severe asphyxia. The mechanical causes listed in Table 22-4 should quickly be ruled out.
5. It is very unusual for a neonatal resuscitation to require either cardiac massage or drugs, and almost all newborns respond to ventilation with supplemental oxygen. If compressions are

**TABLE 22-4** MECHANICAL CAUSES OF  
FAILED RESUSCITATION

| CATEGORY  | EXAMPLES  |
|---|---|
| Equipment failure                               | Malfunctioning bag, oxygen not connected or running   |
| Endotracheal tube malposition                   | Esophagus, right mainstem bronchus                    |
| Occluded endotracheal tube                      |   |
| Insufficient inflation pressure to expand lungs |   |
| Space-occupying lesions in the thorax           | Pneumothorax, pleural effusions, diaphragmatic hernia |
| Pulmonary hypoplasia                            | Extreme prematurity, oligohydramnios                  |

required, they need to be coordinated with bagging at a 3:1 ratio (90 compressions to 30 breaths/min). It is even less common to need medications (Table 22-5). The optimal delivery route is through an umbilical venous line.

- The appropriateness of continued resuscitative efforts should always be reevaluated in an infant who fails to respond to all of the previously mentioned efforts. Today, resuscitative efforts are made even in “apparent stillbirths,” that is, infants whose 1-min Apgar scores are 0 to 1. However, efforts should not be sustained in the face of little or no improvement despite an appropriate resuscitation over a reasonable period of time (i.e., 10 to 15 minutes).<sup>22</sup>

\*For correction of metabolic acidosis only after adequate ventilation has been achieved; give slowly over several minutes. There is no evidence to support routine use.

†Infuse slowly over 5 to 10 minutes.

‡Insufficient evidence to support safety and efficacy of subcutaneous dose.

§Use after proceeding with proper airway management and other resuscitative techniques. ET, endotracheal; IM, intramuscular; IV, intravenous; SC, subcutaneous.

Resuscitation of term newborns should begin with room air because of the potential harmful effects of 100% oxygen, in particular the generation of oxygen free radicals.<sup>23,24</sup> Oxygen should be used and titrated to achieve normal saturations for age in minutes (see Fig. 22-8).<sup>22</sup> If resuscitation is started with room air and no improvement is seen, supplemental oxygen can be given. **Normal healthy term infants require approximately 10 to 15 minutes to achieve oxygen saturations above 90%.**<sup>25</sup>

A few special circumstances merit discussion at this point. Infants in whom respiratory depression secondary to narcotic administration is suspected may be given naloxone, although evidence to support efficacy is limited. However, this should not be done until the airway has been managed and the infant is resuscitated in the usual fashion. In addition, naloxone should not be given to the infant of an addicted mother because it will precipitate withdrawal.

A second special group are the **preterm infants**. Minimizing heat loss improves survival, so prewarmed towels should be available, and the environmental temperature of the delivery suite should be raised. The infant should be placed in a plastic covering after birth to minimize evaporative heat loss.<sup>26</sup> In the infant with an extremely low birthweight (<1000 g), proceed quickly to administration of continuous positive airway pressure (CPAP) and consider early intubation for surfactant administration. Volume expanders should be infused slowly to avoid rapid swings in blood pressure. Resuscitation in preterm infants should begin with 21% to 30% oxygen.<sup>24,27</sup>

A third special circumstance is the presence of **meconium-stained amniotic fluid**. Meconium aspiration syndrome (MAS) is a form of aspiration pneumonia that occurs most often in term or postterm infants who have passed meconium in utero (7% to 20% of all deliveries).<sup>28</sup> **Overall, 2% to 9% of children born through meconium-stained fluid are diagnosed with MAS.**<sup>28</sup> Delivery room management of meconium in the amniotic fluid has been historically based on the notion that aspiration takes place with the initiation of extrauterine respiration and that the pathologic condition is related to the aspirated contents, which resulted in the practice of oropharyngeal suction on the perineum after delivery of the head, followed by airway visualization and suction by the resuscitator after delivery. However, both of the foregoing assumptions are not entirely true. In utero aspiration has been induced in animal models and confirmed in autopsies of human stillbirths. In addition, the combined suction approach has not been uniformly successful in decreasing the incidence of MAS. These data have been confirmed by a large multicenter, prospective, randomized controlled trial (RCT) that assessed selective intubation of apparently vigorous meconium-stained infants.<sup>29</sup> Compared with expectant management, intubation and tracheal suction did not result in a decreased incidence of

MAS or other respiratory disorders. Finally, oropharyngeal suction on the perineum before delivery of the shoulders does not prevent MAS.<sup>30</sup> **The current recommended approach to meconium in the amniotic fluid is as follows:**

1. The obstetrician carefully performs bulb suctioning of the oropharynx and nasopharynx after delivery of the baby.
2. If the baby is active and breathing and requires no resuscitation, the airway need not be inspected, thus avoiding the risk of inducing vagal bradycardia.
3. Any infant in need of resuscitation does not need the airway inspected and suctioned before instituting positive-pressure ventilation.
4. Suction the stomach when airway management is complete and vital signs are stable.

### Cord Clamping

Although delayed cord clamping is not currently part of the Neonatal Resuscitation Program (NRP), the practice is now recommended for both term and preterm births. Historically, clamping and cutting of the umbilical cord took place within seconds; however, it has been found that delaying this separation of the newborn from the placental circulation for 30 to 60 seconds results in (1) a more gradual perinatal transition after birth, (2) transfusion of placental blood to the newborn, and (3) a variety of improved outcomes, in particular, for preterm newborns.<sup>31-33</sup> This practice is now endorsed for preterm births by the American College of Obstetricians and Gynecologists (ACOG), although specific patient populations and situations require further study.<sup>33</sup>

### Sequelae of Birth Asphyxia

The incidence of birth asphyxia is about 0.1% in term infants, with an increased incidence in infants at lower gestational ages.<sup>34</sup> The acute sequelae that need to be managed in the neonatal period are listed in Table 22-6. With asphyxia, widespread organ injury is evident. Management focuses on supportive care and treatment of specific abnormalities; this includes careful fluid management, blood pressure support, intravenous (IV) glucose, and treatment of seizures. Phenobarbital (40 mg/kg) given 1 to 6 hours after the event as neuroprotective therapy is associated with an improved neurologic outcome. **Especially if started within the first 6 hours of life, hypothermia (whole body or selective head cooling) improves outcomes at 6 to 7 years of age.**<sup>35-37</sup> The roles of oxygen free-radical scavengers, excitatory amino acid antagonists, and calcium channel blockers

in minimizing cerebral injury after asphyxia are still being investigated.

If the infant survives, the major long-term concern is permanent central nervous system (CNS) damage. The challenge lies in the identification of criteria that can provide information about the risk of future problems for a given infant. A variety of markers have been examined to identify birth asphyxia and risk for adverse neurologic outcome. Marked fetal bradycardia is associated with increased risk, but use of electronic fetal monitoring and cesarean delivery have not altered the incidence of cerebral palsy over the last several decades. **Low Apgar scores at 1 and 5 minutes are not predictive, but infants with low scores that persist at 15 and 20 minutes after birth have a 50% chance of manifesting cerebral palsy if they survive. Cord pH is predictive of adverse outcome only if the pH is less than 7. The best predictor of outcome is the severity of the neonatal neurologic syndrome.**<sup>38</sup> Infants with mild encephalopathy survive and are normal on follow-up examination. Moderate encephalopathy carries a 25% to 50% risk of severe handicap or death, whereas the severe syndrome carries a greater than 75% risk of death or disability. Although outcomes are improved with hypothermia initiated in the first 6 hours of life, these patients remain at high risk for poor neurodevelopment.<sup>35-37</sup> Diagnostic aids that include electroencephalograms and magnetic resonance imaging (MRI) scans can also aid in predicting outcome. The circulatory response to hypoxia is to redistribute blood flow to provide adequate oxygen delivery to critical organs (e.g., brain, heart) at the expense of other organs. Thus an insult severe enough to damage the brain should be accompanied by evidence of other organ dysfunction.

**The long-term neurologic sequelae of intrapartum asphyxia are cerebral palsy with or without associated cognitive deficits and epilepsy.** Although cerebral palsy can be related to intrapartum events, the large majority of cases are of unknown causes. Furthermore, cognitive deficits and epilepsy, unless associated with cerebral palsy, cannot be related to asphyxia or to other intrapartum events. **To attribute cerebral palsy to peripartum asphyxia, there must be an absence of other demonstrable causes, substantial or prolonged intrapartum asphyxia (fetal heart rate abnormalities, fetal acidosis), and clinical evidence during the first days of life of neurologic dysfunction in the infant (Box 22-1).**<sup>39</sup>

**TABLE 22-6 ACUTE SEQUELAE OF ASPHYXIA**

| SYSTEM           | MANIFESTATIONS  |
|------------------|---|
| Central nervous  | Cerebral edema, seizures, hemorrhage, hypoxic-ischemic encephalopathy   |
| Cardiac          | Papillary muscle necrosis, transient tricuspid insufficiency, cardiogenic shock   |
| Pulmonary        | Aspiration syndromes (meconium, clear fluid), acquired surfactant deficiency, persistent pulmonary hypertension, pulmonary hemorrhage |
| Renal            | Acute tubular necrosis with anuria or oliguria  |
| Adrenal          | Hemorrhage with adrenal insufficiency   |
| Hepatic          | Enzyme elevations, liver failure  |
| Gastrointestinal | Necrotizing enterocolitis, feeding intolerance  |
| Metabolic        | Hypoglycemia, hypocalcemia  |
| Hematologic      | Coagulation disorders, thrombocytopenia   |

### BIRTH INJURIES

Birth injuries are those sustained during labor and delivery. **Factors that predispose to birth injury include macrosomia, cephalopelvic disproportion, shoulder dystocia, prolonged or difficult labor, precipitous delivery, abnormal presentations (including breech), and use of operative vaginal delivery.**<sup>40</sup> Injuries range from minor, requiring no therapy, to life threatening (Table 22-7).

Soft tissue injuries are most common. Most are related to dystocia and to the use of operative vaginal delivery. Accidental lacerations of the scalp, buttocks, and thighs may be inflicted with the scalpel during cesarean delivery. Cumulatively, these injuries are of a minor nature and respond well to therapy. Hyperbilirubinemia, particularly in the premature infant, is the major neonatal complication related to soft tissue bruising.

A **cephalohematoma** occurs in 0.2% to 2.5% of live births. Caused by rupture of blood vessels that traverse from the skull

### BOX 22-1 RELATIONSHIP OF INTRAPARTUM EVENTS AND CEREBRAL PALSY

#### Neonatal Signs Consistent With an Acute Peripartum or Intrapartum Event

- Evidence of a metabolic acidemia in fetal umbilical cord arterial blood obtained at delivery (pH <7.00 and base deficit  $\geq 12$  mmol/L)
- Apgar score of less than 5 at 5 and 10 min
- Neuroimaging evidence of acute brain injury seen on brain magnetic resonance imaging or magnetic resonance spectroscopy consistent with hypoxia-ischemia
- Presence of multisystem organ failure consistent with hypoxic-ischemic encephalopathy

#### Type and Timing of Contributing Factors Consistent With an Acute Peripartum or Intrapartum Event

- Sentinel hypoxic or ischemic event occurring immediately before or during labor and delivery such as a severe placental abruption
- Fetal heart rate monitor patterns consistent with an acute peripartum or intrapartum event
- Timing and type of brain injury patterns based on imaging studies consistent with an etiology of an acute peripartum or intrapartum event
- No evidence of other proximal or distal factors that could be contributing factors

#### Developmental Outcome Is Spastic Quadriplegia or Dyskinetic Cerebral Palsy

Modified from American College of Obstetricians and Gynecologists (ACOG), American Academy of Pediatrics (AAP). Neonatal Encephalopathy and Neurologic Outcome. Washington DC: ACOG; 2014.

TABLE 22-7 BIRTH INJURIES

| CLASSIFICATION          | EXAMPLE  |
|-------------------------|--|
| Soft tissue injuries*   | Lacerations, abrasions, fat necrosis   |
| Extracranial bleeding   | Cephalohematoma,* subgaleal bleed  |
| Intracranial hemorrhage | Subarachnoid, subdural, epidural, cerebral, cerebellar   |
| Nerve injuries          | Facial nerve,* cervical nerve roots (brachial plexus palsies,* phrenic nerve, Horner syndrome), recurrent laryngeal nerve (vocal cord paralysis) |
| Fractures               | Clavicle,* facial bones, humerus, femur, skull, nasal bones  |
| Dislocations            | Extremities, nasal septum  |
| Eye injuries            | Subconjunctival* and retinal hemorrhages, orbital fracture, corneal laceration, breaks in Descemet membrane with corneal opacification           |
| Torticollis†            |  |
| Spinal cord injuries    |  |
| Visceral rupture        | Liver, spleen  |
| Scalp laceration*       | Fetal scalp electrode, scalpel   |
| Scalp abscess           | Fetal scalp electrode  |

\*More common occurrences.

†Secondary to hemorrhage into the sternocleidomastoid muscle.

to the periosteum, the bleeding is subperiosteal and is therefore limited by suture lines; the most common site of bleeding is over the parietal bones. Associations include prolonged or difficult labor and mechanical trauma from operative vaginal delivery. Linear skull fractures beneath the hematoma have been reported

in 5.4% of cases but are of no major consequence except in the unlikely event that a leptomenigeal cyst develops. Most cephalohematomas are reabsorbed in 2 weeks to 3 months. **Subgaleal bleeds**, which are not limited by suture lines, can occur in association with vacuum extraction alone—especially with multiple pop-offs and prolonged traction—in combination with the use of forceps or with difficult forceps deliveries, and they can result in life-threatening anemia, hypotension, or consumptive coagulopathy. Depressed skull fractures are also seen in neonates, but most do not require surgical elevations.

**Intracranial hemorrhages** related to trauma include epidural, subdural, subarachnoid, and intraparenchymal bleeds.<sup>41</sup> With improvements in obstetric care, subdural hemorrhages fortunately are now rare. Three major varieties of **subdural bleeds** have been described: (1) posterior fossa hematomas due to tentorial laceration with rupture of the straight sinus, vein of Galen, or transverse sinus or due to occipital osteodiasis (a separation between the squamous and lateral portions of the occipital bone); (2) falx laceration, with rupture of the inferior sagittal sinus; and (3) rupture of the superficial cerebral veins. The clinical symptoms are related to the location of bleeding. With tentorial laceration, bleeding is infratentorial, leading to brainstem signs and a rapid progression to death. Falx tears cause bilateral cerebral signs (e.g., seizures and focal weakness) until blood extends infratentorially to the brainstem. Subdural hemorrhage over the cerebral convexities can cause several clinical states that range from an asymptomatic newborn to one with seizures and focal neurologic findings. Infants with lacerations of the tentorium and falx have a poor outlook. In contrast, the prognosis for rupture of the superficial cerebral veins is much better, and the majority of survivors are normal. **Primary subarachnoid hemorrhage is the most common variety of neonatal intracranial hemorrhage.**<sup>41</sup> Clinically, these infants are often asymptomatic, although they may present with a characteristic seizure pattern that begins on day 2 of life, and the infants are “well” between convulsions. In general, the prognosis for subarachnoid bleeds is good.

Trauma to peripheral nerves produces another major group of birth injuries. **Brachial plexus injuries are caused by stretching of the cervical roots during delivery, usually when shoulder dystocia is present. Upper arm palsy (Erb-Duchenne paralysis), the most common brachial plexus injury, is caused by injury to the fifth and sixth cervical nerves; lower arm paralysis (Klumpke paralysis) results from damage to the eighth cervical and first thoracic nerves. Damage to all four nerve roots produces paralysis of the entire arm.** Outcome for these injuries is variable, and some infants are left with significant residual damage. Horner syndrome as a result of damage to sympathetic outflow through nerve root T1 may accompany Klumpke paralysis, and approximately 5% of patients with Erb paralysis have an associated phrenic nerve paresis. Facial palsy is another fairly common injury caused either by pressure from the sacral promontory or fetal shoulder as the infant passes through the birth canal or by operative vaginal delivery. Most of these palsies resolve, although in some infants, paralysis is persistent.

The majority of bone fractures that result from birth trauma involve the clavicle and result from shoulder dystocia or breech extractions that require vigorous manipulations. Clinically, many of these fractures are asymptomatic, and when present, symptoms are mild. Prognosis for both clavicular and limb fractures is uniformly good. The most commonly fractured long bone is the humerus.

Spinal cord injuries are a relatively infrequent but often severe form of birth injury. Accurate incidence is difficult to assess, because symptoms mimic other neonatal diseases and autopsies often do not include a careful examination of the spine. Depressed tone, hyporeflexia, and respiratory failure are clues to this diagnosis. Excessive longitudinal traction and head rotation during forceps delivery predispose to spinal injury, and hyperextension of the head in a footling breech is particularly dangerous. Outcomes include death or stillbirth caused by high cervical or brainstem lesions, long-term survival of infants with paralysis from birth, and minimal neurologic symptoms or spasticity.

## NEONATAL THERMAL REGULATION

### Physiology

The range of environmental temperatures over which the neonate can survive is narrower than that of an adult as a result of the infant's inability to dissipate heat effectively in warm environments and, more critically, to maintain temperature in response to cold. This range narrows with decreasing gestational age.

Although some increases in activity and shivering have been observed, **nonshivering thermogenesis is the most important means of increased heat production in the cold-stressed newborn.**<sup>42</sup> It can be defined as an increase in total heat production without detectable (visible or electrical) muscle activity. The site of this increased heat production is brown fat located between the scapulae; around the muscles and blood vessels of the neck, axillae, and mediastinum; between the esophagus and trachea; and around the kidneys and adrenal glands. Brown fat cells contain more mitochondria and fat vacuoles and have a richer blood and sympathetic nerve supply compared with white fat cells.

Heat loss to the environment is dependent on both an **internal temperature gradient, from within the body to the surface, and an external temperature gradient, from the surface to the environment.** The infant can change the *internal gradient* by altering vasomotor tone and, to a lesser extent, by postural changes that decrease the amount of exposed surface area. The *external gradient* is dependent on purely physical variables. **Heat transfer from the surface to the environment involves four routes: radiation, convection, conduction, and evaporation.** *Radiant heat loss*, heat transfer from a warmer to a cooler object that is not in contact, depends on the temperature gradient between the objects. Heat loss by *convection* to the surrounding gaseous environment depends on air speed and temperature. *Conduction*, heat loss to a contacting cooler object, is minimal in most circumstances. Heat loss by *evaporation* is cooling secondary to water loss at the rate of 0.6 cal/g water evaporated and is affected by relative humidity, air speed, exposed surface area, and skin permeability. In infants in excessively warm environments, such as those under overhead radiant heat sources, or in very immature infants with thin, permeable skin, evaporative losses increase considerably. Table 22-8 summarizes the neonate's efforts to maintain a stable core temperature in the face of cold or heat stress. It is advantageous to maintain an infant in a neutral thermal environment (Fig. 22-11). The neutral thermal environment for a given infant depends on size, gestational age, and postnatal age.<sup>43</sup> **In general, maintaining the abdominal skin temperature at 36.5° C minimizes energy expenditure.**

**TABLE 22-8** NEONATAL RESPONSE TO THERMAL STRESS

| STRESSOR | RESPONSE                               | TERM | PRETERM |
|----------|--|------|---------|
| Cold     | Vasoconstriction                       | ++   | ++      |
|          | ↓Exposed surface area (posture change) | ±    | ±       |
|          | ↑Oxygen consumption                    | ++   | +       |
| Heat     | ↑Motor activity, shivering             | +    | —       |
|          | Vasodilation                           | ++   | ++      |

++, Maximum response; +, intermediate; ±, may have a role; —, no response.

## CLINICAL APPLICATIONS

### Delivery Room

In utero, fetal thermoregulation is the responsibility of the placenta and is dependent on maternal core temperature; fetal temperature is 0.5° C higher than maternal temperature. At birth, the infant's core temperature drops rapidly from 37.8° C because of evaporation from its wet body and radiant and convective losses to the cold air and walls of the room. Even with an increase in oxygen consumption to the maximum capability of the newborn (15 mL/kg/min), the infant can produce only 0.075 cal/kg/min and will rapidly lose heat. **Measures taken to reduce heat loss after birth depend on the clinical situation. For the well term infant, drying the skin and wrapping the baby with warm blankets is sufficient. When it is necessary to leave an infant exposed for close observation or resuscitation, the infant should be dried and placed under a radiant heat source. Room temperature can be elevated as an added precaution for the low-birthweight infant.**

### Nursery

Babies are cared for in the newborn nursery wrapped in blankets in bassinets (cot-nursed), in isolettes, or under a radiant heat source. Healthy full-term infants (>2.5 kg) need only be clothed and placed in a bassinet under a blanket. Infants weighing 2 to 2.5 kg who are either slightly premature or growth restricted should be allowed 12 to 24 hours to stabilize in an isolette and should then be advanced to a bassinet. Lower-birthweight babies (<2 kg) will require care in either isolettes or under radiant heat sources. **Adequate thermal protection of the low-birthweight (LBW) infant is essential. This is especially important for the very-low-birthweight (VLBW) infant (<1.5 kg), who often does not behave like a mature homeotherm.** These neonates can react to a small change in environmental temperature with a change in body temperature rather than a change in oxygen consumption. In addition, warmer environments hasten growth of the premature infant.

The isolette, which heats by convection, is the most commonly used heating device for the LBW nude infant. The major source of heat loss while in a neutral thermal environment is radiant to the walls of the isolette. The magnitude of this loss is predictable if room temperature is known, and losses can be minimized using double-walled isolettes in which the inner wall temperature is very close to the air temperature within the isolette. Once clinical status has been stabilized, the infant can be dressed, which will afford increased thermal stability.

Radiant warmers can also be used to ensure thermal stability of both LBW and full-sized infants. Radiant warmers are used most effectively for short-term warming during initial

**FIG 22-11** Effect of environmental temperature on oxygen consumption and body temperature. (Modified from Klaus MH, Fanaroff AA. The physical environment. In Klaus MH, Fanaroff AA [eds]: *Care of the High-Risk Neonate*, 5th ed. Philadelphia: WB Saunders; 2001:130.)

resuscitation and stabilization and for performing procedures. They provide easy access to the infant while ensuring thermal stability. The main heat losses are convection, which can be significant because of variable air speed in a room, and evaporation. **Evaporative heat loss that results in significant fluid losses is a major concern for the VLBW premature infant cared for under a radiant warmer.** Placing a plastic shield over the infant or covering the skin with a semipermeable membrane can minimize these fluid losses.

**The most economical means of thermal support for the LBW infant is skin-to-skin contact with a parent.**<sup>44</sup>

## NEONATAL NUTRITION AND GASTROENTEROLOGY

At birth, the newborn infant must assume various functions performed by the placenta during fetal life. Cardiopulmonary transition and thermoregulation have already been discussed. The final critical task for the newborn is the assimilation of calories, water, and electrolytes.

### Infant Feeding

For the well term or slightly preterm infant, institution of oral feedings within the first 2 to 4 hours of life is reasonable practice. For infants who are small for gestational age (SGA) or large for gestational age (LGA), earlier feedings may be indicated to avoid hypoglycemia. Premature infants (<34 weeks' gestation) who are unable to nipple feed present a more complex set of circumstances. In addition to an inability to suck and swallow

efficiently, such infants face a number of problems: (1) relatively high caloric demand; (2) small stomach capacity; (3) incompetent esophageal-cardiac sphincter that leads to gastroesophageal reflux; (4) poor gag reflex, which creates a tendency for aspiration; (5) decreased digestive capability, especially for fat; and (6) slow gastric emptying and intestinal motility. These infants can initially be supported adequately with parenteral nutrition, followed by institution of nasogastric tube feedings when their cardiopulmonary status is stable.

**Although a wide range of infant formulas satisfy the nutritional needs of most neonates, breast milk remains the standard on which formulas are based** (see Chapter 24). The distribution of calories in human milk is 7% protein, 55% fat, and 38% carbohydrate. The whey/casein ratio is 70:30, which enhances ease of protein digestion and gastric emptying, whereas fat digestion is augmented by the presence of a breast milk lipase. Despite the low levels of several vitamins and minerals, bioavailability is high. **In addition to the nutritional features, breast milk's immunochemical and cellular components provide protection against infection.**<sup>45</sup>

The growth demands of the LBW infant exceed what can be provided by human milk in terms of protein, calcium, phosphorus, sodium, zinc, copper, and possibly other nutrients. These shortcomings can be addressed through the addition of human milk fortifiers to mother's preterm breast milk.<sup>46</sup> Advantages of breast milk for the premature infant include its antiinfective properties, possible protection against NEC, and its role in enhancing neurodevelopmental outcome.<sup>47</sup> The importance of breast milk for the preterm infant has been emphasized with

**TABLE 22-9** GUIDELINES FOR SUCCESSFUL BREASTFEEDING

|                     | FIRST 8 HR  | 8 TO 24 HR   | DAY 2   | DAY 3  | DAY 4  | DAY 5   | DAY 6 ON  |
|---------------------|---|--|---|--|--|---|---|
| Milk supply         | You may be able to express a few drops of milk.   |  | Milk <i>should</i> come in between days 2 and 4.  |  |  | Milk should be in. Breasts may be firm and may leak milk.                             | Breasts should feel softer after nursing.                       |
| Baby's activity     | Baby is usually wide awake in the first hour of life and should be put to the breast within 30 min. | Wake up your baby. Babies may not wake up on their own to feed.  | Baby should be more cooperative and less sleepy.  | Look for early feeding cues such as rooting, lip smacking, and hands to the face.  |  |   | Baby should appear satisfied after feedings.                    |
| Feeding routine     | Baby may go into a deep sleep 2 to 4 hours after birth.   | Use a chart to write down each feeding time. Feed your baby every 1 to 4 hr or as often as the baby wants to nurse but at least 8 to 12 times a day. |   |  |  | Baby may go one longer interval (up to 5 hr between feeds) in a 24-hour period.       |   |
| Breastfeeding       | Baby will wake up and be alert and responsive for several more hours after initial sleep.           | As long as the mother is comfortable, nurse at both breasts as long as the baby is actively sucking.   | Try to nurse on both sides at each feeding, aiming at 10 min per side. Expect some nipple tenderness. | Consider hand expressing or pumping a few drops of milk to soften the nipple if the breast is too firm for the baby to latch on. | Nurse a minimum of 10 to 30 min per side every feeding for the first few weeks of life. Once milk supply is well established, allow baby to finish the first breast before offering the other one. |   | Mother's nipple tenderness is improving or is gone.             |
| Baby's urine output |   | Baby must have a minimum of one wet diaper in the first 24 hr.   | Baby must have at least one wet diaper every 8 to 11 hr.  | You should see an increase in wet diapers (four to six) in 24 hr.  | Baby's urine should be light yellow.   | Baby should have six to eight wet diapers per day of colorless or light yellow urine. |   |
| Baby's stools       |   | Baby may have a very dark (meconium) stool.  | Baby may have a second very dark (meconium) stool.  | Baby's stools should be in transition from black green to yellow.  |  | Baby should have three to four yellow, seedy stools a day.                            | The number of stools may decrease gradually after 4 to 6 weeks. |

the use of donor banked human milk as a bridge until the mother is producing an adequate amount of milk for her infant.<sup>48,49</sup>

**Few contraindications to breastfeeding exist.** Infants with galactosemia should not ingest lactose-containing milk. Infants with other inborn errors of metabolism such as phenylketonuria may ingest some human milk with close monitoring of the amount. The presence of environmental pollutants has been documented in breast milk, but to date no serious side effects have been reported. Most drugs do not contraindicate breastfeeding, but a few exceptions do exist (see [Chapter 8](#)). Transmission of some viral infections via breast milk is a concern as well. Mothers who are human immunodeficiency virus (HIV) positive should not breastfeed if safe and effective alternatives to breast milk are available. The nursery staff must be aware of problems associated with breastfeeding, and lactation consultants should be available to deal with poor infant latch-on, sore nipples, poor milk supply, and excessive hyperbilirubinemia. The obstetrician and pediatrician should serve as a source of knowledge and, most importantly, support. [Table 22-9](#) illustrates what a mother can expect as she breastfeeds her infant.

## Neonatal Hypoglycemia

Glucose is a major fetal fuel transported by facilitated diffusion across the placenta. After birth, before an appropriate supply of exogenous calories is provided, the newborn must maintain blood glucose through endogenous sources. Hepatic glycogen stores are almost entirely depleted within the first 12 hours after birth in the healthy term neonate and even more rapidly in the preterm or stressed infant if no other glucose source is available. Fat and protein stores are then used for energy, and glucose levels are maintained by hepatic gluconeogenesis.

**In the healthy unstressed neonate, glucose falls over the first 1 to 2 hours after birth, stabilizes at a minimum of about 40 mg/dL, and then rises to 50 to 80 mg/dL by 3 hours of life.<sup>50</sup> Low glucose concentrations can be defined as less than 45 mg/dL. Infants at risk for low blood glucose concentrations and in whom glucose should be monitored include preterm infants, SGA infants, hyperinsulinemic infants (infant of a diabetic mother [IDM]), LGA infants, and infants with perinatal stress or asphyxia.** As in term babies, blood glucose drops after birth in preterm babies, but they are less able to mount a counterregulatory response. In addition, the presence of respiratory distress, hypothermia, and other factors

can increase glucose demand and exacerbate hypoglycemia. **SGA infants are at risk for hypoglycemia resulting from rapidly utilized glycogen stores and impaired gluconeogenesis and ketogenesis.** Onset of hypoglycemia in SGA and preterm infants usually occurs at 2 to 6 hours of life. Hyperinsulinemia occurs in IDMs and in babies with other rare conditions, including Beckwith-Wiedemann syndrome and congenital hyperinsulinism. Onset of hypoglycemia in these infants can be in the first 30 to 60 minutes after birth. In the case of perinatal asphyxia, hypoglycemia is the result of excessive glucose demand and occasionally transient hyperinsulinism.<sup>51,52</sup> Infants with recurrent hypoglycemia over 3 to 4 days should be evaluated for endocrine disorders (hyperinsulinism, decreased counterregulatory hormones—cortisol, growth hormone, and glucagon) and inborn errors of metabolism (Box 22-2).

Symptoms of hypoglycemia include jitteriness, seizures, cyanosis, respiratory distress, apathy, hypotonia, and eye rolling.<sup>50</sup> However, many infants, particularly premature infants, are asymptomatic. **Because of the risk of subsequent brain injury, hypoglycemia should be aggressively treated. However, the single best treatment is prevention by identifying infants at risk, including premature, SGA, IDM, LGA, and stressed infants.** These newborns should have blood glucose screened with a bedside glucose meter. All values less than or equal to 45 mg/dL should be confirmed with a laboratory measurement. Treatment is initiated by early institution of feedings or an IV glucose bolus (2 mL/kg of D<sub>10</sub>W solution) followed by a glucose infusion at a rate of 6 mg/kg/min.<sup>53</sup>

### **Congenital Gastrointestinal Surgical Conditions**

Several congenital surgical conditions of the GI tract interfere with a normal transition to neonatal life. Many of these conditions can be diagnosed with antenatal ultrasound to allow transfer of the mother to a perinatal center for delivery. Examples include tracheoesophageal fistula and esophageal atresia, duodenal atresia, abdominal wall defects (gastroschisis and omphalocele), and congenital diaphragmatic hernia (CDH). CDH infants are ideally delivered in centers with access to advanced therapies such as extracorporeal membrane oxygenation (ECMO).

### **Necrotizing Enterocolitis**

**NEC is the most common acquired GI emergency in the neonatal intensive care unit (NICU).** This disorder predominantly affects premature infants, with higher incidences present with decreasing gestational age, although it is seen in term infants with polycythemia, congenital heart disease, and birth asphyxia. The pathogenesis is multifactorial, with intestinal ischemia, infection, provision of enteral feedings, and gut maturity playing roles to varying degrees in individual patients.<sup>54</sup> Recent research has suggested a critical role for the neonatal intestinal microbiome in the pathogenesis of this complication of prematurity. Use of probiotics appears to be a potentially promising preventative therapy, but data are still insufficient for a general recommendation for their use.<sup>55</sup> **Presumably related to changes in intestinal circulation, tocolysis with indomethacin has been associated with an increased incidence of NEC, whereas antenatal betamethasone may decrease the incidence.**

Clinically, the spectrum of disease varies from a mild GI disturbance to a rapid fulminant course characterized by intestinal gangrene, perforation, sepsis, and shock. The hallmark symptoms are abdominal distension, ileus, delayed gastric emptying, and bloody stools. The radiographic findings are bowel wall edema, pneumatosis intestinalis, biliary free air, and free peritoneal air. Associated symptoms include apnea, bradycardia, hypotension, and temperature instability. Surgical resection of bowel may be necessary with resulting short bowel syndrome in survivors. In addition, severe NEC has a negative impact on neurodevelopmental outcome.<sup>56</sup>

### **Neonatal Jaundice**

**The most common problem encountered in a term nursery population is jaundice.** Neonatal hyperbilirubinemia occurs when the normal pathways of bilirubin metabolism and excretion are altered. Figure 22-12 demonstrates the metabolism of bilirubin. The normal destruction of circulating red cells accounts for about 75% of the newborn's daily bilirubin production. The remaining sources include ineffective erythropoiesis and tissue heme proteins. Heme is converted to bilirubin in the reticulo-endothelial system with carbon monoxide (CO) produced as a by-product. Unconjugated bilirubin is lipid soluble and is transported in the plasma reversibly bound to albumin. Bilirubin enters the liver cells by dissociation from albumin in the hepatic sinusoids. Once in the hepatocyte, bilirubin is conjugated with glucuronic acid in a reaction catalyzed by uridine diphosphoglucuronosyl transferase (UDPGT). The water-soluble conjugated bilirubin is excreted rapidly into the bile canaliculi and into the small intestine. The enzyme  $\beta$ -glucuronidase is present in the small bowel and hydrolyzes some of the conjugated bilirubin. This unconjugated bilirubin can be reabsorbed into the circulation, adding to the total unconjugated bilirubin load (enterohepatic circulation). **Major predisposing factors of neonatal jaundice are (1) increased bilirubin load because of increased red cell volume with decreased cell survival, increased ineffective erythropoiesis, and the enterohepatic circulation; and (2) decreased hepatic uptake, conjugation, and excretion of bilirubin.** These factors result in the presence of clinically apparent jaundice in approximately two thirds of newborns during the first week of life, and in most it is considered physiologic.<sup>57</sup> Infants whose bilirubin levels are above the 95th percentile for age in hours and infants in high-risk groups to develop hyperbilirubinemia require close follow-up (Fig. 22-13 and Box 22-3).<sup>58,59</sup>

### BOX 22-3 RISK FACTORS FOR SIGNIFICANT HYPERBILIRUBINEMIA

Jaundice observed at <24 hr  
 Blood group incompatibility with positive direct Coombs test  
 Other hemolytic disease (G6PD deficiency)  
 Gestational age <35 to 36 wk  
 Previous sibling needing phototherapy  
 Cephalohematoma, subgaleal blood collection, bruising  
 Exclusive breastfeeding, especially if it is not going well  
 East Asian race

Modified from American Academy of Pediatrics Subcommittee on Hyperbilirubinemia. Management of hyperbilirubinemia in the newborn infant 35 or more weeks gestation. *Pediatrics*. 2004;114:297.  
 G6PD, glucose-6-phosphate dehydrogenase.

**Pathologic jaundice during the early neonatal period is indirect hyperbilirubinemia, usually caused by overproduction of bilirubin.** The leading cause in this group of patients is hemolytic disease, of which fetomaternal blood group incompatibilities—ABO, Rh, and other minor antibodies—are the most common (see Chapter 34). Other causes of hemolysis include genetic disorders: specifically, hereditary spherocytosis and nonspherocytic hemolytic anemias, such as glucose-6-phosphate dehydrogenase (G6PD) deficiency. Other etiologies of bilirubin overproduction include extravasated blood (bruising, hemorrhage), polycythemia, and exaggerated enterohepatic circulation of bilirubin because of mechanical GI obstruction or reduced peristalsis from inadequate oral intake. Disease states that involve decreased bilirubin clearance must be considered in patients in whom no cause of overproduction can be identified. Causes of indirect hyperbilirubinemia in this category include familial deficiency of UDPGT (Crigler-Najjar syndrome), Gilbert syndrome, breast milk jaundice, and hypothyroidism. Mixed and direct hyperbilirubinemia are rare during the first week of life.

**A strong association exists between breastfeeding and neonatal hyperbilirubinemia.** The syndrome of breast milk jaundice is characterized by full-term infants who have jaundice that persists into the second and third weeks of life with maximal bilirubin levels of 10 to 30 mg/dL. If breastfeeding is continued, the levels persist for 4 to 10 days and then decline to normal by 3 to 12 weeks. Interruption of breastfeeding is associated with a prompt decline in 48 hours. **In addition to this syndrome, breastfed infants as a whole have higher bilirubin levels over the first 3 to 5 days of life than their formula-fed counterparts (Fig. 22-14).** Rather than interrupting breastfeeding, this early jaundice is responsive to increased frequency of breastfeeding. Suggested mechanisms for breastfeeding-associated jaundice include decreased early caloric intake, inhibitors of bilirubin conjugation in breast milk, and increased intestinal reabsorption of bilirubin. In some patients, overlap is considerable in these described syndromes.

**The overriding concern with neonatal hyperbilirubinemia is the development of bilirubin toxicity that causes the pathologic entity of kernicterus,** the staining of certain areas of the brain—basal ganglia, hippocampus, geniculate bodies, various brainstem nuclei, and cerebellum—by bilirubin. Neuronal necrosis is the dominant histopathologic feature at 7 to 10 days of life. The early symptoms of bilirubin encephalopathy consist of lethargy, hypotonia, and poor feeding that progresses to a high-pitched cry, hypertonicity, and opisthotonos. Survivors usually suffer sequelae that include athetoid cerebral palsy, high-frequency hearing loss, paralysis of upward gaze, and dental dysplasia.<sup>60,61</sup> **The risk of bilirubin encephalopathy is not well defined except in those infants with Rh isoimmunization in whom a level of 20 mg/dL has been associated with an increased risk of kernicterus.** This observation has been extended to the management of other neonates with hemolytic disease, although no definitive data exist regarding these infants. The risk is probably small for term infants without hemolytic disease even at levels higher than 20 mg/dL. **Recent descriptions of bilirubin encephalopathy in breastfed infants, and in late preterm infants in particular, with dehydration and hyperbilirubinemia in whom an adequate supply of breast milk has not been established mandates close follow-up of all breastfeeding mothers.**<sup>60</sup> The true risk for nonhemolytic hyperbilirubinemia to produce brain damage in the preterm

**FIG 22-13** Risk of developing significant hyperbilirubinemia in term and near-term infants based on hour-specific bilirubin determinations. (From Bhutani VK, Johnson L, Sivieri EM. Predictive ability of a predischarge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns. *Pediatrics*. 1999;103:6.)

**FIG 22-14** Distribution of maximum serum bilirubin concentrations in white infants who weigh more than 2500 g. (Modified from Maisels MJ, Gifford KL. Normal serum bilirubin levels in the newborn and the effect of breast-feeding. *Pediatrics*. 1986;78:837.)

infant in the current era of liberal use of phototherapy that prevents marked elevation of severe bilirubin in these infants is unknown. However, most currently available data would suggest this risk is low.

## NEONATAL HEMATOLOGY

### Anemia

Early hematopoietic cells originate in the yolk sac. By 8 weeks' gestation, erythropoiesis is taking place in the liver, which remains the primary site of erythroid production through the early fetal period. By 6 months of gestation, the bone marrow becomes the principal site of red cell development. **Normal hemoglobin levels at term range from 13.7 to 20.1 g/dL. In the very preterm infant, values as low as 12 g/dL are acceptable.** Anemia at birth or appearing in the first few weeks of life is the result of blood loss, hemolysis, or underproduction of erythrocytes.<sup>62</sup> Blood loss that results in anemia can occur prenatally, at the time of delivery, or postnatally. In utero blood loss can be the result of fetomaternal bleeding, twin-to-twin transfusion, or blood loss resulting from trauma (maternal trauma, amniocentesis, external cephalic version). **The diagnosis of fetomaternal hemorrhage significant enough to cause anemia can be made using flow cytometry or the Kleihauer-Betke technique of acid elution to identify fetal cells in the maternal circulation.** Blood loss at delivery can be caused by umbilical cord rupture, incision of the placenta during cesarean delivery, placenta previa, or abruptio placentae. Internal hemorrhage can occur in the newborn, often related to a difficult delivery. Sites include intracranial, cephalohematomas, subgaleal, retroperitoneal, liver capsule, and ruptured spleen. When blood loss has been chronic (e.g., fetomaternal), infants will be pale at birth but well compensated and without signs of volume loss. The initial hematocrit will be low. Acute bleeding will present with signs of hypovolemia (tachycardia, poor perfusion, hypotension). The initial hematocrit can be normal or decreased, but after several hours of equilibration, it will be decreased. Anemia caused by hemolysis from blood group incompatibilities is common in the newborn period. Less common causes of hemolysis include erythrocyte membrane abnormalities, enzyme deficiencies, and disorders of hemoglobin synthesis. Impaired erythrocyte production is a rare cause of neonatal anemia.

### Polycythemia

Elevated hematocrits occur in 1.5% to 4% of live births. **Although 50% of polycythemic infants are average for gestational age (AGA), the proportion of polycythemic infants is greater in the SGA and LGA populations.** Causes of polycythemia include twin-to-twin transfusion, maternal-to-fetal transfusion, intrapartum transfusion from the placenta associated with fetal distress, chronic intrauterine hypoxia (SGA infants, LGA infants of diabetic mothers), delayed cord clamping, and chromosomal abnormalities. The consequence of polycythemia is hyperviscosity, which results in impaired perfusion of capillary beds. Therefore clinical symptoms can be related to any organ system (Table 22-10). Reduction of venous hematocrit to less than 60% may improve acute symptoms, but it has not been shown to improve long-term neurologic outcome.<sup>63</sup>

### Thrombocytopenia

Neonatal thrombocytopenia can be isolated or it can occur associated with deficiency of clotting factors. A differential

**TABLE 22-10** ORGAN-RELATED SYMPTOMS OF HYPERVISCOSITY

| SYSTEM                 | SYMPTOMS   |
|------------------------|--|
| Central nervous system | Irritability, jitteriness, seizures, lethargy  |
| Cardiopulmonary        | Respiratory distress caused by congestive heart failure or persistent pulmonary hypertension |
| Gastrointestinal       | Vomiting, heme-positive stools, abdominal distension, necrotizing enterocolitis              |
| Renal                  | Decreased urine output, renal vein thrombosis  |
| Metabolic              | Hypoglycemia   |
| Hematologic            | Hyperbilirubinemia, thrombocytopenia   |

**TABLE 22-11** DIFFERENTIAL DIAGNOSIS OF NEONATAL THROMBOCYTOPENIA

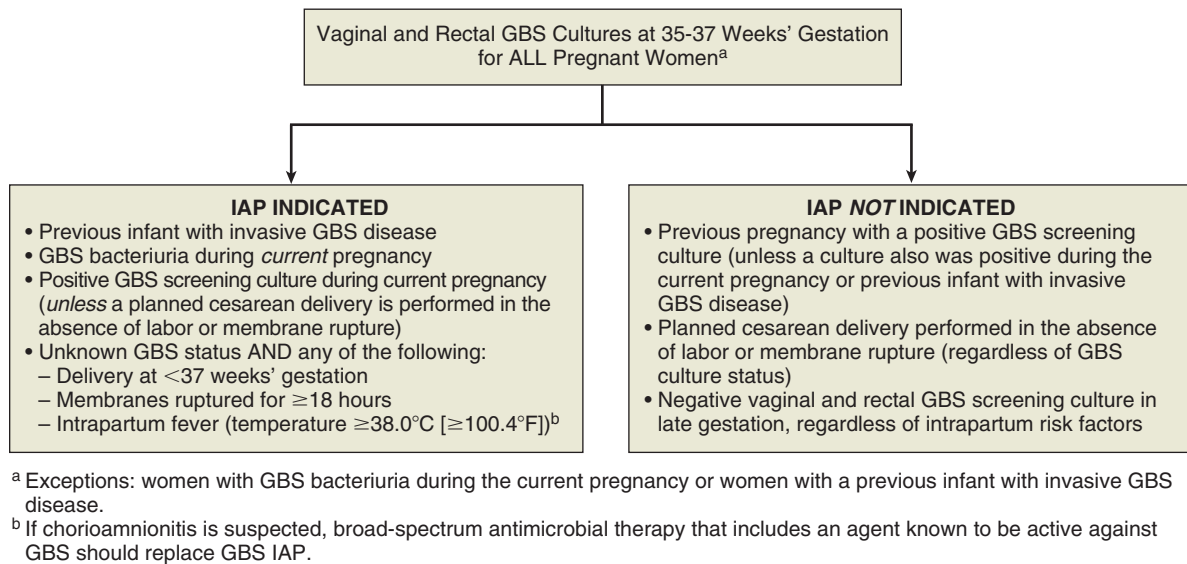

| DIAGNOSIS   | COMMENTS  |
|---|---|
| Immune  | Passively acquired antibody (e.g., idiopathic thrombocytopenic purpura, systemic lupus erythematosus, drug induced) |
|   | Alloimmune sensitization to HPA-1a antigen  |
| Infectious  | Bacterial and congenital viral infections (e.g., cytomegalovirus, rubella)  |
| Syndromes   | Absent radii; Fanconi anemia  |
| Giant hemangioma  |   |
| Thrombosis  |   |
| High-risk infant with RDS, pulmonary hypertension, and so forth | Disseminated intravascular coagulation<br>Isolated thrombocytopenia   |

HPA-1a, human platelet antigen 1a; RDS, respiratory distress syndrome.

**diagnosis is presented in Table 22-11.** The immune thrombocytopenias have implications for perinatal care. In idiopathic thrombocytopenic purpura (ITP), maternal antiplatelet antibodies that cross the placenta lead to destruction of fetal platelets (see Chapter 44). However, only 10% to 15% of infants born to mothers with ITP have platelet counts less than 100,000 per microliter, and even in infants with severe thrombocytopenia, serious bleeding is rare. Alloimmune thrombocytopenia occurs when an antigen is present on fetal platelets but is not present on maternal platelets. On exposure to fetal platelets, the mother develops antiplatelet antibodies that cross the placenta and cause destruction of fetal platelets. In the largest series of cases of suspected alloimmune thrombocytopenia, the majority were caused by human platelet antigen 1a (HPA-1a) alloantibodies. Because the maternal platelet count is normal, the diagnosis is suspected on the basis of a history of a previously affected pregnancy. Intracranial hemorrhage is common with this condition (10% to 20%) and can occur in the antenatal or intrapartum periods.<sup>64</sup> Antenatal treatment is guided by the severity of thrombocytopenia and presence of intracranial hemorrhage in the previously affected fetus. Treatment options include IV immunoglobulin infusions and corticosteroids given to the mother.<sup>64</sup>

### Vitamin K-Deficiency Bleeding of the Newborn

**Vitamin K<sub>1</sub> oxide (1 mg) should be given intramuscularly to all newborns to prevent hemorrhagic disease caused by a deficiency in vitamin K-dependent clotting factors (II, VII, IX, X).**<sup>65</sup> Babies born to mothers who are on anticonvulsant medication are particularly at risk of having vitamin K deficiency. Bleeding occurs in 0.25% to 1.4% of newborns who do

**FIG 22-15** Indications for intrapartum antimicrobial prophylaxis to prevent early onset of disease from Group B *Streptococcus* (GBS) using a universal prenatal culture screening strategy at 35 to 37 weeks' gestation for all pregnant women. IAP, intrapartum antimicrobial prophylaxis. (From Verani JR, McGee L, Schrag SJ; Division of Bacterial Diseases, National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention. Prevention of perinatal group B streptococcal disease—revised guidelines from CDC, 2010. *MMWR Recomm Rep*. 2010;59[RR-10]:1-36.)

not receive vitamin K prophylaxis, generally in the first 5 days to 2 weeks but sometimes as late as 12 weeks. Oral vitamin K has been shown to be effective in raising vitamin K levels, but it is not as effective in preventing late hemorrhagic disease of the newborn, which most commonly occurs in breastfed infants whose courses have been complicated by diarrhea.

## PERINATAL INFECTION

### Early-Onset Bacterial Infection

The unique predisposition of the neonate to bacterial infection is related to defects in both innate and acquired immune responses.<sup>66</sup> The incidence of bacterial infection in infants younger than 5 days of age is 1 to 2 per 1000 live births. **Maternal colonization with group B *Streptococcus* (GBS), rupture of membranes for more than 12 to 18 hours, and the presence of chorioamnionitis increase the risk of infection.**<sup>67,68</sup> Maternal fever from other etiologies (e.g., epidural anesthesia) does not increase the risk of neonatal infection and merits only close observation of the newborn. Irrespective of membrane rupture, infection rates are higher in preterm infants. **The majority of early-onset bacterial infections present on day 1 of life, with respiratory distress the most common presenting symptom.** These infections are most often caused by GBS and gram-negative enteric pathogens. The algorithm for prevention of early-onset GBS infections is presented in Figure 22-15 with the approach to the newborn shown in Figure 22-16. Other etiologies of infection in the newborn are covered in Chapters 52, 53, and 54.

## RESPIRATORY DISTRESS

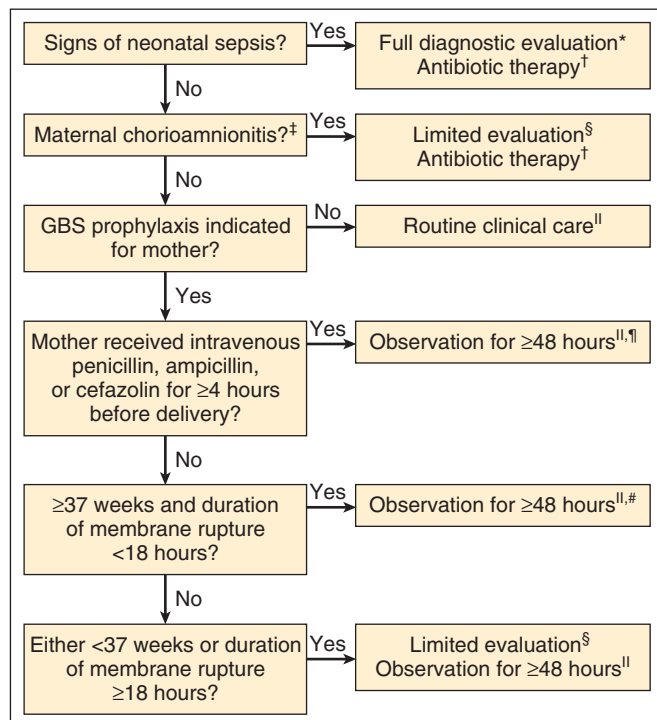

The establishment of respiratory function at birth is dependent on expansion and maintenance of air sacs, clearance of lung fluid, and adequate pulmonary perfusion. In many premature

and other high-risk infants, developmental deficiencies or unfavorable perinatal events hamper a smooth respiratory transition. **The presentation of respiratory distress is among the most common symptom complexes seen in the newborn and may be secondary to both noncardiopulmonary and cardiopulmonary etiologies** (Table 22-12). The symptom complex includes an elevation of the respiratory rate to greater than 60 per minute with or without cyanosis, nasal flaring, intercostal and sternal retractions, and expiratory grunting. The retractions are the result of the neonate's efforts to expand a lung with poor compliance using a very compliant chest wall. The expiratory grunt is caused by closure of the glottis during expiration in an effort to increase expiratory pressure to help maintain FRC. The evaluation of such an infant requires use of history, physical examination, and laboratory data to arrive at a diagnosis. It is important to consider causes other than those related to the heart and lungs, because the natural tendency is to focus immediately on the more common cardiopulmonary etiologies.

### Cardiovascular Causes

Cardiovascular causes of respiratory distress in the neonatal period can be divided into two major groups—those with structural heart disease and those with persistent right-to-left shunting through fetal pathways and a structurally normal heart. **The two presentations of serious structural heart disease in the first week of life are cyanosis and congestive heart failure.**<sup>69</sup> Examples of cyanotic heart disease include transposition of the great vessels, tricuspid atresia, certain types of truncus arteriosus, total anomalous pulmonary venous return, and right-sided outflow obstruction including tetralogy of Fallot and pulmonary stenosis or atresia. Infants with congestive heart failure generally have some form of left-sided outflow obstruction (e.g., hypoplastic left heart syndrome, coarctation of the aorta). **It is now recommended that all newborns have pulse oximetry screening at 24 hours to identify critical heart disease.**<sup>70</sup>

\* Full diagnostic evaluation includes a blood culture, a complete blood count (CBC) including white blood cell differential and platelet counts, chest radiograph (if respiratory abnormalities are present), and lumbar puncture (if patient is stable enough to tolerate procedure and sepsis is suspected).

† Antibiotic therapy should be directed toward the most common cause of neonatal sepsis, including intravenous ampicillin for GBS and coverage for other organisms (including *Escherichia coli* and other gram-negative pathogens) and should take into account local antibiotic resistance patterns.

‡ Consultation with obstetric providers is important to determine the level of clinical suspicion for chorioamnionitis. Chorioamnionitis is diagnosed clinically and some of the signs are nonspecific.

§ Limited evaluation includes blood culture (at birth) and CBC with differential and platelets (at birth and/or at 6-12 hours of life).

¶ If signs of sepsis develop, a full diagnostic evaluation should be conducted and antibiotic therapy initiated.

¶ If ≥37 weeks' gestation, observation may occur at home after 24 hours if other discharge criteria have been met, access to medical care is readily available, and a person who is able to comply fully with instructions for home observation will be present. If any of these conditions is not met, the infant should be observed in the hospital for at least 48 hours and until discharge criteria are achieved.

# Some experts recommend a CBC with differential and platelets at age 6-12 hours.

**FIG 22-16** Algorithm for secondary prevention of early-onset Group B streptococcal disease among newborns. (From Verani JR, McGee L, Schrag SJ; Division of Bacterial Diseases, National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention. Prevention of perinatal group B streptococcal disease—revised guidelines from CDC, 2010. *MMWR Recomm Rep*. 2010; 59[RR-10]:1-36.)

## Pulmonary Causes

Of the causes of respiratory distress related to the airways and pulmonary parenchyma listed in Table 22-12, the differential diagnosis in a term infant includes transient tachypnea, aspiration syndromes, congenital pneumonia, and spontaneous pneumothorax.<sup>71</sup> The syndrome of transient tachypnea presents as respiratory distress in nonasphyxiated term infants or slightly preterm infants. The clinical features include various

combinations of cyanosis, grunting, nasal flaring, retracting, and tachypnea during the first hours after birth. The chest radiograph is the key to the diagnosis, with prominent perihilar streaking and fluid in the interlobar fissures. The symptoms generally subside in 12 to 24 hours, although they can persist longer. The preferred explanation for the clinical features is delayed reabsorption of fetal lung fluid. Transient tachypnea is seen more commonly in infants delivered by elective cesarean section and in the slightly preterm infant (see “Mechanics of the First Breath”).

At delivery, the neonate may aspirate clear amniotic fluid or fluid mixed with blood or meconium. MAS occurs in full-term or postmature infants. The perinatal course is often complicated by chronic intrauterine hypoxia, fetal distress, and low Apgar scores. These infants exhibit tachypnea, retractions, cyanosis, an overdistended and barrel-shaped chest, and coarse breath sounds. Chest radiography reveals coarse, irregular pulmonary densities with areas of diminished aeration or consolidation. The incidence of air leaks is high, and many of the infants exhibit persistent pulmonary hypertension.

**The lungs represent the most common primary site of infection in the neonate.** Both bacterial and viral infections can be acquired before, during, or after birth. The most common route of infection, particularly for bacteria, is ascending from the genital tract before or during labor. Infants with congenital pneumonia present with respiratory distress very early in life. The chest radiograph pattern is often indistinguishable from other causes of respiratory distress, particularly hyaline membrane disease (HMD).

Spontaneous pneumothorax occurs in 1% of all deliveries, but a much lower percentage results in symptoms. The risk is increased by manipulations such as positive-pressure ventilation. Respiratory distress is usually present from shortly after birth, and breath sounds may be diminished on the affected side. The majority of these air leaks resolve spontaneously without specific therapy.

**HMD remains the most common etiology for respiratory distress in the neonatal period.** Initial reports of Avery and Mead<sup>72</sup> demonstrated a high surface tension in extracts of lungs from infants dying of RDS, which led to the present understanding of the role of surfactant in the pathogenesis of HMD. The deficiency of surfactant in the premature infant increases alveolar surface tension and, according to LaPlace's law (see Fig. 22-2), increases the pressure necessary to maintain patent alveoli. The end result is poor lung compliance, progressive atelectasis, loss of FRC, alterations in ventilation-perfusion mismatch, and uneven distribution of ventilation. HMD is further complicated by the weak respiratory muscles and compliant chest wall of the premature infant. Hypoxemia and respiratory and metabolic acidemia contribute to increased pulmonary vascular resistance, right-to-left ductal shunting, and worsening ventilation-perfusion mismatch that exacerbate hypoxemia. Hypoxemia and hypoperfusion result in alveolar epithelial damage with increased capillary permeability and leakage of plasma into alveolar spaces. Leakage of protein into airspaces serves to inhibit surfactant function, which exacerbates the disease process. **The materials in plasma and cellular debris combine to form the characteristic hyaline membrane seen pathologically.** The recovery phase is characterized by regeneration of alveolar cells, including type II cells, with an increase in surfactant activity.

Clinically, neonates with HMD demonstrate tachypnea, nasal flaring, subcostal and intercostal retractions, cyanosis, and

**TABLE 22-12** RESPIRATORY DISTRESS IN THE NEWBORN

| NONCARDIOPULMONARY              | CARDIOVASCULAR                          | PULMONARY                       |

| Asphyxiating thoracic dystrophy |   | Mass lesions                    |
|                                 |   | Lobar emphysema                 |
|                                 |   | Cystic adenomatoid malformation |

**FIG 22-17** **A**, Chest radiograph demonstrates findings consistent with hyaline membrane disease (respiratory distress syndrome) including extensive atelectasis with homogeneous ground-glass appearance to the lung fields and air bronchograms and elevated diaphragm. **B**, Chest radiographs demonstrate changes consistent with bronchopulmonary dysplasia, including heterogeneous areas of atelectasis and hyperlucency.

expiratory grunting. The radiologic appearance of the lungs is consistent with an extensive atelectatic process (Fig. 22-17). The infiltrate is diffuse and has a ground-glass appearance, and major airways are air filled and contrast with the atelectatic alveoli to create the appearance of air bronchograms. The diaphragm is elevated because of profound hypoexpansion. Acute complications of HMD include infection, air leaks, and persistent patency of the ductus arteriosus.

**Of more concern than acute complications are the long-term sequelae suffered by infants with HMD. The major long-term consequences are chronic lung disease (CLD) that requires prolonged ventilator and oxygen therapy and**

**includes bronchopulmonary dysplasia and significant neurologic impairment.** The incidence is especially high in infants born at less than 800 g. The severity is variable and ranges from very mild pulmonary insufficiency to severe disease with prolonged mechanical ventilation, frequent readmissions for respiratory exacerbations after nursery discharge, and a higher incidence of neurodevelopmental sequelae compared with VLBW controls. Although pulmonary function improves over time and most children do well, long-term pulmonary sequelae are evident. **Factors involved in the etiology of CLD are gestational age, elevated inspired oxygen concentration, ventilator volutrauma, severity of underlying disease, inflammation, and infection.**

**TABLE 22-13** CLASSIFICATION OF INTRAVENTRICULAR HEMORRHAGE

| GRADE | DEFINITION   |
|-------|--|
| I     | Subependymal hemorrhage  |
| II    | Intraventricular hemorrhage without ventricular dilatation         |
| III   | Intraventricular hemorrhage with ventricular dilatation            |
| IV    | Intraventricular hemorrhage with associated parenchymal hemorrhage |

Modified from Papile LA, Burstein J, Burstein R, Koffler H. Incidence and evolution of subependymal and intraventricular hemorrhage: a study of infants with birth weights less than 1500 g. *J Pediatr*. 1978;92:529.

## NEONATAL NEUROLOGY

### Intraventricular Hemorrhage and Periventricular Leukomalacia

Periventricular/intraventricular hemorrhage (PVH/IVH) and periventricular leukomalacia (PVL) are the most common neurologic complications of prematurity. The overall incidence of PVH/IVH is 20% to 30% in infants weighing less than 1500 g or at less than 31 weeks' gestation with severe bleeds (grades 3 and 4) at 10%. The highest incidence is observed in babies of the lowest gestational age and birthweight; nearly 50% and 25%, respectively, of all IVH and severe bleeds are seen in babies born at less than 700 g.<sup>73</sup> Bleeds are graded according to severity as indicated in Table 22-13, and diagnosis is confirmed with ultrasound. PVL is reported in about 2% to 4% of infants younger than 32 weeks' gestation,<sup>73</sup> but the cystic PVL reported likely underestimates the full spectrum of PVL.

Cystic PVL comprises multifocal areas of necrosis with cyst formation in deep periventricular white matter. It has been well characterized by ultrasound, and the expanded use of MRI scans in preterm infants has identified infants—especially among those of lower gestational age—with diffuse white matter injury often accompanied by ventricular dilation. These findings are far more common in the preterm population than cystic PVL and represent part of the spectrum of PVL. **The other important clinical correlate with PVL is maternal chorioamnionitis and neonatal infection.**

**The neurodevelopmental outcome of infants with IVH is related to the severity of the original bleed, development of posthemorrhagic hydrocephalus, and the degree of associated parenchymal injury.** Although cranial ultrasound is the primary modality used to diagnose IVH and PVL, it is not a sensitive predictor of outcome. In extremely low-birthweight infants with no abnormalities on cranial ultrasound, nearly one third will have some degree of neurodevelopmental handicap (cerebral palsy or cognitive delays).<sup>74</sup> Infants with grade I or II IVH are at slightly greater risk for handicap.<sup>75</sup> School-aged children who had mild IVH display a variety of neurologic and cognitive abnormalities, including motor incoordination, hyperactivity, attention and learning deficits, and visual motor difficulties.<sup>76</sup> Infants with progressive ventricular dilatation (grade III) or periventricular hemorrhagic infarction (grade IV) are at higher risk for major neurodevelopmental handicap as well as less severe neurologic and cognitive disabilities.<sup>77,78</sup> The presence of severe cystic PVL carries a guarded prognosis with a high risk of cerebral palsy and associated cognitive deficit.

Although the incidence and severity of intracranial hemorrhage have progressively decreased as a result of advances in both

obstetric and neonatal care, the therapeutic focus continues to be on strategies to prevent this complication of prematurity. Both antenatal and postnatal approaches have been developed. For the most part, postnatal pharmacologic strategies have not had a major effect in decreasing the incidence, severity, and neurodevelopmental outcomes of IVH. **Because IVH and PVL are likely perinatal events, antenatal prevention holds the most promise. Although not used specifically to decrease the incidence of IVH and PVL, antenatal corticosteroids decrease the frequency of these complications and likely represent the most important antenatal strategy to prevent intracranial hemorrhage.**<sup>5</sup> Furthermore, antenatal magnesium sulfate also is used for neuroprotection of the newborn prior to preterm delivery, although long-term benefits are unclear.<sup>79,80</sup>

## CLASSIFICATION OF NEWBORNS BY GROWTH AND GESTATIONAL AGE

**In assessing the risk for mortality or morbidity in a given neonate, evaluation of birthweight and gestational age together provide the clearest picture.** When large populations are considered, maternal dates remain the single best determinant of gestational age. Early obstetric ultrasound is a very useful adjunct (see Chapter 9). However, in the individual neonate, especially when dates are uncertain, a reliable postnatal assessment of gestational age is necessary. A scoring system that appraises gestational age on the basis of physical and neurologic criteria was developed by Dubowitz and colleagues and later simplified and updated by Ballard and associates (Fig. 22-18).<sup>81</sup> The Ballard examination is less accurate before 28 weeks' gestation, but additional features can be examined to aid in the determination of an accurate gestational age. The anterior vascular capsule of the lens reveals complete coverage of the lens by vessels at 27 to 28 weeks. Foot length (from the heel to the tip of the largest toe) is 4.5 cm at 25 weeks and increases by 0.25 cm/wk. Using growth parameters and gestational age, infants can then be classified by means of intrauterine growth curves such as those developed by Lubchenco and colleagues (Fig. 22-19).<sup>82</sup> **Infants born between 37 and 42 weeks are classified as term infants; less than 37 weeks is preterm; and greater than 42 weeks is postterm** (see Chapter 36). In each grouping, infants are then identified according to growth; *AGA* if birthweight falls between the 10th and 90th percentiles, *SGA* if birthweight is below the 10th percentile, and *LGA* if birthweight is above the 90th percentile. Knowledge of a baby's birthweight in relation to gestational age is helpful in anticipating neonatal problems.

**The causes of growth restriction are numerous** (see Chapter 33). Those operative early in pregnancy such as chromosomal aberrations, congenital viral infections, and some drug exposures induce symmetric restriction of weight, length, and head circumference. In most cases, the phenomenon occurs later in gestation and leads to more selective restriction of birthweight alone. Such factors include hypertension or other maternal vascular disease and multiple gestation. Neonatal problems in addition to chromosomal abnormalities and congenital viral infections common in SGA infants include birth asphyxia, hypoglycemia, polycythemia, and hypothermia. In addition, congenital malformations are seen more frequently among undergrown infants.<sup>83</sup>

The most common identifiable conditions that lead to excessive infant birthweight are maternal diabetes and maternal

## Neuromuscular Maturity

|                       | -1       | 0        | 1             | 2             | 3            | 4        | 5        |

| 15    | 30    |
| 20    | 32    |
| 25    | 34    |
| 30    | 36    |
| 35    | 38    |
| 40    | 40    |
| 45    | 42    |
| 50    | 44    |

**FIG 22-18** Assessment of gestational age. ant., anterior. (From Ballard JL, Khoury JC, Wedig K, et al. New Ballard Score, expanded to include extremely premature infants. *J Pediatr*. 1991;119:417.)

obesity. Other conditions associated with macrosomia are erythroblastosis fetalis, other causes of fetal hydrops, and Beckwith-Wiedemann syndrome. LGA infants are at risk for hypoglycemia, polycythemia, congenital anomalies, cardiomyopathy, hyperbilirubinemia, and birth trauma.

## NURSERY CARE

Nurseries are classified on the basis of the level of care provided (Box 22-4). **Level I nurseries care for infants presumed healthy, with an emphasis on screening and surveillance. Level II nurseries can care for infants at more than 32 weeks'**

**FIG 22-19** Intrauterine growth curves for weight, length, and head circumference for singleton births in Colorado.  $100 \text{ w grams/L}^3 \text{ centimeters}$ , weight in grams divided by 100, with the quotient divided by the length cubed. (From Lubchenco LO, Hansman C, Boyd E. Intrauterine growth in length and head circumference as estimated from live births at gestational ages from 26 to 42 weeks. *Pediatrics*. 1966;37:403.)

#### BOX 22-4 LEVELS OF NURSERY CARE

**Level 1:** A nursery with personnel and equipment to perform neonatal resuscitation, evaluate and provide newborn care for healthy infants, stabilize and provide care for infants born at 35 to 37 weeks' gestation who remain physiologically stable, and stabilize ill infants and those at less than 35 weeks' gestation before transport to a higher-level facility.

**Level 2:** A facility able to provide care to infants born at more than 32 weeks' gestation weighing more than 1500 g who have physiologic immaturity, are moderately ill with problems expected to resolve quickly, and do not need urgent subspecialty care; and they can provide convalescent care for infants after intensive care.

2A: Does *not* do mechanical ventilation or nasal CPAP

2B: Can do short-term (<24 hr) ventilation.

**Level 3:** Provides care for the sickest and most complex infants.

3A: Provides care for infants beyond 28 weeks and 1000 g who are in need of conventional mechanical ventilation.

3B: Can provide care for infants at less than 28 weeks and 1000 g, including high-frequency ventilation, inhaled nitric oxide, on-site subspecialists, advanced imaging, on-site or nearby pediatric surgeons, and anesthesiologists.

3C: Can provide ECMO and repair of complex congenital heart disease.

Modified from the American Academy of Pediatrics Committee on Fetus and Newborn. Levels of neonatal care. *Pediatrics*. 2004;114:1341. CPAP, continuous positive airway pressure; ECMO, extracorporeal membrane oxygenation.

gestation who weigh at least 1500 g but who require special attention but will probably not need subspecialty services. **Level III nurseries** care for all newborn infants who are critically ill regardless of the level of support required.<sup>84</sup> A perinatal center encompasses both high-risk obstetric services and level III nursery services. Survival for VLBW infants is improved with delivery at centers with a higher volume (>100) of VLBW deliveries per year and a higher-level nursery.<sup>85</sup> This survival advantage may extend to moderately preterm newborns as well.<sup>86</sup>

Care of the normal newborn involves observation of transition from intrauterine to extrauterine life, establishing breast or bottle feedings, noting normal patterns of stooling and urination, and surveillance for neonatal problems. Signs suggestive of illness include temperature instability, change in activity, refusal to feed, pallor, cyanosis, jaundice, tachypnea and respiratory distress, delayed (>24 hr) passage of the first stool or void, and bilious vomiting. In addition, the following laboratory screens should be performed: (1) blood type and direct and indirect Coombs test on infants born to mothers with type O or Rh-negative blood; (2) glucose screen in infants at risk for hypoglycemia; (3) hematocrit in infants with signs and symptoms of anemia or polycythemia; and (4) mandated screening for inborn errors of metabolism, such as phenylketonuria (PKU) and galactosemia, sickle cell disease, hypothyroidism, cystic fibrosis, and congenital adrenal hyperplasia. Many states now mandate or offer expanded newborn screening by tandem mass spectroscopy that looks for a variety of other inborn metabolic errors. **All newborns should also have an initial hearing screen performed before discharge.** Finally, babies routinely receive 1 mg of vitamin K intramuscularly to prevent vitamin K–deficient hemorrhagic disease of the newborn, and erythromycin ointment is used to prevent gonococcal ophthalmia neonatorum. Hepatitis B vaccine should be given to all newborns, and hepatitis B immunoglobulin is also administered to infants born to HBsAg-positive mothers (see Chapter 52). Infants should be positioned supine for sleep to minimize the risk of sudden infant death syndrome (SIDS).<sup>87</sup>

Discharge of the normal newborn is safe provided all criteria are met in Box 22-5. The initial follow-up visit needs to occur 48 to 72 hours after discharge.<sup>88</sup>

**Circumcision is an elective procedure to be performed only in healthy, stable infants.** The procedure probably has medical benefits that include prevention of phimosis, paraphimosis, and balanoposthitis as well as a decreased incidence of cancer of the penis, cervical cancer in partners of circumcised men, sexually transmitted diseases (including HIV), and urinary tract infection in male infants. Most parents, however, make the decision regarding circumcision for nonmedical reasons. The risks of the procedure include local infection, bleeding, removal of too much skin, and urethral injury. The combined incidence of these complications is less than 1%. **Local anesthesia** (dorsal penile nerve block or circumferential ring block) **with 1% lidocaine without epinephrine is safe and effective and should always be used.** Techniques that allow visualization of the glans throughout the procedure (Plastibell and Gomco clamp) are preferred to a “blind” technique (Mogen clamp) because of occasional amputation of the glans with the latter. Circumcision is contraindicated in infants with genital abnormalities. In infants with a family history of bleeding disorders, appropriate laboratory evaluation should be performed before the procedure.

## Care of the Parents

Klaus and Kennell<sup>89</sup> have outlined the steps in maternal-infant attachment: (1) planning the pregnancy; (2) confirming the pregnancy; (3) accepting the pregnancy; (4) noting fetal movement; (5) accepting the fetus as an individual; (6) going through labor; (7) giving birth; (8) hearing and seeing the baby; (9) touching, smelling, and holding the baby; (10) caretaking; and (11) accepting the infant as a separate individual. Numerous influences can affect this process. A mother's and father's actions and responses are derived from their own genetic endowment and their own interfamily relationships, cultural practices, past experiences with this or previous pregnancies, and, most important, how they were raised by their parents. Also critical is the in-hospital experience surrounding the birth—how doctors and nurses act, separation from the baby, and hospital practices.

**The 60- to 90-minute period after delivery is a very important time.** The infant is alert, active, and able to follow with his or her eyes, allowing meaningful interaction to transpire between infant and parents. The infant's array of sensory and motor abilities evokes responses from the mother and initiates communication that may be helpful for attachment and induction of reciprocal actions. Whether a critical period for these initial interactions exists is unclear, but improved mothering behavior does seem to occur with increased contact over the first 3 postpartum days. **The practical implications of this information are that labor and delivery should pose as little anxiety as possible for the mother, and parents and baby should have time together immediately after delivery if the baby's medical condition permits.**

**Mothers with high-risk pregnancies are at increased risk for subsequent parenting problems.** It is important for both obstetrician and pediatrician alike to be involved prenatally to allow time to prepare the family for anticipated aspects of the baby's care and to provide reassurance that the odds are heavily in favor of a live baby who will ultimately be healthy. If it is possible before birth to anticipate the need for neonatal intensive care, such as with a known congenital anomaly or with refractory premature labor, maternal transport to a center with a unit that can care for the baby should be planned. Before delivery, it is also very helpful to allow the parents to tour the unit their baby will occupy.

**The basic principle in dealing with parents of a sick infant is to provide essential information clearly and accurately to both parents, preferably when they are together.** With improved survival rates, especially in premature infants, most babies will do well despite early problems. Therefore it is reasonable in most circumstances to be positive about the outcome. There is also no reason to emphasize problems that might occur in the future or to deal with individual worries of the physician. If asked, questions need to be answered honestly, but the list of parents' worries does not need to be voluntarily increased.

Before the parents' initial visit to the unit, a physician or nurse should describe what the baby and the equipment look like. When they arrive in the nursery, this can again be reviewed in detail. If a baby must be moved to another hospital, the mother should be given time to see and touch her infant before the transfer. The father should be encouraged to meet the baby at the receiving hospital so he can become comfortable with the intensive care unit. He can serve as a link between baby and mother with information and photographs.

**BOX 22-5 INFANT CRITERIA FOR EARLY DISCHARGE**

1. The newborn is term, defined as an infant born between 37 and 41 completed weeks of gestation.
2. No abnormalities are present that require continued hospitalization.
3. Vital signs are documented as being within normal ranges with appropriate variations based on physiologic state and stable for the 12 hours preceding discharge.
4. The infant has urinated regularly and has passed stool spontaneously.
5. The infant has completed at least two successful consecutive feedings.
6. No significant bleeding is present at the circumcision site.
7. The clinical risk of development of subsequent hyperbilirubinemia has been assessed, and appropriate management and/or follow-up plans have been instituted.
8. The infant has been adequately evaluated and monitored for sepsis on the basis of maternal risk factors and in accordance with current guidelines for prevention of perinatal Group B streptococcal disease.
9. Maternal blood test and screening results are available and have been reviewed, including those for maternal syphilis, hepatitis B surface antigen status, and a test for HIV in accordance with state regulations.
10. Infant blood tests are available and have been reviewed, such as cord or infant blood type and direct Coombs test results as clinically indicated.
11. Newborn metabolic and hearing screenings have been completed per hospital protocol and state regulations.
12. The mother's knowledge, ability, and confidence to provide adequate care for her infant have been assessed for competency regarding:
  - Breastfeeding or bottle feeding (the breastfeeding mother and infant should be assessed by trained staff regarding breastfeeding position, latch-on, and adequacy of swallowing)
  - The importance and benefits of breastfeeding for both mother and infant
  - Appropriate urination and defecation frequency for the infant
  - Cord, skin, and genital care for the infant, including circumcision care
  - The ability to recognize signs of illness and common infant problems, particularly jaundice
  - Infant safety (such as use of an appropriate car safety seat, supine positioning for sleeping, maintaining a smoke-free environment, and room sharing)
13. Family, environmental, and social risk factors have been assessed, and the mother and her other family members have been educated about safe home environment. These risk factors include but are not limited to:
  - Untreated parental substance abuse or positive urine toxicology results in the mother or newborn
  - History of child abuse or neglect
  - Mental illness in a parent who is in the home
  - Lack of social support, particularly for single and first-time mothers
  - Mothers who live in a shelter, a rehabilitation home, or on the street
  - History of domestic violence, particularly during this pregnancy
  - Communicable illness in a parent or other members of the household
  - Adolescent mother, particularly if other above-listed conditions apply
14. A medical home for continuing medical care for the infant has been identified, and a plan for timely communication of pertinent clinical information to the medical home is in place. For newborns discharged less than 48 hours after delivery, an appointment should be made for the infant to be examined by a licensed health care professional, preferably within 48 hours of discharge based on risk factors but no later than 72 hours in most cases.
15. Barriers to adequate follow-up care for the newborn—such as lack of transportation to medical care services, lack of easy access to telephone communication, and non-English-speaking parents—have been assessed and, whenever possible, assistance has been given to the family to make suitable arrangements to address them.

**The birth of an infant with a congenital malformation provides another situation in which staff support is essential.** Parents' reactions to the birth of a malformed infant follow a predictable course. For most, there is initial shock and denial, a period of sadness and anger, gradual adaptation, and finally an increased satisfaction with and the ability to care for the baby. The parents must be allowed to pass through these stages and, in effect, to mourn the loss of the anticipated normal child.

**The death of an infant or a stillborn is a highly stressful family event.** This fact has been emphasized by Cullberg,<sup>90</sup> who found that psychiatric disorders developed in 19 of 56 mothers studied 1 to 2 years after the deaths of their neonates. One of the major predispositions was a breakdown of communication between parents. The health care staff needs to encourage the parents to talk with each other, discuss their feelings, and display emotion. The staff should talk with the parents at the time of

death and then several months later to review the findings of the autopsy, answer questions, and see how the family is doing.

### Kangaroo Care

As a baby's course proceeds, the nursery staff can help the parents become comfortable with their infant. This can include participation in caretaking as well as skin-to-skin contact with the infant (kangaroo maternal care [KMC]). **In addition to benefits for thermoregulation, in the LBW population (<2500 g), KMC improves rates of mortality, nosocomial infection/sepsis, and length of hospital stay.** A benefit also may exist for infant growth and breastfeeding rates.<sup>44</sup> Individualized developmentally based care has also shown some benefit for high-risk infants.<sup>91</sup> It is also important for the staff to discuss among themselves any problems that parents may be having as well as to keep a record of visits and phone calls. This approach will allow early intervention to deal with potential problems.

## OUTCOME OF NEONATAL INTENSIVE CARE AND THRESHOLD OF VIABILITY

More sophisticated neonatal care has resulted in improved survival of VLBW (<1500 g) infants, in particular those less than 1000 g (Fig. 22-20). Current survival rates are 90% or greater for infants greater than 1000 g and 28 weeks' gestation, 85% at 800 to 1000 g and 26 to 27 weeks' gestation, and nearly 70% to 75% for infants at 700 to 800 g and 25 weeks' gestation, with a considerable drop in survival below 700 g and at less than 25 weeks.<sup>92,93</sup> **Predictions of survival can be significantly improved by consideration of clinical data in addition to birthweight and gestational age.** These data include an appropriate course of antenatal steroids, sex of the baby, and whether the pregnancy is a singleton gestation. It is important to note that survival in terms of best obstetric estimate is greater at very low gestational ages than survival in terms of postnatal assessment of gestational age. **The numbers in terms of best obstetric estimate based on data at the institution of birth should be referred to for antenatal counseling. Alternatively, data from the National Institute of Child Health and Human Development (NICHD) can be referenced as well.** It is critically important when making decisions at the thresholds of viability that a shared understanding is reached among neonatology, obstetrics, and the family. Paramount to that discussion is that improved survival comes with a price, because a variety of morbidities are seen in these infants. **The rate of severe neurologic disability is fairly constant at 10% of all VLBW**

**survivors from 1000 to 1500 g.** The number increases from 10% to 25% in infants of extremely low birthweight (<1000 g) and is particularly troubling for infants born at less than 25 weeks' gestation. In these infants, approximately half of the survivors have moderate or severe neurosensory disability (Fig. 22-21).<sup>92</sup> **In addition to the increase in severe disability, these infants have an increased rate of lesser disabilities that include deficits in academic achievement, behavior and attention problems, and the need for special education in school** (see Fig. 22-20).<sup>94-96</sup> **Finally, recent information has begun to demonstrate an increase in autism spectrum disorders in preterm infant survivors.**<sup>97</sup> Risk factors for neurologic morbidity include seizures, major intracranial hemorrhage or PVL, severe intrauterine growth restriction (IUGR), NEC, chorioamnionitis in the mother, neonatal infection, need for mechanical ventilation, chronic lung disease (CLD), poor early head growth, retinopathy of prematurity, and low socioeconomic class.

In addition, other morbidities need to be considered. Because the number of survivors weighing less than 1000 g has increased, a reemergence of **retinopathy of prematurity** has been seen. This disorder is caused by retinal vascular proliferation that leads to hemorrhage, scarring, retinal detachment, and blindness. It is triggered by low concentrations of insulin-like growth factor 1 (IGF-1) and relative hyperoxia in the early postnatal period, which leads to delayed retinal vessel growth. Later increases in IGF-1 allow vascular endothelial growth factor (VEGF)-induced angiogenesis and result in an abnormal vascular proliferation.<sup>98</sup>

**FIG 22-20** Cognitive scores according to sex and completed weeks of gestation at birth for 241 extremely preterm children and 160 age-matched classmates who were full term at birth. The scores are the Kaufman Assessment Battery for Children scores for the Mental Processing Composite or developmental scores according to the Griffiths Scales of Mental Development and NEPSY (a developmental neuropsychological assessment). Bars indicate mean scores, and the dashed line is the mean of a standardized population. (From Marlow N, Wolke D, Bracewell MA, et al: Neurologic and developmental disability at six years of age after extremely preterm birth. *N Engl J Med*. 2005;352:9.)

**FIG 22-21** Outcomes at 18 and 22 months by birthweight in extremely low-birthweight infants. FU, follow-up. (From Gargus RA, Vohr BR, Tyson JE, et al: Unimpaired outcomes for extremely low birth weight infants at 18 to 22 months. *Pediatrics*. 2009;124:112.)

Incidence of acute proliferative retinopathy by birthweight is less than 10% in infants who weigh more than 1250 g, 20% in those 1000 to 1250 g, 50% to 60% in those 750 to 1000 g, and 70% in those less than 750 g.<sup>73</sup> Severe retinopathy is evident in 5% of the infants 1000 to 1250 g, in 10% of infants 750 to 1000 g, and in 25% to 40% of infants less than 750 g. Of the infants with severe retinopathy, 10% (4% of the total population) will go on to have severe visual problems. The other major neurosensory morbidity is hearing loss, which occurs in 2% of NICU survivors. Other sequelae of neonatal intensive care include CLD, growth failure, short gut, and need for postdischarge rehospitalization.

The information presented earlier on outcome is relevant to discussions about obstetric and neonatal intervention at the threshold of viability. **If the end point of survival without major disability is considered, this occurs in 0% at 22 weeks, less than 10% at 23 weeks, approximately 20% to 25% at 24 weeks, and approximately 45% to 50% at 25 weeks.**<sup>92,93</sup> With this information in mind, most neonatologists believe that care is clearly beneficial beyond 25 completed weeks, whereas less than half believe that care is beneficial at 24 to 24 6/7 weeks, and even fewer feel care is beneficial at less than 24 completed weeks. That said, more than half would intervene on behalf of an infant beyond 23 weeks' gestation. These discussions need to be modified depending on circumstances. For instance, morbidity and mortality would increase in the face of overt infection or severe IUGR. **A reasonable approach would seem to be to encourage interventions on behalf of a fetus or newborn beyond 25 completed weeks' gestation and to not intervene at less than 23 weeks' gestation. The range between 23 and 25 weeks should be evaluated on a case-by-case basis.**

## LATE PRETERM INFANT

The rate of preterm births in the United States has been increasing, especially for births between 34 0/7 and 36 6/7 weeks, which now make up 70% of all preterm births. Of these births, as many as 23% had no recorded indication for early delivery noted on the birth certificate.<sup>99</sup> **Compared with term infants, late preterm infants have a higher mortality and prevalence of acute neonatal problems that include respiratory distress, temperature instability, hypoglycemia, apnea, jaundice, and feeding difficulties.**<sup>97</sup> The respiratory issues are caused by delayed clearance of fetal lung fluid, surfactant deficiency, or both and can on occasion progress to respiratory failure. Feeding issues are caused by poor coordination of suck and swallow, which can interfere with bottle feeding and can cause failure to establish successful breastfeeding. This can put the infant at risk for both dehydration and excessive jaundice. Late preterm infants have at least twice the risk of an infant born at term to have significantly elevated serum bilirubin concentrations. Rehospitalizations due to jaundice, proven or suspected infection, feeding difficulties, and failure to thrive are much more common than in term infants. Long-term neurodevelopmental outcome is also compromised with reports of cognitive and emotional regulation difficulties, school problems, and slightly lower IQs.<sup>100</sup> An increase in deficits in lung function are apparent that may persist into adulthood because of immaturity of the respiratory system at birth.<sup>101</sup>

**Late preterm infants, even if similar in size to their term counterparts, should be considered preterm, rather than near term, and need close in-hospital monitoring for potential**

**complications.** Discharge of these babies should be delayed until they have demonstrated reliable oral intake and resolution of any acute neonatal problems. The initial outpatient follow-up visit should occur within 48 to 72 hours of discharge.

## KEY POINTS

- ◆ Surfactant maintains lung expansion on expiration by lowering surface tension at the air-liquid interface in the alveolus.
- ◆ Respiratory distress syndrome in premature infants is in part caused by a deficiency of surfactant and can be treated with surfactant replacement therapy.
- ◆ Antenatal corticosteroids accelerate fetal lung maturation and decrease neonatal mortality and respiratory distress syndrome in preterm infants. In addition, corticosteroids are associated with a decrease in intracranial hemorrhage and necrotizing enterocolitis.
- ◆ Transition from intrauterine to extrauterine life requires removal of fluid from the lungs, switching from fetal to neonatal circulation, and establishment of a normal neonatal lung volume.
- ◆ The most important step in neonatal resuscitation is to achieve adequate expansion of the lungs.
- ◆ Meconium aspiration syndrome is likely the result of intrauterine asphyxia with mortality related to associated persistent pulmonary hypertension.
- ◆ The best predictor of neurologic sequelae of birth asphyxia is the presence of hypoxic ischemic encephalopathy in the neonatal period. The neurologic sequelae of birth asphyxia is cerebral palsy. However, the great majority of cerebral palsy is of unknown origin or has some etiology other than perinatal asphyxia.
- ◆ The major neurologic complications seen in premature infants are periventricular hemorrhage/intraventricular hemorrhage and periventricular leukomalacia.
- ◆ Hypoglycemia is a predictable and preventable complication in the newborn.
- ◆ With improved methods of neonatal intensive care, survival has increased—in particular for infants weighing less than 1000 g—but it comes at the price of medical and neurodevelopmental sequelae.

The postpartum period, also called the *puerperium*, lasts from delivery of the placenta until 6 to 12 weeks afterward. Most of the physiology that has changed in pregnancy will have returned to its prepregnancy state by 6 weeks. However, **many of the cardiovascular changes and psychological changes may persist for many more months; and some, such as changes in the pelvic musculature and cardiac remodeling, will last for years.**

The postpartum period is associated with as much tradition and superstition as any other rite of passage in life because the health of a new infant is so important to the survival of any family or clan. In order to support the successful recovery of the mother and a healthy transition through the neonatal period, customs, taboos, and rituals have developed in most cultures. Indeed, many of the current medical recommendations for the puerperium have developed from adaptations of socially acceptable traditions rather than from science. For example, the 6-week postpartum checkup approximates the end of the 40 days of rest and sexual separation required in traditional societies.

Cultures throughout the world have specific postpartum traditions that include both restrictions on activity and prescribed activities, different foods for the newly delivered mother, and particular and unique taboos regarding postpartum care (Box 23-1, e-Fig. 23-1). For example, bathing after delivery is taboo in some cultures. Because women often cherish these rituals, it is essential for physicians, midwives, and nurses to be sensitive to these customs even though a woman's place of delivery may be far from her native country.

This chapter examines the normal physiologic changes of the puerperium and the transitions to prepregnancy physiology. With respect to these changes, we evaluate the principles and practices of postpartum care and the role of the provider in helping the patient through the transition. We will also discuss the major puerperal disease states, health maintenance postpartum, and pregnancy prevention.

## POSTPARTUM INVOLUTION

### Uterus

The crude weight of the pregnant uterus at term—excluding the fetus, placenta, membranes, and amniotic fluid—is about 1000 g, approximately 10 to 20 times heavier than the nonpregnant uterus.<sup>1</sup> **The specific time course of uterine involution**

**e-FIG 23-1** Lactation has long been considered sacred and divine. The term *galaxy* is derived from the Greek word *galaxos*, for breast milk, from the Greek mythologic explanation for the Milky Way. The Greek god Zeus had his mortal son, Hercules, brought to nurse at the breast of the sleeping Hera because breastfeeding from a goddess would convey immortality. Hera awoke and, not recognizing the strange infant, pushed him away. Her breast milk spilled out into the sky and formed the *Galaxia Kuklos*, Greek for *Path of Breast Milk*. In Latin, this was translated *Via Lactea*, or *Roadway of Breast Milk*, or as we know it in English, the “Milky Way.” (From “Birth of the Milky Way,” by Peter Rubens. Courtesy Prado Museum, Madrid, Spain.)

**BOX 23-1 EXAMPLES OF POSTPARTUM RITUALS**

Cultural practices in regard to postpartum activity are found worldwide:

- In the rural Philippines, the mother, who works until she goes into labor, is prohibited from working after delivery, and she is given a new name. The maternal grandmother visits daily and does the housework and cooking for 8 weeks. The mother is bathed by the grandmother daily. When the umbilical cord falls off the infant, a feast is prepared, and the cord is blessed at the feast. The new father is prohibited from building stone walls and from driving nails for 6 months. For 2 months, relatives tend the fields.

Postpartum taboos related to *hot and cold* are found worldwide:

- In some Asian, African, and Latin American cultures, heat and cold must be maintained in balance to promote health and prevent disease. Because blood, which is “hot,” is lost during delivery, the parturient must replenish her “heat” by staying bundled and drinking warm liquids.
- In several traditional Middle Eastern areas, it is believed that exposure to cold creates a vulnerability to disease. Bathing is often taboo for traditional women, and sponge baths may be substituted.
- In parts of rural India, the new mother returns to her mother’s house for 16 weeks. She is given a hot bath every day. Cold baths are taboo because cold water is associated with disease.

Many cultures have rituals regarding treatment of the placenta and umbilical cord:

- The placenta may be dried and turned to powder for its “medicinal” powers.
- The umbilical cord was hung in a nearby tree by some eastern Native American tribes.
- In Eastern European tradition, in order to ensure prosperity, the cord was buried under specific corners of the house.

**has not been fully elucidated, but within 2 weeks after birth, the uterus has usually returned to the pelvis, and by 6 weeks, it is usually normal size as estimated by palpation.**

The gross anatomic and histologic characteristics of the involutional process are based on the study of autopsy, hysterectomy, and endometrial biopsy specimens.<sup>2</sup> The decrease in the size of the uterus and cervix during the puerperium has been demonstrated with serial magnetic resonance imaging (MRI).<sup>3</sup> The findings are consistent with those of serial sonography and computed tomography (CT).

Immediately after delivery, the rapidly decreasing endometrial surface area facilitates placental shearing at the decidual layer. The average diameter of the placenta is 18 cm; in the immediate postpartum uterus, the average diameter of the site of placental attachment measures 9 cm. In the first 3 days after delivery, the placental site is infiltrated with granulocytes and mononuclear cells, a reaction that extends into the endometrium and superficial myometrium. By the seventh day, the regeneration of endometrial glands is evident, and they often appear atypical with irregular chromatin patterns, misshapen and enlarged nuclei, pleomorphism, and increased cytoplasm. By the end of the first week, regeneration of the endometrial stroma is also evident, and mitotic figures are noted in gland epithelium; by postpartum day 16, the endometrium is fully restored.

Decidual necrosis begins on the first day, and by the seventh day, a well-demarcated zone can be seen between necrotic and viable tissue. An area of viable decidua remains between the necrotic slough and the deeper endomyometrium. Sharman<sup>2</sup> described how the nonnecrotic decidual cells participate in the reconstruction of the endometrium, a likely role given their original role as endometrial connective tissue cells. By the sixth week, decidual cells are rare. The immediate inflammatory cell infiltrate of polymorphonuclear leukocytes and lymphocytes persists for about 10 days and presumably serves as an antibacterial barrier. The leukocyte response diminishes rapidly after day 10, and plasma cells are seen for the first time. The plasma cell and lymphocyte response may last as long as several months. In fact, endometrial stromal infiltrates of plasma cells and lymphocytes are a sign, and they may be the only sign, of a recent pregnancy.

**Hemostasis immediately after birth is accomplished by arterial smooth muscle contraction and compression of vessels by the involuting uterine muscle.** Vessels in the placental site are characterized during the first 8 days by thrombosis, hyalinization, and endophlebitis in the veins and by hyalinization and obliterative fibrinoid endarteritis in the arteries. The mechanism for hyalinization of arterial walls, which is not completely understood, may be related to the previous trophoblastic infiltration of arterial walls that occurs early in pregnancy. Many of the thrombosed and hyalinized veins are extruded with the slough of the necrotic placental site, but hyalinized arteries remain for extended periods as stigmata of the placental site. Restoration of the endometrium in areas other than the placental site occurs rapidly, a process that is complete by day 16 after delivery. The gland epithelium does not undergo the reactivity, nor does it take on the pseudoneoplastic appearance noted in glands at the placental site.

The postpartum uterine discharge, or *lochia*, begins as a flow of blood that lasts several hours, then rapidly diminishes to a reddish brown discharge through the third or fourth day postpartum. This is followed by a transition to a mucopurulent, somewhat malodorous discharge called *lochia serosa*, which requires several perineal pad changes per day. The median duration of lochia serosa is 22 to 27 days.<sup>4,5</sup> However, 10% to 15% of women will have lochia serosa at the time of the 6-week postpartum examination. In most patients, the lochia serosa is followed by a yellow-white discharge, called *lochia alba*. Breast-feeding or the use of oral contraceptive agents does not affect the duration of lochia. **Frequently, a sudden but transient increase is observed in uterine bleeding between 7 and 14 days postpartum.** This corresponds to the slough of the eschar over the site of placental attachment. Myometrial vessels greater than 5 mm in diameter are present for up to 2 weeks postpartum and account for the dramatic bleeding that can occur with this phenomenon.<sup>5</sup> **Although it can be profuse, this bleeding episode is usually self-limited and requires nothing more than reassurance of the patient.** If it does not subside within 1 or 2 hours, the patient should be evaluated for possible retained placental tissue.

Ultrasound may be helpful in the management of abnormal postpartum bleeding. The empty uterus with a clear midline echo can often be distinguished from the uterine cavity expanded by clot (sonolucent) or retained tissue (echo dense; Fig. 23-1).<sup>6</sup> Serial ultrasound examinations of postpartum patients showed that in 20% to 30%, some retained blood or tissue was apparent within 24 hours after delivery. By the fourth postpartum day,

**FIG 23-1** **A**, Sonogram of a normal postpartum uterus. **B**, Postpartum uterus with retained tissue. (From Poder L. Ultrasound evaluation of the Uterus. In Callen PW: *Ultrasonography in Obstetrics and Gynecology*, 5th ed. Philadelphia: Saunders; 2000:939, 940.)

only about 8% of patients showed endometrial cavity separation, a proportion of whom eventually had abnormal postpartum bleeding because of retained placental tissue.<sup>7</sup> **In cases of abnormal postpartum bleeding, ultrasound examination may be a useful adjunct in detecting patients who have retained tissue or clot and who will therefore benefit from uterine evacuation and curettage.** Those who have an empty uterine cavity may respond to therapy with oxytocin or methylergonovine.<sup>8</sup>

### Cervix

During pregnancy, the cervical epithelium increases in thickness, and the cervical glands show both hyperplasia and hypertrophy. Within the stroma, a distinct decidual reaction occurs. These changes are accompanied by a substantial increase in the vascularity of the cervix. Colposcopic examination performed after delivery has demonstrated ulceration, laceration, and ecchymosis of the cervix. Regression of the cervical epithelium begins within the first 4 days after delivery, and by the end of the first week, edema and hemorrhage within the cervix are minimal. Vascular hypertrophy and hyperplasia persist throughout the first week postpartum. By 6 weeks, most of the antepartum

changes have resolved, although round cell infiltration and some edema may persist for several months.

### Fallopian Tube

The epithelium of the fallopian tube during pregnancy is characterized by a predominance of nonciliated cells, a phenomenon maintained by the balance between the high levels of progesterone and estrogen. After delivery, in the absence of progesterone and estrogen, further extrusion of nuclei from nonciliated cells occurs along with diminution in height of both ciliated and nonciliated cells. The number and height of ciliated cells can be increased in the puerperium by treatment with estrogen.

Fallopian tubes removed between postpartum days 5 and 15 demonstrate inflammatory changes of acute salpingitis in 38% of cases, but no bacteria are found. The specific cause of the inflammatory change is unknown. Furthermore, no correlation has been found between the presence of histologic inflammation in the fallopian tubes and puerperal fever or other clinical signs of salpingitis.

### Ovarian Function

Most women who breastfeed their infants are amenorrheic for extended periods of time, often until the infant is weaned. Using a variety of methods to indicate ovulation, several studies have demonstrated that **ovulation occurs as early as 27 days after delivery, with the mean time being about 70 to 75 days in nonlactating women.**<sup>9</sup> **Among women who are breastfeeding their infants, the mean time to ovulation is about 6 months.**

Menstruation resumes by 12 weeks postpartum in 70% of women who are not lactating. The mean time to the first menstruation is 7 to 9 weeks. Depending on the population, as well as social and nutritional factors of the lactating woman, regular menstruation may be delayed as long as 36 months. The duration of anovulation depends on the frequency of breastfeeding, the duration of each feed, and the proportion of supplementary feeds.<sup>10</sup> **In a woman exclusively breastfeeding, the likelihood of ovulation within the first 6 months postpartum is 1% to 5%.**

The hormonal basis for puerperal ovulation suppression in lactating women appears to be the persistence of elevated serum prolactin levels. Prolactin levels fall to the normal range by the third week postpartum in nonlactating women but remain elevated into the sixth week in lactating women. Estrogen levels fall immediately after delivery in both lactating and nonlactating women and remain depressed in lactating patients. In those who are not lactating, estrogen levels begin to rise 2 weeks after delivery and are significantly higher than in lactating women by postpartum day 17. Follicle-stimulating hormone (FSH) levels are identical in breastfeeding and nonbreastfeeding women, which suggests that the ovary does not respond to FSH stimulation in the presence of increased prolactin levels.

### Weight Loss

One of the most welcome changes for most women who have recently given birth is the loss of the weight that was gained during pregnancy. The immediate loss of 10 to 13 lb is attributed to the delivery of the infant, placenta, and amniotic fluid and to blood loss. However, most women will not manifest that loss until 1 to 2 weeks after delivery because of postpartum fluid retention. The physiologic stress of labor and delivery induces hormonal changes, including increased antidiuretic hormone,

that lead to a short period of sodium and water retention. With operative birth or epidural anesthesia with fluid boluses, the total body water increases dramatically. Mild pedal edema is also common as the extra fluid moves temporarily into the third space. Women may be reassured that this temporary dependent edema is secondary to this fluid retention. The short period of weight gain from fluid retention that occurs immediately after delivery is sometimes referred to as the *ebb phase* of physiologic response. The diuresis at 4 to 7 days is sometimes called the *flow phase*. It is not uncommon to have a newly delivered mother express mild anxiety about “gaining weight” after delivery.

**For most women, weight loss postpartum does not tend to compensate for weight gain during gestation. By 6 weeks postpartum, only 28% of women will have returned to their prepregnant weight.** The remainder of any weight loss occurs from 6 weeks postpartum until 6 months after delivery, with most weight loss concentrated in the first 3 months. **Women with excess weight gain in pregnancy (>35 lb) are likely to have a net gain of 11 lb.** Breastfeeding has relatively little effect on postpartum weight loss. With a program of diet and exercise, weight loss of about 0.5 kg/week between 4 and 14 weeks in overweight breastfeeding women did not affect the growth of their infants.<sup>11</sup> Similarly, aerobic exercise has no adverse effect on lactation.<sup>12</sup> In a longitudinal study of pregnancy weight gain, 540 women were followed for 5 to 10 years (mean, 8.5 years) after their index pregnancy. Women who returned to their prepregnancy weight by 6 months after delivery were much more likely to have gained less weight at the 5- to 10-year follow-up compared with women who retained their pregnant weight gains. In this cohort, breastfeeding and aerobic exercise were associated with a significantly lower weight gain over time.<sup>13</sup> A study of 1656 deliveries in a retrospective cohort found that pregnant weight gain greater than the recommended amount was directly related to the increased weight of women 1 year later.<sup>14</sup> Postpartum exercise programs improve long-term effects on health and risks for chronic disease.<sup>15,16</sup> Phelan<sup>17</sup> emphasized that pregnancy and the postpartum period are “teachable moments,” ideal for counseling women about weight control. Given the epidemic of obesity in Western society, dietary counseling—along with recommendations for exercise—is an important addition to health maintenance. However, interventions are, as might be expected, more effective for postpartum weight loss and retention of weight loss.<sup>18</sup> A Cochrane Review analyzed literature on weight-loss programs and found that **diet and diet plus exercise are most effective for postpartum weight loss.**<sup>19</sup>

### Thyroid Function

Thyroid size and function (see Chapter 42) throughout pregnancy and the puerperium have been quantitated with ultrasonography and thyroid hormone levels.<sup>20</sup> Thyroid volume increases about 30% during pregnancy and regresses to normal gradually over a 12-week period. Thyroxine and triiodothyronine, both elevated throughout pregnancy, return to normal within 4 weeks postpartum. For women taking thyroid medications, it is appropriate to check thyroid levels at 6 weeks postpartum to adjust dosing. It is now recognized that the postpartum period is associated with an increased risk for the development of a transient autoimmune thyroiditis that may in some cases evolve into permanent hypothyroidism. The relationship between subclinical thyroid dysfunction and postpartum depression (PPD) is controversial.<sup>21-23</sup>

**Postpartum thyroiditis (PPT) is an autoimmune disease that may present with hyperthyroid or hypothyroid symptoms, and it occurs in 2% to 17% of women with a mean incidence of about 10%. PPT will occur in up to 25% of women with type 1 diabetes.** Women with gestational and type 2 diabetes also have a slightly increased risk. Only that subset of women who develop symptoms should be treated. Puerperal hypothyroidism often presents with symptoms that include mild dysphoria; consequently, thyroid function studies are suggested in the evaluation of patients with suspected PPD that occurs 2 to 3 months after delivery. Hyperthyroid symptoms are best treated with  $\beta$ -blockers, and hypothyroid symptoms with thyroid supplementation. Both are acceptable with breastfeeding. Methimazole and propylthiouracil are also safe during lactation. **From 5% to 30% of women with PPT eventually develop hypothyroidism.** If a woman becomes symptomatic and is treated, it is reasonable to stop medications after 1 year and reevaluate thyroid status before the patient considers becoming pregnant again.<sup>21-23</sup>

### Cardiovascular System, Immunity, and Coagulation

Blood volume increases throughout pregnancy to levels in the third trimester that are about 35% above nonpregnant values. The greatest proportion of this increase consists of an expansion in plasma volume that begins in the first trimester and amounts to an additional 1200 mL of plasma, which represents a 50% increase by the third trimester. Red blood cell volume increases by about 250 mL.

Immediately after delivery, plasma volume is diminished by about 1000 mL secondary to blood loss. By the third postpartum day, the plasma volume is replenished by a shift of extracellular fluid into the vascular space. In contrast, the total blood volume declines by 16% of the predelivery value, which suggests a relative and transient anemia. By 8 weeks postpartum, the red cell mass has rebounded and the hematocrit is normal in most women. As total blood volume normalizes, venous tone also returns to baseline. In a prospective evaluation of 42 women, at 4 and 42 days postpartum, significant reduction in deep vein vessel size and a concomitant increase in venous flow velocity in the lower extremities were observed.<sup>24</sup>

Pulse rate increases throughout pregnancy, as does stroke volume and cardiac output. Immediately after delivery, these remain elevated or rise even higher for 30 to 60 minutes. Following delivery, a transient rise of about 5% occurs in both diastolic and systolic blood pressures throughout the first 4 days postpartum. Data are scant regarding the rate at which cardiac hemodynamics return to prepregnancy levels. Early studies suggested cardiac output had returned to normal when measurements were made 8 to 10 weeks postpartum. Clapp and Capeless<sup>25</sup> performed longitudinal evaluations of cardiac function at bimonthly intervals in 30 healthy women using M-mode ultrasound before pregnancy; during gestation; and at 12, 24, and 52 weeks postpartum. Cardiac output and left ventricular volume peaked at 24 weeks' gestation, with a slow return to prepregnancy values over the year of the study. However, **even 1 year after delivery, a significantly higher cardiac output was observed in both nulliparous and multiparous women compared with prepregnancy values.** The authors suggested that this “cardiac remodeling” from pregnancy may last for an extended time in healthy women. Anecdotally, elite athletes have tried to take advantage of this physiologic boost to

cardiac function by planning pregnancies a year before major sporting events.

Pregnancy is known to be a time of significantly increased coagulability that persists into the postpartum period (see Chapter 45).<sup>26</sup> The greatest level of coagulability is observed immediately after delivery and for the following 48 hours. Fibrinogen concentrations gradually diminish over the first 2 weeks postpartum. Compared with antepartum values, a rapid decrease in platelets is observed in some patients, whereas no change or an increase is seen in others. Within 2 weeks after delivery, the platelet count rises, possibly as a marker of increased bone marrow output as red cell mass is replaced. Fibrinolytic activity increases in the first 1 to 4 days after delivery and returns to normal in 1 week as measured by levels of plasminogen activation inhibitor 1. D-dimer levels are increased over pregnancy levels and are a poor marker of thrombus formation. Protein-S levels and activated protein-C resistance are decreased for up to 6 weeks or longer. In general, tests for thrombophilia and hemostasis should be delayed if possible for 10 to 12 weeks. The changes in the coagulation system, together with vessel trauma and immobility, account for the increased risk for thromboembolism noted in the puerperium, especially when an operative delivery has occurred. **A large multicenter study<sup>27</sup> over a 4½-year period in California found that in 1,688,000 primiparous deliveries, the incidence of thrombotic events was higher in the first 6 weeks after delivery compared with the same period 1 year later (odds ratio [OR], 10.8; 95% confidence interval [CI], 7.8 to 15.1). However, the authors noted that the risk remained increased between 7 and 12 weeks postpartum (OR, 2.2; 95% CI, 1.5 to 3.1). The risk of a thrombotic event increased to 22.1 per 100,000 deliveries from delivery to 6 weeks postpartum and was increased by 3.0 per 100,000 from 7 through 12 weeks.**

The immune system, which is mildly suppressed during pregnancy—particularly cellular-mediated immunity—rebounds after delivery. This rebound may lead to “flare-ups” of autoimmune disease and latent infections with inflammatory reactions. The inflammatory reactions are what often produce the clinical symptoms. **Autoimmune thyroiditis, multiple sclerosis, and lupus erythematosus are examples of some of the diseases that may show an increase in disease activity in the first few months postpartum.**<sup>28</sup> Large cross-sectional studies of population databases have noted hospital admission rates after delivery to be higher than expected for age-matched controls; readmissions are related to infections such as pneumonia, cholecystitis, and appendicitis. **Overall, postpartum readmission rates vary from 0.8% to 1.5% for vaginal delivery and 1.8% to 2.7% for cesarean birth.**<sup>29-31</sup>

## Urinary Tract and Renal Function

It is generally accepted that the urinary tract becomes dilated during pregnancy, especially the renal pelvis and the ureters above the pelvic brim. These findings, demonstrated 70 years ago, show that the collecting system of the right kidney is affected more than that of the left, and this dilation is caused by compression of the ureters by the adjacent vasculature and enlarged uterus, combined with the effects of progesterone. Ultrasound studies of the urinary tract also document the enlargement of the collecting system throughout pregnancy. A study of serial ultrasound examinations of the urinary tract in 20 women throughout pregnancy included a single postpartum examination 6 weeks after delivery. The overall trend was that

of dilation of the collecting system throughout pregnancy, estimated by measurements of the separation of the pelviciceal echo complex, from a mean of 5 mm (first trimester) to 10 mm (third trimester) in the right kidney and from 3 to 4 mm in the collecting system for the left kidney. Measurements in all but two patients had returned to prepregnancy status at the time of the 6-week postpartum examination.

Serial nephrosonography on 24 patients throughout pregnancy and the puerperium<sup>32</sup> demonstrated that more than half of the patients at 12 weeks postpartum had persistence of urinary stasis, described as a slight separation of the renal pelvis. This finding is evidence of hyperdistensibility and suggests that pregnancy has a permanent effect on the size of the upper renal tract. Intravenous urography studies also suggest that subtle anatomic changes take place in the ureters that persist long after the pregnancy has ended. Ureteral tone above the pelvic brim, which in pregnancy is higher than normal, returns to nonpregnant levels immediately after cesarean delivery.

Studies in which water cystometry and uroflowmetry were performed within 48 hours of delivery and again 4 weeks postpartum demonstrated a slight but significant decrease in bladder capacity (from 395.5 to 331 mL) and volume at first void (from 277 to 224 mL) in the study interval. Nevertheless, all the urodynamic values studied were within normal limits on both occasions. The results were not affected by the weight of the infant or by an episiotomy; however, prolonged labor and the use of epidural anesthesia appeared to diminish postpartum bladder function transiently.

The most detailed study of renal function in normal pregnancy is that of Sims and Krantz,<sup>33</sup> who studied 12 patients with serial renal function tests throughout pregnancy and for up to 1 year after delivery. Glomerular filtration, which increased by 50% early in pregnancy and remained elevated until delivery, returned to normal nonpregnant levels by postpartum week 8. Endogenous creatinine clearance, similarly elevated throughout pregnancy, also returned to normal by the eighth postpartum week. Renal plasma flow increased by 25% early in pregnancy, gradually diminished in the third trimester (even when measured in the lateral recumbent position), and continued to decrease to below-normal values in the postpartum period for up to 24 weeks. Normal values were finally established by 50 to 60 weeks after delivery. The reason for the prolonged PPD of renal plasma flow is not clear.

**Because of the variable changes in renal clearance, mothers who take medications whose dosages have been changed because of the physiologic adaptations of pregnancy will need to have medication levels rechecked. This should be done at 4 to 6 weeks postpartum.**

## Hair Growth and Bone Loss

Hair growth is altered in pregnancy and postpartum. After delivery, a more rapid hair turnover is seen for up to 3 months. As a greater percentage of hair begins to undergo the growth phase, more hair falls out with combing and brushing. The loss is in a diffuse, not balding, pattern. **This transient phenomenon is called telogen effluvium, and the patient may be reassured that her hair growth will return to normal within a few months and that the excess hair lost in the comb or brush will regrow.**

Several investigators have reported on bone mineral changes with lactation and the associated amenorrhea. After delivery, a generalized decrease in bone mineralization is seen that is

temporary and resolves by 12 to 18 months postpartum in most women.<sup>34</sup> Bone loss appears to be greater in the femoral neck than in other areas of the skeleton.<sup>35,36</sup> Calcium supplementation does not seem to ameliorate the bone loss because it is not a problem of inadequate calcium stores, and exercise does not prevent it.<sup>37</sup> For almost all women, the bone loss is self-limited and reversible. Recent investigations have found that postpartum aerobic exercises decrease the bone loss associated with lactation.<sup>38</sup>

### Management of the Puerperium

For most parturients, the immediate puerperium is spent in the hospital or birthing center. The ideal duration of hospitalization for patients with uncomplicated vaginal births has been controversial and culturally determined. During World War II, early discharge with nurse follow-up was initiated to support the “war bride” baby boom.<sup>39</sup> In the 1950s, the lying-in period after delivery was 8 to 14 days.<sup>40</sup> Today, most women stay in the hospital 24 to 48 hours after a vaginal birth. For patients with an uncomplicated postoperative course following cesarean delivery, the postpartum stay is 2 to 4 days. The optimal time is dependent on a patient’s needs and home support. About 3% of women who have vaginal deliveries and 9% of women who have cesarean deliveries have at least one childbirth-related complication that requires longer hospitalization after delivery or readmission to the hospital.<sup>41</sup> Studies that have evaluated the safety and outcomes of discharge before 48 hours have relied on nurse or midwife home visits. Unfortunately, most insurers do not cover this service.

In one study, 1249 randomly selected patients were questioned 8 weeks after delivery about health problems that occurred during the puerperium.<sup>42</sup> Eighty-five percent reported at least one problem during their hospitalization, and 76% noted at least one problem that persisted for 8 weeks. Many types of problems were reported by the patients, including a painful perineum, difficulty with breastfeeding, urinary tract infection, urinary and fecal incontinence, and headache. Three percent of the patients had been rehospitalized, most commonly for abnormal bleeding or infection. This study draws attention to a substantial amount of symptomatic morbidity that occurs during the puerperium. Although longer hospitalization may not improve perineal pain or incontinence, open lines of communication with patients between discharge and the 6-week visit affect patient self-care and promote a more positive patient experience. A study<sup>43</sup> of 597,000 women from New Zealand who delivered over an 8-year period documented that shorter postpartum hospital stays had no effect on readmission rates. **In this study, lactation/breast problems, delayed postpartum hemorrhage, and post-cesarean delivery wound infections were the major causes of readmission.**

In particular, lactation consultation may help to improve effective breastfeeding, and consideration should be given to postponing discharge in primiparas until this service can be performed. As is obvious, home visits and interventions improve lactation effectiveness and duration, postpartum weight loss, and psychological well-being after pregnancy loss.

If a patient has adequate support at home (i.e., help with housekeeping and meal preparation), an extended hospital stay is of little value, provided the mother is adequately educated about infant care and feeding and in the identification of danger signs in either the infant or herself. **Except for an increased incidence of rehospitalization of some neonates for**

**hyperbilirubinemia, postpartum hospitalization of less than 48 hours has few disadvantages for many patients.**<sup>44-47</sup> For mothers who do not have adequate support at home and who are insecure about infant care and feeding, extending the hospital stay will provide time for them to gain adequate education and some measure of self-confidence. Written and video presentations are also efficient means of patient education. To be most helpful, educational material should be presented before delivery, sometime in the late third trimester, and at the postpartum discharge. **Home nursing visits can be helpful in providing support, education, and advice to mothers in selected situations.** Written materials or handouts are particularly necessary because memory is temporarily affected by the sleep deprivation that is the rule in the first few days after delivery.

**Before discharge, women should be offered any vaccines that may be necessary to protect immunity.** The measles, mumps, and rubella (MMR) vaccine should be given to rubella-nonimmune mothers. Hepatitis B; tetanus, diphtheria, and pertussis (Tdap); MMR; and influenza vaccines are the four most common vaccines given. All are safe with breastfeeding.<sup>48</sup> **As recommended in 2012 by the Centers for Disease Control and Prevention (CDC), Tdap should be administered during pregnancy to all pregnant women, regardless of the interval since the last Tdap.**<sup>49</sup> **If Tdap was not given during pregnancy, it should be given immediately after delivery. The varicella vaccine should be initiated postpartum in those with a negative varicella titer.**<sup>48</sup>

**The time from delivery until complete physiologic involution and psychological adjustment has been called “the fourth trimester.”**<sup>50</sup> Patients should understand that lochia will persist for 3 to 8 weeks and that on days 7 to 14, there is often an episode of heavy vaginal bleeding, which occurs when the placental eschar sloughs. Tampons are permissible if they are comfortable upon insertion and are changed frequently and if there are no perineal, vaginal, or cervical lacerations that preclude insertion of a tampon until healing has occurred. **Physical activity such as walking up and down stairs, lifting moderately heavy objects, riding in or driving a car, and performing muscle-toning exercises can be resumed without delay if the delivery has been uncomplicated.** Minig and associates<sup>51</sup> reviewed the scientific evidence behind many postpartum recommendations and noted that very few if any of the traditional recommendations are evidence based. Lifting, sexual activity, driving, and exercise do not need to be overly restricted, even for women after cesarean births. Instructions regarding exercise are patient specific. Studies have found that postpartum exercise has no effect on lactation but may decrease anxiety levels and symptoms of PPD.<sup>52-54</sup> As such, exercise may have benefits beyond the mother’s desire to “get back into shape.” The most troublesome postpartum symptoms are lethargy and fatigue. Consequently, every task or activity should be a brief one in the first few days of the puerperium. Mothers whose lethargy persists beyond several weeks must be evaluated, especially for thyroid dysfunction and PPD.

**Sexual activity may be resumed when the perineum is comfortable and when bleeding has diminished.** The desire and willingness to resume sexual activity in the puerperium varies greatly among women, depending on the site and state of healing of perineal or vaginal incisions and lacerations, the amount of vaginal atrophy secondary to breastfeeding, and the return of libido,<sup>55</sup> which is greatly affected by sleep patterns among other new issues. Although the median time to vaginal

intercourse after delivery is 6 weeks, 90% of women resume sexual activity by 3 months.<sup>56</sup> Nevertheless, as many as 80% of women have sexual problems at 8 to 12 weeks, including painful intercourse,<sup>56,57</sup> and a substantial proportion have dyspareunia that lasts for a year or more.<sup>58,59</sup> Signorello and coworkers<sup>60</sup> noted a 2.5-fold increased risk for dyspareunia 6 months after operative vaginal delivery compared with other subsets of postpartum women. For all women, breastfeeding at 6 months is associated with a more than fourfold increase in dyspareunia. Similarly, a large review of studies examining postpartum sexuality noted the greatest incidence of sexual dysfunction to be associated with operative vaginal delivery.<sup>61</sup> **Cesarean delivery is associated with a decreased incidence of dyspareunia compared with vaginal birth only for the first 6 months, after which the rates become similar.** In contrast, 25% of all women reported a heightened sexual pleasure 6 months after delivery.

Postpartum dyspareunia is not always related to vulvar trauma and occurs in some women who have a cesarean delivery. Dyspareunia has also been observed in women who use oral contraceptives and do not breastfeed, suggesting that lack of estrogen effect on the vagina is not the major cause of postpartum dyspareunia. In a study of 50 parturients, Ryding<sup>62</sup> found that 20% had little desire for sexual activity 3 months after delivery, and an additional 21% had complete loss of desire or aversion to sexual activity. This variation in attitude, desire, and willingness must be acknowledged when counseling women about the resumption of sexual activity. Women who breastfeed tend to begin intercourse later than the average, and women who have had a cesarean delivery tend to begin sooner.<sup>63</sup> Clinicians commonly advise pregnant women on the use of vaginal lubricants for sexual activity in the first few months postpartum because of the decreased natural lubrication with lower estrogen levels. This may be included in the written handouts given to patients when they go home. Astroglide gel and Comfort gel are more commonly recommended lubricants; KY Jelly is typically too dry. If patients are using barrier contraception, they should be advised against the use of petroleum-based lubricants such as Vaseline. If dyspareunia persists, a small amount of estrogen cream applied daily to the vagina may be helpful in breastfeeding women with atrophic changes. Clinicians may also counsel women about using different sexual positions if deeper penetration with male partners is uncomfortable.<sup>51</sup>

Many patients return to work situations outside the home after their pregnancies. Frequently, the physician must complete insurance or employer forms to establish maternity leave for patients. As mentioned earlier, the 6-week return in the United States is derived from tradition, and 8 weeks are often allowed after a cesarean delivery. Women will often experience discomfort, tiredness, and breast soreness well beyond 6 weeks. **Similar to the return to exercise and sexual activity, the return to work should be individualized.** Other nations and cultures have different standards for returning to prepregnancy routines. In China, 30 days is common, whereas in Western Europe and Canada, maternity leave from several months to a year is common.

## HEALTH MAINTENANCE

**The postpartum visit is scheduled at the time of discharge and routinely occurs 4 to 6 weeks after delivery. Some women may benefit from a visit sooner, such as women at risk for depression, those with a more complicated labor and**

**delivery, and women who underwent a cesarean section for delivery.** At this visit, breastfeeding can be addressed along with incisional checks and assessment of mood. Studies have shown that a routine postpartum visit to the physician 1 or 2 weeks after delivery or a home visit by a nurse midwife does little to reduce maternal or infant morbidity.<sup>64,65</sup> However, for the patient with antepartum or intrapartum difficulties, this early postpartum visit or home visit by a nurse or nurse midwife is more productive in detecting problems and providing support for the mother. Thus the need for this visit should be individualized.<sup>66</sup> Late puerperal infections, PPD, and problems with infant care and feeding often occur before the 6-week postpartum visit. Open-ended questions should be asked to detect problems.

**At the routine postpartum visit, questions regarding depression, energy, sexuality, contraception, and future pregnancies should be addressed.** Unfortunately, some women skip their 6-week postpartum check, deferring questions of contraception. A copy of the Edinburgh postnatal depression scale (EPDS) is provided in Box 23-2. It may be used as a fast, reliable, and user-friendly tool to screen for depression. It is helpful to solicit questions about how women feel after the delivery because they may be hesitant to ask questions spontaneously, especially with regard to sexuality and incontinence. If health issues need to be addressed, such as blood glucose or thyroid level assessment, they may be performed or scheduled at this visit.

**Women with chronic medical diseases such as collagen vascular disease, autoimmune disorders, and neurologic conditions should be considered for visits at closer intervals because many patients with these disorders experience flare-ups of their symptoms after delivery. Ideally, these visits should be scheduled in advance with the patient's primary care or subspecialty physician.** Prophylactic therapy is not recommended for women with systemic lupus erythematosus or multiple sclerosis. However, warning patients to be attuned to signs and symptoms that reflect a flare-up of their illness allows for early and more effective interventions. For women with epilepsy, special attention to medication doses with the changing renal clearance is necessary. Additionally, increased postpartum sleep deprivation may induce a lower seizure threshold.

## Perineal and Pelvic Care

Many women who give birth have lacerations of the perineum or vagina. When an episiotomy is performed in the United States, it is often performed as a midline, rather than as a mediolateral, incision. In the absence of hematoma or extensive ecchymosis, and provided that the incision or laceration does not extend beyond the transverse perineal muscle, if a satisfactory repair has been accomplished, there is little need for perineal care beyond routine cleansing with a bath or shower. Analgesia can be accomplished in most patients with nonsteroidal antiinflammatory drugs (NSAIDs) such as ibuprofen or naproxen sodium. These drugs are superior to acetaminophen or propoxyphene for episiotomy pain and uterine cramping. Furthermore, because of a low milk/maternal plasma drug concentration ratio, a short half-life, and transformation into glucuronide metabolites, ibuprofen is safe for nursing mothers.

A patient who has had a mediolateral episiotomy, third- or fourth-degree perineal laceration, periurethral lacerations, or extensive perineal bruising may experience considerable perineal pain.<sup>67</sup> Occasionally, the pain and periurethral swelling prevent

**BOX 23-2 EDINBURGH POSTNATAL DEPRESSION SCALE**

In the past 7 days:

1. I have been able to laugh and see the funny side of things.
  - ☐ As much as I always could
  - ☐ Not quite so much now
  - ☐ Definitely not so much now
  - ☐ Not at all
2. I have looked forward with enjoyment to things.
  - ☐ As much as I ever did
  - ☐ Rather less than I used to
  - ☐ Definitely less than I used to
  - ☐ Hardly at all
3. I have blamed myself unnecessarily when things went wrong.
  - ☐ Yes, most of the time
  - ☐ Yes, some of the time
  - ☐ Not very often
  - ☐ No, never
4. I have been anxious or worried for no good reason.
  - ☐ No, not at all
  - ☐ Hardly ever
  - ☐ Yes, sometimes
  - ☐ Yes, very often
5. I have felt scared or panicky for no good reason.
  - ☐ Yes, quite a lot
  - ☐ Yes, sometimes
  - ☐ No, not much
  - ☐ No, not at all
6. Things have been getting on top of me.
  - ☐ Yes, most of the time I haven't been able to cope at all.
  - ☐ Yes, sometimes I haven't been coping as well as usual.
  - ☐ No, most of the time I have coped quite well.
  - ☐ No, I have been coping as well as ever.
7. I have been so unhappy that I have had difficulty sleeping.
  - ☐ Yes, most of the time
  - ☐ Yes, sometimes
  - ☐ Not very often
  - ☐ No, not at all
8. I have felt sad or miserable.
  - ☐ Yes, most of the time
  - ☐ Yes, quite often
  - ☐ Not very often
  - ☐ No, not at all
9. I have been so unhappy that I have been crying.
  - ☐ Yes, most of the time
  - ☐ Yes, quite often
  - ☐ Only occasionally
  - ☐ No, never
10. The thought of harming myself has occurred to me.
  - ☐ Yes, quite often
  - ☐ Sometimes
  - ☐ Hardly ever
  - ☐ Never

Response categories are scored 0, 1, 2, and 3 according to increased severity of the symptom. Items 3 and 5 through 10 are reverse scored (3, 2, 1, 0). The total score is calculated by adding together the scores for each of the 10 items.

From Cox JL, Holden JM, Sagovsky R. Detection of postnatal depression: development of the 10-item Edinburgh Postnatal Depression Scale. *Br J Psychiatry*. 1987;150:782.

the patient from voiding, making urethral catheterization necessary. When a patient complains of inordinate perineal pain, the first and most important step is to reexamine the perineum, vagina, and rectum in an effort to detect and drain a hematoma or to identify a perineal infection. **Perineal pain may be the first symptom of the rare but potentially fatal complications of angioedema, necrotizing fasciitis, or perineal cellulitis.**

In cases of moderate perineal pain, sitz baths will provide additional pain relief. Although hot sitz baths have long been customary therapy for perineal pain, **there is rationale for using cold or "iced" sitz baths.** This therapy is similar to that for the treatment of athletic injuries, for which considerable success has been achieved with cold therapy. Cold provides immediate pain relief as a result of decreased excitability of free nerve endings and decreased nerve conduction. Further pain relief comes from local vasoconstriction, which reduces edema, inhibits hematoma formation, and decreases muscle irritability and spasm. Patients who have alternated using hot and cold sitz baths usually prefer the cold. The technique for administering a cold sitz bath is to first have the patient sit in a tub of room-temperature water to which ice cubes are then added; this avoids the sensation of sudden immersion in ice water. The patient remains in the ice water for 20 to 30 minutes. Patients with perineal incisions or lacerations should be advised to postpone sexual intercourse until perineal discomfort has abated. The application of a perineal ice pack beyond the customary 6 to 8 hours may also be considered. Tampons may be inserted whenever the patient is

comfortable doing so. However, to avoid any risk for toxic shock syndrome, the use of tampons should be confined to daytime to prevent leaving a tampon in the vagina for prolonged periods.

Frequently, what appears to be severe perineal pain is in fact the pain of prolapsed hemorrhoids. Witch hazel compresses, suppositories that contain corticosteroids, or local anesthetic sprays or emollients may be helpful. Occasionally, a thrombus occurs in a prolapsed hemorrhoid. When performed by an obstetrician or a general surgeon trained in this procedure, it is a simple task to remove the thrombus through a small scalpel incision using local anesthesia. Dramatic relief of pain usually follows this procedure. Stool softeners, laxatives, or both should be discussed for women with hemorrhoids. Some women suffer from prolonged pelvic girdle pain. Predictors of this type of pain include a history of low back pain, pelvic girdle pain during pregnancy, and painful postures at their place of employment.<sup>68</sup>

**Urinary and anal incontinence is a significant problem in women after delivery.**<sup>69</sup> Weidner and colleagues<sup>70</sup> studied 58 primiparous women after delivery and found levator ani neuropathy in 14 of 58 women (24.1%) at 6 weeks. Nine women recovered by 6 months. Seventeen of the 58 women had the neuropathy unresolved at 6 months postpartum, which included 12 newly identified injuries. Elective cesarean delivery was protective for neuropathy in this series, yet labor with subsequent cesarean delivery was not protective. About one third of women at 8 weeks and 15% of women at 12 weeks had urinary

incontinence. As would be expected, incontinence has a very detrimental effect on quality of life.<sup>71</sup> A strong predictor for incontinence after delivery is a history of prior urinary incontinence or new-onset incontinence during the index pregnancy. In addition to urinary incontinence, 3% to 10% of women have anal incontinence 3 months after vaginal birth, and most experience flatal, rather than fecal, incontinence.<sup>69,72,73</sup> Forceps-assisted, but not vacuum-assisted, vaginal delivery is associated with a twofold increased risk for fecal incontinence in primiparas.<sup>74</sup> Similarly, anal sphincter disruption in nulliparas is associated with a 2.3-fold increase in anal incontinence 5 years after delivery.<sup>75</sup> Nulliparous women with sphincter disruption or operative vaginal delivery should be screened specifically for symptoms at follow-up visits.

Perineal exercises were developed by Kegel in 1948 and involve voluntary contraction of the pelvic floor. These exercises and consequent refinements are termed *pelvic floor muscle training* (PFMT). The exercises are best taught by a trained instructor in a comfortable environment. PFMT may be initiated before delivery or after, and exercises are performed several times a day. Multiple well-designed studies and reviews have evaluated data from over 10,000 women to assess the value of PFMT for both prevention and treatment.<sup>69,76-79</sup> The results of PFMT appear mixed. In summary, training begun antepartum and reinforced after delivery shows significant benefits for prevention of urinary incontinence up to 6 months postpartum. Counseling and handouts are significantly inferior to instructor training with biofeedback; the more intense the program, the more effective. PFMT begun postpartum for a mixed population of symptomatic and asymptomatic women is minimally effective. However, **symptomatic women experience significant improvement when PFMT is begun postpartum with instructor training and reinforcement.** Long-term (10-year) benefits for incontinence and pelvic prolapse are minimal, although symptom rates are mildly decreased in women who performed PFMT. All studies emphasize the value of hands-on interventions and follow-up as well as the difficulty of studying mixed populations with varying degrees of vaginal disruption.<sup>69-75</sup>

**If symptoms of either urinary or flatal incontinence persist for more than 6 months, evaluation should be undertaken to define the specific neuromuscular or anatomic abnormality so that the appropriate treatment can be initiated.** Women should be counseled regarding this plan at their postpartum visit so that they can return if symptoms persist. If possible, antepartum PFMT should be offered to primiparous women.

### Delayed Postpartum Hemorrhage and Postpartum Anemia

The causes and management of immediate postpartum hemorrhage are discussed in [Chapter 18](#). **Delayed postpartum uterine bleeding of sufficient volume to require medical attention occurs in 1% to 2% of patients. One of the most common causes of postpartum hemorrhage seen 2 to 5 days after delivery is von Willebrand disease.** Von Willebrand factor increases in pregnancy, and thus excessive bleeding usually does not occur in the first 48 hours after birth. Women who present with bleeding more than 48 hours after delivery should be screened for this condition.

Delayed bleeding occurs most frequently between days 8 and 14 of the puerperium.<sup>80</sup> Significant bleeding may require treatment with uterotonic agents or curettage. When suction evacuation and curettage are performed, retained gestational

products—usually in small amounts—will be found in about 40% of cases.<sup>81,82</sup> Whether small placental remnants are the cause is unknown. **In the management of patients with heavy delayed bleeding, ultrasound examination can be used to help determine whether a significant amount of retained material is present, although it is sometimes difficult to distinguish between blood clot and retained placental fragments** (see [Fig. 23-1](#)). Suction evacuation of the uterus is successful in arresting the bleeding in almost all cases regardless of whether histologic confirmation of retained gestational products is obtained. If curettage is required at this time, especially if a sharp curette is used, a course of broad-spectrum antibiotics with anaerobic coverage should be initiated before surgery for their possible benefit in reducing the formation of uterine synechiae and the sequelae of Asherman syndrome. The curettage should be performed with care because the postpartum uterine wall is soft and easy to perforate. In those rare instances in which delayed postpartum hemorrhage does not respond to the use of oxytocic agents and curettage, selective arterial embolization may be effective in controlling the bleeding. Women with postpartum hemorrhage and subsequent anemia often have excessive fatigue in the postpartum period. Some investigators have advocated the use of recombinant erythropoietin and parenteral iron as alternatives to transfusion for symptomatic women with anemia.

Significant postpartum hemorrhage may lead to problems with mother-infant interactions and lactation both immediately after delivery and in the first few weeks postpartum, particularly with fatigue or readmission. Early and continued attention to this issue is important. A study of 206 women with postpartum hemorrhage of 1500 mL or greater found that, other than more readmissions for infection and recurrent bleeding, this cohort of women did not manifest a greater frequency of PPD or other health complications.<sup>83</sup>

### Postpartum Infection

Although the standard definition of postpartum febrile morbidity is a temperature of 38° C (100.4° F) or higher on any two of the first 10 days after delivery, exclusive of the first 24 hours, most clinicians do not wait two full days to begin evaluation and treatment of patients who develop a fever in the puerperium. **The most common cause of postpartum fever is endometritis, which occurs after vaginal delivery in about 2% of patients and after cesarean delivery in about 10% to 15%.** The differential diagnosis includes urinary tract, lower genital tract, wound, and pulmonary infections in addition to thrombophlebitis and mastitis. The diagnosis and management of postpartum infection are discussed in detail in [Chapters 53](#) and [54](#). Almost all antibiotics are safe during lactation, and these are discussed in [Chapter 8](#).

### Maternal-Infant Attachment

Klaus and colleagues<sup>84</sup> were among the first investigators to study maternal-infant attachment and to bring attention to the importance of the first few hours of maternal-infant association. Their studies, as well as those of others, have contributed substantially to major changes in hospital policies for dealing with patients during labor and delivery and in the postpartum period. **It is now recognized that constant opportunities should be provided for parents to be with their newborns, particularly from the first few moments after birth and as frequently as possible during the first days thereafter. Immediate**

**skin-to-skin contact is recommended.** Separation of the mother and her infant in the first hours after birth has been shown to diminish or delay the development of characteristic mothering behaviors,<sup>85</sup> a problem that is intensified when medical, obstetric, or newborn complications require intensive care for either the mother or her newborn infant.

Robson and Powell<sup>86</sup> summarized the literature on early maternal attachment and emphasized how difficult it is to perform valid research studies about this phenomenon because of the multiple confounders. Although it is generally agreed that early association of the mother and infant is beneficial and should not be interfered with unnecessarily, doubts continue to surround the long-term implications, if any, of a lack of early maternal-infant association. In their monograph summarizing their investigations about parent-infant attachment, Klaus and Kennel<sup>87</sup> warn against drawing far-reaching conclusions. Although favoring the theory of a “sensitive period” soon after birth, during which close parent-infant interaction facilitates subsequent attachment and beneficial parenting behavior, these investigators concur that humans are highly adaptable and state that “there are many fail-safe routes to attachment.” Many hospitals and birth centers have recognized the importance of, and have placed emphasis on, the mother-baby interactions in the first several hours after delivery. **Delaying the first bath, eliminating well-baby nurseries, putting the baby onto the mother’s chest in skin-to-skin contact (even during cesarean delivery), and keeping the baby in the room with the mother during the first pediatric evaluation are all steps to support and promote that interaction.**

The modern maternity unit should enhance and encourage parent-infant attachment by such policies as free visiting hours for the other parent, encouragement of the other parent to room in with the mother and baby whenever possible, encouragement of the mother to have the infant room in with her, and strong support of breastfeeding. These policies also allow the nursing staff to observe parenting behavior and to identify inept, inexperienced, or inappropriate behavior toward the infant. Some situations may call for more intensive follow-up by visiting nurses, home health visitors, or social workers to provide further support for the family during the posthospital convalescence. The role of postpartum home visits in enhancing parenting behavior is controversial, and Gray and colleagues<sup>88</sup> found this approach beneficial. Conversely, when Siegel and coworkers<sup>89</sup> studied the effect of early and prolonged mother-infant contact in the hospital and a postpartum visitation program on attachment and parenting behavior, they found that early and prolonged maternal-infant contact in the hospital had a significant effect on enhancing subsequent parenting behavior, but the postpartum home visitations had no impact.

The development of the qualities associated with good parenting depends on many factors. Certainly, it does not depend solely on what transpires in the few hours surrounding the birth experience. Evidence suggests that specific identification of an infant with its mother’s voice begins in utero during the third trimester. Furthermore, the parents’ own experiences as children, as well as their intellectual and emotional attitudes about children, play a significant role in their own parenting behavior. Areskog and associates<sup>90</sup> showed that women who expressed fear of childbirth during the antenatal period had more complications and more pain in labor and also had more difficulties in attachment to their infants. Consequently, the peripartum period provides opportunities to enhance parenting behavior

and to identify families for which follow-up after birth may be necessary to ensure the most favorable child development. For example, adolescents, particularly primiparous adolescents, are a particularly high-risk group because rates of domestic abuse are especially high in adolescent mothers.

In summary, **the postpartum unit should be an environment that provides parents ample opportunity to interact with their newborn infant.** Personnel—including nurses, nurses’ aides, and physicians caring for mothers and infants—should be alert to signs of abnormal parenting (e.g., refusal of the mother to care for the infant, use of negative or abusive names in describing or referring to the infant, inordinate delay in naming the infant, or obsessive and unrealistic concerns about the infant’s health). These or other signs that maternal-infant attachment is delayed or endangered are as deserving of frequent follow-up during the postpartum period as are any of the traditional medical or obstetric complications.

Lactation and breastfeeding are reviewed in detail in [Chapter 24](#). All cultures have emphasized the importance of breastfeeding, and multiple steps should be taken during the postpartum period to promote and enhance breastfeeding. The use of audiovisual aids, telephone hotlines, and in-service training for personnel have been shown to increase the incidence of successful breastfeeding. The addition of home visits and active phone interventions cannot be underestimated (see [Chapter 24](#)).

## PREGNANCY PREVENTION

Postpartum contraception use can decrease unintended pregnancy and provides women with a method to control the timing of their pregnancies. **A recent meta-analysis found that birth intervals shorter than 18 months are significantly associated with small size for gestational age, preterm birth, and infant death in the first year of life.**<sup>91</sup> The ideal timing of family planning advice and education about contraception has not been determined. Although antenatal contraceptive counseling is important, and women value the opportunity to discuss contraception during this time, several studies have demonstrated that antenatal education had very little effect on postpartum contraceptive use or subsequent pregnancy rates.<sup>92,93</sup> **Discussion about contraception has become a standard component of postpartum care.** Lopez and colleagues<sup>94</sup> conducted a systematic review to examine randomized trials that evaluated the effectiveness of postpartum education about contraceptive use. They identified and included 10 trials in their review and found that about half of the postpartum interventions led to fewer repeat pregnancies or births and more contraceptive use. One study found that written material given at the time of hospitalization plus a discussion is most helpful to mothers. **Whereas the ideal method and timing of providing contraceptive education postpartum has not been identified, its importance cannot be disputed.**

The percentage of women who choose to breastfeed is increasing. In the United States in 2010, the percentage of women who began breastfeeding after delivery was 77%. The percentage of women still breastfeeding at 6 months was 49%, up from 35% in 2000; at 12 months, it was 27%, up from 16%.<sup>95</sup> Elevated levels of prolactin encountered during breastfeeding act at the level of the pituitary and the ovary to produce lactational amenorrhea and anovulation.<sup>96</sup> The contraceptive efficacy of lactation is dependent on the nutritional status of the mother, the intensity of suckling, and the amount of supplemental food added to the infant diet.<sup>97</sup> **If a woman is exclusively breastfeeding on**

**demand both day and night, is amenorrheic, and the infant is less than 6 months old, the contraceptive efficacy of lactational amenorrhea is 98%.**<sup>98,99</sup> Bleeding or spotting during the first 6 to 8 weeks postpartum in a fully breastfeeding woman is normal and is not due to ovulation. If suckling intensity and/or frequency is reduced, the contraceptive efficacy of lactational amenorrhea is reduced. After 6 months, even fully breastfeeding mothers have a need for contraception as infants start taking in other sources of nutrition. Women who pump breast milk do not do so at the same frequency as on-demand nursing, and pumping does not produce the same intensity that suckling produces; therefore a mother who pumps breast milk cannot rely on lactational amenorrhea to be 98% effective.

In nonbreastfeeding women, prolactin levels return to baseline by the third to fifth postpartum week. In two series, women did not ovulate prior to 25 days postpartum.<sup>98,100</sup> Therefore in nonbreastfeeding women, birth control is needed as soon as 3 weeks postpartum. An argument could be made for a postpartum visit scheduled earlier than 6 weeks because of this observation. Traditionally, women are told not to have intercourse prior to 6 weeks. However, studies demonstrate that many couples have already resumed intercourse prior to this.

A patient should be made aware of the various options for pregnancy prevention in terms that she and her partner can understand. This may be done by individual instruction from nurses, physicians, or midwives or by a variety of films or videos. The decision about family planning methods depends on the patient's motivation, number of children, state of health, whether she is breastfeeding, and the religious background of the couple. It cannot be assumed that because a woman has used a method of contraception effectively before the current pregnancy, she will need no counseling thereafter. More than half of patients change contraceptive techniques between pregnancies. [Table 23-1](#) lists contraceptive options, failure rates, and continuation rates by method.

### Long-Acting Reversible Contraception

**Long-acting reversible contraception (LARC) methods, which include intrauterine devices (IUDs) and contraceptive implants, are the most effective reversible methods available to women, with failure rates of less than 1%.** They are

convenient methods, especially for new mothers, because they require little of the patient other than coming in for insertion. In addition to their ease of use, LARC methods are cost effective, and fertility returns immediately after removal, so they are good methods to use for women in their childbearing years. LARC is also very safe, well studied, and has few contraindications ([Table 23-2](#)). LARC methods are also safe for women to use while breastfeeding.

The hormonal IUD contains the progestin levonorgestrel (LNG), which is released at an initial rate of 20 µg/day and lasts for up to 5 years.<sup>101</sup> The LNG IUD prevents pregnancy primarily by thickening the cervical mucus so that sperm cannot reach the upper genital tract. This IUD also thins the lining of the uterus but does not reliably inhibit ovulation. The main side effects are related to menstrual bleeding changes. Women should be counseled about irregular bleeding and/or spotting for several months after insertion. This typically improves over time and by 1 year, approximately 30% to 40% of women will be amenorrheic.<sup>102-104</sup> For others, the amount of bleeding will be approximately 90% less than their normal periods.<sup>102-104</sup>

The nonhormonal IUD contains copper and can be used for 10 to 12 years. Copper ions are released into the uterine cavity and cause spermicidal actions. The main side effects to discuss with patients regarding the copper IUD are related to menstrual bleeding changes. With the copper IUD, women need to be counseled about possible heavier periods, worsened dysmenorrhea, and longer periods by approximately 1.5 days. The copper IUD may not be a first choice for women with a history of heavy, painful periods.

The final LARC method is the single-rod implant, usually placed in the inner aspect of the nondominant arm. The contraceptive implant contains etonogestrel and acts primarily by inhibiting ovulation; it also causes changes to bleeding patterns, with irregular spotting or bleeding or amenorrhea. The bleeding patterns for this device are more unpredictable. The implant can be used for up to 3 years. Continuation rates for all three LARC methods are high (see [Table 23-1](#)).

LARC methods can be placed immediately after delivery or at another time. If IUDs are placed postpartum, the best practice is to place the device within 10 minutes of placental delivery. Insertion of an IUD is not recommended if intrauterine infection is present. Devices placed immediately after delivery have an up to 20% risk for expulsion; those placed at the time of cesarean delivery versus vaginal delivery have a lower risk of expulsion.<sup>105</sup> **The use of a single-rod implant in postpartum women does not result in changes in milk volume,**

**TABLE 23-1** CONTRACEPTIVE EFFECTIVENESS: PERCENTAGE OF WOMEN WHO EXPERIENCE AN UNINTENDED PREGNANCY DURING THE FIRST YEAR OF TYPICAL AND PERFECT CONTRACEPTIVE METHOD USE AND PERCENTAGE OF CONTINUING USE AT 1 YEAR\*

| METHOD      | TYPICAL USE | PERFECT USE | USE AT 1 YEAR |
|-------------|-------------|-------------|---------------|
| LNG IUD     | 0.2         | 0.2         | 80            |
| Copper IUD  | 0.8         | 0.6         | 78            |
| ETG Implant | 0.05        | 0.05        | 84            |
| DMPA        | 6           | 0.3         | 56            |
| Ring        | 9           | 0.3         | 68            |
| Patch       | 9           | 0.3         | 68            |
| COCs, POPs  | 9           | 0.3         | 68            |
| Male condom | 15          | 2           | 49            |

\*Includes users who fail to use a method consistently or correctly.

COC, combination oral contraception; DMPA, depot medroxyprogesterone acetate; ETG, etonogestrel; IUD, intrauterine device; LNG, levonorgestrel; POP, progestin-only contraception.

**TABLE 23-2** ABSOLUTE CONTRAINDICATIONS TO AN INTRAUTERINE DEVICE

| DEVICE             | CONTRAINDICATION  |
|--------------------|---|
| Levonorgestrel IUD | Current breast cancer   |
| Copper IUD         | Copper allergy (Wilson disease)   |
| Both IUDs          | Pregnancy, puerperal sepsis, current gonorrhea or <i>Chlamydia</i> infection, purulent cervicitis, immediately postseptic abortion, current PID, known uterine anomaly or distorted uterine cavity, endometrial or cervical carcinoma, unevaluated unexplained vaginal bleeding, persistently elevated β-hCG levels or malignant disease in a setting of GTD, pelvic tuberculosis |

GTD, gestational trophoblastic disease; hCG, human chorionic gonadotropin; IUD, intrauterine device; PID, pelvic inflammatory disease.

**milk constituents, or infant growth rates.** Although package labeling advises initiating the implant at 6 weeks postpartum, clinical experience and limited randomized trial data with immediate postpartum initiation is reassuring, and placement at this time may be in the patient's best interest for the prevention of a rapid repeat pregnancy. Gurtcheff and colleagues<sup>106</sup> randomized women to receive the implant 1 to 2 days postpartum, versus 4 to 8 weeks, and found no difference between groups in lactation failure, time to lactogenesis stage II, use of formula supplementation, and milk composition at 6 weeks.

### Injectable Contraception

Depot medroxyprogesterone acetate (DMPA) is an injectable progestin-only contraceptive given every 3 months. It is available in intramuscular and subcutaneous formulas and has a typical use failure rate of 6%. The mechanism of action of DMPA is to block the luteinizing hormone (LH) surge to prevent ovulation. DMPA is compatible with breastfeeding and can be given immediately after delivery. When initiated immediately or at 6 weeks postpartum, DMPA has not been shown to decrease the duration of lactation or to affect infant weight gain.<sup>107</sup> The main side effects of DMPA are irregular bleeding or amenorrhea, breast tenderness, weight gain, and depression. The side effect most likely related to discontinuation of the method is bleeding changes, which includes both irregular bleeding and amenorrhea.<sup>108</sup> Irregular bleeding decreases with increased length of time used. During the first year of use, the incidence of irregular bleeding is 70%, compared with 10% thereafter. Amenorrhea rates increase with increased duration of use as well. At 1 year, 50% of users are amenorrheic; after 5 years, amenorrhea rates reach 80%. Counseling about the expected bleeding profile is important at the initiation of DMPA because many women will not return for a second injection because of frustrations with bleeding. It is also important to counsel women about the delayed return to fertility after discontinuation of DMPA. The average delay to conception after the last injection of DMPA is 9 months, and the duration of DMPA use does not affect the return to conception.<sup>109</sup>

Limited evidence suggests that some caution should be used when prescribing DMPA in Hispanic women with a history of gestational diabetes. Some evidence suggests that in this group of women, DMPA use is associated with increased risk of type 2 diabetes. Much of this increased risk can be explained by clinical characteristics that placed the women at an increased risk for type 2 diabetes before starting DMPA.<sup>110</sup> Both the World Health Organization (WHO) and the Centers for Disease Control and Prevention (CDC) give all progestin-only methods a category 1 rating in women with a history of gestational diabetes, meaning no restrictions are suggested for use of the method.

Concern has also been expressed about DMPA causing mood changes and worsening depression, but findings from clinical trials have been reassuring, with no worsening of depression symptoms even in those women with high depression scores at baseline.<sup>111,112</sup> **Use of DMPA immediately after delivery does not result in higher rates of PPD.**<sup>113</sup>

Because DMPA inhibits ovarian function, estradiol levels are reduced, which leads to a temporary bone loss during use of DMPA. This bone loss is greatest during the first 2 years of use and declines thereafter. Reassuringly, bone mineral density (BMD) levels return to baseline with discontinuation of DMPA.<sup>114,115</sup> Cross-sectional studies that have demonstrated that BMD in former DMPA users is similar to that of never

users have provided reassurance that loss of BMD associated with DMPA is likely transient.<sup>116,117</sup> The clinical outcome of interest is whether DMPA use causes fracture risk, but no quality data are available to help answer this question. The American College of Obstetricians and Gynecologists (ACOG), American Academy of Pediatrics (AAP), and the WHO acknowledge that DMPA is an effective and convenient contraceptive method, and although providers should inform patients of the potential effects on bone, DMPA use should not be restricted or limited. In addition, BMD testing in DMPA users is not indicated.

### Combined Hormonal Contraception

Combined hormonal contraception (CHC) includes oral, transdermal, and vaginal estrogen- and progestin-containing contraception. All of these methods have a typical use failure rate of 9%. The progestin component inhibits the LH surge and blocks ovulation, whereas the estrogen component inhibits FSH and dominant follicle formation; the added estrogen also results in a more regular bleeding pattern, which many women prefer. Before prescribing CHC, appropriate screening of the patient must occur because the estrogen component carries a slightly increased risk of venous thromboembolism (VTE) in healthy reproductive-age women. Box 23-3 provides a list of contraindications to estrogen. During the postpartum period, the risk of VTE is also increased 22-fold to 84-fold compared with that of nonpregnant, nonpostpartum reproductive-age women.<sup>118</sup> This risk is highest during the first weeks postpartum and decreases with time, and the VTE risk returns to baseline by 42 days postpartum (see Chapter 45). Adding estrogen-containing birth control during this timeframe may increase the VTE risk

#### BOX 23-3 ABSOLUTE CONTRAINDICATIONS TO ESTROGEN

- Age  $\geq 35$  years and smoking  $\geq 15$  cigarettes per day
- Multiple risk factors for arterial cardiovascular disease (older age, smoking, diabetes, hypertension)
- Blood pressure  $\geq 160$  mm Hg systolic or  $\geq 100$  mm Hg diastolic
- Hypertension with vascular disease
- Acute DVT/PE
- Higher risk for recurrent DVT/PE or history of recurrent DVT/PE
- Prolonged immobilization
- Known thrombogenic mutations
- Ischemic heart disease or a history of ischemic heart disease
- Stroke
- Complicated valvular heart disease
- $<6$  months since peripartum cardiomyopathy
- Moderately or severely impaired cardiac function
- Positive (or unknown) antiphospholipid antibodies
- Migraine with aura
- Current breast cancer
- Diabetes with end-organ vascular disease or duration  $>20$  years
- Severe acute viral hepatitis
- Severe cirrhosis
- Hepatocellular adenoma
- Liver carcinoma
- Complicated solid-organ transplantation

DVT, deep venous thromboembolism; PE, pulmonary embolism.

even more; thus caution must be exercised when using CHC in postpartum women. In nonbreastfeeding women, CHC should not be used prior to 21 days postpartum.<sup>119</sup> In women without additional risk factors for VTE, CHC can be used after 21 days. In postpartum women with additional risk factors for VTE—such as age 35 or older, smoking, or recent cesarean delivery—CHC should not be used until after 42 days postpartum, when VTE risk returns to baseline. In breastfeeding women, initiation of CHC should be delayed until after 30 days because of evidence of its detrimental effects on lactation, such as decreased duration of breastfeeding, declines in milk production, and the need for increased supplementation for the newborn.<sup>120</sup> Breastfeeding women who have additional risk factors for VTE should delay initiation of CHC until after 42 days postpartum.

### Progestin-Only Oral Contraception

Often called the *mini pill*, progestin-only pills (POPs) contain a low dose of progestin and are taken daily. The mechanism of action is thickening of the cervical mucus to block sperm entry into the upper genital tract. Because the hormone dose is low and the effects on the cervical mucus begin wearing off after 22 hours, POPs are less forgiving if taken late. Typical use failure rate for POPs is 9%. POPs are safe to take while breastfeeding and have no effect on milk volume or infant growth and development.<sup>120</sup> Immediate initiation of POPs has not been shown to adversely affect breastfeeding, so they can be started immediately after delivery.<sup>121</sup> Like DMPA, evidence is limited that suggests in overweight or obese Hispanic women with prior gestational diabetes who are breastfeeding, POPs tripled the risk for type 2 diabetes.<sup>122</sup>

### Emergency Contraception

Emergency contraception (EC) is used after unprotected sex or after known contraceptive failure. Available options include the levonorgestrel-containing progestin-only method—known as the *Yuzpe method*, in which combination estrogen-progestin birth control pills are used—and the copper IUD. These EC options can be used up to 5 days after unprotected sex, but they are more effective the sooner they are used. Ulipristal acetate is the newest EC option. It is a progestin receptor agonist/antagonist and can also be used up to 5 days after unprotected sex. Ulipristal acetate is different in that it is as effective on the fifth day as on the first,<sup>123</sup> although women who are breastfeeding should not take it.

### Sterilization

**Male and female sterilization are the most frequently used methods of contraception in the United States, used by 37% of all contraceptive users.** In women who desire sterilization, the puerperium is a convenient time for tubal ligation procedures because they can be performed at the time of a cesarean delivery or within the first 24 to 48 hours after vaginal delivery. In some hospitals, the operation is performed immediately after delivery in uncomplicated patients, especially when epidural anesthesia is given for labor analgesia. With the use of a small paraumbilical incision, the procedure seldom prolongs the patient's hospitalization.

The 10-year failure rate of postpartum partial salpingectomy is 0.75%.<sup>124</sup> Several modifications of this procedure include the Pomeroy, Parkland, Uchida, and Irving techniques. Because of the relaxed abdominal wall and the easy accessibility of the fallopian tubes, the mini-laparotomy has the advantages of

convenience and speed without the possible risks for visceral injury that might occur with the trocar of the laparoscope.

Postpartum female sterilization can also be performed as an interval procedure unrelated to a pregnancy. One method is laparoscopic tubal ligation, which can be performed with titanium clips, Silastic bands, or cautery. Because of the newly discovered role the fallopian tube may play in the development of ovarian cancer, laparoscopic sterilization may also be chosen to be accomplished with bilateral salpingectomy.<sup>125</sup> A second type of interval sterilization is hysteroscopic transcervical sterilization, in which the tubal ostia are identified hysteroscopically and cannulated with titanium and nickel coils. Over 3 months, ingrowth of the tubes into the coils occurs and the tubes become occluded. One advantage of hysteroscopic sterilization is that it may be performed with or without anesthesia in an outpatient setting. One disadvantage is that the woman is not sterilized the day of the procedure and must continue to use a reliable method of contraception until a hysterosalpingogram is performed 3 months later to confirm tubal occlusion. All interval methods of tubal sterilization can be accomplished with a minimum of morbidity as outpatient procedures.

Whether performed in the puerperium or as an interval procedure, the risks of tubal ligation procedures include the short-term problems of anesthetic accidents; injury to bowel, bladder, or blood vessels; and infection. Hysteroscopic sterilization also carries the risk of uterine perforation and failure of cannulization of the tubal ostia. The overall risk for complication is 1.6%. Independent risk factors for complications are general anesthesia, diabetes, previous abdominal or pelvic surgery, and obesity. One to two deaths per 100,000 procedures occur and most often are attributed to anesthesia.

**Obstetricians must remember that vasectomy is often a more advisable and desirable alternative for a couple considering sterilization.**<sup>126</sup> It can be performed as an outpatient procedure under local anesthesia with an insignificant loss of time from work or family. Furthermore, **almost all failures—about 3 to 4 per 1000 procedures—can be detected by a postoperative semen analysis. This is a decided advantage over tubal ligation, in which failures are discovered only when a pregnancy occurs.** The azoospermia rate at 3 months is 60%, and it is 98% to 99% at 6 months. Interval contraception is required until azoospermia is confirmed. Vasectomy is less expensive and overall is associated with fewer complications than female sterilization; it has no sexual effects, and studies of long-term health effects found no evidence of an increased risk for atherosclerotic heart disease or other chronic illnesses.<sup>126</sup>

**Most women who choose sterilization do not regret their decision.** In the U.S. Collaborative Review of Sterilization study,<sup>127</sup> the cumulative risk for sterilization regret over 14 years was 12.7%. Age was a risk factor for regret. For women older than 30, risk for regret was 5.9%. In contrast, women 30 and younger had a risk of regret of 20.3%. Other factors that contribute to regret of sterilization are having incomplete information about the procedure; having less access to information about, or less support for use of, alternative birth control methods; and having made the decision for sterilization because of pressure from a spouse or because of a medical condition. Comprehensive counseling is important when couples are considering sterilization.

Tubal ligation can be reversed but it is expensive and is often not covered by insurance; therefore a patient should not undergo sterilization if she is contemplating reversal. Success, as measured

by the occurrence of pregnancy after tubal reanastomosis, varies from 40% to 85%, depending on the type of tubal ligation performed and on the length of functioning tube that remains. Success rates for vas reanastomosis vary from 37% to 90%, and higher success rates are associated with shorter intervals from the time of vas ligation.

### Barrier Methods

Barrier methods of contraception and vaginal spermicides were long used in Europe and England before they were manufactured in this country beginning in the 1920s. The diaphragm was the first woman-controlled contraceptive method available in the United States. The typical use failure rate for the diaphragm is 16%, with a range of 2% to 23%. Because this method of contraception requires substantial motivation, instruction, and experience, it is more effective in older women who are familiar with the technique. However, younger women may also be successful users with appropriate counseling. A diaphragm fits behind the pubic bone and completely covers the cervix. To get the appropriately sized diaphragm, a fitting with a gynecologic provider is required. **Because of the physical changes of pregnancy and delivery, a diaphragm should not be fitted until 6 weeks postpartum.** Even if a woman was previously using a diaphragm, she requires a refitting. In women who are breastfeeding, anovulation leads to vaginal dryness and tightness, which may make the proper fitting of a diaphragm more difficult. The diaphragm should be used with one of the spermicidal lubricants, all of which contain nonoxynol-9.

Condoms are an effective contraceptive method and also provide protection from sexually transmitted infections (STIs). The various types of condoms available include latex and non-latex varieties, such as polyurethane, silicone rubber, and natural membrane condoms. It is important to note that whereas natural membrane condoms prevent sperm penetration, they do not protect well against STIs. Spermicide is no longer advocated for use with condoms because of the vaginal irritation and microtears in the vaginal mucosa that can result in—and increase the risk for—infection, especially human immunodeficiency virus (HIV). The typical use failure rate for condoms is 17%, but it can be as low as 2%, depending on the age and motivation of the population studied.

The female condom is more expensive and more awkward to use than the male condom, but it has the advantage of being controlled by the woman. It has a typical use failure rate of 27%.

### Natural Family Planning Methods

Natural family planning (NFP) methods, also known as *periodic abstinence* or *fertility awareness* methods, involve women having a great knowledge of their own menstrual cycles and being keyed in to signs and symptoms of the fertile phase of the cycle, during which time they abstain from intercourse. To use these methods with success, a woman must have a regular menstrual cycle in addition to commitment from her partner. Postpartum women should not rely on NFP methods until regular menstrual cycles have resumed.

Several NFP methods can be used and include the *rhythm method*, or *calendar method*, in which the fertile period of one month can be predicted by the timing of the past cycle. The *cervical mucus method* requires a woman to monitor her cervical mucus for estrogen-related changes. The *symptothermal method* typically combines cervical mucus monitoring with basal body

temperature monitoring. The *standard days* method has the lowest failure rate of the NFP methods because it has the greatest number of abstinence days. A 26- to 32-day cycle is required for this method, and intercourse is avoided on days 8 through 19. When used perfectly, the pregnancy rate for the first year of use was 3.1%.<sup>128</sup> **Typical use failure rates for NFP methods range from 12% to 25%.** NFP methods are unforgiving if the rules of periodic abstinence are not followed.

## POSTPARTUM PSYCHOLOGICAL REACTIONS

**The psychological reactions experienced following childbirth include the common, relatively mild physiologic and transient “maternity blues” (occurring in 50% to 70% of women), true depression (occurring in 8% to 20% of women), and frank puerperal psychosis (occurring in 0.14% to 0.26% of women).**

Overall, anxiety is the most common emotional symptom in the puerperium. These problems are discussed in [Chapter 55](#). In patients with underlying depression or a history of PPD and in those who report symptoms that develop during the immediate postpartum period, it is essential that a postpartum visit be scheduled sooner than the traditional 6 weeks. Other risk factors for PPD include a family history of depression, a mother with PPD, a poor social situation, and prolonged separation from the infant. The moderately depressed mother often experiences such guilt and embarrassment secondary to her sense of failure in her mothering role that she is unable to call her physician or admit the symptoms of her depression. Consequently, ample time must be set aside to explore in depth even the slightest symptoms or signs of depression. Home visits in this situation may be appropriate to assess the patient. **When a patient calls with a seemingly innocuous question, she should be asked two or three open-ended questions about her general status.** Such questions allow the patient to open up if underlying depression is an issue, and she feels too guilty or afraid to express herself spontaneously. Examples of sample questions are:

1. How do you feel things are going?
2. How are things with the baby?
3. Are you feeling how you expected to feel?

Because nursing staff often triage phone calls for physicians and midwives, it is important that such personnel be instructed to be alert to this protocol. Additionally, we recommend that both parents be warned before hospital discharge that if the maternity blues seem to be lasting longer than 2 weeks or become too tough to handle, either partner should call. An easy screening depression scale, the EPDS, is shown in [Box 23-2](#). Puerperal thyroid disease will often present with symptoms such as mild dysphoria; consequently, thyroid function studies are suggested in the evaluation of patients with suspected PPD that occurs 2 to 3 months after delivery.

## MANAGING PERINATAL GRIEVING

For the most part, perinatal events are happy ones and are occasions for rejoicing. **When a patient and her family experience a loss associated with a pregnancy, special attention must be given to the grieving patient and her family.**

The most obvious cases of perinatal loss are those in which a fetal or neonatal death has occurred. Other, more subtle losses can be associated with a significant amount of grieving, such as the birth of a critically ill or malformed infant, an unexpected

hysterectomy performed for intractable postpartum hemorrhage, or even a planned postpartum sterilization procedure. **Grief occurs with any significant loss, whether it is the actual death of an infant or the loss of an idealized child in the case of the birth of an infant with an illness or potential disability.**

The clinical signs and symptoms of grief and their psychological ramifications as they relate to loss suffered by women during their pregnancies have been given special consideration in recent years. In studying the relatives of servicemen who died in World War II, Lindemann recognized five manifestations of *normal grieving*. These include somatic symptoms of sleeplessness, fatigue, digestive symptoms, and sighing respirations; preoccupation with the image of the deceased; feelings of guilt; feelings of hostility and anger toward others; and disruption of the normal pattern of daily life. He also described the characteristics of what is now recognized as *pathologic grieving*, which may occur if acute mourning is suppressed or interrupted. Some of the manifestations of this so-called morbid grief reaction are overactivity without a sense of loss; appearance or exacerbations of psychosomatic illness; alterations in relationships with friends and relatives; furious hostility toward specific persons; lasting loss of patterns of social interaction; activities detrimental to personal, social, and economic existence; and agitated depression.

Kennel and associates<sup>129</sup> studied the reaction of 20 mothers to the loss of their newborn infants. Characteristic signs and symptoms of mourning occurred in all the patients, even when the infant was nonviable. Similar grief reactions occurred in most of the parents of 101 critically ill infants who survived after referral to a regional neonatal intensive care unit, showing that separation from a seriously ill newborn is sufficient to provoke a typical grief reaction. **Interestingly, studies over the last 15 years have found that women who do not see their stillborn infant actually have less depression; this suggests that best practice is to give mothers the choice of seeing and holding their infant after delivery but not to necessarily encourage them to do it.**

It is important that the characteristics of a grieving patient be recognized and understood by the health professionals who care for them; otherwise, substantial misunderstanding and mismanagement of the patient will occur. For example, if the patient's reaction of anger and hostility is unanticipated, a nurse or physician may take personally the hostile statements or actions of the patient or her family and may avoid contact at the very time the grieving patient most needs consolation and support. Because of their own discomfort with the implications of death, physicians, nurses, and others on the postpartum unit often find it difficult to deal with patients whose fetus or infant has died. As a consequence, reluctance to discuss the death with the patient is understandable, as is the tendency to rely on the use of sedatives or tranquilizers to deal with the patient's symptoms of grief. **What is actually beneficial at such a time is a sympathetic listener and an opportunity for the patient to express and discuss feelings of guilt, anger, and hopelessness and to allow the other symptoms of mourning.**

It is not surprising that PPD is more common and more severe in families that have suffered a perinatal loss. In one study, the prolonged grief response occurred more often in those women who became pregnant within 5 months of the death of the infant. This finding suggests that in counseling women after the loss of an infant, it is best to ignore the traditional advice of

encouraging the family to embark soon on another pregnancy as a "replacement" for the infant who died. Just how long the normal grief reaction lasts is unknown, and surely it varies with different families. Lockwood and Lewis<sup>130</sup> studied 26 patients who had suffered a stillbirth, and they followed several patients for as long as 2 years. Their data suggest that grief in this situation is usually resolved within 18 months, invariably with a resurgence of symptoms at the first anniversary of the loss.

Somatic symptoms of grief—such as anorexia, weakness, and fatigue—are now well recognized. Spontaneous abortion and infertility increase among couples who attempt to conceive after the loss of an infant. Physical changes that occur with grieving may account for this increase in poor reproductive success. Although the most intense suppression is noted within the first month after a loss, a modified response may last for as long as 14 months.

The regionalization of perinatal health care has resulted in a large proportion of the perinatal deaths occurring in tertiary centers. In some of these centers, teams of physicians, nurses, social workers, and pastoral counselors have evolved to aid specifically in the management of families that suffer a perinatal loss. Although this approach ensures an enlightened, understanding, and consistent approach to bereaved families, it suggests that the support of a grieving patient is a highly complex endeavor that can be accomplished only by a few specially trained individuals who care for postpartum patients. Enlightened and compassionate counseling of parents who have suffered a perinatal loss may be accomplished by any of the mother's health care professionals by using the guidelines listed in [Box 23-4](#). Clearly, management of grief is not solely a postpartum responsibility, and this is particularly true when a prenatal diagnosis is made of fetal death or abnormality. A continuum of support is essential as the patient moves from the prenatal setting, to labor and delivery, to the postpartum ward, and finally to her home. Relaxation of many of the traditional hospital routines may be necessary to provide the type of support these families need. For example, allowing a loved one to remain past visiting hours, providing a couple a private setting in which

#### BOX 23-4 GUIDELINES FOR MANAGING PERINATAL LOSS

- Keep parents informed; be honest and forthright.
- Recognize and facilitate anticipatory grieving.
- Inform parents about the grieving process.
- Encourage the support person to remain with the mother throughout labor.
- Encourage the mother to make as many choices about her care as possible.
- Support parents in seeing, touching, or holding the infant.
- Describe the infant in detail, especially for couples who choose not to see the infant.
- Allow photographs of the infant.
- Prepare the couple for hospital paperwork, such as autopsy requests.
- Discuss funeral or memorial services.
- Assist the couple in the process of informing siblings, relatives, and friends.
- Discuss subsequent pregnancy.
- Liberal use of follow-up home or office visits.

Modified from Kowalski K. Managing perinatal loss. *Clin Obstet Gynecol.* 1980;23:1113.

to be with their deceased infant, or allowing unusually early discharge with provisions for frequent phone calls and follow-up visits often facilitates the resolution of grief.

**It is also important to realize that after the death of a fetus or neonate, fathers have somewhat different grief responses than do mothers.** In a study of 28 fathers who had lost infants, grief was primarily characterized by self-blame, feelings of diminished self-worth, a need to keep busy with increased work, and limited ability to ask for help. Stoic responses are typical of men and may obstruct the normal resolution of grief.

### Postpartum Posttraumatic Stress Disorder

**Posttraumatic stress disorder (PTSD) may occur after any physical or psychological trauma. The disorder commonly occurs after a labor and delivery experience in which a woman is confronted with circumstances (pain, loss, trauma) that her defenses or sense of well-being cannot overcome. Thus some women develop PTSD from an experience that other women will cope with easily or that a clinician may find fairly unremarkable.**

PTSD may lead to behavioral sequelae that include flashbacks, avoidance, and inability to function. Emergency operative deliveries, both vaginal and abdominal, and severe unexpected pain have been reported to produce posttraumatic stress. The reaction may lead to fear of a subsequent delivery that may become incapacitating as well as more generalized symptoms of this disorder. **Whenever an emergency procedure is indicated, debriefing afterward—both early and a few weeks later—may help to decrease the incidence of this problem.** Women with adverse outcomes frequently experience transference of their previous experience as the next delivery approaches. If anxiety is a predominant symptom at the postpartum visit, discussions of a PTSD reaction may be indicated. The symptom complex of PTSD is less severe and is sometimes eliminated with early intervention. Thus if a woman seems to express psychological symptoms out of proportion to her labor and delivery experience, referral for further evaluation is appropriate.

#### KEY POINTS

- ◆ By 6 weeks postpartum, only 28% of women have returned to their prepregnant weight.
- ◆ About 50% of parturients experience diminished sexual desire during the 3 months that follow delivery.
- ◆ Postpartum uterine bleeding of sufficient quantity to require medical attention occurs in 1% to 2% of parturients. Of patients who require curettage, 40% will be found to have retained placental tissue.
- ◆ LARC methods are the most effective contraceptive available and are safe methods for postpartum women, including those who are breastfeeding.
- ◆ In nonbreastfeeding postpartum women, combined hormonal contraceptive methods (pill, patch, ring) should not be used prior to 21 days because of the risk of venous thromboembolism; in postpartum women with additional risk factors, combined hormonal contraceptives should not be used until after 42 days.
- ◆ Breastfeeding results in 98% contraceptive protection when the woman is exclusively breastfeeding on demand

both day and night, is amenorrheic, and the infant is less than 6 months old.

- ◆ Progestin-only contraceptives do not diminish lactation performance.
- ◆ Postpartum major depression occurs in 8% to 20% of parturients; if possible, risk factors should be considered to identify patients for increased screening and surveillance.
- ◆ Puerperal hypothyroidism often presents with symptoms that include mild dysphoria; consequently, thyroid function studies are suggested in the evaluation of patients with suspected PPD that occurs 2 to 3 months after delivery.

Breastfeeding and breast milk are the global standard for infant feeding in undeveloped and developed countries. The World Health Organization (WHO), the U.S. Surgeon General, the American Academy of Pediatrics (AAP),<sup>1</sup> the American College of Obstetricians and Gynecologists (ACOG),<sup>2</sup> the American Academy of Family Practice, and the Academy of Breastfeeding Medicine have endorsed this recommendation for over two decades. **They recommend exclusive breastfeeding for the first 6 months and continued breastfeeding at least through 12 months with subsequent weaning as a mutual decision by the mother and infant dyad in the subsequent months and years.** Historic and physioanthropologic data suggest that except for the last century, humans have breastfed their children 3 to 4 years throughout history.

Unfortunately, the United States has failed to meet the exclusivity and duration goals set out by world and national health organizations. Figure 24-1 describes the historic trends in breastfeeding behaviors in the United States. The latest estimates (2011) of breastfeeding performance (<http://www.healthypeople.gov/2020>) are that 79.2% of women initiate breastfeeding in the hospital, and only 49.4% of those are still breastfeeding at 6 months. Approximately 26.7% of American infants meet the standard of breastfeeding 1 year or more. Only 40.7% and 18.8% of American infants are exclusively breastfeeding at 3 and 6 months, respectively, and more than 19.4% received supplemental formula in the first 48 hours of life.

Specific populations are at greater risk for failure to initiate and continue breastfeeding. **Women of lower socioeconomic status, those with less education, and teenagers initiate breastfeeding at about half to two thirds the rate of mature high school graduates of middle and upper socioeconomic statuses.** Black women tend to have lower rates of initiation and maintenance of breastfeeding than other cultural and

**FIG 24-1** Incidence of breastfeeding in the hospital, any breastfeeding at 6 months, and exclusive breastfeeding at 6 months.

**ethnic populations.<sup>3</sup> Fortunately, since 1989, more women at greatest risk for feeding their infants artificial breast milk are initiating breastfeeding in the hospital.**

A recent prospective study has clarified breastfeeding behaviors in the first year after birth.<sup>4</sup> In the Centers for Disease Control and Prevention (CDC) and U.S. Food and Drug Administration (FDA)-sponsored Infant Feeding Practices Study II, 1147 women initiated breastfeeding and stopped breastfeeding during the study period (2005 through 2007). All women were recruited in the third trimester. Approximately 60% of mothers did not meet their personal plans for the duration of breastfeeding; the mean duration of breastfeeding in women who met their intention for breastfeeding was 7.8 months, and it was 3.8 months in those who did not meet their intention. In the multivariable analysis, women who failed to meet their desired duration of breastfeeding had initial challenges with latch-on and nipple pain or injury, perceived that the baby was not getting enough nutrition, or needed to take medications for a maternal illness.

Cultural attitudes underlie the desired duration of breastfeeding and affect the failure to breastfeed through the first year. In an effort to mobilize mothers to increase breastfeeding rates, the U.S. Surgeon General has set goals for the country. The Healthy People 2020 Maternal, Infant, and Child Health (MICH) objectives are (1) any breastfeeding, 81.9%; (2) any breastfeeding at 6 months, 60.6%; (3) any breastfeeding at 12 months, 34.1%; (4) exclusive breastfeeding at 3 months, 46.2%; (5) exclusive breastfeeding at 6 months, 25.5%; and (6) to reduce the number of infants who receive supplemental formula in the first 48 hours to 14.2%. MICH 22 sets a goal that 38% of employers have a worksite lactation support program, and MICH 24 sets a goal that 81% of live births occur in facilities that provide recommended care for the breastfeeding dyad.

Although dysfunctional cultural and familial attitudes are outside the direct control of medicine, these attitudes may directly affect the care delivered by physicians. The normal function of the breasts, to produce breast milk, is muted by three cultural attitudes. First is the association of breasts with sexual attraction; the media is replete with examples that show beautiful, well-formed breasts as a sexual ideal. A corollary of this attitude is that breastfeeding will cause the breasts to sag and lose their sex appeal. Second, an opposing cultural attitude is

that breastfeeding restricts self-fulfillment; mothers who stay at home to breastfeed and care for their babies are considered poor examples of the modern, independent professional woman. Finally, the attitude or myth is prevalent that artificial breast milk, formula, and bottle-feeding are an equivalent source of nutrition to breastfeeding, although research has proven this is not the case.

The latter attitudes are exacerbated by a lack of lay public and health care provider knowledge about breastfeeding and breast milk. The normal function of the breasts is excluded from the curriculum of primary and secondary schools on the basis of the connection between breasts and sex. After completion of their education, few women experience any examples of successful breastfeeding—that is, any breastfeeding for longer than 1 year. Between 1970 and 1990, when they gave birth, only 30% to 50% of today's grandmothers initiated breastfeeding, and less than a quarter breastfed for more than a few weeks. **The lack of exposure to successful, experienced breastfeeding mothers seriously compromises the chances of success for today's women who attempt to breastfeed.**

Physicians are products of the same culture as the women they serve. Unfortunately, many have the same cultural biases as their patients and the same lack of primary and secondary education regarding the normal physiology of breastfeeding. Although the curricula of medical school and residency training programs have improved in the last 5 years, the general lack of didactic education and clinical exposure to successfully breastfeeding mother-infant dyads contribute to the lack of breastfeeding knowledge. Most physicians who reflect on their own education will identify neither a structured curriculum nor practical experiences with successfully breastfeeding mother-infant dyads. On obstetric rotations, medical students and obstetrics residents rarely see normal breastfeeding dyads longer than 1 to 3 days postpartum. On pediatric rotations, students often see the baby only in the nursery and rarely see the normal mother breastfeed as an inpatient or at newborn visits. Although pediatric residents observe and support the mother who nurses or pumps milk for her growing preterm infant, the exposure is often negative. As a result, serious gaps exist in physicians' knowledge as they attempt to serve the over 3 million newborns and mothers per year who initiate breastfeeding. In fact, the most commonly cited resource for physicians is another non-medical individual or a breastfeeding spouse.

The purpose of this chapter is to begin the educational process through which obstetricians will adopt the lactating mother as their patient. **In order to support the breastfeeding mother, the obstetrician must be convinced of the biologic superiority of breastfeeding and human breast milk over formula.** This chapter reviews breast anatomy and the physiology of lactation in a framework pertinent to breastfeeding management. This chapter describes the vast differences between breast milk and formula, a difference directly related to unique needs and the short- and long-term health of the infant and mother. Specific issues related to the obstetrician and other health care providers will be addressed, including the role of the obstetrician in preconception counseling, prenatal care, delivery room management, and postpartum care for the breastfeeding mother.

## BREAST ANATOMY AND DEVELOPMENT

The size and shape of the breast vary greatly by stage of development, physiologic state, and phenotype. Usually, the breast

projects into each axilla and thus forms the *tail of Spence*. The mature breast weighs about 200 g in the nonpregnant state; during pregnancy, 500 g; and during lactation, 600 to 800 g. As long as glandular tissue and the nipple are present, the size or shape of the breast has little to do with the functional success of the breast. **The adequacy of glandular tissue for breastfeeding is ascertained by inquiring whether a woman's breasts have enlarged during pregnancy. If the breast fails to enlarge as the result of pregnancy, especially if associated with minimal breast tissue on examination, the clinician should be wary of primary failure of lactation.**

The areola is a circular pigmented area that darkens during pregnancy; the nipple, or *papilla mammae*, is a conical elevation in the middle of the areola, or *areola mammae*. The contrast between the areola and the fairer skin of the rest of the body provides a visual cue for a newborn attempting to latch-on. The areola contains multiple small elevations called *Montgomery tubercles*, which enlarge during pregnancy and lactation. These tubercles contain multiple ductular openings of sebaceous and sweat glands that secrete lubricating and antiinfective substances (immunoglobulin A [IgA]) that protect the nipple and areola during nursing. When the breasts and nipples are washed with soap or alcohol-containing compounds, these substances are washed away, which leaves the nipple prone to cracking and infection.

Unlike the dermis of the body of the breast, which includes fat, the areola and nipple contain smooth muscle and collagenous and elastic tissue. With light touch or anticipation of nursing, these muscles contract, and the nipple erects to form a teat. The contraction pulls the lactiferous sinuses into the nipple-areola complex, which allows the infant to withdraw the breast milk from these reservoirs.

**The tip of the nipple contains the openings (0.4 to 0.7 mm diameter) of 15 to 20 milk ducts (2 to 4 mm diameter). Each of the milk ducts empties one tubuloalveolar gland, embedded in the fat of the body of the breast.** A sphincter mechanism at the opening of the duct limits the ejection of milk from the breast, although the competency of this mechanism varies. About 80% of women demonstrate milk ejection from the contralateral breast when milk ejection is stimulated. If milk leakage is demonstrated from the contralateral breast during nursing, it is indicative of an intact let-down reflex and is highly suggestive of milk transfer to the infant.

The milk ducts widen (5 to 8 mm) into the lactiferous sinuses 5 to 10 mm from their outlet (Fig. 24-2). These sinuses are pulled into the teat during nursing, and the infant uses its tongue, facial muscles, and mouth to squeeze the milk from the sinuses into its oropharynx. The tubuloalveolar glands (15 to 20) form lobes, which are arranged in a radial fashion from the central nipple-areola complex. The lobes and lactiferous ducts extend into the tail of Spence. Ten to 40 lactiferous ducts connect to each lactiferous sinus, and each forms a lobule. Each lobule arborizes into 10 to 100 alveoli that become the tubulosaccular secretory units. **The alveoli are the critical units in the production and ejection of milk: a sac of alveolar cells is surrounded by a basket of myoepithelial cells, and the alveolar cells are stimulated by prolactin to produce milk.** The myoepithelial cells are stimulated by oxytocin to contract and eject the milk into the lactiferous ducts, lactiferous sinuses, and beyond.

The radial projection of lactiferous ducts prompts important considerations relative to breast surgery on women who are

breastfeeding or who will breastfeed. **Surgical skin incisions parallel to the circumareolar line, especially at the circumareolar line, have better cosmetic healing and are often chosen by surgeons. However, if the incision is taken deep into the parenchyma, the lactiferous ducts may be compromised; a superficial, parallel skin incision and a radial deep incision are preferred. In women who intend to breastfeed, a circumareolar incision should be avoided because it compromises breastfeeding in three ways: (1) by occlusion of lactiferous ducts, (2) by restriction of the formation of a teat during nursing, and (3) by injury to the lateral cutaneous branch of the fourth intercostal nerve.**

**Surgical disruption of the lateral cutaneous branch of the fourth intercostal nerve can have devastating effects on the success of breastfeeding.** This nerve is critical to the production and ejection of breast milk. Furthermore, the nerves provide organ-specific control of regional blood flow, and a tremendous increase in mammary blood flow occurs during a nursing episode. Disruption of this autonomic control may severely compromise lactation performance. The rate of breastfeeding failure is two to three times higher when a circumareolar incision has been performed; therefore the obstetrician needs to be alert to old surgical incisions when a pregnant patient expresses a desire to breastfeed or when a breast biopsy is anticipated in a reproductive-age woman.

As mammals, humans have the potential to develop mammary tissue (glandular or nipple tissue) anywhere along the milk line, also called the *galactic band*. The milk line extends from the axilla and inner upper arm down the abdomen along the midclavicular line to the upper lateral mons and upper inner thigh. When accessory glands occur, this is termed *hypermastia*, which may involve accessory glandular tissue, supernumerary nipples, or both. Two to 6% of women have hypermastia, and the response to pregnancy and lactation is variable. **The most common site for accessory breast tissue is the axilla. These women may present at 2 to 5 days postpartum, at initiation of galactogenesis, with painful enlargements in the axilla. Ice and symptomatic therapy for 24 to 48 hours is sufficient treatment. Supernumerary nipples (*polythelia*) are associated with renal abnormalities (11%).**

## PHYSIOLOGY OF LACTATION

The best and most extensive research concerning the physiology of lactation focuses on the production of milk and has its roots in the research conducted by the multibillion-dollar dairy industry. Good milk-producing cattle, whose milk composition (i.e., fat percentage) can be controlled, create a competitive advantage in the marketplace. The translation of dairy research to human research plus the expected interest of pediatricians in infant nutrition has led to a preponderance of data on maternal milk production and delivery and its impact on neonatal and childhood outcomes. With the exception of hypothalamic hypogonadism in the breastfeeding mother and its effect on menses and child spacing, very little is understood about the physiologic changes during the breastfeeding episode, such as vascular adaptation to the rapid production (10 to 30 minutes) of 100 to 200 mL of an extremely complex liquid. **Most maternal and child benefits of breastfeeding are accrued in a dose-dependent fashion; the longer (>12 months) and the more intense (exclusive breastfeeding), the better the outcomes in terms of, for example, premenopausal breast cancer or**

**FIG 24-2** Anatomy of the breast.

**cardiovascular disease.** We are beginning to ask the questions “why” and “how.” Are the benefits of breastfeeding to the mother’s health related to the duration of the hormonal changes? Are they from the “antistress” effects of oxytocin? Or do they result from changes in gastrointestinal (GI) absorption of substrates? Does the intense pair-bonding that occurs between a mother and her breast-fed children affect allostatic load later in life? The answers to these questions will greatly improve our knowledge of the human breastfeeding experience.

**The physiology of lactation has three major components: (1) the stages of lactogenesis, (2) endocrinology of lactogenesis, and (3) nursing behavior/milk transfer.** The following sections summarize what is known about the physiology of human lactation.<sup>5</sup> The composition of mature human breast milk will also be described, with a focus on the differences between breast milk and formula.

### Stages of Lactogenesis

Full alveolar development and maturation of the breast must await the hormones of pregnancy—progesterone, prolactin, and human placental lactogen (hPL)—for completion of the developmental process at delivery. This is termed *lactogenesis stage I*. By midpregnancy, the gland is competent to secrete milk (colostrum), although full function is not attained until the tissues are released from the inhibition of high levels of circulating progesterone.

*Lactogenesis stage II* occurs as the progesterone levels fall after delivery of the placenta, during the subsequent 7 days. During the first 2 to 4 days after delivery, incremental secretion of colostrum occurs (50 to 400 mL/day). Until lactogenesis stage II has fully developed, the breasts secrete colostrum, which is very different from mature milk in volume and constituents.

**Colostrum has more protein, especially secretory immunoglobulins, and more lactose; it also has a lower fat content than mature milk.** Prolactin and glucocorticoids play important promoter roles in this stage of development.

At 2 to 5 days postpartum, a dramatic increase occurs in mammary blood flow and oxygen/glucose uptake by the breast. **The secretion of milk is copious, 500 to 700 mL/day when “the milk comes in.” This is the most common time for engorgement if the breasts are not drained by efficient, frequent nursing.**

After *lactogenesis stage II*, which occurs from 3 to 7 days postpartum, lactation enters an indefinite period of milk production formerly called *galactopoiesis*, now termed *lactogenesis stage III*. The duration of this stage is dependent on the continued production of breast milk and the efficient transfer of breast milk to the infant. **Prolactin appears to be the single most important galactopoietic hormone because selective inhibition of prolactin secretion by bromocriptine disrupts lactogenesis; oxytocin appears to be the major galactokinetic hormone.** Stimulation of the nipple and areola and infant behavioral cues cause a reflex contraction of the myoepithelial cells that surround the alveoli and trigger ejection of milk from the breast.

The final stage of lactation, *lactogenesis stage IV*, is involution and cessation of breastfeeding. As the frequency of breastfeeding is reduced to less than six episodes in 24 hours, and the produced milk volume is less than 400 mL in 24 hours, prolactin levels fall in proportion to the frequency of nipple stimulation, which ultimately leads to a total cessation of milk production. After 24 to 48 hours of no transfer of breast milk to the infant, increasing intraductal pressure and production of **lactation inhibitory**

**factor** from the alveolar epithelium appear to initiate apoptosis of the secretory epithelial cells and proteolytic degradation of the basement membrane. Lactation inhibitory factor is a protein secreted in the milk, and its increasing concentration in the absence of milk drainage appears to decrease milk production by the alveolar cells. It counterbalances pressures to increase milk supply (i.e., increased frequency of nursing) and allows for the day-to-day adjustment in infant demands.

### Endocrinology of Lactogenesis

Prolactin is the major hormone that promotes milk production, and thyroid hormones selectively enhance the secretion of lactalbumin. Cortisol, insulin, parathyroid hormone, and growth hormone are supportive metabolic hormones in the production of carbohydrates and lipids in breast milk. Ovarian hormones are not required for the maintenance of established milk production and are suppressed by high levels of prolactin.

**The alveolar cell is the principal site for the production of milk.** Neville<sup>5</sup> describes five pathways for milk synthesis and secretion in the mammary alveolus, including four major transcellular and one paracellular pathway: (1) exocytosis (merocrine secretion) of milk protein and lactose in Golgi-derived secretory vesicles; (2) milk fat secretion via milk fat globules (apocrine secretion); (3) secretion of ions and water across the apical membrane; (4) pinocytosis-exocytosis of immunoglobulins; and (5) a paracellular pathway for plasma components and leukocytes. During lactation, as opposed to during pregnancy, very few of the constituents of breast milk are transferred directly from maternal blood. The junctions between cells, also known as *tight junctions*, are closed. As weaning occurs, the tight junctions are released and sodium and other minerals easily cross to the milk, which changes the taste of the milk. The change in taste may affect the interest of the infant to continue to breastfeed.

The majority of milk is produced *de novo* by the breast, rather than by direct absorption from the maternal gut or from manufacture by maternal organs such as the liver, kidneys, and so on. The substrates for milk production are primarily absorbed from the maternal gut or are produced in elemental form by the maternal liver. **Glucose is the major substrate for milk production.** It serves as the main source of energy for other reactions and is a critical source of carbon. The synthesis of fat from carbohydrates plays a predominant role in fat production in human milk, whereas proteins are built from free amino acids derived from plasma.

**A sizable proportion of breast milk is produced during the nursing episode.** In order to supply the substrates for milk production, blood flow increases to the mammary glands (20% to 40%), GI tract, and liver. Cardiac output is increased by 10% to 20% during a nursing episode. The vasodilation of the regional vascular beds is under the control of the autonomic nervous system, and oxytocin may play a critical role in directing the regional distribution of maternal cardiac output through an autonomic, parasympathetic action.

**Given that milk is produced during the nursing episode, variation in content during a feed is expected. During a feeding episode, the lipid content of milk rises by more than twofold to threefold (1% to 5%) with a corresponding 5% fall in lactose concentration.** The protein content remains relatively constant. At the extreme, there can be a 30% to 40% difference in the volume obtained from each breast. Likewise, intraindividual variations have been observed in lipid and lactose concentrations.

The rising lipid content during a feed has practical implications in breastfeeding management. **If a woman limits feedings to less than 4 minutes but nurses more frequently, the calorie density of the milk is lower, and the infant's hunger may not be satiated.** As a result, the infant wishes to feed sooner, and the frequency of nursing accelerates; this stimulates more milk production and creates a scenario of a hungry infant despite apparent good volume and milk transfer. **Lengthening the nursing episode or using one breast for each nursing episode often solves the problem.**

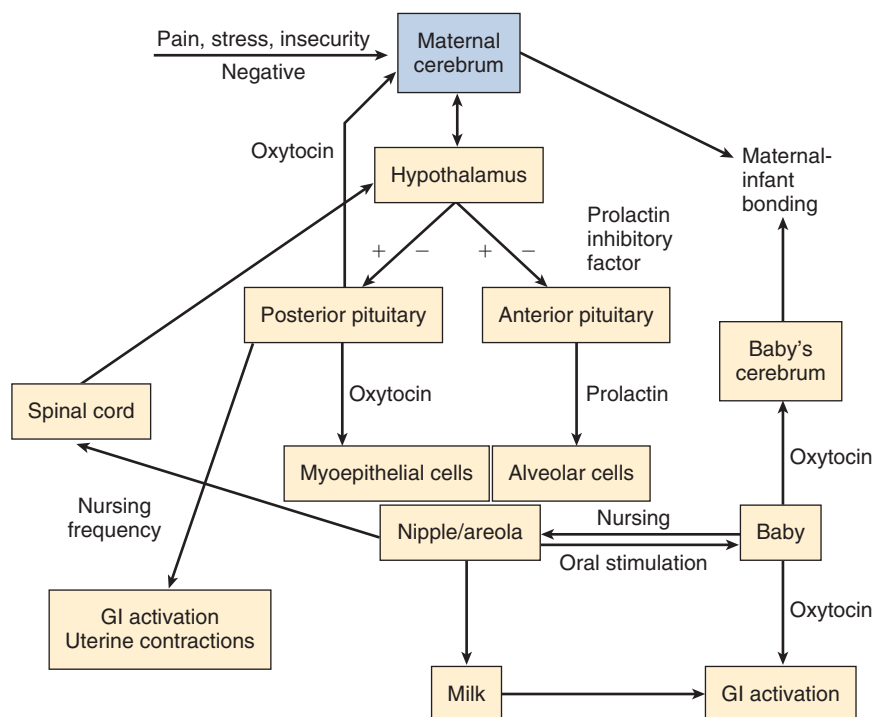

The volume and concentration of constituents also vary during the day. The volume per feed increases by 10% to 15% in the late afternoon and evening. Nitrogen content peaks in the late afternoon and falls to a nadir at 5:00 AM. Fat concentrations peak in the early morning and reach a nadir at 9:00 PM. Lactose levels stay relatively stable throughout the day. The variation in milk volume and content in working women who nurse only when at home has not been studied. The variation in volume and content is preserved if the woman pumps breast milk adequately (every 2 to 3 hours) during the day.

**Does diet affect the volume and constitution of breast milk? For the average American woman with the range of diets from teenagers to mature, health-conscious adults, the answer is no.** No convincing evidence suggests that the macronutrients in breast milk—protein, fats, and carbohydrates—vary across the usual range of American diets, although volume may vary in the extremes. In developing countries where starvation is widespread and daily calorie intake is less than 1600 kcal/day during prepregnancy and pregnancy, the mother's milk volume and its caloric density are only minimally decreased (5% to 10%) in underweight breastfeeding women.<sup>6</sup> In a controlled

experiment,<sup>7</sup> well-nourished European women reduced their calorie intake by 33% for 1 week. Milk volume was not reduced when the diet was maintained at greater than 1500 kcal/day. If the daily energy intake was less than 1500 kcal, milk volume was reduced by 15%. **Moderate dieting and weight loss postpartum (4.5 lb/month) are not associated with changes in milk volume, nor does aerobic exercise have any adverse effect.**<sup>8,9</sup>

In the first year of life, the infant undergoes tremendous growth: infants double their birthweight in 180 days. Infants fed artificial breast milk (formula) lose up to 5% of their birthweight during the first week of life, and breast milk–fed infants lose about 7% of their birthweight. A maximum weight loss of 10% of birthweight is tolerated in the first week of life in breast-fed infants. If this threshold is exceeded, the breastfeeding dyad needs immediate intervention by a trained health care provider. Although supplementation with donor breast milk or artificial breast milk may be a necessary part of the intervention, the key focus of intervention is establishing good breast milk transfer by ensuring adequate production, correct nursing behavior, correct latch-on, and adequate frequency. Once *lactogenesis stage III* occurs, “the milk has come in”; the term infant will gain about 0.75 to 1 oz/day with adequate breast milk transfer. **By 14 days, the breast-fed infant should have returned to its birthweight.**

Food intake and energy needs are not constant. The infant's need for energy and fluids can vary daily or weekly because of growth spurts; greater activity; immunologic challenges, such as when fighting an illness; or with greater fluid losses, as in hot weather. Mammals have developed an extremely efficient mechanism to adjust milk supply within 24 to 48 hours, depending on demand, via oxytocin and the let-down reflex (Fig. 24-3) and

**FIG 24-3** Oxytocin and the let-down reflex. The major reflex includes feedback stimulation from the nipple/areola to the hypothalamus to increase/decrease the release of oxytocin from the posterior pituitary and prolactin inhibitor factor (PIF, dopamine). The PIF affects the release of prolactin, which increases milk production; oxytocin causes milk ejection, and the release of both hormones is affected by positive or negative influences from the upper central nervous system (CNS). Oxytocin has three different target sites: the gastrointestinal (GI) tract (motility), uterus (contractions), and the upper CNS (mother-infant bonding). Oral stimulation in the infant initiates oxytocin release to improve GI function and maternal-infant bonding.

prolactin production. **The prolactin and oxytocin travel to their target cells: prolactin goes to the alveolar epithelium in the breast, and oxytocin goes to the myoepithelial cells that shroud the alveolar epithelium.** In lactating women, baseline prolactin levels are 200 ng/mL at delivery, 75 ng/mL between 10 and 90 days postpartum, 50 ng/mL between 90 and 180 days postpartum, and 35 ng/mL after 180 days postpartum. Maternal serum prolactin levels rise by 80% to 150% of baseline levels within seconds of nipple stimulation. **As long as nursing frequency is maintained at more than eight episodes a day for 10 to 20 minutes with each episode, the serum prolactin levels will suppress the luteinizing hormone (LH) surges and ovarian function. Serum oxytocin levels also rise with nipple stimulation.** However, the oxytocin response is much more affected by operant conditioning, and its response may precede the rise in prolactin levels. The maternal cerebrum is influenced by exposure to nursing cues and to the influences of nipple stimulation. The cerebrum either stimulates or inhibits the hypothalamus to increase or decrease the production of prolactin inhibitory factor (dopamine) and, subsequently, this drives the release of oxytocin from the posterior pituitary. Cerebral influences have a lesser effect on the release of prolactin. Positive sights, sounds, or smells related to nursing often stimulate the production of oxytocin, which in turn causes the myoepithelial cells to contract and allows milk to leak from the breasts. This observation is a good clinical clue to indicate an uninhibited let-down reflex.

**In a classic series of experiments in 1958, Newton and Egli<sup>10</sup> demonstrated the power of noxious influences to inhibit the release of oxytocin and reduce milk transfer to the infant.** The baseline milk production per feed was measured in controlled situations at about 160 g per feed. During a consecutive feed, a noxious event (i.e., saline injection) was administered during the feed. The amount of milk produced was cut in half, to 80 to 100 g per feed. Subsequently, the milk production was measured in a trial in which a noxious event was administered and intranasal oxytocin was given concomitantly. The milk production was restored to almost 90% of baseline production, 130 to 140 g. A wide variety of noxious events elicited the same decrease in milk production, including placing the mother's feet in ice water, applying electric shocks to her toes, having her trace shapes while looking only through a mirror, or requiring her to proof-read a document in a timed fashion. These observations have important implications concerning the management of breastfeeding. **Pain, anxiety, and insecurity may be hidden reasons for breastfeeding failure through inhibition of the let-down reflex.**

**In contrast, the playing of a soothing motivational/educational audio tape to women who were pumping milk for their premature infants has improved milk yields.** These observations have been confirmed by measuring the inhibition of oxytocin release by psychological stress. The positive and negative influences of the cerebrum are further highlighted by the observation that 75% of women who had a positive attitude during pregnancy were likely to be successful at breastfeeding. In contrast, 75% of women who had a negative attitude during pregnancy had an unsuccessful breastfeeding experience. When the mother's attitude was good or very good and family was present, the exclusive breastfeeding rate was 20% at 6 months; if the mother's attitude was fair, the breastfeeding rate at 6 months was 5%.

Oxytocin has additional target cells in the mother (see Fig. 24-3), and **the effect of oxytocin on uterine activity is well known. Uterine involution is enhanced with breastfeeding.** Animal and human research suggests that oxytocin is a neuro-hormone associated with an anti-fight/flight response in the autonomic nervous system, better toleration of stress by the mother, and improved maternal-infant bonding.<sup>11</sup>

In addition to the antistress effect, surges in oxytocin levels are associated with the release of GI hormones and increased GI motility. In the mother, these actions enhance the absorption of substrates necessary for lactogenesis, and a growing body of knowledge indicates similar associations with oxytocin surges in infants. Skin-to-skin contact and the oral stimulation of nursing stimulate a parasympathetic, anti-fight/flight response in the infant. So-called kangaroo care of premature newborns, with skin-to-skin contact, is associated with a physiologically stable state, improved stress responses, and improved weight gain.<sup>12</sup> Oxytocin appears to mediate this response. Breastfeeding is associated with far more skin-to-skin contact and maternal behaviors than bottle feeding.

Whereas the central nervous system (CNS) locus for imprinting is unknown, imprinting immediately after birth is an important predictor of breastfeeding success. The survival of lambs depends on nursing within an hour after birth. If the lamb has not nursed during the critical period, maternal-infant bonding becomes dysfunctional, and the lamb suffers failure to thrive. In humans, the consequences are not nearly as drastic. **Several trials with random assignment of subjects to early nursing (delivery room) or late nursing (2 hours after birth) demonstrated a 50% to 100% higher number of breastfeeding mothers at 2 to 4 months postpartum among those who had nursed in the delivery room. One of the keys to obstetric management is have the mother nurse her newborn in the delivery room within 30 to 60 minutes of birth.**

## Milk Transfer

Milk transfer to the infant is a key physiologic principle in lactation.<sup>13</sup> The initial step of milk transfer is a good latch-on. With light tactile stimulation of the infant's cheek and lateral angle of the mouth, the infant reflexively turns its head and opens its mouth, as in a yawn (Fig. 24-4). The nipple is tilted slightly downward using a "C-hold," or *palmar grasp*. In this hand position, the fingers support the breast from underneath and the thumb lightly grasps the upper surface 1 to 2 cm above the areola-breast line. The infant is brought firmly to the breast by the supporting arm, being careful not to push the back of the baby's head (Fig. 24-5). The nipple and areola are drawn into the mouth as far as the areola-breast line. The posterior areola may be less visible than the anterior areola, and the lower lip of the infant is often curled out. The infant's lower gum lightly fixes over the lactiferous sinuses.

The mechanics of normal breastfeeding behaviors relative to oropharyngeal movements and intraoral pressures have been eloquently demonstrated by transbuccal ultrasound.<sup>14,15</sup> A slight negative pressure exerted by the infant's oropharynx and mouth holds the length of the teat and breast in place and reduces the "work" to refill the lactiferous sinuses after they are drained. **The milk is extracted not by negative pressure but by a peristaltic wave from the tip to the base of the tongue.** There is no stroking or friction, and little in-and-out motion of the teat is apparent; the action is more undulating. The buccal mucosa and tongue mold around the teat, leaving no space.

**FIG 24-4** The latch-on reflex.

**FIG 24-5** The successful C-hold with appropriate latch-on.

The peristaltic movement of the infant's tongue is most frequent in the first 3 minutes of a nursing episode; the mean latency from latch-on to milk ejection is 2.2 minutes. After milk flow is established, the frequency of sucking falls to a much slower rate. **The change in cadence is recognizable as suck-suck-swallow-breath.** Audible swallowing of milk is a good sign of milk transfer. At the start of a feeding, the infant obtains 0.10 to 0.20 mL per suck. As infants learn how to suck, they become more efficient at obtaining more milk in a shorter period of time. **From 80% to 90% of the milk is obtained in the first 5 minutes the infant nurses on each breast, but the fat-rich and calorie-dense hind milk is obtained in the remainder of the time sucking at each breast, usually less than 20 minutes total.** A bottle-feeding infant sucks steadily in a linear fashion and receives about 80% of the artificial breast milk in the first 10 minutes.

Sucking on a bottle is mechanically very different from nursing on the human teat (Figs. 24-6 and 24-7).<sup>16</sup> The relatively inflexible artificial nipple resists the milking motion of the infant's tongue and mouth. The diameter of the artificial nipple

**FIG 24-6** The mechanics of breastfeeding.

FIG 24-7 The mechanics of bottle feeding.

expands during a suck, whereas the human teat collapses during the milk flow. The infant who is sucking on a bottle learns to generate strong negative pressures ( $>100$  mm Hg) in order to suck the milk out of the bottle. Because rapid flow from the bottle can gag the infant, he or she quickly learns to use the tongue to regulate flow. **When the infant who has learned to bottle feed is put to the breast, the stopper function of the tongue may abrade the tip of the nipple and force it out of the infant's mouth.** The efficiency of milk transfer falls drastically, and the hungry infant becomes frustrated and angry. A similar rejection may occur 4 to 8 weeks postpartum, when the exclusively breastfeeding infant is given a bottle in preparation for the mother's return to work.

Milk transfer is made more efficient by proper positioning of the infant to the breast, which places the infant and mother chest-to-chest. The infant's ear, shoulder, and hip are in line. The most common maternal positions are the cradle hold, chest-to-chest, side-lying, or the football hold (Figs. 24-8 and 24-9). Each has its advantages. Rotating positions for nursing allows improved drainage of different lobules, which is important in the management of a "plugged" duct or mastitis. **Maternal comfort and convenience are the major reasons for changing nursing positions; the football hold and side-lying positions are more comfortable when the mother has an abdominal incision.**

**The neonate should be fed every 2 to 3 hours or 8 to 12 times a day on demand.** One of the important educational keys is for the mother to recognize the signs of a hungry baby before the baby is crying, angry, or stressed. The signs include lip smacking, hand movement to the mouth, restlessness, and vocalizations.

Baseline prolactin levels appear to be the major determinant of the maternal hormonal state during lactation, a state of high prolactin and low estrogen and progesterone levels. **As the frequency of nursing decreases below eight in 24 hours, the baseline prolactin levels drop below a level at which ovulation is suppressed (35 to 50 ng/mL), LH levels rise, and menstrual cycling is initiated.**<sup>5</sup> The intensity (adjusted odds ratio [OR]) of factors that initiate the onset of menses are the duration of sucking episodes less than 7 minutes (OR 2.4), night feedings less than four per 24 hours (OR 2.3), maternal age 15 to 24 years (OR 2.1), maternal age 25 to 34 years (OR 1.7),

FIG 24-8 Side-lying nursing.

FIG 24-9 The football hold.

and day feedings less than seven per 24 hours (OR 1.6).<sup>17</sup> In women who feed their infants exclusively artificial breast milk, serum prolactin levels drop to prepregnant levels (8 to 14 ng/mL) within days. In summary, **the total number of nursing episodes per day (more than eight per 24 hours) and night nursings are critical to the successful management of breastfeeding.**

One of the major determinants of nursing frequency is the introduction of substitute nutriment sources for the infant, artificial breast milk, or solids. **Breast milk has the nutritional content to satisfy the growth needs of the infant for at least 6 months postpartum.** In the first 6 months, feeding with artificial breast milk (i.e., formula) affects the physiology of successful lactation in three ways: (1) it reduces proportionally the nutriment requirements from breast milk; (2) it increases the gastric emptying time (digestion is slower than with breast milk), with a subsequent decrease in frequency of nursing episodes; and

**FIG 24-10** Breastfeeding and engorgement. The firm, swollen breast parenchyma pushes the newborn's face away, and she is unable to pull the teat into her mouth. Her tongue abrades the tip of the nipple.

(3) it reduces the efficiency of nursing from use of an opposing sucking technique on the artificial nipple.

Starting the infant on solid foods (e.g., eggs, cereals, pureed food) has a similar effect on the hormonal milieu of the lactating woman, and **one of the errors in Western child care is the early, forced introduction of solids. In most cases, the infant's gut is filled with slowly digesting food with less nutritional value than breast milk, the long-term result of which may be childhood and adolescent obesity.** The most logical time to start solid food substitution is when the infant has reached the neurologic maturity to grasp and bring food to its mouth from its mother's plate, which usually occurs at about 6 months. As the infant matures, his or her ability to feed improves, and the proportion of the diet supplied by solid food gradually increases.

**The failure to develop good milk transfer is the major cause of lactation failure and breast pain, especially in the neonatal period. Inhibition of the let-down reflex and failure to empty the breasts completely leads to ductal distension and parenchymal swelling from extravascular fluid. This is termed engorgement, and it compromises the mechanics of nursing (Fig. 24-10); alveolar distension reduces secretion of milk by the alveolar cells.** Without adequate transfer of milk to the infant, lactation is doomed to fail. Distension of the alveoli by retained milk causes a rapid (6 to 12 hours) decrease in milk secretion and enzyme activity by the alveolar epithelium. The decreased production of milk is explained by pressure inhibition and by an inhibitor secreted in breast milk. Distension of the alveoli inhibits secretion directly, rather than indirectly, by a decrease in nutrient or hormonal access.

## BREAST MILK: THE GOLD STANDARD

One of the most common misconceptions by physicians and the lay public, and one that is heavily marketed by the formula industry, is that modern "formulas" are equivalent to breast milk. The age-old reality remains: human breast

**milk is uniquely suited to our biologic needs and remains the best source of nutrition for the human infant.** Human breast milk has a composition very different than that of bovine milk or soybean plants from which artificial breast milk is produced.<sup>17</sup> Nutritional, host-defense, hormonal, and psychophysiological differences between human breast milk and breastfeeding versus formula and bottle feeding make the health benefits of breastfeeding understandable. This section will link the latter differences to a summary of a massive amount of basic and clinical research that demonstrates better health outcomes associated with breast milk and breastfeeding compared with formula and bottle feeding.

## Overview

**The composition of mature human milk is very different from artificial breast milk (formula). Most artificial breast milk products use bovine milk or soybean constituents as a substrate. Minerals, vitamins, proteins, carbohydrates, and fats are added to pasteurized bovine milk for perceived nutritional needs, as well as marketing aims, to make a product that will successfully compete with human breast milk.** For example, human breast milk appears "thinner" than bovine milk. **Artificial breast milk manufacturers add constituents (e.g., palm- or coconut-based oils) to make artificial breast milk appear rich and creamy,** thereby creating a product that is more easily marketed to the American public.

Extensive research describes the unique composition of human milk. The infant formula industry has produced even greater volumes of data concerning their attempts to exactly reproduce human milk. In 1980, the U.S. Congress passed the Infant Formula Act (with revisions in 1985) as the result of severe health consequences when artificial breast milk failed to include key vitamins and minerals in new formula compositions. This law now requires that all formulas for artificial breast milk contain minimum amounts of essential nutrients, vitamins, and minerals. Although life-threatening omissions are unlikely, **current formulas have major differences in the total quantities and qualities of proteins, carbohydrates, minerals, vitamins, and fats when compared with human milk.** The reader is reminded that the recommended daily allowance (RDA) is the amount needed to prevent a deficiency disease, not the amount needed for the best health.

**Breast milk promotes optimal somatic growth and metabolic competence.** Human breast milk has evolved to ensure the most efficient digestion by the human infant, which is not the case with bovine or soybean-derived formulas.<sup>18</sup> Gastric emptying is faster in neonates fed breast milk versus formula, 1 to 2 hours versus 3 to 4 hours, respectively. The greater speed of digestion with breast milk relates to differences in casein/whey protein ratio, fatty acid content, fatty acid attachment to the glycerol backbone, and presence of GI enzymes and GI hormones to facilitate digestion, motility, and function. Bovine formulas contain only limited and degraded hormones and enzymes appropriate for calves, and none of these important constituents is found in formulas that use a soybean base. In addition, the bioavailability of naturally supplied vitamins and minerals in breast milk is 20% to 50% higher than that of the vitamins and minerals added to artificial breast milk.

The nutritional differences between formula and human milk are reflected in differences in the growth patterns of infants who are exclusively breastfed for 4 to 6 months and infants who are fed artificial breast milk. **In general, breast-fed infants have**

In general, odds ratio (OR) was adjusted for age, parity, race, and socioeconomic status. CI, confidence interval.

faster linear and head growth, whereas formula-fed infants tend to have greater weight gain and fat deposition. The greater deposition in fat may relate in part to the earlier introduction of solid foods in the infants fed formula, a factor that has not been adequately controlled in current studies.

Regardless of the cause, formula has important adverse effects on the metabolic competence of the child, adolescent, and future adult (Table 24-1). Since 2007, when the extensive evidence-based reviews were published by the Agency for Healthcare Research and Quality (AHRQ)<sup>19-26</sup>—and after follow-up analysis by Ip and colleagues<sup>20</sup> in 2009—these findings have been verified, proving a dose-response relationship and providing an improved understanding of the physiologic and endocrine causes for the benefits seen with prolonged breastfeeding.<sup>22-26</sup>

**Breastfeeding enhances cognitive development.** Human breast milk has superior capacity to enhance the development of the infant's brain and its integrative capacity through many defined and undefined differences between human breast milk and formula. The currently identified constituents of human breast milk that enhance integrative capacity include growth hormones, oligosaccharides, nucleotides, glycoproteins, and long-chain polyunsaturated fatty acids (LCPUFAs). **In high-risk, premature neonates, human breast milk given by gavage enhances the infant's later intelligence quotient (IQ) and performance on psychometric testing in a dose-dependent fashion after controlling for maternal intelligence, family education, and socioeconomic status.**<sup>27</sup> A recent large cohort study that compared very-low-birthweight infants<sup>14</sup> demonstrated that for every 10 mL/kg/day increment of breast milk fed to these high-risk neonates, neurodevelopmental outcomes improved.<sup>28</sup>

Although the effect is most dramatic among high-risk infants, smaller effects on IQ are seen in term infants (adjusted increment [95% CI], 3.16 points [2.35 to 3.98] vs. low birthweight infants, 5.18 points [3.59 to 6.77]).<sup>29</sup> A population-based birth cohort was launched in 1982 in Pelotas, Brazil among 5914 neonates.<sup>30</sup> Initiation, exclusivity, and duration of breastfeeding was recorded between 19 and 42 months. At 30 years of age, 3701 of the enrollees (68% follow-up) underwent ascertainment of their IQ, educational achievement, and family income. In the confounder-adjusted analysis, those who were breastfed 12

months or more had higher IQ scores (+3.76; 95% CI, 2.20 to 5.33), more years of education (+0.91 years; 95% CI, 0.41 to 1.40), and higher monthly income than those who were breastfed for less than 1 month.<sup>30</sup>

The information regarding breastfeeding, LCPUFAs, and improved intelligence has been powerful enough for formula companies to change their concoctions to include more LCPUFAs. However, just adding LCPUFAs does not change the other deficiencies in formula. Another recent example of neurodevelopmental enhancement with breastfeeding is the strong association found between breastfeeding and enhanced visual acuity. Conversely, infants fed LCPUFA-enhanced formula had similar deficiencies in high-grade foveal stereoacuity (adjusted OR, 2.5; 95% CI, 1.4 to 4.5), as did those infants fed standard formula.<sup>31</sup>

**Breastfeeding enhances infant responses to infection and reduces allergic disease.** At birth, the fetus enters an unsterile world with a naïve and immature immune system. Full development of the immune system may take up to 6 years. **Breast milk has a wide array of antiinfective properties that will support the developing immune system. The major mechanisms for the protective properties of breast milk include active leukocytes, antibodies, antibacterial products, competitive inhibition, enhancement of nonpathogenic commensal organisms, and suppression of proinflammatory immune responses.**<sup>32-34</sup>

A critical event in host resistance is the recognition of pathogenic agents in the environment and the production of an antigen-specific adaptive immune response. Breastfeeding provides a unique system to help the infant fight infection with an adaptive antigen-specific response. Through breast milk, the neonate takes advantage of maternal recognition of these infectious agents (Fig. 24-11). This important mechanism was described by Slade and Schwartz.<sup>35</sup> An antigen or infectious agent—such as a virus, bacterium, fungus, or protozoan—stimulates the activity of leukocytes in the GI or respiratory tract of the mother. Lymphocytes encoded with the antigen signature travel to the nearest lymph node and stimulate lymphoblasts to develop cytotoxic T cells, helper T cells, and plasma cells programmed to destroy the initiating antigen through phagocytosis or complement/immunoglobulins produced by the B cells. The response is amplified by the migration of committed helper lymphocytes to other sites of white blood cell production, the spleen and bone marrow, where they stimulate the production of antigen-specific committed white blood cells. Some of the committed, antigen-specific helper lymphocytes travel to the mucosa of the breast in the lactating mother. Plasma cells, which produce secretory immunoglobulin A (sIgA), constitute 50% to 80% of the leukocytes in the breast submucosa. They may migrate into the breast milk (macrophages) or may produce immunoglobulins (sIgA, IgG—lymphocytes or plasma cells). Both are uniquely programmed to fight the specific infectious agent that challenges the mother. **Active leukocytes are completely eliminated by pasteurization (formula) and freezing (stored, pumped breast milk).**

**Immunoglobulins are a unique component of breast milk that are absent in artificial breast milk.** In contrast to *monomeric serum* IgA, the *secretory* IgA (sIgA) in breast milk is dimeric or polymeric; polymerization improves transport across the maternal alveolar cells into the breast milk. The immunoglobulins in breast milk appear to be fully functional. The sIgA is produced locally by plasma cells and does not activate complement or promote opsonic complement subfragments. As a

**FIG 24-11** The adaptive immunology of the breast. IgG, immunoglobulin G; sIgA, secretory immunoglobulin A.

consequence, sIgA is not bactericidal. It appears that sIgA blocks the mucosal receptors (adhesins) on the infectious agent. The virulence of pathogens is related to their ability to use adhesins capable of interacting with complementary gut epithelial cell-surface receptors. When the antigen-specific sIgA attaches, the pathogen is effectively neutralized.

In the last 5 to 10 years, an increasing amount of research has focused on critical imprinting between neonatal gut flora and future immune responses.<sup>33-38</sup> The neonate is an antigen-naïve organism whose adaptive response is delayed by a lack of exposure. In addition, the cytokine response to TOLL-like receptor (TLR) stimulation appears to be exaggerated, especially in the preterm infant in whom injury is partly cytokine mediated (i.e., periventricular leukomalacia, necrotizing enterocolitis, and bronchopulmonary dysplasia). The adaptive immune system takes between 4 and 8 days to develop an effective defense; **the neonate bombarded by new antigens/organisms during the birth process must rely on an innate host defense system to provide an immediate but controlled response during the first critical 7 days of breastfeeding.**

Human breast milk actively limits pathogenic microbes (e.g., *Escherichia coli*) and promotes the growth of nonpathogenic, commensal microbes (e.g., *Bifidobacterium bifidum* and other species). **One of the most important breast milk constituents in the innate host defense system are human-specific oligosaccharides.** Oligosaccharides are indigestible complex carbohydrate structures that have a microbe (genus)-specific ability to bind to cell-surface receptors of the microbe. The unique oligosaccharide binding to the surface receptor blocks the binding of the microbe to the infant's mucosal receptors, thereby limiting microbe virulence. On the other hand, human milk contains an

oligosaccharide homologous to the infant's mucosal receptors. The oligosaccharide-mucosal receptor complex allows specific attachment of *Bifidobacterium* species to the intestinal mucosa, further competitively inhibiting the attachment of pathogenic organisms.

A similar attachment of *B. bifidum* to dendritic cells, which interdigitate through the intestinal epithelial cells, allows for a critical modulation of the developing neonatal immune system. The interaction upregulates the antiinflammatory cytokine system—interleukin (IL)-10, soluble IL-1 receptor antagonist, and so on—and orchestrates the conversion of naïve T-helper cells into a mature, balanced response. These early imprinting interactions may have profound effects on the incidence of inflammatory diseases in the adult, intrinsic bowel disease, asthma, rheumatoid arthritis, and perhaps cardiovascular diseases. In addition to the crosstalk between commensal gut bacteria and the immune system of the neonate, human colostrum contains large quantities of a soluble form of the bacterial pattern recognition receptor, cluster of differentiation 14 (sCD14). CD14 is a known modulator of host response to bacterial lipopolysaccharides (LPSs). In particular, CD14 binds to TLR-4 receptors and limits the binding of LPS from gram-negative rods. The failure to activate the TLR-4 receptor reduces the exaggerated immature cytokine response possible in neonates. Recent therapeutic interventions have used the immune-modulating qualities of the commensal bacteria–host interactions to successfully treat several important human diseases: necrotizing enterocolitis, inflammatory bowel disease, *Clostridium difficile*-associated colitis, acute gastroenteritis, and atopic dermatitis.

Known and unknown constituents of human breast milk inhibit the growth of and actively destroy pathogenic organisms;

**TABLE 24-2** REDUCTION OF INFECTION AND ALLERGIC DISEASE WITH BREASTFEEDING

| OUTCOME                      | BENEFIT OF BREASTFEEDING ADJUSTED OR (95% CI) | RISK OF "FORMULA" ADJUSTED OR (95% CI) |
|------------------------------|---|--|
| Acute otitis media           | 0.77 (0.64-0.94)                              | 1.30 (1.06-1.56)                       |
| Gastrointestinal infections  | 0.36 (0.32-0.41)                              | 2.78 (2.44-3.12)                       |
|                              | 0.54 (0.36-0.80)                              | 1.85 (1.25-2.78)                       |
| Lower respiratory infections | 0.28 (0.14-0.54)                              | 3.57 (1.85-7.14)                       |
| Asthma                       | 0.73 (0.59-0.92)                              | 1.37 (1.09-1.69)                       |
| Atopic dermatitis            | 0.58 (0.41-0.92)                              | 1.72 (1.09-2.44)                       |

In general, odds ratio (OR) was adjusted for age, parity, race, and socioeconomic status. AHRQ, Agency for Healthcare Research and Quality; CI, confidence interval.

formula has none of these constituents. Certain vitamins and minerals are essential for the growth of pathogenic bacteria, and a major mechanism by which breast milk protects the infant is the competition for "essential" nutrients for pathogenic bacteria. **Iron and vitamin B<sub>12</sub> are two essential nutrients for pathogenic bacteria that have been studied relative to breast milk.** Breast milk contains lactoferrin, an iron-binding glycoprotein, in large quantities (5.5 mg/mL in the colostrum to 1.5 mg/mL in mature milk); this is absent in artificial breast milk. The free-iron form of lactoferrin competes with siderophilic bacteria for ferric iron and thus disrupts the proliferation of these organisms. The binding of iron to lactoferrin also enhances iron absorption; less iron is required in breast milk in order to satisfy the iron needs of the infant. The antibacterial role of lactoferrin is more complex than simple competition for ferric iron.<sup>39</sup> Lactoferrin causes a release of LPS molecules from the bacterial cell wall. This appears to sensitize the bacterial cell wall to attack by lysozyme, and lactoferrin and lysozyme work together to destroy the pathogenic organisms.

Table 24-2 describes the effects of breastfeeding on the adaptive and innate host defenses. The cause of sudden infant death syndrome (SIDS) is not clear, but a current theory includes an aberrant immune response.

**The hormonal changes of lactation—low estrogen, low progesterone, and hyperprolactinemic amenorrhea—favor a reduction in maternal reproductive cancers,** but the relationship is undefined, and the relationship between the maternal immune system and the mother's experience with breastfeeding has not been adequately explored. However, in a dose-dependent fashion, breastfeeding reduces breast cancer per year of cumulative breastfeeding by 4.3% (95% CI, 2.9% to 5.8%). Likewise, breastfeeding for greater than 12 months in the mother's lifetime reduces ovarian cancer (adjusted OR, 0.72; 95% CI, 0.54 to 0.97); conversely, exclusive feeding with formula is associated with an enhanced risk of ovarian cancer (adjusted OR, 1.39; 95% CI, 1.03 to 1.85).<sup>19-21</sup>

**Breastfeeding enhances mother-infant bonding and reduces poor social adaptation.** The human newborn infant is born entirely dependent on the mother for transportation, food, warmth, and social conditioning. Survival depends on a unique bond between mother and infant to enhance maternal protective behaviors. **Like all other mammals, humans have a critical imprinting period (0.5 to 1 hour) for the establishment of**

**mother-infant bonding.** The most visible manifestation of the new bond is the duration of breastfeeding. Numerous studies with random assignment of breastfeeding dyads to early (<1 hour) or later (>2 hours) initiation of breastfeeding demonstrate a significantly higher incidence of any breastfeeding or exclusive breastfeeding at 2 to 4 months after birth in those dyads who initiated breastfeeding early.

A 2007 review by Moore and colleagues<sup>12</sup> in the Cochrane Database of Systematic Reviews supports the benefits of early skin-to-skin contact. Their conclusions from a review of 30 studies that involved 1925 mother-infant dyads were that early skin-to-skin contact was associated with babies who interacted more with their mothers, stayed warmer, and cried less. **Babies were more likely to be breastfed, and to breastfeed longer, if they had early skin-to-skin contact.** More recently, a study with random assignment of subjects to immediate skin-to-skin contact or not—with timing of first feeding being mother directed and independently recorded—suggested that **early skin-to-skin contact was a better predictor of duration of exclusive breastfeeding than the timing of the first sucking episode.**<sup>40</sup> This observation complements the success of so-called kangaroo care in the performance of high-risk neonates in the neonatal intensive care unit (NICU).

Recent human studies based on robust animal data<sup>41</sup> suggest that continued skin-to-skin contact and breastfeeding greatly affect the responsiveness to stress in the infant and mother. Experimental physiologic and psychological stressors produce measured stress-induced changes in adrenocorticotrophic hormone and cortisol and in autonomic responses in breastfeeding women versus women feeding their infants formula exclusively. In keeping with numerous animal studies, **the breastfeeding mothers had a significantly blunted response of the hypothalamic-pituitary-adrenal (HPA) axis, also known as "fight or flight response," to the experimental stressors.**<sup>41,42</sup> A reciprocal relationship is apparent in the breastfeeding infant, who has greater parasympathetic tone and a blunted HPA-axis response compared with a similar infant fed formula. These observations may be partially explained by a decrease in skin-to-skin contact in infants fed formula. Whereas kangaroo care has a salutary effect on breastfeeding incidence, the positive effects on weight gain and the blunted stress response are independently associated with the amount of skin-to-skin contact.<sup>12,42,43</sup>

The association between breastfeeding and better psychosocial outcomes has been the topic of much epidemiologic research over many decades. Critics have repeatedly pointed out the selection bias inherent with these studies. However, improved epidemiologic research design has confirmed the lifelong value for the breastfeeding dyad in subsequent stressful situations. Two powerful studies illustrate the risk of not breastfeeding. In the first study, **Strathearn and colleagues<sup>44</sup> explored whether breastfeeding was protective against maternal-perpetrated child maltreatment.** The study design monitored prospectively 7223 Australian mother-infant pairs (identified at first prenatal visit) and followed them over a 15-year period after birth. The primary outcome was substantiated maltreatment reports by a governmental child protection agency. Maternally perpetrated substantiated abuse or neglect was identified in 313 pairs (4.3% of the cohort). The analysis adjusted for the 18 confounding variables, which included five sociodemographic variables; four prenatal behaviors/attitudes (i.e., substance abuse, anxiety, attitude toward pregnancy); four infant factors, including NICU admission; seven postnatal behaviors/attitudes (i.e.,

mother-infant separation, maternal stimulation/teaching the baby, maternal depression). **The adjusted OR for maternal maltreatment cases among children fed exclusively formula was 2.2 (95% CI, 1.5 to 3.2) versus any breastfeeding, and it was 3.8 (95% CI, 2.1 to 7.0) versus exclusive breastfeeding for 4 months or longer.**

In a second study, the response of the child was measured. Montgomery and colleagues<sup>45</sup> used data collected in the 1970 British Cohort Study, in which subjects were followed for 10 years; 8958 (71%) had complete data and were used in the analysis. The study analyzed childhood anxiety associated with parental divorce or separation as reported by their teachers on an analog scale of 0 to 50 related to the question, "Was (the subject) worried and anxious about many things?" **Exclusive feeding with formula, after adjustment for many factors, was associated with a dramatic increase in perceived childhood anxiety** (adjusted OR, 8.8; 95% CI, 5.3 to 12.2), **whereas breastfeeding at entry had no significant effect on childhood anxiety associated with divorce** (adjusted OR, 1.3; 95% CI, -3.6 to 6.1).

**Breastfeeding is cost effective for the family and society. The nonmedical costs of artificial breast milk (formula) feeding are considerably higher than for breastfeeding.**<sup>46</sup> The direct cost of artificial breast milk feeding includes the cost of the artificial formula (900 mL/day), bottles, and supplies. In eastern North Carolina (April 2015), the average retail cost of 900 mL of brand name prepared formula was about \$8.00 daily (\$2920 yearly); of brand name concentrate, about \$5.50 daily (\$2008 yearly); and of powdered formula, about \$4.65 daily (\$1697 yearly). Store brands cost about two thirds of the price of brand names. Special formulas—including soy-based, LCPUFA-enhanced, and hypoallergenic formulas—cost 50% to 200% more. A major indirect cost of artificial breast milk feeding is the environmental impact of large dairy herds to supply the bovine milk substrate and the mountains of packaging material discarded in landfills or incinerated.

Breastfeeding provides the right amount of a superior product at precisely the right time and at the right temperature. The nonmedical costs of breastfeeding include the cost of increased dietary calorie and protein needs (\$2 to \$3 daily), nursing bras and breast pads, and an increased number of diapers in the first 2 to 3 months. If a rented electric breast pump is used when the woman returns to work, the cost of breastfeeding will increase \$2 to \$4 per day.

**Increase in acute medical diseases will manifest as increased costs of medical care for those families who choose to feed their infant artificial breast milk or formula.**<sup>45-49</sup> Among Medicaid populations in Colorado and California and in health maintenance organizations (HMOs) in Arizona, the medical cost of artificial breast milk feeding amounts to \$350 to \$600 per year per infant. Among patients who belonged to a large HMO in Tucson, Arizona, **the excess yearly medical costs of 1000 never-breast-fed infants versus 1000 infants who were exclusively breastfed for at least 3 months was \$331,041** (Table 24-3).<sup>49</sup>

The health care benefits are also reflected in the reduction of medical leave taken by the working mother to care for the sick child. **The data demonstrate fewer days for sick leave in women who work and continue to breastfeed than working women who formula feed.**

A cost analysis by Bartick and Reinhold<sup>147</sup> calculated the excess pediatric costs with U.S. breastfeeding initiation rates in 2005

Modified from Bartick M, Reinhold A. The burden of suboptimal breastfeeding in the United States: a pediatric cost analysis. *Pediatrics*. 2010;125:1048.

\*In 2007 U.S. dollars.

(74%) and exclusive breastfeeding rates at 6 months (12.3%) compared with 80% exclusive breastfeeding for 6 months using the published AHRQ analysis.<sup>19-20</sup> The total excess cost amounted to almost \$10.5 billion and 714 deaths per year (Table 24-4). Their estimates do not account for the excess burden of chronic disease in the mother and child, obesity, type 2 diabetes, and cardiovascular disease; therefore the true burden is many times greater than just the pediatric costs. A recent similar study<sup>48</sup> in the United Kingdom based on 2009 and 2010 data showed that support for women who are exclusively breastfeeding at 1 week to continue to exclusively breastfeed until 4 months will reduce the incidence of gastroenteritis, lower respiratory infections, and otitis media with a savings of at least £11 million. Similarly, doubling the proportion of women currently breastfeeding for a total of 7 to 18 months is likely to reduce the incidence of maternal breast cancer and will save at least £31 million over a lifetime based on 2009/2010 values.<sup>48</sup>

In the past, the failure to correctly reproduce human milk led to significant infant disease. In 1980, the U.S. Congress passed

the Infant Formula Act, with subsequent revisions in 1985, as the result of severe health consequences when artificial breast milk failed to include key vitamins and minerals in new formula compositions. This law now requires that all formulas for artificial breast milk contain minimum amounts of essential nutrients, vitamins, and minerals. Although life-threatening omissions are unlikely, **current formulas have major differences in the total quantities and qualities of proteins, carbohydrates, minerals, vitamins, and fats when compared with human milk.** The reader is reminded that the recommended daily allowance (RDA) is the amount needed to prevent a deficiency disease, not the amount needed for the best health.

### ROLE OF THE OBSTETRICIAN AND GYNECOLOGIST

The gynecologist plays a primary role in support of breastfeeding.<sup>21,50,51</sup> Between 50% and 70% of women make a decision regarding how they will feed their infants *before* their pregnancies. The gynecologist needs to start promotion before the first pregnancy. When the reproductive-age woman seeks initial family planning advice and contraception, the likelihood is high that she will become pregnant in the next 2 to 5 years. **The breast examination is a regular part of the family planning visit;** it is used extensively to screen for breast cancer despite its rare occurrence at the ages of usual pregnancies (<35 years). **This visit is a good opportunity to reassure the woman of her normal breast anatomy and build her self-confidence for lactation success through vocal and visible support of breastfeeding.**

The obstetrician/gynecologist amplifies support for breastfeeding by community advocacy, office environment, and personal choices. The office environment needs to be “breastfeeding friendly.” **Visible, active support of breastfeeding includes the presence of breastfeeding mothers, patient educational programs on breastfeeding, a quiet area for nursing mothers, an absence of material supplied by formula companies, and visible support for office personnel who choose to breastfeed.** In a trial with random assignment of a prenatal education packet produced by formula companies versus an educational packet produced by a breastfeeding-friendly pediatrician, the formula company packets resulted in less initiation and shorter duration of breastfeeding.<sup>52</sup> The physician, especially a female obstetrician/gynecologist, can be a positive role model for patients. Women will ask the female gynecologist whether and how long she breastfed her children, and her answers will have a powerful influence.

An important role of the obstetrician is to identify early in pregnancy those women who cannot breastfeed or who may have challenges (Table 24-5). The liberal use of galactagogues and tube feeding devices and having lactation consultants as case managers can mediate challenges related to breast milk production or breast milk transfer. The World Health Organization (WHO) has valuable guidelines regarding the use of formula when breastfeeding is contraindicated.<sup>54</sup>

In the second and third trimester, the obstetrician plays a major role in directing and supporting prenatal patient education about breastfeeding. Patient education has been shown to increase the initiation and maintenance of breastfeeding. A review<sup>55</sup> by the U.S. Preventive Service Task Force of 38 well-conducted trials with **random assignment of subjects to primary care interventions to promote breastfeeding versus**

**TABLE 24-5** IDENTIFICATION OF WOMEN AT HIGH RISK FOR UNSUCCESSFUL BREASTFEEDING OUTCOMES

| CONDITION   | RISK ASSESSMENT                           | MANAGEMENT  |
|---|---|---|

| Failure of breasts to enlarge during pregnancy, small tubular breasts | Moderate to high risk                     | Prenatal consultation with lactation consultant and pediatrician  |
| Unsuccessful breastfeeding with prior child                           | Moderate risk                             | Identify issues, prenatal education, prenatal consultation with lactation consultant  |

HIV, human immunodeficiency virus.

**“usual care” demonstrated significantly increased rates of short-term (1 to 3 months) and long-term (6 to 8 months) exclusive breastfeeding.** In subgroup analysis, a combined prenatal and postnatal intervention had a greater effect on increasing breastfeeding duration than a prenatal or postnatal intervention alone. **Interventions that included individual-level professional support and lay counselors had the most impact.** At the 36-week visit, the obstetrician readdresses the mother’s choice and knowledge regarding breastfeeding. Simple concepts of breastfeeding physiology are reinforced: early feeds (<1 hour postpartum), frequent feeds (>10 per day), a supportive environment, and no supplementation unless directed by a pediatrician. The obstetrician reinforces the appropriate way to get the baby to latch on to the breast and ensures that the increase in the mother’s breast size reflects hormonal readiness for breastfeeding. The patient is warned of hospital policies and attitudes that interfere with breastfeeding success. **The 36-week visit is also a good time to address the appropriateness of medications and breastfeeding.**

The delivery experience has a tremendous impact on the initiation and maintenance of breastfeeding.<sup>51,52</sup> Obstetric and pediatric care providers, including the nursing team, adapt to maternal, fetal, and neonatal health to enhance or reduce the success of breastfeeding. In the 1980s, international professional organizations recognized that several primarily hospital-based behaviors enhance the initiation and maintenance of breastfeeding. **In 1989, the essential 10 steps (Box 24-1) in protecting, promoting, and supporting breastfeeding were published in**

**BOX 24-1 10 STEPS TO SUCCESSFUL BREASTFEEDING**

1. Have a written policy to support breastfeeding.
2. Train all health care providers in Baby-Friendly Hospital Initiative protocols.
3. Inform all pregnant women about the benefits of breastfeeding.
4. Initiate breastfeeding within 1 hour after birth.
5. Show mothers how to express breast milk and maintain lactation even if they are separated from their infants.
6. Give newborn infants no food or drink other than breast milk unless medically indicated.
7. Allow mothers and infants to remain together 24 hours a day (i.e., rooming in).
8. Encourage breastfeeding on demand.
9. Give no artificial teats or pacifiers.
10. Foster the establishment of breastfeeding support groups and refer mothers to them on discharge from the hospital or clinic.

Modified from WHO/UNICEF. Protecting, promoting, and supporting breastfeeding: the special role of maternity services, a joint WHO/UNICEF statement. Geneva, World Health Organization, 1989.

**a joint statement by the WHO and the United Nations Children's Fund (UNICEF).**

The WHO Ten Steps have become institutionalized in the Baby-Friendly Hospital Initiative (BFHI) and accreditation process. **These steps are well founded on evidence-based medicine that demonstrates improvement in breastfeeding success.**<sup>51,55-57</sup>

Newer population research designs demonstrate increased breastfeeding rates and improved population health while reducing the self-selection bias that confuses much epidemiologic research in breastfeeding. Cluster-randomized trials of breastfeeding promotion interventions modeled on the WHO/UNICEF Baby-Friendly Hospital Initiative (see [Box 24-1](#)) have been used in at least two separate populations. In these studies, maternity clinics and hospitals are assigned randomly to receive intensive educational programs to increase breastfeeding rates. The outcomes of interest are breastfeeding rates and short-term neonatal morbidities (infections, atopic dermatitis, etc.) In both studies, breastfeeding rates were improved significantly ( $P < .001$ ) with exclusive breastfeeding at 3 months, 43.4% versus 6.4% in Belarus and 79% versus 48% in India. The interventions were associated with a 30% to 50% lower prevalence of GI infections and atopic dermatitis and better infant growth in their respective populations.

Unfortunately, the United States is far behind the rest of the world in designating their maternity facilities as “baby friendly”; in 2014, only 7.79% of live births occurred in a BFHI-designated facility. In 2008, the CDC started reporting breastfeeding-related maternity practices and outcomes (see <http://cdc.gov/breastfeeding/data>).<sup>58</sup> These data are used to grade and compare the quality of care given by hospitals and their providers related to breastfeeding support. **The obstetrician is a key player in quality improvement related to breastfeeding and in the application of the essential 10 steps, that is, the BFHI.**

A hospital's BFHI designation does not absolve the obstetric care provider from advocacy and action to support breastfeeding. Support for obstetric quality initiatives such as no elective delivery prior to 39 weeks and initiatives to reduce the primary

cesarean delivery rate will reduce the number of neonates starting the process of learning to breastfeed with additional challenges—that is, more hyperbilirubinemia in early term birth and more transient tachypnea of the newborn delivered by cesarean.

As the “captain of the ship” in the delivery room, the delivering provider is instrumental in getting the baby skin-to-skin with the mother and breastfeeding within 30 minutes.<sup>55,59</sup> In a multivariate analysis of 300 consecutive term patients in a BFHI-certified tertiary care hospital, the four variables that predicted exclusive breastfeeding in the last 24 hours prior to postpartum discharge were at least partially under the control of the obstetric care provider. They included prenatal desire to breastfeed (positive predictor), cesarean delivery (negative predictor), neonate to the breast within 1 hour (positive predictor), and supplementation within the first 48 hours (negative predictor).<sup>60</sup>

As the result of obstetric interventions, health care providers often want to supplement the neonate with 1 to 2 bottles of formula to “allow the mother to recover.” In a prospective cohort study, one or more bottles of formula were given to neonates during the postpartum hospitalization whose mothers wished to exclusively breastfeed in the prenatal clinic.<sup>61</sup> Early supplementation had a significant impact on the duration of both breastfeeding and exclusive breastfeeding. No supplementation versus early supplementation resulted in a rate of *not* exclusively breastfeeding at 60 days of 37% versus 68% and of breastfeeding cessation by day 60 of 11% versus 33%, respectively. In addition, the use of one or two bottles of cow's milk-based formula will provide primary sensitization to cow's milk proteins in neonates at risk for atopy.

After postpartum discharge, the obstetrician is primarily focused on maternal concerns about breastfeeding: maternal diet, breast symptoms and signs, hormonal function postpartum, contraception, maternal medications, and a breastfeeding advocate when the mother is referred to other specialists (see [Chapter 23](#)). A secondary but equally important focus is the growth and development of the infant. Traditionally, the obstetrician sees the mother at 4 to 6 weeks postpartum, but often the obstetrician and the mother communicate before that visit. By inquiring about the growth and feeding of her infant, the obstetrician provides both reinforcement of the mother's decision to breastfeed and a screen for the pediatrician regarding the growth and feeding of the infant; both are important. The obstetrician can identify critical or developing problems for the pediatrician regarding infant growth and feeding, so the obstetrician must know the indicators of adequate infant growth and clinical indicators that milk is being produced and transferred. **When the obstetrician remains a verbal participant in the mother's breastfeeding experience at the 4- to 6-week postpartum visit, the likelihood that the mother will continue to breastfeed at 16 weeks is almost doubled.**

During the interpregnancy interval, the obstetrician/gynecologist can identify the challenges, myths, and obstacles when a woman has not met her goals for breastfeeding in the last lactation period and can help correct them for any subsequent lactation period. During this interval, the obstetric care provider improves breastfeeding success in the next lactation cycle through an appropriate delay in pregnancy (>18 months), identification of type 2 diabetes or impaired glucose tolerance by glucose screening in women with gestational diabetes, and control and loss of pregnancy weight gain. These foci will reduce adverse pregnancy outcomes and will subsequently improve

breastfeeding success in the next lactation cycle. Good long-term reversible contraception to allow for a planned pregnancy is a key feature of this interval.

## FOCUSED ISSUES IN THE SUCCESSFUL MANAGEMENT OF BREASTFEEDING

The successful management of breastfeeding requires the active cooperation of the mother, her support group, the obstetric care provider, and the infant care provider; in our current culture, a lactation consultant often becomes an active participant in the care of the breastfeeding dyad. Numerous reliable resources are available for additional information (Table 24-6).

**Several issues are in the domain of the obstetric care provider: anatomic abnormalities of the breast, the impact of breast surgeries, labor and delivery management, breast**

**milk expression, breast and nipple pain, maternal nutrition and exercise during lactation, mastitis and breast abscess and masses, milk transfer and infant growth, galactogogues, maternal disease, back-to-work issues, contraception, and weaning.**

## ANATOMIC ABNORMALITIES OF THE BREAST

The relationship between breast anatomy and lactation should be addressed during the well-woman or family-planning visits in women who anticipate future pregnancy. During pregnancy, infant feeding becomes a major focus, and the woman needs this issue addressed because she often has hidden questions and concerns regarding her adequacy to breastfeed. The breast examination at the first prenatal visit is an excellent opportunity to address infant feeding concerns and myths relative to breast

anatomy. Self-doubt concerning the size or shape of the breasts should be addressed, and the patient should be reassured that fewer than 5% of lactation failures are caused by faulty anatomy.

**Excluding inverted nipples, congenital abnormalities of the breasts are rare and occur in fewer than 1 in 1000 women. The most significant defect is glandular hypoplasia, in which abnormal or no development of one or both breasts is apparent during sexual maturation.** Women with no development of the breasts often have normally shaped and sized nipples and areolas, and they may have sought consultation from a plastic surgeon. One manifestation of abnormal development is referred to as the *tubular breast*. The nipple and areola—which are often normal in size, shape, and appearance—are attached to a tube of fibrous cords. **Whatever the shape or size of the breasts in a nonpregnant woman, the final evaluation of adequate glandular tissue must await the expected growth during pregnancy.** The size of the average breast will grow from 200 to 600 g during pregnancy; most women will easily recognize this growth. **A routine screening question at the 36-week prenatal visit should be, “Have your breasts grown during pregnancy?”** If the response is negative in a woman with unusually small or abnormally shaped breasts, lactation failure is a possibility, and prenatal consultation with a lactation expert is recommended. Unilateral abnormalities are usually not a problem except for increased asymmetry because the normal breast can usually produce more than enough milk for the infant. The texture of the breast and tethering of the nipple are also assessed. An inelastic breast gives the impression that the skin is fixed to dense underlying tissue, whereas the elastic breast allows elevation of the skin and subcutaneous tissue from the parenchyma. Lack of elasticity may complicate nursing because of increased rigidity with engorgement. Massage of the periareolar tissue four times a day for 10 minutes is recommended. Engorgement should be assiduously avoided in the postpartum period by early, frequent nursing.

Congenital tethering of the nipple to underlying fascia is diagnosed by squeezing the outer edge of the areola (Fig. 24-12); normally, the nipple will protrude. **Severe tethering is manifested by an inverted nipple.** The most severe forms of tethering occur in fewer than 1% of women. Although successful breastfeeding is possible in these severe cases, prenatal consultation and close follow-up are very important to identify and treat poor milk transfers. Flat or inverted nipples are much less likely to preclude successful breastfeeding. Three prenatal methods of treating tethered nipples have been described: (1) nipple pulling, (2) Hoffman exercises, and (3) nipple cups, or shells. **A controlled trial<sup>62</sup> failed to demonstrate efficacy of either shells or Hoffman exercises and recommended that these should be abandoned.**

In the early neonatal period, a breast pump may help women with flat or inverted nipples; the breast is gently pumped at low settings until the teat is drawn out, and the infant is immediately offered that breast. The same procedure is performed on the other side; usually this is only required for a few days. Unfortunately, no controlled trials support their efficacy.

Modern clothing, especially protective brassieres, prevents friction that toughens the skin and also helps protect the nipple from cracking during early lactation. **However, washing with harsh soaps; buffing the nipple with a towel; and using alcohol, benzoin, or other drying agents is not helpful and may increase the incidence of cracking.** Normally, the breast

FIG 24-12 Assessment of nipple tethering.

is washed with clean water and should be left to air dry. A cautiously used sunlamp or hair dryer may facilitate drying. Trials involving application of breast cream or expression of colostrum have not shown a reduction in nipple trauma or sensitivity when compared with untreated nipples.<sup>63</sup>

### Previous Breast Surgeries

Previous breast surgery may have significant adverse effects on breastfeeding success. The major issues are loss of sensation in the nipple or areola by nerve injury or compromise of the lactiferous ducts. Women who have had breast biopsy or breast or chest surgery, including augmentation, have a threefold higher incidence of unsuccessful breastfeeding.<sup>64,65</sup> Circumareolar skin incisions—which are used for cosmetic considerations in breast biopsies, reductions, and augmentations—may compromise both the nerve and ducts.

Breast augmentation has significant potential to disrupt breastfeeding.<sup>64,65</sup> In a carefully conducted prospective series, **64% of women (27 of 42) who exclusively breastfed after preconceptional breast augmentation had insufficient lactation**, and the infant growth rate was less than 20 g/day; a circumareolar incision was the dominant predictor of insufficient lactation. One half of women with a submammary or axillary incision had insufficient lactation, whereas 11

**women who had a circumareolar incision for breast augmentation all had lactation failure.** Compromise of the lactiferous ducts and loss of nipple sensation contribute to lactational insufficiency. Loss of nipple sensation occurs in one third to half of patients after a circumareolar incision. If a woman has had a silicone implant, she can be reassured that no evidence suggests that breastfeeding places her infant at any risk. The concentration of silicone in artificial breast milk (formula) is 5 to 10 times higher than that of breast milk from women who have silicone implants. **Large epidemiologic studies of infants who have nursed from breasts with silicone implants have not shown excess adverse events.**<sup>66</sup>

Reduction mammoplasty is always associated with lactation insufficiency if exclusive breastfeeding is relied upon for infant nutrition. If the reduction involves the removal of greater than 500 g per breast or the procedure uses the free nipple graft technique, the production of even a nominal amount of breast milk is rare. If the nipple and areola are relocated on a pedicle of vascular tissue and ducts, partial breastfeeding is remotely possible. **In any case of reconstructive surgery of the breast, the breastfeeding dyad is considered at high risk for lactation failure.** This observation was confirmed by a controlled study.<sup>67</sup> The control and reduction mammoplasty groups reported rates of any breastfeeding at 1 month of 94% and 58%, respectively. Similarly, the rate of exclusive breastfeeding at 1 month was 70% and 21% in the respective groups. Prenatal referral to an expert on lactation is appropriate for women who have had reconstructive surgery.

## LABOR AND DELIVERY MANAGEMENT

Approximately 15% of women who state they wish to breastfeed at the onset of term labor are discharged either completely feeding their infant artificial breast milk (formula) or giving formula at the majority of the infant's feedings. A combination of obstetric management, hospital policies, and pediatric management contribute to this attrition. Obstetric interventions are often critical for the health of the mother or infant, and they may affect the success of lactation.<sup>55-56</sup> Few if any interventions directly inhibit the physiology of lactation. Most obstetric interventions reduce the success of lactation by indirect interference with physiology. Induction of labor is not associated with lactation failure, but a long, tiring induction and labor will reduce the likelihood that the mother will get appropriate amounts of infant contact in the delivery room and in the first 24 hours after birth. Cesarean delivery reduces the incidence of breastfeeding by 10% to 20% in the first week after birth. **After most cesarean deliveries and difficult vaginal deliveries, the infant is not put to the breast immediately after birth, nor will the mother breastfeed her infant more than eight times in the first 24 hours.** Well-meaning nurses become concerned for the baby's nutrition and give the infant formula until the mother "recovers." In 2011, in the United States, one in five breastfeeding neonates was given a bottle of formula in the first 24 hours. That 15% of women desiring to breastfeed are discharged exclusively formula feeding reflects, in part, the mismanagement and/or lack of support for the breastfeeding dyad during their peripartum hospitalization.

Labor analgesia (i.e., meperidine and promethazine) has long been associated with poor breastfeeding success. Intrapartum narcotics appear to adversely affect the infant's ability to nurse effectively. **Epidural anesthesia with local anesthetic agents**

**seems to be better for breastfeeding than parenteral narcotics.** Epidural anesthesia with local anesthetics does not appear to have a major effect. On the other hand, an epidural with intrathecal narcotics has been shown to decrease correct sucking behavior and to reduce lactation success. The **presence of a doula**, or a labor companion other than family, appears to be an effective method to reduce the need for epidural anesthesia and operative deliveries. An added benefit is earlier initiation and longer duration of breastfeeding.<sup>68</sup>

Postsurgical pain control is best achieved with morphine rather than meperidine, which adversely affects neonatal behavior. Obstetric and pediatric protocols can be very effective in separating mother and baby. Several prominent examples include magnesium sulfate therapy for preeclampsia, intravenous antibiotics for a positive maternal group B *Streptococcus* culture, maternal fever workup, and diabetes mellitus/hypoglycemia protocols. All of these medical interventions produce major barriers to nursing in the delivery room and to an adequate frequency of nursing in the first 24 to 48 hours.

**The peripartum period is critical for achieving successful lactation. During this time, the obstetrician must attend to the five basic principles of lactation physiology: (1) early imprinting, (2) frequent nursing, (3) good latch-on, (4) a confident and comfortable mother, and (5) no supplementation unless medically indicated.** Nursing should be initiated within 30 minutes after birth, preferably in the delivery room. Contraindications include a heavily medicated mother, an infant with a 5-minute Apgar score less than 7, or a premature infant at less than 34 to 36 weeks' gestation.

The instructor, perhaps the obstetric care provider, should pay special attention to the mother's position during the first feeding; she should be relaxed and comfortable. With skin-to-skin contact, the infant is presented to the breast with its ventral surface to the mother's ventral surface with the neonate's ear, shoulder, and hip in a line. A dry neonate, skin-to-skin contact, and supplemental radiant heating will prevent neonatal cold stress. **Routine eye prophylaxis should be delayed because it can disrupt the important family bonding process.**

**In the recovery room and on the postpartum floor, the best place for the neonate is with the mother. This maximizes mother-infant bonding and allows on-demand feeding every 1 to 2 hours.** Rooming in allows the mother to participate in the care of her baby and gives her an opportunity to ask questions. **The mother should be encouraged to sleep when the neonate sleeps.** Because the usual adult diurnal pattern in the hospital may not foster a restful environment for the mother, she should be discharged as early as safely possible so she can rest at home.

The frequency of early feeding is proportional to milk production and weight gain in neonates<sup>69</sup>; therefore supplementation with glucose or formula should be discouraged. Supplementation decreases milk production through both a reduction in nursing frequency by satiation of the neonate and slower digestion of formula. Supplementation also undermines the mother's confidence about the adequacy of her lactation. Nipple and breast pain may cause the mother not to reach her breastfeeding goals. Improper positioning and poor latch-on are the major causes of nipple trauma, breast pain, and incomplete emptying. **In the early postpartum period, nursing technique should be evaluated in three areas: (1) presentation and latching on, (2) maternal-infant positioning, and (3) breaking of the suction.** The infant should not have to turn its head to nurse.

A ventral surface–ventral surface presentation is necessary (see Fig. 24-4). When latching on to the nipple, the neonate should take as much of the areola as possible into its mouth. This is facilitated by gently stimulating the baby's cheek to elicit a yawn-like opening of its mouth and rapid placement of the breast into it. A supporting hand on the breast helps; the C-hold involves four fingers cupping and supporting the weight of the breast, which is especially important in the weak or premature neonate, whose lower jaw may be depressed by the weight of the breast. The thumb rests above and 1 to 2 cm away from the areolar edge and points the nipple downward (see Fig. 24-5). Retraction by the thumb will pull the areola away from the mouth and will cause an incorrect placement. Any position that is comfortable and convenient, while allowing the appropriate mouth-areola attachment, should be encouraged; the sitting position is the most common in patients who have had a cesarean delivery because pressure on the abdomen is uncomfortable. Therefore a side-lying or football hold may be better. **A rotation of positions is recommended to reduce focal pressure on the nipple and to ensure complete emptying.** Removal of the nursing infant can be a problem because the neonate can injure the nipple if suction is not broken prior to disengagement. **A finger inserted between the baby's lips and the breast will break the suction.**

**The single most difficult management issue is the control of routines and hospital attitudes detrimental to lactation, and the genesis in step 1 of the WHO/UNICEF Ten Steps is a standard written hospital policy that supports breastfeeding.** Policies that work against the physiology of lactation include formula distribution and supplementation without a medical indication, constant questioning of the mother about breastfeeding, preprinted orders for lactation suppression medication, a requirement for pediatric clearance prior to the first feeding, limited maternal access to the infant, and little educational material for new mothers or staff.

When providers are not well informed or are apathetic about lactation, successful lactation is unlikely. This theme underscores the role of the obstetrician as an opinion leader in the education of patients, nursing staff, and support personnel about the physiology and benefits of lactation (step 2 of the WHO/UNICEF Ten Steps is to train *all* health care providers).

## Breast Milk Expression

When an unexpected separation of the mother and baby for longer than 4 to 6 hours occurs, breast milk expression may be critical to prevent stage IV of lactogenesis from occurring prematurely—that is, to avoid reduced production of milk. Despite the ready availability of mechanical breast pumps, in an emergency, the lactating mother may be unable to obtain one within 12 to 24 hours. Her knowledge on how to manually express milk will reduce her anxiety and the pain of acute breast engorgement.

Manual expression of breast milk is a relatively easy technique for the obstetric care team to teach the new mother. The mother's hands are washed with mild soap and warm water prior to manual or mechanical expression. The flow of milk can be improved by placing the mother in a quiet, relaxed, and comfortable environment. The breast is massaged in a spiral fashion, starting at the top and moving toward the areola; the fingers are moved in a circular fashion from one spot to another, much like a breast examination. After the massage and while the woman leans forward, the breast is stroked from the top of the breast to

the nipple with a light stroke and is shaken. Once milk starts to flow, manual expression is begun.

Manual expression is performed by holding the thumb and first two fingers on either side of the areola in a half circle, but the breast should not be cupped. The hand pushes the breast straight into the chest wall, as the thumb and fingers are rolled forward. Large, pendulous breasts may need lifting prior to this. The maneuver is repeated in all four quadrants of the areola to drain as many reservoirs as possible. The procedure is repeated rhythmically and gently; squeezing, sliding, or pulling may injure the breast. The sequence of massage, stroke, shake, and express is useful to provide milk immediately for the vigorous infant; it allows an improved latch-on by reducing periareolar engorgement, and it reduces high suction pressures on a traumatized nipple. Manual expression may take 20 to 30 minutes to drain both breasts. The expressed milk is drained into a clean, dry cup and is fed to the neonate if possible. A video that demonstrates this technique can be found online at <http://newborns.stanford.edu/Breastfeeding/HandExpression.html>.

**The mechanical, preferably electric breast pump is a critically important adaptation when breastfeeding is expected to be difficult or impossible.** Breast pumps have allowed women and their children to get through the difficult times, and it lets a woman successfully feed her infant breast milk for a prolonged period. These women will accrue much of the benefit of breastfeeding—a much better choice than formula feeding. In most peripartum cases, such as with a preterm delivery or a severely ill mother, the hospital-grade electric breast pump will be used by the hospital staff. After the delivery of the placenta, stage II of lactogenesis evolves with the loss of progesterone inhibition. Early drainage of the breast is critical to a healthy evolution to full milk production, whether the drainage occurs with an infant sucking or from using an electric breast pump.

The delay in early drainage is often prolonged when a neonate with very low birthweight is admitted to the NICU. One recent study<sup>70</sup> randomly assigned mothers with neonates of very low birthweight to initiate breast pumping within 1 hour or breast pumping between 1 and 6 hours after birth. The treatment effect was significant despite a very small sample size of 10 women in each arm. When breast pumping was started within 1 hour, women produced almost twice as much milk at 7 days and twice as much daily milk at 3 weeks and 6 weeks. It was found that they experienced earlier maturation of lactogenesis stage II (when “the milk comes in”) than those who initiated pumping within 1 to 6 hours after birth. Clearly, the obstetrician plays a major role in getting the mother to the breast pump within 1 hour in these high-risk situations.

Proper fitting and hygiene is an important safety issue when expressing and storing breast milk (Boxes 24-2 and 24-3). Breast milk expression with portable or stationary hospital-grade mechanical breast pumps is increasingly used for the convenience of bottle feeding human milk, particularly for working mothers rather than in emergency situations. A series of recent publications have focused on the results of an FDA and CDC study from May 2005 to June 2007, the Infant Feeding Practices Study II (IFPS II). A broad, national sample included mothers identified in their third trimester who were at least 18 years old and who gave birth to healthy infants born at 35 weeks' or more gestation that weighed more than 2.25 kg. The mothers completed 10 surveys at monthly intervals until 12 months. A key focus was the method of feeding in the previous week<sup>71</sup>: breastfed only, breastfed and human milk by bottle, breastfed and

**BOX 24-2 KEY POINTS IN USING AN ELECTRIC BREAST PUMP**

1. Have the mother and the principal support individual learn from an expert how to assemble and disassemble the pump apparatus.
2. As in manual expression, a soothing, quiet, and comfortable environment is optimal for milk let-down.
3. The mother should wash her hands before each use of the breast pump.
4. A double-pumping system improves prolactin response and increases milk production.
5. The flange should be wide enough to allow the nipple to move in and out without pain yet not so large as to compromise a pressure seal. A poorly fitted flange can be a major source of nipple trauma and discomfort.
6. Each mother should use only her own collection kit and labeled storage containers.
7. After each use, the pump collection kit should be rinsed to remove milk residue; cleansed with hot, soapy water; and air-dried. Dishwasher cleaning is adequate; however, always follow manufacturer's instructions regarding cleaning.
8. In general, pumping should last about 10 minutes per side and should occur at least every 3 hours.

**BOX 24-3 KEY POINTS IN BREAST MILK STORAGE**

1. Milk storage containers should be washed with warm, soapy water before and after each use.
2. Hard plastic containers of polycarbonate or polypropylene are recommended for long-term storage of expressed human milk. Label milk containers with the date and time the milk was expressed, and use the oldest milk first.
3. Maximum duration of human milk storage by temperature: Room temperature ( $<25^{\circ}\text{C}$ ), 4 hours; refrigerator ( $<4^{\circ}\text{C}$ ), 96 hours; previously thawed refrigerated milk, 24 hours; refrigerator freezer/deep freezer ( $-20^{\circ}\text{C}$ ), 6 months.
4. Frozen milk should be thawed in a waterless warmer or in a container of tepid, not hot, water. Do not thaw frozen milk in the microwave. The thawed milk should be stored in the refrigerator and should be used within 24 hours.

nonhuman milk by bottle, human milk and nonhuman milk by bottle, human milk by bottle, or nonhuman milk by bottle. Analyses were conducted on three groups of infants at 1.5 to 4.5 months ( $n = 1564$ ); 4.6 to 6.5 months ( $n = 1128$ ); and 6.6 to 9.5 months ( $n = 914$ ). In the youngest group, 85% of mothers had successfully expressed milk since their child was born, more than half in the first week after birth, and 25% expressed breast milk on a regular basis. The adjusted odds ratios for working mothers to express breast milk in a regular fashion in each infant age group ranged from 3.99 to 5.94, and all were highly significant.

In observational surveys, many of these women will report themselves as exclusively breastfeeding when they are actually partially breastfeeding and partially feeding breast milk obtained through a breast pump, often frozen and fed by bottle at a later time. Pumping and bottle-feeding the breast milk later upsets the delicate supply-and-demand relationship in the dyad and reduces skin-to-skin contact. Freezing may affect the nutritional

and antiinfective qualities of stored breast milk, and the use of bottles can increase acute otitis media and may negate the positive benefits seen in breastfeeding dyads; bottle-feeding is a strong predictor of acute otitis media. **Research is limited on the quality of stored breast milk, health outcomes relative to breastfeeding versus bottle-feeding breast milk, and the behavioral impacts of bottle-feeding.**<sup>72</sup> Data from the IFPS II demonstrate that feeding breast milk from a bottle is associated with faster weight gain during the first year of life than feeding infants by breast only. Data showed that infants who received breast milk only by bottle gained about 89 g/month more than infants who were exclusively breastfed. Infants fed human milk from a bottle in more than 66% of their feedings were more likely to finish their bottle and consumed about 10% more milk every day than infants who received a bottle of breast milk in more than 33% of feedings.<sup>73</sup> This suggests that bottle-fed infants have weaker self-regulation of food intake than breast-fed infants. Clearly, this area is a great opportunity for further research.

**MATERNAL NUTRITION AND EXERCISE DURING LACTATION**

The efficiency of conversion of maternal foodstuff to milk is about 80% to 90%. **If the average milk volume per day is 900 mL, and milk has an average energy content of 75 kcal/dL, the mother must consume an extra 794 kcal/day unless stored energy is used. During pregnancy, most women store an extra 2 to 5 kg (19,000 to 48,000 kcal) in tissue, mainly as fat, in physiologic preparation for lactation.** These calories and nutrients supplement the maternal diet during lactation. As a result, the required dietary increases are easily attainable in healthy mothers and infants.

In lactation, most vitamins and minerals should be increased 20% to 30% over nonpregnant requirements. However, folic acid should be doubled; and calcium, phosphorus, and magnesium should be increased by 40% to 50%, especially in the teenager who is lactating. In practical terms, these needs can be supplied by the following additions to the diet: 2 cups of milk, 2 oz of meat or peanut butter, a slice of enriched or whole wheat bread, a citrus fruit, a salad, and an extra helping ( $\frac{1}{2}$  to  $\frac{3}{4}$  cup) of a dark green or yellow vegetable. **The appropriate intake of vitamins can be ensured by continuing prenatal vitamins with 1 mg of folic acid throughout lactation.** The mother should drink at least 1 L of extra fluid every day to make up for the fluid lost through breastfeeding.

**Calcium and vitamin D are of special importance in women whose infants are breastfeeding exclusively. The daily diet and a lack of sunlight exposure creates baseline deficiencies in many American women.** Almost all of the calcium in a pregnant woman and her fetus is located in the bones and teeth. Lactation, like pregnancy, is associated with increased bone turnover to meet these needs. The calcium secreted in breast milk appears to be from a net removal of calcium from trabecular bone and by a reduction in the amount of calcium excreted in the urine. Consuming additional calcium does not appear to prevent bone loss, and after weaning or resumption of menstruation, calcium absorption returns to normal. This may not be true for women who have marginal or low dietary calcium intake, therefore ensuring a woman obtains adequate calcium before, during, and after lactation is important for her health.

There is widespread consensus about the role of vitamin D in bone health, and great interest has been paid to its role in other conditions. Current research links newborn and infant vitamin D deficiency with various clinical outcomes that include rickets, failure to thrive, type 1 diabetes, allergic disease, lower respiratory tract infections, wheezing and asthma, and other immune-related diseases. Breast-fed infants are at risk of developing a deficiency if the mother's milk contains inadequate levels of 25-hydroxyvitamin D for infant nutrition. It has been demonstrated that when sunlight exposure is limited or restricted, intensified vitamin D supplementation of lactating mothers and infants is needed to improve vitamin D status. In 2008, the American Academy of Pediatrics (AAP) recommended 400 IU of vitamin D supplementation for all infants; however, the level of adherence with this recommendation has been low, and women report reluctance to adding supplements to their breast milk. **Except for those that have been fortified, relatively few foods are good sources of vitamin D, therefore leading breastfeeding advocates recommend that women be supplemented for prevention of vitamin D deficiency in themselves and in their breastfeeding infants.** Although the daily recommended intake (DRI) for vitamin D remains unchanged at 15 µg/day (600 IU) in lactation, two recent randomized controlled trials (RCTs) have questioned this level because a growing body of evidence points to the potential role of vitamin D in immune function, which affects maternal and child health. To achieve circulating serum levels greater than 20 ng/mL, a level considered sufficient by the Institute of Medicine, at least 2000 IU/day was required, and 4000 IU/day improved physiologic optimization of active vitamin D without adverse effects. Further research is required to establish the need, safety, and efficacy of supplementation, especially at these dosages or higher during lactation. Women with limited sun exposure and those with darker skin are at an increased risk for maternal and infant vitamin D deficiency.

Vegetarianism has become increasingly more common, and if the nursing mother is a vegetarian, dietary deficiencies may include B vitamins (especially B<sub>12</sub>), total protein, and the full complement of essential amino acids. In these patients, the clinician should take a good dietary history with a focus on protein, iron, calcium, vitamin D, and the B vitamins. Nutrition should include supplementation with soy flour, molasses, or nuts with use of complementary vegetable protein combinations and avoidance of excess phytate and bran.

Many women are concerned about losing weight postpartum. Investigators<sup>6-8</sup> have examined the effects of diet and exercise on maternal weight, breast milk volume and composition, and infant growth through random assignment of affluent, highly motivated, and exclusively breastfeeding women to intervention and control groups. The exercise group had training to reach a level of 45 minutes at 60% to 70% of heart rate reserve four to six times a week for 12 weeks. The target diet was individually adjusted to reduce calories and maintain protein intake. In these controlled populations, **the women lost 1.0 to 1.5 kg/week, and no significant changes were seen in the volume or composition of their breast milk.** The infant grew approximately 2000 g in both the intervention and control groups. On a practical level, if 700 to 1200 kcal are used daily to nourish an infant, a mother could lose weight by not increasing her caloric intake, but a thoughtful selection of food groups and the elimination of "empty calories" are necessary. A reduction of total calories (<25 kcal/kg) and total protein (<0.6 g/kg) may reduce the daily

milk volume by 20% to 30%, but it does not affect the milk quality unless the mother is more than 10% below her ideal body weight. **Because dieting mobilizes fat stores that may contain environmental toxins, women with high exposure to such toxins should not lose weight during lactation** (see Chapters 5 and 8).

## BREAST AND NIPPLE PAIN

Breast and nipple pain is one of the most frequent complaints of lactating mothers and a leading cause for women not to meet their intended durations of breastfeeding. Among the enrollees in the IFPS II study, 60% of 1177 women failed to achieve their desired duration of breastfeeding. **Breast pain, nipple injury, and/or breast infection were the cited reasons in the majority of women who stopped breastfeeding early.** The frequency of breast and nipple pain is related to failure in the initial management of lactation related to a late first feeding, decreased frequency of feedings, poor nipple grasp, and/or poor positioning. The differential diagnosis of breast pain includes problems with latching on, engorgement, nipple trauma, mastitis, and occasionally the let-down reflex.

Symptoms and the infant's personality help make the differential diagnosis. In some cases, the nipple and breast pain starts with latching on and diminishes with let-down. Women describe the let-down reflex as painful; this occurs after the first minute of sucking and usually lasts only a minute or two as the ductal swelling is relieved by nursing. Classically, this pain pattern is associated with an anxious, vigorous infant who sucks strongly against empty ducts until the let-down occurs. Contact pain suggests nipple trauma, and pain can persist as long as the nipple is manipulated. The nipple-confused infant who chews on the nipple and abrades the tip with its tongue is associated with this pattern.

**Engorgement causes a dull, generalized discomfort in the whole breast that gets worse just before a feeding and is then relieved by it. Localized, unilateral, and continuous pain in the breast may be caused by mastitis.** A physical examination and observation of nursing technique can confirm the impression left by a good history. Through observation of a nursing episode, an infant's personality and nursing technique can be assessed. The whole of the nipple and much of the areola should be in the infant's mouth. An examination of the nipple may reveal a fissure or blood blister; bilateral breast firmness and tenderness may indicate engorgement that may be peripheral, periareolar, or both. Mastitis is characterized by fever, malaise, localized erythema, heat, tenderness, and induration (see below).

Infection may be a cofactor associated with the pain of nipple injury. When the microbiology of the nipple and milk of 61 lactating women with nipple pain was compared with that of 64 lactating women without nipple pain and 31 nonlactating women, *Candida albicans* (19%) and *Staphylococcus aureus* (30%) **were more common in women with pain and nipple fissures than in controls (3% to 5%).**<sup>74</sup> Unfortunately, current data suggest that antibiotics are ineffective in the treatment of nipple pain and trauma.<sup>63</sup>

The management of breast pain consists of general and specific steps, and prevention is a key component. Appropriate nursing technique and positioning will prevent, or significantly decrease, the incidence of nipple trauma, engorgement, and mastitis. Rotation of the nursing position will reduce the suction pressure on the same part of the nipple and will ensure complete

emptying of all lobes of the breast, and frequent nursing will reduce engorgement and milk stasis. **The use of soaps, alcohol, and other drying agents on the nipples tends to increase nipple trauma and pain. The nipples should be air dried for a few minutes after each feeding; clean water is sufficient to cleanse the breast, if necessary.** Some experts recommend that fresh breast milk be applied to the nipples and allowed to dry after each feeding.

Stimulating a let-down response for manual expression of milk is useful in the management of many breast problems. The let-down produced by manual expression is never as complete as a normally elicited one; however, an effective let-down can be elicited by initiating nursing on the side without nipple trauma or mastitis. This will effectively reduce breast pain.

In the first 5 days after birth, about 35% of the nipples of breastfeeding mothers show damage, and 69% of mothers have nipple pain.<sup>75</sup> The management of painful, tender, or injured nipples includes prefeeding manual expression, correction of latching on, rotation of positions, and initiation of nursing on the less painful side first, with the affected side exposed to air. Drying is facilitated by the cautious application of dry heat, such as with a hair dryer on a low setting, for 20 minutes four times per day. Aspirin or codeine (15 to 30 mg) given half an hour before nursing may be helpful in severe cases. Engorgement can be avoided, but if it occurs, feeding frequency should be maintained or increased by pumping. **A wide variety of preparations have been applied to traumatized nipples, including lanolin, A&D ointment, white petrolatum, antibiotics, vitamin E oil, and used tea bags, but few of these have been evaluated scientifically, and systematic review fails to show any benefit.**<sup>63</sup> **Soap and alcohol have been shown to injure nipples.** Nipple shields should be used only as a last resort because they are associated with a 20% to 60% reduction in milk consumption. Thin latex shields may be better than the traditional red rubber ones, although milk flow is still reduced by 22%.<sup>75</sup>

Engorgement of the breast occurs when drainage of milk is inadequate.<sup>76</sup> Swollen, firm, and tender breasts are caused by distension of the ducts and increased extravascular fluid. Aside from the discomfort, engorgement leads to dysfunctional nursing behavior and nipple trauma (see Fig. 24-10). The firm breast tissue pushes the infant's face away from the nipple, the widened base of the nipple disrupts the attachment, and the infant's thrusting tongue abrades the tip. This leads to further engorgement, decreased milk production, and in some cases, early termination of breastfeeding.

The best treatment is prevention, but when this has not occurred, management is centered on symptomatic support and relief of distension. Proper elevation of the breasts is important. The mother should wear a firm-fitting nursing brassiere with neither thin straps nor a plastic lining. A warm shower or bath with manual expression before feeding is effective. Frequent suckling every 1 to 2 hours is the most effective mechanism to relieve engorgement, and postfeeding electric pumping of both breasts may be helpful. In selected cases, intranasal oxytocin may be given just prior to each feeding if let-down seems to be inhibited.

## MASTITIS AND BREAST ABSCESS

Mastitis is a common condition in lactating women. Estimates of incidence from prospective studies range from

3% to 20%, depending on the method of ascertainment, case definition, and duration of follow-up. A practical case definition of *mastitis* is an infectious process of the breast characterized by high fever ( $>38.5^{\circ}\text{C}$ ), localized erythema, tenderness, induration, and palpable heat over the area.<sup>77</sup> Signs and symptoms of a systemic cytokine release, shaking chills (rigor), malaise, flulike symptoms, a white cell count below 4000 or above 12,000 cells/mL, and nausea and vomiting differentiate mastitis from other inflammatory processes of the lactating breast (i.e., plugged ducts or severe engorgement). Antibiotic therapy should not be delayed in patients who meet the above case definition; septic shock, toxic shock syndrome, and abscess formation are possible serious outcomes with delayed antibiotic therapy. Patients with a temperature above  $38.5^{\circ}\text{C}$  and no systemic signs or symptoms can be managed with aggressive breast drainage, especially with the involved lobules and with correction of latch-on. Mastitis occurs most frequently in the first 2 to 4 weeks postpartum. Risk factors include maternal fatigue, poor nursing technique, nipple trauma, rapid reduction in nursing frequency, constrictive clothing, and epidemic *Staphylococcus aureus*. The most common organisms associated with mastitis are *S. aureus*, which includes methicillin-resistant *S. aureus* (MRSA); *S. epidermidis*; streptococci; and occasionally gram-negative rods.

Until recently, the management of mastitis has been directed by retrospective clinical reviews of experience. In most cases, this consisted of bed rest, continued lactation, and antibiotics and came with an 80% to 90% cure rate, a 10% abscess rate, a 10% recurrence rate, and a 50% cessation of breastfeeding. Starting in the 1980s, several important articles were published concerning the pathophysiology, diagnosis, and treatment of mastitis. **The diagnosis and prognosis of inflammatory symptoms of the breast could be established by counts of leukocytes and bacteria in breast milk.** This is obtained after careful washing of the mother's hands and breasts with warm, soapy water. The milk is manually expressed, and the first 3 mL are discarded. A microscopic analysis is performed on an unspun specimen. **When the leukocyte count was greater than  $10^6$  leukocytes/mL, and the bacterial count was less than  $10^3$  bacteria/mL, the diagnosis was noninfectious inflammation of the breast.** With no treatment, the inflammatory symptoms lasted 7 days; 50% developed mastitis, and only 21% returned to normal lactation. When the breast was emptied frequently by continued lactation, the symptoms lasted 3 days, and 96% returned to normal lactation.

**If the breast milk showed greater than  $10^6$  leukocytes/mL and greater than  $10^3$  bacteria/mL, the diagnosis was mastitis.** Delay in therapy resulted in abscess formation in 11%, and only 15% returned to normal lactation. Frequent emptying of the infected breast by continued nursing eliminated abscess formation, but only 51% returned to normal lactation. Additional antibiotic therapy increased the return to normal lactation in 97% with resolution of symptoms in 2.1 days.

In summary, the management of mastitis includes (1) breast support, (2) an appropriate intake of fluids, (3) assessment of nursing technique, (4) nursing initiated on the uninfected side first to establish let-down, (5) the infected side emptied by nursing with each feeding (occasionally, a breast pump helps to ensure complete drainage), and (6) dicloxacillin 250 mg every 6 hours for 14 days. Erythromycin may be used in patients allergic to penicillin. It is important to continue antibiotics for a full 14 days because abscess formation

**is more likely with shorter courses of treatment.** In the hospital and at home, maternal hand washing before each feeding reduces infection rates. In the hospital, hand washing and the use of antiseptic gels by health care workers reduces nosocomial infection rates and, more importantly, reduces MRSA-associated mastitis. In the era before universal hand washing by hospital personnel, rooming in did not reduce the acquisition of hospital strains of *S. aureus*, nor did it reduce infection rates. In the more infection-conscious environment of today, isolation (rooming in) and early discharge may add to the benefits of hand washing by reducing the rates of MRSA-associated mastitis and abscess.<sup>78</sup>

Breast abscess will occur in about 10% of women who are treated for bacterial mastitis. The signs include a high fever (>39°C) and a localized area of erythema, tenderness, and induration. A fluctuant area may be present in the center, but it is difficult to palpate. The patient feels sick, like she “has the flu.” Abscesses usually occur in the upper outer quadrants, and *S. aureus* is usually cultured from the abscess cavity.

**The management of a breast abscess is similar to that for mastitis except that drainage of the abscess is indicated, and breastfeeding should be limited to the uninvolved side during the initial therapy.** The infected breast should be mechanically pumped every 2 hours and with every let-down. Serial percutaneous needle aspirations under ultrasound guidance are the standard and best method to drain the abscess, although occasionally, surgical drainage is required. The skin incision should be made over the fluctuant area in a manner parallel to and as far as possible from the areolar edge. Whereas the skin incision follows skin lines, the deeper extension should be made bluntly in a radial direction. Sharp dissection perpendicular to the lactation ducts increases blood loss, the risk of a fistula, and the risk of ductal occlusion. Once the abscess cavity is entered, all loculations are bluntly reduced, and the cavity is irrigated with saline. American surgeons pack the wound open for drainage and secondary closure, whereas British surgeons advocate removal of the abscess wall and primary closure. In either case, wide closure sutures should be avoided because they may compromise the ducts. Patients have a protracted recovery of 18 to 32 days, and recurrent abscess formation occurs in 9% to 15% of patients. Breastfeeding from the involved side may be resumed if skin erythema and underlying cellulitis have resolved, which may occur in 4 to 7 days.

*C. albicans* infection is considered a common cause of breast pain, and ***Candida* infection of the breast is commonly diagnosed by clinical presentation: women describe severe pain when the infant nurses, “like a red hot poker being driven through my chest.”** Often the patient has received antibiotics recently and has diabetes, or the infant has evidence of oral thrush or diaper rash (*C. albicans*). The areola and nipple are erythematous with a scaly sheen to the nipple. Unfortunately, the clinical presentation of candidal infection of the breast is not as specific or as accurate as a prudent clinician needs it to be. The differential diagnosis includes let-down pain, poor latch-on, nipple trauma, an allergic reaction, Raynaud phenomenon of the nipple, and early bacterial mastitis.

Often the mother is given strong antifungal agents for symptoms not amenable to antifungal agents. In a study by Hale and colleagues,<sup>79</sup> only 1 of 21 patients with a “classic” presentation of *Candida* mastitis had a breast milk specimen positive for yeast. **Given the nonspecificity of the clinical diagnosis, a focused physical examination and biologic confirmation**

**of *Candida* is prudent. Biologic confirmation is obtained through a microscopic examination and culture of a midstream sample of breast milk.** First, the nipples and areola are gently cleaned with warm water. Next, a let-down of breast milk is induced and a sample of the milk is obtained after the first 3 mL have been discarded. A potassium hydroxide (KOH) smear can confirm the diagnosis. A drop of the midstream milk is combined with a drop of 10% KOH and is examined under high-power light microscopy. A typical pattern of hyphae and spores will be visualized. The remainder of the sample is sent for culture and isolation of bacteria and fungi. In cases in which multiple antibiotics and antifungal agents have been used, a sensitivity panel on the fungal isolates may be helpful. A fungal culture may take 7 to 10 days for isolation and identification, longer than for antibiotic sensitivities. **Given the intensity of maternal symptoms and the risk of discontinuing breastfeeding, empiric therapy is warranted prior to the availability of culture results.**

The initial treatment is to massage nystatin cream or miconazole oral gel into both nipples after each feeding and in the infant's mouth three times a day for 2 weeks. Recurrent or persistent *Candida* mastitis can be treated by swabbing the infant's mouth with gentian violet liquid (0.5%) and immediately latching the baby to the breast; this should be done twice a day for 3 days. The major disadvantage of this therapy is the permanent staining associated with gentian violet. An alternative therapy in severe cases is oral fluconazole in a 200-mg loading dose followed by 100 mg/day for no more than 14 days.

## MILK TRANSFER AND INFANT GROWTH

When is an exclusive diet of breast milk insufficient to supply the nutritional needs of the growing infant? Women who wean in the first 8 weeks most often say that insufficient milk is the reason for quitting, and well-meaning family members often ask, “When are you going to start feeding your baby *real* food?”

Correct answers are not readily available. Many nondietary factors affect the growth of infants, and poor growth is associated with high birth order (more than four living children), lower maternal age, low maternal weight, poor maternal nutrition during pregnancy, short birth interval, birthweight less than 2.4 kg, multiple gestation, infection, death of either of the infant's parents, or their divorce or separation.

In addition, inconsistencies exist in older standard reference charts for growth and nutritional needs. Most older growth charts are based on formula-fed infants, who often receive solid food supplementation earlier and in greater proportion than comparable breast-fed infants. The WHO and the CDC recognized the weakness and have developed appropriate infant growth charts (<http://www.cdc.gov/growth> chart).<sup>80</sup> Because milk volume is a quantitative measure of nutrition, variations in volume and concentrations of constituents caused by individual variation and different methods of collection confound the interpretation.

Despite the latter concerns, it is apparent that **a healthy and successfully breastfeeding mother can supply enough nutrition through breast milk alone for 6 months.** The clinical markers for adequate breast milk transfer include an alert, healthy appearance; good muscle tone; good skin turgor; six wet diapers per day; eight or more nursing episodes per day; three or four loose stools per day; consistent evidence of a let-down

with operant conditioning; and consistent weight gain (0.75 to 1.0 oz/day after lactogenesis stage III has started; that is, when engorgement occurs, or the “milk comes in”).

**The term *failure to thrive* has been used loosely to include all infants who show any degree of growth failure. For the breastfeeding mother, it may just be a matter of comparing the growth of her infant to growth charts compiled from formula-fed infants.** This loosely applied term can seriously undermine the mother's confidence, and ill-advised supplementation further compromises milk volume and may mask other important underlying causes. The infant should be evaluated for failure to thrive or slowed growth if (1) it continues to lose weight after 7 days of life, (2) it does not regain birthweight by 2 weeks, or (3) it gains weight at a rate below the 10th percentile beyond the first months of age. If the mother or the maternal care provider recognize jaundice after the first 7 to 10 days of life, the neonate needs to have a serum bilirubin test and should be seen by the care provider in an emergent fashion (<12 hours). If the infant is premature, ill, or small for gestational age, other growth measurements (ponderal index, height, skinfold thickness, etc.) can be used to define adequate growth. The causes of failure to thrive are often complex and are beyond the scope of this chapter.

## JAUNDICE IN THE NEWBORN

**Jaundice is one of the more common neonatal markers for prompt intervention; most often, a major focus on breast milk transfer is the solution. Ten to 15% of breast-fed neonates will have jaundice, defined by a peak serum bilirubin greater than 12 mg/dL in term infants.**<sup>81</sup> Pediatric concerns include hemolysis, liver disease, or infection as underlying causes and kernicterus as a consequence. **Unconjugated serum bilirubin greater than 20 mg/dL, or 15 mg/dL for high-risk neonates, is considered the critical level for the development of kernicterus in healthy term infants because the risk of permanent brain injury is markedly increased.** When the serum bilirubin is greater than 5 mg/dL in the first 24 hours, a serious disease process such as hemolysis may be present, and intervention is appropriate.

The focus on breastfeeding as related to neonatal jaundice results from the characterization of two syndromes, **breastfeeding jaundice syndrome**, described above, and **breast milk jaundice syndrome**. In the early 1960s, 5% to 10% of lactating women were found to have a steroid metabolite of progesterone—5 $\beta$ -pregnane-3( $\alpha$ ), 20( $\beta$ )-diol—in their icterogenic milk, but the compound was not found in the milk of women whose infants were normal (breast milk jaundice syndrome). This metabolite is associated with an inhibition of glucosyl transferase in the liver, differences in the metabolism of long-chain unsaturated fatty acids, and/or increased resorption of bile acids in jaundiced infants.

**In breast milk jaundice syndrome, the neonates are healthy and active. The hyperbilirubinemia develops after the fourth day of life and may last several months, with a gradual fall in the bilirubin level. When breastfeeding is stopped for 24 to 48 hours, a 30% to 50% decline in bilirubin level is observed.** With resumption of nursing, serum levels will rise slightly (1 to 2 mg/dL), reach a plateau, and then start to fall slowly regardless of feeding method. **After excluding other causes of jaundice, and with careful monitoring of serum bilirubin, breastfeeding can continue.**

Unfortunately, the focus on rare breast milk jaundice cases, the concern about kernicterus, and the increased bilirubin in many breast-fed neonates between 2 and 7 days old has led to routine supplementation of infants with water, glucose, and formula even when bilirubin concentrations were in the moderate range of 8 to 12 mg/dL. The cause of the elevated bilirubin, reduced feeding frequency, or low milk transfer is often unrecognized. **It has been clearly demonstrated that feeding frequency greater than eight feedings per 24 hours is associated with lower bilirubin levels. Likewise, water supplementation studied in a controlled fashion does not decrease the peak serum bilirubin.** Management consists of prevention by improvement in the quality and frequency of nursing. Rooming in and night feedings should be encouraged. If the mother, family, or obstetrician recognizes jaundice in an infant more than 7 days old, an immediate referral should be made to the child's physician, and a serum bilirubin level should be obtained; this is a pediatric emergency.

## GALACTOGOGUES: DRUGS TO IMPROVE MILK PRODUCTION

Obstetricians may interface with the breastfeeding dyad when there is a question of adequate milk production and transfer by the mother. The mother and/or the pediatrician often ask for a galactagogue to be prescribed by the obstetrician.<sup>82</sup>

Numerous agents have been shown to increase prolactin production in nonpregnant women, and galactorrhea is a relatively common clinical issue for women on phenothiazines or metoclopramide. It is reasonable that these drugs might be used where milk supply seems insufficient. The most understandable clinical scenarios include glandular hypoplasia, reduction mammaplasty, premature delivery that requires mechanical pumping, and relactation (nursing an adoptive child). The most common clinical presentation is perceived poor milk supply or inhibited milk let-down (oxytocin inhibition). Clinical trials with random assignment of subjects have demonstrated the effectiveness of metoclopramide, sulpiride, and domperidone. When let-down (milk ejection) is obstructed, nasal oxytocin is given to increase milk ejection.<sup>82</sup>

**Metoclopramide (Reglan) is used to promote GI tone; however, a secondary effect is to increase prolactin levels. Most studies demonstrate a manifold increase in basal prolactin levels and a 60% to 100% increase in milk volume.** The effects of metoclopramide are very dose dependent; the usual dose is 10 to 15 mg orally three times a day, but the side effects—gastric cramping, diarrhea, and depression—often limit its use. The incidence of depression increases with long-term use, therefore treatment should be tapered over time and limited to less than 4 weeks. There appears to be little effect on the infant. The dose that the infants receive is much less than the amount used therapeutically to treat esophageal reflux, regardless of the time postpartum. The U.S. Food and Drug Administration has issued a black box warning concerning the association of tardive dyskinesia and the use of metoclopramide for more than 3 months.

Domperidone, an agent similar to metoclopramide, blocks the dopamine receptors in the gut and brainstem but with fewer of the psychoneurologic side effects. Domperidone is used in Canada as an antiemetic, but it is not FDA approved in the United States. **In placebo-controlled trials in mothers with decreased milk supply, domperidone increased prolactin**

**levels and milk supply twofold to threefold.** The usual dose to improve milk supply is 10 to 20 mg three to four times a day. Slow tapering (reduce by 10 mg/week) is suggested because acute withdrawal rapidly diminishes milk supply. The relatively high protein binding in maternal serum limits transfer to the neonate, and the relative infant dose is 0.04%. Recently, the FDA issued a warning against use of domperidone because of a risk of cardiac arrhythmias. These potentially life-threatening reactions occurred in older patients with hypokalemia who were receiving chemotherapy for cancer, in whom intravenous domperidone was used in high doses as an antiemetic.

**Sulpiride is a selective dopamine antagonist** used in Europe as an antidepressant and antipsychotic. Smaller doses (50 mg twice daily) do not produce neuroleptic effects in the mother, **but prolactin and milk production are increased significantly. Clinical studies suggest an increase in milk production (20% to 50%) but less than that seen with metoclopramide.** In a placebo-controlled study with random assignment of 130 subjects, sulpiride 50 mg twice daily for the first 7 days postpartum increased the total milk yield from 916 mL ( $\pm 66$ ) in the control group to 1211 mL ( $\pm 65$ ) in the sulpiride-treated group. The transfer of sulpiride to the breast milk was minimal, and no adverse effects were seen in the infants. Sulpiride is not available in the United States.

**Intranasal oxytocin substitutes for endogenous oxytocin to contract the myoepithelial cells and cause milk let-down.** In theory, its use is to overcome an inhibited let-down reflex. Oxytocin is destroyed by GI enzymes and is not given orally. Until recently, oxytocin was available as an intranasal spray, but it has been taken off the market. A pharmacist can prepare an intranasal spray with a concentration of 2 IU per drop. The let-down dose is a spray (3 drops) to each nostril; the total let-down dose is approximately 12 IU, taken within 2 or 3 minutes of each nursing episode. The suggested duration of therapy is unclear. Underlying causes for an inhibited let-down reflex need to be identified and controlled.

Few clinical trials have used oxytocin alone to improve milk production. **In a double-blind group sequential trial, intranasal oxytocin alone was used to enhance milk production in women during the first 5 days after delivery of a premature infant. The cumulative volume of breast milk obtained between the second and fifth days was 3.5 times greater in primiparas given intranasal oxytocin than in primiparas given placebo.** This benefit accrues from more complete emptying of the breast with each feed. Because of oxytocin's complementary mechanism to prolactin-stimulating medications, they are often used in combination.

Although metoclopramide, domperidone, sulpiride, and oxytocin appear to be effective and relatively safe for the mother and infant, they are only secondary support interventions. The primary focus should be to enhance prolactin and oxytocin through natural mechanisms—that is, with appropriate and frequent stimulation of the nipple and areola. Galactagogues should only be used for a short duration (2 to 4 weeks) and in conjunction with hands-on counseling by an individual with the time, energy, and knowledge to enhance the “natural” production of breast milk.

## MATERNAL DISEASE

In the vast majority of cases of lactating mothers with intercurrent disease, no medical reason exists to stop breastfeeding.

However, appropriate management requires individualizing the care of the nursing dyad in order to preserve the supply-and-demand relationship of lactation. For example, a hospitalized nursing mother should have her nursing baby with her in the hospital for on-demand feedings. This situation stretches the flexibility of hospital administrators and nursing services, but the problem can be overcome by education.

**The first principle is to maintain lactation.** An acute hospitalization for a surgical procedure is a common complication. **If breast milk was the neonate's only source of nutrition, an acute reduction in nursing may lead to breast engorgement, a confusing postoperative fever, and mastitis. The infant should be put to the breast just before premedication, and the breasts should be emptied in the recovery room. The most effective way is to have the mother nurse. Although some anesthetic may be present in the milk, most are compatible with lactation.** If there is legitimate concern or if the mother cannot communicate (because she is on a ventilator, for example), the breasts should be pumped mechanically in the recovery room and subsequently emptied every 2 to 3 hours by nursing or pumping.

**The second principle is to adjust for the special nutritional requirements of nursing mothers.** This principle is especially pertinent when intake is restricted postoperatively and when maternal diet must be manipulated. In the postoperative period, the surgeon must account for the calories and fluid required for lactation. **Until oral intake is established, a lactating mother needs an additional 800 mL of fluid per day. Early return to a balanced diet is essential to offset the additional energy and protein requirements of lactation and wound healing.**

**The third principle is to ensure that the maternal disease will not harm the infant.** This is most pertinent with infectious disease, but it is equally important in cases in which a mother's judgment is in question, such as with severe mental disease, substance abuse, or a history of physical abuse. The benefits of breastfeeding in the latter situations must be carefully evaluated using the resources of the patient, her family, and social services.

**Infection is the most common condition in which breastfeeding is questioned.** In general, the necessary exposure of the infant to the mother in day-to-day care is such that breastfeeding does not add to the risk. This recommendation assumes that appropriate therapy is being given to both mother and infant. Isolation of infected areas should still be practiced, such as with a mask in the case of respiratory infection and lesion isolation in herpes. **The four acute infections in which breastfeeding is contraindicated are (1) herpes simplex lesions of the breast; (2) acute maternal varicella in the first 3 days of the neonate's life (only until the neonate has received varicella-zoster immunoglobulin [VZIG]); (3) untreated active tuberculosis (chest x-ray positive with documented presence of *Mycobacterium*, not just purified protein derivative [PPD] positive); and (4) human immunodeficiency virus (HIV) disease when it occurs in developed countries.**

**The fourth principle is to evaluate adequately the need and type of medication used for therapy** (see [Chapter 8](#)). The drug management of chronic hypertension illustrates this principle. First, the need for medication must be scrutinized, and considerable controversy exists in the literature as to whether to treat patients with mild chronic hypertension (diastolic blood

pressure 90 to 100 mm Hg). The desire of a mother with mild hypertension to breastfeed may change the risk/benefit ratio such that antihypertensive drug therapy should be delayed until after lactation. Second, the medication should be evaluated for its effect on milk production. **In the first 3 to 4 months of therapy, diuretics reduce intravascular volume and, subsequently, milk volume.** On the other hand, if a patient has been on low doses of thiazide diuretics for more than 6 months, the effect on milk volume is minimal as long as adequate oral intake is maintained. Third, the medication should be evaluated for its secretion in breast milk and its possible effects on the infant. Thiazide diuretics, ethacrynic acid, and furosemide also cross into breast milk in small amounts. These agents have the potential to displace bilirubin, and their use during lactation is of concern when the infant is less than 1 month old or is jaundiced. In general, most other antihypertensive drugs are compatible with breastfeeding. Although new drugs come onto the market often, it is wise to use drugs that have had a long history of clinical use.

**A fifth principle and a constant challenge is the blanket proscription by radiologists and x-ray technicians to “pump and dump” breast milk for 24 to 48 hours when contrast agents are used. Most agents have very poor oral bioavailability, and the effective infant dose is less than 0.1%.** The guidelines of the American College of Radiology (2004) reviewed the use of contrast media in breastfeeding mothers. On a practical level, the mother should feed her infant just before the injection of the contrast media. The delay of 2 to 3 hours until the next feeding allows the mother to clear the agent before potential infant exposure; the half-life of many of these agents is less than 2 to 3 hours. If the mother is comfortable with expression or pumping, stored breast milk is an alternative for interim feeds for two to three half-lives.

## DRUGS IN BREAST MILK

Most medications taken by the mother appear in the breast milk, but the calculated doses consumed by the nursing infant range from 0.001% to 5% of the standard therapeutic doses and are tolerated by infants without toxicity (see Table 24-6 and Chapter 8).

The following guidelines are helpful:

1. Evaluate the therapeutic benefit of medication. Are drugs really necessary, and are there safer alternatives? Diuretics given for ankle swelling provide very different benefits from diuretics used for congestive heart failure. Choose the drugs most widely tested and with the lowest milk/maternal plasma ratio.
2. Choose drugs with the lowest oral bioavailability.
3. Select the least toxic drug with the shortest half-life.
4. Avoid long-acting forms. Usually, these drugs are detoxified by the liver or are bound to protein.
5. Schedule doses so that the smallest amount gets into the milk. The rate of maternal absorption and the peak maternal serum concentration are helpful in scheduling dosage. Usually, it is best for the mother to take the medication immediately after a feeding.
6. Monitor the infant during the course of therapy. Many pharmacologic agents for maternal use are also used for infants. This implies the availability of knowledge about therapeutic doses and the signs and symptoms of toxicity.

## BREAST MASSES DURING LACTATION

**Breast cancer is the most common cancer of the reproductive organs of the female. Whereas the risk of breast cancer increases tremendously after the age of 40, 1% to 3% of all breast cancers occur during pregnancy and lactation** (see Chapter 50). Breast cancer diagnosed during lactation may have its origin before or during pregnancy. As a result of this assumption and the small numbers of pregnant or lactating women, most studies have lumped these populations together. Researchers in Japan have analyzed breast cancer in age-matched controls ( $n = 192$ ), women who were pregnant at diagnosis ( $n = 72$ ), and women who were lactating at diagnosis ( $n = 120$ ). **The prognosis for breast cancer diagnosed during pregnancy or lactation is poorer than for breast cancer diagnosed at other times.** The 10-year survival for age-matched controls without lymph node metastasis was 93%; for women who were diagnosed during pregnancy or lactation, the survival was 85%. When the lymph nodes were involved, the 10-year survival was 62% in controls and 37% in women who were diagnosed during pregnancy or lactation. The difference in survival is partially explained by a longer duration of symptoms prior to diagnosis (6.3 vs. 5.4 months), tumor size on palpation (4.6 vs. 3.0 cm), and tumor size on cut surface (4.3 vs. 2.6 cm) in lactating women versus controls, respectively. **The delay in diagnosis and the greater size at diagnosis in lactating women is a failure of the obstetric care provider and/or the lactating woman to aggressively pursue the evaluation of a breast mass.**

The lactating woman is most likely to recognize a breast mass through her daily manipulations of her breasts. In her framework of reference, she usually considers this mass a “plugged duct.” She should be encouraged to report a plugged duct that persists more than 2 weeks despite efforts to initiate drainage of that lobule. Her provider faces an expanded differential diagnosis; the most common diagnosis is that of a dilated milk duct, a completely benign diagnosis. Fibromas and fibroadenomas are more common in young women; these solid tumors are rubbery, nodular, and mobile, and they may grow rapidly with the hormonal stimulation of pregnancy. A needle aspiration of the mass is the mainstay of diagnosis. **Percutaneous fine-needle aspiration is performed in the same manner as in nonpregnant women.** The use of local anesthetic is optional; infiltration of the area around a small lesion may increase the likelihood of a nondiagnostic aspiration. The area over the mass is swabbed with iodine or alcohol and, using sterile techniques, the lesion is fixed between the thumb and fingers of the nondominant hand. Using a 22-gauge needle attached to a 20-mL syringe, the center of the lesion is probed. Initial aspiration usually reveals the nature of the lesion. If milk or greenish fluid (fibrocystic disease) is found and the lesion disappears, no further diagnostic procedures need to be performed. If the tumor is solid or fails to disappear completely after aspiration, the needle is passed several times through the lesion under strong negative pressure. The aspirated tissue fluid is air-dried on a slide and sent for cytologic evaluation. The pathology requisition should note the age and lactating status. **Fine-needle aspiration biopsy appears to have the same accuracy in pregnancy and lactation as in the nonpregnant, nonlactating woman.** In a study of 214 fine-needle aspirations during pregnancy and lactation, eight (13.7%) were cancer, and the sensitivity, specificity, and positive predictive values were 100%, 81%, and 61%, respectively.

**Ultrasound is an accurate method of determining the cystic nature of a breast mass in lactating women. Mammography is more difficult to interpret during lactation.** Young breasts are generally more dense, and the massive increase in functioning glands may obscure small cancers. However, the accuracy is still good if the films are interpreted by experienced radiologists. In general, mammography is a secondary diagnostic modality.

**A core biopsy using ultrasound or radiographic guidance is a reasonable option to avoid a surgical procedure.** If a surgical biopsy is required, the surgeon will usually need guidance regarding the management of lactation. Most breast biopsies can be performed under local anesthesia. **If the mother nurses just before the procedure, she will empty the breast—which makes the surgery easier—and will allow 3 to 4 hours to pass before the next feeding.** Local anesthetics are not absorbed orally and pose no risk to the infant, so the mother should be allowed to nurse on demand. Most anesthetics used for general anesthesia enter the breast milk in small amounts (1% to 3%) of the maternal dose, and minimal behavioral effects in infants have been observed. In most cases, the mother can nurse within 4 hours of the anesthetic. The mother's breasts should be pumped 3 to 4 hours after the last feeding regardless of the anesthetic status; she will begin to feel the discomfort of engorgement, and the fever of engorgement may confuse the postoperative picture as early as 8 or 10 hours. Failure to empty the breasts within 6 to 8 hours will begin to adversely affect milk supply.

**Surgical biopsy usually has little effect on breastfeeding performance unless the procedure is done in the periareolar area or the nerves that supply the nipple are compromised. Circumareolar incisions are to be avoided if possible.** Milk fistulae are an uncommon risk (5%) of central biopsy, although fistulae are usually self-limited and will spontaneously heal over several weeks. Prohibiting breastfeeding does not change the likelihood of ultimate healing.

## BACK-TO-WORK ISSUES

**In 2009, according to the CDC, about 50% of women in the workplace had a child at home younger than 12 months old.** One third returned to work within 3 months of birth, and two thirds returned within 6 months. The IFPS II study prospectively surveyed employed breastfeeding mothers ( $n = 810$ ) over the first 12 months after birth for strategies that combined employment and breastfeeding.<sup>83</sup> **The important findings were that the average age of the infant when the mother returned to work was a mean of 11.4 weeks, the median hours of work per week was 24.8, and the median duration of breastfeeding after return to paid work was 25.6 weeks.** The strategies used to continue breastfeeding in the first month after the mother returned to work included to (1) feed directly from the breast (31.3%), (2) pump and feed directly from the breast (9.4%), (3) pump only and bottle feed breast milk only (43.4%), and (4) neither pump nor feed directly during the day. Directly breastfeeding and a pump-and-feed strategy resulted in the longest durations of breastfeeding after returning to work: 31.4 weeks ( $n = 250$ ) and 32.4 weeks ( $n = 75$ ), respectively. Pumping and bottle-feeding breast milk only averaged 26.3 weeks ( $n = 346$ ), and neither pumping nor feeding breast milk during the work day averaged 14.3 weeks ( $n = 128$ ) and had a significantly shortened duration of breastfeeding. The obstetric provider

should support breastfeeding, and if breastfeeding is not possible during the day, the provider should suggest that the mother pump breast milk to provide bottles for the child care giver to supply to her infant during the work day.

Safe and clean storage of pumped breast milk is critical to the breastfeeding working mother (see the earlier section, “**Breast Milk Expression**,” and also **Boxes 24-2** and **24-3**). The Academy of Breastfeeding Medicine has a specific protocol to help mothers safely store their milk.<sup>84</sup>

As a consequence of these findings, the CDC, other national organizations, and state legislatures have enhanced or initiated major campaigns to support breastfeeding in the workplace. The CDC has guidelines for workplace safety for working mothers who wish to express breast milk (<http://www.cdc.gov/breastfeeding/promotion/employment.htm>). **In March 2011, federal law amended Section 7 of the Fair Labor Standards Act to require employers to provide “reasonable break time for an employee to express breast milk for her nursing child for 1 year after the child’s birth each time such employee has need to express the milk.”**

The separation between mother and infant adversely affects the psychology and physiology of lactation through breast engorgement, a decrease in the frequency of nursing, and unsatisfied needs of the baby. The anxiety and fatigue associated with the combination of employment and lactation inhibits the let-down reflex, weakens maternal host defenses, and disrupts family dynamics. The infant must adapt to another caregiver, a new sucking technique, and unfamiliar infectious agents found in day care settings. Therefore it is not surprising that formula feeding is viewed as an improvement in mothers’ lives, even though it creates feelings of inadequacy and guilt in some women. Fortunately, the rapid increase in breast pump options and technology allows many working mothers (70%) to provide bottled human breast milk to their infant during the work day.

Breastfeeding during employment is both possible and fulfilling. Preparation, milk storage, and choice of child care are the cornerstones to easy adaptation to employment. Preparation involves preemployment change in lifestyle to accommodate the increased stresses. **Lactation should be well established with frequent nursing (10 to 14 times per day) and no supplementation prior to return to work.** Return to full-time work prior to 4 months has a greater negative impact than return to work after 4 months. Part-time work lessens the impact. About 2 weeks prior to work, the mother should change her nursing schedule at home. During the workday, she should express or pump her breasts two or three times a day, while increasing her nursing with short, frequent feedings before and after work times. The infant should be fed bottles of stored breast milk by a different person in a different place to allow easier adaptation.

During the 2 weeks prior to employment, the day care arrangements should be carefully selected and observed. In addition to references, several questions are pertinent to the selection of the day care setting. Is the sitter a mother herself, and does the sitter have experience with nursing babies? Is the mother welcome to use the child care site for a midday nursing? Does the day care center provide in-arm feeding, or are high chairs and propped bottle-feedings used? Is the time and activity of the center highly structured and rigid, or is it flexible to the needs and requests of the mother and infant? Does the staff treat the parents and children with respect? Many of these questions can

be answered by an extended (1- to 2-hr) observation of the center and its children.

**Fatigue is the number one enemy of the working mother, and emotional and physical support of the mother is critical.** Some helpful suggestions include bringing the infant's bed into the parent's room or construction of a temporary extension to the parents' bed; use of labor-saving devices, division of domestic chores, and the elimination of less important household chores to reduce the workload; and taking naps and frequent rest periods to conserve energy.

Continued stimulation of the breast during working hours is important. Pumping not only improves milk supply, it also supplies human milk for the infant. Manual expression and/or mechanical pumping should be performed more frequently (two to three times during the workday) in the first 6 months postpartum. After 6 months, the workday frequency can be reduced and eliminated as the infant's diet is complemented by fluids or solids during the day.

## CONTRACEPTION

Adequate family planning—that is, intentional pregnancy at an appropriate interpregnancy interval (>18 months)—is a critical medical and social principle. Both a shortened interpregnancy interval (<18 months) and unintended pregnancy significantly increase adverse pregnancy outcomes. Having two children in diapers adds considerable social and fiscal stress to the family. The discussion of contraception during breastfeeding is the unique responsibility of the obstetric care provider. Prenatal discussion of contraceptive choices are critically important in a woman who is anticipating breastfeeding, especially a first mother who may have concerns about the effects of hormonal contraception on her breastfeeding infant.

The key issues of contraceptive education are delaying pregnancy at least 18 months and making the next pregnancy intentional. Most women return to sexual relations by 4 to 8 weeks postpartum; if they have had more than two consecutive days of vaginal (“menstrual”) bleeding after 56 days postpartum, they are at risk for an often unintended pregnancy. A corollary of the two key contraception educational issues is to provide contraception that does not complicate or potentially affect the success of breastfeeding; or, the converse, to make patients aware that breastfeeding may affect the efficacy of the contraceptive method. A tired, stressed mother with poor support may not be as effective in remembering to use daily (oral hormonal contraceptives) or episodic contraceptives (barrier methods).

Permanent sterilization (i.e., postpartum tubal ligation) is the most effective contraceptive, with a pregnancy rate of 3 to 7 per 1000 woman-years. Postpartum sterilization, even if delayed until after the first 4 hours (for first feeding, skin-to-skin contact, and mother/family bonding), can be performed and completed using the same labor epidural within a short period of time and with minimal impact on breastfeeding. Male sterilization can be performed as an outpatient procedure before delivery with similar effectiveness, as long as postprocedure sperm analysis shows no sperm, usually after 15 ejaculations.

If more children are desired, effective child spacing occurs with lactational amenorrhea. This contraceptive effect has been quantified since the early 1970s.<sup>85</sup> The lactational amenorrhea method (LAM) of birth control utilizes the normal physiology of lactation—a low-estrogen/progesterone, high-prolactin state. If the mother is exclusively breastfeeding, is less than 6 months

postpartum, and has no menses—that is, no bleeding perceived by the mother as menses that occurs after 56 days postpartum or any consecutive 2 days of bleeding—the unintended pregnancy rate is 0.5 to 2 per 100 woman-years. If these conditions are not met, an additional contraceptive is needed. In the first 6 months postpartum, LAM is as effective as the mini pill, or progesterone-only hormonal contraception pill.

When LAM is deemed to be unreliable or the strict conditions are not met, other contraception is needed to prevent unintended pregnancy during the lactation period. The copper intrauterine device (IUD) is very effective, with a pregnancy rate of 3 to 8 per 1000 woman-years, and does not pose concerns related to hormonal exposure to the lactating breasts and neonate. Heavy menses and copper sensitivity are uncommon side effects. Of note, emergency contraception with levonorgestrel is the preferred option, rather than combined oral contraceptives, because it has fewer side effects; in addition, levonorgestrel comes with none of the concerns of high-dose estrogen, which includes reduction of milk volume. Generally, levonorgestrel has little effect on lactation.

In many cases, progesterone-only contraceptives, progestin-releasing IUDs, injections (depot medroxyprogesterone acetate [DMPA]), or implants are the contraception of choice for lactating women who want or need more protection than LAM after the onset of lactogenesis stage III on days 5 to 7 postpartum. Although unproven, a theoretic concern exists for disruption of lactogenesis with a pharmacologic dose of progesterone (i.e., DMPA) when withdrawal of progesterone with placental removal might initiate lactogenesis stage II.

In 2010, the Contraceptive CHOICE Project<sup>86</sup> analysis impacted the recommendations for contraception among lactating women. Long-acting reversible contraception (LARC) addresses the key issues related to contraception during lactation. LARC in this study included the levonorgestrel intrauterine system (LNG-IUD), the copper IUD (Cu-IUD), and the etonogestrel (ETG) implant. Non-LARC methods included all other methods of contraception, such as daily hormonal contraceptive pills, hormonal patches and vaginal rings, and DMPA. Continuation rates at 2 years for LARC methods and non-LARC methods were 71% versus 41%, respectively. **Non-LARC users were 22 times more likely to have an unintended pregnancy than LARC users.** In the prenatal clinic, the obstetric care provider needs to address the very clear implications of this population study to their patients who intend to breastfeed. **LARC methods are far better for achieving a 2-year interpregnancy interval and for reducing unintended pregnancy than non-LARC methods that included oral contraceptives, patches, injectables, and rings.**

## WEANING

**The AAP recommends exclusive breastfeeding for the first 6 months of life and continuation beyond the first 12 months of life.** Breastfeeding is a biologic process modified by cultural expectations. The culture of the United States feels increasingly more uncomfortable when a mother breastfeeds more than a year. From a broader biologic and historic perspective, the U.S. experience reflects cultural bias, not biologic reality. In a remarkable review, Dettwyler<sup>87</sup> **makes a very cogent argument for the “natural” age of weaning in the human to be 3 to 4 years.** She has several arguments, the first being that traditional and prehistoric societies have always weaned between the third and

fourth year. Based on weaning when the infant weight is four times its birthweight, similar to other primates, weaning should occur between 2 and 3 years. If weaning corresponds to attainment of one third the adult weight, weaning would occur between 3 and 4 years. If humans behaved like chimpanzees or gorillas and weaned at six times the gestational period, humans would wean at 4.5 years. The dental, neurologic, and immunologic systems are still developing until 6 years of age, and breastfeeding and breast milk provide unique support for these systems up to 4 to 6 years. Developmentally, the infant is able to place solid food in its mouth at 6 months; but if left to the infant's own skills, this intake would not reach a significant proportion of the nutritional requirements until 18 to 24 months. The ability to drink from a cup occurs close to the second year. As the infant supplements an increasing proportion of its nutritional needs with solid or liquid food, the mother will begin to ovulate, and subsequent pregnancy is increasingly more likely. **Through its suppression of gonadal function, breastfeeding can maintain a birth interval of 3 to 4 years. Breastfeeding into the third year is a cultural exception in the United States, but prolonged breastfeeding does *not* constitute abnormal or deviant behavior, an attitude expressed by many so-called modern Americans.** As we learn more about the benefits of long-term lactation, our culture may return to more reasonable expectations for the duration of breastfeeding.

### KEY POINTS

- ◆ The World Health Organization, the U.S. Surgeon General, the American Academy of Pediatrics, the American Academy of Family Practice, the American College of Obstetricians and Gynecologists, and the Academy of Breastfeeding Medicine endorse breastfeeding as the gold standard for infant feeding.
- ◆ Breastfeeding accrues many health benefits for the infant, including protection against infection, fewer allergies, better growth, better neurologic development, and lower rates of chronic diseases, such as type 1 diabetes and childhood cancer.
- ◆ Breastfeeding accrues more health benefits for the mother, including faster postpartum involution, improved postpartum weight loss, less premenopausal breast cancer, lower rates of cardiovascular disease, less type 2 diabetes mellitus, and better mother-infant bonding. Breastfeeding also decreases the economic burden.
- ◆ Formula lacks key components of breast milk, including defenses against infection, hormones and enzymes to aid digestion, polyunsaturated fatty acids necessary for optimal brain growth, and adequate composition for efficient digestion.
- ◆ Prolactin is the major promoter of milk synthesis, and oxytocin is the major initiator of milk ejection. The release of prolactin and oxytocin results from the stimulation of the sensory nerves that supply the areola and nipple.
- ◆ Oxytocin released from the posterior pituitary can be operantly conditioned and is influenced negatively by pain, stress, or loss of self-esteem.

- ◆ Contact with the breast within 30 minutes of birth increases the duration of breastfeeding. Correct positioning of the nursing infant and correct latch-on promote efficient milk transfer and reduce the incidence of breast pain and nipple injury. A frequency of nursing greater than eight feedings per 24 hours, night nursing, and a duration of nursing longer than 15 minutes are needed to maintain adequate prolactin levels and milk supply.
- ◆ The nursing actions on a human teat versus on an artificial teat are very different. Poor lactation is the major cause of nipple injury and poor milk transfer. Perceived or real lack of milk transfer is the major reason for the discontinuation of nursing.
- ◆ Milk production is reduced by an autocrine pathway through a protein that inhibits milk production by the alveolar cells and by distension and pressure against the alveolar cells.

Approximately 1 in 500 women will require nonobstetric surgery during pregnancy.<sup>1</sup> The care of the pregnant surgical patient requires a multidisciplinary approach that involves the obstetrician, surgeon, anesthesiologist, and pediatrician. Numerous unique challenges arise when caring for a pregnant woman who presents with symptoms that may require surgery. Evaluation of these patients is often confounded by the various changes in maternal physiology, concern for fetal well-being, and the potential risk to the continuing pregnancy. The introduction of new imaging diagnostic modalities has increased our diagnostic capabilities; however, their safety for use during pregnancy continues to be evaluated. In this chapter, we focus on (1) specific physiologic and anatomic adaptations to pregnancy that the clinician needs to be aware of when evaluating a gravid patient; (2) the diagnostic challenges concerning evaluation of a pregnant woman, with specific attention to radiologic studies; (3) the unique issues that arise when providing surgical anesthesia

during pregnancy; and (4) the potential risks to the pregnancy that are assumed when nonobstetric surgery becomes necessary. Finally, although some of the more common indications for surgery in pregnancy—such as trauma, appendicitis, and cholecystitis—are addressed in more detail elsewhere ([Chapters 26, 47, and 48](#)), we address clinical circumstances that are being seen with increasing frequency during pregnancy, including the use of laparoscopy, the evaluation and treatment of adnexal masses, issues related to obesity and bariatric surgery, and the challenges associated with cardiac and neurosurgery in pregnancy.

## MATERNAL PHYSIOLOGY

**Pregnancy-induced changes in maternal physiology and anatomy can confuse the clinical picture when evaluating the gravid patient who presents with abdominal symptoms.** Abdominal discomfort, nausea, vomiting, diarrhea, and constipation are often encountered in pregnancy in the absence of intraabdominal pathology. Furthermore, laboratory changes commonly seen as abnormal in the nonpregnant surgical patient may be normal in the gravid state. Therefore familiarity with these changes is essential when evaluating pregnant women who present with abdominal discomfort and gastrointestinal symptoms (see [Chapter 3](#)).

Pregnancy causes profound changes in cardiovascular, hematologic, and respiratory physiology. Cardiovascular adaptations to pregnancy include a significant increase in cardiac output, heart rate, and intravascular volume.<sup>2,3</sup> Because the heart rate increases by up to 15 to 20 beats/min compared with the non-gravid state, it may be difficult to determine whether a mild tachycardia is physiologic or related to an underlying pathologic condition.

Respiratory physiology is also altered in pregnancy. The gravid uterus leads to a decrease in functional residual capacity and total lung capacity. In addition, the stimulatory effect of

progesterone on respiratory drive leads to an increase in tidal volume and minute ventilation. Of note, the respiratory rate remains unchanged. As a result, pregnancy is associated with a state of relative hyperventilation and mild respiratory alkalosis.

The physical examination of the pregnant abdomen may present a unique challenge. The enlarging gravid uterus becomes an abdominal organ after 12 weeks' gestation and may displace or compress other intraabdominal organs, making localization of pain difficult. For example, progressive upward displacement of the appendix occurs, and the appendix does not return to its original position until 1 to 2 weeks postpartum.<sup>4</sup> **However, despite the altered location, the most consistent and reliable symptom in pregnant women with appendicitis remains right lower quadrant pain.**<sup>5,6</sup> Many other classic signs and symptoms of appendicitis—such as nausea, vomiting, and leukocytosis—may be normal findings in pregnancy. Similarly, physical examination findings of rebound and guarding may not be reliable indicators of intraperitoneal inflammation in pregnancy.<sup>7,8</sup> In addition, abdominal tenderness may be a sign of a pregnancy-specific complication, such as chorioamnionitis or placental abruption. Thus the evaluation of abdominal pain in pregnancy can present a challenging diagnostic dilemma.

**The gravid uterus may also limit diagnostic imaging of abdominal organs. After the first trimester, the maternal adnexa are displaced cephalad and may be difficult to image with ultrasound.** Some anatomic changes related to the growing uterus may confound the interpretation of diagnostic imaging. For example, mild to moderate hydronephrosis is commonly encountered in pregnancy secondary to compression of the distal ureters by the uterus and progesterone-induced smooth muscle relaxation. Because the incidence of both pyelonephritis and nephrolithiasis is increased in pregnancy, it is important to recognize that a degree of dilation of the upper urinary tract is often a normal finding.

Laboratory values are also altered in normal pregnancy (see Chapter 58). Maternal blood volume is increased out of proportion to the increase in red blood cell mass. This leads to a dilutional anemia of pregnancy, especially in the later stages. This physiologic anemia may be mistaken for occult blood loss in the patient being evaluated for a surgical abdomen. Pregnancy is also associated with a progressive rise in peripheral white blood cell count, with a mean value of 14,000 cells/mm<sup>3</sup> during the second trimester. This physiologic leukocytosis, in conjunction with tachycardia and anemia, may confound the clinical picture and lead to an incorrect diagnosis. Other laboratory values—such as D-dimer, serum creatinine, and alkaline phosphatase—are significantly altered in pregnancy, which limits their role in the diagnostic evaluation of the pregnant patient.

These significant changes in normal maternal physiology and diagnostic evaluation can complicate the evaluation of the pregnant patient who presents with concerning symptoms. The utmost vigilance is necessary to identify true pathology and arrive at the correct diagnosis in a timely fashion so that the appropriate management can be implemented.

## DIAGNOSTIC IMAGING

A common concern that arises when evaluating a pregnant woman is the safety of diagnostic radiologic tests. When considering the potential risks related to imaging, it is important to balance any potential for harm against the significant risks associated with an erroneous or delayed diagnosis. It is important to

**TABLE 25-1** FETAL EFFECTS OF RADIATION EXPOSURE BY GESTATIONAL AGE

| GESTATIONAL AGE (FROM LMP)                | ADVERSE EFFECT                                 | ESTIMATED MINIMUM RADIATION DOSE |
|---|--|----------------------------------|
| Weeks 3-4 (first 2 weeks post-conception) | Embryonal demise (all or none)                 | 5-20 cGy                         |
| Weeks 5-8                                 | Death, congenital anomalies, IUGR              | 20-50 cGy                        |
| Weeks 9-15*                               | IUGR, microcephaly, severe mental retardation† | 6-50 cGy                         |
| Weeks 16-25                               | Mental retardation                             | 25-150 cGy                       |

IUGR, intrauterine growth restriction; LMP, last menstrual period.

recognize that failure to accurately diagnose a serious condition in a timely manner can cause significant harm to the woman and her fetus.

## Ionizing Radiation

**The overwhelming concern related to diagnostic imaging is exposure of the developing fetus to ionizing radiation. The critical factors that determine the risk to the fetus are the dose of radiation to which the fetus is exposed and the gestational age at the time of the exposure (Table 25-1; see Chapter 8).** Very early in gestation, within the first 2 weeks of conception, any significant cell damage caused by radiation is generally believed to result in miscarriage. This is believed to be an “all or none” phenomenon; that is, if the fetus remains viable after this early exposure, no adverse effects are expected. Radiation doses greater than 50 to 100 mGy (5 to 10 rad [1 mGy = 0.1 rad]) are likely necessary to cause embryonic death. Postconception weeks 2 through 8 are particularly sensitive to teratogenicity because this is the period of organogenesis. At this stage, the embryo is more resistant to radiation-induced death, and doses of more than 250 to 500 mGy (25 to 50 rad) are necessary to cause fetal demise.<sup>9,10</sup>

The fetal central nervous system is sensitive to radiation damage between 8 and 25 weeks and particularly during weeks 8 to 15 because this is a period of rapid neuronal development. However, increasingly high doses of radiation are necessary to result in any significant damage. After 25 weeks, the fetus is fairly resistant to radiation-induced abnormalities.<sup>9,10</sup>

In addition to teratogenic risk, a concern remains for potential carcinogenic effects of ionizing radiation to the developing fetus. Some authors have estimated that the incidence of childhood leukemia and other cancers may increase by about 0.06% from baseline with each centigray of exposure.<sup>11</sup> Given the low background risk, diagnostic doses of radiation do not appear to significantly increase the absolute risk to the fetus.<sup>9,12</sup> Also, the causative link between fetal exposure to diagnostic radiation and childhood leukemia has been called into question.<sup>9</sup>

Table 25-2 shows the estimated doses of fetal radiation exposure from various commonly used diagnostic imaging examinations.<sup>12-14</sup> It is important to note that the amount of

**TABLE 25-2** ESTIMATED FETAL EXPOSURE TO RADIATION FROM COMMON DIAGNOSTIC RADIOLOGIC STUDIES

\*Fetal dose can vary significantly based on a variety of patient and imaging parameters. If necessary, more precise estimates can be obtained through consultation with a radiation safety officer or radiation physicist.  
CT, computed tomography.

radiation exposure from any of these diagnostic studies is well below the dose threshold for teratogenic risk. **Therefore when evaluating a pregnant woman who presents with significant symptoms, the patient should be reassured that the radiation exposure to the fetus from diagnostic imaging does not confer a significant risk for fetal harm.**<sup>15,16</sup> It is important for the clinician to be familiar with the relative radiation doses delivered by commonly ordered tests because this information may aid in the decision to choose one modality over another. When clinically appropriate, consideration should be given to other diagnostic modalities, such as ultrasound or magnetic resonance imaging (MRI), that do not involve ionizing radiation. The general principle of **ALARA** (as low as reasonably achievable) applies to both mother and baby. Optimization of computed tomography (CT) scan protocols, appropriate shielding, and judicious use of radiation-based imaging remains an important principle.

Although much attention is given to potential risks of fetal exposure, it is thought that the pregnant woman may have an increased sensitivity to radiation compared with other adults. For example, when evaluating a pregnant woman for a suspected pulmonary embolus, current recommendations often favor a ventilation-perfusion study over a CT scan in patients with normal chest radiographs. Despite similarly low fetal radiation exposures, the exposure to the maternal breasts and lungs is significantly higher with a CT scan.<sup>17</sup> **Therefore, although patients should be counseled that no single diagnostic test should be considered harmful to the fetus, justification of the need for imaging should be confirmed with respect to maternal benefit.**

Fluoroscopy, which uses real-time radiography, has been increasingly used in numerous diagnostic and therapeutic procedures. For example, cardiovascular comorbidities are increasingly common in pregnancy, and diagnostic cardiac catheterization, electrophysiology studies, ablation procedures, and cardiac valve interventions all use fluoroscopic guidance. The absolute fetal exposure varies greatly among procedures, but most can be safely performed during pregnancy.<sup>18</sup> Numerous

variables can be controlled for in order to limit the maternal and fetal exposure to radiation and to comply with the ALARA principle during pregnancy.<sup>19</sup>

Overall, the use of diagnostic radiation in pregnant women requires adequate patient counseling to allay concerns of fetal harm and to balance any small potential risk against the need to arrive at an accurate and timely diagnosis. According to the American College of Obstetricians and Gynecologists (ACOG), “Women should be counseled that x-ray exposure from a single diagnostic procedure does not result in harmful fetal effects. **Specifically, exposure to less than 50 mGy (5 rads) has not been associated with an increase in fetal anomalies or pregnancy loss.**”<sup>12</sup>

## Ultrasound

Ultrasound remains the initial imaging modality of choice in the evaluation of the pregnant woman who presents with acute abdominal pain. Ultrasound involves the use of sound waves and is not a form of ionizing radiation. Although ultrasound does have the potential to transfer energy to the tissues being imaged,<sup>20</sup> no confirmed adverse fetal effects of diagnostic ultrasound procedures have been reported. Nonetheless, attention should be given to the thermal and mechanical indices in pregnancy. **Overall, the safety and versatility of ultrasonography makes it the first-line diagnostic tool during pregnancy whenever appropriate to address the clinical question at hand.**

## Magnetic Resonance Imaging

There are numerous advantages to MRI use during pregnancy. **Like ultrasound, MRI does not use ionizing radiation, and no harmful effects to the mother or fetus have been reported.** In recent years, the use of MRI has expanded greatly as the image quality and availability have increased. For example, MRI has proved useful for evaluation of pathologies such as adrenal tumors, uterine and ovarian masses, gastrointestinal lesions, and retroperitoneal space evaluation while avoiding the radiation exposure associated with CT scanning.<sup>21</sup>

## Contrast in Pregnancy

Commonly used radiocontrast, such as low-osmolality iodinated contrast media, is known to cross the placenta and be excreted in the fetal urine. Overall, the small quantities and transient exposure is not believed to have any teratogenic effects on the fetus. Theoretic effects on fetal thyroid function have not been observed using clinical doses, and no specific neonatal surveillance is warranted for fetuses exposed to these agents in pregnancy.<sup>22</sup>

No known adverse effects have been observed using gadolinium-based contrast in pregnancy. In addition, the limited data from exposed pregnancies have not revealed any proven harm; therefore gadolinium can be considered in clinical scenarios where the potential exists for significant benefit to the patient or fetus that outweighs the theoretic harms. However, given that gadolinium can concentrate in the amniotic fluid with a potentially long half-life, current recommendations do not support routine use of gadolinium in pregnancy.<sup>22</sup>

## ANESTHESIA DURING NONOBSTETRIC SURGERY

When anesthesia is required during pregnancy, the concern for possible adverse effects exists. However, it is also important to

consider the physiologic changes of pregnancy that affect the delivery of safe and effective anesthesia.

### Anesthesia and Teratogenicity

As is the case when examining the potential teratogenicity of any prenatal exposure, much of the data are limited to retrospective information from case series and registries. However, because prospective research focused on the teratogenicity of a medication is not ethically or logistically feasible, patients must be counseled based on the existing data, with acknowledgment of the inherent limitations.

Several early studies raised the possibility that exposure to anesthesia in the first trimester may be associated with an increased risk for central nervous system malformations.<sup>23,24</sup> However, the methodologies used to arrive at these conclusions have been challenged and are not supported by subsequent studies.<sup>25</sup>

**Most studies have been reassuring and have concluded that a significant risk for congenital malformations is unlikely when surgery is performed during the first trimester.**<sup>25,26</sup> For example, Mazze and Kallen<sup>26</sup> described 5405 women from the Swedish Birth Registry who underwent nonobstetric surgery during pregnancy, 40% of which occurred during the first trimester. They found no significant difference in the rate of congenital malformations compared with women who had no exposure to surgery during pregnancy. Furthermore, a more recent systematic review of the literature identified more than 12,000 pregnancies exposed to nonobstetric surgery and reported an overall 2% incidence of congenital malformations, 3.9% when surgery occurred in the first trimester.<sup>27</sup> Although no control group was available in this review, the observed rate of malformations falls within the expected range in the general population. Whereas the best available data support the lack of a significantly increased risk for malformations among pregnancies exposed to nonobstetric surgery and anesthesia, **it may be preferable to defer most surgical interventions until the second trimester, when the theoretic risk of teratogenicity—as well as the established risk of spontaneous miscarriage—is further decreased.**

### Anesthesia and Pregnancy Physiology

As discussed earlier (see Chapter 16), many significant physiologic changes occur in pregnancy that can have a profound impact on the delivery of safe and effective anesthesia in pregnancy. For example, several physiologic changes contribute to the increased risk for aspiration in pregnant women who undergo general anesthesia. Gastric emptying time is prolonged in pregnancy, especially in the third trimester and in obese women.<sup>28</sup> In addition, progesterone-mediated diminished tone is present at the gastroesophageal junction. **Therefore strategies to decrease the risk for aspiration are essential, such as preoperative fasting, antacid prophylaxis (e.g., 30 mL of sodium citrate), and airway protection.** In some situations, administration of a histamine 2 ( $H_2$ ) blocker or a gastric motility agent such as metoclopramide, or both, should be considered as well.

Oropharyngeal edema and narrowing of the opening of the glottis are common in pregnancy and can affect the safe access to the airway in a pregnant patient, especially in an emergency situation. **The Mallampati airway examination is often used to assess the airway and predict the degree of difficulty of intubation, with progression from low-risk airways (class I) to high-risk airways (class IV; Fig. 25-1).**<sup>29</sup> A 34% increase in

**FIG 25-1** Mallampati airway classifications with corresponding laryngoscopic view of the vocal cords. (Modified from Hughes SC, Levinson, G, Rosen MA [eds]. *Shnider & Levinson's Anesthesia for Obstetrics*, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2002.)

**the frequency of class IV Mallampati airways is seen at term compared with the first trimester.<sup>30</sup> These changes are more pronounced in the third trimester, in obese women, and in women with preeclampsia.**

One of the most significant physiologic phenomena in pregnancy is related to aortocaval compression by the gravid uterus, especially in the supine position. In the latter half of pregnancy, this leads to a decreased preload and cardiac output with a resultant decrease in uterine and placental perfusion. In addition, venous stasis in the lower extremities increases the risk for venous thromboembolism. Thus it is essential for pregnant women who undergo a surgical procedure to be positioned with a lateral tilt to relieve some of this compression by displacing the gravid uterus to the side. This can often be accomplished by placing a wedge under the right hip.

### NONOBSTETRIC SURGERY AND PREGNANCY OUTCOME

The largest study to explore pregnancy outcomes in women undergoing nonobstetric surgery was based on the Swedish Birth Registry. Mazze and Kallen<sup>26</sup> identified 5405 nonobstetric surgeries from more than 720,000 births between 1973 and 1981, a prevalence of 0.75%. The nonobstetric surgeries included 1331 abdominal surgeries, 1008 genitourinary or gynecologic procedures, and 868 laparoscopies. Out of 2929 procedures (54% of all cases) performed under general anesthesia, the type of anesthesia was documented for only 68% of cases. The authors found no increased risk for congenital malformations or stillbirth compared with a control population. However, the rates of low birthweight (<2500 g) and very low birthweight (<1500 g) were significantly higher in the surgical group, with odds ratios of 2.0 and 2.2, respectively. The authors noted that the observed reduced birthweight was due to both fetal growth restriction and prematurity. The incidence of preterm birth was increased in the surgery group (7.5% vs. 5.1%;  $P < .001$ ). Another significant finding was an increased rate of neonatal death within 7 days (incidence, 1%; odds ratio [OR], 2.1; 95% confidence interval [CI], 1.6 to 2.7). However, it is difficult to separate the multiple confounding factors that could potentially play a causative role in the development of these adverse

pregnancy outcomes, such as type of operation, anesthesia method, and underlying indication for surgery. Because the authors did not identify a specific surgical procedure or mode of anesthesia that had a significantly increased rate of adverse outcome, they concluded that the underlying condition that led to the surgery likely played an important role in determining the outcome.

Cohen-Kerem and coworkers<sup>27</sup> reviewed the literature from 1966 to 2002 and identified 12,452 pregnancies that underwent nonobstetric surgery. The incidence of major birth defects was 2%, and the rate of prematurity was 8.2%. Overall, they found that surgical intervention led to delivery of the fetus in 3.5% of cases, although they could not differentiate whether this was caused by the procedure itself or the underlying condition that necessitated surgical intervention. Although the lack of matched controls limits the interpretation of their data, it does support the conclusion that most pregnancies that undergo nonobstetric surgery will have favorable outcomes.

**Taken together, it would seem reasonable to reassure pregnant patients faced with the need for surgery in pregnancy that the rate of adverse perinatal outcome is relatively low. In addition, although the risk for low birthweight, preterm birth, and neonatal demise may be increased, these risks may be associated with complications related to the underlying indication for surgery.** In cases of semielective surgery, such as for an enlarged adnexal mass or refractory biliary colic, it is still prudent to defer surgery until after the first trimester, when the risk for spontaneous miscarriage is decreased and the theoretic concerns of teratogenicity are avoided. Similarly, surgery in the late-second and third trimesters may affect intraoperative visibility and lead to an increased risk for preterm birth. Therefore **the early second trimester is considered the optimal time for elective surgery that cannot be safely deferred until after the pregnancy.**

## FETAL MONITORING

The question of whether continuous intraoperative fetal monitoring should be used when a pregnant woman requires nonobstetric surgical intervention is a matter of debate.<sup>31,32</sup> Factors in favor of monitoring include the potential for changes in fetal heart rate (FHR) and uterine activity during the surgery, the potential for fetal well-being to serve as an indicator of maternal status, and the potential to intervene in a case of persistently nonreassuring fetal status. On the other hand, interpretation of the FHR tracing may be particularly unreliable in the very preterm fetus. In addition, the changes in FHR tracing occasionally seen—such as a decreased variability and lower baseline heart rate—are often transient and are not necessarily an indication of fetal compromise. Thus continuous intraoperative fetal monitoring may lead to an unnecessary emergent cesarean delivery with significant risk for both maternal and neonatal morbidity. Furthermore, performing an emergent cesarean delivery can significantly complicate the nonobstetric surgery being conducted and has the potential to significantly increase maternal morbidity. A recent survey of the Association of Professors of Gynecology and Obstetrics (APGO) found that most respondents do not routinely perform intraoperative fetal monitoring but simply monitor the fetus before and after the procedure.<sup>33</sup>

**Accordingly, the American College of Obstetricians and Gynecologists (ACOG) recommends that at a minimum, fetal monitoring should be conducted before and after the**

**procedure in cases with a viable fetus. However, in select cases, intraoperative monitoring may be performed after consultation with an obstetrician who can properly counsel the pregnant woman facing surgery and individualize the decision based on factors such as gestational age, type of surgery, and facilities available.**<sup>34,35</sup>

## LAPAROSCOPY IN PREGNANCY

Although the safety of laparoscopy in pregnancy is widely accepted, several important considerations specific to pregnancy must be considered. Pneumoperitoneum further decreases functional residual capacity and can cause ventilation-perfusion mismatch and hypercapnia. These effects can be further exacerbated by Trendelenburg positioning. Bhavani-Shankar and colleagues<sup>36</sup> prospectively demonstrated that end-tidal carbon dioxide pressures correlate well with arterial PCO<sub>2</sub> and that maintaining an end-tidal CO<sub>2</sub> of about 32 mm Hg and a systolic blood pressure within 20% of baseline was effective in preventing respiratory acidosis during laparoscopy. Once again, a left lateral maternal position is essential to displace the gravid uterus and helps to relieve aortocaval compression and also optimizes cardiac output.

**The intraabdominal pressure required to obtain adequate laparoscopic visualization during surgery can have significant physiologic effects for both the pregnant woman and the fetus.** Early animal studies showed that cardiac output decreases with increasing intraperitoneal pressure. Reedy and colleagues<sup>37</sup> performed laparoscopic baboon studies and compared intraabdominal pressures of 10 and 20 mm Hg. At the higher pressure, a significant increase was seen in pulmonary capillary wedge pressure, central venous pressure, pulmonary artery pressure, and peak airway pressure. In addition, a significant increase in ventilator rate was required to maintain oxygenation and end-tidal CO<sub>2</sub>. A pressure of 20 mm Hg was also associated with an increased risk for respiratory acidosis. **Similar studies have shown significant changes in both maternal and fetal physiology at pressures greater than 15 mm Hg.**<sup>36</sup> Therefore although lower insufflation pressures may lead to limited surgical visualization, it is important to try and keep insufflation pressures below 15 mm Hg. If higher pressures are required to safely complete the procedure, it would be advisable to periodically release the pneumoperitoneum to allow for physiologic recovery. This is particularly important in obese patients, who often require higher pressures to counteract the weight of the anterior abdominal wall. Although various techniques, such as gasless laparoscopy<sup>38,39</sup> and mechanical lift retractors,<sup>40</sup> have been proposed to avoid high intraabdominal pressures during laparoscopy, they are not widely utilized.

## Laparoscopic Entry Techniques in Pregnancy

Although the conventional entry approach has been using a Veress needle, a variety of other closed and open techniques have been proposed in an effort to decrease the incidence of entry complications in nonobstetric laparoscopic procedures. However, review of the literature fails to support a significant difference in complications between the various approaches.<sup>41,42</sup> Nonetheless, accidental placement of a Veress needle into a 21-week uterus with subsequent pneumoamnion and pregnancy loss has been reported.<sup>43</sup> Thus it may be prudent to use an open approach in the latter half of pregnancy. The Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) guidelines support laparoscopic entry with any technique provided that the location

of the entry is adjusted to account for the gravid uterus (Box 25-1).<sup>44</sup> Procedures performed in the later stages of pregnancy may require a left upper quadrant insertion of the initial trocar. The upper limit of gestational age up to which a laparoscopic approach can be performed safely in pregnancy has not been determined. Concerns related to the space occupied by the gravid uterus have led some to recommend that laparoscopy be avoided in the third trimester.<sup>45</sup> However, current practice guidelines do not impose such a limitation, and the decision regarding the optimal surgical approach should therefore be individualized.<sup>44</sup>

### Laparoscopy and Pregnancy Outcome

Laparoscopy has become increasingly prevalent in both pregnant and nonpregnant populations. The minimally invasive nature of laparoscopy allows for an easier recovery with less pain, earlier return of bowel function, and shorter hospital stay. Furthermore, earlier postoperative ambulation helps reduce the potential for venous stasis and deep venous thrombosis, which is especially important in a pregnant population already at increased risk for such complications.

The safety of laparoscopy in pregnancy is supported by the analysis of the Swedish Birth Registry. Reedy and coworkers<sup>46</sup> compared fetal outcomes of 2181 pregnancies that underwent laparoscopy between 4 and 20 weeks' gestation to 1522 pregnancies that underwent laparotomy. No differences were noted in any of the fetal outcomes considered. Several other series have further supported the safety of laparoscopy in pregnancy.<sup>47-52</sup> Nevertheless, several reports and case series have been published that raise concerns over the possible increased risk for adverse outcomes when laparoscopy is performed during pregnancy.<sup>53</sup>

Walsh and coworkers<sup>54</sup> performed a systematic review of the literature and concluded that an open appendectomy may be safer than a laparoscopic approach when managing appendicitis. This conclusion was based on the 5.8% incidence of fetal loss following a laparoscopic appendectomy compared with a 3.1% incidence reported after open appendectomy ( $P = .001$ ). However, multiple potential confounders—such as severity of the appendicitis, gestational age at the time of surgery, background rate of miscarriage, and reporting bias—may have significantly affected their results. Furthermore, open appendectomy was associated with a significant increase in preterm delivery (8.1% vs. 2.1%;  $P < .0001$ ). **In summary, no definitive data support a significantly increased risk for adverse pregnancy outcome using the laparoscopic approach for appendectomy during pregnancy.**

McGory and colleagues<sup>55</sup> identified more than 3000 cases of appendectomy in pregnancy using the California Inpatient File and found that after controlling for several potential confounders, laparoscopic appendectomy was associated with an increased risk for fetal loss compared with open appendectomy (OR, 2.31; 95% CI, 1.51 to 3.55). However, the gestational age at the time of surgery was not available. Furthermore, they defined *fetal loss* as the presence of a diagnosis code for spontaneous abortion or intrauterine death or of a procedure code for a dilation and curettage associated with the same hospital admission as the appendectomy. The limitations and potential inaccuracies of this method of data collection must be considered.

Finally, in the largest review and meta-analysis to date of laparoscopic versus open appendectomy in pregnancy, which involved a review of 11 studies with a total of 3145 patients, the rate of fetal loss with the laparoscopic approach was almost two

#### BOX 25-1 RELEVANT GUIDELINES FOR LAPAROSCOPY IN PREGNANCY FROM THE SOCIETY OF AMERICAN GASTROINTESTINAL AND ENDOSCOPIC SURGEONS

- Diagnostic laparoscopy is safe and effective when used selectively in the workup and treatment of acute abdominal processes in pregnancy.
- Laparoscopic treatment of acute abdominal processes has the same indications in pregnant and nonpregnant patients.
- Laparoscopy can be safely performed during any trimester of pregnancy.
- Gravid patients should be placed in the left lateral recumbent position to minimize compression of the vena cava and the aorta.
- Initial access can be safely accomplished with open (Hassan), Veress needle, or optical trocar technique if the location is adjusted according to fundal height, previous incisions, and experience of the surgeon.
- CO<sub>2</sub> insufflation of 10 to 15 mm Hg can be safely used for laparoscopy in the pregnant patient. Intraabdominal pressure should be sufficient to allow for adequate visualization.
- Intraoperative CO<sub>2</sub> monitoring by capnography should be used during laparoscopy in the pregnant patient.
- Intraoperative and postoperative pneumatic compression devices and early postoperative ambulation are recommended prophylaxis for deep venous thrombosis in the gravid patient.
- Laparoscopic cholecystectomy is the treatment of choice in the pregnant patient with gallbladder disease regardless of trimester.
- Laparoscopic appendectomy may be performed safely in pregnant patients with suspicion of appendicitis.
- Laparoscopic adrenalectomy, nephrectomy, and splenectomy are safe procedures in pregnant patients when indicated, and standard precautions are taken.
- Laparoscopy is safe and effective treatment in gravid patients with symptomatic adnexal cystic masses. Observation is acceptable for all other adnexal cystic lesions provided ultrasound is not worrisome for malignancy and tumor markers are normal. Initial observation is warranted for most adnexal cystic lesions smaller than 6 cm.
- Laparoscopy is recommended for both diagnosis and treatment of adnexal torsion unless clinical severity warrants laparotomy.
- Fetal heart monitoring should occur before and after operation in the setting of urgent abdominal surgery during pregnancy.
- Obstetric consultation can be obtained before and after operation based on the acuteness of the patient's disease, gestational age, and availability of the consultant.
- Tocolytics should not be used prophylactically but should be considered perioperatively, in coordination with obstetric consultation, when signs of preterm labor are present.

**FIG 25-2** Meta-analysis of pregnancy outcome. Fetal loss after laparoscopic appendectomy (LA) versus open appendectomy (OA). *CI*, confidence interval. (From Wilasrusmee C, Sukrat B, McEvoy M, Attia J, Thakkinstian A. Systematic review and meta-analysis of safety of laparoscopic versus open appendectomy for suspected appendicitis in pregnancy. *Br J Surg*. 2012;99:1470-1478.)

times greater than in cases of open appendectomy. No significant differences were observed between the groups in the rate of preterm delivery, Apgar score, or wound infection after surgery (Fig. 25-2). Although the results of this meta-analysis should be interpreted with caution because most studies reviewed were observational, the significantly higher rate of fetal loss associated with laparoscopy warrants caution and further study.<sup>56</sup> **In conclusion, if a laparoscopic procedure is considered in pregnancy, the SAGES practice guidelines should be used until further recommendations are made by national societies based on new data** (see Table 24-3).<sup>44</sup>

## ADNEXAL MASSES IN PREGNANCY

The increased use of prenatal ultrasound, the high prevalence of physiologic cysts related to ovulation, and the use of ovulation induction in the treatment of infertility make the evaluation of an adnexal mass in pregnancy commonplace in obstetric practice. The reported prevalence of adnexal masses in pregnancy ranges from less than 1% to 25% and is dependent on a variety of factors, such as gestational age and the criteria used to characterize an adnexal finding as a mass rather than a simple ovarian follicle.<sup>57</sup>

**Fortunately, most adnexal masses encountered in pregnancy are benign and spontaneously resolve during the course of pregnancy. In fact, rates of spontaneous resolution have been reported to be as high as 72% to 96%.<sup>57</sup>** Most of these cysts are simple follicular cysts—thin-walled, unilocular cysts that contain anechoic fluid. Alternatively, a corpus luteum cyst may develop that contains varying amounts of hemorrhage within the thick-walled and unilocular cyst (Fig. 25-3). These are also benign and transient findings, which generally resolve by the second trimester and rarely require further surveillance.

In women who have undergone ovulation induction for the treatment of infertility, thin-walled multicystic ovaries that contain anechoic fluid and lack internal septations or papillae may be encountered. These usually resolve during the course of the pregnancy, although they can cause patient discomfort if they are particularly enlarged (see Fig. 25-3). *Theca lutein cysts* are multicystic ovarian masses related to significant elevations of  $\beta$ -human chorionic gonadotropin, such as in gestational trophoblastic disease and multiple gestation. They appear as thick-walled multicystic masses with no papillae. Although they generally contain anechoic fluid, internal hemorrhage can occur, especially in large masses (see Fig. 25-3). These usually persist throughout the gestation, although they generally resolve on their own postpartum (see Fig. 25-3, E).

Although most benign masses encountered in pregnancy are physiologically related to the gestation, it is not uncommon to incidentally detect other benign ovarian masses, such as mature cystic teratomas (i.e., dermoid cysts), cystadenomas, or endometriomas. *Dermoids* can contain a variety of tissue types and have a variable appearance on ultrasound. Often, a hyperechoic area known as a *Rokitansky tubercle* can help confirm the nature of these masses, which are benign and persist throughout the pregnancy. Fortunately, malignant degeneration is exceedingly rare, especially in women of childbearing age, therefore increased surveillance and surgical intervention are rarely necessary in an asymptomatic woman. As with all sizable masses, the patient should be counseled about the risk for ovarian torsion and must be educated about the typical presenting symptoms. *Cystadenomas* often contain thin internal septations and may exhibit a small mural nodule (Fig. 25-4, B). These masses are generally hypovascular and may contain anechoic fluid (serous cystadenomas) or fluid with low-level echoes (mucinous cystadenomas (see Fig. 25-4, C). *Endometriomas*, benign ovarian masses that

**FIG 25-3** **A** and **B**, Variable appearance of a corpus luteum. The layered echogenicity represents hemorrhage within the cyst. Circumferential vascularity on power Doppler imaging is a typical finding. **C**, A theca lutein cyst is seen as a thick-walled and multiloculated cyst with anechoic fluid. **D**, Typical appearance of a stimulated ovary with multiple follicular cysts after infertility treatment. **E**, Bilateral theca lutein cysts at time of cesarean delivery. (**D**, From Schwartz N, Timor-Tritsch IE, Wang E. Adnexal masses in pregnancy. *Clin Obstet Gynecol*. 2009;52:570-585.)

**FIG 25-4** **A**, Dermoid cyst with heterogeneous contents and a typical Rokitansky nodule (arrow). **B**, Benign serous cystadenoma presenting as an anechoic cyst with a small mural nodule. **C**, This cystic mass with thin internal septations was shown to be a mucinous cystadenoma. **D**, Endometriomas often present as cystic masses that contain homogeneous low-level echoes. (From Schwartz N, Timor-Tritsch IE, Wang E. Adnexal masses in pregnancy. *Clin Obstet Gynecol*. 2009;52:570-585.)

contain ectopic endometrial tissue, most often display a characteristic appearance with diffuse, low-level echoes (see Fig. 25-4, D). Affected patients often have a history of endometriosis or dysmenorrhea. These masses generally persist throughout pregnancy without a significant change in size. Occasionally, an endometrioma can undergo decidualization during pregnancy as the endometrial tissue responds to the hormonal changes. In these cases, the mass may appear heterogeneous with increased vascularization and papillary projections, sharing many of the sonographic features of an ovarian malignancy (Fig. 25-5). A known history of an endometrioma before pregnancy may be helpful in differentiating this mass from a malignancy, but close surveillance and thorough patient counseling are necessary.

**Although most adnexal masses encountered in pregnancy are benign, the rare possibility of malignancy should not be discounted. In fact, between 1% and 3% of masses removed in pregnancy are found to be malignant.<sup>58,59</sup>** However, these data are confounded by the indication for surgery and likely represent a high-risk group of patients. In the largest series of adnexal masses in pregnancy, Leiserowitz and coworkers<sup>58</sup> identified 9375 adnexal masses associated with pregnancy, of which

87 (0.93%) were found to be malignant. In their population, the incidence of ovarian cancer was 1 per 56,000 deliveries. An additional 115 cases (1.25%) were found to be borderline tumors. Taken together, the prevalence of clinically significant ovarian tumors was 1 in 23,800 deliveries. In addition to being extremely rare, ovarian cancer in pregnancy is associated with more favorable characteristics, such as lower stage and a higher proportion of germ cell tumors (see Chapter 50).<sup>58,59</sup> This is likely because of the younger patient population and the incidental detection of these masses in asymptomatic women.

Although other imaging modalities, such as MRI, may be helpful in some cases—for example, when a thorough evaluation of the mass is difficult because of the gravid uterus—ultrasound examination remains the diagnostic tool of choice when evaluating the adnexa. **Several sonographic features have been associated with an increased risk for malignancy, such as size greater than 7 cm, heterogeneity with solid and cystic components, papillary excrescences or mural nodules, thick internal septations, irregular borders, increased vascularity, and low-resistance blood flow.** However, the specificity of any of these findings remains limited, and no single high-risk feature

**FIG 25-5** **A** and **B**, Complex and heterogeneous mass with thickened septations and increased vascularity in a patient with a known endometrioma. The sonographic features were suspicious for malignancy, which led to surgical excision in the second trimester. Pathology showed it to be a decidualized endometrioma. **C** and **D**, A similar-appearing heterogeneous mass with increased vascularity. This was also excised and was shown to be a stage I cystadenocarcinoma. (From Schwartz N, Timor-Tritsch IE, Wang E. Adnexal masses in pregnancy. *Clin Obstet Gynecol*. 2009;52:570-585.)

is pathognomonic for malignancy. For example, in a retrospective review of 126 pregnancies with a persistent ovarian mass of 5 cm or more, 69 of which underwent surgical excision during or after pregnancy, no cases of malignancy were reported.<sup>60</sup> Rather, overall pattern recognition by experienced sonographers is likely the most accurate diagnostic approach.<sup>61-63</sup> Surgical resection may become necessary when the degree of suspicion is high.

**Another potential complication of an adnexal mass is ovarian torsion, which is estimated to occur in up to 7% of adnexal masses in pregnancy; 60% of torsions occur in the first trimester.**<sup>64,65</sup> Concern for this complication often leads to the recommendation to electively resect masses in pregnancy. However, Lee and colleagues<sup>64</sup> compared 36 cases of emergency surgery for torsion in pregnancy with 53 cases of electively removed adnexal masses and found no difference in pregnancy outcomes, which indicates that reserving intervention for acute torsion may not necessarily put the patient at increased risk for complications. Thus because nonobstetric surgery in pregnancy is not without risk, preventive surgical intervention may not be

appropriate in most cases. **Rather, patients with persistent adnexal masses in pregnancy should be counseled about the signs and symptoms of ovarian torsion, with surgical resection reserved for symptomatic patients and those in whom there is a suspicion of malignancy.**

When ovarian torsion is confirmed during surgery, a question exists as to whether detorsion plays a role in ovarian conservation when no extensive necrosis is apparent (Fig. 25-6). Some evidence lends support to this approach in nonpregnant women.<sup>66-68</sup> **Although pregnancy data are more limited, several reports are available of successful management of ovarian torsion in pregnancy with preservation of the ovary.**<sup>69-71</sup> However, a case of ovarian necrosis that required a repeat operation 2 days after a detorsion in pregnancy has also been noted.<sup>72</sup> In addition, the potential for recurrence must be taken into account when deciding to preserve the twisted ovary. Some authors recommend performing an oophoropexy to stabilize the ovary in the hope of minimizing recurrence, although this cannot be recommended as a routine approach. If a discrete ovarian cyst or mass is noted, excision of the mass should reduce

**FIG 25-6** Intraoperative photograph of an ovarian torsion at 11 weeks' gestation. A 9-cm adnexal mass (upper left) was torsed around an edematous vascular pedicle. The mass was removed by laparotomy because of concern for necrosis of the fimbria (asterisk). The normal-appearing left ovary and tube are seen on the right; the gravid uterus is in the center. Pathology confirmed a dermoid cyst with areas of necrosis. (Courtesy Stephanie Jean, MD.)

the chance of recurrence, especially if there is any concern for potential malignancy. **Ultimately, the decision to untwist and preserve the torsed ovary should be individualized based on intraoperative findings and risk factors for recurrence.**

Overall, when presented with an adnexal mass that requires surgical resection, the decision to proceed with laparoscopy or laparotomy is based on the same approach taken outside of pregnancy. Laparoscopy has been shown to be a safe and effective method to remove adnexal masses in pregnancy,<sup>73-75</sup> although laparotomy may be preferred in certain scenarios, such as in patients with prior abdominal surgeries or large masses and in those who present late in pregnancy, when visualization may be compromised. In general, although some have reported the safe aspiration of large simple cysts in pregnancy, this method runs the risk for leakage of cyst contents into the abdomen, which would be especially harmful if an unsuspected malignancy were present. In addition, cytologic analysis of the cyst contents may not be an accurate method to determine the pathology of the mass.<sup>76</sup> For this reason, cyst aspiration cannot be considered a standard approach for managing adnexal masses in pregnancy. Regardless of the surgical approach, it is important to remember that prior to 8 weeks' gestation, the corpus luteum is the primary source of progesterone for the pregnancy. Therefore progesterone supplementation should be administered to women who undergo adnexal surgery before 8 to 10 weeks' gestation.

## OBESITY, BARIATRIC SURGERY, AND PREGNANCY

Maternal obesity is an increasingly common condition in pregnancy and is discussed in greater detail in [Chapter 41](#). In 2010, over a third of adults in the United States were considered obese.<sup>77</sup> Obesity is associated with an increased risk for numerous significant medical comorbidities that include diabetes, hypertension, cardiac disease, and respiratory conditions. Furthermore, maternal obesity is an independent risk factor for

several pregnancy-related complications that include gestational diabetes, preeclampsia, cesarean delivery, infectious morbidity, and thromboembolism. An increase has also been noted in fetal complications such as congenital malformations, macrosomia, and stillbirth.<sup>78-80</sup> **Bariatric surgery is an increasingly common and effective treatment for obesity and has been associated with a significant improvement in overall health and a reduction in adverse pregnancy outcomes.**<sup>81,82</sup> For this discussion, it is important to review the special considerations related to surgery in the obese pregnant patient as well as the implications of prior bariatric surgery in pregnancy.

Obesity presents unique management challenges in the perioperative period and is a risk factor for a multitude of adverse outcomes related to both general anesthesia and surgery.<sup>80-86</sup> Intubation is often more difficult in obese patients, and preoperative assessment of the airway using the Mallampati classification is essential.<sup>87-89</sup> Furthermore, gestational changes in respiratory physiology, such as a decreased functional residual capacity and increased work of breathing, can lead to impaired ventilation and an increase in adverse respiratory events in obese pregnant patients who undergo anesthesia. In addition, the aortocaval compression seen in pregnancy may be exacerbated by maternal body habitus. For these reasons, many authors recommend various maneuvers, such as adjusting patient positioning and preoperative hyperoxygenation, when caring for the obese patient.

Another consideration unique to obese patients undergoing anesthesia is related to the altered pharmacokinetics of anesthetic drugs and to the volume of distribution and concentration of lipophilic drugs in the adipose tissues. Therefore care must be taken when dosing anesthetic agents for the obese patient and when monitoring the recovery from anesthesia after surgery.<sup>90,91</sup>

**Regional anesthesia should be considered if possible to avoid some of these risks, although the type of surgery and difficulty accomplishing regional anesthesia may not allow for this approach in some cases.**

**Obesity is also an independent risk factor for venous thromboembolism in the postoperative period; therefore early ambulation should be encouraged. Prophylaxis with pneumatic compression devices should be undertaken until full ambulation is achieved. Subcutaneous heparin should also be considered. In addition, given the increased risk for wound infection and dehiscence in obese patients, adequate antibiotic prophylaxis is recommended.**<sup>86</sup>

Significant weight loss before pregnancy is the most effective means of reducing the medical risks related to obesity, including pregnancy-related risks.<sup>81,82</sup> One of the most successful treatments for obesity is bariatric surgery, which is becoming an increasingly common procedure in the United States. Thus it is imperative for obstetric providers to be familiar with some of the unique concerns that arise in pregnant patients who have previously undergone bariatric surgery. Furthermore, clinical guidelines for the perioperative nutritional, metabolic, and non-surgical support of the bariatric surgical patient have been recently updated with a total of 74 recommendations.<sup>83</sup>

In general, bariatric surgery can be divided into *restrictive procedures*, such as gastric banding, and *malabsorptive procedures*, such as gastric bypass. Restrictive procedures are less invasive and can often be accomplished laparoscopically. This approach does not result in the dramatic weight reduction seen with malabsorptive procedures, but they are associated with a lower risk for nutrient deficiencies and other complications related to

malabsorption. The gastric band can be adjusted to lessen the degree of gastric restriction and allow for adequate food intake in pregnancy.

The most commonly performed malabsorptive procedure is the Roux-en-Y gastric bypass, in which a proximal stomach pouch is created and most of the stomach and proximal small bowel is bypassed. This often leads to rapid and significant weight loss, especially in the first 1 to 2 years. In fact, some recommend that pregnancy be delayed until 1 to 2 years after the procedure to avoid having rapid weight loss during pregnancy, and thus thorough contraception counseling is imperative.<sup>92,93</sup> Conception rates shortly after bariatric surgery appear to be increased,<sup>93,94</sup> which may be related to poor absorption of oral contraceptives, resumption of regular menstrual cycles, and inadequate contraceptive counseling. **The reduced absorptive capacity of the stomach and proximal small bowel often leads to deficiencies in several essential nutrients, including iron, vitamins B<sub>12</sub> and D, folate, and calcium. Unfortunately, long-term compliance with vitamin supplementation is poor among bariatric surgery patients.<sup>95,96</sup> Obtaining a baseline evaluation of these nutrients before conception or early in pregnancy is recommended. In addition, consultation with a nutritionist should be considered.<sup>97</sup>**

Although no evidence suggests that pregnancy increases the risk for postoperative complications related to prior bariatric surgery, these problems may occur during gestation.<sup>98-99</sup> It is important, therefore, for obstetric providers to be familiar with the possible complications so that the bariatric surgeon can be notified. Some known complications include anastomotic leaks, bowel obstruction, internal hernias, and erosion or migration of gastric bands. **Many of these complications first manifest with symptoms commonly experienced during normal pregnancy—such as nausea, vomiting, and abdominal discomfort—so the potential exists for accurate diagnosis of these complications to be delayed in a pregnant patient, and maternal deaths have been reported.<sup>100,101</sup>** Therefore clinicians should have a high degree of suspicion when these patients present with significant abdominal complaints.<sup>97</sup> Another complication that can be encountered in pregnant patients with a history of malabsorptive bariatric surgery is *dumping syndrome*, in which the consumption of simple sugars can lead to significant fluid shifts into the small intestine, causing cramping, nausea, vomiting, and diarrhea. In severe cases, the patient can become tachycardic and diaphoretic and may complain of palpitations. Consideration should be given to monitoring maternal blood glucose levels because hypoglycemia can result from the relative hyperinsulinemia observed in pregnancy. Patients sensitive to sugar intake may not tolerate the glucose load used to test for gestational diabetes. Having the patient monitor fasting and postprandial glucose levels for 1 to 2 weeks may be a reasonable screening approach in sensitive patients.<sup>102</sup>

Overall, bariatric surgery and successful weight loss may improve pregnancy outcomes by reducing some of the medical complications seen with morbid obesity. However, in the largest population-based matched cohort study done in Sweden,<sup>103</sup> bariatric surgery was associated with a greater risk for preterm birth, both spontaneous and medically indicated (OR, 1.7; 95% CI, 1.4 to 2.0) and a greater risk for infants who are small for gestational age (OR, 2.0; 95% CI, 1.5 to 2.5) compared with control patients starting pregnancy with a body mass index (BMI) below 35. This large population study did not address the reason for these differences, but a micronutrient deficiency

can be speculated to be a contributing factor. A more recent study of the Swedish Medical Birth Register of 670 pregnancies after bariatric surgery noted a decreased risk for gestational diabetes and infants large for gestational age in these patients.<sup>104</sup>

**With the increasing prevalence of surgical treatment of obesity among young women, clinicians should familiarize themselves with some of the unique concerns that arise when managing these patients during pregnancy, and they should educate and monitor such patients for potential preterm delivery and intrauterine growth restriction (IUGR).**

## CARDIAC SURGERY IN PREGNANCY

As mentioned above, cardiac comorbidities are increasingly common in pregnancy. Many diagnostic and therapeutic procedures are minimally invasive and can be safely performed in pregnancy when indicated with attention to minimization of fetal radiation exposure during fluoroscopy. However, invasive cardiac procedures that require cardiopulmonary bypass represent a unique clinical scenario because the profound changes in maternal perfusion can impact fetal oxygenation. Nonpulsatile blood flow, low perfusion pressures and pump flow, hypothermia, and acid-base disturbances are all critical factors that can affect fetal well-being. Optimizing each of these variables may help limit the fetal risk during these procedures. In fact, cardiopulmonary bypass may be a circumstance in which continuous intraoperative fetal monitoring can help optimize perfusion to the benefit of both mother and fetus.<sup>105</sup>

## NEUROSURGERY IN PREGNANCY

Neurosurgical anesthesia often involves several techniques aimed at regulating cerebral blood flow, but these may also impact uteroplacental perfusion. For example, controlled hypotension can lead to reduced placental perfusion and transient FHR abnormalities. Similarly, whereas pregnancies can usually tolerate hypothermia, hyperventilation, and diuresis, potential fetal effects cannot be disregarded.<sup>104</sup> In most cases, maternal health should be the primary focus and should supersede potential fetal effects. Nonetheless, a basic understanding of these effects can help the obstetrician guide the surgical and anesthesia teams caring for the patient.

### KEY POINTS

- ◆ Care of the pregnant surgical patient requires a multidisciplinary approach with an understanding of the physiologic changes that accompany normal pregnancy.
- ◆ Expansion of maternal blood volume during pregnancy may mask signs of maternal hemorrhage, and clinically significant blood loss can occur before hemodynamic changes are evident.
- ◆ Delay in surgical intervention can result in increased maternal and fetal morbidity and mortality, which significantly increases the risk for preterm labor and fetal loss.
- ◆ Diagnostic doses of radiation (<5 cGy) from radiographs and CT scans are unlikely to pose any significant harm to the developing fetus. MRI and ultrasound can

be safely used when appropriate to further minimize radiation exposure.

- ◆ No significant increased risk is apparent for congenital malformations in women who require nonobstetric surgery during pregnancy. Although the risk for preterm birth, low birthweight, and neonatal death may be increased, this may be due to the underlying illness rather than the surgical procedure.
- ◆ Although laparoscopy as a first approach to abdominal surgery in pregnancy seems reasonable, its safety continues to be studied. Abdominal insufflation pressures should be kept below 15 mm Hg whenever possible, and the SAGES guidelines should be followed. The use of a laparoscopic approach in the latter stages of pregnancy should be individualized based on indications and experience of the surgeon.
- ◆ Adnexal masses are commonly encountered in pregnancy, although most ovarian masses are benign. Pregnant women diagnosed with an adnexal mass should be counseled about the signs and symptoms of ovarian torsion. Surgical resection can generally be reserved for symptomatic women or for masses suspicious for malignancy.
- ◆ Data are lacking to recommend routine continuous fetal heart rate monitoring during surgery in pregnant women. In most cases, preoperative and postoperative FHR monitoring is appropriate.
- ◆ Preoperative corticosteroid administration to promote fetal lung maturity should be based on gestational age and the nature and risks of the planned surgery.
- ◆ Thromboembolic prophylaxis with pneumatic compression devices should be considered for all gravid surgical patients.
- ◆ Obesity presents unique management considerations during the perioperative period, most notably related to anesthesia risk, intraoperative risk, antibiotic prophylaxis, and thromboembolic prophylaxis. Early ambulation should be encouraged. If early ambulation is not possible, subcutaneous heparin prophylaxis should be considered.
- ◆ Bariatric surgery with subsequent weight loss may reduce the risk for medical complications in pregnancy. However, it may increase the risk for preterm delivery and intrauterine growth restriction. Women who have undergone bariatric surgery should be evaluated for nutritional deficiencies.
- ◆ The gravid patient with a history of bariatric surgery who presents with vague abdominal complaints should be critically evaluated because delay in diagnosis of internal hernias, bowel obstruction, or anastomosis leaks can often lead to catastrophic events.

## INCIDENCE OF TRAUMA IN PREGNANCY

**Because of underreporting, the actual incidence of trauma during pregnancy is unknown. However, traumatic injury has been reported to complicate 6% to 8% of all pregnancies and is the leading cause of nonobstetric maternal death.<sup>1-3</sup>**

Approximately 30,000 pregnant women in the United States sustain treatable injuries each year as a result of trauma.

Worldwide, trauma is responsible for at least 1 million deaths annually and is the leading cause of death in individuals under 40 years of age in the United States.<sup>4</sup>

The risk of maternal death is related to injury severity. In a large California database study of women hospitalized for trauma between 1991 and 1997, El Kady and colleagues<sup>5</sup> found that intraabdominal injuries are the most common type of injury leading to maternal death, and intracranial injury resulting from trauma was the second most common cause of maternal death.

In addition to risk for maternal morbidity and mortality, traumatic injuries can have significant fetal effects that include an increased risk for fetal death and other adverse outcomes.<sup>4</sup> The incidence of spontaneous abortion (SAB), preterm birth, preterm premature rupture of membranes (PPROM), uterine rupture, cesarean delivery, placental abruption, and stillbirth are all increased.

A 3-year, 16-state fetal death certificate review calculated the rate of fetal death from maternal trauma at 2.3 per 100,000 live births, and placental abruption was the leading contributing factor.<sup>6,7</sup> Based on a review of Pennsylvania fetal death certificates, it is estimated that motor vehicle crashes (MVCs) result in between 90 and 367 fetal deaths in the United States annually.<sup>6</sup>

However, because of nonstandardized reporting of fetal death or injury resulting from maternal trauma, the exact magnitude of disease burden to the fetus from trauma is believed to be underestimated.<sup>4</sup> Factors associated with an increased risk for traumatic injury during pregnancy include young maternal age, African-American or Hispanic ethnicity, domestic violence, lack of seatbelt use, and drug or alcohol use.<sup>1,8</sup>

In 2002 in the United States, 4.1 injury-related hospitalizations of pregnant women occurred per 1000 deliveries; and of those hospitalizations, it was estimated that 1 in 3 pregnant women admitted to the hospital for trauma underwent delivery during that hospitalization.<sup>9</sup> Alcohol may be involved in as many as 45% of MVCs that involve pregnant women, and the use of illicit substances has been implicated frequently in maternal trauma during pregnancy.<sup>8</sup>

Traumatic injuries may be categorized according to type and include blunt trauma, penetrating trauma, fractures, and thermal injuries. An updated systematic review reported prevalence rates for the various mechanisms of trauma.<sup>10</sup> MVCs had an estimated

incidence of 207 per 100,000 live births,<sup>10,11</sup> and the incidence of domestic violence (DV) or intimate partner violence (IPV) was 8307 per 100,000 live births compared with an incidence outside of pregnancy of 5239 per 100,000 women.<sup>10,12</sup> Falls, burns, homicide, suicide, and toxic exposure are also major contributors to traumatic injury.<sup>10</sup> Gunshot wounds and burns account for 4% and 1% of maternal trauma respectively.<sup>13</sup> The most common obstetric complications following maternal trauma are those associated with blunt trauma and include abruptio placentae, preterm labor, and fetal loss.<sup>14</sup>

## ANATOMIC AND PHYSIOLOGIC CHANGES OF PREGNANCY

**The importance of maternal physiologic changes during pregnancy and an understanding of fetal physiology are critical to effective resuscitation of the injured pregnant woman. This is especially important relative to the maternal response to stress and hypovolemia in the setting of trauma.** Fundamental differences exist in the physiologic responses as a result of pregnancy, and a working knowledge of these differences is important to trauma resuscitation.

### Fetal Physiology

Several factors are important in determining the impact of a traumatic event on pregnancy outcome. These include gestational age, type and severity of trauma, and the extent of disruption of normal maternal and fetal physiology.<sup>15,16</sup>

In the first week following conception, the nonimplanted embryo is relatively resistant to noxious stimuli. During the first trimester, the uterus resides relatively safely within the confines of the bony pelvis and has reached just above the pubic symphysis by 13 to 14 weeks' gestation. As such, the uterus is protected to a large degree from direct trauma. At any gestational age after implantation, however, maternal hypovolemia may have a significant impact on the developing embryo/fetus. Pregnancy loss in the first trimester is not likely related to direct uterine injury but more so from physiologic cardiovascular changes that occur with maternal hypovolemia and associated hypotension, which results in hypoperfusion of the uterus and the developing fetus. Uterine blood flow is not autoregulated and is maximally dilated in the normal physiologic state. Maternal hypovolemia may result in vasoconstriction in vascular beds, including the uterine vessels. In experimental hypovolemic shock, pregnant sheep will decrease uterine blood flow at rates greater than would be expected with a decrease in maternal blood pressure alone. Even in the absence of uterine artery vasoconstriction, decreases in maternal blood pressure as a result of hypovolemia will result in decreased uterine blood flow. These phenomena underlie the importance of maintaining adequate maternal blood volume as an initial step in fetal resuscitation. The third-trimester fetus can adapt to decreased uterine blood flow and oxygen delivery by redistributing blood flow to the heart, brain, and adrenal glands. Furthermore, because fetal hemoglobin has a greater affinity for oxygen than adult hemoglobin, fetal oxygen consumption does not decrease until oxygen delivery is reduced by 50%.<sup>17</sup>

**The leading cause of blunt abdominal trauma in pregnancy is motor vehicle accidents.** Penetrating trauma is typically the result of gunshot and stab injuries. Both blunt and penetrating trauma may result in rupture of the amniotic membranes. In the mid second trimester, rupture with oligohydramnios may result in pulmonary hypoplasia or orthopedic deformity. Injury to the

placenta may precipitate placental abruption and lead to fetal anemia, hypoxemia, or hypovolemia. **Maternal mortality risk with penetrating trauma is more favorable than with blunt trauma because nonreproductive viscera are provided some protection by the gravid uterus, which absorbs the projectile objects.**<sup>18,19</sup>

### Maternal Anatomic and Physiologic Changes

Nearly every maternal organ system undergoes anatomic or physiologic changes during pregnancy. The description that follows emphasizes consideration of these changes that affect trauma management.

A major concern in the management of trauma victims is internal hemorrhage and hypovolemia. The sentinel findings on examination are vital sign abnormalities, typically hypotension and tachycardia. Consideration should be given to the normal decrease in systemic vascular resistance that results in a decrease in mean blood pressure of 10 to 15 mm Hg and an increase in pulse of 5 to 15 beats/min, particularly in the second trimester. These changes can be accentuated if the trauma victim is placed in the supine position (e.g., strapped to a long board to secure the cervical spine). The resultant potential decrease in venous return from the lower extremities can reduce central venous volume and result in a diminished cardiac output by as much as 30%. Simple manual displacement of the uterus to the left or placement of a rolled towel under the backboard while ensuring that the spine remains secure alleviates most of this effect.

Blood volume increases by a mean of 50% in the singleton gestation. This is usually maximal by 28 to 30 weeks' gestation. Red blood cell mass increases to a lesser degree than does plasma volume, resulting in a slight decrease in hemoglobin concentration and a decrease in hematocrit. Iron-deficiency anemia is also common during pregnancy, and together with the normal dilution, hemoglobin concentrations may often be as low as 9 to 11 g/dL. These hematologic changes have two potential implications: anemia may be confused with active bleeding and hypovolemia, and blood volume estimates should be adjusted upward during fluid resuscitation.

Several major pregnancy-induced changes in the gastrointestinal tract are also important for trauma management. Compartmentalization of the bowel upward serves to protect it during lower abdominal trauma but increases the risk of injury when penetrating trauma to the upper abdomen occurs late in pregnancy. Complex injuries to the small bowel can be encountered with multiple entry and exit wounds as a result of its being crowded and compacted into the upper abdomen. Decreased gastric motility results in a prolonged gastric emptying time thereby increasing the risk of aspiration associated with general anesthesia. Rebound tenderness and guarding may be less apparent in later gestation because of stretching and attenuation of the abdominal musculature and peritoneum.

**The dramatic increase in uterine blood flow, up to 600 mL/min, may result in rapid exsanguination in the event of an avulsion or injury to the uterine vasculature or rupture of the uterus. Retroperitoneal hemorrhage from remarkably hypertrophied pelvic vasculature is a common complication of pelvic fracture.**

## BLUNT TRAUMA

Enlargement of the uterus makes it susceptible to direct abdominal trauma. Injury to the uterus (uterine laceration or rupture),

its contents (abruptio placentae or direct fetal injury), or adjacent organs (bladder rupture) are more likely during pregnancy, especially in the second half of gestation. Although some of these complications are associated with more direct and violent trauma—for example, direct fetal injury or uterine rupture—some injuries, such as abruptio placentae, can occur following relatively minor trauma.

**Blunt trauma to the maternal abdomen is an important cause of abruptio placentae. This is because blunt trauma exposes the gravid uterus to acceleration-deceleration forces that have a differential effect on the uterus and the attached placenta.** By changing its shape, the myometrial tissue can stretch and adapt to these forces, but the placenta is relatively inelastic. This mismatch between myometrial and placental ability to stretch creates a shearing force at the uteroplacental interface that, if sufficient, can result in separation of the placenta from its myometrial attachments (i.e., placental abruption).<sup>4,14,18</sup> Placental abruption leads to a compromise in fetal oxygen transfer and has the potential for fetal death depending on severity. Because amniotic fluid is noncompressible, impact against the uterine wall results in amniotic fluid displacement and uterine distension. **As such, seemingly minor or nonseverely injured pregnant women are at increased risk for placental abruption. Abruption may occur immediately after the abdominal impact or may be delayed for several hours after the trauma episode.** Maternal trauma may also result in intramyometrial bleeding that leads to increased uterine contractile activity through activation of thrombin, lysosomal enzymes, cytokines, and prostaglandins.<sup>14</sup> Severe blunt trauma may also lead to maternal splenic, hepatic, and retroperitoneal injuries that result in maternal hemorrhage and hemodynamic instability.<sup>14</sup>

### Motor Vehicle Crashes

A number of human factors are related to traffic-related injuries and fatalities in the United States. For many reasons, drivers have become more distracted while driving. According to the National Highway Transportation Safety Administration (NHTSA) report for 2012, a motor vehicle crash (MVC) occurs every 14 seconds, an injury every 14 seconds, and a death on average every 16 minutes in the United States.<sup>19</sup> **MVCs are the most common cause of trauma-associated fetal loss in the United States.<sup>4</sup> The likelihood that an MVC will result in fetal loss is directly related to crash severity and to the severity of the maternal injury.<sup>4,16</sup> For example, estimates based on case series would suggest that only about 1% of minor MVCs will result in abruptio placentae, whereas clinically evident abruption occurs in as many as 40% to 50% of cases of severe blunt maternal trauma.<sup>14</sup>** In addition, lack of seatbelt use has been found to be associated with fetal loss, particularly if the mother has experienced ejection from the vehicle and head trauma.<sup>16,20</sup> However, even a nonsevere MVC without substantial maternal injury may result in placental abruption and fetal loss because of exposure to the shearing acceleration-deceleration forces described earlier.<sup>2,4,16</sup>

### Falls

Because pregnancy changes the center of gravity and results in postural instability, loss of balance is not uncommon, and the likelihood of a significant fall is increased.<sup>21-23</sup> A retrospective study found that as many as a quarter of pregnant women experience a fall at some time during pregnancy.<sup>21</sup> Like

**MVCs, falls expose the placenta to the shearing forces associated with blunt trauma. However, compared with MVCs, the likelihood that a fall may result in placental abruption and fetal death is low, accounting for only 3% of trauma-associated fetal deaths in one series.<sup>6</sup>** In a more recent prospective cohort study that involved 153 women who experienced falls during pregnancy, no instances of placental abruption were reported.<sup>24</sup> Nonetheless, compared with pregnant women who did not experience a fall-related hospitalization during pregnancy, women hospitalized for falls remain at increased risk for adverse outcomes of pregnancy. One retrospective cohort study of 693 women hospitalized for falls during pregnancy, most of whom were in the third trimester, found that these women were at increased risk for preterm labor, placental abruption, cesarean delivery, “fetal distress,” and fetal hypoxia.<sup>23</sup>

### Domestic Violence and Intimate Partner Violence

Pregnant women are at increased risk to suffer violent assault compared with nonpregnant women.<sup>25</sup> **The period prevalence of intimate partner violence (IPV) during pregnancy has been reported to range from 6% to 22%, and up to 45% of pregnant women report a history of domestic abuse at some time during their lifetime.<sup>25</sup>** The rates of suicide and homicide in pregnancy have been reported as approximately 2.0 per 100,000 and 2.9 per 100,000 live births, respectively.<sup>26</sup> Black women account for nearly half (44.6%) of pregnancy-related homicides but only 17.7% of live births, and 45.3% were associated with IPV. Victims of suicide were more likely to be older and white, and 54.3% of pregnancy-associated suicides involved IPV.<sup>26</sup> Common methods of self-inflicted attempted suicide are drug overdose and poisoning with a corrosive substance.<sup>27</sup> In one study,<sup>28</sup> murder was the most frequent cause of death during pregnancy and in the subsequent year, and the majority of the perpetrators were found to be current or former intimate partners. **This analysis of pregnancy-associated homicides found that intimate partner homicides were most likely to occur during the first 3 months of pregnancy. In a United States study, 5% of female homicide victims were pregnant.<sup>29</sup> Although domestic violence occurs in all ethnic and socioeconomic groups, black and Native American women and women from households with lower incomes are at increased risk.<sup>25</sup>** Intentional trauma during pregnancy has a 2.7-fold risk (95% confidence interval [CI], 1.3 to 5.7) for preterm birth and a 5.3-fold risk (95% CI, 3.99 to 7.3) for low birthweight.<sup>30</sup> According to a California database study<sup>31</sup> of maternal discharge records between 1991 and 1999, assaults were significantly associated with uterine rupture and conferred significant risks for placental abruption and low birthweight, even if the victim was not delivered during the initial hospitalization.

## SPECIFIC INJURIES

### Fractures

Fractures are the most common type of maternal injury to require hospitalization during pregnancy, and the lower extremities are the most common site of fractures that complicate pregnancy.<sup>3</sup> Although pelvic fractures are less frequent than fractures of the extremities, pelvic fractures are most likely to result in adverse outcomes of pregnancy, including placental abruption and perinatal and infant

**FIG 26-1** The arrow points to a pelvic fracture before (A) and after (B) fixation in a pregnancy in the late third trimester that resulted in fetal death. (From Brown, Haywood L. Trauma in pregnancy. *Obstet Gynecol.* 2009;114[1]:147-160.)

**mortality** (Fig. 26-1).<sup>3</sup> Leggon and colleagues<sup>32</sup> reported on a total of 101 pelvic or acetabular fractures in pregnant women, and the three most common reasons for injury were motor vehicle accidents (73%), falls (14%), and pedestrian struck by an automobile (13%). The overall fetal mortality rate in pelvic and acetabular fractures was 35% compared with 9% maternal mortality. Thus pelvic fractures are thought to be an independent risk factor for adverse fetal outcome.<sup>32</sup> Pelvic fractures may also be associated with significant maternal hemorrhage and shock as a result of significant hypertrophy of the pelvic retroperitoneal vasculature and subsequent laceration of these vessels because of sharp bone fragments.<sup>33</sup> Pelvic fractures may also be associated with bladder and urethral trauma.<sup>1</sup> Pelvic fractures are not a contraindication to vaginal delivery unless the fracture results in obstruction of the birth canal or if the pelvic fracture is unstable; more than 80% of women who have sustained pelvic fractures can deliver vaginally.<sup>33</sup>

### Penetrating Trauma

Gunshot and stab wounds are the most frequent types of penetrating trauma during pregnancy.<sup>4,20</sup> Penetrating trauma in a pregnant woman is less likely to result in death than penetrating trauma in a nonpregnant individual owing to the protective effect of the gravid uterus when penetrating wounds occur in the upper abdomen. However, penetrating trauma poses major risk for complex maternal bowel injury because of the compartmentalization of the bowel in the upper abdomen by the enlarged uterus.<sup>20</sup> Gunshot wounds to the abdomen require exploratory surgery to determine the degree of abdominal viscera injury and debridement of damaged tissues. A stab wound in a pregnant woman should be managed the same as in a nonpregnant woman. Bowel injury with spillage of the intestinal contents increases the risk for peritonitis and pregnancy loss from infection. Penetrating trauma to the uterus is strongly associated with poor fetal outcome.<sup>4,14</sup> Fetal death is dependent upon the degree of

placental or umbilical cord disruption. The risk of fetal death has been reported to be as high as 71% after gunshot wounds and as high as 42% following stabbings.<sup>20</sup>

### Thermal Injuries (Burns)

**Maternal and fetal prognosis after thermal injury is a reflection of the percentage of body surface involved.**<sup>33,34</sup> Minor burns that involve 10% or less of the body surface area are unlikely to result in maternal or fetal compromise and do not always require hospitalization.<sup>14</sup> **Significant burns of 50% or more of the body surface have been associated with high maternal and fetal mortality.**<sup>34</sup> In the past, delivery of the fetus was recommended in an attempt to improve maternal prognosis.<sup>33</sup> More recent studies have suggested that maternal prognosis after severe thermal injury is not different between pregnant and nonpregnant individuals.<sup>33</sup> However, because of maternal physiologic changes associated with pregnancy, a pregnant woman with a severe burn will require more aggressive fluid resuscitation than a nonpregnant individual. Major burns may result in maternal hypovolemia and cardiovascular instability in addition to sepsis, respiratory distress, renal failure, and liver failure.<sup>14</sup> Because of the decreased colloid osmotic pressure and increased body surface area associated with pregnancy, pregnant individuals who sustain burns are at risk for increased fluid loss compared with nonpregnant individuals.<sup>34</sup> Preterm labor may result from maternal hypovolemia, which can also result in decreased uteroplacental perfusion. Aggressive fluid resuscitation is critical to forestall this complication.<sup>14,34</sup>

Individuals who suffer from major burns may also sustain inhalation injuries, which carry higher maternal mortality and fetal risk.<sup>14,35</sup> In particular, carbon dioxide freely crosses the placenta and is highly bound by fetal hemoglobin, thus increasing the risk for fetal cardiac failure.<sup>14</sup> Administration of oxygen to the mother is recommended to reduce the half-life of carboxy-hemoglobin.<sup>14</sup>

## Direct Fetal Injuries

Direct fetal injuries are uncommon because of the protection by the uterus and amniotic fluid. Fetal injury complicates fewer than 1% of pregnancies with blunt trauma<sup>36</sup> but are most likely to occur with both direct and severe abdominal or pelvic impact and also in later pregnancy, when the fetal head is engaged in the maternal pelvis.<sup>4,14</sup> Direct injury has been reported to result in rupture of the fetal spleen, fracture of the fetal skull, fetal intracranial hemorrhage, and cerebral edema.<sup>4</sup> Near term the fetal head is in the maternal pelvis, thereby increasing the risk for fetal skull fracture and brain injury with maternal pelvic fractures. Blunt trauma due to violence can lead directly to fetal injury.<sup>37</sup> These injuries have been reported to result in long-term developmental disabilities that result from vascular infarctions, global cerebral damage, and periventricular leukomalacia.<sup>4</sup>

## PATHOPHYSIOLOGY OF FETAL LOSS RESULTING FROM MATERNAL TRAUMA

Maternal hypotension and hypovolemia associated with trauma are important predictors of poor fetal outcome.<sup>6,16,20</sup> Fetal loss may result from placental hypoperfusion due to maternal hemorrhagic shock.<sup>13</sup> In the instance of severe blood loss that results from maternal trauma, maternal blood is redistributed away from the uterus via uterine artery vasoconstriction, thereby allowing continued perfusion of the heart and brain. Fetal mortality in the setting of maternal hemorrhagic shock has been estimated at 80%.<sup>38</sup>

## PREDICTORS OF FETAL MORTALITY

Abruptio placentae is by far the leading cause of fetal death in published series and accounts for between 50% and 70% of all fetal losses due to trauma.<sup>33</sup> Placental abruption will complicate about 1% to 2% of cases of maternal trauma with low injury severity scores and up to 40% of severe maternal abdominal trauma.<sup>20</sup> If a placental abruption occurs, the risk of fetal mortality has been reported to be as high as 50% to 80%.<sup>4</sup> Maternal death has been reported as the next most frequent cause of fetal death after placental abruption, accounting for about 10% of losses.<sup>14</sup> In a large California database study, gestational age at delivery was the strongest predictor of fetal, neonatal, or infant death.<sup>5</sup> MVCs (82%) are the most frequent mechanism of injury leading to fetal death, followed by gunshot wounds (6%) and falls (3%).<sup>4</sup> In particular, lack of seatbelt use is a substantial risk factor for poor fetal outcome, morbidity, and mortality.<sup>20,39,40</sup>

Schiff and colleagues<sup>41,42</sup> used the injury severity score to categorize the severity of maternal injuries. The risk for adverse maternal, fetal, and neonatal outcomes was greatest among the women with severe injuries but was also increased for women with mild injuries compared with uninjured controls. They found that injury severity scoring had limited predictive accuracy for placental abruption and fetal death and that even relatively minor injuries can result in these adverse fetal outcomes.<sup>41,42</sup> **Because minor injuries are much more common than severe injuries, they are responsible for 60% to 70% of fetal losses attributable to trauma, even though a severe injury is much more likely to result in fetal loss than a non-severe injury.**<sup>4</sup>

## MANAGEMENT CONSIDERATIONS

### Initial Approach

The most important initial step in the management of the pregnant trauma victim is a thorough evaluation and stabilization for transport to a trauma center. This initial evaluation is typically provided by on-site emergency medical technicians (EMTs). Most EMT personnel are familiar with the designated trauma units in the community equipped to deal with cases of severe trauma. This is especially important for the pregnant trauma victim, for whom both maternal and fetal survival is a priority. **The Centers for Disease Control and Prevention (CDC) has provided published guidelines for first responders and emergency medical personnel who provide care in the field to injured pregnant women.**<sup>43</sup> *Guidelines for emergency medical personnel include displacing the uterus from the inferior vena cava by positioning the mother in the lateral decubitus position.*<sup>38</sup> *During the initial evaluation, the spine immobilization board may be tilted leftward by 15 degrees by placing a 6-inch rolled towel under the long board to achieve the same result.*<sup>38</sup> *The CDC panel recommended that if possible, women with a pregnancy of at least 20 weeks' gestation be transported to a trauma center with access to obstetric care.* If a pregnant trauma victim must be transported to a closer facility than a designated trauma center because of concerns for maternal survival, the emergency team at that facility must be prepared to make the acute management decisions, stabilize, and then transport to a higher level center.

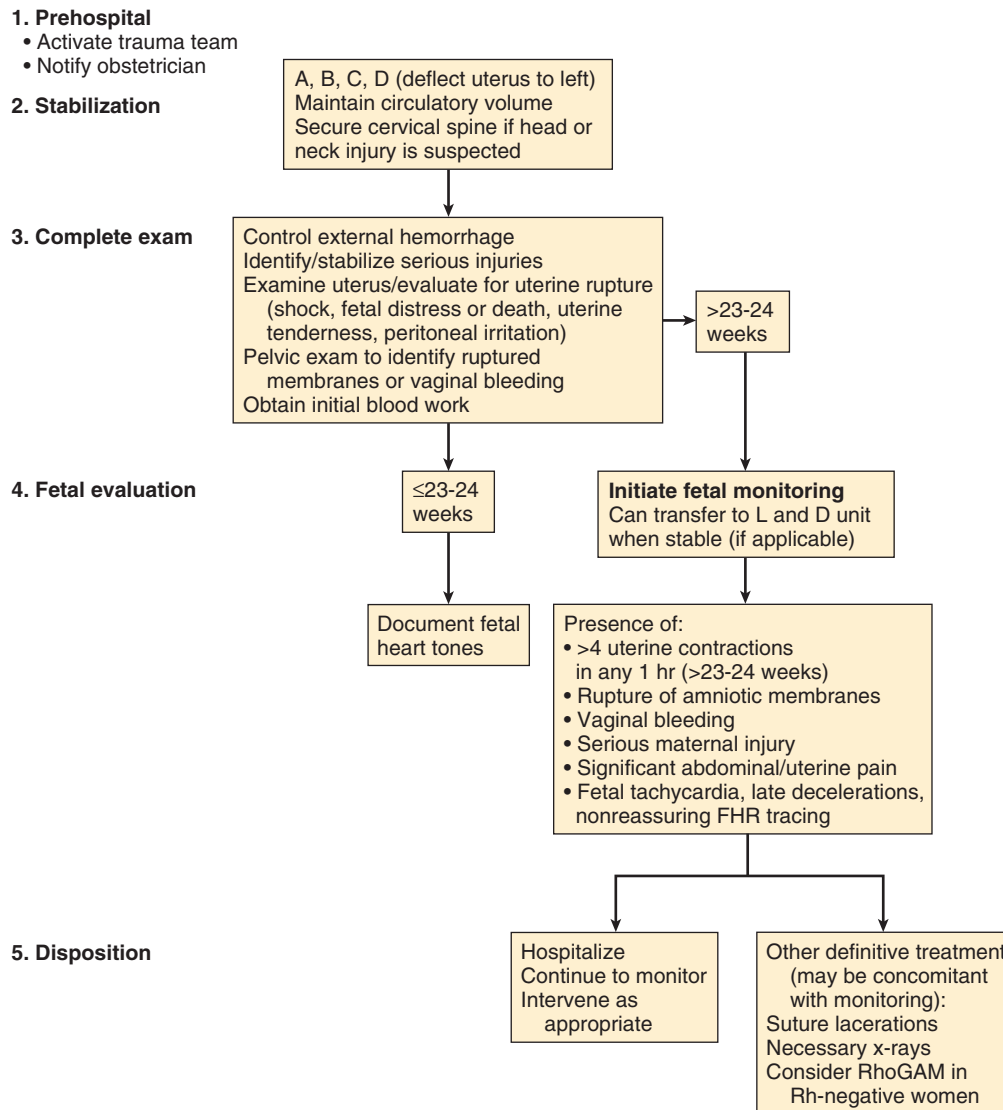

Improved outcomes can be expected by following a coordinated approach among emergency medicine physicians, trauma surgeons, and obstetricians. **Regardless of gestational age, all pregnant women who sustain or who are suspected to have sustained serious injuries should be first evaluated in the emergency department (ED) with the principle that maternal well-being is prioritized over fetal concerns.** Maternal and fetal survival will depend on this coordinated team effort, which should begin as soon as the ED is notified that a pregnant trauma victim is being transported. **Stabilization of the mother with identification of the maternal injury is the initial priority. Fetal evaluation and interventions can be conducted in the ED as needed.** Pregnancy should not delay the decision to intubate, especially with the likelihood that surgical intervention will become necessary. The fetus is vulnerable to hypoxia, neurologic injury, or death; therefore all pregnant trauma victims should be provided with supplemental oxygen and avoidance of hypotension even if intubation is not required.

A suggested algorithm for care of the pregnant trauma patient is presented in Figure 26-2.

### Evaluation on Labor and Delivery

**After clearance for severe maternal injury has been completed in the ED, the obstetrics team should provide a more thorough physical and obstetric assessment.** A thorough physical examination should look for old and new ecchymosis and bruises over the entire body in the event the injuries might suggest violence as an origin. The vaginal examination can detect bleeding, rupture of membranes, and vaginal lacerations that can occur if there has been a pelvic fracture. An ultrasonographic examination should be performed early in the assessment to document fetal heart activity, viability, and gestational age. **Depending on the labor and delivery gestational age criteria for assumption of care at the facility, the stable patient with**

## EMERGENCY DEPARTMENT MANAGEMENT: TRAUMA IN PREGNANCY

**FIG 26-2** Algorithm with suggested care plan for pregnant women who experience trauma. FHR, fetal heart rate; L and D, labor and delivery.

trauma at or beyond 23 weeks' gestation (the threshold of fetal viability) should be admitted to labor and delivery for further observation and monitoring for signs and symptoms of placental abruption and preterm labor. Women at fewer than 20 weeks' gestation or prior to fetal viability can be evaluated for fetal life in the ED but do not necessarily require admission to labor and delivery. Based on the patient's clinical presentation and uterine contraction frequency, the patient is observed for 4 to up to 24 hours prior to hospital discharge.

### Fetal Monitoring

Fetal and uterine contraction monitoring is the most sensitive method for detecting abruptio placentae following trauma. In pregnant women who are beyond 23 to 24 weeks' gestation, frequent uterine contractions are nearly always present in women who develop placental abruption following trauma.<sup>44,45</sup> Moreover, a nonreassuring fetal heart rate (FHR) pattern may reflect maternal hemorrhagic shock or hypotension.<sup>18</sup> Uterine contraction monitoring is unquestionably

more sensitive than ultrasound in detecting placental abruption, and ultrasound detects only about 40% of abruptio placentae in the setting of trauma.<sup>18,20,46</sup> Although several authors have recommended incorporating assessment of fetal status into the standard focused abdominal sonography for trauma (FAST) exam, it should not replace fetal monitoring.<sup>14,47</sup> The standard FAST exam is performed to evaluate for intraperitoneal hemorrhage and has replaced diagnostic peritoneal lavage in many centers because of its excellent sensitivity (80% to 83%) for detection of intraperitoneal fluid.<sup>47</sup> A fetal biophysical profile test and middle cerebral artery Doppler studies may be performed at the time of the FAST exam for further information regarding fetal well-being, although its ability to predict fetal outcome in the setting of trauma has not been thoroughly assessed.<sup>14,47</sup> The FHR tracing has been called the "fifth vital sign" because it may provide the earliest evidence of maternal hypovolemia or hypotension (Fig. 26-3).<sup>14</sup> Likewise, frequent uterine contractions provide the most reliable warning sign of placental abruption or preterm labor.<sup>15,46,48</sup>

**FIG 26-3** Tracing shows a sinusoidal pattern in a woman with fetal-maternal hemorrhage at 30 weeks' gestation after an automobile accident. The infant was severely anemic at birth. (From Brown, Haywood L. Trauma in pregnancy. *Obstet Gynecol.* 2009;114[1]:147-160.)

The time within which a pregnant woman with trauma should receive fetal monitoring is variable. The rationale for a prolonged period of monitoring is the concern for delayed abruption, which has been reported up to 6 days after a traumatic event.<sup>49</sup> If uterine contractions occur less frequently than every 15 minutes over 4 hours of observation, placental abruption is unlikely to occur.<sup>15,45,46</sup> In fact, delayed placental abruption is unlikely if contraction frequency is less than every 10 minutes with normal fetal heart activity over a 4- to 6-hour period of observation. Adverse outcomes directly related to trauma has a reported negative predictive value of 100% when monitoring was normal and the early warning symptoms of bleeding and abdominal pain were absent.<sup>50</sup> **Therefore if the fetus is at or beyond 24 weeks' gestation, the recommended minimal time for monitoring is at least 4 hours from the occurrence of the trauma. Monitoring should be continued if uterine tenderness, contractions, or irritability; abnormal fetal heart activity; or vaginal bleeding are evident.** If deteriorating fetal status is apparent, delivery is indicated at a viable gestational age even if placental abruption is not clinically evident. **If frequent contractions are noted (every 15 minutes or more often) even though no other signs and symptoms for abruption are present, 24 hours of monitoring is recommended because delayed abruptio placentae has been reported up to 48 hours or longer after maternal trauma.**<sup>14,18,46</sup>

### Laboratory Testing

Laboratory tests that may be helpful in the evaluation of trauma include a complete blood count with platelets, type, and Rhesus factor (Rh) testing; evaluation of coagulation function if abruptio placentae is a concern; and a Kleihauer-Betke (KB) test in the Rh-negative woman.<sup>14</sup> The KB test is an acid elution test designed to quantify the amount of fetal

blood in the maternal circulation.<sup>51</sup> Fetal-maternal hemorrhage can be a complication of maternal trauma that leads to fetal anemia, exsanguination, hypoxia, and fetal death. This increase in fetomaternal hemorrhage appears to be most important in ensuring that Rh-negative women are adequately protected against isoimmunization.

The KB test may be used to determine whether additional vials of Rh immune globulin are required to prevent sensitization in Rh-negative women who experience trauma.<sup>13,46</sup> For approximately 90% of pregnant women who experience trauma, fetal-maternal hemorrhage will be less than 30 mL, and 1 vial of Rh immune globulin will be sufficient to prevent sensitization.<sup>18</sup> Some controversy surrounds the utility of this test among Rh-positive women. Based on a series of 71 women, Muench and colleagues<sup>52</sup> recommended its use as a predictor of risk for preterm labor after trauma. These authors found that the KB test had a 100% sensitivity for the prediction of preterm labor.<sup>52</sup> Other studies have not supported the routine use of this test as a predictor of adverse fetal outcome.<sup>48,53</sup> These reports acknowledge that KB testing has utility for determining those few Rh-negative women who require additional Rh immune globulin to protect against isoimmunization but has little predictive value of other adverse pregnancy outcomes such as abruptio placentae, preterm birth, or fetal hypoxemia. Moreover, the use of fetal monitoring is much more likely to provide a timely diagnosis of these complications of pregnancy than KB testing.

When gestational age is less than 20 weeks, 300 µg of Rh immune globulin should be sufficient to cover a fetal-maternal bleed because the expected fetal blood volume is not likely to exceed that covered with a standard dose of 300 µg. It is reasonable to provide Rh immune globulin within 72 hours for all nonsensitized Rh-negative women who experience abdominal trauma irrespective of KB status. Coagulation studies that include prothrombin time (PT), partial thromboplastin time (PTT), platelets, and fibrinogen may be useful in the presence of evidence or suspicion of abruptio placentae or if the patient is experiencing massive hemorrhage that may result in dilutional coagulopathy. A urinalysis may be obtained as well. Hematuria on urinalysis may be associated with pelvic fractures or renal tract injury.<sup>20</sup> Given the strong association of drug and alcohol use with traumatic injuries, a urine toxicology screen may be clinically indicated, especially if the woman has injuries that might require nonobstetric or obstetric surgical intervention.<sup>20</sup>

## DIAGNOSTIC IMAGING

### Ultrasound

Ultrasound may be used to assess fetal well-being without exposing the fetus to ionizing radiation. Additionally, abdominal ultrasound may be a useful tool in the evaluation of the pregnant trauma victim for free intraperitoneal fluid, with reported sensitivity between 61% and 83% but specificity between 94% and 100%.<sup>54</sup> **Ultrasound is not particularly sensitive for detecting abruptio placentae, with reported identification in approximately 40% of cases. No clear guidelines have been established as to whether further imaging is necessary in the event of a negative ultrasound study in a hemodynamically stable patient.** The Food and Drug Administration (FDA) has arbitrarily established a safe upper limit for energy exposure during ultrasonography at 94 mW/cm.<sup>2,55</sup>

**TABLE 26-1** BIOLOGIC EFFECTS OF IN UTERO EXPOSURE TO IONIZING RADIATION

| MENSTRUAL OR GESTATIONAL AGE   | CONCEPTION AGE                 | <50 mGy (<5 rad) | 50-100 mGy (5-10 rad)  | >100 mGy (>10 rad)  |
|--------------------------------|--------------------------------|------------------|--|---|
| 0-2 weeks (0-14) days          | Prior to conception            | None             | None   | None  |
| Weeks 3 and 4 (15-28) days     | Weeks 1 and 2 (1-14) days      | None             | Probably none  | Possible spontaneous abortion   |
| Weeks 5 and 10 (29-70) days    | Weeks 3 and 8 (15-56) days     | None             | Potential effects are scientifically uncertain and probably too subtle to be clinically detectable | Possible malformations increase in likelihood as dose increases   |
| Weeks 11 and 17 (71-119) days  | Weeks 9 and 15 (57-105) days   | None             | Potential effects are scientifically uncertain and probably too subtle to be clinically detectable | Increased risk of deficits in IQ or mental retardation that increase in frequency and severity with increasing dose |
| Weeks 18 and 27 (120-189) days | Weeks 16 and 25 (106-175) days | None             | None   | IQ deficits are not detectable at diagnostic doses  |
| >27 weeks (>189 days)          | >25 weeks (>175 days)          | None             | None   | None applicable to diagnostic medicine  |

Modified from American College of Radiology. *Practice Guidelines for Imaging Pregnant or Potentially Pregnant Adolescents and Women with Ionizing Radiation*. American College of Radiology Practice Parameter, amended 2014 (Resolution 39). Available at: [www.acr.org/guidelines](http://www.acr.org/guidelines).

## Ionizing Radiation

Because of concerns about fetal exposure to ionizing radiation, clinicians may be hesitant to order indicated diagnostic tests in the setting of maternal trauma. However, maternal radiologic studies that include radiographs, magnetic resonance imaging (MRI), and computed tomography (CT) should not be deferred over concerns for the fetus if they are required for thorough assessment of the pregnant woman, and certainly if the pregnancy is at a previsible gestational age. Concerns regarding exposure to ionizing radiation involve both risk for teratogenesis and risk for development of cancer in later life.<sup>56</sup> The most significant risk for fetal malformation involves microcephaly and mental retardation, which has been observed after human exposure to doses of 100 to 200 cGy. Exposure to ionizing radiation in utero may elevate the risk of childhood leukemia from a background of 1 in 3000 to a risk after exposure to 1 in 2000.<sup>55,57</sup> Similarly, exposure to 50 mGy (5 rads) ionizing radiation during pregnancy may be associated with a 2% lifetime attributable risk for development of malignancy.<sup>58</sup> The risk of teratogenesis or carcinogenesis with exposure to ionizing radiation is dose dependent.<sup>58</sup> According to the American College of Radiology (ACR), no single diagnostic procedure provides a radiation dose sufficient to threaten the well-being of the developing embryo or fetus, especially in the mid to late weeks of gestation.<sup>59</sup> Both the ACR and the American College of Obstetricians and Gynecologists (ACOG) have published imaging guidelines for the use of diagnostic radiologic techniques during pregnancy.<sup>55,58</sup> However, in the setting of maternal trauma, the risk to the fetus for morbidity or mortality from untreated maternal injury far outweighs theoretic concerns for risks of development of malignancy in later life. Table 26-1 summarizes effects of in utero exposure to ionizing radiation during different stages of pregnancy; radiation doses associated with common diagnostic tests are listed in Table 26-2.

## Magnetic Resonance Imaging

MRI may be an attractive option because it does not involve the use of ionizing radiation, although less evidence is available to show the efficacy and safety of its use during pregnancy than for other, more established methods. Currently, the FDA states that the safety of MRI for the fetus “has not been established.”<sup>57</sup> However, no evidence exists from studies of children exposed to MRI in utero of any teratogenic effects or of any long-term

**TABLE 26-2** RADIATION DOSES ASSOCIATED WITH COMMON DIAGNOSTIC PROCEDURES

| PROCEDURE  | FETAL DOSE     |
|--|----------------|

Modified from ACOG Committee on Obstetric Practice: ACOG Committee Opinion 299: Guidelines for Diagnostic Imaging During Pregnancy and American College of Radiology (ACR) Practice Guidelines for Imaging Pregnant or Potentially Pregnant Adolescents and Women with Ionizing Radiation. ACOG, American College of Obstetricians and Gynecologists; CT, computed tomography.

adverse developmental consequences.<sup>39,42</sup> The ACR described guidelines for the safe use of MRI and provided support for the use of MRI during all trimesters of pregnancy if necessary for accurate diagnosis.<sup>54,60</sup> **The precise role for the use of MRI in the management of trauma in pregnancy has not yet been clearly established but may have benefit in the evaluation of soft tissue injury and spaces of the maternal pelvis.**

## Contrast Agents

Iodinated contrast agents cross the placenta via simple diffusion.<sup>61</sup> Because they are taken up by the fetal thyroid and may pose a theoretic risk for fetal hypothyroidism, iodinated contrast images are generally avoided during pregnancy unless clearly necessary for diagnosis.<sup>55,61</sup> However, no cases of fetal goiter or abnormal neonatal thyroid function have been reported after clinical use of iodinated contrast agents.<sup>61</sup> Neonates whose mothers have received iodinated contrast media during pregnancy should be screened for hypothyroidism, an already standard practice.<sup>57</sup> A recent guideline for use of CT and MRI during pregnancy has posited that the use of iodinated contrast agents during pregnancy is preferable to the patient receiving repetitive CT studies because of the suboptimal nature of studies performed without contrast agents.<sup>57</sup>

The use of gadolinium for MRI in pregnancy is controversial. Gadolinium crosses the placenta and accumulates in amniotic fluid,<sup>61</sup> although it has not been found to be teratogenic or carcinogenic in doses used clinically.<sup>20,61</sup> However, administration of gadolinium to children and adults with underlying renal insufficiency has resulted in a syndrome known as *nephrogenic*

**FIG 26-4** Algorithm with suggested plan for diagnostic imaging studies for pregnant women who experience trauma. CT, computed tomography; IV, intravenous; MRI, magnetic resonance imaging; US, ultrasound. (Modified from Patel SJ, Reede DL, Katz DS, et al. Imaging the pregnant patient for nonobstetric conditions: algorithms and radiation dose considerations. *Radiographics*. 2007;27:1719.)

*systemic fibrosis* in rare cases, which raises a theoretic concern of toxicity after fetal exposure.<sup>57,62</sup> Thus the use of gadolinium should be avoided in patients with acute or chronic renal insufficiency.

### Suggested Guidelines for Radiologic Evaluation of Trauma

A recent evidence-based guideline and additional report on use of diagnostic imaging after maternal trauma has recommended the use of ultrasound as the initial modality but recommend the use of CT as the preferred method of evaluation when visceral injuries or injuries of the chest, aorta, mediastinum, spine, bones, bowel, or bladder are suspected (Fig. 26-4).<sup>54,57</sup>

### EXPLORATORY SURGERY FOR TRAUMATIC INJURIES DURING PREGNANCY

When nonobstetric surgery is necessary in a pregnant woman, attention to adequate maternal oxygenation, blood volume, and uterine perfusion is important in providing an environment to prevent fetal hypoxia. Penetrating trauma is the most common indication for nonobstetric surgery for traumatic injuries during pregnancy.<sup>14</sup> Historically, surgical exploration was recommended for evaluation and repair of abdominal injuries that resulted from penetrating trauma; however, given the differing pattern of abdominal injuries that result from penetrating trauma during pregnancy, the decision for expectant management or surgery should be individualized.<sup>14</sup> Muench and Canterino<sup>14</sup> recommend an individualized approach to penetrating trauma depending on whether the wound is in the upper or lower abdomen. Because of the significantly increased risk for bowel injury after penetrating trauma to the upper abdomen, women with such wounds should

undergo surgical exploration. Because the gravid uterus provides some protection from visceral injury, pregnant women who sustain penetrating wounds to the lower abdomen may be managed conservatively if they are hemodynamically stable. Penetrating wounds to the gravid uterus increase risk for direct fetal injury but may be managed conservatively if they do not extend past the myometrium.<sup>14</sup> Conservative management may include diagnostic peritoneal lavage, which may be undertaken safely in all trimesters using an open direct-visualization technique through a supraumbilical incision under ultrasound guidance.<sup>14,20</sup> **Indications for surgical exploration include penetrating trauma to the upper abdomen, gunshot wounds to the abdomen, clinical evidence of active intraabdominal hemorrhage, or suspicion for bowel injury.**

The surgical team should not allow the enlarged uterus to compromise adequate surgical exploration and management. If exploratory laparotomy is undertaken, care should be taken to minimize traction on the gravid uterus, and the nature and extent of any injuries should be evaluated.<sup>14</sup> Exploratory laparotomy is not a reflex indication for delivery of the fetus.<sup>20</sup> **In the event that fetal death has occurred prior to surgical exploration, vaginal delivery after induction of labor may be a preferable approach, although Brown recommends surgical uterine evacuation while the mother is under a current anesthetic if there is abruption and potential for coagulopathy.**<sup>20</sup> Coagulopathy further complicates the hemorrhagic picture and leads to a more complicated perioperative course, which includes acute respiratory distress in the mother. In some circumstances, delivery of the fetus may be necessary to adequately explore the abdomen or to facilitate surgical repair of injured viscera.

**If the pregnancy is at or beyond 24 weeks, fetal monitoring should be carried out intermittently during the surgical procedure. If nonreassuring fetal status is detected during the**

procedure, in most instances it can be alleviated by attention to and correction of maternal hypovolemia or hypoxemia. If these supportive measures are not effective, cesarean delivery may be necessary.<sup>20</sup>

### Uterine Rupture

Both blunt and penetrating injuries can result in uterine rupture, which occurs in approximately 0.6% to 1% of instances of maternal trauma.<sup>20,46</sup> Uterine rupture most often results from direct abdominal impact and may occur at any gestational age, although the risk increases as the uterus becomes an abdominal organ later in pregnancy.<sup>1,63</sup> The risk for uterine rupture is particularly increased for women who have experienced assault.<sup>31</sup> Most instances of uterine rupture as a result of maternal trauma are fundal in location.<sup>46</sup> Uterine rupture may also result in complete avulsion of the uterine arteries and massive hemorrhage.<sup>1</sup> Signs of uterine rupture may range from FHR abnormalities in a hemodynamically stable patient to maternal cardiovascular instability and hypovolemic shock.<sup>46</sup> Uterine rupture carries a poor prognosis for the fetus and requires immediate laparotomy. Whether a hysterectomy is required depends on the extent of the myometrial and vascular injury and to what extent the surgeon feels the uterus can be repaired expeditiously. Because uterine rupture may be associated with massive maternal hemorrhage because of the increased uterine vascularity associated with pregnancy; aggressive replacement of red cells and clotting factors is recommended.<sup>20</sup> Maternal mortality has been reported to be as high as 10% following traumatic uterine rupture.<sup>4</sup>

### Implications of Cardiac Arrest and Perimortem Cesarean Section

In instances of severe maternal injury and maternal cardiac arrest, cardiopulmonary resuscitation may be less successful because of maternal physiologic alterations associated with pregnancy. The gravid uterus may interfere with systemic perfusion by compression of the inferior vena cava and interference with venous return. The use of left lateral tilt to reduce the impact of aortocaval compression on utero placental perfusion compromises cardiopulmonary resuscitation (CPR) efforts and efficacy of chest compressions; therefore emptying the uterus should facilitate more effective maternal resuscitation. **The chance of maternal survival after cardiac arrest despite aggressive attempts at resuscitation is significantly diminished compared with the nonpregnant state. Long-term outcomes for children born after maternal cardiac arrest are more likely to be favorable if the child is delivered within 5 minutes of cessation of maternal circulation.<sup>38</sup> Perimortem cesarean should be considered early in the resuscitation process in the trauma victim. If the pregnancy has extended beyond an acceptable gestation of viability, the decision to perform a perimortem cesarean should be immediate and decisive. Therefore if the pregnancy is at or beyond fetal viability (23 to 24 weeks' gestation), perimortem cesarean delivery should commence within 4 minutes after maternal cardiac arrest if resuscitation has not restored maternal circulation.<sup>14</sup>**

The incision should be midline from xiphoid to the pubis through all abdominal wall layers and through a midline vertical uterine incision. Once the neonate is delivered, resuscitation efforts can continue, and if successful, the patient can be transferred to the operating theater for closure of the uterus and abdominal wound and to ensure adequate hemostasis.

## OTHER CONSIDERATIONS

### Medical and Legal Implications After Maternal Trauma

Accurate and careful documentation of all history, physical examination findings, clinical care, and follow-up for the mother and fetus is critical for the pregnant woman who has suffered trauma. It is highly likely, particularly if there is an adverse outcome for the pregnancy, that these records will be revisited if legal action is pursued. The clinicians involved in the initial and follow-up care of the woman will likely have to offer a medical opinion as to causation.

The obstetric evaluation and adherence to monitoring recommendations based on clinical history and clinical observation for up to 4 hours after an accident or injury is necessary as a critical assessment period for maternal and fetal well-being. A documented record should reflect the maternal and fetal status throughout the period of observation. For example, the timing of an emergency cesarean or placental abruption relative to the time of the traumatic event or preterm labor and/or preterm delivery in the days or weeks following the event may have implications to causation. However, labor and subsequent delivery several weeks removed from a traumatic event, when all observational documentation revealed normal findings, is unlikely to be directly related to the acute event.

For all trauma in pregnancy, it is therefore important for all care providers to document throughout the course of care from the ED, labor room, and surgical suite through discharge and follow-up.

### Long-Term Effects of Trauma

**In some reports, up to 38% of women who experience trauma during pregnancy will require delivery in the same hospitalization,<sup>20</sup> although in most published experiences, the great majority of pregnant women who experience trauma will be discharged undelivered.<sup>4,44</sup> Although most placental abruptions that result from maternal trauma will occur within the first 24 hours after the event, some reports suggest that women who have experienced trauma remain at risk for other complications that include fetal growth restriction, intrauterine fetal demise, "fetal distress," placental abruption, and a higher risk of cesarean delivery.<sup>3,4,64</sup> By contrast, a prospective controlled study demonstrated that pregnancy outcomes beyond 48 hours in injured women are similar to those in the uninjured controls.<sup>44</sup> Suggested discharge instructions are shown in Box 26-1.**

### Prevention of Trauma

A Canadian study suggests that pregnancy, particularly in the second trimester, is associated with a 42% relative increase in a serious MVC compared with the nonpregnant state. The crash rate was equal to 4.55 events per 1000 individuals, about twice the population average of 2 crashes per 1000 drivers annually.<sup>65</sup> The factors that surround this statistical increase during the second trimester are highly subjective. **Education and reinforcement of seatbelt use during pregnancy should be undertaken as a routine part of prenatal education and care.** In a primate model of motor vehicle impact trauma and its fetal effects, three-point restraints significantly reduced fetal mortality compared with two-point restraints.<sup>2</sup> In a recent study of MVCs that involved 43 pregnant women between 1996 and 1999, Klinich and colleagues<sup>16</sup> from the Times New Romanity of Michigan demonstrated that proper use of seatbelts was

significantly associated with good fetal outcome. The authors speculated that proper seatbelt use could prevent as many as 84% of adverse fetal outcomes. Proper counseling by the obstetric care provider for seatbelt usage has also been shown to significantly improve compliance with seatbelt use during pregnancy.<sup>66</sup>

Because of reasonable evidence that restraint use reduces both maternal and fetal morbidity and mortality, ACOG recommends seatbelt use in pregnancy to reduce the chances of

maternal and fetal morbidity and mortality.<sup>67</sup> **The NHTSA recommends that pregnant women wear their seatbelts with the shoulder harness portion positioned over the collarbone between the breasts and the lap belt portion under the pregnant abdomen as low as possible on the hips and across the upper thighs and not above or over the abdomen.** Placement of the lap belt over the dome of the uterus increases pressure transmission and the risk of uterine injury during a significant crash. Restraint use in pregnancy is inconsistent, and the relative risk for perinatal death with lack of restraint use has been reported as high as 5.2:1.<sup>68</sup>

Airbags can be life saving in automobile crashes. However, airbags detonate with more than 1200 lb of force at speeds that can exceed 230 mph. No evidence suggests that the effect of airbag deployment during the third trimester increases risk for fetal injury; however, minor maternal injuries from airbag deployments have been reported. **The NHTSA recommends that when a pregnant woman rides in front of an airbag, the airbag should be at least 10 inches away from the dashboard or steering wheel and the seat should be moved back from the gravid uterus as the pregnant abdomen grows.** Although some have expressed concern about possible harmful effects of airbag deployment in the event of an MVC during pregnancy, the NHTSA and ACOG do not recommend disabling airbags during pregnancy.<sup>46,69</sup> Indeed, a retrospective cohort study of pregnant women involved in MVCs in the state of Washington between 2002 and 2005 concluded that airbags do not increase the risk for adverse outcomes of pregnancy.<sup>70</sup> The forces that lead to placental abruption after motor vehicle trauma are depicted in Figure 26-5, and proper use of seatbelt restraints is depicted in Figure 26-6.

#### BOX 26-1 SUGGESTED DISCHARGE INSTRUCTIONS FOR PREGNANT WOMEN HOSPITALIZED FOR OBSERVATION AFTER TRAUMA

- Discharge after 24 hours of observation.
- Discharge may be indicated in the absence of signs or symptoms of labor, abruption, rupture of membranes, fetal compromise, or maternal compromise.
- Health education
  - After discharge, the woman should be instructed to call Labor and Delivery with decreased fetal movement, vaginal bleeding, rupture of membranes, abdominal pain, or more than three uterine contractions per hour.
  - Advise fetal movement count twice daily.
  - Advise follow-up with provider within the week.
  - Advocate correct seatbelt use: shoulder belt between breasts and uterine fundus, lap belt under the uterus and across the spines of the pelvis.
  - If domestic violence is suspected, order social work consult.

**FIG 26-5** Impact sequence. Relationship between body motion, uterine pressure, and belt tension. (Modified from Hankins CVD. *Operative Obstetrics*. Stamford, CT: Appleton & Lange, 1995, Fig. 35-3, p 655.)

**FIG 26-6** **A**, Improper use of a lap belt in pregnancy showing placement across the abdominal dome. **B**, Lap belt appropriately placed below the abdominal dome. (Illustration by John Yanson. Modified from Brown, Haywood L. Trauma in pregnancy. *Obstet Gynecol.* 2009; 114[1]:147-160.)

#### BOX 26-2 SUGGESTED DOMESTIC VIOLENCE SCREENING QUESTIONS

Because violence is so common in many women's lives and because there is help available for women being abused, I now ask every patient about domestic violence:

1. Within the past year or since you have been pregnant, have you been hit, slapped, kicked, or otherwise physically hurt by anyone?
2. Are you in a relationship with a person who threatens or physically hurts you?
3. Has anyone forced you to have sexual activities that made you feel uncomfortable?

#### Screening and Identification of Women at Risk for Domestic Violence

Traumatic injuries may also be prevented by early screening and detection of IPV during pregnancy. ACOG recommends screening all pregnant women for IPV at the first prenatal visit and at least once per trimester of pregnancy. They recommend use of a brief three-question screening tool to identify women at risk for domestic violence during pregnancy (Box 26-2).<sup>71</sup>

#### KEY POINTS

- ◆ Maternal trauma is the most frequent cause of nonobstetric maternal death.
- ◆ In cases of significant trauma, such as motor vehicle accidents, maternal stabilization and evaluation in the emergency department should occur prior to transfer to labor and delivery.
- ◆ Fetal monitoring should occur as soon as possible while maternal evaluation takes place.
- ◆ Abruptio placentae complicates 1% to 2% of cases of minor blunt abdominal trauma and up to 40% of cases of severe abdominal trauma.

- ◆ Following cases of blunt trauma, fetal monitoring is recommended for a period of 4 to 24 hours depending on the findings.
- ◆ Placental abruption is the most frequent cause of fetal death after trauma.
- ◆ Most abruptions occur within 24 hours of an accident, but delayed abruption can occur.
- ◆ Rhogam should be administered to Rh-negative women who experience trauma.
- ◆ Kleihauer-Betke testing is recommended for Rh-negative women who experience trauma beyond 20 weeks of gestation.
- ◆ Concerns about fetal effects of ionizing radiation should not delay imaging necessary to care for pregnant trauma victims.
- ◆ Seatbelt use may reduce adverse fetal outcome resulting from trauma by as much as 84%.
- ◆ All pregnant women should be screened for domestic violence during each trimester.

Not all conceptions result in a live-born infant, and human reproduction is extremely inefficient compared with that of other mammal species.<sup>1</sup> **About 50% to 70% of spontaneous conceptions are lost before completion of the first trimester, most before implantation or during the first month after the last menstrual period.** These losses are often not recognized as conceptions. **Of clinically recognized pregnancies, 10% to 15% are lost.** Although epidemiologic data are limited on animals living in the wild, such as monkeys, laboratory rodents are known to have postimplantation pregnancy loss rates of less than 10%.<sup>1</sup> Among married women in the United States, 4% have experienced two fetal losses, and 3% have experienced three or more.<sup>2</sup> A subset of women manifest repetitive spontaneous miscarriages, as opposed to randomly having repeated untoward events. This chapter considers the frequency and timing of pregnancy losses, the causes of fetal wastage, and the management of couples who experience repetitive losses.

## FREQUENCY AND TIMING OF PREGNANCY LOSS

Embryos implant 6 days after conception, although physical signs are not generally appreciated until 5 to 6 weeks after the last menstrual period. **Fewer than half of preimplantation embryos persist, as witnessed by assisted reproductive technology (ART) success rates rarely exceeding 30% to 40% of cycles initiated; even after implantation, judged preclinically by the presence of  $\beta$ -human chorionic gonadotropin ( $\beta$ -hCG), about 30% of pregnancies are lost.**<sup>1</sup> **After clinical recognition, 10% to 12% are lost. Most clinical pregnancy losses occur before 8 weeks.** Before widespread availability of ultrasound, embryonic demise was often not appreciated until 9 to 12 weeks' gestation, at which time bleeding and passage of tissue (products of conception) occurred. With widespread availability of ultrasound, it has been shown that fetal demise actually occurs weeks before overt clinical signs are manifested. This conclusion was reached on the basis of cohort studies that showed that only 3% of viable pregnancies are lost after 8 weeks' gestation<sup>3</sup>; studies involving obstetric registrants reached similar conclusions. Fetal viability thus ceases weeks before maternal symptoms of pregnancy loss. That almost all losses are retained in utero for some time before clinical recognition means that virtually all losses could be considered "missed abortions," thus this once widely used term is actually archaic.

**After the first trimester, pregnancy losses occur at a slower rate. Loss rates are only 1% in women confirmed by ultrasound to have viable pregnancies at 16 weeks.** Two confounding factors that influence clinical pregnancy loss rates are clinically relevant: **maternal age is positively correlated with pregnancy loss rates,** and a 40-year-old woman has twice the risk of a 20-year-old woman. This occurs in euploid and aneuploid pregnancies, as discussed later. **Prior pregnancy loss also increases loss rates, but far less than once believed.** Among nulliparous women who have never experienced a loss, the likelihood of pregnancy loss is only 5% to 10% (Table 27-1). After one loss, the risk of another is increased but does not exceed 30% to 40% even for women with three or more losses.<sup>4</sup> These risks apply not only to those women whose losses were recognized at 9 to 12 weeks' gestation but also to those whose pregnancies were ascertained in the fifth week of gestation.<sup>5</sup> Of clinical relevance, no scientific evidence suggests that women with three losses are etiologically distinct from those with two

**TABLE 27-1** APPROXIMATE RECURRENCE RISK FIGURES USEFUL FOR COUNSELING WOMEN WITH REPEATED SPONTANEOUS ABORTIONS

|                               | PRIOR SPONTANEOUS ABORTIONS | RISK (%) |
|-------------------------------|-----------------------------|----------|

Data from Regan L. A prospective study on spontaneous abortion. In: Beard RW, Sharp F (eds). *Early Pregnancy Loss: Mechanisms and Treatment*. London: Springer-Verlag; 1988, p 22; Warburton D, Fraser FC. Spontaneous abortion risks in man: data from reproductive histories collected in a medical genetic unit. *Am J Hum Genet*. 1964;16:1; and Poland BJ, Miller JR, Jones DC, et al. Reproductive counseling in patients who have had a spontaneous abortion. *Am J Obstet Gynecol*. 1977;127:685. Recurrence risks are slightly higher for older women.

losses or even one loss. The situation may be different if four or more losses have occurred, and different etiologic factors may exist in this uncommon subgroup.

**The clinical consequence of the above information is that in order to be judged efficacious in preventing recurrent first-trimester spontaneous abortions, therapeutic regimens must show success rates substantially greater than 70%. Essentially no therapeutic regimen can make this claim.**

## PLACENTAL ANATOMIC CHARACTERISTICS OF SUCCESSFUL AND UNSUCCESSFUL PREGNANCIES

**As judged by adult tissue criteria, the human fetus develops in a low-oxygen environment.** Development of the human placenta is modulated heavily by the intrauterine environment.<sup>6-9</sup> During the first trimester, development takes place in a low-oxygen environment supported by histotrophic nutrition from the endometrial glands. Consequently, the rate of growth of the chorionic sac is almost invariable across this period and is remarkably uniform among individuals. **Toward the end of the first trimester, the intrauterine environment undergoes radical transformation in association with onset of the maternal arterial circulation and the switch to hemotrophic nutrition (Chapter 1).** The accompanying rise in intraplacental oxygen concentration poses a major challenge to placental tissues, and extensive villous remodeling takes place at this time.

The human gestational sac is designed to minimize the flux of oxygen ( $O_2$ ) from maternal blood to the fetal circulation.<sup>1,6</sup> In particular, the extravillous trophoblast that migrates inside the uterine tissue to anchor the pregnancy creates a cellular shell with plugs inside the tip of the uteroplacental arteries.<sup>2,9</sup> This additional barrier keeps most of the maternal circulation outside the placenta and thus reduces the chemical activity of free oxygen radicals inside the placenta during most of the first trimester of the human pregnancy.<sup>6,7</sup> In normal pregnancies, the onset of the maternal circulation is a progressive phenomenon that starts at about 9 weeks at the periphery of the placenta and gradually extends toward the center.<sup>2,7,9</sup> This process correlates closely with the pattern of trophoblast invasion across the placental bed (Fig. 27-1).

**FIG 27-1** A gestational sac at the end of the second month (8 to 9 weeks) showing the myometrium (M), decidua (D), placenta (P), exocoelomic cavity (EEC), amniotic cavity (AC), and secondary yolk sac (SYS). (From Jauniaux E, Cindrova-Davies T, Johns T, et al. Distribution and transfer pathways of antioxidant molecules inside the first trimester human gestational sac. *J Clin Endocrinol Metab*. 2004;89:1452.)

In about two thirds of early pregnancy failures, anatomic evidence of defective placentation is apparent, which is mainly characterized by a thinner and fragmented trophoblast shell and reduced cytotrophoblast invasion of the lumen at the tips of the spiral arteries.<sup>2,10-12</sup> This is associated with premature onset of the maternal circulation throughout the placenta in most cases of miscarriages.<sup>2,9,10-12</sup> These defects are similar in euploid and in most aneuploid miscarriages but are more pronounced in hydatidiform moles (Fig. 27-2). In vivo ultrasound and histopathologic data indicate that in most early pregnancy losses, the onset of the intervillous circulation is premature and widespread owing to incomplete transformation and plugging of the utero-placental arteries.<sup>7,10,11</sup> In about 80% of missed miscarriages, the onset of the maternal placental circulation is both precocious and generalized throughout the placenta. This occurs independent of the karyotype of the conceptus,<sup>11</sup> leading to higher O<sub>2</sub> concentrations during early pregnancy, widespread trophoblastic oxidative damage, and placental degeneration. Although in vitro studies have demonstrated the ability of damaged syncytium to regenerate from the underlying cytotrophoblast, it is likely that in the face of extensive damage, this ability will be overwhelmed, leading to complete pregnancy failure.<sup>2,12</sup>

### NUMERICAL CHROMOSOMAL ABNORMALITIES: THE MOST FREQUENT CAUSE OF EARLY PREGNANCY LOSS

Chromosomal abnormalities are the major cause of both preimplantation and clinically recognized pregnancy loss. Of

**FIG 27-2** Placentation in a normal ongoing pregnancy (A), in an early pregnancy failure (B), and in a complete hydatidiform mole (C). A, Note the continuous trophoblastic shell, the plugs in the lumens of the spiral arteries, and the interstitial migration of the extravillous trophoblast through the decidua down to the superficial layer of the myometrium. B, Note the discontinuous trophoblastic shell, the absence of plugs, and the reduced migration of extravillous trophoblastic cells. C, Note the absence of trophoblastic plugs and interstitial migration. (From Jauniaux E, Burton GJ. Pathophysiology of histological changes in early pregnancy loss. *Placenta*. 2005;26:114.)

all morphologically *normal* embryos, 25% to 50% show chromosomal abnormalities (aneuploidy or polyploidy).<sup>13</sup> The highest figure occurs in women over age 45, and a more generalizable figure is 25% in the third decade increasing to 50% by late in the fourth decade. The frequency of chromosomal abnormalities in morphologically abnormal embryos is even higher. The high aneuploidy rate in morphologically normal embryos is consistent with 5% to 10% aneuploidy in sperm of ostensibly normal men and 20% aneuploidy in oocytes (deduced from polar bodies) of women undergoing ART.

**Not surprisingly, at least 50% of clinically recognized pregnancy losses result from a chromosomal abnormality.**<sup>14</sup> The frequency is probably higher, because if chorionic villi recovered by chorionic villus sampling (CVS) are analyzed immediately after ultrasound diagnosis of fetal demise, rather than culturing spontaneously expelled products, the chromosomal abnormalities are detected in 75% to 90%.<sup>15</sup> However, these cohorts were older than the general population.

Among second-trimester and third-trimester losses, chromosomal abnormalities are more similar in type to those observed in live-born infants: trisomies 13, 18, and 21; monosomy X; and sex chromosomal polysomies. This also holds true among losses after 20 gestational weeks (stillborn infants), for which the frequency of chromosomal abnormalities detected by karyotype has traditionally been cited as approximately 5%. The frequency is over 20% if anatomic abnormalities are present and chromosomal microarray (comparative genomic hybridization [CGH]) is used because cell culture is not needed to obtain information.<sup>16</sup> The American College of Obstetricians and Gynecologists (ACOG) now recommends array CGH for this purpose.<sup>17</sup> Of stillborn infants, 8.3% show cytogenomic abnormalities such as aneuploidy, microdeletions or microduplication based on array CGH, and copy number variants versus 5.8% by karyotype.<sup>17</sup> Overall, the frequency of demonstrable abnormalities is much less than that observed in earlier abortuses but is much higher than that found among liveborn infants (0.6%). Formal recommendations for the management of couples who have had a stillborn infant is undertaken later in this chapter.

## Types of Numerical Chromosomal Abnormalities

### Autosomal Trisomy

**Autosomal trisomies represent the largest single class (about 50%) of chromosomal complements in cytogenetically abnormal spontaneous abortions.** That is, 25% of all abortuses are aneuploid, given half of all abortuses have a chromosomal abnormality. Frequencies of various trisomies are listed in Table 27-2. Trisomy for every chromosome has been observed, but the most common is trisomy 16, which is lethal and is not observed in liveborn infants. Most trisomies show a maternal age effect, but the effect varies markedly among chromosomes. The increased maternal age effect is especially impressive for double trisomies.

Trisomies incompatible with life predictably show slower growth than those compatible with life (e.g., trisomies 13, 18, 21); but otherwise, usually no features distinguish the two groups. Abortuses from the former group may show anomalies consistent with those found in full-term, liveborn trisomic infants. Malformations present have been said to be more severe than those observed in induced abortuses following prenatal diagnosis.

**TABLE 27-2** CHROMOSOMAL COMPLETION IN SPONTANEOUS ABORTIONS RECOGNIZED CLINICALLY IN THE FIRST TRIMESTER

| CHROMOSOMAL COMPLEMENT               | FREQUENCY | PERCENT |
|--------------------------------------|-----------|---------|
| Normal 46,XX or 46,XY                |           | 54.1    |

Data from Simpson JL, Bombard AT. Chromosomal abnormalities in spontaneous abortion: frequency, pathology and genetic counseling. In: Edmonds K (ed). *Spontaneous Abortion*. London: Blackwell; 1987.

Attempts have been made to correlate placental morphologic abnormalities with specific trisomies, but these relationships are imprecise. Comparison of ultrasound findings and placental histology indicates that villous changes following in utero fetal demise could explain the low predictive value of placental histology in identifying aneuploidy or another nonchromosomal etiology. By contrast, the histologic features of complete and partial hydatidiform molar gestations are so distinctive that most molar miscarriages can be correctly diagnosed by histologic examination alone.

**Aneuploidy usually results from errors at maternal meiosis I, and these are associated with advanced maternal age.**<sup>18,19</sup> Once thought to involve mostly missegregation of whole chromosomes, it is now clear that chromatid errors are an equally prevalent cause of maternal meiotic errors.<sup>20</sup> The cytologic mechanism involves decreased or absent meiotic recombination.

The cytologic origin is not the same for all chromosomes. In trisomy 13 and trisomy 21, 90% to 95% of these maternal cases arise at meiosis I; almost all trisomy 16 cases arise in maternal meiosis I.<sup>18</sup> In trisomy 18, two thirds of the 90% of maternal meiotic cases arise at meiosis II.<sup>18</sup>

One practical consequence of the maternal origin of aneuploidy is that deducing the chromosomal status of oocytes is possible by analysis of the polar bodies. In preimplantation genetic diagnosis, the most common approach is now blastocyst biopsy (5-day embryo), but diagnosis based on the first polar body uniquely allows preconception assessment, which in certain cultures or venues is the only option (Chapter 10). **Errors in paternal meiosis account for 10% of acrocentric (13, 14, 15, 21, and 22) trisomies.**<sup>18</sup> Among nonacrocentric chromosomes, paternal contribution is uncommon.

### Polyploidy

In polyploidy, more than two haploid chromosomal complements are present. Nonmosaic triploidy ( $3n = 69$ ) and tetraploidy ( $4n = 92$ ) are common in abortuses. Triploid abortuses are usually 69,XXY or 69,XXX as a result of dispermy. An association exists between diandric (paternally inherited) triploidy and hydatidiform mole, a “partial” mole said to exist if molar tissue and fetal parts coexist. The more common “complete” (classic) hydatidiform mole is 46,XX; androgenetic in origin; and composed exclusively of villous tissue. Pathologic findings in diandric triploid and tetraploid placentae include a disproportionately large gestational sac, focal (partial) hydropic degeneration of placental villi, and trophoblast hyperplasia. Placental hydropic changes are progressive and may be difficult to identify in early pregnancy. By contrast, placental villi often undergo hydropic degeneration after fetal demise. This can occur in all types of miscarriage; thus histologic and cytogenetic

investigations are essential to differentiate between true mole and pseudomole because only a true mole can be associated with persistent trophoblastic disease. Fetal malformations associated with triploid miscarriage include neural tube defects and omphaloceles, anomalies reminiscent of those observed in triploid conceptuses that survive to term. Facial dysmorphism and limb abnormalities have also been reported. Tetraploidy is uncommon and rarely progresses beyond 2 to 3 weeks of embryonic life. This chromosomal abnormality can also be associated with persistent trophoblastic disease and thus needs to be identified in order to offer human chorionic gonadotropin (hCG) follow-up.

### Sex Chromosome Polysomy (X or Y)

The complements 47,XXY and 47,XYY have long been stated to occur in about 1 per 800 liveborn male births; 47,XXX occurs in 1 per 800 female births. X and Y polysomies are only slightly more common in abortuses than in live-born infants. Recent work based on cell-free fetal DNA for detection of certain autosomal trisomies and sex chromosome polysomies indicates the incidence of the latter may be less than traditionally stated.<sup>21</sup> Irrespective, the group is not a major contributor to spontaneous abortion.

### Monosomy X

**Monosomy X is the single most common chromosomal abnormality among spontaneous abortions, accounting for 15% to 20% of abnormal specimens** (see Table 27-2). Monosomy X embryos usually consist of only an umbilical cord stump. Later in gestation, anomalies characteristic of Turner syndrome may be seen, such as cystic hygromas and generalized edema (Fig. 27-3). Unlike adult 45,X individuals, 45,X abortuses show germ cells; however, most germ cells in abortuses do

**FIG 27-3** Photograph of a 45,X abortus. (From Simpson JL, Bombard AT. Chromosomal abnormalities in spontaneous abortion: frequency, pathology and genetic counseling. In Edmonds K, Bennett MJ [eds]: *Spontaneous Abortion*. London: Blackwell; 1987:51.)

From Warburton D, Kline J, Stein Z, et al. Does the karyotype of a spontaneous abortion predict the karyotype of a subsequent abortion? Evidence from 273 women with two karyotyped spontaneous abortions. *Am J Hum Genet.* 1987;41:465.

not develop beyond the primordial germ cell stage. The pathogenesis of 45,X germ cell failure thus involves not so much failure of germ cell development as more rapid attrition in 45,X compared with 46,XX embryos.<sup>24,25</sup> Monosomy X usually occurs (80%) as a result of paternal sex chromosome loss, consistent with lack of a maternal age effect.

### Relationship Between Recurrent Losses and Numerical Chromosomal Abnormalities

In both preimplantation and first-trimester abortions, recurrent aneuploidy occurs more often than would be expected by chance. Recurrent aneuploidy is a frequent explanation, at least until the number of losses reaches or exceeds four. **In a given family, successive abortuses are likely to be either recurrently normal or recurrently abnormal.** Table 27-3 shows that if the complement of the first abortus is abnormal,<sup>26,27</sup> recurrence usually involves aneuploidy, although not necessarily of the same chromosome. Further supporting recurrent aneuploidy as a genuine phenomenon is the occurrence of trisomic preimplantation embryos in successive ART cycles.<sup>28,29</sup>

The concept of recurrent aneuploidy implies certain corollaries, one of which has often been the subject of controversy. One is that in recurrent losses, couples should either be experiencing repetitive chromosomally abnormal abortuses or repetitive euploid (chromosomally normal) abortuses. Given that 50% of all abortuses are abnormal cytogenetically, aneuploidy should be as likely to be detected in a randomly karyotyped abortus as in a sporadic abortus. Among 420 abortuses obtained from women with repeated losses, Stephenson and colleagues<sup>31</sup> found 46% had chromosomal abnormalities; 31% of the original sample was trisomic. Their comparison was unselected pooled data, which showed 48% of abortuses to be abnormal; 27% of the original sample was trisomic.

In contrast to these data, a fetal loss—recurrent or not—is much more likely to be cytogenetically normal (85%) when it occurs after the first trimester. Carp and coworkers<sup>32</sup> found that among women with three or more abortuses, the likelihood that the abortus would have an abnormal karyotype was only 29%. However, in that series, inclusion criteria extended to 20 weeks' gestation, a time at which there is less reason to expect recurrent aneuploidy than recurrence of other etiologies.

### Genetic Counseling and Management for Recurrent Aneuploidy

**Couples predisposed to recurrent aneuploidy are at increased risk not only for aneuploid abortuses but also for aneuploid**

**liveborn neonates.** The trisomic autosome in a subsequent pregnancy might be compatible with life (e.g., trisomy 21). Indeed, the risk for liveborn trisomy 21 following an aneuploid abortus is considered clinically to be about 1% (see Chapter 10). A 1% recurrence risk is considered similar following other autosomal aneuploidies. Bianco and associates<sup>34</sup> provided a useful counseling algorithm applicable following a prior abortion of unknown karyotype. If abortions are recurrent but no information is available on the chromosomal status, the odds ratio can be used to derive a patient-specific risk. For example, if the a priori Down syndrome risk is 1 in 300 and the odds ratio is 1.5, a woman's calculated risk after three abortions would be  $1/300 \times 1.5$ , or 1 in 200.

If no information is available concerning the chromosomal status of prior abortuses, paraffin blocks of archived products of conception can be retrieved to detect aneuploidy using array CGH, given that array CGH requires only DNA and not the cultured cells needed for a karyotype. Paraffin block or results of other archived DNA showing a prior trisomy confers increased risk for liveborn trisomy in subsequent pregnancies. If no information can be obtained, it is arguable whether prenatal genetic diagnosis is appropriate. The absolute risk for aneuploid offspring can, however, be calculated as shown by Bianco and associates.<sup>34</sup> The small but finite risk for amniocentesis or CVS is troublesome to couples who have had difficulty achieving a live birth. At present, noninvasive cell-free DNA approaches (see Chapter 10) are typically the chosen option. However, sensitivity for detecting aneuploidy by noninvasive methods is not the nearly 100% possible with CVS or amniocentesis. Preimplantation genetic diagnosis (PGD; see Chapter 10) is another option, and it is the only one if the couple eschews clinical pregnancy termination. Selective transfer of euploid embryos clearly decreases the rate of clinical abortions in couples who experience repeated losses.<sup>35,36</sup> When avoiding another loss is paramount, PGD should be offered.

## CHROMOSOMAL REARRANGEMENTS

### Translocations

**Structural chromosomal abnormalities** are an unequivocal explanation for repetitive abortions. The most common structural rearrangement encountered is a translocation, **found in about 5% of couples who experience repeated losses.** Individuals with balanced translocations are phenotypically normal, but their offspring—abortuses and abnormal liveborn infants—may show chromosomal duplications or deficiencies as a result of normal meiotic segregation. Among couples with repetitive

abortions, about 60% of translocations are reciprocal and 40% are robertsonian. **Women are about twice as likely as men to show a balanced translocation.**<sup>37</sup>

The clinical consequences of a balanced translocation vary depending on the chromosome involved and the type of translocation. If a child has Down syndrome as result of a centric fusion (robertsonian) translocation, the rearrangement will have originated de novo in 50% to 75% of cases. That is, a balanced translocation will not exist in either parent. The likelihood of Down syndrome recurring in subsequent offspring is minimal. On the other hand, the recurrence is significant when an offspring has Down syndrome as result of transmission of a parental translocation. The theoretic risk for having a child with Down syndrome is 33%, but empiric risks are considerably less. The risk is only 2% if the father carries the translocation; the risk is 10% if the mother carries the translocation.<sup>38,39</sup> If robertsonian (centric fusion) translocations involve chromosomes other than 21, liveborn empiric risks are lower; this reflects embryonic lethality. In t(13q;14q), the risk for liveborn trisomy 13 is 1% or less.

**Reciprocal translocations involve not centromeric fusion but rather interchanges between two or more chromosomes.** Empiric data for specific translocations are usually not available, but generalizations can be made on the basis of pooled data derived from many different translocations.<sup>40</sup> Again, theoretic risks for abnormal offspring (unbalanced reciprocal translocations) are far greater than empiric risks applicable to liveborn infants or even prenatal genetic diagnosis. **Overall, the risk is 12% for offspring of either female heterozygotes or male heterozygotes.**<sup>38,39</sup> Detecting a chromosomal rearrangement thus profoundly affects subsequent pregnancy management. Antenatal cytogenetic studies should be offered. The frequency of unbalanced fetuses is lower if parental balanced translocations are ascertained through repetitive abortions (3%) rather than through anomalous liveborn infants (nearly 20%).<sup>38</sup> Presumably more unbalanced products are lethal.

**PGD of embryos from couples who have a balanced translocation reveals that most embryos are unbalanced:** 58% in robertsonian translocations and 76% in reciprocal translocations. This means almost all these conceptuses would be lost preclinically. When a balanced translocation is detected in a couple who experiences recurrent abortions, the *cumulative* prognosis for a liveborn infant differs little from that if a translocation had not been detected.<sup>42</sup> However, the length of time to achieve pregnancy is greatly increased (mean, 4 to 6 years). Thus a more realistic strategy is to use PGD to identify and transfer only the few balanced embryos, thereby increasing the statistical likelihood of conception.<sup>43</sup> This strategy is most attractive when the prospective mother is in her fourth or early fifth decade. Using array CGH, an unbalanced embryo can be readily excluded; however, unlike fluorescence in situ hybridization (FISH), array CGH does not distinguish a balanced (translocation heterozygote) from a normal embryo lacking the translocation.

Rarely, a translocation precludes normal liveborn infants. This occurs when a translocation involves homologous, acrocentric chromosomes (e.g., t[13q13q] or t[21q21q]). If the father carries such a structural rearrangement, artificial insemination may be appropriate. If the mother carries the rearrangement, donor oocytes or donor embryos and ART should be considered.

## Inversions

Inversions are uncommon parental chromosomal rearrangements but are responsible for repetitive pregnancy losses analogous to translocations. **In inversions, the order of the genes is reversed.** Individuals heterozygous for an inversion should be normal if their genes are merely rearranged. However, individuals with inversions suffer untoward reproductive consequences as a result of normal meiotic phenomena.<sup>44</sup> Crossing over that involves the inverted segment yields unbalanced gametes. Pericentric inversions are present in perhaps 0.1% of women and 0.1% of men who experience repeated spontaneous abortions. Paracentric inversions are even rarer.

**Women with a pericentric inversion have a 7% risk for abnormal liveborn infants; men carry a 5% risk.**<sup>40</sup> Pericentric inversions ascertained through phenotypically normal probands are less likely to result in abnormal liveborn infants. Inversions that involve only a small portion of the total chromosomal length paradoxically are less significant clinically because large duplications or deficiencies arise following crossing over, which usually confers lethality. By contrast, inversions that involve only 30% to 60% of the total chromosomal length are relatively more likely to be characterized by duplications or deficiencies compatible with survival. Prenatal cytogenetic studies should be offered.

*Paracentric* inversions should carry less risk for unbalanced products than pericentric inversions because nearly all paracentric recombinants should in theory be lethal. However, abortions and abnormal liveborn infants have rarely been observed within the same kindred, and the risk for unbalanced viable offspring has been tabulated at 4%.<sup>45</sup> Prenatal cytogenetic studies should thus still be offered.

## MENDELIAN AND POLYGENIC/MULTIFACTORIAL ETIOLOGY

That 30% to 50% of first-trimester abortuses show no chromosomal abnormalities does not mean genetic causation is excluded. Fetal demise may have occurred as a result of other genetic etiologies. Specifically, neither mendelian nor polygenic/multifactorial disorders show chromosomal abnormalities, and these etiologies account for more congenital anomalies than do chromosomal abnormalities. It would thus be naïve to assume that mendelian and polygenic/multifactorial factors do not play pivotal roles in embryonic mortality. The difficulty is that it is challenging to identify developmental genes expressed only during embryogenesis. Most likely to be mendelian or polygenic in etiology are abortuses that demonstrate isolated structural anomalies. Cytogenetic data are often lacking on dissected specimens, making it nearly impossible to determine the relative role of cytogenetic versus mendelian or polygenic mechanisms in early embryonic maldevelopment. However, Philipp and Kalousek<sup>46</sup> correlated cytogenetic status of missed abortuses with morphologic abnormalities at embryoscopy. Embryos with chromosomal abnormalities usually showed one or more external anomalies, although some euploid embryos also showed anatomic anomalies.

In addition to traditional single-gene perturbations (mendelian etiology), novel nonmendelian forms of inheritance probably play a greater role in embryonic loss than in liveborn abnormalities. **Mosaicism may be restricted to the placenta, the embryo per se being normal. This phenomenon is termed confined placental mosaicism.**

## LUTEAL PHASE DEFECTS

Implantation in an inhospitable endometrium is a plausible explanation for pregnancy loss. Progesterone deficiency in particular could result in the estrogen-primed endometrium being unable to sustain implantation. Luteal phase deficiency (LPD) has long been hypothesized, specifically caused by inadequate progesterone secreted by the corpus luteum.

**Once almost universally accepted as a common cause of fetal wastage, LPD is now generally considered an uncommon explanation.** One pitfall is that endometrial histology identical to that observed with luteal phase “defects” is observed in fertile women. Efficacy of treatment has also never been proved—no randomized studies exist. Indeed, meta-analysis has shown<sup>47</sup> no beneficial effect of progesterone treatment. **The current consensus is that LPD is either an arguable entity or not proved to be treated successfully with progesterone or progestational therapy.**

Luteal phase abnormalities that arise during ovulation stimulation and necessitated during ART could be a different phenomenon. It is considered standard to administer progesterone until about 9 weeks’ gestation. In this circumstance, the cells that surround the oocyte, which would ordinarily contribute to the corpus luteum, may have been removed when the oocyte was aspirated.

## THYROID ABNORMALITIES

**Decreased conception rates and increased fetal losses are logically associated with overt hypothyroidism or hyperthyroidism** (see Chapter 42). The role of subclinical thyroid dysfunction is less clear and is not generally considered an explanation for repeated losses. However, Negro and colleagues<sup>48</sup> reported that pregnancy loss was higher in thyroid peroxidase-negative women whose thyroid-stimulating hormone (TSH) level was 2.5 to 4 mIU/L compared with those whose TSH level was less than 2.5 mIU/L (6.1% vs. 3.6%). Increased frequency of thyroid antibodies has in addition been observed in several series, and some consider autoimmune thyroid disease a significant cause.<sup>49</sup> The value of treatment in such circumstances is unproved.

Elevations of maternal thyroid hormone per se are clearly deleterious. This effect was shown by a family from the Azores, in whom a gene that conferred resistance to thyroid hormone was segregating.<sup>50</sup> Family members with an autosomal dominant mutation in the thyroid receptor beta (TR-β) gene *Arg243Gln* secreted large amounts of TSH to compensate for end-organ resistance. During pregnancy, the fetus of such a mother becomes unavoidably exposed to high levels of maternal TSH because TSH and thyroxine readily cross the placenta. Loss rates were 22.8% in pregnancies of mothers who had the *Arg243Gln* mutation, 2% in those of normal mothers whose male partner had the mutation, and 4.4% when neither parent had the mutation.

## DIABETES MELLITUS

**Women whose diabetes mellitus is poorly controlled are at increased risk for fetal loss.** Mills and colleagues<sup>51</sup> showed in a National Institute of Child Health and Human Development (NICHD) collaborative study that women whose glycosylated hemoglobin (Hgb) level was greater than 4 standard deviations

(SDs) above the mean had higher pregnancy loss rates than women with lower glycosylated Hgb levels. This finding is consistent with that of many retrospective studies.<sup>52</sup> Poorly controlled diabetes mellitus should be considered one cause for early pregnancy loss. On the other hand, well-controlled or subclinical diabetes should not be considered a cause of early miscarriage. Neither the Royal College of Obstetricians and Gynaecologists (RCOG) nor ACOG recommend testing for occult diabetes mellitus.

## INTRAUTERINE ADHESIONS (SYNECHIAE)

**Intrauterine adhesions could interfere with implantation or early embryonic development.** Adhesions may follow intrauterine surgery (e.g., myomectomy), endometritis, or overzealous uterine curettage during the postpartum period. Curettage is the usual explanation, with adhesions most likely to develop when the procedure is performed 3 or 4 weeks after delivery. Individuals with uterine synechiae usually manifest hypomenorrhea or amenorrhea, but perhaps 15% to 30% have repeated spontaneous abortions. If adhesions are detected in a woman who experiences repetitive losses, lysis under direct hysteroscopic visualization should be performed. Postoperatively, an intrauterine device (IUD) or inflated Foley catheter temporarily placed postoperatively in the uterus discourages reapposition of healing uterine surfaces. Estrogen administration should also be initiated. About 50% of patients conceive after surgery, but the frequency of pregnancy losses remains high.

## MÜLLERIAN FUSION DEFECTS

**Müllerian fusion defects are an accepted cause of second-trimester losses and pregnancy complications.** Low birthweight, breech presentation, and uterine bleeding are the most common abnormalities associated with müllerian fusion defects compared with pregnancies in women who have hysterosalpingogram-proven normal uteri.<sup>53</sup> However, reports typically lack controls.

**Losses are more likely to be associated with a uterine septum than a bicornuate uterus.**<sup>54</sup> In 509 women with recurrent losses studied by three-dimensional (3-D) ultrasound, Salim and associates<sup>55</sup> found greater uterine distortion in women who recounted a history of losses. However, the major problem in attributing cause and effect for second-trimester complications and uterine anomalies is that uterine anomalies are frequent in the general population; thus adverse outcomes could merely be coincidental. For example, in the Salim study, 23.8% of women with recurrent miscarriage had some uterine anomalies on 3-D ultrasound.<sup>55</sup> In another study, unsuspected bicornuate uteri were found in 1.2% of 167 women undergoing laparoscopic sterilization; 3.6% had a severely septate uterus, whereas 15.3% had fundal anomalies.<sup>56</sup> In another series, müllerian defects were found in 22 of 679 fertile women (3.2%), and 20 of the 22 defects were septate.<sup>57</sup>

Treatment has traditionally involved surgical correction, namely metroplasty. Ludmir and colleagues<sup>58</sup> wondered whether aggressive nonsurgical treatment could be just as efficacious. A total of 101 women with an uncorrected malformation were tracked longitudinally. After first being followed without surgery and without a defined nonsurgical regimen, the same women underwent a surgically conservative but medically aggressive protocol that consisted of decreased physical activity and

tocolysis. However, fetal survival rates in both bicornuate and septate groups were not significantly different before (52% and 53%, respectively) or after (58% and 65%, respectively) the change in management.

**In conclusion, early first-trimester abortions may be caused by müllerian fusion defects, but other explanations are more likely even when such a defect is found.** Septate uteri are most plausibly causative, with implantation occurring on a poorly vascularized and inhospitable surface. Abortions that occur after ultrasonographic confirmation of a viable pregnancy—say, at 8 or 9 weeks—may more properly be attributed to uterine fusion defects. Women who experience second-trimester losses could benefit from uterine reconstruction, but reconstructive surgery is not necessarily advisable if losses are restricted to the first trimester.

## LEIOMYOMAS

Although leiomyomas are common, relatively few women develop symptoms that require medical or surgical therapy. That leiomyomas cause first- or second-trimester pregnancy wastage per se, rather than obstetric complications such as prematurity, is plausible but probably uncommon. Analogous to uterine anomalies, the coexistence of two common phenomena—uterine leiomyomas and reproductive losses—need not necessarily imply a causal relationship. Hartmann and Herring<sup>59</sup> correlated ultrasonographically detected leiomyomas with pregnancy outcome in a cohort of North Carolina women. Of 1313 women studied early in pregnancy, the 131 with leiomyomas as ascertained by ultrasound had an increased prior spontaneous abortion rate (odds ratio [OR], 2.17). One pitfall is that uterine contractions can mimic fibroids on ultrasound.

**Location of leiomyomas is probably more important than size.** Submucous leiomyomas are more likely to cause abortion than subserous leiomyomas. Postulated mechanisms that lead to pregnancy loss include (1) thinning of the endometrium over the surface of a submucous leiomyoma, predisposing to implantation in a poorly decidualized site; (2) rapid growth caused by the hormonal milieu of pregnancy, compromising the blood supply of the leiomyoma and resulting in necrosis (“red degeneration”) that in turn leads to uterine contractions and eventually fetal expulsion; and (3) encroachment of leiomyomas on the space required for the developing fetus, leading to premature delivery through mechanisms presumably analogous to those operative in incomplete müllerian fusion. In pregnancies that are not lost, the relative lack of space can also lead to fetal deformations (i.e., positional abnormalities that arise in a genetically normal fetus).

Surgical procedures to reduce leiomyomas may occasionally be warranted in women who experience repetitive second-trimester abortions. **More often, however, leiomyomas have no etiologic relationship to pregnancy loss. Surgery should be reserved for women whose abortuses were both phenotypically and karyotypically normal and in whom viability until at least 9 to 10 weeks was documented.**

## CERVICAL INSUFFICIENCY

A functionally intact cervix and lower uterine cavity are obvious prerequisites for a successful pregnancy. Characterized by painless dilation and effacement, *cervical incompetence*—now preferably called *cervical insufficiency*—usually occurs during the

middle second or early third trimester and usually follows traumatic events such as cervical amputations, lacerations, or conization or forceful cervical dilation. However, the etiology may be genetic; for example, perturbation of a connective tissue gene (e.g., collagen, fibrillin). Indications for surgery and techniques to correct cervical incompetence are discussed in [Chapter 28](#).

## INFECTIONS

**Infections are a known cause of late fetal losses and a logical cause of early fetal losses.** Along with vaccinia, microorganisms associated with spontaneous abortion include variola, *Salmonella typhi*, *Campylobacter fetus* (*Vibrio fetus bacterin*), malaria, cytomegalovirus, *Brucella*, *Toxoplasma gondii*, *Mycoplasma hominis*, *Chlamydia trachomatis*, and *Ureaplasma urealyticum*. Transplacental infection occurs with each of these microorganisms, following which sporadic losses could logically result. However, **infection as a cause of repetitive losses is much less likely.**

Of the many organisms implicated in repetitive abortion, *U. urealyticum* and *M. hominis* seem most plausibly related to repetitive spontaneous abortions because they fulfill two important prerequisites: first, the putative organism can persist in an asymptomatic state; second, virulence is not always so severe as to cause infertility as a result of fallopian tube occlusion and, hence, it does not preclude the opportunity for pregnancy. Studies have also suggested a relationship between bacterial vaginosis (BV), presumed to be *Gardnerella vaginalis*, and spontaneous abortion. However, the latter is more typically, if not exclusively, associated with complications (premature delivery) in the second and third trimesters. A recent systematic review and meta-analysis<sup>60</sup> on the risks associated with BV in infertile patients has shown that it is associated with a significantly elevated risk of preclinical pregnancy loss but is not associated with an increased risk of first-trimester miscarriage.

Given lack of evidence for causality for recurrent losses, it could be questioned whether the infectious agents discussed previously actually cause fetal losses or merely arise after fetal demise from other causes. Cohort surveillance for infections can best shed light on the true role of infections in early pregnancy loss. The frequency of clinical infections was assessed prospectively in 386 diabetic subjects and 432 control subjects seen weekly or every other week beginning early in the first trimester.<sup>61</sup> Infection occurred no more often in the 112 subjects who experienced pregnancy loss than in the 706 who experienced successful pregnancies. This held true both for the 2-week interval in which a given loss was recognized clinically and the prior 2-week interval. Similar findings were observed in both control and diabetic subjects and were substantiated when data were stratified into ascending genital infections only versus systemic infection only.

In conclusion, infections doubtless explain some early pregnancy losses and certainly many later losses. However, in the first trimester, attributable risk is low even in sporadic cases, and in recurrent losses, infections are much less likely.

## ACQUIRED THROMBOPHILIAS

**An association between second-trimester pregnancy loss and certain autoimmune diseases is well accepted<sup>16</sup> (see [Chapter 46](#)).** For first-trimester losses, consensus holds that a less

**significant relationship exists.** The spectrum of antibodies found in women with pregnancy loss encompasses nonspecific antinuclear antibodies as well as antibodies against individual cellular components such as phospholipids, histones, and single- or double-stranded DNA. The primary antigenic determinant is  $\beta_2$ -glycoprotein, which has an affinity for negatively charged phospholipids.<sup>62</sup> The **antiphospholipid syndrome** encompasses lupus anticoagulant (LAC) antibodies, anticardiolipin (aCL) antibody, or anti- $\beta_2$ -glycoprotein. Values for the latter two should be greater than the 99th percentile of moderate or higher titers, with two positive results obtained 12 weeks apart. Descriptive studies in the 1980s initially seemed to show increased aCLs in women with first-trimester pregnancy losses; however, a pitfall proved to be selection bias because it only studied couples following spontaneous abortions. That antibodies did not arise until *after* the pregnancy loss was also not excluded. To address this, Simpson and associates<sup>63</sup> analyzed sera obtained prospectively from women within 21 days of conception. A total of 93 women who later experienced pregnancy loss were matched 2 to 1 with 190 controls who subsequently had a normal liveborn offspring. No association was observed between pregnancy loss and presence of either aPL or aCL.

**In the most recent ACOG bulletin on the topic,<sup>62</sup> three or more losses before the tenth week of pregnancy is considered to fulfill diagnostic criteria for antiphospholipid syndrome in the sense of justifying prophylactic heparin therapy.** It was stated that this assumes neither anatomic or hormonal abnormalities, nor paternal or maternal chromosomal abnormalities. However, ACOG provided the caveat that such an increase neither explains many losses nor confers a greatly increased risk for another loss. Given this, treatment regimens should be judicious, perhaps with aspirin and heparin if embarked on at all. Control groups of fertile women showed similar loss frequencies.

## INHERITED THROMBOPHILIAS

**Inherited maternal hypercoagulable states are unequivocally associated with increased fetal losses in the second trimester but less convincingly in the first trimester (see Chapter 45).** Postulated associations include factor V Leiden (Q1691G→A), prothrombin 2021G→A, and homozygosity for 677C→T in the methylenetetrahydrofolate reductase gene *MTHFR*. A meta-analysis<sup>64</sup> of 31 studies published in 2003 revealed **associations between recurrent (two or more) fetal losses earlier than 13 weeks for thrombophilias related to factor V Leiden (G1691A), activated protein-C resistance, prothrombin (20210A0 gene), and protein-S deficiency.** No associations were found between deficiencies of *MTHFR*, protein C, and antithrombin and recurrent pregnancy loss. A second meta-analysis of 16 studies published by Kovalesky and coworkers<sup>65</sup> reported an association between *recurrent pregnancy loss*, defined as two or more losses in the first two trimesters, and maternal heterozygosity for either factor V Leiden or prothrombin 20210G7→A.

Evidence is less strong for an association between inherited thrombophilias and recurrent early pregnancy loss (REPL) before 10 weeks of gestation. Most authors recommend testing for factor V Leiden, activated protein-C resistance, fasting homocysteine, antiphospholipid antibodies (aPLs), and the prothrombin gene. Pending salutary results in randomized controlled trials (RCTs), treatment for recurrent first-trimester losses

with heparin or other antithrombotic or anticoagulant therapies should be initiated with caution.

## EXOGENOUS AGENTS

**Various exogenous agents have been implicated in fetal losses, although studies fail to stratify these by sporadic and recurrent losses (see Chapter 8).** Of course, every pregnant woman is exposed to low doses of ubiquitous agents, and data are rarely adequate to determine with confidence the role these exogenous factors play in early pregnancy losses.

Outcomes following exposures to exogenous agents can usually be derived only on the basis of case-control studies. In such studies, women who experienced an adverse event (e.g., spontaneous abortion) recalled exposure to the agent in question more often than controls. However, case-control studies have inherent biases. The primary bias is accuracy of recall because controls have less incentive to recall antecedent events than subjects who experience an abnormal outcome. Employers also naturally attempt to limit exposure to women of reproductive age; thus exposures to potentially dangerous chemicals are usually unwitting and, hence, poorly documented. Pregnant women are also exposed to many agents concurrently, making it nearly impossible to attribute adverse effects to a single agent. Given these caveats, **physicians should be cautious about attributing pregnancy loss to exogenous agents.** On the other hand, common sense dictates that exposure to potentially noxious agents should be minimized.

## Radiation and Chemotherapeutic Agents

Irradiation and antineoplastic agents in high doses are acknowledged abortifacients. Of course, therapeutic radiographs or chemotherapeutic drugs are administered during pregnancy only to seriously ill women whose pregnancies often must be terminated for maternal indications. More frequently encountered, pelvic x-ray exposure of up to perhaps 10 cGy places a woman at little to no increased risk. The exposure is usually to far lower doses (1 to 2 cGy). **It is also prudent for pregnant hospital workers to avoid handling chemotherapeutic agents and to minimize radiation exposures during diagnostic imaging.**

## Alcohol

Alcohol consumption should be avoided during pregnancy for reasons independent of pregnancy loss (see Chapters 6 and 8). However, alcohol probably increases pregnancy loss only slightly. Some authors found a slightly increased risk for spontaneous abortion in women who drank in the first trimester, whereas others<sup>66</sup> found alcohol consumption to be nearly identical in women who did and did not experience an abortion: 13% of women who aborted and 11% of control women drank on average three to four drinks per week, and other investigations have reached a similar conclusion. Armstrong and colleagues<sup>67</sup> found the odds ratio to be 1.82 with 20 drinks or more per week.

Abstinence from alcohol should not be expected to prevent pregnancy loss, and evaluation for other causes is still in order. **Thus women should not attribute a loss to social alcohol exposure during early gestation.**

## Caffeine

In data gathered in cohort fashion, Mills and colleagues<sup>68</sup> showed that the odds ratio for association between pregnancy loss and

caffeine (coffee and other dietary forms) was only 1.15 (95% confidence interval [CI], 0.89 to 1.49). Women exposed to much higher levels may, however, be at greater risk. Klebanoff and coworkers<sup>69</sup> reported an association between pregnancy losses and caffeine ingestion greater than 300 mg daily (a 1.9-fold increase). A confounding problem with investigating caffeine is difficulty in taking into account the effects of nausea, which is believed to be more common in successful pregnancies.

**In general, reassurance can be given concerning moderate caffeine exposure and pregnancy loss.**

### Contraceptive Agents

Conception with an IUD in place increases the risk for fetal loss and can result in second-trimester sepsis characterized by a flulike syndrome, albeit rarely. If the device is removed before pregnancy, there is no increased risk for spontaneous miscarriage. **Oral contraceptive use before or during pregnancy is not associated with fetal loss.** The same applies for injectable or implantable contraceptives. No evidence suggests increased pregnancy loss after spermicide exposure before or after conception.

### Chemicals

Limiting exposure to potential toxins in the workplace is prudent for pregnant women. The difficulty lies in first defining the precise effect of lower exposures and then attributing a specific risk. False alarms concerning potential toxins are frequent. **Various chemical agents have been claimed to be associated with fetal losses, but only a few are accepted as potentially causative.**<sup>70</sup> These include anesthetic gases, arsenic, aniline dyes, benzene, solvents, ethylene oxide, formaldehyde, pesticides, and certain divalent cations (lead, mercury, cadmium). Workers in rubber industries, battery factories, and chemical production plants are among those at potential risk.

### Cigarette Smoking

**Active and passive maternal smoking has a damaging effect in every trimester of human pregnancy. Cigarette smoke contains scores of toxins that exert a direct effect on the placental and fetal cell proliferation and differentiation and can explain the increased risk for miscarriage, fetal growth restriction (FGR), stillbirth, preterm birth, and placental abruption** reported by epidemiologic studies.<sup>71</sup> Smoking during pregnancy is often claimed to cause miscarriage, but in available studies, confounding variables are rarely excluded. Increased miscarriage rates reported in smokers do, however, appear to be independent of maternal age and alcohol consumption<sup>72</sup>; based on urinary cotinine levels, 400 women with spontaneous abortions were compared with 570 who experienced ongoing pregnancies. Women with urinary cotinine had increased risk for miscarriage, but the odds ratio was only 1.8 (95% CI, 1.3 to 2.6). A recent systematic review and meta-analysis<sup>73</sup> has shown that any active smoking is associated with increased risk of miscarriage (relative risk ratio [RR], 1.23; 95% CI, 1.16 to 1.30) and that the risk increases with the amount smoked (1% increase in RR per cigarette smoked per day). Furthermore, **secondhand (passive) smoke exposure during pregnancy increases the risk of miscarriage by 11%.**

Smoking is associated, from early pregnancy, with a thickening in the placenta of the trophoblastic basement membrane, an increase in collagen content of the villous mesenchyme, and a decrease in vascularization. These anatomic changes are

associated with changes in placental enzymatic and synthetic functions. In particular, nicotine depresses active amino acid uptake by human placental villi and trophoblast invasion, and cadmium decreases the expression and activity of 11 $\beta$ -hydroxysteroid dehydrogenase type 2, which is causally linked to FGR.<sup>71</sup> Within this context, direct damage to placental tissue could explain the higher rate of miscarriage in heavy smokers.

### TRAUMA

Women commonly attribute pregnancy losses to trauma, such as a fall or blow to the abdomen (see Chapter 26). Actually, fetuses are well protected from external trauma by intervening maternal structures and amniotic fluid. The temptation to attribute a loss to minor traumatic events should be avoided. A nested case-control study of 392 cases and 807 controls showed no relationship between physical violence and miscarriage.<sup>74</sup>

### PSYCHOLOGICAL FACTORS

That impaired psychological well-being predisposes to early fetal losses has been claimed but never proven. Certainly, mentally ill women experience losses, but so do normal women. Whether the frequency of losses is higher in the mentally ill is less certain because potential confounding variables have not been taken into account, nor have confounding genetic factors been considered. Mental illness in pregnancy is discussed in detail in Chapter 55.

Investigations most frequently cited as showing a benefit of psychological well-being are those of Stray-Pedersen and Stray-Pedersen.<sup>75</sup> Pregnant women who previously experienced repetitive spontaneous abortions received increased attention but no specific medical therapy ("tender loving care"). These women ( $n = 16$ ) were more likely (85%) to complete their pregnancy than women ( $n = 42$ ) not offered such close attention (36%). One pitfall was that only women living close to the university were eligible to be placed in the increased-attention group. Women who lived farther away served as controls; however, these women may have differed from the experimental group in other ways as well. Other studies have also reported a beneficial effect of psychological well-being.<sup>75,76</sup> Again, pitfalls exist in study design, and the biologic explanation for this salutary effect remains obscure.

### COMMON MEDICATIONS

Nonsteroidal antiinflammatory drugs (NSAIDs) are widely used during pregnancy. A recent cohort of 65,457 women found no increased risk of early pregnancy loss for specific NSAID drugs except for a significantly increased risk with exposure to indomethacin.<sup>77</sup>

A large Danish epidemiologic study of 22,061 pregnancies exposed to antidepressants found a slightly increased risk of miscarriage.<sup>78</sup> Among women with a diagnosis of depression, antidepressants in general, and individual selective serotonin reuptake inhibitors (SSRIs) in particular, are not associated with miscarriage. In a similar study from Denmark, women taking antiepileptic drugs were not at a higher risk of early pregnancy loss.<sup>79</sup>

## MANAGEMENT OF RECURRENT EARLY PREGNANCY LOSS

Although some epidemiologic, clinical, and biochemical risk factors are clearly associated with REPL, a specific etiology in most cases remains unknown. **Two main concepts have dominated the literature on this topic in the last two decades: (1) that REPL is mainly caused by aneuploid conceptions and other genetic errors and that the recurrence rate can be explained by the combination of chance and increased risk and (2) that maternal thrombophilic, endocrine, or immune system abnormalities play a main role in causing loss of euploid conceptions.**

Faced with a couple who has experienced a miscarriage, the obstetrician has several immediate obligations that are to (1) provide the couple information on the overall frequency of fetal wastage (10% to 12% of clinically recognized pregnancies<sup>80</sup> and many more unrecognized) and likely etiology (genetic and especially cytogenetic); (2) provide them with individual applicable recurrence risks (see Table 27-2); and (3) determine the necessity for a formal clinical evaluation that includes ultrasound screening for uterine anomalies and laboratory screening of parental chromosomes and maternal aPLs. Fulfilling the responsibility to inform patients can be facilitated by summarizing the salient facts cited in this chapter, emphasizing common etiologies responsible for fetal losses. Explicitly worth citing is the positive correlation between loss rates and both maternal age and prior losses. The maternal age effect is not solely the result of increased aneuploid conception but is also reflective of endometrial vascular, endocrinologic, and immunologic factors.

### When Is Formal Evaluation Necessary?

**A couple who experiences even one loss should be counseled and provided with recurrence risk rates. However, not every couple needs formal assessment and a battery of tests.** Infertile couples in which the female partner is in her late thirties or older may choose to be evaluated formally after only two losses and may opt for PGD aneuploidy testing if they require in vitro fertilization (IVF). After three losses, couples have traditionally been directed to formal evaluation. **Although a firm scientific basis for waiting until three losses is lacking, this is the benchmark for the RCOG and the European Society of Human Reproduction and Embryology (ESHRE).**<sup>80</sup> **The ACOG defines recurrent loss as either two or three consecutive losses.** This 2001 ACOG guideline<sup>81</sup> is perhaps more defensible scientifically, but the “consecutive” part is arguable.

A couple being evaluated should undergo all the tests used by a given practitioner. Little rationale exists for pursuing certain studies after two losses yet deferring others until three or more losses. **Any couple who has a stillborn or anomalous liveborn infant should undergo cytogenetic studies unless the stillborn was known to have a normal chromosomal complement.** Parental chromosomal (conventional metaphase) rearrangements (i.e., translocations or inversions) should be excluded. If chromosomal studies on the stillborn were unsuccessful, common aneuploidies can still be ruled out by performing FISH on stored deparaffined tissue.

### Recommended Evaluation

Couples who experience only one first-trimester spontaneous abortion should receive relevant information but not necessarily

a formal evaluation. They should be apprised of the relatively high (10% to 15%) pregnancy loss rate in the general population and also the beneficial effects of miscarriage in eliminating abnormal conceptuses. The clinician can also provide relevant recurrence risks; usually 20% to 25% of subsequent losses occur to couples who had a prior liveborn infant, and this statistic is only slightly higher in the absence of a prior liveborn infant (see Table 27-1). However, risks are higher for older women than younger women. If a specific medical illness exists, treatment is obviously necessary. If present, intrauterine adhesions should be lysed. Otherwise, no further evaluation need be undertaken, even if uterine anomalies or leiomyomas are present.

Investigation may or may not be necessary after two spontaneous abortions, depending on the patient's age and personal desires; after three, evaluation is usually indicated. If not done previously, the clinician should (1) obtain a detailed family history, (2) perform a complete physical examination, (3) discuss recurrence risks, and (4) order selected tests enumerated in this chapter. Occurrence of a stillborn or liveborn infant with anomalies warrants genetic evaluation irrespective of the number of pregnancy losses.

Parental chromosomal studies should be undertaken on all couples who experience repetitive losses. Antenatal chromosomal studies should be offered if a balanced chromosomal rearrangement is detected in either parent or if autosomal trisomy occurred in any previous abortus.

Although it is perhaps impractical to karyotype all abortuses, cytogenetic information on abortuses is valuable. Detection of a trisomic abortus suggests recurrent aneuploidy, which justifies prenatal cytogenetic studies in future pregnancies. Performing invasive prenatal cytogenetic studies solely on the basis of repeated losses is more arguable but not unreasonable among women aged 30 years and older.

Endocrine causes for repeated fetal losses include poorly controlled diabetes mellitus, overt thyroid dysfunction, and elevated maternal TSH levels. Subclinical diabetes or subclinical thyroid disease (TSH >2.5 mIU/L) should not be considered firm explanations.<sup>82</sup> Luteal phase defects are also no longer considered a likely explanation, although luteal support (progesterone) is still prescribed in pregnancies achieved with IVF. Progesterone supplementation is safe for both mother and baby, but data are insufficient to support its routine use in women with REPL. Larger trials are currently underway to inform treatment for this group of women.

Of infectious agents, only *C. trachomatis* and *U. urealyticum* seem equally plausible because these two agents generate chronic infections and potentially repetitive losses, whereas others are more likely to cause only sporadic losses. The endometrium could be cultured for *U. urealyticum*. Alternatively, a couple could be treated empirically with doxycycline. The prevalence of chronic endometritis is 7% in REPL, and the live birth rate is increased after antibiotic therapy; this suggests a subgroup of REPL may benefit from this management approach.<sup>83</sup>

If spontaneous abortion occurs after 8 to 10 weeks' gestation, a uterine anomaly should be considered a potential cause, and the uterine cavity should be explored by hysteroscopy or hysterosalpingography. Intrauterine adhesions should be lysed. If a müllerian fusion defect (septate or bicornuate uterus) is detected in a woman who has experienced one or more second-trimester spontaneous abortions, surgical correction may be warranted.

Women with either acquired or inherited thrombophilias appear to have a slightly increased risk for first-trimester

pregnancy loss. Thrombophilias explain at best only a small portion of first-trimester losses. The likelihood is much greater that thrombophilias are the cause of a second-trimester loss. Anticoagulant agents such as aspirin and heparin have been shown to increase the chance of live birth in subsequent pregnancies in women with REPL associated with antiphospholipid syndrome.<sup>84</sup> Whether antithrombotic therapy increases the chances of live birth in women with inherited thrombophilia remains unknown. RCTs have consistently shown no beneficial effect of antithrombotic therapy in women with unexplained REPL.<sup>85,84</sup>

The clinician should discourage exposure to cigarettes and alcohol yet not necessarily ascribe cause and effect in an individual case. Similar counsel should apply for exposures to other potential toxins. Identification of substance abuse and environmental history during the preconception period provides an opportunity to assist women in reducing major health risks in addition to reducing early pregnancy loss (see Chapters 6 and 8).

Idiopathic secondary REPL may be associated with an abnormal maternal immune response to subsequent pregnancies, and some authors have proposed that women with REPL should be investigated for autoimmune and cellular immune abnormalities. It is speculated that in women, an elevation of natural killer (NK) cells may have an effect on reproductive performance, and NK cell levels in blood are currently being used as a diagnostic test to guide the initiation of therapies in both infertile women<sup>86</sup> and in those who present with REPL. A recent meta-analysis of studies that evaluated peripheral NK cell percentages and numbers in women with recurrent miscarriage (RM) versus controls showed significantly higher NK cell percentages in women with RM.<sup>86</sup> Several immunotherapies have been used to treat women with otherwise unexplained losses. Paternal cell immunization, third-party donor leukocytes, trophoblast membranes, and intravenous immunoglobulin provide no significant beneficial effect over placebo in improving the live birth rate.<sup>87,88</sup>

LATE PREGNANCY LOSS (STILLBIRTH)

**Stillbirth is the term used to describe pregnancy loss at 20 weeks' gestation or greater.** By weight, the definition is 350 g, the 50th percentile at that week of gestation. The frequency of stillbirths in the United States is 1 in 160 deliveries, or 25,000 annually. Stillbirths are increased in a large number of conditions whose management is discussed elsewhere in this text (see Chapter 11). These conditions include obesity, multiple gestations with or without prematurity, infections (e.g., parvovirus-B19), advanced maternal age, and a host of systemic maternal diseases that include but are not limited to diabetes mellitus, chronic and gestational hypertension, autoimmune diseases, and renal and thyroid diseases. Passive and active smoking and illicit drug use during pregnancy separately or in combination are associated with an increased risk of stillbirth (OR 1.94).<sup>89</sup> Table 27-4 shows prevalence and estimated rates compiled in 2005 by Fretts<sup>90</sup> and reproduced in 2009 by ACOG.<sup>16</sup>

Pregnancy loss after 20 weeks is higher overall in blacks (11 per 1000) than in other ethnic groups (6 per 1000), which include Hispanics and Native Americans.<sup>16</sup>

Recurrence

Recurrence reflects disease severity and ability to treat; thus no single risk factor is necessarily appropriate. However, a few risk

TABLE 27-4 ESTIMATES OF MATERNAL RISK FACTORS AND RISK FOR STILLBIRTH

| CONDITION                                      | PREVALENCE AMONG STILLBORNS | ODDS RATIO |
|--|-----------------------------|------------|
| General population                             | —                           | 1.0        |
| Previous growth-restricted infant (<10%)       | 7%                          | 2-4.6      |
| Previous stillbirth                            | 1%                          | 1.4-3.2    |
| Multiple gestation:                            |                             |            |
| Twins  | 3%                          | 1.0-2.8    |
| Triplets                                       | 0.1%                        | 2.8-3.7    |
| Low-risk pregnancies                           | 80%                         | 0.86       |
| Hypertensive disorders:                        |                             |            |
| Chronic hypertension                           | 6%-10%                      | 1.5-2.7    |
| Pregnancy-induced hypertension                 |                             |            |
| Mild   | 6%-8%                       | 1.2-4.0    |
| Severe   | 1%-3%                       | 1.8-4.4    |
| Diabetes:                                      |                             |            |
| Treated with diet                              | 3%-5%                       | 1.2-2.2    |
| Treated with insulin                           | 2.4%                        | 1.7-7.0    |
| Systemic lupus erythematosus                   | <1%                         | 6 to 20    |
| Renal disease                                  | <1%                         | 2.2-30     |
| Thyroid disorders                              | 0.2%-2%                     | 2.2-3.0    |
| Thrombophilia                                  | 1%-5%                       | 2.8-5.0    |
| Cholestasis of pregnancy                       | <0.1%                       | 1.8-4.4    |
| Smoking >10 cigarettes daily                   | 10%-20%                     | 1.7-3.0    |
| Obesity (prepregnancy):                        |                             |            |
| Body mass index 25-29.9 kg/m <sup>2</sup>      | 21%                         | 1.9-2.7    |
| Body mass index >30                            | 20%                         | 2.1-2.8    |
| Advanced maternal age (reference <35 yr):      |                             |            |
| 35-39 years                                    | 15%-18%                     | 1.8-2.2    |
| ≥40 years                                      | 2%                          | 1.8-3.3    |
| Black women compared with white women          | 15%                         | 2.0-2.2    |
| Low educational attainment (<12 yr vs. ≥12 yr) | 30%                         | 1.6-2.0    |

Modified from the American College of Obstetricians and Gynecologists (ACOG). Practice Bulletin: Management of Stillbirth. No. 102:1. Washington, DC: ACOG; 2009.

factors are broadly applicable. Maternal age is positively correlated with stillborn risk. This reflects not only the predictable known fetal etiologies (e.g., chromosomal abnormalities) but also maternal complications that are simply age related.

**Stillbirth occurs more often in primiparous women of a given age than in multiparous women of comparable age.** This may correlate to difficulty in achieving pregnancy, which is of greatest relevance to women who require ART. Women who are subfertile (increased time to pregnancy) but never require ART have an increased risk for birth defects compared with women who achieve pregnancy in less than 1 year.<sup>91</sup> **Offspring of both ART couples and subfertile couples who do not require ART have 20% to 30% more birth defects (OR 1.2 to 1.3) than offspring of women who previously became pregnant within 12 months of attempting.**<sup>91</sup>

**Risks for stillbirth are highest (twofold) in women delivered of a growth-restricted infant earlier than 32 weeks' gestation.**<sup>92,93</sup> This risk is, incidentally, independent of mode of delivery (cesarean or vaginal). Using Scottish morbidity records (1981 to 2000), the odds ratio for stillbirth recurring in the second pregnancy was 1.94.<sup>94</sup> A recent systematic review and meta-analysis indicated that compared with vaginal birth, women with a previous cesarean delivery (CD) are at higher risk of unexplained stillbirth.<sup>95</sup> The etiology behind the higher rates

of stillbirth in subsequent pregnancies after CD remains unknown, but a higher incidence of placental abruption after CD suggests impaired placentation.

### Genetic Factors

Genetic factors for stillbirths are receiving increased recognition by the ACOG, which has provided specific management recommendations. **Chromosomal abnormalities or significant copy number variants (microdeletions, microduplications) are detected in 8% to 13% of stillbirths.<sup>17,96,97</sup> Thus special effort should be made to determine chromosomal status of a stillborn.** It is now recognized that the traditional approach of obtaining fetal tissue after a stillborn infant has been delivered is suboptimal. Cell culture often fails and leads to no results in perhaps 50% to 75% of cases. **Successful culture for chromosomal analysis occurs in 80% when amniocentesis is used to obtain cells.** It is tempting to eschew an invasive procedure in an already stressed patient, but this would not be in her long-term best interest. Alternatively, as discussed earlier, array CGH does not require cultured cells and further detects microdeletions and microduplications not detectable by a karyotype.

Detecting even trisomies clinically by examination of a stillbirth is unexpectedly difficult because maceration occurs within days of fetal demise. Thus medical records that state lack of dysmorphism should be suspect, save for obvious structural defects (e.g., cleft lip, myelomeningocele). Ultrasound results obtained when the pregnancy was still viable are probably more reliable. If amniocentesis cannot be performed or if cultures fail, an attempt should be made to obtain FISH results to exclude common trisomies. This can be done on placental tissues, umbilical cord segments, or internal (noncontaminated) tissues such as connective tissue.

**The major yield of autopsy for a stillborn fetus is detection of an unrecognized mendelian explanation.** This obviously alters management in subsequent pregnancies, for which reason a major effort should be exerted. Whole-body photographs and whole-body radiographs are appropriate, as is placental examination by a physician with requisite expertise. Considerable progress has been made in particular in diagnosing skeletal dysplasia, often an autosomal-recessive disorder that can recur in subsequent pregnancies. Other disorders may be autosomal-dominant disorders that arise as a result of de novo mutations. Distinguishing between these two possibilities is important because the recurrence risk should be almost nil if the etiology is a de novo autosomal dominant disorder. If parents refuse autopsy, the provider should attempt to obtain as much information as possible: photographs, radiographs or magnetic resonance images, ultrasound, and examination by a geneticist. A head-sparing autopsy is preferable to no autopsy and may be acceptable to the parents.

### Polygenic/Multifactorial Disorders

The frequency of virtually any isolated birth defect is higher among stillborn fetuses than among neonates. This reflects adverse selection in utero, a phenomenon recognized for years in ultrasound surveillance. If an isolated, organ-specific defect occurs (e.g., cardiac), polygenic/multifactorial etiology and recurrence risks (2% to 5%) usually apply. On the other hand, such a defect may be merely the only one evident but is actually a component of a multiple-malformation complex. Ability to distinguish between these possibilities is a major reason for

#### BOX 27-1 MATERNAL LABORATORY TESTS RECOMMENDED BY THE AMERICAN COLLEGE OF OBSTETRICIANS AND GYNECOLOGISTS AFTER STILLBIRTH

##### All Mothers of Stillborn Infants

- Complete blood count
- Kleihauer-Betke or other test for fetal cells in the maternal circulation
- Human parvovirus-B19 immunoglobulin G; immunoglobulin M antibody
- Syphilis
- Lupus anticoagulant
- Anticardiolipin antibody
- Thyroid-stimulating hormone

##### Selected Mothers of Stillborn Infants

- Thrombophilia:
  - Factor V Leiden
  - Prothrombin gene mutation
  - Antithrombin III
  - Homocysteine (fasting)
- Protein-S and protein-C activity
- Parental karyotypes
- Indirect Coombs test
- Glucose screening (oral glucose tolerance test, hemoglobin A1c)
- Toxicology screen

Data from the American College of Obstetricians and Gynecologists (ACOG). Practice Bulletin: Management of Stillbirth. No. 102:1. Washington, DC: ACOG; 2009.

autopsy. **The multiple malformation syndrome could indicate mendelian etiology.**

### Maternal Evaluation

**Certain maternal laboratory tests are recommended by ACOG (Box 27-1).** Of course, a mother whose pregnancies have medical complications has already undergone many tests, and the cause of the stillbirth may seem obvious (e.g., diabetes mellitus). It is prudent, however, to order all these laboratory tests because the ostensible diagnosis may prove erroneous. Of note, ACOG does not recommend testing for antinuclear antibodies and certain serologies (toxoplasmosis, rubella, cytomegalovirus, herpes simplex virus), nor do they recommend genetic tests other than a karyotype. However, it is likely in the foreseeable future that array CGH (see Chapter 10), a panel of organ-specific mutations (e.g., skeletal dysplasias), or other genetic tests will prove practical. Caution is necessary before concluding that a stillbirth was caused by a condition signified by a positive laboratory test (e.g., thrombophilia), and such a finding does not obviate the need for fetal autopsy and fetal genetic tests.

### Management in Subsequent Pregnancies

Quality ultrasound and vigilant fetal surveillance are universally recommended. Induction is recommended at 38 weeks, but before that time, only with demonstrated fetal lung maturity. Management otherwise will focus on any specific maternal factors identified (e.g., diabetes mellitus). In some pregnancies, management will differ little from that of the general obstetric patient. In others, prenatal genetic diagnosis will be necessary.

## OBSTETRIC OUTCOME AFTER EARLY PREGNANCY COMPLICATIONS

Most early pregnancy complications occur before 12 weeks of gestation and involve placentation and early placental development. Increasing evidence shows that many failures of placentation are associated with an imbalance of free radicals, which will further affect placental development and function and may subsequently have an influence on both the fetus and the mother but are often ignored by clinicians.<sup>2</sup>

Complications that include miscarriage, threatened miscarriage with or without an intrauterine hematoma, and vanishing twin are extremely common in early pregnancy throughout the world. Very little is known about the short- and long-term consequences of these complications on ongoing and, in particular, subsequent pregnancies. Most data available are derived from small retrospective series of many different complications and pathologies or large series that describe specific pathology but with wide variations in the definitions of the pathophysiology.

**Recent meta-analysis and reviews have indicated an increased risk for adverse outcome in ongoing pregnancies after an early pregnancy event.** Clinically relevant associations of adverse outcome in the *subsequent* pregnancy with an odds ratio higher than 2 after complications in a previous pregnancy are the risk for perinatal death after a single previous miscarriage; the risk for very preterm delivery (VPTD) after two or more miscarriages; and the risk for placenta previa, premature preterm rupture of membranes (PPROM), VPTD, and low birthweight (LBW) after recurrent miscarriage.<sup>98</sup> Clinically relevant associations of adverse obstetric outcome in the *ongoing* pregnancy with an odds ratio higher than 2 after complications in the index pregnancy are the risks for preterm delivery (PTD), VPTD, placental abruption, small for gestational age (SGA), LBW, and very low birthweight (VLBW) after a threatened miscarriage episode; pregnancy-induced hypertension, preeclampsia, placental abruption, PTD, SGA, and low 5-minute Apgar score following the detection of an intrauterine hematoma; and VPTD, VLBW, and perinatal death after a vanishing twin phenomenon.<sup>99</sup> These data indicate a link between early pregnancy complications that involve the placenta and subsequent adverse obstetric and perinatal outcomes.

Heterogeneity is observed among most studies, and many of the older controlled studies did not make adjustments for relevant confounders for adverse obstetric outcome—such as age, ART, economic status, education level, ethnicity, height, marital status, parity, previous obstetric outcome, prolonged infertility, smoking, and maternal weight—or they did not stratify for other first-trimester complications.<sup>98,99</sup> However, overall more recent large meta-analyses and controlled population-based prospective studies have confirmed previous data that indicate a strong association between specific early pregnancy events and subsequent late obstetric complications in the subsequent or ongoing pregnancy.<sup>99</sup> **In particular, the risk for PTD and VPTD is increased after most first-trimester complications.** This suggests that early detection of these risk factors could improve the screening of women at high risk for specific obstetric complications in ongoing and subsequent pregnancies. Furthermore, the antenatal identification of these parameters during the first half of pregnancy should enable better management protocols and new therapeutic guidelines aimed at improving the perinatal outcome in these groups of women at higher risk for abnormal pregnancy outcome.

## KEY POINTS

- ◆ About 50% to 70% of conceptions are lost, most in the first trimester. Losses in preimplantation embryos are especially high: 25% to 50% of morphologically normal and 50% to 75% of morphologically abnormal embryos.
- ◆ Pregnancy loss is age dependent, and 40-year-old women have twice the loss rate of 20-year-old women. Most of these pregnancies are lost before 8 weeks' gestation.
- ◆ At least 50% of clinically recognized pregnancy losses show a chromosomal abnormality, and those in abortuses differ from those found in liveborn infants, although autosomal trisomy still accounts for 50% of abnormalities. A balanced translocation is present in 5% of couples with REPL.
- ◆ Many nongenetic causes of REPL have been proposed, but few are proven. Efficacy of treatment often remains uncertain.
- ◆ Uterine anomalies are accepted causes of second-trimester losses, but their role in first-trimester losses is less clear. Couples who experience a second-trimester loss may benefit from metroplasty or hysteroscopic resection of a uterine septum.
- ◆ Drugs, toxins, and physical agents are uncommon causes of early pregnancy loss, especially repetitive loss. It should not be assumed that exposures to toxicants explain repetitive losses. Passive and active smoking and illicit drug use are associated with higher rates of both early pregnancy loss and stillbirth.
- ◆ Antiphospholipid syndrome (antibodies to LAC, aPL, and anti- $\beta_2$ -glycoprotein) is an accepted cause of second-trimester losses; its role in first-trimester losses is arguable. Strict ACOG criteria exist for applying the diagnosis of antiphospholipid syndrome to a woman who had had repeated first-trimester REPL.
- ◆ In REPL, prognosis is good even without therapy. The live birth rate is 60% to 70% even with up to four losses and no prior liveborn infants. An efficacious therapeutic regimen should show success rates greater than these expected background rates, or these should be assessed in an RCT. Women who have had more than four losses are less likely to have a cytogenetic explanation and may have a different prognosis.
- ◆ The frequency of chromosomal abnormalities in stillbirths (losses after 20 weeks' gestation or weighing at least 350 g) is underappreciated, as are nonchromosomal genetic factors (e.g., syndromes). Tissue for cytogenetic studies should be obtained by amniocentesis or chorionic villus sampling; cultures initiated from post-delivery products often lead to unsuccessful culture.
- ◆ A major effort should be exerted to obtain full autopsy and imaging on all stillbirths because findings can alter management in future pregnancies. If a couple declines an autopsy, whole-body radiographs, magnetic resonance imaging, and other noninvasive imaging should be pursued.
- ◆ Adverse first-trimester events or complications in a current or previous pregnancy may interfere with normal placentation and increases the risks for specific later obstetric complications.

## OVERVIEW

Since the initial description in 1658 of the cervix being “so slack that it cannot keep in the seed” by Cole and Culpepper,<sup>1</sup> few subjects in obstetrics have generated as much controversy as the term *cervical incompetence*, now more correctly termed **cervical insufficiency**. The competent or “sufficient” human uterine cervix is a complex organ that undergoes extensive changes throughout gestation and parturition. It is a key structure responsible for keeping the fetus and membranes inside the uterus until the end of gestation and for undergoing significant changes to allow the delivery of the baby during spontaneous or induced labor.

**The cervix is primarily fibrous connective tissue composed of an extracellular matrix that consists of collagen types I and II, elastin, proteoglycans, and a cellular portion that consists of smooth muscle and blood vessels.** A complex remodeling process of the cervix occurs during gestation that involves timed biochemical cascades, interactions between the extracellular and cellular compartments, and cervical stromal infiltration by inflammatory cells.<sup>2</sup> Any disarray in this timed interaction could result in early cervical ripening, cervical insufficiency, and preterm birth (PTB) or miscarriage.

**The incidence of cervical insufficiency in the general obstetric population is reported to vary between approximately 1/100 and 1/2000.<sup>3</sup> If women with a singleton gestation, a prior spontaneous preterm birth (sPTB), and a current transvaginal ultrasound (TVU) cervical length (CL) less than 25 mm are labeled as having cervical insufficiency, the incidence is about 3% to 4%.<sup>4</sup>** Wide variations in estimating the incidence are likely due to real biologic differences among study populations, the criteria used to establish the diagnosis, and reporting bias between general practitioners and referral centers. Once considered a discrete entity reserved for patients with a

history of midtrimester loss associated with painless cervical dilation, in the last few years, this diagnosis has become a component of the spontaneous preterm birth syndrome (see Chapter 29). Strategies that include the identification of a short cervix in the index gestation have been developed with different management protocols utilized to reduce the rate of PTB.

### CERVICAL INSUFFICIENCY: A DISTINCT ENTITY OR EVIDENCE OF PRETERM PARTURITION?

In 1962, Danforth and Buckingham<sup>5</sup> suggested that **cervical incompetence was not an all-or-none phenomenon; rather it comprised degrees of insufficiency, and combinations of factors could cause “cervical failure.”** These classic investigations demonstrated that unlike the uterine corpus, the normal cervix is composed predominantly of connective tissue. This fibrous band is the chief mechanical barrier against the loss of the enlarging products of conception. The cervix and mucous glands also play an important immunologic role in preventing vaginal flora from ascending into the normally sterile intrauterine environment.

In a subsequent report, these investigators analyzed cervical biopsies taken from postpartum women and compared them with hysterectomy specimens from nonpregnant patients.<sup>6</sup> Pregnancy was associated with increased water content, a marked decline in collagen and glycoprotein, and increased glycosaminoglycans. **The cellular and biochemical changes suggested that cervical dilation in pregnancy is a dynamic process,** and this might explain why a woman could have a pregnancy outcome consistent with cervical insufficiency in one pregnancy but then, without treatment, have a subsequent term birth. Presumably, the factors that incite the pathologic cervical changes might vary among pregnancies. Women with a more muscular cervix might have heightened susceptibility to factors that lead to cervical changes and PTB.

These earlier observations were enlarged by Leppert and colleagues,<sup>7</sup> who reported an absence of elastic fibers in the cervix of women with clinically well-characterized cervical insufficiency on the basis of their reproductive history. Conversely, cervical biopsy specimens from women with normal pregnancies showed normal amounts and orientation of these elastic fibers. It is unknown whether these microstructural and biochemical phenomena were congenital, acquired from previous trauma, or the result of other pregnancy-associated pathologic conditions. Collectively, these biochemical and ultrastructural findings support the variable, and often unpredictable, clinical course of women with a history of cervical insufficiency.<sup>8</sup>

Whereas the traditional paradigm depicted the cervix as either competent or incompetent, both clinical data<sup>9,10</sup> and interpretative reviews<sup>11,12</sup> suggest that, **as with most other biologic processes, cervical “competence” is rarely an all-or-none phenomenon.** The term *cervical insufficiency* has been historically thought to represent a defect inherent in the cervix itself that leads to an inability to retain a pregnancy. Initial treatment, as we will discuss later, was aimed at preventing pregnancy loss by reinforcing the structural integrity of the cervix and repairing the defect in the cervical stroma. However, as we have gained more insight into the various surgical, mechanical, and biochemical modalities used to treat cervical pathology, investigators have questioned whether abnormal cervical anatomy is

the dominant cause or whether, at times, other factors play a major role.

**Cervical insufficiency, as classically defined, is recurrent painless cervical dilation that leads to three or more midtrimester births.**<sup>13</sup> However, painful contractions are not a prominent feature of early cervical change, with the magnitude of contraction-related pain inversely proportional to the extent of cervical ripening prior to their onset.<sup>14</sup> In contrast to a proposed mechanism of defective cervical tissue, although some patients may have tangible anatomic evidence of poor cervical integrity, most women with a clinical diagnosis of cervical insufficiency have ostensibly normal cervical anatomy. Knowing whether cervical integrity was compromised by a primary mechanical deficiency, versus other local or systemic factors, would help to define the optimal therapy. **In a proposed model of cervical competence as a continuum, a poor obstetric history attributed to cervical insufficiency likely results from a process of premature cervical ripening induced by myriad underlying processes that include infection, inflammation, local or systemic hormonal effects, or even genetic predisposition.** If and when cervical integrity is compromised, other processes may be stimulated (e.g., premature membrane rupture, preterm labor) and appear clinically as the spontaneous preterm parturition syndrome, which may also contain features related to the uterus and chorioamnion.<sup>15</sup> Thus the term *cervical insufficiency* may be increasingly considered a clinically convenient label to describe a complex and poorly understood process of premature cervical ripening and the midtrimester onset of parturition. Given this, we recognize that newer approaches to the management of cervical insufficiency have been included within the broader topic of PTB prevention.

### SHORT CERVIX

Traditionally, *cervical insufficiency* (CI) has been defined by criteria based solely on obstetric history: painless cervical dilation that leads to recurrent second-trimester births in the absence of other causes. The modern approach allows the diagnosis of CI to be made in primigravidas or in multigravidas without multiple prior pregnancy losses. **This new description defines CI by the presence of both (1) TVU cervical length less than 25 mm and/or cervical changes detected on physical examination before 24 weeks of gestation and (2) prior sPTB at less than 37 weeks.** Regarding this second criterion, some limit it to sPTB up to 34 weeks.<sup>4</sup> TVU screening is the gold standard for evaluation of the CL for prediction of PTB. CL can also be measured with transabdominal ultrasound (TAU) or translabial ultrasound (TLU), but these techniques should not be used clinically for prediction of PTB because TVU is superior in many ways. The TAU CL measurement is less sensitive in detecting a short CL, is noted to overestimate CL and underdiagnose short CL,<sup>16</sup> and has several additional limitations: (1) a full bladder is needed; (2) the cervix maybe obscured by the fetal parts; and (3) the image is of poorer quality because of the distance from the abdominal probe to the cervix.<sup>17</sup> TVU CL screening has been shown to have superior cost-effectiveness compared with TAU because TVU is associated with better prevention of PTB.<sup>18</sup> All major guidelines that have described CL screening have clearly recommended TVU, including the Society for Maternal-Fetal Medicine (SMFM),<sup>19</sup> American College of Obstetricians and Gynecologists (ACOG),<sup>20</sup> and the Royal College of Obstetricians and Gynaecologists (RCOG).<sup>21</sup>

TLU is also less sensitive and less predictive than TVU.<sup>17,21</sup> Given this evidence, TAU or TLU should not be used for CL screening. Moreover, TVU has been shown to be more predictive of sPTB compared with digital manual examination of the cervix.<sup>22</sup>

**TVU CL screening should be done using the technique described by the Cervical Length Education and Review (CLEAR) program<sup>23</sup> and the SMFM through its Perinatal Quality Foundation.** The CLEAR program provides an official education program on TVU CL screening with examination and continuing image review to certify perinatologists, obstetricians, residents/fellows in training, and sonographers. TVU CL screening should be performed in clinical practice only after this program has been completed.

TVU CL measurement is a safe, acceptable, and reliable screening test that is now widely used to screen women for their risk for PTB.<sup>24</sup> TVU CL screening is done after the patient has emptied her bladder. Then, a sterile transvaginal probe is inserted into the anterior vaginal fornix. Initially the probe is withdrawn until the image blurs to reduce compression from the transducer, then just enough pressure is reapplied to create the best image. The TVU image of the cervix should occupy 75% of the screen, and the lower tip of the bladder should also be visible. The anterior width of cervical thickness should be equal to the posterior cervical thickness, and there should be no increased echogenicity in the cervix because of excessive pressure. Prior to the measurement, the internal and external os and the entire endocervical canal should be identified. The calipers should be correctly placed to measure the distance from the internal to the external os (Fig. 28-1). Three measurements of CL are usually obtained, then mild fundal pressure is applied for about 15 seconds to watch for funneling and/or cervical shortening. It is advisable to reduce probe pressure while fundal or suprapubic pressure is applied. The total time for TVU CL screening should be no less than approximately 5 minutes. With proper technique, the intraobserver and interobserver variabilities are both less than 10%. The population studied can affect the performance of CL screening. These include singleton versus multiple gestations, symptomatic versus asymptomatic women, intact membranes versus ruptured membranes, and prior PTB versus no prior PTB, as well as many others.<sup>24-30</sup> Because TVU

CL has different predictive characteristics in these different patient populations, they should be evaluated separately. Currently, the most appropriate groups to be considered for TVU CL screening are<sup>24</sup>:

- Asymptomatic singleton pregnancies without prior PTB
- Asymptomatic singleton pregnancies with prior PTB
- Asymptomatic multiple pregnancies
- Symptomatic singleton pregnancies

The sensitivity and positive predictive value (PPV) of a short CL is very different, for example, in women with or without a prior PTB. In singleton gestations with no history of sPTB, the sensitivity of a short CL for subsequent PTB is approximately 35% to 45%<sup>10,25</sup> and the PPV is approximately 20% to 30%, which means that the majority of women with a short cervical length will deliver at 35 weeks or later.<sup>10</sup> The sensitivity of TVU CL is also approximately 35% in twins.<sup>27</sup> However, **the sensitivity of a short CL is much higher, about 70%, in a singleton pregnancy with a prior sPTB.**<sup>26</sup>

## RISK FACTORS FOR CERVICAL INSUFFICIENCY

Based largely on the epidemiologic associations between the clinical diagnosis of cervical insufficiency and antecedent historic factors, numerous risk factors for CI have been suggested. **Risk factors include prior cervical destructive surgery (i.e., trachelectomy, loop electrosurgical excision procedure [LEEP], large loop excision of the transformation zone [LLETZ], laser conization, or cold-knife cone biopsy), in utero diethylstilbestrol (DES) exposure, prior induced or spontaneous first- and second-trimester abortions, uterine anomalies, multiple gestations, or even prior sPTBs that did not meet typical clinical criteria for cervical insufficiency.** Because DES usage was effectively abandoned in the early 1970s, this congenital risk factor is now only of historic interest.

Conversely, forced cervical dilation, which generally accompanies midtrimester dilation and evacuation, has been associated with midtrimester spontaneous loss in older studies. A review by Atrash and colleagues<sup>31</sup> of literature published prior to 1987 indicated a nominal relative risk of 3. The authors appropriately recognized the limitations of older investigations that did not include proper control groups or consider important confounders. Particularly unclear was whether and to what extent the recorded spontaneous abortions were characterized by clinical circumstances consistent with CI. Women whose first pregnancy was terminated by an induced abortion, generally by vacuum aspiration, do not appear to have a significant risk for CI but do have a risk of PTB.<sup>31,32</sup> A recent series of midtrimester surgical abortion after cervical dilation with osmotic dilators up to 24 weeks' gestation did not confirm the risks observed in the older literature<sup>33</sup>; however, the investigators speculate that their primary use of osmotic dilators, as opposed to mechanical dilators, may have diminished the associated risks.

Because trachelectomy is now rarely performed in reproductive-age women, the associated risks in contemporary practice are difficult to ascertain; however, older series confirm an appreciable risk of early PTB.<sup>34</sup> Whether LEEP, LLETZ, and cervical conization (cold knife or laser) are significant risk factors for CI is still debated because the relevant outcome data are both contradictory for a significant pregnancy effect and investigators have generally focused on the risk of PTB and not CI per se. These associations are further confounded by the presence of and risk factors for intraepithelial neoplasia in addition to the type

**FIG 28-1** Normal cervical length as measured by transvaginal ultrasound.

of procedure used; the amount of cervical tissue removed, especially after repeat procedures; and the residual CL. Moreover, because almost all studies are retrospective and subject to considerable bias, existing evidence must be cautiously interpreted. Given the increasingly widespread use of LEEP/LLETZ and the obvious public health concerns, defining its associated risk is of particular importance.<sup>35-37</sup>

**Most but not all investigators have reported an increased risk of PTB before 37 weeks after LEEP or conization.** In a meta-analysis that incorporated data from 27 studies, cold knife conization was associated with a 2.6-fold increased risk of PTB before 37 weeks (95% confidence interval [CI], 1.80 to 3.72). Women with prior LEEP were found to have a 1.7-fold increased risk of PTB (95% CI, 1.24 to 2.35) and a nearly threefold increased risk of preterm premature rupture of membranes (PPROM; 95% CI, 1.62 to 4.46); no increased risk was observed after laser ablation. A subgroup analysis that controlled for age, parity, and smoking also revealed an increased relative risk for preterm delivery after LEEP (relative risk [RR], 2.10; 95% CI, 1.34 to 2.69).<sup>38</sup> Two studies that utilized large Finnish registries reported an increased risk of PTB after LEEP or conization.<sup>39,40</sup> The first one reported a nearly threefold increased risk for PTB after repeat LEEP,<sup>39</sup> consistent with other literature. **The second noted a 2.9 relative risk (95% CI, 2.2 to 3.7) of very preterm delivery (28 to 31 weeks) and a 2.1 relative risk (95% CI, 1.47 to 2.99) of extremely preterm delivery (<28 weeks) following cervical conization in a population of over 25,000 women who had undergone surgical treatment of cervical intraepithelial neoplasia (CIN).**<sup>40</sup> Possibly the most compelling association between surgical treatment of intraepithelial neoplasia and midtrimester birth comes from a recent systematic review and meta-analysis.<sup>41</sup> These investigators identified 14 studies that reported early pregnancy outcomes, eight of which included midtrimester births. Although seven of these did not individually report a significant association, the inclusion of a large population-based study from Norway<sup>42</sup> confirmed a highly significant association with a pooled risk ratio of 2.6 (95% CI, 1.5 to 4.7). The authors suggested that this increased risk was the result of cervical insufficiency after proportionally large excisions but could not confirm that other components of the sPTB syndrome were excluded.

Analogous to the findings of Sadler and colleagues,<sup>43</sup> several investigators have studied the effect of actual specimen size from LEEP or conization as a better predictor of PTB. Leiman<sup>44</sup> concluded that the risk of PTB was increased only when the maximum cone height was greater than 2 cm or the volume was greater than 4 mL. Raio and colleagues<sup>45</sup> performed a matched cohort study of 64 women who had undergone prior laser conization and observed no difference in the incidence of PTB compared with their controls (9.4% vs. 4.7%). They further reported statistically similar birthweights and gestational ages at delivery. However, in a secondary analysis, a laser cone height greater than 10 mm was a significant independent risk factor for PTB. In a more recent retrospective study<sup>46</sup> of 321 pregnancies following LEEP, a threefold increase in PTB at less than 37 weeks was observed if the excision volume exceeded 6 mL (95% CI, 1.45 to 5.92) or if the thickness of the excised tissue was greater than 12 mm (95% CI, 1.27 to 7.01).

Some investigators have proposed that PTB risk increases merely in the presence of cervical dysplasia, suggesting that the indication for the procedure—rather than the surgical procedure itself—is the more important biologic risk factor. In a recent

meta-analysis that compared 6589 patients with a history of LEEP to over 1 million patients without a history of excision, Conner and associates<sup>47</sup> reported a modestly increased risk of PTB before 37 weeks following LEEP (RR, 1.61; 95% CI, 1.35 to 1.92). However, on further analysis, those with prior LEEP had a risk of PTB similar to those with known dysplasia who had never undergone surgical excision. In a recent retrospective study<sup>39</sup> that utilized a Finnish registry of approximately 450,000 patients, prior LEEP was associated with a 1.61-fold increased risk for preterm delivery before 37 weeks, but the severity of CIN did not increase this risk. Instead, the investigators reported a twofold increased risk (95% CI, 1.5 to 2.9) of PTB in those who underwent LEEP for non-CIN lesions confirmed on histopathology (e.g., condyloma acuminatum); these data suggest that surgery does pose an independent risk.

Poon and colleagues<sup>48</sup> performed a secondary analysis of data from a clinical trial of PTB prevention and suggested that the risk of PTB from prior LEEP may be better reflected by a mid-gestation CL. In the study, 26,867 women undergoing routine prenatal care had transvaginal sonographic CL screening performed between 20 and 24 6/7 weeks of gestation. In 473 women who had a previous LEEP, the rate of preterm delivery before 34 weeks was increased (3.4% vs. 1.3%,  $P = .0002$ ), and the median CL was significantly shorter (32 mm; interquartile range [IQR], 27 to 38 mm) versus 34 mm (IQR, 30 to 39 mm;  $P < .0001$ ). After controlling for cervical length, prior LEEP was not a significant predictor of PTB.

Regarding history-indicated “prophylactic” treatment of presumptive insufficiency following cervical surgery, Kuoppala and Saarikoski<sup>49</sup> retrospectively reviewed 62 women who had undergone cone biopsy and an equal number of matched control patients. The pregnancy outcomes of the 22 who underwent history-indicated cerclage were similar to those managed without cerclage, with fetal salvage rates of 97% and 100%, respectively. On the basis of their findings and a review of seven other published reports, they concluded that history-indicated cerclage should not be routinely recommended for this possible risk factor. Of note, in the largest published randomized trial<sup>34</sup> of history-indicated cerclage for risk factors, summarized later, women with one or more cone biopsies or cervical amputations had an overall PTB rate before 33 weeks of 35%; however, in this population, no benefit was reported from history-indicated cerclage placement.

**In summary, the weight of available evidence confirms an association between the surgical treatment of CIN and spontaneous PTB.** However, it should be noted that these data do not confirm a disproportionate incidence of midtrimester loss with a clinical presentation consistent with the clinical diagnosis of cervical insufficiency. Women who have had a large cone specimen removed that included cervical amputations and those who have undergone multiple LEEP or conization procedures are the ones most at an increased risk of sPTB and presumably earlier deliveries. Whether history-indicated cerclage would be an effective preventive strategy in these at-risk women remains speculative. Because the available clinical trial data do not suggest a benefit from history-indicated cerclage, these women may be followed for evidence of premature cervical changes suggestive of insufficiency. **Women with a history of prior cervical surgery and recurrent spontaneous midtrimester loss that suggests a clinical diagnosis of insufficiency should be considered for a history-indicated cerclage in future pregnancies. Those with a history of LEEP or conization without**

a history of prior spontaneous midtrimester loss may be considered as candidates for clinical surveillance.

## TESTS FOR CERVICAL INSUFFICIENCY

Because cervical insufficiency is likely part of a broader preterm parturition syndrome, there are few proven objective criteria other than perhaps a rare, gross cervical defect. For this reason, along with the greater research initiatives into PTB prevention, considerable effort has been devoted to developing objective and reproducible criteria for cervical insufficiency.

Most of the earlier reported tests for cervical insufficiency were based on the physiology of the internal os in the nonpregnant state and are of historic interest. Attempts at objective assessments include passage of a #8 Hegar dilator into the nonpregnant cervical canal without resistance,<sup>50</sup> diminished force required to dislodge a Foley catheter whose balloon was placed above the internal os and filled with 1 mL of saline solution,<sup>51</sup> and assessment of cervical elastic properties.<sup>52</sup>

All such attempts at providing an objective diagnosis of cervical insufficiency failed because the tests were not evaluated with regard to standard characteristics (e.g., sensitivity, specificity) against some reference standard for the diagnosis. Moreover, none of these tests could reasonably predict pregnancy-associated conditions that would lead to premature ripening and cervical dilation (i.e., *functional* insufficiency). **Finally, because no universally applicable standard exists for the diagnosis of cervical insufficiency, and because the results of such tests were never evaluated and linked to a proven effective treatment, their clinical utility was at best theoretic. Because no test for cervical insufficiency in the nonpregnant patient has been validated, none of these tests are in common use today.**

Although the literature devoted to screening for cervical insufficiency has been dominated by cervical length measurements, there is far more of importance beyond length in assessing the pregnant cervix.<sup>53</sup> Multiple approaches have been described to assess the cervical microstructure, encompassing techniques to evaluate tissue hydration, collagen structure, and tissue elasticity. In a recent review by Feltoich and colleagues,<sup>53</sup> several of these techniques were designated as having high clinical promise in assessment of the cervix, including Raman spectroscopy, back-scattered power loss, and shear wave speed. Currently, these innovative modalities are still in the early stages of development. However, they may ultimately improve our understanding of the physiology of the cervix and may have a role in the clinical prediction of premature cervical ripening.

## CLINICAL DIAGNOSIS OF CERVICAL INSUFFICIENCY

### Patient History

Cervical insufficiency has primarily been a clinical diagnosis characterized by a history of recurrent painless dilation and spontaneous midtrimester (16 to 24 weeks) birth of a non-anomalous living fetus that usually suffers neonatal death or serious long-term morbidities from extreme prematurity. The diagnosis is usually retrospective and made only after poor obstetric outcomes have occurred. On occasion, a patient will be seen who has experienced painless cervical dilation before delivery. In such cases, careful documentation of what has happened is essential. In most cases, however, a careful history and

### BOX 28-1 DIAGNOSTIC CRITERIA FOR THE CLINICAL DIAGNOSIS OF CERVICAL INSUFFICIENCY

- History of (recurrent) painless cervical dilation and midtrimester birth
- Painless midtrimester cervical shortening and dilation detected by serial digital evaluations

review of the past obstetric records are crucial to the diagnosis. However, in many instances, the records are incomplete or unavailable, and many women cannot provide a reliable history. Even with excellent records and accurate history, clinicians might disagree except in the most classic cases. Confounding factors in the history, records, or physical examination might be used to either support or refute the diagnosis based on their perceived importance.

As noted above, **the physician managing a patient who experiences a spontaneous midtrimester birth is in the optimal position to assess and document whether the clinical criteria for cervical insufficiency were met** (e.g., hourglassing membranes without painful regular uterine contractions) **and to rule out other causes of midtrimester birth** (e.g., placental abruption, antecedent fetal death, or fetal anomaly). However, because the preterm parturition syndrome includes other anatomic components, it is possible that some cases of cervical insufficiency are preceded by premature chorioamnion rupture or develop clinically apparent uterine activity. Although intra-uterine infection might conceivably exclude the diagnosis, if cervical ripening and occult dilation have caused loss of the mucus plug, the normal barrier between the vaginal flora and chorioamnion is disrupted, and infection might be the presenting clinical event.<sup>54</sup> Although insufficiency is generally considered a diagnosis of exclusion, precisely how other causes of PTB should be excluded has never been explicitly defined.

Because cervical insufficiency is generally a retrospective diagnosis that depends on a history of poor outcomes, clinicians have sought criteria that might lead to a prospective and more objective diagnosis. In women considered to be at risk for cervical insufficiency based on an atypical history, prior cerclage for questionable historic indications, or because of other identified risk factors as mentioned above, serial examinations may be performed to detect progressive shortening and dilation, leading to a presumptive diagnosis of insufficiency, which may then be amenable to therapeutic intervention (Box 28-1). Use of cerclage merely for the presence of various risk factors, as described above, is not recommended.

## SONOGRAPHIC DIAGNOSIS OF CERVICAL INSUFFICIENCY

Over the past several decades, numerous investigators have suggested that cervical insufficiency can be diagnosed by midtrimester sonographic evaluation of the cervix. Various sonographic findings that include CL, funneling at the internal os, and dynamic response to provocative maneuvers (e.g., fundal pressure) have been proposed (Fig. 28-2). In these earlier reports, the sonographic evaluations were not blinded, which led to uncontrolled interventions and difficulty determining their value. Diagnostic criteria were disparate and, in some cases, were not described in a quantitative or reproducible manner.

Later, large, blinded observational studies that used reproducible methods were published.<sup>10,22,26</sup> These investigators reported

**FIG 28-2** Short cervix (calipers) by transvaginal sonogram at 20<sup>5/7</sup> weeks' gestation. Note the presence of a biofilm (sludge) that has been associated as a potential marker for subclinical infection. (From Romero R, Kusamovic JP, Espinoza J, et al. What is amniotic fluid "sludge"? *Ultrasound Obstet Gynecol.* 2007;30:793-798.)

the relationship between midtrimester cervical sonographic findings and PTB and sought to identify cervical changes that indicated a dominant cervical etiology and the possibility for intervention. The Eunice Kennedy Shriver National Institutes of Child Health and Human Development (NICHD) Maternal-Fetal Medicine Units (MFMU) Network<sup>10</sup> completed a study of 2915 unselected women with a singleton pregnancy who underwent a blinded cervical sonographic evaluation at 22 to 24 weeks' gestation: **the relative risk of sPTB increased steadily as the measured CL shortened. In spite of this highly significant relationship, as a test for predicting spontaneous PTB at less than 35 weeks, a CL cutoff of less than 26 mm** (the population 10th percentile) **had low sensitivity (37%) and poor PPV (18%).** Midtrimester birth consistent with cervical insufficiency was not specifically reported, but examination of the survival curve suggests that less than 5% of women with a CL of 25 mm or less at 22 to 24 weeks delivered prior to 28 weeks. Moreover, the circumstances of these early births were not reported, so clinical criteria for insufficiency could not be assessed. Thus in an unselected population, shortened CL at 22 to 24 weeks appeared to be a very ineffective tool for identifying women with cervical insufficiency.

In a subsequent study, the NICHD MFMU Network<sup>26</sup> examined the utility of cervical ultrasound as a predictor of sPTB at less than 35 weeks in high-risk women, defined as those having at least one prior sPTB at less than 32 weeks. Women with a clinical diagnosis of cervical insufficiency were excluded. Beginning at 16 to 18 weeks of gestation, 183 gravidas underwent serial, biweekly sonographic evaluations until the 23rd week of gestation. The study design permitted analysis of the shortest observed CL over time, which also included any fundal pressure-induced or spontaneously occurring CL shortening. As in the previous study,<sup>10</sup> a highly significant inverse relationship was found between CL and spontaneous PTB. However, in this high-risk population, at a CL cutoff of less than 25 mm, the sensitivity increased to 69%, and the PPV increased to 55%. Importantly, a secondary analysis of the data suggested that these high-risk women with a shortened CL might have a clinically significant *component* of diminished cervical competence because

#### BOX 28-2 CRITERION FOR THE SONOGRAPHIC DIAGNOSIS OF CERVICAL INSUFFICIENCY

- Shortened cervical length (<25 mm) detected by midtrimester sonography in women with singletons and a history of spontaneous preterm birth at <34-37 weeks

a preponderance of midtrimester births occurred at less than 27 weeks in this group.<sup>55</sup>

These reports<sup>10,26</sup> support the concept of shortened CL as a surrogate measure of cervical competence, but the actual identification of an appropriate CL cutoff that should lead to clinical intervention and confirmation of the potential contribution of related cervical sonographic findings (e.g., funneling at the internal os) remains problematic. Clearly, cervical sonography has a lower sensitivity (about 30% to 40%) as a screening test in low-risk women (i.e., singleton gestations without prior sPTB),<sup>10</sup> but it appears to have significant utility for identifying clinically significant cervical pathology in women with a prior early sPTB.<sup>26,56</sup>

Although some investigators have included women with various risk factors in their study populations composed primarily of women with previous sPTB, the results could not be subcategorized because of small sample sizes.<sup>56</sup> However, in a recent series of 64 women with various uterine anomalies, the authors observed an overall preterm delivery rate at less than 35 weeks of 11% and found a significant relationship between CLs of less than 25 mm and PTB,<sup>30</sup> with summary predictive values similar to those of other high-risk populations.<sup>26</sup>

Use of cervical ultrasound in twin gestations has also been reported.<sup>57</sup> However, the screening test characteristics, especially sensitivity and PPV (<40%), appear to be generally lower than for women with a prior early sPTB. A systematic review<sup>58</sup> summarized the predictive value of vaginal sonography for PTB in 46 published series of both asymptomatic and symptomatic gravidas carrying singleton or twin gestations. Eleven series of asymptomatic women with twins were included. The relationship between cervical shortening and PTB was much stronger in the singleton, as opposed to the twin, populations in both receiver operator curve and meta-analytic assessment of likelihood ratios. Because the management of twins with shortened CL has been particularly problematic, it is unclear how we should be using CL measurements in multiple gestations outside of clinical trials (Box 28-2).

#### DIAGNOSIS OF CERVICAL INSUFFICIENCY ON PHYSICAL EXAMINATION

Uncommonly, a patient in the midtrimester will present with vague pelvic symptoms such as increased pressure and vaginal discharge with increased urinary frequency but without other symptoms of urinary tract infection. Physical exam with a speculum reveals a relatively uneffaced but dilated cervix (at least 1 to 2 cm but generally less than 5 cm) and membranes visible at or beyond the level of the external os. **Fetal parts or the umbilical cord might be seen behind the membranes or even contained in the prolapsing sac.** Significant uterine contractions and clinical evidence of intrauterine infection (e.g., fever, uterine tenderness) are absent, and a period of observation and monitoring for overt infection and labor are generally

performed to establish a diagnosis. **This is termed *acute cervical insufficiency*.** Presumably, these findings were antecedent events in most if not all cases of midtrimester birth later attributed to cervical insufficiency based on historic criteria. However, this presentation provides a unique clinical opportunity to witness the natural history of cervical insufficiency, explore possible etiologies, and consider the effectiveness of different interventions (Box 28-3).

## TREATMENT: CERCLAGE

The contemporary mainstay of treatment has been a surgical approach using one of the classic cerclage procedures, although both medical treatments and other mechanical supportive therapies have been used.

### Cerclage Technique

The proper placement of a suture in the uterine cervical stroma and/or around its perimeter to treat cervical insufficiency or prevent preterm delivery has been the subject of debate because of the lack of proper randomized studies to assess different perioperative strategies.<sup>59</sup> Techniques based on indications are described below.

### History-Indicated Cerclage

Women with a history of recurrent midtrimester losses characterized by painless cervical dilation in the absence of overt labor or placental abruption are considered candidates for history-indicated cerclage. This may also be utilized in women with a

prior history of cerclage placement secondary to painless cervical dilation in the midtrimester; that is, those with a prior cerclage based on findings on physical examination.<sup>60</sup> History-indicated cerclage placement is generally performed at 12 to 15 weeks of gestation to avoid the complications of early spontaneous loss often attributable to chromosomal abnormalities.<sup>61</sup>

In 1950, Lash and Lash<sup>62</sup> described repair of the cervix in the nonpregnant state that involved partial excision of the cervix to remove the area of presumed weakness. Unfortunately, this technique was associated with a high incidence of subsequent infertility. In 1955, Shirodkar<sup>63</sup> reported successful management of cervical insufficiency with the use of a submucosal band. Initially, he used catgut as suture material, and later he used Mersilene (Ethicon, Somerville, NJ) placed at the level of the internal cervical os. The procedure required anterior displacement of the bladder in an attempt to place the suture as high as possible at the level of cervical internal os. This type of procedure resulted in a greater number of patients being delivered by cesarean delivery because of the difficulty in removing the suture buried under the cervical surface, and it often required leaving the suture in place postpartum. Several years later, McDonald<sup>64</sup> described a suture technique in the form of a purse string that did not require cervical dissection and that was easily placed during pregnancy. This technique involves taking four or five bites as high as possible in the cervix, trying to avoid injury to the bladder or the rectum, with placement of a knot anteriorly to facilitate removal (Fig. 28-3). Most randomized studies of cerclage have used the McDonald technique. A randomized controlled trial (RCT) based in Europe utilizing the Shirodkar technique did not demonstrate benefit.<sup>65</sup> Therefore, **owing to its simplicity and effectiveness, a McDonald technique is recommended as the first-line procedure.**

Several types of suture material have been used, and no randomized studies had been done to compare the different types of cerclage suture and/or the preferable type of needle to use.<sup>66</sup> We have been successful in using a Mersilene tape. However, the use of thinner suture material, such as Prolene (Ethicon) or other synthetic nonabsorbable sutures like Ethibond (Ethicon), is advocated by others with the argument that the width of the

#### BOX 28-3 CRITERIA FOR THE DIAGNOSIS OF CERVICAL INSUFFICIENCY ON PHYSICAL EXAMINATION

- Midtrimester cervical dilation and membranes visible at or beyond the external os in the absence of clinically defined antecedent labor or overt intrauterine infection
- Significant (serial) asymptomatic cervical dilation detected by palpation at midtrimester

**FIG 28-3** Placement of sutures for McDonald cerclage. **A**, Double-headed Mersilene band with four bites in the cervix, avoiding the vessels. **B**, The suture is placed high up in the cervix, close to the cervicovaginal junction, approximately at the level of the internal os.

**FIG 28-4** Transvaginal sonogram of the cervix after cerclage placement. The internal os is closed, and no funneling is evident. Echogenic spots in the cervix correspond to cerclage (arrows).

Mersilene tape places the patient at greater risk for infection.<sup>67-68</sup> **Currently, no evidence suggests that placing two sutures results in better outcomes than placing one.** A recent large retrospective study did not show a difference in PTB rates between the two- versus one-stitch groups.<sup>69</sup> Furthermore, placement of a second occlusive suture at the level of the external os to keep the mucous plug in place has not shown benefit in a recent RCT.<sup>70</sup>

Preoperative patient preparations that include the use of prophylactic antibiotics or tocolytics have not been proven to be of benefit, and evidence is insufficient to recommend their use. The value of performing cultures before the cerclage procedure has not been properly studied, and this practice—as well as giving perioperative antibiotics—should be individualized. Similarly, the use of amniocentesis prior to cerclage has not been subjected to RCTs. **It appears that for a history-indicated cerclage, the rate of subclinical intraamniotic infection (IAI) is very low, and amniocentesis does not seem justifiable.** However, for ultrasound-indicated cerclage, the rate of subclinical IAI could be as high as 1% to 2%.<sup>71</sup> The value of amniocentesis in this setting needs to be evaluated by an RCT.<sup>59</sup>

The choice of anesthesia for cerclage varies.<sup>72</sup> Chen and colleagues<sup>73</sup> did not observe a difference in outcome between general versus regional anesthesia. In our experience, a short-acting regional anesthetic is sufficient, and spinal anesthesia appears to be the preferred anesthesia for cerclage.

The value of bed rest postoperatively has been questioned and even criticized,<sup>74</sup> and its value in the setting of cerclage placement has not been studied. Decisions regarding physical activity and intercourse are individualized and are based on the status of the cervix as determined by outpatient digital evaluation or sonographic findings (Fig. 28-4).

The approach to the patient with preterm contractions and a cerclage in place has not been sufficiently evaluated. Most authorities will only remove the cerclage if there is tension in the suture because of the concern for cervical lacerations if the suture is left behind. **The suture is usually removed electively at 36 to 37 weeks.** Systematic review of the literature showed

that planned removal of cervical cerclage before the onset of labor at 36 to 37 weeks is associated with a 28% nonsignificant reduction in the incidence of cervical lacerations compared with removal in labor (6.4% vs. 11.4%; RR, 0.72; 95% CI, 0.35 to 1.49). The mean interval between cerclage removal and spontaneous delivery is 14 days.<sup>75</sup>

**In patients with a prior failed vaginal cerclage, an abdominal cerclage has been recommended.**<sup>76</sup> A prior history-indicated vaginal cerclage resulting in an sPTB before 33 weeks (i.e., a failed cerclage) is currently the only indication proven by controlled studies to show benefit from a transabdominal cerclage compared with a repeat transvaginal cerclage. This procedure is usually done either in pregnancy between 11 and 12 weeks gestation or prior to conception.<sup>77</sup> The procedure can be done either with a laparotomy or using a laparoscopic or robotic approach. A bladder flap may or may not be created. The procedure requires the placement of a Mersilene tape at the level of the junction between the lower uterine segment and the cervix lateral to the uterus and medial to the uterine vessels (Fig. 28-5). Greater morbidity, including injury to the uterine vessels, requires expertise when performing this procedure. In our experience, we have found it helpful to have an assistant provide fundal traction, while the surgeon grasps the uterine vessels and retracts them laterally to expose an avascular space between the artery and the cervix. A right-angle clamp is passed anterior to posterior through this avascular space, tenting and incising the posterior leaf of the broad ligament and grasping a Mersilene tape brought back through the space. The same procedure is repeated on the opposite side, and the tape is tied anteriorly (Figs. 28-6 through 28-9). Several investigators have reported extensive experience with this procedure with low morbidity and favorable outcomes.<sup>77,78</sup> **Cesarean delivery is necessary, and the suture is left in place if future fertility is desired.**

In cases of pregnancy complications that require midtrimester delivery, we have either performed a posterior colpotomy, cutting the tape and allowing for vaginal delivery, or a laparotomy and hysterotomy, leaving the suture intact. In most of the reported series of abdominal cerclage, including ours, this surgical

**FIG 28-5** Abdominal cerclage. Surgical placement of circumferential Mersilene tape around uterine isthmus and medial to uterine vessels. Knot is tied anteriorly.

procedure was performed during gestation.<sup>78</sup> However, Groom and colleagues<sup>77</sup> described this procedure as an interval cerclage in the nonpregnant state with subsequent good pregnancy outcome. Advantages of an interval procedure include avoidance of laparotomy in pregnancy and less bleeding morbidity. Disadvantages include the inability to become pregnant, and for the clinician, the difficulties of pregnancy management arise if the gestation results in a first-trimester miscarriage. No studies have compared preconception versus abdominal cerclage during gestation that would enable us to make specific recommendations about timing of the procedure.

**In the last few years, a laparoscopic abdominal approach to the cervix has been described using the same principles as an abdominal cerclage.<sup>79</sup> The procedure has been described**

primarily in the nonpregnant state with subsequent good pregnancy outcome. Cho and colleagues<sup>80</sup> performed laparoscopic abdominal cerclage during pregnancy in 20 patients with minimal morbidity and reported a successful outcome in 19 of them. In a review<sup>81</sup> of the literature that encompassed 31 studies—6 reporting a laparoscopic approach and 26 using laparotomy, either interval or during pregnancy—both approaches were associated with favorable outcomes. A total of 78.5% of those with a laparoscopic abdominal cerclage and 84.8% of those with an abdominal cerclage placed by laparotomy delivered a viable infant after 34 weeks. Midtrimester loss occurred in 8.1% of those using the laparoscopic approach and in 7.8% with laparotomy. Recently, robotic-assisted laparoscopic placement of transabdominal cerclage during pregnancy has been

**FIG 28-8** Abdominal cerclage. Surgeon retracts uterine vessel laterally to create an avascular space between uterus and vessel, before passing a right angle clamp with Mersilene tape through this space.

**FIG 28-9** Abdominal cerclage. Mersilene tape has been placed circumferentially around the uterine isthmus and tied anteriorly. Notice ballooning of the lower uterine segment above the suture.

**FIG 28-10** Transvaginal cerclage under ultrasound guidance. (Modified from Ludmir J, Jackson GM, Samuels P. Transvaginal cerclage under ultrasound guidance in cases of severe cervical hypoplasia. *Obstet Gynecol.* 1991;75:1067.)

described by Wolfe and colleagues,<sup>82</sup> and we have started to use this technique in selected cases. Because of the lack of proper evaluation of these newer modalities of cerclage placement, recommendations based on evidence cannot be made. **Randomized trials are needed to evaluate these newer techniques in nonpregnant and pregnant states and to compare laparoscopic techniques with a vaginal approach to determine the best management of patients with a history of failed cerclage or an extremely short cervix that prevents a vaginal approach.**

To avoid an abdominal procedure in selected patients, we have described the placement of a transvaginal cerclage in cases of a hypoplastic cervix or when the cervix is flush against the vaginal wall.<sup>83</sup> Under ultrasound guidance, the supravaginal portion of the cervix is dissected away from the bladder, and

a suture is placed either in a purse-string fashion or in a cross configuration from 12 to 6 o'clock and 3 to 9 o'clock (Fig. 28-10). We have performed this procedure in 32 patients, avoiding an abdominal procedure, with successful pregnancy outcomes: 50% of our patients have had a cesarean delivery, and the rest delivered vaginally after the suture was cut through a small posterior colpotomy incision.

### Physical Examination–Indicated Cerclage

Patients who demonstrate cervical change either by ultrasound or by digital evaluation may benefit from a cerclage.<sup>84</sup> However, the gestational age limit for cerclage placement is poorly defined. **Although some clinicians offer this therapeutic modality up to 28 weeks, we do not advocate the use of cerclage beyond**

**24 weeks' gestation because of our concerns about fetal viability should the procedure contribute to a preterm delivery.**<sup>85</sup> The perioperative management of these patients has not been subject to rigorous study, and recommendations based on evidence cannot be given.<sup>59</sup> IAI is present in approximately 13% to 50% of patients with acute cervical insufficiency. As discussed below,<sup>85</sup> the value of amniocentesis to rule out IAI is currently being assessed in an RCT.

When the cervix has dilated enough to allow visualization of the membranes, or the membranes have prolapsed into the vagina, placing a cerclage may be difficult but should be considered.<sup>86</sup> Amnioreduction has been suggested to facilitate cerclage placement; in a European study,<sup>87</sup> this procedure was associated with prolonged gestation. Several techniques have been described to reduce the prolapsing membranes that include placing the patient in the Trendelenburg position, using a pediatric Foley catheter to tease the membranes into the endocervical canal, and instilling 1 L of saline into the bladder with upper displacement of the lower uterine segment (Fig. 28-11).<sup>88</sup> The efficacy of antibiotics and tocolytics have not been properly studied in this setting. **Although clinicians have been reluctant to offer cerclage in patients with protruding membranes, some reports have suggested a salvage rate in excess of 70% despite advanced cervical dilation, with only 40% delivering before 35 weeks.**<sup>89</sup> Cerclage may be effective at up to 4-cm dilation, but in the face of advanced cervical dilation and bulging membranes, the correct assessment of cervical dilation is difficult; however, cerclage should be considered even in cases of advanced dilation.

### Risks of Cerclage

Cervical lacerations at the time of delivery are one of the most common complications from a cerclage and occur in 1% to 13% of patients.<sup>90</sup> Three percent of patients require cesarean delivery because of the inability of the cervix to dilate secondary to cervical scarring and dystocia.<sup>90</sup> Although the risk of infection is minimal with a history-indicated cerclage, the risk increases significantly in cases of advanced dilation with exposure of membranes to the birth canal.<sup>91</sup> However, this infectious morbidity may be the result of subclinical chorioamnionitis. Cervical cerclage displacement occurs in a small number of patients. We have not performed revision of the cerclage during the index pregnancy, although small series have reported successful surgical treatment of a failed cerclage. At this time, evidence is insufficient to recommend the placement of a reinforcing suture.<sup>92</sup>

### Cerclage in the Presence of Premature Rupture of Membranes or Preterm Labor

When the clinician is faced with premature rupture of membranes (PROM) distant from term in a patient with cerclage, the decision to remove or leave the suture in place is controversial. Our own data suggest that with suture retention, the latency period is increased at the expense of an increased risk for neonatal sepsis and mortality.<sup>93</sup> These data have been challenged by reports from Jenkins and colleagues,<sup>94</sup> which suggest an increased latency period (244 vs. 119 hours) without an increase in neonatal morbidity in cases of retained cerclage, and by McElrath and colleagues,<sup>95</sup> who did not find differences in latency or neonatal outcome in patients when the suture was left in situ after rupture of the membranes. A recent randomized study<sup>96</sup> that was not completed because of inability to recruit patients showed no difference in latency, infection, or neonatal outcome

in those patients managed with immediate cerclage removal versus suture retention. However, less infectious morbidity was seen with cerclage removal. **Decisions to remove the suture at the time of ruptured membranes should be individualized until more information becomes available.** In the face of preterm contractions, the decision to remove the cerclage should be individualized based on findings such as tension or cervical tearing, although the subject has not been studied appropriately. Finally, even though cerclage placement is considered a benign procedure, a maternal death secondary to sepsis in a patient with retained cerclage has been reported.<sup>97</sup> Because of associated risks and questionable effectiveness, the liberal use of this surgical procedure is discouraged, and the decision should be carefully balanced against potential harm, in particular for patients in whom the indications for cerclage are unclear.

## CERCLAGE EFFECTIVENESS BASED ON EVIDENCE

### History-Indicated Cerclage

Four randomized trials have been done that included women with various risk factors for sPTB and *possible* cervical insufficiency whose managing physicians did not believe they required a prophylactic cerclage for a typical history of cervical insufficiency.<sup>34,98-100</sup> Three of the trials were relatively small and were based on a scoring system,<sup>98</sup> twin gestation,<sup>99</sup> and recurrent sPTB.<sup>100</sup> None of these trials showed a benefit to cerclage, but together they generally confirmed a higher rate of hospitalizations and medical interventions in the cerclage groups. The largest randomized trial of cerclage was conducted by the RCOG between 1981 and 1988.<sup>34</sup> A total of 1292 women were enrolled in 12 countries because of uncertainty on the part of their managing physicians as to whether a history-indicated cerclage was warranted. As anticipated, these patients comprised a heterogeneous group with at least six distinct risk-factor subgroups identified on the basis of their dominant history or physical examination findings. Although women assigned to cerclage had a significantly lower rate of PTB earlier than 33 weeks (13% vs. 17%,  $P = .03$ ), the investigators estimated that approximately 25 cerclage procedures would be required to prevent one such birth. Moreover, women assigned to cerclage received more tocolytic medications and spent more time in the hospital. Puerperal fever was significantly more common in the cerclage group. Of interest is the finding in a secondary analysis that only the subgroup of women with multiple pregnancies affected—defined as at least three prior sPTBs, including midtrimester losses—appeared to benefit from cerclage with lower rates of PTB (15% vs. 32%;  $P = .02$ ). This secondary analysis emphasized the importance of assessing clinical history in considering the diagnosis and treatment of cervical insufficiency.

Data on the efficacy of history-indicated transvaginal cerclage have been varied. As above, in a subgroup analysis of the RCOG RCT, cerclage was found to be beneficial and was associated with a small reduction in PTB (<33 weeks) if placed in the setting of a history of three or more prior PTBs (RR, 0.75; 95% CI, 0.58 to 0.98). A more recent meta-analysis does not support this finding and reports no overall reduction in pregnancy loss or PTB rates in the setting of history-indicated cerclage.<sup>101</sup> When compared with ultrasound-indicated cerclage, multiple studies have noted no change in perinatal outcome but roughly double the number of cerclage procedures performed in the history-indicated group.<sup>60,102</sup> A meta-analysis of the four RCTs that

**FIG 28-11** Emergent cerclage for bulging membranes at 23 weeks. **A**, Cervix dilated 3 cm with membranes protruding through the external cervical os into the vagina. **B**, Patient placed in Trendelenburg position and bladder filled with saline. Stay silk sutures are placed on anterior and posterior lip for traction while reducing membranes. McDonald cerclage is placed distal to reduced membranes.

compared a policy of history-indicated cerclage with a policy of TVU CL screening and cerclage only if CL shortened before 24 weeks in singleton gestations with prior PTBs showed similar maternal, perinatal, and PTB outcomes except that only 42% of women in the TVU CL group had a cerclage.<sup>102</sup> Despite the limited evidence to support history-indicated cerclage, one study performed by Fox and colleagues<sup>103</sup> reported that 75% of maternal-fetal medicine (MFM) specialists who responded to a

survey would place a cerclage in a patient with a history of a prior painless midgestation loss.

Branch and Cousins collectively tabulated over 25 case series of cerclage efficacy published between 1959 and 1981. Branch<sup>104</sup> estimated a precerclage survival range of 10% to 32% versus a perinatal survival range of 75% to 83% in the same cohorts of women managed with Shirodkar cerclage. Similarly, a case series that used McDonald cerclage reported a cohort perinatal

survival range of 7% to 50% before and 63% to 89% after cerclage. Cousins<sup>105</sup> estimated a “mean” survival before Shirodkar of 22% versus 82% post therapy and 27% and 74%, respectively, for investigators who used the McDonald technique. In total, more than 2000 patients have been reported in these historic cohort comparisons. As noted by Cousins, interpretation of these series is limited because (1) diagnostic criteria were inconsistent or were not always reported; (2) definitions of treatment success were inconsistent but were generally recorded as perinatal survival, as opposed to a gestational age-based end point; (3) treatment approaches were not always detailed and might involve multiple combinations of surgery, medication, bed rest, and other uncontrolled therapies; and (4) cases were not subcategorized according to etiology (e.g., anatomic defects versus a presumed functional cause). Nevertheless, based on compelling but potentially biased efficacy data, the surgical management of women with a history of clinically defined cervical insufficiency has become standard practice, and it has clearly shaped the way the average MFM provider practices. Although interpretation of efficacy based on historic control groups is always problematic, collectively these reports demonstrate that even women with typical histories may have successful pregnancies without cerclage and that cerclage as a treatment is not universally effective. Both of these observations support the multiple etiologies and interactive pathways characteristic of the spontaneous PTB syndrome.

**Because of its unproven efficacy in randomized clinical trials and the attendant surgical risks, the recommendation for history-indicated cerclage should be limited to women with multiple midtrimester sPTBs when a careful history and physical examination suggest a dominant cervical component. Unless the physical examination confirms a significant cervical anatomic defect consistent with disruption of its circumferential integrity, the clinician should assess the history for other components of the PTB syndrome. Cervical insufficiency remains a diagnosis of exclusion.**

### Ultrasound-Indicated Cerclage

Under the presumption that shortened cervical length, with or without funneling at the internal os, is diagnostic of cervical insufficiency if it occurs in a singleton gestation and in a patient with a prior sPTB, several investigators have studied the effect of ultrasound-indicated cerclage on pregnancy outcomes. Retrospective analyses of uncontrolled use of cerclage in various

at-risk populations have given conflicting results, which suggests that cerclage was either effective<sup>106</sup> or ineffective.<sup>56,107</sup>

Later, five randomized trials of cerclage for sonographic indications were published (Table 28-1). Althuisius and colleagues in the Netherlands randomized high-risk patients, the majority of whom were believed to have cervical insufficiency based on their symptoms or obstetric history and midtrimester CL less than 25 mm. Both the cerclage and no-cerclage groups were instructed to use modified home rest. Of the 19 assigned to cerclage, no PTBs were reported before 34 weeks versus a 44% rate in the no cerclage–home rest group ( $P = .002$ ). Rust and colleagues<sup>109</sup> enrolled 138 women who had various risk factors for PTB (including 12% with multiple gestations) and randomly assigned them to receive a McDonald cerclage or no cerclage after their CL shortened to less than 25 mm or they developed funneling of at least 25%. PTB before 34 weeks was observed in 35% of the cerclage group versus 36% of controls.

In a multinational trial, To and colleagues<sup>65</sup> screened 47,123 unselected women at 22 to 24 weeks’ gestation with vaginal ultrasound to identify 470 with a shortened CL of 15 mm or less. Of these 470, 253 participated in a randomized trial whose primary outcome was the intergroup rates of delivery before 33 weeks’ gestation. Women assigned to the cerclage group ( $n = 127$ ) underwent a Shirodkar procedure. They had a similar rate of PTB as the control population ( $n = 126$ ) 22% versus 26% ( $P = .44$ ). The authors did not specifically comment on the proportion of women in the control group who were delivered in the midtrimester after a presentation consistent with clinically defined cervical insufficiency; however, they observed four stillbirths attributed to birth at 23 to 24 weeks and five neonatal deaths in deliveries at 23 to 26 weeks. In the cerclage group, the respective counts were three and four.

Berghella and colleagues<sup>110</sup> screened women with various risk factors for sPTB (e.g., prior PTB, curettages, cone biopsy, DES exposure) with vaginal scans every 2 weeks from 14 to 23 weeks’ gestation and randomly assigned 61 with a cervical length less than 25 mm or funneling of at least 25% to a McDonald cerclage or to a no-cerclage control group. PTB before 35 weeks was observed in 45% of the cerclage group and in 47% of the control group.

The trial by Althuisius and colleagues<sup>108</sup> focused on women whom they believed had a clinical diagnosis of cervical insufficiency and who may have been candidates for history-indicated cerclage in the United States. Nevertheless, their study does

suggest a potential role for cervical ultrasound in women with a clinical diagnosis of cervical insufficiency if the intent is to avoid cerclage when the CL is maintained at 25 mm or greater.

A meta-analysis<sup>111</sup> of the four randomized trials described earlier analyzed patient-level data to estimate whether certain subgroups of women with midtrimester cervical shortening might benefit from cerclage, where benefit was defined as a reduction in the relative risk of PTB before 35 weeks. They observed a marginal benefit from cerclage in women with singleton gestations and especially in those who had experienced a prior sPTB (RR, 0.6; 95% CI, 0.4 to 0.9). Paradoxically, they demonstrated a significant *detriment* in women with multiple gestations (RR, 2.15; 95% CI, 1.15 to 4.01). This harmful effect has never been confirmed in a randomized trial, nor have authors of cohort studies observed this relationship.<sup>112-113</sup>

Based on an earlier review of the utility of vaginal ultrasound for the diagnosis of cervical insufficiency,<sup>114</sup> a fifth randomized trial was performed by a consortium of 15 centers in the United States<sup>4</sup> and included only women who had had at least one prior sPTB at 17 to 34 weeks' gestation. They were followed with serial vaginal scans beginning at 16 weeks' gestation. As long as CL was at least 30 mm, scans were scheduled every 2 weeks, but the frequency was increased to weekly if the CL was 25 to 29 mm. Women who developed a short cervix (<25 mm) between 16 and 22 6/7 weeks were assigned to McDonald cerclage or no cerclage. These investigators observed a statistically significant decrease in previable births before 24 weeks (6% vs. 14%), perinatal mortality (9% vs. 16%), and birth before 37 weeks (45% vs. 60%), but a nonsignificant decrease was seen in the comparative rates of PTB before 35 weeks (32% vs. 42%). The number of patients with a short cervix that needed to be treated with cerclage to prevent one previable birth was 13. Of note was the observation that the benefit of cerclage was closely linked to cervical status. Women with a CL of less than 15 mm at randomization accrued a much greater benefit than those who were randomized with a CL of 15 to 24 mm. This finding suggested that shorter lengths are more likely to be associated with a primary cervical etiology and are thus more amenable to mechanical support, although the "optimal" CL (e.g., <25 mm, <15 mm) for recommending cerclage could not be established. Similarly, the finding of a U-shaped funnel (but not a V-shaped funnel) was also a significant additional risk factor for earlier birth, even considering CL; in these women, the beneficial effect of cerclage for prolonging gestation was also significantly pronounced.<sup>115</sup>

Considering the results of the multicenter trial mentioned above,<sup>4</sup> Berghella and colleagues performed a follow-up meta-analysis that included the findings of this trial with the original four studies.<sup>116</sup> **This patient-level analysis confirmed significant benefit of ultrasound-indicated cerclage for CLs less than 25 mm observed before 24 weeks' gestation in women with prior sPTB. Cerclage reduced PTB at cutoffs of less than 37, 35, 32, 28, and 24 weeks, and composite neonatal mortality and morbidity were also significantly lower** (RR, 0.64; 95% CI, 0.45 to 0.91).

Not uncommonly a patient presents with a prior midtrimester spontaneous birth that does not meet clinical criteria for cervical insufficiency. In these circumstances, she may have even undergone a history-indicated cerclage. Whether these women needed a history-indicated cerclage or if they should have had a repeat cerclage is controversial, and clinical judgment is important. However, accumulating evidence suggests that it is safe to follow

#### BOX 28-4 PATIENT AT RISK FOR CERVICAL INSUFFICIENCY: HISTORY-INDICATED VERSUS ULTRASOUND-INDICATED CERCLAGE

- Preterm births will occur regardless of strategy chosen.
- Both strategies have similar rates of preterm birth.
- Fewer cerclages are performed with the ultrasound-indicated cerclage strategy.
- It seems reasonable to follow at-risk patients with sonography and to perform a cerclage based on sonographic findings.

these women with CL measurements and avoid cerclage. A recent meta-analysis by Berghella and colleagues<sup>102</sup> of four randomized trials indicated that using sonographic CL to select women for cerclage, most women (58%) would avoid surgery yet have no greater risk of PTB than the cohorts who underwent history-indicated cerclage (RR, 0.97; 95% CI, 0.73 to 1.29).

**In summary, collective results have established the utility of cervical length screening and ultrasound-indicated cerclage for a short cervix less than 25 mm in women with a prior sPTB (Box 28-4).**

#### Physical Examination–Indicated Cerclage

Women who present with acute cervical insufficiency are often considered candidates for a physical examination–indicated cerclage. The limited data on the efficacy of this procedure reflect its rare presentation. Some investigators have reported fetal salvage rates in excess of 70%.<sup>117</sup> Aarts and colleagues<sup>118</sup> reviewed eight series published between 1980 and 1992 that comprised 249 patients who received a physical examination–indicated cerclage and estimated a mean neonatal survival rate of 64% (reported range, 22% to 100%). Novy and colleagues<sup>106</sup> published 35 cases of insufficiency in evolution (cervical dilation 2 to 5 cm); the two cohorts included 19 women who received physical examination–indicated cerclage and 16 who were managed with bed rest. Neonatal survival was 80% in the cerclage cohort versus 75% in the bed rest group. Two recent retrospective studies have supported the use of physical exam–indicated cerclage and reported a mean neonatal survival ("take-home-baby") rate of 50.7% and 64% and a mean pregnancy prolongation of 7.4 and 8.2 weeks, respectively.<sup>119,120</sup> Similar to previous reports,<sup>118</sup> Guducu and colleagues<sup>119</sup> further reported a diminished success rate (31%) in patients with membrane prolapsing into the vagina.

In a prospective, uncontrolled use of cerclage versus bed rest with cerclage utilized at the discretion of the attending physician, Olatunbosun and colleagues<sup>121</sup> studied women who presented with advanced cervical dilation greater than 4 cm. The cerclage group comprised 22 women, versus 15 in the bed-rest group. Although neonatal survival was not significantly different (17/22 with cerclage vs. 9/15 with bed rest,  $P = .3$ ), gestational age at birth was a mean 4 weeks older in the cerclage group (33 vs. 29 weeks,  $P = .001$ ). Rates of chorioamnionitis were similar between the two groups. A historic cohort study conducted by the Global Health Network for Perinatal and Reproductive Health examined outcomes in women between 14.0 and 25 6/7 weeks gestation when cervical dilation was identified.<sup>122</sup> Of 225 women, 152 received a physical examination–indicated cerclage, and 73 were managed expectantly. Although the groups were dissimilar because women with cervical dilation of 4 cm or more were more likely to be managed expectantly, cerclage was

associated with a longer interval from presentation to delivery, improved neonatal outcome, and fewer births before 28 weeks compared with expectant management.

Althuisius and colleagues<sup>123</sup> performed a randomized clinical trial of physical examination–indicated cerclage plus bed rest versus bed rest alone in 23 women who presented with cervical dilation and membranes prolapsing to or beyond the external os before 27 weeks gestation. Both singleton and twin gestations were eligible; however, cervical dilation data were omitted, and so it is not known whether the groups were comparable. They observed a longer mean interval from presentation to delivery (54 days vs. 20 days;  $P = .046$ ) in the cerclage group. Neonatal survival was 56% (9/16) with cerclage and 29% (4/14) in the bed-rest group. Although the survival differences were not statistically significant, composite neonatal morbidity, which included neonatal death, was significantly lower in the cerclage and bed-rest groups (63% [10/16] vs. 100% [14/14]) in the bed-rest alone group;  $P = .02$ ).

Additional reports show that women who present with acute cervical insufficiency have an appreciable, approximately 50% incidence of bacterial colonization of their amniotic fluid or they demonstrate other markers of subclinical chorioamnionitis<sup>124</sup> or have proteomic markers of inflammation or bleeding.<sup>125</sup> Women with abnormal amniotic fluid markers have a much shorter presentation-to-delivery interval regardless of whether they receive a cerclage or are managed expectantly with bed rest. Mays and colleagues<sup>124</sup> performed amniocentesis in 18 women who presented with this syndrome and analyzed the amniotic fluid for glucose, lactate dehydrogenase, Gram stain, and culture; abnormal results suggested subclinical infection. Of 11 women who underwent cerclage with no evidence of subclinical infection, the neonatal survival was 100%, and the mean latent-phase duration from presentation to delivery was 93 days. Of the seven women with abnormal biochemistries in whom cerclage was withheld, no neonatal survivors were observed, and the mean latent phase was 4 days. In addition, seven women declined amniocentesis but did receive an emergent cerclage. Given that some of this group probably also had subclinical infection, it was predictable that the mean latent phase in this cohort was intermediate (17 days) as compared with the groups with amniotic fluid analyses. These investigators suggested that amniocentesis could aid in selecting candidates for emergent therapeutic cerclage. Diago-Almela and colleagues<sup>126</sup> have recently supported this finding in a prospective study of 31 patients presenting with bulging membranes who accepted amniocentesis. Of these, 20 amniotic fluid specimens revealed intraamniotic inflammation, or subclinical chorioamnionitis, defined as at least two of the following: interleukin 6 (IL-6) levels greater than 2.5 ng/mL, glucose levels below 15 mg/dL, leukocyte levels greater than 50/mm<sup>3</sup>, or positive leukocyte esterase. The remaining 11 had normal amniotic fluid markers, and nine of these patients accepted rescue cerclage. Four of nine delivered at term, and one patient who declined cerclage delivered at term. Those with intraamniotic inflammation/subclinical chorioamnionitis, in spite of being treated with antibiotics and bed rest, all delivered preterm, and 12 losses were seen in this group. Interestingly, of those with amniotic fluid that revealed inflammation, only seven had positive cultures at 5 days, and none had positive cultures in the normal-amniotic-fluid group. Receiver operating characteristic curve (ROC) analysis revealed that of the amniotic fluid markers, IL-6 had the highest diagnostic accuracy for survival using a cutoff of 2.90 ng/mL; all pregnancies with IL-6 above

this level were lost. Their regression analysis further supported physical examination–indicated cerclage with low IL-6 and cervical length less than 30 mm as the best predictors of outcome. Interestingly, a sonographic marker of intrauterine subclinical infection, also known as “sludge,” has been reported (see Fig. 28-2)<sup>127</sup> and is associated with suboptimal outcomes in several studies. Nevertheless, its clinical utility remains uncertain. **Although not currently standard practice, the evaluation of amniotic fluid for markers of infection and/or inflammation appears to have important prognostic value, but it is still unclear whether and to what extent the results should direct patient management.**

**In summary, the optimal management of women who present with acute cervical insufficiency in evolution remains unclear. Although physical examination–indicated cerclage may benefit some, patient selection remains largely empiric. Although limited data exist on which to base firm management recommendations, collectively they demonstrate several important concepts: the earlier the gestational age at presentation, the more advanced the cervical dilation, and the presence of prolapsed membranes and IAI impart greater risk of poor neonatal outcome.**

### Cerclage in Multiple Gestations

Level 1 data are very limited on the effectiveness of cerclage in twin gestations with a short TVU CL. Cerclage is not beneficial and may in fact be harmful in these patients (215% increase in sPTB before 34 weeks) as per a meta-analysis of the only 49 twins with TVU CL less than 25 mm before 24 weeks, randomized to cerclage or no cerclage.<sup>111</sup> Larger RCTs are needed to determine whether cerclage in twins with a short TVU CL is beneficial. The subject of physically indicated cerclage in twins has not been studied in a proper RCT, and the data have been controversial. Until further studies in twins are properly evaluated, cerclage in twin gestations should be discouraged.

## ALTERNATIVE TREATMENTS TO CERVICAL CERCLAGE

Nonsurgical interventions have been advocated for patients with presumed cervical insufficiency.

### Activity Restriction

The rationale for the recommendation for bed rest alone or in conjunction with cerclage relies in the theoretic concept of putting less pressure on the cervix while in the recumbent position. **The validity of bed rest for treatment has not been scientifically proven, and some data suggest worse outcomes in patients placed on bed rest.**<sup>74</sup>

### Pessary

Since the description by Vitsky in 1961 of the use of a vaginal pessary, instead of cerclage, for patients with cervical insufficiency,<sup>128</sup> several studies, mainly in Europe, suggest the same outcome for patients managed with this noninvasive modality compared with a surgical intervention. Arabin and colleagues<sup>129</sup> studied the use of a vaginal pessary in patients with a sonographically detected short cervix (Fig. 28-12). Patients managed with a pessary gained 99 days compared with 67 days for patients managed with bed rest alone ( $P < .02$ ). In the last 2 years, several randomized studies have been done of asymptomatic pregnant patients with a short cervix detected by ultrasound in the

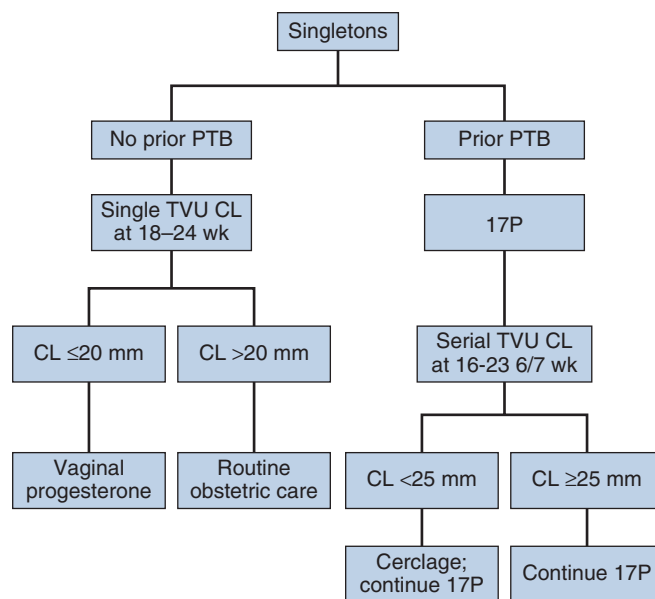

**FIG 28-12** Vaginal pessary (Arabin type).

midtrimester, comparing an Arabin-type pessary to no intervention, and these have shown conflicting results. In the PECEP study (cervical pessary to prevent prematurity) conducted in Spain, patients with a singleton pregnancy with a cervical length less than 25 mm in the midtrimester were randomized to a pessary versus no intervention. The rates of preterm delivery before 34 weeks and 28 weeks were dramatically reduced in the patients managed with a pessary: 27% versus 6% ( $P < .0001$ ) and 8% versus 2% ( $P < .00058$ ). Furthermore, the pessary was not associated with maternal complications except for an increase in vaginal discharge.<sup>130</sup> In contrast, a similar study in China did not show differences in rates of preterm delivery before 37, 34, and 28 weeks in patients with a short cervix randomized to receive a pessary. Some of the criticisms of this study include the lack of adequate patient volume for adequate power and the low incidence of preterm delivery at less than 34 weeks (5.5%) in patients with a short cervix and no intervention.<sup>131</sup> In the only randomized study published to date of pessary use for prevention of prematurity in twin gestations (Pro TWIN study), the rate of prematurity was the same between control patients and the ones randomized to a pessary. However, benefit was found in patients whose cervical length was less than 38 mm (less than the tenth percentile).<sup>132</sup>

Several randomized studies of pessaries in singleton and multiple gestations with short CL are being conducted in both Europe and the United States ([www.clinicaltrials.gov](http://www.clinicaltrials.gov)). **We must await the results of ongoing trials and assess the need for further prospective, randomized trials that compare pessary, cerclage, and progesterone before conclusions regarding the efficacy of any of these interventions can be established.**

### Progesterone

RCTs<sup>133,134</sup> have shown that weekly 17- $\alpha$ -hydroxyprogesterone (17-OH-P) 250 mg intramuscularly (IM) started at about 16 weeks until about 36 weeks is associated with a significant, approximately 30% decrease in recurrent PTB. Based on these data, both the ACOG and SMFM have recommended that all

**FIG 28-13** Use of progesterone for prevention of preterm birth. 17-P, 17- $\alpha$  hydroxyprogesterone; CL, cervical length; PTB, preterm birth; TVU, transvaginal ultrasound. (Modified from Society for Maternal-Fetal Medicine Publications Committee. Progesterone and preterm birth prevention: translating clinical trials data into clinical practice. *Am J Obstet Gynecol.* 2012;206[5]:376-386.)

women with a singleton pregnancy and a prior sPTB should receive this prophylactic therapy.<sup>19,20</sup> We agree that all women with an sPTB between 16 0/7 to 36 6/7 weeks should be eligible for this therapy. ACOG and SMFM use the algorithm seen in [Figure 28-13](#) for management. At least two RCTs<sup>136,137</sup> have proposed that vaginal progesterone is also effective, and perhaps more effective, than 17-OH-P<sup>137</sup> in this clinical scenario. TVU CL is indicated in this population of singleton gestations with prior sPTB, even if the patient has already been given IM 17-OH-P or vaginal progesterone for prophylaxis. Although

nonsignificant given their small numbers, studies have shown that cerclage for patients with TVU CL less than 25 mm before 24 weeks with a prior sPTB even on progesterone is associated with further cumulative prevention of sPTB.<sup>138,139</sup> **Further research is necessary to confirm the benefit of cerclage for women taking 17P and to evaluate the possible cumulative effects of other interventions for short TVU CL, including not only cerclage and progesterone but also perhaps nonsteroidal antiinflammatory agents, other tocolytics, and other pharmacologic agents.**

## COMPARATIVE TRIALS OF TREATMENT OF CERVICAL INSUFFICIENCY

We have reviewed various approaches used to treat cervical insufficiency and their respective efficacies. Because randomized trial data are variously limited for each of the interventions compared with no-intervention controls, trials that compare the available treatment modalities are even less common. To date, nine systematic reviews to report on the above treatment modalities in the prevention or treatment of cervical insufficiency or PTB have been published in the Cochrane Database. Within these reviews, only one comparison trial between modalities has been included. In a study conducted by Keeler and colleagues,<sup>140</sup> 79 asymptomatic women with a short cervix ( $\leq 25$  mm) detected on transvaginal CL screening between 16 and 24 weeks were randomized to either weekly IM injections of 17-OH-P caproate ( $n = 37$ ) or McDonald cerclage ( $n = 42$ ). No difference in spontaneous PTB prior to 35 weeks was observed (RR, 1.14; 95% CI, 0.67 to 1.93). A post hoc analysis conducted of women with a prior PTB again revealed no difference. However, secondary analysis of patients with a cervical length of 15 mm or less showed a 52% risk reduction in sPTB before 35 weeks with cerclage (RR, 0.48; 95% CI, 0.24 to 0.97).<sup>141</sup> In a retrospective cohort study conducted by Mackeen and colleagues of women who received a history-indicated cerclage, the authors compared 14 women who had received 17-OH-P with 80 women who had not. Once all outcomes were assessed, including PTB at various gestational age cutoffs, it was found that interval between cerclage placement and delivery, gestational age at delivery, and infant birthweight did not differ between groups.<sup>142</sup> A similar conclusion was reached by Szychowski and coworkers in a secondary analysis of the Vaginal Ultrasound Consortium Trial, where outcomes of women receiving 17-OH-P who had been randomized to cerclage or no cerclage in the setting of a short cervix (cervical length  $< 25$  mm). Of the 99 women who received 17-OH-P, 47 received cerclage and 52 did not. Although a 36% decrease was noted in the odds of PTB  $< 35$  weeks in those with a cerclage, this difference was not significant (aOR 0.64, 95% CI 0.27-1.52), possibly secondary to beta error.<sup>139</sup>

In a study conducted by Alfirevic and colleagues, the authors retrospectively and indirectly compared three management strategies for shortened cervical length in women with singletons and a prior spontaneous PTB before 34 weeks: ultrasound-indicated cerclage, vaginal progesterone, and cervical pessary. A total of 142 patients from the United States had undergone cerclage, 59 patients from the United Kingdom received vaginal progesterone, and 42 women from Spain received a cervical pessary.<sup>143</sup> The authors reported no difference in perinatal loss, neonatal morbidity, or PTB among the three groups, and concluded that cerclage, vaginal progesterone and pessary had similar efficacy in high risk patients with a short midtrimester cervical length.

Given the study design and different patient populations, definitive conclusions cannot be reached. Similarly, Conde-Agudelo and colleagues performed an adjusted, indirect meta-analysis of randomized controlled trials of different treatment strategies for midtrimester shortened cervical length in women with singleton pregnancies and a prior history of PTB. Within their analysis, they included four studies that compared vaginal progesterone to placebo (158 patients) and five studies evaluating cerclage versus no cerclage (504 patients). They concluded that either intervention was associated with a statistically significant reduction in both PTB  $< 32$  weeks and composite perinatal morbidity and mortality when compared to placebo/expectant management. Further, their adjusted indirect meta-analysis showed that both interventions had similar efficacy.<sup>144</sup> The recommendations from these indirect meta-analyses should be considered with caution because of the significant differences in baseline characteristics of the populations studied, making true comparisons difficult to interpret.

**The above data highlight the need for quality randomized clinical trials comparing the various available interventions and, importantly, combinations of interventions (for example, progesterone plus cerclage).** In the hopes of preventing adverse perinatal outcomes, providers might recommend dual or even triple intervention with the assumption that they will act synergistically (e.g. 17-OH-P for a history of PTB, ultrasound-indicated cerclage for cervical shortening and a supporting pessary when post-cerclage cervical changes are detected). A recent editorial by Griffin cautions against the use of combined strategies that have not been proven efficacious in combination.<sup>145</sup>

## SUMMARY

Cervical insufficiency is rarely a distinct and well-defined clinical entity but only one part of a larger and more complex spontaneous preterm birth syndrome. The original paradigm of obstetric and gynecologic trauma as a common antecedent of cervical insufficiency has been replaced by the recognition of functional, as opposed to anatomic deficits as the more prevalent origin. Cervical competence functions along a continuum, influenced by both endogenous and exogenous factors that interact through various pathways with other recognized components of the PTB syndrome: uterine contractions and decidual/membrane activation. **The clinically convenient term, cervical insufficiency, probably represents an oversimplified, incomplete version of the broader, although poorly understood, pathophysiologic process.** Consequently, the continued use of traditional therapies, unsubstantiated by results of clinical trials, must be questioned. Effective, evidence-based management guidelines will stem from a more complete understanding of the PTB syndrome. This will improve patient selection and permit specifically tailored treatment regimens, confirmed by the results of well-designed intervention trials.

**Cervical insufficiency remains primarily a clinical diagnosis. Cervical ultrasound demonstrating a short cervix has emerged as a proven, clinically useful screening and diagnostic tool in selected populations of asymptomatic high-risk women based on an obstetric**

**history of a prior (early) spontaneous PTB. Women with history of preterm delivery who then develop shortened mid-trimester cervical length appear to have a treatable component of cervical insufficiency.** Surgical intervention in the form of history-indicated cerclage, sonographically indicated cerclage, and physically indicated cerclage, may be beneficial in selective patients. The vast majority of women with prior sPTB can be followed with TVU CL screening, with ultrasound-indicated cerclage if the TVU CL becomes less than 25 mm before 24 weeks. Evidence continues to be developed for perioperative management strategies for cerclage placement. The use of abdominal/laparoscopic and/or robotic cerclage may be reasonable in rare, carefully selected patients. Additive and/or alternative interventions such as progesterone and vaginal pessary demonstrate promise but still require further evaluation to make final recommendations in the treatment of patients with a history consistent with cervical insufficiency or patients with a short cervical length in the midtrimester.

### KEY POINTS

- ◆ Cervical insufficiency is primarily a clinical diagnosis characterized by recurrent painless dilatation and spontaneous midtrimester loss.
- ◆ Cervical insufficiency is rarely a distinct and well-defined clinical entity, but only one component of the larger and more complex spontaneous preterm birth syndrome.
- ◆ Current evidence suggests that cervical competence functions along a continuum, influenced by both endogenous and exogenous factors, such as uterine contractions and decidual/membrane activation.
- ◆ The traditional nomenclature of cerclage type as prophylactic, therapeutic, and emergent should be replaced by history-indicated, ultrasound-indicated, and physical examination–indicated cerclage.
- ◆ There is no objective preconceptional diagnostic test for cervical insufficiency.
- ◆ History-indicated cerclage for patients with a clinical history of cervical insufficiency remains a reasonable approach.
- ◆ Cervical ultrasound for cervical insufficiency performs poorly as a screening test in low-risk women, but it has been proven to be a clinically useful screening and diagnostic tool in selected high-risk populations such as those with a prior sPTB who may have a treatable component of cervical insufficiency.
- ◆ In the vast majority of women with prior sPTBs, and even those with nonclassic clinical histories of cervical insufficiency, serial sonographic evaluations of the cervix may be an acceptable alternative approach to history-indicated cerclage.
- ◆ Physical examination–indicated cerclage may be beneficial in reducing PTB in a subgroup of patients without markers of infection.
- ◆ Abdominal cerclage may be considered for those rare patients with a history of failed vaginal cerclage.
- ◆ Ultrasound indicated cerclage in twin gestation should not be performed because of the increase risk for preterm delivery with this intervention.
- ◆ There is a need for randomized studies to evaluate alternative treatments for cervical insufficiency such as pharmacologic therapy, and vaginal pessary.

The average duration of a normal human pregnancy is 267 days, counted after conception, or 280 days (40 weeks) from the first day of the last normal menstrual period. Infants born at 39 and 40 weeks of gestation have the lowest rates of adverse outcomes. **Complications related to preterm birth (PTB) account for more newborn and infant deaths than any other cause.<sup>1</sup> Although advances in neonatal care have led to increased survival and reduced short- and long-term morbidity for infants born preterm, surviving infants have increased risks of visual and hearing impairment, chronic lung disease, cerebral palsy, and delayed development in childhood. The causes of PTB are diverse but can be usefully considered according to whether the parturitional process—which includes cervical remodeling, decidual membrane activation, and myometrial contractions—had begun before birth occurred. Preterm births that do not follow spontaneous initiation of parturition most often are iatrogenic, when the health of the mother or fetus is at risk (e.g., with major hemorrhage, hypertension, or poor fetal growth).**

## DEFINITIONS

A *preterm birth* is commonly defined as one that occurs after 20 weeks' gestation and before the completion of 37 menstrual weeks of gestation regardless of birthweight. *Low birthweight* (LBW) is defined as birthweight below 2500 g regardless of gestational age; *very low birthweight* (VLBW) is birthweight below 1500 g, and *extremely low birth weight* (ELBW) is birthweight below 1000 g. Gestational age (GA) and birthweight (BW) are related by the terms *small for gestational age* (SGA; a BW less than the 10th percentile for GA), *average for gestational age* (AGA; BW between the 10th and 90th percentiles), and *large for gestational age* (LGA; BW above the 90th percentile). A *preterm* or *premature* infant is one born before 37 weeks of gestation—that is, 259 days from the first day of the mother's last normal menstrual period or 245 days after conception. The gestational boundaries of 20 and 37 weeks are historic, not scientific.<sup>2</sup> Infants born at 36, 37, and even 38 weeks of gestation may experience neonatal and even lifetime morbidity related to immaturity of one or more organs. The risk factors, etiologies, and recurrence risk for spontaneous births at 16 to 19 weeks do not differ from those of births at 20 to 25 weeks.<sup>3,4</sup> The American College of Obstetricians and Gynecologists (ACOG) and the Society for Maternal-Fetal Medicine (SMFM) have adopted the nomenclature *later preterm* (34<sup>0/7</sup> to 36<sup>6/7</sup> weeks of gestation) and *early term* (37<sup>0/7</sup> to 38<sup>6/7</sup> weeks of gestation) to acknowledge the contribution of gestational age in these ranges to neonatal risks.<sup>5</sup> **Recognition that some infants born after 37 weeks are not fully mature and that many births before 20 weeks arise from the same causes that lead to preterm births has led to reevaluation of these definitions and boundaries.<sup>6</sup>**

## FREQUENCY OF PRETERM AND LOW-BIRTHWEIGHT DELIVERY

The World Health Organization (WHO) has estimated **that 9.6% of all births in 2005 were preterm—almost 13 million worldwide.** Africa and Asia accounted for almost 11 million.<sup>7</sup> Rates are lowest in Europe (6.2%), and the highest rates are seen in Africa (11.9%) and North America (10.6%). In the United States, the PTB rate rose from 10.6% in 1990 to 12.8% of all births in 2006. The rise resulted from improved pregnancy dating by ultrasound, which shifted the gestational age distribution to the left; increased use of assisted reproduction technology (ART); and, most importantly, from increased willingness to choose delivery when medical or obstetric complications occur after 34 weeks' gestation. The rate of PTB fell to its most recent nadir of 11.4% in 2013 (Fig. 29-1). The decline has been attributed to improved fertility practices that reduce the risk of higher-order multiple gestation; quality improvement programs that limit scheduled late-preterm and near-term births to only those with valid indications; and increased use of strategies to prevent recurrent PTB.

The rates of PTB vary substantially across the United States (Fig. 29-2). Reasons for the geographic variation are complex but are heavily influenced by the percentage of the population that is black. **Blacks have rates of PTB that are almost twofold higher than those of other racial/ethnic groups (Fig. 29-3).**

## Outcomes for Infants Born Preterm

Gestational age at birth is strongly correlated with adverse pregnancy outcomes that include stillbirth (fetal death after 20 weeks' gestation), deaths of neonates (<28 days) and infants (<12 months), and long-term physical and intellectual morbidities.

## PERINATAL MORTALITY

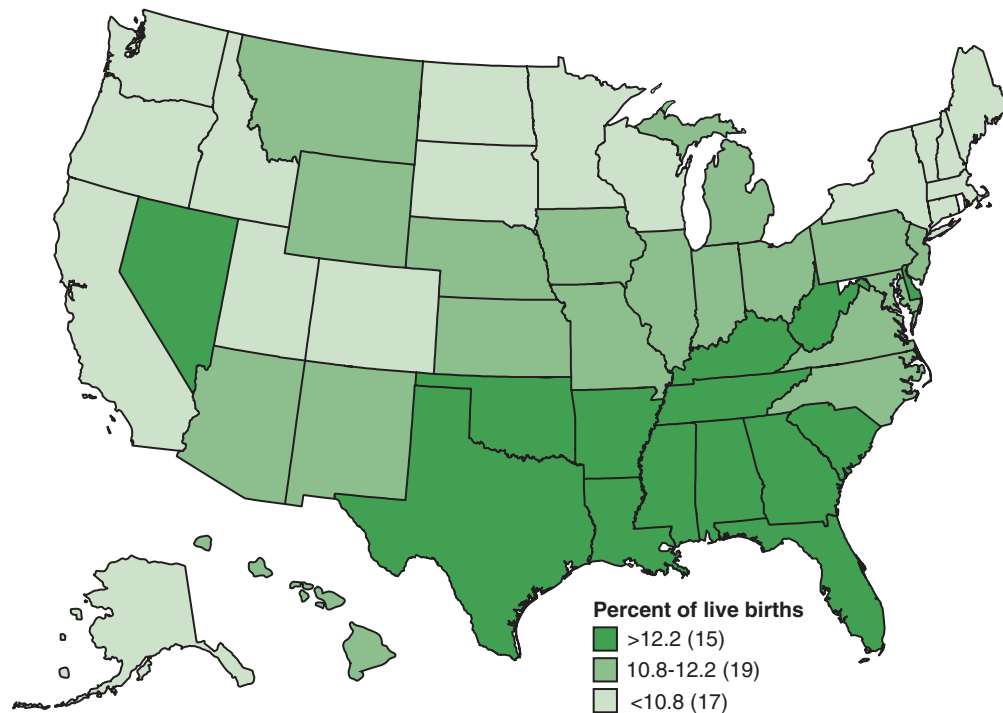

*Perinatal mortality* is defined as the sum of stillbirths after 20 weeks' gestation plus neonatal deaths through 28 days of life per 1000 total births (liveborn plus stillborn). Perinatal mortality increases markedly as gestational age and birthweight decline. Because this measure encompasses prenatal, intrapartum, and neonatal events, it reflects obstetric and neonatal care. Stillbirth and PTB have a similar epidemiologic profile, especially before 32 weeks. Rates of perinatal mortality declined between 1990 and 2003, mainly because of a decrease in fetal deaths after 27 weeks' gestation.<sup>8</sup>

## Infant Mortality

The infant mortality rate is the number of deaths among live-born infants before 1 year of age per 1000 *live* births. Although congenital malformations are often listed as the leading cause of infant mortality, this ranking is achieved by separating

**FIG 29-1** Preterm and low-birthweight rates: United States, final 1981 through 2009, preliminary 2009. (Modified from Hamilton BE, Martin JA, Ventura SJ. Births: preliminary data for 2009. *Natl Vital Stat Rep.* 2010;59[3].)

**FIG 29-2** Percentage of live preterm births in the United States by state, 2013. (From National Center for Health Statistics, final natality data. Available at [www.marchofdimes.org/peristats](http://www.marchofdimes.org/peristats).)

conditions related to PTB into several categories. The proportion of all infant deaths in the United States in 2008 by gestational age at birth is shown in [Figure 29-4](#).

**Infant and childhood mortality and morbidity in surviving preterm infants rise as gestational age at birth declines, and they vary with the level of neonatal care received.** In 2008, the overall infant mortality rate was 6.6 infant deaths per 1000 live births; however, infant mortality rates varied widely by gestational age. For infants born at less than 32 weeks' gestation, the infant mortality rate was 175.5 infant deaths per 1000 live births, compared with a rate of 2.1 for infants born at 39

to 41 weeks' gestation, the age group with the lowest risk. Infant mortality rates generally decreased with increasing gestational age, and even infants born at 37 to 38 weeks had a mortality rate that was 50% higher than that for infants born at 39 to 41 weeks.

Regionalized care for high-risk mothers and preterm LBW infants, antenatal administration of corticosteroids, neonatal administration of exogenous pulmonary surfactant, and improved ventilator technology have improved outcomes for very preterm infants. Survival rates rise with gestational age at birth, from 6% for infants born at 22 weeks' gestation to more

**FIG 29-3** Percentage of live preterm births by racial group. (Data from Martin JA, Hamilton BE, Sutton PD, et al. Births: final data for 2008. *Natl Vital Stat Rep.* 2010;59[1]:1, 3-71.)

**FIG 29-4** Proportion of all infant deaths in the United States in 2008 by gestational age at birth. (Modified from Centers for Disease Control and Prevention. Mathews TJ, MacDorman MF. Infant mortality statistics from the 2008 period linked birth/death data set. *Natl Vital Stat Rep.* 2012; 60[5]:1-27. Available at [www.cdc.gov/nchs/vitalstats.htm](http://www.cdc.gov/nchs/vitalstats.htm).)

than 90% at 28 weeks' gestation for infants cared for in tertiary intensive care units (ICUs).<sup>9</sup> Outcomes can be more accurately predicted by considering fetal number (singleton or multiple), gender, exposure or nonexposure to antenatal corticosteroids, and birthweight in addition to gestational age.<sup>9</sup> Probabilities of infant outcomes based upon antenatal factors can be estimated utilizing an online calculator available from the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD) Neonatal Research Network.<sup>10</sup> Long-term survival rates by gestational age at birth in 903,402 infants born in Norway<sup>11</sup> are shown in Figure 29-5.

### Perinatal Morbidity

Preterm infants are at risk for specific diseases related to immaturity of various organ systems as well as to the causes and circumstances of PTB. **Common complications in premature infants include respiratory distress syndrome (RDS), intraventricular hemorrhage (IVH), bronchopulmonary dysplasia (BPD), patent ductus arteriosus (PDA), necrotizing enterocolitis (NEC), sepsis, apnea, and retinopathy of prematurity (ROP).** Rates of morbidity vary primarily by gestational age but are also affected by birthweight, fetal number (singleton

**FIG 29-5** Cumulative long-term survival by gestational age at birth in 903,402 infants born in Norway. (Modified from Moster D, Lie RT, Markestad T. Long-term medical and social consequences of preterm birth. *N Engl J Med.* 2008;359[3]:262-273.)

vs. multiple gestations), **geographic location, proximity to a neonatal intensive care unit (NICU), and any maternal or fetal conditions that may have led to PTB.** The frequency of major morbidity rises as gestational age decreases, especially before 30 weeks' gestation. Wide geographic variation is apparent in the frequency of neonatal morbidities, especially for VLBW infants. Reports of survival and morbidity also vary according to the denominator used. Obstetric datasets include all living fetuses at entry to the obstetric suite, whereas neonatal datasets exclude intrapartum and delivery room deaths and thus report rates based on newborns admitted to the nursery. Rates of survival and morbidity at the same gestational age and birthweight are thus somewhat higher in neonatal datasets.

### Long-Term Outcomes

Major neonatal morbidities related to PTB that carry lifetime consequences include chronic lung disease, grades 3 and 4 intraventricular hemorrhage (associated with cerebral palsy), NEC, and vision and hearing impairment. Follow-up

**BOX 29-1 DEMOGRAPHIC PROFILE OF WOMEN WITH SPONTANEOUS PRETERM BIRTH**

- History of genital tract colonization, infection, or instrumentation
  - Urinary tract infection and bacteriuria
  - Sexually transmitted infections such as *Chlamydia*, gonorrhea, human papillomavirus, or *Trichomonas*
  - Bacterial vaginosis
  - Cervical dysplasia and treatment for this diagnosis
  - Spontaneous or induced abortion
- Black race
- Bleeding of uncertain origin in pregnancy
- History of a previous spontaneous preterm birth
- Uterine anomaly
- Use of assisted reproductive technology
- Multifetal gestation
- Cigarette smoking, substance abuse
- Prepregnancy underweight (body mass index <19.6) and prepregnancy obesity (body mass index >30)
- Periodontal disease
- Limited education, low income, and low social status
- Late registration for prenatal care
- High levels of personal stress in one or more domains of life

**studies of infants born preterm and of LBW infants reveal increased rates of cerebral palsy, neurosensory impairment, reduced cognition and motor performance, academic difficulties, and attention-deficit disorders.**

The incidence of long-term morbidity in survivors is especially increased for those born before 26 weeks' gestation. In a study from the United Kingdom, 78% of 308 survivors born before 25 weeks' gestation were followed and compared with classmates of normal birthweight. Almost all had some disability at age 6 years: 22% had severe neurocognitive disabilities (cerebral palsy, IQ more than 3 standard deviations [SDs] below the mean, blindness, or deafness), 24% had moderate disability, 34% had mild disability, and 20% had no neurocognitive disability.

**EPIDEMIOLOGY OF PRETERM BIRTH**

The numerous maternal and fetal diagnoses that precede PTB may be considered according to whether parturition began spontaneously or not. **Spontaneous preterm parturition may first manifest as cervical softening and ripening, decidual activation, and/or uterine contractions. Cervical softening is the most common initial evidence that parturition has begun.** In women who later delivered spontaneously between 28 and 36 weeks' gestation, cervical length measurements at 22 to 24 weeks' gestation were significantly shorter than in women who delivered at term, indicating that cervical softening had begun before 24 weeks.<sup>12</sup> This same study found that more than half of women with evidence of very preterm cervical effacement delivered after 35 weeks' gestation, indicating that spontaneous preterm parturition does not always progress to PTB. Women with signs and symptoms of spontaneous preterm parturition often have one or more of the demographic characteristics shown in Box 29-1, but it is important to note that **approximately half of women who deliver preterm have no obvious risk factors.** Among 2521 women who received prenatal care at 10 collaborating university clinics, 323 (12.8%) delivered before 37 weeks' gestation. Of these, 234 (9.3% of the total and 72%

**BOX 29-2 DEMOGRAPHIC AND MEDICAL PROFILE OF WOMEN WITH INDICATED PRETERM BIRTH**

- Diabetes mellitus diagnosed before or during pregnancy
- Chronic or acute (preeclamptic) hypertension
- Obstetric disorders or risk conditions in the current or previous pregnancy
  - Preeclampsia
  - Previous uterine surgery (e.g., prior cesarean delivery via a vertical or T-shaped uterine incision)
  - Cholestasis
  - Placental disorders
    - Placenta previa
    - Premature separation (abruption) of the placenta
- Medical disorders
  - Seizures
  - Thromboembolism
  - Connective tissue disorders
  - Asthma and chronic bronchitis
  - Maternal human immunodeficiency virus or herpes simplex virus
  - Obesity
  - Smoking
- Advanced maternal age
- Fetal disorders
  - Fetal compromise
    - Chronic (poor fetal growth)
    - Acute (fetal distress; for example, abnormal fetal testing on a nonstress test or biophysical profile)
  - Excessive (polyhydramnios) or inadequate (oligohydramnios) amniotic fluid
  - Fetal hydrops, ascites, blood group alloimmunization
  - Birth defects
  - Fetal complications of multifetal gestation (e.g., growth deficiency, twin-to-twin transfusion syndrome)

of those delivered preterm) were born after spontaneous initiation of parturition, and 89 (3.5% of the total and 27% of those delivered preterm) were born preterm because of medical or obstetric indications.<sup>12</sup>

As noted above, women whose PTB is not preceded by spontaneous parturition have medical and/or obstetric conditions that lead to the onset of parturition or to iatrogenic intervention to benefit the mother or fetus. Their demography reflects this (Box 29-2), and efforts to prolong pregnancy are primarily aimed at optimal management of their medical condition. This strategy is more successful in some—for example, those with diabetes mellitus, in whom maintenance of euglycemia often leads to birth at term—than in others, such as those with chronic hypertension, in whom effective blood pressure control does not prevent preeclampsia.

**CLINICAL RISK FACTORS FOR SPONTANEOUS PRETERM BIRTH**

**Risk factors for spontaneous preterm birth (sPTB) arise from maternal factors, prior pregnancy history, and current pregnancy risks.**

**Maternal Factors**

Many maternal factors impact PTB. These may be medical or dental, such as infection or disease; behavioral, related to

maternal demographics or stress; or related to genetics and anatomy, including abnormalities of the genitourinary tract. Each of these factors will be discussed.

## Medical Infections

**Systemic and genital tract infections** are associated with PTB. In women in spontaneous preterm labor with intact membranes, lower genital tract flora are commonly found in the amniotic fluid, placenta, and membranes. The flora include *Ureaplasma urealyticum*, *Mycoplasma hominis*, *Fusobacterium* species, *Gardnerella vaginalis*, peptostreptococci, and *Bacteroides* species. Clinical and histologic evidence of intraamniotic inflammation and infection is more common as the gestational age at delivery decreases, especially before 30 to 32 weeks. **Bacteria in the amniotic fluid, whether detected by cultivation or by molecular methods, have been reported in 20% to 60% of women with preterm labor before 34 weeks' gestation.** The frequency of positive cultures increases as gestational age decreases, from 20% to 30% after 30 weeks to 60% at 23 to 24 weeks' gestation. Evidence of infection is less common after 34 weeks.

Bacterial vaginosis (BV) is a condition in which the ecosystem of the vagina is altered so that gram-negative anaerobic bacteria (e.g., *Gardnerella vaginalis*, *Bacteroides*, *Prevotella*, *Mobiluncus*, and *Mycoplasma* species) largely replace the normally predominant lactobacilli. **BV is associated with a twofold increased risk of sPTB. The association between BV and PTB is stronger when BV is detected early in pregnancy.** Despite the association, antibiotic eradication of BV does not consistently reduce the risk of PTB. Infections outside the genital tract have also been related to PTB, most commonly urinary tract and intraabdominal infections (e.g., pyelonephritis and appendicitis). The presumed mechanism of disease is inflammation of the nearby reproductive organs, but infections at remote sites—especially if they are chronic—have also been associated with increased risk of sPTB.

## Periodontal Disease

Women with periodontal disease have an increased risk of PTB that is not reduced by periodontal care, suggesting shared susceptibility rather than a cause-effect relation. The genitourinary and alimentary tracts are both major sites of microbial colonization where host immune factors defend the interior of the body, so shared risk factors are not surprising.

## Genitourinary Tract Factors

### Cervical Length

Cervical length (CL) as measured by transvaginal ultrasound is inversely related to the risk of PTB in both singletons and twins. Women whose CL at 22 to 24 weeks' gestation was at or below the 10th percentile (25 mm by endovaginal ultrasound) had a 6.5-fold increased risk (95% confidence interval [CI], 4.5 to 9.3) of PTB before 35 weeks' gestation and a 7.7-fold increased risk (95% CI, 4.5 to 13.4) of PTB before 32 weeks' gestation when compared with women whose CL measurement was greater than the 75th percentile.<sup>13</sup> The explanation for the linkage between CL and PTB risk was once thought to reflect a "continuum of cervical competence" in which variable cervical resistance to uterine contractions explained the relationship. However, there is now substantial evidence that contractions do not herald the onset of PTB<sup>14</sup> and that progesterone supplementation slows the progression of cervical shortening and reduces the risk of PTB

when initiated before 24 weeks in women with and without a prior PTB.<sup>15-19</sup> These studies support the conclusion that **preterm cervical shortening (softening and ripening) is not the passive result of tissue weakness but instead is an active process indicating that pathologic preterm parturition has begun, regardless of its underlying cause.**<sup>12</sup>

## Cervical Procedures

A history of cervical surgery, including conization and the loop electrosurgical excision procedure (LEEP), has been suggested to be a risk factor for PTB. A recent meta-analysis supports the concept that when women with a history of LEEP are compared with women with prior dysplasia but no cervical excision, the risk of PTB is similar. This finding suggests that common factors for both PTB and dysplasia confound the association between LEEP and PTB.

## Congenital Abnormalities of the Uterus

Congenital structural abnormalities of the uterus, known as *müllerian fusion defects*, may affect the cervix, the uterine corpus, or both. **The risk of PTB in women with uterine malformations is 25% to 50% depending on the specific malformation and the obstetric history.** Implantation of the placenta on a uterine septum may lead to PTB by means of placental separation and hemorrhage. A T-shaped uterus in women exposed in utero to diethylstilbestrol (DES) has also been associated with an increased risk of preterm labor and birth.

## Behavioral

In general, studies of behavioral influences on PTB have not found a consistent relationship between maternal activities and PTB, except with tobacco smoking.

## Smoking and Substance Abuse

Smoking is associated with an increased risk of PTB, and unlike most other risks, it is amenable to intervention during pregnancy.

## Physical Activity

Controversy exists as to whether excessive physical activity is associated with early delivery.

## Nutritional Factors

Low maternal prepregnancy weight (body mass index [BMI] <19.8 kg/m<sup>2</sup>) has been consistently found to be associated with an increased risk of PTB.<sup>20,21</sup> Prepregnancy overweight and obesity are also linked to an increased risk of PTB, especially extremely preterm birth.<sup>22</sup> Women who consume one or more servings of fish per month have lower rates of PTB than women who rarely or never eat fish.<sup>23</sup> Numerous studies of various nutritional deficiencies have been reported to be related to the risk of PTB, but there are few if any for which supplementation has been found to reduce the incidence of prematurity.

## Demography, Stress, and Social Determinants of Health

Social disadvantage is persistently associated with increased risk of PTB: poverty; educational attainment; geographic residence in disadvantaged neighborhoods, states, and regions; and lack of access to prenatal care are all linked to significantly higher rates of PTB.<sup>24</sup> These associations were once deemed to be social, not medical, and thus beyond the reach of medical care. Stress<sup>25</sup> and depression<sup>26</sup> are consistently reported to have a moderate

**TABLE 29-1** MAGNITUDE OF INCREASED RISK BASED ON EDUCATION AND RACE/ETHNICITY

Data from National Committee on Health Statistics for U.S. birth cohorts from 1998 to 2000 and from Behrman RE, Butler AS. *Sociodemographic and Community Factors Contributing to Preterm Birth: Causes, Consequences, and Prevention*. Institute of Medicine (US) Committee on Understanding Premature Birth and Assuring Healthy Outcomes. Washington, DC: National Academies Press; 2007.

**FIG 29-6** Risk of preterm birth according to educational level (years) by race/ethnicity (see Table 29-1). (Data from Behrman RE, Stith Butler A. Committee on understanding premature birth and assuring healthy outcomes: causes, consequences, and prevention. Washington, DC: National Academies Press; 2007.)

association with PTB, although the mechanisms again remain uncertain.

The effect of the social environment on reproduction has since been examined in greater detail and reveals evidence of a causative relationship. The magnitude of the increased risk of PTB according to educational level and race/ethnicity is shown in Table 29-1 and Figure 29-6.

A nearly twofold difference is seen in the rate of PTB for women of all racial and ethnic groups between those with the highest and lowest levels of education. Equally striking is the persistence of the disparity in rates of PTB in black women

regardless of their educational level, and in Table 29-2 and as shown in Figure 29-7, their access to early prenatal care.

### BLACK RACE

Black women have a uniquely increased risk for PTB when compared with women from any other racial or ethnic background.<sup>27</sup> In 2005 through 2007, the rate of PTB averaged 18.4% among black women, compared with 10.8% in Asian American, 11.6% in white, 12.6% in Hispanic, and 14.2% in Native American women. The disparity in the PTB rate persists after social and medical risk factors are accounted for<sup>24,27,28</sup> and

**FIG 29-7** Risk of preterm birth according to access to early prenatal care by race/ethnicity and trimester (see Table 29-2). (Data from National Center for Health Statistics: U.S. Birth Cohorts From 1998 to 2000. From Berhman RE, Butler AS. *Sociodemographic and Community Factors Contributing to Preterm Birth: Causes, Consequences, and Prevention*. Institute of Medicine (US) Committee on Understanding Premature Birth and Assuring Healthy Outcomes. Washington, DC: National Academies Press; 2007.)

is evident in black Americans but not in African women. The origins of the disparity are not well understood. Regardless of the etiology, **all African American women may be considered to have an increased risk of PTB even in the absence of other risk factors.**

### Genetic Contributors to Preterm Birth

The notion of some genetic contribution to PTB is based on several observations. First, a woman's family history of PTB influences her own risk. **Porter and colleagues found that a mother who was herself born preterm had an increased risk for delivering a child preterm; the magnitude of that increased risk was inversely related to the gestational age of her own birth.** The odds ratio for PTB ranged from 1.18 (95% CI, 1.02 to 1.37) for women who were born at 36 weeks' gestation to 2.38 (95% CI, 1.37 to 4.16) for women who were born at 30 weeks' gestation. A second set of observations from twin studies supports a genetic contribution to PTB. Treloar and colleagues<sup>29</sup> studied 905 Australian female twin pairs to determine whether delivery had occurred more than 2 weeks before term. In this study, "all-cause" PTB was the outcome.<sup>29,30</sup> Twin-pair correlations were higher from monozygotic twin pairs than from dizygotic twin pairs ( $r = 0.3 \pm 0.08$  vs.  $0.03 \pm 0.11$  standard error [SE], respectively). Heritability was calculated at 17% for preterm delivery in the first pregnancy and 27% for preterm delivery in any pregnancy. A population-based twin study in Scandinavia investigated 868 monozygotic and 1141 dizygotic female twin pairs who delivered singletons between 1973 and 1993.<sup>29,30</sup> Correlation for gestational length was higher for monozygotic compared with dizygotic twins, and heritability estimates from model fitting were approximately 30% for gestational age and 36% for PTB. This heritability appears to be the result of maternal, rather than paternal, lineage. The pattern

of PTBs that occur in family pedigrees suggests that the most likely form of inheritance is nonmendelian; rather, the observed pedigrees are more consistent with the influence of many genes. Numerous studies have aimed at discovering variation in genes that contribute to PTB, and many associations have failed to replicate across populations. However, four genes are significantly associated with PTB in genome-wide studies: follicle-stimulating hormone receptor (*FSHR*), insulin-like growth factor 1 receptor (*IGF1R*), protein col-52, and serpin peptidase inhibitor, clade B, member 2 (*SERPINB2*). **Insights into the complex genetics of PTB hold promise for giving insight into pathophysiology and, potentially, to risk identification; at present, neither of these potential benefits influences clinical care.**

### Pregnancy History

**The strongest historic risk factor is a previous birth between 16 and 36 weeks' gestation.** This history is often reported to confer a 1.5-fold to twofold increased risk but varies widely according to the number, sequence, and gestational age of prior PTBs (Fig. 29-8).

When the prior PTB occurs in a twin pregnancy, the risk of PTB in a subsequent singleton gestation rises as the gestational age at delivery of the twins falls below 34 weeks' gestation. There is minimal if any increased risk for women whose prior twin birth occurred after 34 weeks' gestation, but the risk of singleton PTB may be as much as 40% when the prior twin birth occurred before 30 weeks' gestation.

**Prior stillbirth**<sup>31</sup> and pregnancies ending between 16 and 20 weeks' gestation<sup>3</sup> are also associated with increased risk of PTB in subsequent pregnancies.

**Pregnancy termination** in the first and second trimesters is linked to an increased risk of subsequent PTB, especially when

PRIOR PRETERM DELIVERY STATUS BY ORDER AND GESTATIONAL AGE AT DELIVERY

**FIG 29-8** Risk of recurrent preterm birth in 19,025 women with two prior births according to the order and gestational age of the previous birth. Very preterm, 21 to 31 weeks' gestation; moderate preterm, 32 to 36 weeks' gestation. (Modified from McManamy J, Cooke E, Amon E, Leet T. Recurrence risk for preterm delivery. *Am J Obstet Gynecol.* 2007;196[6]:576.e1-e7.)

performed with mechanical dilation or curettage or when performed repeatedly.<sup>32</sup> Increased risk of PTB has been found after spontaneous, as well as induced, abortion.<sup>33</sup>

### Current Pregnancy Risks

**Mode of conception** also affects the risk of PTB. The increased rate of PTB after assisted reproduction is due not only to the increased occurrence of multiple gestations but also to an increased rate of PTBs in singleton pregnancies as well. **A nearly twofold increased risk of PTB is observed in singleton pregnancies conceived with all methods of fertility care, including ovulation promotion.**<sup>34</sup> A meta-analysis of 15 studies that compared 12,283 pregnancies resulting from in vitro fertilization (IVF) with 1.9 million spontaneously conceived singleton births found approximately twofold increased rates of perinatal mortality, PTB, LBW and VLBW, and SGA infants born after IVF. Rates of PTB among multiple gestations do not appear to be increased after assisted conception relative to spontaneously conceived twins and triplets, so the explanation for the increased rates in singletons is unclear. Microbial colonization of the upper genital tract, increased stress among infertile couples, side effects of superovulation, and increased rates of birth defects have been proposed as possible causes.

### Bleeding and Vanishing Twins

**Women who experience unexplained vaginal bleeding after the first trimester have an increased risk of subsequent PTB that increases with the number of bleeding episodes.** Perhaps reflecting similar causes, the risk of PTB is also increased in women whose pregnancies are complicated by a vanishing twin (see Chapter 32) or by an unexplained elevation in maternal serum alpha-fetoprotein.

### Multifetal Gestation and Uterine Distension

**Multifetal gestation is one of the strongest risk factors for PTB.** Rates of preterm, very preterm, LBW, and VLBW births according to fetal number are described in Chapter 32. Slightly more than 50% of women with twins deliver before 37 weeks' gestation. The risk of early birth rises with the number of fetuses, which suggests uterine overdistension and fetal signaling as

potential pathways to the early initiation of labor. In addition to spontaneous preterm labor, multiple gestations are more commonly complicated by medical and obstetric disorders that lead to indicated preterm delivery. Poor fetal growth, fetal anomalies, hypertension, abruptio placentae, and fetal compromise are more common in multiple gestations and increase with the number of fetuses. The chorionicity of twin gestations is also an important factor in the risk for adverse pregnancy outcomes. **Monochorionic twin pregnancies are more likely than dichorionic twin gestations to be complicated by stillbirth and fetal growth restriction.** Newborn monochorionic twins are more likely than dichorionic twins to experience NEC and neurologic morbidity. It is unclear how much of the excess rate of PTB among monochorionic twins is due to indicated versus spontaneous PTB.

### Risk-Scoring Systems

**Attempts to develop scoring systems based on historic and epidemiologic data plus current pregnancy risk factors have had low sensitivity to identify women who will give birth preterm, but they have not included some of the historic risks listed here.**

## PATHOPHYSIOLOGY OF SPONTANEOUS PRETERM BIRTH

Term and preterm parturition share anatomic, physiologic, and biochemical features that are considered part of the common pathway of parturition. This pathway includes (1) cervical changes (*softening, and ripening*), (2) membrane/decidual activation, and (3) increased uterine contractility. However, although spontaneous labor at term results from physiologic activation of the common pathway of parturition, preterm labor is the result of a *pathologic activation* of this pathway. The insult responsible for activation may lead to asynchronous recruitment of each pathway. **Asynchrony is recognized clinically as (1) cervical insufficiency when the process affects predominantly the cervix; (2) preterm uterine contractions when the process affects the myometrium; or (3) preterm premature rupture of membranes (PPROM) if**

**the insult acts on the chorioamniotic membranes.** Synchronous activation in the preterm gestation would be labeled as preterm labor with intact membranes. Whether at or before term, parturition culminates in a common pathway composed of cervical changes, persistent uterine contractions, and activation of the decidua and membranes. The fundamental difference is that labor at term is a normal physiologic activation of the common pathway, whereas preterm parturition is the result, entirely or in part, of pathologic processes that activate one or more of the components of the common pathway.

Although labor is of short duration (hours or days at the most), parturition is a longer process that includes a preparatory phase of the key tissues involved in the common pathway. **Thus cervical changes occur over weeks, myometrial contractility is increased before the onset of labor, and the appearance of fetal fibronectin (FFN) in the cervicovaginal mucus can be considered to reflect extracellular matrix (ECM) degradation, which indicates activation of the decidua and membranes.**

A fetal maturity–based signal for labor originates in the fetal hypothalamus and leads to increased secretion of corticotropin-releasing hormone (CRH), which in turn stimulates adrenocorticotrophic hormone (ACTH) and cortisol production by the fetal adrenals, which ultimately leads to activation of the common pathway of parturition. The fetus may contribute to the onset of preterm labor in the context of the **fetal inflammatory response syndrome** (see below).

**Spontaneous PTB may best be understood as a syndrome in which the clinical presentations of preterm labor, preterm ruptured membranes, and preterm cervical effacement and dilation without labor occur as the result of multiple etiologies that can occur alone or in combination.** Some act to initiate preterm parturition acutely—for example, with acute posttraumatic placental abruption—but most follow a more subacute or indolent path over several weeks. It is helpful to remember that the normal process of parturition proceeds for several weeks before clinically evident labor begins. Thus pathologic stimuli of parturition may act in concert with the normal physiologic preparation for labor, especially after 32 weeks' gestation. Before 30 to 32 weeks, a greater proportion of preterm labor has a pathologic stimulus.

### Cervical Changes: Softening and Ripening

**The cervix is a critical structure in pregnancy and parturition; it must maintain structural integrity and act as a physical barrier during pregnancy and subsequently transition to allow passage of the fetus during delivery.** This change is not acute; physiologic parturition occurs over the course of gestation and requires evolving biochemical and biomechanical changes in the cervix that manifest as cervical ripening.<sup>35,36</sup> Molecular processes that underlie cervical ripening are different between physiologic and pathologic parturition and may differ among etiologies of pathologic parturition.

**Although collagen is the main contributor to the tensile strength of the cervix, glycosaminoglycans (GAGs) are critical to determining the viscoelastic properties of the tissue.** GAGs are long, unbranched polysaccharides—vital components of the ECM—that serve many roles: they help to determine tissue hydration, which contributes to viscous tissue properties, and they stabilize the overall architecture of the ECM. In addition, small leucine-rich proteoglycans (GAGs linked to core proteins) such as decorin have been shown to interact with

soluble growth factors and mediators of inflammation. Tight junctions in the cervical epithelial cells provide structural support and regulate fluid fluxes.

Cervical epithelia have numerous functions that include proliferation, differentiation, maintenance of fluid balance, protection from environmental hazards, and paracellular transport of solutes via tight junctions. Epithelial functions must be carefully regulated during pregnancy and parturition, and molecules important in epithelial integrity and function are key components of cervical changes in animal models and in women at term. ECM turnover in the cervix is high, and thus the mechanical properties of the cervix can change rapidly. Changes in ECM during cervical ripening include **an influx of inflammatory cells—macrophages, neutrophils, mast cells, eosinophils, and so on—into the cervical stroma in a process similar to an inflammatory response. These cells produce cytokines and prostaglandins that affect ECM metabolism.** Prostaglandins effect cervical ripening physiologically and have been widely used as pharmacologic agents to ripen the cervix for induction of labor. Cervical ripening is influenced by estrogen, which induces ripening by stimulating collagen degradation, and by progesterone, which blocks these estrogenic effects. Furthermore, administration of a progesterone receptor antagonist can induce cervical ripening, and administration of progesterone has been reported to delay or even reverse ripening. Another mediator implicated in the mechanisms of cervical ripening is nitric oxide (NO), which can act as an inflammatory mediator.

Cervical changes normally precede the onset of labor, are gradual, and develop over several weeks. PTB is often preceded by cervical ripening over a period of weeks in the second and third trimesters, evidenced on clinical examination by softening and thinning of the cervix and on ultrasound examination of the cervix by cervical “funneling” and shortening of the length of the endocervical canal.

### Increased Uterine Contractility

Labor is characterized by a change in uterine contractility from episodic uncoordinated myometrial contractures that last several minutes and produce little increase in intrauterine pressure to more coordinated contractions of short duration that produce marked increases in intrauterine pressure that ultimately effect delivery. **The change from the contracture to the contraction pattern typically begins at night, which suggests neural control.** The transition from contractures to contractions may progress to normal labor or may occur dys-synchronously as the result of inflammation (e.g., with maternal infection or abdominal surgery). Fasting may also induce the switch in humans. Oxytocin is produced by the decidua and the paraventricular nuclei of the hypothalamus, indicating both an endocrine and a paracrine role. **Plasma concentrations of oxytocin mirror uterine contractility, which suggests oxytocin may mediate the circadian rhythm in uterine contractility.**

Cellular communication is another feature of labor, promulgated by formation of gap junctions that develop in the myometrium before labor and disappear after delivery. Gap-junction formation and the expression of the gap-junction protein connexin 43 in the human myometrium is similar in term and preterm labor. These findings suggest that **the appearance of gap junctions and increased expression of connexin 43 may be part of the underlying molecular and cellular events responsible for the switch from contractures to**

**contractions before the onset of parturition.** Estrogen, progesterone, and prostaglandins have been implicated in the regulation of gap-junction formation and in influencing the expression of connexin 43. Lye and colleagues have proposed that changes in a set of distinct proteins called *contraction-associated proteins* are characteristic of this stage of parturition.

### Decidual Membrane Activation

The maternal decidua and adjacent fetal membranes undergo anatomic and biochemical changes during the final weeks of gestation that ultimately result in a spontaneous rupture of the membranes. **Premature activation of this mechanism leads to PPROM, the clinical antecedent for up to 40% of all preterm deliveries.** Although rupture of the membranes normally occurs during the first stage of labor, histologic studies of prematurely ruptured membranes show decreased amounts of collagen types I, III, and V; increased expression of tenascin, expressed during tissue remodeling and wound healing; and disruption of the normal wavy collagen pattern, which suggests that preterm rupture is a process that precedes the onset of labor.

Structural ECM proteins such as collagens have been implicated in the tensile strength of the membranes, whereas the viscoelastic properties have been attributed to elastin. Dissolution of extracellular cements (e.g., fibronectins) is thought to be responsible for the process that allows the membranes to separate from the decidua after the birth of the infant. Degradation of the ECM, assessed by the detection of FFN, is part of the common pathway of parturition. The presence of FFN or pathogen-associated molecular patterns (PAMPs) in cervicovaginal secretions between 22 and 37 weeks' gestation is evidence of disruption of the decidual-chorionic interface and is associated with an increased risk of PTB.

The precise mechanism of membrane/decidua activation is uncertain, but matrix-degrading enzymes and apoptosis—programmed cell death—have been proposed. Increased levels of matrix metalloproteinases (MMPs) and their regulators (tissue inhibitors of metalloproteinases [TIMPs]) have been documented in the amniotic fluid of women with PPROM.

Apoptosis may also play a role in the mechanism of membrane rupture through increased expression of proapoptotic genes and decreased expression of antiapoptotic genes. MMP-9 may induce apoptosis in the amnion.

### Fetal Participation in the Onset of Labor

**A fetal signal contributes to the onset of labor in animals and humans.** Destruction of the paraventricular nucleus of the fetal hypothalamus results in prolongation of pregnancy in sheep. The human counterpart to this animal experiment is anencephaly, which is also characterized by prolonged pregnancy when women with polyhydramnios are excluded. The current paradigm is that **once maturity has been reached, the fetal brain—specifically the hypothalamus—increases CRH secretion that, in turn, stimulates ACTH and cortisol production by the fetal adrenals. This increase of cortisol in sheep and of dehydroepiandrosterone sulfate (DHEAS) in primates eventually leads to activation of the common pathway of parturition.**

### Preterm Parturition Syndrome

Obstetric taxonomy is largely based on clinical presentation, not the mechanism of disease. **Preterm labor may occur as the**

**common clinical presentation of infection, vascular insult, uterine overdistension, abnormal allogeneic recognition, stress, or other pathologic processes. Often more than one of these factors is operative in the same patient. Thus preterm labor is a syndrome for which no single diagnostic test or treatment exists.** Obstetric syndromes share the following features:

- Multiple etiologies
- Chronicity
- Fetal involvement
- Clinical manifestations that are adaptive
- Variable susceptibility due to gene-environment interactions

Each of these features is true of PTB. As listed earlier, preterm labor clearly has *multiple etiologies*. Pathways to preterm labor are demonstrated to be *chronic*, as seen in the time interval between observation of a short cervix or increased concentrations of FFN in vaginal fluid in the midtrimester of pregnancy and subsequent preterm labor or delivery. *Fetal involvement* has been demonstrated in women with microbial invasion of the amniotic cavity, in which fetal bacteremia and cytokine production have been detected in 30% of women with PPROM and an amniotic fluid culture positive for microorganisms. Similarly, neonates born after spontaneous preterm labor or PPROM are more likely to be small for gestational age, which suggests chronically compromised fetal supply. Preterm labor may be seen as an *adaptive* mechanism of host defense against infection that allows the mother to eliminate infected tissue and allows the fetus to exit a hostile environment. If the clinical manifestations are adaptive, it is not surprising that treatments aimed at the common terminal pathway of parturition, such as tocolysis or cerclage, and not at the fundamental mechanism of disease-inducing activation of the pathway—myometrial contractility, cervical dilation, and effacement—would not be effective. Increasing evidence suggests gene-environment interaction in the steps leading to preterm labor complicated by the presence, and even perhaps the conflicting interests, of two genomes: maternal and fetal. This is most evident in studies of the relationship between maternal genital tract colonization and PTB. Finally, additional mechanisms may be at play that have not yet been identified.

**Pathologic processes implicated in the preterm parturition syndrome include intrauterine inflammation/infection, vascular disorders, uterine overdistension, breakdown of maternal-fetal tolerance, allergy-induced causes, cervical insufficiency, and endocrine disorders.**

### Intrauterine Infection

Systemic maternal infections such as pyelonephritis and pneumonia are frequently associated with the onset of premature labor in humans. **Intrauterine infection is a frequent and important mechanism of disease leading to preterm delivery.** Intrauterine infection or systemic administration of microbial products to pregnant animals can result in preterm labor and delivery, and substantial evidence shows that subclinical intrauterine infections are associated with preterm labor and delivery. Moreover, fetal infection and inflammation have been implicated in the genesis of fetal or neonatal injury leading to cerebral palsy and chronic lung disease. **Microbiologic and histopathologic studies suggest that infection-related inflammation may account for 25% to 40% of cases of preterm delivery.**

### Frequency of Intrauterine Infection in Spontaneous Preterm Birth

The prevalence of amniotic fluid cultures positive for microorganisms in women with preterm labor and intact membranes is approximately 13%, with additional instances of infection that are identifiable using polymerase chain reaction (PCR) techniques rather than culture. The earlier the gestational age at PTB, the more likely that microbial invasion of the amniotic cavity is present. **In PPROM, the prevalence of positive amniotic fluid cultures for microorganisms is approximately 32%.** Among women with a dilated cervix in the midtrimester, the prevalence of positive amniotic fluid cultures is 51%. Microbial invasion of the amniotic cavity occurs in 12% of twin gestations with preterm labor and when delivering a preterm neonate. The most common microorganisms found in the amniotic cavity are *Mycoplasma* and *U. urealyticum*.

### Intrauterine Infection as a Chronic Process

Evidence in support of chronicity of intrauterine inflammation/infection is derived from studies of the microbiologic state of the amniotic fluid, as well as the concentration of inflammatory mediators, at the time of genetic amniocentesis. Genital mycoplasmas that include *M. hominis* and also *U. urealyticum* have been recovered from amniotic fluid samples obtained at second-trimester genetic amniocentesis, with subsequent preterm delivery and histologic chorioamnionitis, especially in those with *U. urealyticum*. **Increased levels of many inflammatory markers have been found in second-trimester amniotic fluid samples obtained from women who subsequently delivered preterm.** These observations suggest that infection and inflammation in the amniotic cavity in the midtrimester of pregnancy can lead to preterm delivery weeks later. The most advanced stage of intrauterine infection is fetal infection. Fetal bacteremia has been detected in blood obtained by cordocentesis in 33% of fetuses with positive amniotic fluid culture and in 4% of those with negative amniotic fluid culture.

Molecular mediators that trigger parturition (cytokines and other inflammatory mediators) are similar to those that protect the host against infection. **The onset of preterm labor in response to intrauterine infection is thus very likely a host defense mechanism with survival value for the mother and, after viability, for the fetus.**

### Infection, Preterm Labor, and Neonatal Outcomes

The scenario postulated from the preceding evidence is that **microorganisms that reside in or ascend to reach the decidua may, depending on host defense and environmental influences, stimulate a local inflammatory reaction and the production of proinflammatory cytokines, chemokines, and inflammatory mediators.** This inflammatory process, which is initially extraamniotic, may produce cervical effacement, further inflammation of the choriodecidual interface, and uterine contractions, and it may progress to the amniotic fluid and ultimately to the fetus. Microorganisms are known to cross intact membranes into the amniotic cavity, where inflammatory mediators are produced by resident macrophages and other host cells within the amniotic cavity. Finally, microorganisms that gain access to the fetus may elicit a systemic inflammatory response, the fetal inflammatory response syndrome (FIRS), characterized by increased concentrations of interleukin-6 (IL-6) and other cytokines as well as cellular evidence of neutrophil and monocyte activation.

**FIRS is a subclinical condition originally described in fetuses of mothers with preterm labor and intact membranes and PPROM.** Fetuses with FIRS have a higher rate of neonatal complications and are frequently born to mothers with subclinical microbial invasion of the amniotic cavity. Evidence of multisystemic involvement in cases of FIRS includes increased concentrations of fetal plasma MMP-9, neutrophilia, a higher number of circulating nucleated red blood cells, and higher plasma concentrations of granulocyte-colony stimulating factor (G-CSF). The histologic hallmark of FIRS is inflammation in the umbilical cord (funisitis) or chorionic vasculitis. The systemic fetal inflammatory response may result in multiple organ dysfunction, septic shock, and death in the absence of timely delivery. Newborns with funisitis are at increased risk for neonatal sepsis and long-term handicaps that include BPD and cerebral palsy.

When the inflammatory process does not involve the chorioamniotic membranes and decidua, systemic fetal inflammation and injury may occur in the absence of labor with eventual delivery at term. An example of this is fetal alloimmunization (see [Chapter 34](#)), in which fetal plasma concentrations of IL-6 are elevated, but preterm labor does not occur.

### Gene-Environment Interactions

Gene-environment interactions underlie many complex disorders such as atherosclerosis and cancer. **A gene-environment interaction is said to be present when the risk of a disease (occurrence or severity) among individuals exposed to both genotype and an environmental factor is greater or less than that predicted from the presence of either the genotype or the environmental exposure alone.** The inflammatory response to the presence of microorganisms is modulated by interactions between the host genotype and environment that determine the likelihood and course of some infectious diseases. An example of such an interaction has been reported for BV, an allele for tumor necrosis factor alpha (TNF- $\alpha$ ) and preterm delivery. Maternal BV is a consistently reported risk factor for spontaneous preterm delivery, yet treatment of BV does not reliably prevent PTB in women with BV. One potential explanation has come from a study of PTB rates in women according to their carriage of BV and whether or not they had allele 2 of TNF- $\alpha$ , known to be associated with sPTB. Both BV (odds ratio [OR], 3.3; 95% CI, 1.8 to 5.9) and TNF- $\alpha$  allele 2 (OR, 2.7; 95% CI, 1.7 to 4.5) were associated with increased risk for preterm delivery, but the risk of sPTB was substantially increased (OR, 6; 95% CI, 1.9 to 21.0) in women with both BV and the TNF- $\alpha$  allele 2. It is reasonable to assume that other gene-environment interactions may contribute to PTB.

### Uteroplacental Ischemia and Decidual Hemorrhage

**After inflammation, the most common abnormalities seen in placental pathology specimens from sPTBs are vascular lesions of the maternal and fetal circulations.** Maternal lesions include failure of physiologic transformation of the spiral arteries, atherosclerosis, and thrombosis. Fetal abnormalities include a decreased number of villous arterioles and fetal arterial thrombosis.

One proposed mechanism linking vascular lesions and preterm labor/delivery is **uteroplacental ischemia**, evidenced in primate models and in studies that found failure of physiologic transformation in the myometrial segment of the spiral

arteries—a phenomenon typical of preeclampsia and intrauterine growth restriction (IUGR)—in women with preterm labor and intact membranes and PPRM. Abnormal uterine artery Doppler velocimetry indicative of increased impedance to flow in the uterine circulation has been reported in women with apparently idiopathic preterm labor.

The mechanisms responsible for preterm parturition in cases of ischemia have not been determined, but uterine ischemia has been postulated to lead to increased production of uterine renin from the fetal membranes. Angiotensin II can induce myometrial contractility directly or through the release of prostaglandins.

**Decidual necrosis and hemorrhage can activate parturition through production of thrombin, which stimulates myometrial contractility in a dose-dependent manner.** Thrombin also stimulates production of MMP-1, urokinase-type plasminogen activator (uPA), and tissue-type plasminogen activator (tPA) by endometrial stromal cells in culture. Directly or indirectly, these factors can digest important components of the ECM in the chorioamniotic membranes. Thrombin/antithrombin complexes, a marker of in vivo generation of thrombin, are increased in plasma and amniotic fluid of women with preterm labor and PPRM. The decidua is a rich source of tissue factor, the primary initiator of coagulation and of thrombin activation. These observations are consistent with clinical associations among vaginal bleeding, retroplacental hematomas, and preterm delivery.

**Uterine ischemia should not be equated with fetal hypoxemia. Studies of fetal cord blood do not support fetal hypoxemia as a cause or consequence of preterm parturition.**

### Uterine Overdistension

**The mechanisms responsible for the increased frequency of PTB in multiple gestations and other disorders associated with uterine overdistension are unknown.** Central questions are how the uterus senses stretch, and how these mechanical forces induce biochemical changes that lead to parturition. Increased expression of oxytocin receptor, connexin 43, and the *c-fos* messenger RNA (mRNA) have been consistently demonstrated in the rat myometrium near term. Progesterone blocks stretch-induced gene expression in the myometrium. Mitogen-activated protein kinases have been proposed to mediate stretch-induced *c-fos* mRNA expression in myometrial cells. Stretch can have effects on the membranes; for example, in vitro studies have demonstrated an increase in the production of collagenase, interleukin 8 (IL-8), and prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) as well as the cytokine pre-B-cell colony-enhancing factor. These observations provide a possible link between the mechanical forces that operate in an overdistended uterus and in the rupture of membranes.

### Breakdown of Fetal-Maternal Tolerance

The fetoplacental unit is the most successful transplant. This is made possible by the development of a tolerogenic state, a state of immune tolerance during normal pregnancy that requires participation of the maternal and fetal immune systems as well as active suppression at the maternal-fetal interface. Recent evidence suggests that maternal antifetal rejection is a common mechanism of disease in premature labor. Chronic chorioamnionitis, a lesion in which maternal lymphocytes infiltrate the chorioamniotic membranes, is the most common pathologic finding in sPTB. Maternal lymphocytes can induce destruction of the

trophoblast in the chorion and can thus induce preterm labor. This lesion, as well as chronic villitis, is considered to represent evidence of maternal antifetal rejection.<sup>37,38</sup>

### Allergy-Induced Preterm Labor

Case reports indicate that preterm labor has occurred after exposure to an allergen that generates an allergic-like mechanism (type I hypersensitivity reaction) and that some women with preterm labor have eosinophils as the predominant cells in amniotic fluid, suggesting a **form of uterine allergy**. Mast cells in the uterus produce histamine and prostaglandins, both of which can induce myometrial contractility. Premature birth can be induced by exposure to an allergen in sensitized animals, and it can be prevented by treatment with a histamine H<sub>1</sub> receptor antagonist.

### Cervical Insufficiency

**Prompted by knowledge of the relationship between a sonographic short cervix with and a subsequent PTB, the understanding of cervical function evolved from a categorical concept of cervical incompetence versus competence to one of “competence as a continuum.”**<sup>13</sup> However, subsequent analyses of these same data<sup>12</sup> were conducted in response to clinical trials that demonstrated that preterm cervical shortening (softening and ripening) is not the passive result of tissue weakness but instead is an active process that can be slowed or prevented by progesterone supplementation in some women.<sup>15-19</sup> These studies have led to the conclusion that a short cervix in the second trimester of pregnancy is evidence that parturition has begun, presumably triggered by decidual membrane activation in response to microbial colonization and/or decidual hemorrhage, perhaps aided by cervical factors and/or subclinical myometrial activity. Figure 29-9 shows the length of the cervix at 22 to 24 weeks' gestation and the subsequent rate of cervical

**FIG 29-9** Length of the cervix at 22 to 24 weeks' gestation and the subsequent rate of cervical shortening in women who present after 28 weeks with preterm labor (PTL) or preterm premature rupture of membranes (PPROM) compared with women who delivered at term or preterm for medical indications.

shortening in women who later presented after 28 weeks' gestation with preterm labor or PPRM compared with women who delivered at term or preterm because of a medical indication. Significant differences in CL were already evident at 22 to 24 weeks, more than a month before clinical presentation, and accelerated for several weeks before clinical presentation.

### Endocrine Disorders

Estrogen and progesterone play a central role in the endocrinology of pregnancy. **Progesterone is thought to maintain myometrial quiescence and inhibit cervical ripening. Estrogens have been implicated in increasing myometrial contractility and excitability as well as in the induction of cervical ripening before the onset of labor.** In many species, a fall in maternal serum progesterone concentration occurs before spontaneous parturition, but the mechanism for this progesterone withdrawal depends primarily on whether the placenta or the corpus luteum is the major source of progesterone.

A decrease in serum progesterone levels has not been demonstrated before parturition in humans. Nevertheless, inhibition of progesterone action could result in parturition. Alternative mechanisms posited to explain a suspension of progesterone action without a serum progesterone withdrawal include binding of progesterone to a high-affinity protein and thus a reduction in the functional active form; increased cortisol concentration that competes with progesterone for binding to the glucocorticoid receptors, resulting in functional progesterone withdrawal; and conversion of progesterone to an inactive form within the target cell before interaction with its receptor. None of these hypotheses are proven. Recent research has focused on alterations in the number and function of estrogen-progesterone receptors and progesterone binding.

The human progesterone receptor (PR) exists as two major subtypes, PR-A and PR-B. Another isoform, PR-C, has recently been described, but its function is not well understood. The human estrogen receptor (ER) also exists as two major subtypes, ER $\alpha$  and ER $\beta$ . A functional progesterone withdrawal has been proposed in which expression of PR-A in the myometrium suppresses progesterone responsiveness and that functional progesterone withdrawal occurs by increased expression of PR-A relative to PR-B. An alternative mechanism of functional progesterone withdrawal has been proposed wherein activation of nuclear factor kappa B (NF $\kappa$ B) in the amnion represses progesterone function. Regardless of the mechanism, consensus is building for the idea that a localized functional progesterone withdrawal occurs in the myometrium during human parturition.

### Summary of the Preterm Parturition Syndrome

Preterm parturition is a syndrome caused by multiple etiologies with several clinical presentations, including uterine contractility (preterm labor), preterm cervical ripening without significant clinical contractility (cervical insufficiency or advanced cervical dilation and effacement), or rupture of the amniotic sac (PPROM). The clinical presentation varies with the type and timing of the insult or stimulus to the components of the common pathway of parturition, the presence or absence of environmental cofactors, and individual variations of the host response by both mother and fetus. This conceptual framework has implications for the understanding of the mechanisms responsible for the initiation of preterm parturition as well as the diagnosis, treatment, and prevention of PTB.

## CLINICAL CARE FOR WOMEN IN PRETERM LABOR

**Clinical evaluation of preterm parturition begins with assessment of potential causes of labor, looking first for conditions that threaten the health of the mother and fetus.** Acute maternal conditions—for example, pyelonephritis, pneumonia, asthma, peritonitis, trauma, and hypertension—or obstetric conditions that include preeclampsia, placental abruption, placenta previa, and chorioamnionitis, may mandate delivery. **Fetal compromise** may be acute, manifested by an abnormal fetal heart rate tracing, or it may be chronic, indicated by fetal growth restriction (FGR) or oligohydramnios; it may require delivery depending on the severity and potential for in utero versus ex utero treatment. **Fetal growth restriction** is more common in infants delivered after preterm labor or PPRM, even in apparently otherwise uncomplicated pregnancies. **Conditions that suggest specific therapy, such as preterm ruptured membranes or cervical insufficiency, should then be sought and treated accordingly.**

**The next concerns are the accuracy of preterm labor diagnosis and the balance of risks and benefits that accompany active attempts to inhibit labor versus allowing delivery (Box 29-3).**

## DIAGNOSIS OF PRETERM LABOR

Given the pathways for preterm parturition described earlier, clinical recognition of preterm labor requires attention to the biochemical, as well as the biophysical, features of the onset of labor. Pathologic uterine contractility rarely occurs in isolation; cervical ripening and decidual membrane activation are almost always in progress as well, most often before uterine contractions are clinically evident. **Therefore preterm labor must be considered whenever a pregnant woman reports recurrent abdominal or pelvic symptoms that persist for several hours in the second half of pregnancy.** Symptoms of preterm labor such as pelvic pressure, increased vaginal discharge, backache, and menstrual-like cramps occur frequently in normal pregnancy and suggest preterm labor more by persistence than by severity. **Contractions may be painful or painless, depending**

### BOX 29-3 DIAGNOSIS OF PRETERM LABOR AND INITIAL ASSESSMENT

- What is the gestational age, and what is the level of confidence about the accuracy of the gestational age?
- In the absence of advanced labor (cervical effacement >80% with dilation >2 cm) and a clear cause of preterm labor, what is the accuracy of the diagnosis of preterm labor?
- Are confirmatory diagnostic tests such as cervical sonography, fetal fibronectin, or amniocentesis for infection necessary?
- What is the anticipated neonatal morbidity and mortality at this gestational age in this clinical setting?
- Should labor be stopped?
- Is transfer to a more appropriate hospital required?
- Should fetal lung maturity be tested?
- What interventions can be applied that will reduce the risks of perinatal morbidity and mortality?
- Should drugs to arrest labor (tocolytics), glucocorticoids, or antibiotics be given?

**on the resistance offered by the cervix.** Contractions against a closed, uneffaced cervix are likely to be painful, but persistence of recurrent pressure or tightening may be the only symptoms when cervical effacement precedes the onset of contractions.

For decades, the clinical diagnosis of preterm labor has been based on the presence of regular, painful uterine contractions accompanied by cervical dilation and/or effacement. These criteria assume a crisp demarcation between preterm *parturition* and preterm *labor* that is increasingly understood as being more gradual than previously thought. If considered a screening criteria for the outcome “preterm birth,” clinical signs and symptoms demonstrate poor sensitivity and specificity. Identifying women with preterm contractions who will actually deliver preterm is an inexact process. In like fashion, identifying those women who are at increased risk of not just PTB, but imminent PTB, remains elusive. A systematic review noted that approximately 30% of preterm labor cases resolved spontaneously. In subsequent studies, 50% of patients hospitalized for preterm labor actually delivered at term.

The inability to accurately distinguish women with an episode of preterm labor who will deliver preterm from those who deliver at term has greatly hampered the assessment of therapeutic interventions because as many as 50% of untreated (or placebo-treated) subjects do not actually deliver preterm. Optimal criteria for initiation of treatment are unclear. A contraction frequency of six or more per hour, cervical dilation of 3 cm, effacement of 80%, ruptured membranes, and bleeding are symptoms of preterm labor most often associated with preterm delivery. When lower thresholds for contraction frequency and cervical change are used, a *false-positive* diagnosis—defined in randomized controlled trials (RCTs) as delivery at term after treatment with placebo only—occurs in nearly 40% of women, but sensitivity does not rise. Difficulty in accurate diagnosis is the product of the high prevalence of the symptoms and signs of early preterm labor in normal pregnancy, the gradual onset of preterm labor discussed earlier, and the imprecision of digital examination of the cervix below 3 cm dilation and 80% effacement. The practice of initiating tocolytic drugs for contraction frequency without additional diagnostic criteria results in unnecessary treatment of women who are not at increased risk of imminent sPTB.<sup>39</sup>

### Diagnostic Tests for Preterm Labor

Symptomatic women whose cervical dilation is less than 2 cm and whose effacement is less than 80% present a diagnostic challenge. Diagnostic accuracy may be improved in these patients by testing other features of parturition such as cervical ripening; measurement of CL by transvaginal ultrasound; and decidual activation, tested by an assay for FFN in cervicovaginal fluid.<sup>40,41</sup> Both tests aid diagnosis primarily by reducing false-positive results. Transabdominal ultrasound (TAU) has poor reproducibility for cervical measurement and should not be used clinically without confirmation by a transvaginal ultrasound (TVU). If the examination is properly performed, a CL of 30 mm or more by endovaginal sonography indicates that preterm labor is unlikely in symptomatic women.

Similarly, a negative FFN test in women with symptoms before 34 weeks' gestation with cervical dilation less than 3 cm can also reduce the rate of false-positive diagnosis if the result is returned promptly and the clinician is willing to act on a negative test result by not initiating treatment. When both tests were performed in a study of 206 women with possible preterm labor,

### BOX 29-4 CLINICAL EVALUATION OF PATIENTS WITH POSSIBLE PRETERM LABOR

1. Patient presents with signs/symptoms of preterm labor
  - Persistent contractions, painful or painless
  - Intermittent abdominal cramping, pelvic pressure, or backache
  - Increase or change in vaginal discharge
  - Vaginal spotting or bleeding
2. General physical examination
  - Sitting pulse and blood pressure
  - Temperature
  - External fetal heart rate and contraction monitor
3. Sterile speculum examination
  - pH
  - Fern
  - Pooled fluid
  - Fibronectin swab (posterior fornix or external cervical os, avoiding areas with bleeding)
  - Cultures for *Chlamydia* (cervix), *Neisseria gonorrhoeae* (cervix), and group B *Streptococcus* (outer third of vagina and perineum)
4. Transabdominal ultrasound examination
  - Placental location
  - Amniotic fluid volume
  - Estimated fetal weight and presentation
  - Fetal well-being
5. Cervical examination (after ruptured membranes are excluded)
  - a. Cervix >3 cm dilation, ≥80% effaced
    - Preterm labor diagnosis confirmed. Evaluate for tocolysis.
  - b. Cervix 2 to 3 cm dilation, <80% effaced
    - Preterm labor likely but not established. Monitor contraction frequency and repeat digital examination in 30 to 60 minutes. Diagnose preterm labor if cervix changes. If not, send fibronectin or obtain transvaginal cervical ultrasound. Evaluate for tocolysis if any cervical change occurs, cervical length is <20 mm, or fibronectin is positive.
  - c. Cervix <2 cm dilation and <80% effaced
    - Preterm labor diagnosis uncertain. Monitor contraction frequency, send fibronectin and/or obtain cervical sonography, and repeat digital examination in 1 to 2 hours. Evaluate for tocolysis if change in cervical dilation is 1 cm, effacement is >80%, cervical length is <20 mm, or fibronectin is positive.
6. Use of cervical ultrasound
  - Cervical length <20 mm and contraction criteria met: preterm labor
  - Cervical length 20 to 30 mm and contraction criteria met: probable preterm labor
  - Cervical length >30 mm: preterm labor very unlikely regardless of contraction frequency

the FFN test improved the performance of sonographic CL only when the sonographic CL was less than 30 mm (Box 29-4).

### Amniocentesis for Women With Preterm Labor

The goal of care for women with preterm labor is to reduce perinatal morbidity and mortality, most of which is caused by immaturity of the respiratory, gastrointestinal, coagulation, and central nervous systems of the preterm infant. Fetal pulmonary immaturity is the most frequent cause of serious newborn illness,

and the fetal pulmonary system is the only organ system whose function is directly testable before delivery. If the quality of obstetric dating is good and intrauterine fetal well-being is not compromised, the likelihood of neonatal RDS may be estimated from the gestational age.

Amniotic fluid studies may be useful in women with possible preterm labor in the following circumstances:

1. **Fetal pulmonary maturity testing.** Gestational age at birth is the best predictor of the frequency and severity of the consequences of prematurity to the newborn. Labor inhibition and antenatal glucocorticoid therapy are used when birth is anticipated to occur between 24 and 34 weeks' gestation. When dates are uncertain—such as with late prenatal care or fetal size larger than expected for dates, suggestive of a more advanced gestation—it may be reasonable in some circumstances to use amniotic fluid lung maturity studies to help guide management decisions.
2. **Testing for infection.** Among women with preterm labor and intact membranes, early gestational age, a short cervix, and progressive labor despite a tocolytic are all risk factors for occult amniotic fluid infection. In this setting, amniotic fluid studies for infection may guide the counseling of women and can influence management decisions in regard to antibiotics, inhibition of labor, and delivery. Amniotic fluid glucose (levels <20 mg/dL suggest intraamniotic infection) and Gram stain for bacteria, cell count, and culture may be used.
3. **Determining fetal karyotype.** The presence of polyhydramnios or a fetal anomaly suggests that preterm labor may have occurred because of uterine distension or placental insufficiency associated with fetal aneuploidy. Fluorescence in situ hybridization (FISH) studies for the most common aneuploid conditions can be available within 48 hours and do not require culture; chromosomal microarrays likewise do not require cell culture (see [Chapter 10](#)). In the absence of other fetal features suggestive of aneuploidy, the presence of preterm labor alone is an insufficient indication for the determination of a fetal karyotype.

## TREATMENT FOR WOMEN IN PRETERM LABOR

Successful treatment with tocolytic drugs to inhibit labor after contractions have begun and cervical change has been documented is well established. However, treatment after membranes have ruptured does not prolong pregnancy sufficiently to allow further intrauterine growth and maturation, but therapy can often delay PTB long enough to permit **four interventions that have been shown to reduce neonatal morbidity and mortality**:

1. Antenatal transfer of the mother and fetus to the most appropriate hospital
2. Antibiotics in labor to prevent neonatal infection with group B *Streptococcus* (GBS)
3. Antenatal administration of glucocorticoids to the mother to reduce neonatal morbidity and mortality due to RDS, IVH, and other causes
4. Administration of maternal magnesium sulfate at the time of PTB before 32 weeks to reduce the incidence of cerebral palsy

## Maternal Transfer

Many states have adopted systems of regionalized perinatal care in recognition of the advantages of concentrating care

**for preterm infants, especially those born before 32 weeks.** Hospitals and birth centers that care for normal mothers and infants are designated as **level I**. Larger hospitals that care for the majority of maternal and infant complications are designated as **level II** centers; these hospitals have NICUs staffed and equipped to care for most infants with birthweights greater than 1500 g. **Level III** centers typically provide care for the sickest and smallest infants and for maternal complications that require intensive care. This three-tiered approach has been associated with improved outcomes for preterm infants.

## Antibiotics

**Women with preterm labor should be treated with antibiotics to prevent neonatal GBS infection** (see [Chapters 53](#) and [54](#)). Because preterm infants have a greater risk of neonatal GBS infection than those born at term, intrapartum prophylaxis with penicillin is recommended.<sup>42</sup> This policy has successfully reduced the incidence of neonatal GBS infection to such a degree that most such infections now occur in full-term infants. Evidence also shows that infants born to women with PPRM have reduced perinatal morbidity when antepartum antibiotic prophylaxis has been administered for 3 to 7 days.

**Antibiotic therapy in women with preterm labor and intact membranes is not effective in prolonging pregnancy or preventing preterm delivery.** The failure of antibiotics to prolong pregnancy may be attributed to treatment of women whose preterm labor did not result from infection and to the timing of treatment relative to the infectious process. Rather than an acute infection due to the recent ascent of vaginal organisms into the uterus, the pathologic sequence in which infection-driven preterm labor occurs is often much more indolent. **Antimicrobial therapy for women in preterm labor should be limited to GBS prophylaxis, women with PPRM, or treatment of a specific pathogen** (e.g., urinary tract infection).

## Antenatal Corticosteroids

**Glucocorticoids act generally in the developing fetus to promote maturation over growth. In the lung, corticosteroids promote surfactant synthesis, increase lung compliance, reduce vascular permeability, and generate an enhanced response to postnatal surfactant treatment.** Glucocorticoids have similar maturational effects on other organs including the brain, kidneys, and gut.

Studies by Liggins of mechanisms of parturition in sheep led to the discovery of the beneficial effect of antenatal glucocorticoids on the maturation and performance of the lung in prematurely born infants. Subsequent studies have shown conclusively that antepartum administration of the glucocorticoids betamethasone or dexamethasone to the mother reduces the risk of death, RDS, IVH, NEC, and PDA in the preterm neonate. Guidelines for appropriate clinical use of antenatal glucocorticoids have evolved from initial skepticism and selective use, through a period of broad and repeated treatment following the first NICHD panel report in 1994, to the practice of a single course of treatment for all women between 24 and 34 weeks' gestation who are at risk for preterm delivery within 7 days as recommended by the NICHD Consensus Panel in 2000. More recently, clinical trials support the notion that administration of a single rescue course of corticosteroids before 33 weeks' gestation improves neonatal outcome (e.g., it decreases RDS, ventilator support, and surfactant use) without apparent increased short-term risk.<sup>43</sup> **A single rescue course of antenatal**

corticosteroids may be considered if the antecedent treatment was given more than 2 weeks prior, the gestational age is less than 32<sup>6/7</sup> weeks, and the woman is judged by the clinician to be likely to give birth within the coming week. However, regularly scheduled repeat courses or multiple courses (i.e., more than two) are not recommended.<sup>44</sup> Betamethasone and dexamethasone, the only drugs found beneficial for this purpose, are potent glucocorticoids with limited if any mineralocorticoid effect. **A course of treatment consists of two doses of 12 mg of betamethasone; the combination of 6 mg each of betamethasone acetate and betamethasone phosphate, administered intramuscularly twice, 24 hours apart; or four doses of 6 mg of dexamethasone given intramuscularly every 12 hours.** Other corticosteroids (prednisolone, prednisone) and routes of administration (oral) are not suitable alternatives because of reduced placental transfer, lack of demonstrated benefit, and, in the case of oral dexamethasone, increased risk of adverse effects when compared with the intramuscular (IM) route.

### Fetal Effects

Randomized placebo-controlled trials and meta-analyses confirm the beneficial effects of antenatal corticosteroids. **Infants born to treated women were significantly less likely to experience RDS (OR, 0.53), IVH (OR, 0.38), or neonatal death (OR, 0.60). The beneficial effects on IVH are independent of the effects on respiratory function. Other morbidities of PTB are also reduced by antenatal glucocorticoids, including NEC, PDA, and BPD. Although both are considered effective, betamethasone may be superior to dexamethasone with respect to reduction of morbidity and mortality in the preterm newborn.**

### Other Fetal Effects of Glucocorticoids

**Transient reduction in fetal breathing and body movements sufficient to affect the interpretation of the biophysical profile (BPP) have been described with both drugs but are more common after administration of betamethasone, typically lasting 48 to 72 hours after the second dose.** Transient suppression of neonatal cortisol levels has been reported, but neonatal response to ACTH stimulation was unimpaired.

### Maternal Effects

**Antenatal glucocorticoids produce a transient rise in maternal platelet and white blood cell (WBC) counts that lasts 72 hours; a WBC count in excess of 20,000 is rarely due to steroids.** Maternal glucose tolerance is also challenged, and treatment often requires insulin therapy to maintain euglycemia in those with previously well-controlled gestational or pregestational diabetes. Maternal blood pressure is unaffected by antenatal steroid treatment; neither betamethasone nor dexamethasone has a significant mineralocorticoid effect. Women treated with multiple courses of steroids during pregnancy had a blunted response to ACTH stimulation later in pregnancy and in the puerperium.

### Duration of Benefit

The duration of the beneficial fetal effects after a single course of glucocorticoids is unclear. The issue is difficult to study because the interval between treatment and delivery in clinical trials is variable and because some effects may be transient, whereas others are permanent. **Neonatal benefit has been most**

**easily observed when the interval between the first dose and delivery exceeds 48 hours, but some benefit is evident after an incomplete course.** One large multicenter trial found evidence of benefit for as long as 18 days after the initial course of treatment.

### Risks of Antenatal Corticosteroid Treatment

The recommendation of the 1994 NICHD Consensus Conference to increase the use of antenatal steroids, coupled with uncertainty about the duration of neonatal protection from a single course of treatment and difficulty in predicting imminent preterm delivery, resulted in increased treatment of mothers at risk. Although more women received treatment, many did not deliver within 7 days but remained at risk and were treated weekly until delivery or 34 weeks' gestation. **The safety and benefit of one course of steroids has never been questioned. Long-term follow-up studies of infants in the original cohorts of infants treated with a single course of antenatal steroids have displayed no differences in physical characteristics or mental function when compared with gestational age-matched controls.** The increasing use of repeated courses prompted animal and human studies that have raised concerns about the effects of prolonged exposure to steroids on fetal growth and neurologic function. The animal studies may be summarized as showing reduced fetal growth and adverse brain and neurologic development in several species.

Human studies also observed reduced growth in fetuses exposed to multiple courses of antenatal steroids. An Australian study found a twofold increase in birthweights below the 10th percentile and significantly reduced head circumference in infants exposed to more than three antenatal courses of steroids. Others have also found reduced head circumference. Follow-up work from this Australian study noted that babies exposed to weekly doses of repeat antenatal corticosteroids demonstrate postnatal growth acceleration 3 to 5 weeks after birth.<sup>45</sup>

### Sequelae of Antenatal Treatments to Reduce Fetal/Neonatal Morbidity

#### Respiratory Distress

The occurrence of RDS among infants born to women treated with steroid therapy has led to the investigation of alternative treatment approaches to further enhance pulmonary maturation. **Neonatal treatment with surfactant is an effective adjunctive therapy that adds independently and synergistically to the benefit of corticosteroids in reducing RDS-related morbidity.** More than 4600 women have been enrolled in 13 trials of maternal treatment with antenatal thyrotropin-releasing hormone (TRH) to reduce neonatal lung disease. No benefits to antenatal TRH have been found, compared with corticosteroids alone, for any neonatal outcome. Prenatal treatment with TRH actually increased the risk of adverse outcomes for infants in some trials.

#### Neurologic Morbidity

Antenatal maternal treatment with phenobarbital, vitamin K, and magnesium sulfate has been studied to reduce or prevent neonatal neurologic morbidity. Phenobarbital was not effective in reducing IVH when given alone or in combination with vitamin K.

Antenatal maternal treatment with magnesium has been inconsistently associated with reduced rates of IVH, cerebral palsy, and perinatal mortality in premature infants. **A**

**randomized placebo-controlled trial of antenatal magnesium conducted in 1062 women who delivered before 30 weeks' gestation found significantly lower rates of gross motor dysfunction and nonsignificant trends of reduced mortality and cerebral palsy in surviving infants in the treated group at 2 years of age.** No significant adverse effects were noted in infants exposed to antenatal magnesium sulfate. In the 1990s, observational studies suggested an association between prenatal exposure to magnesium sulfate and less frequent subsequent neurologic morbidities. Subsequently, several large clinical studies have evaluated the evidence regarding magnesium sulfate, neuroprotection, and PTBs.<sup>46-49</sup> If tocolysis is indicated, the most effective agent with the most favorable side-effect profile should be given. None of the trials demonstrated significant pregnancy prolongation when magnesium sulfate was given for neuroprotection. **However, the available evidence suggests that magnesium sulfate given before anticipated early PTB reduces the risk of cerebral palsy in surviving infants.**<sup>50</sup>

The impact of gestational age on the neuroprotective effect of antenatally administered magnesium was assessed in a meta-analysis that included the five trials in the Cochrane review.<sup>51</sup> These trials were stratified by the gestational age at randomization: less than 32 to 34 weeks' gestation (5235 fetuses) or less than 30 weeks' gestation (3107 fetuses). Major findings were similar for both gestational age ranges<sup>51</sup>:

- No significant difference was found in the primary outcome of death or cerebral palsy at 18 to 24 months of corrected age or for the outcome of perinatal/infant death.
- The largest reduction in risk was for moderate to severe cerebral palsy.
- At less than 32 to 34 weeks' gestation, relative risk was 0.60 (95% CI, 0.43 to 0.84).
- At less than 30 weeks' gestation, relative risk was 0.54 (95% CI, 0.36 to 0.80).
- Statistically significant reductions were found in the risk of cerebral palsy (RR, 0.7 and 0.69 at less than 32 to 34 weeks' gestation and at less than 30 weeks' gestation, respectively) and for death or moderate to severe cerebral palsy (RR, 0.85 and 0.84 at less than 32 to 34 weeks' gestation and at less than 30 weeks' gestation, respectively).
- The numbers needed to treat to prevent one case of cerebral palsy in the less than 32 to 34 weeks' gestation group and in the less than 30 weeks' gestation group were 56 and 46, respectively.

**A 4-g bolus of magnesium sulfate with a 1-g/hr maintenance dose is a regimen anticipated to have a more favorable side effect and safety profile than a higher-dose regimen.** Neither the neuroprotective mechanism nor the dose response to magnesium sulfate is well understood. Although it seems likely that the neuroprotective effects of magnesium sulfate are secondary to residual concentrations of the drug in the neonate's circulation, data are insufficient regarding the maternal dose that confers neonatal benefit.

**Administration of magnesium sulfate is appropriate for women with PPROM or preterm labor who have a high likelihood of imminent delivery (e.g., within 24 hours) or before an indicated preterm delivery. If emergency delivery is necessary given maternal or fetal status, it should not be delayed to administer magnesium sulfate.** Therapy should be reserved for women who are at high risk of imminent delivery rather than for those who simply are diagnosed with preterm labor or PPROM. We do not recommend continuing the

magnesium infusion for longer than 24 hours if delivery has not occurred.

### TREATMENT PROTOCOL

We suggest limiting magnesium sulfate for neuroprotection to women who are at 24 to 32 weeks' gestation, given that the two largest trials of neuroprotective effects did not enroll women beyond this gestational age range.<sup>49,52</sup>

Magnesium sulfate must be given parenterally to achieve serum levels greater than the normal range. Therapeutic dosage regimens are similar to those used for intravenous (IV) seizure prophylaxis of preeclampsia. A loading dose of 4 g is given over 30 minutes, followed by an infusion of 1 g/hr.

If renal function is normal, magnesium is excreted rapidly in the urine. In patients with evidence of renal impairment—for example, oliguria or serum creatinine levels greater than 0.9 mg/dL—magnesium should be administered cautiously and should be followed with frequent vital signs, deep tendon reflexes, and magnesium serum levels, and doses should be adjusted accordingly. Magnesium sulfate should not be used in patients with myasthenia gravis because the magnesium ion competes with calcium. **Below is a clinical protocol for magnesium sulfate for fetal neuroprotection.**

1. Administer loading dose of 4 g magnesium sulfate in 10% to 20% solution over 30 minutes (60 mL of 10% magnesium sulfate in 1 L D<sub>5</sub> 0.9 normal saline).
2. Maintenance dose of 1 g/hr (40 g of magnesium sulfate added to 1 L D<sub>5</sub> 0.9 normal saline or Ringer's lactate at 50 mL/hr).
3. Limit IV fluid to 125 mL/hr. Follow fluid status closely; an indwelling urinary catheter is recommended.
4. Patients treated with magnesium sulfate should be assessed with the following examinations:
  - a. Deep tendon reflexes and vital signs, including respiratory rate, should be recorded hourly.
  - b. Intake and output should be measured every 2 to 4 hours.
  - c. Magnesium levels should be monitored if any clinical concern about side effects exists.
5. Calcium gluconate should be readily available to reverse the respiratory depression that can be caused by magnesium.

### Tocolysis in Preterm Labor

Because the contracting uterus is the most often recognized antecedent of PTB, stopping contractions has been the focus of therapeutic approaches. This strategy is based on the naïve assumption that clinically apparent contractions are commensurate with the initiation of the process of parturition; by logical extension, successfully inhibiting contractions should prevent delivery. The inhibition of myometrial contractions is called *tocolysis*, and an agent administered to that end is referred to as a *tocolytic*. **Although no medications have been approved for the indication of tocolysis by the U.S. Food and Drug Administration (FDA), a number of classes of drugs are used for this purpose.**

### Efficacy

The efficacy of tocolytic drugs has been addressed through studies that compare one tocolytic drug with another, or less commonly, that compare a drug with a placebo in their ability to prolong pregnancy for 48 hours (the time sufficient to attain the benefit of antenatal corticosteroids), or 1 week (the time considered sufficient to gain significant additional in utero fetal

maturation). **No studies have shown that any tocolytic can reduce the rate of PTB.** Most studies have been too small to allow firm conclusions, so reviews or meta-analyses wherein several studies of similar design are combined are the best available means to judge efficacy. The Cochrane Collaboration ([www.cochrane.org](http://www.cochrane.org)) regularly produces meta-analyses of obstetric interventions that include tocolytic drugs. **Recent Cochrane meta-analyses of tocolytic agents indicate that calcium channel blockers and oxytocin antagonists can delay delivery by 2 to 7 days with the most favorable ratio of benefit to risk, that  $\beta$ -mimetic drugs delay delivery by 48 hours but carry greater side effects, that evidence is insufficient regarding cyclooxygenase (COX) inhibitors, and that magnesium sulfate is ineffective.**

Meta-analyses of studies of individual tocolytic drugs typically report limited prolongation of pregnancy but no decrease in PTB, and they rarely offer information about whether prolongation of pregnancy was accompanied by improved infant outcomes. Delayed delivery for 48 hours to allow antenatal transport and corticosteroids to reduce neonatal morbidity and mortality are thus the main rationale for use of these drugs.

### Choosing a Tocolytic Agent

#### PHARMACOLOGY

Figure 29-10 depicts a myometrial cell and the sites of action of commonly used tocolytic agents. The key process in actin-myosin interaction, and thus contraction, is myosin light-chain phosphorylation. This reaction is controlled by myosin light-chain kinase (MLCK). **The activity of tocolytic agents can be explained by their effect on the factors that regulate the activity of this enzyme, notably calcium and cyclic adenosine monophosphate (cAMP).** For the myometrium to contract in a coordinated and effective manner (i.e., labor, whether term or preterm), individual smooth muscle cells must be functionally interconnected and able to communicate with adjacent cells. No agents used for tocolysis influence the function or expression of gap junctions.

### CONTRAINDICATIONS TO TOCOLYSIS

**Common maternal contraindications to tocolysis include preeclampsia or gestational hypertension with severe features, hemorrhage, and significant maternal cardiac disease.** Although vaginal spotting may occur in women with preterm labor because of cervical effacement or dilation, any bleeding beyond light spotting is rarely due to labor alone. Placenta previa and placental abruption must be considered because both may be accompanied by uterine contractions. In general, both diagnoses place a woman at greater risk of hemodynamic compromise in the setting of tocolytic treatment. However, in rare instances, use of tocolysis in women with these dangerous diagnoses may be considered to achieve time for corticosteroids in the setting of extreme prematurity, when the bleeding is believed to occur in response to contractions. Such treatment is fraught with difficulty because even low doses of some tocolytic agents can be hazardous in a patient with bleeding.  $\beta$ -Mimetic agents and calcium channel blockers may hamper maternal cardiovascular response to hypotension, and cyclooxygenase inhibitors may impair platelet function. Cardiac disease is a contraindication because of the risks of tocolytic drug treatment in these patients. **Fetal contraindications to tocolysis include gestational age of greater than 37 weeks, fetal demise or lethal anomaly, chorioamnionitis, and evidence of acute or chronic fetal compromise.**

**Tocolytic drugs may be safely used when standard protocols are followed. The choice of tocolytic requires consideration of the efficacy, risks, and side effects for each patient.** Table 29-3 describes the side-effect profiles of commonly used tocolytic agents.

### CALCIUM CHANNEL BLOCKERS

Calcium channel blockers are commonly used for treatment of hypertension, angina, and arrhythmias and are increasingly being used as tocolytic drugs. **Nifedipine** is the calcium channel blocker most studied as a tocolytic agent; it more selectively inhibits uterine contractions compared with other calcium blockers such as verapamil. Calcium channel blockers directly

**FIG 29-10** Site of action of commonly used tocolytics. ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate; COX, cyclooxygenase; IP<sub>3</sub>, inositol triphosphate; PIP<sub>3</sub>, phosphatidylinositol triphosphate.

**TABLE 29-3** SIDE-EFFECT PROFILES OF TOCOLYTIC AGENTS

| SIDE EFFECTS                          |  |  |   |
|---------------------------------------|--|--|---|
| AGENT OR CLASS                        | MATERNAL   | FETAL OR NEONATAL  | CONTRAINDICATIONS   |
| $\beta$ -Adrenergic-receptor agonists | Tachycardia and hypotension, tremor (39% vs. 4% with placebo), shortness of breath (15% vs. 1% with placebo), chest discomfort (10% vs. 1% with placebo), pulmonary edema (0.3%), hypokalemia (39% vs. 6% with placebo), hyperglycemia (30% vs. 10% with placebo)  | Tachycardia  | Tachycardia-sensitive maternal cardiac disease, poorly controlled diabetes mellitus   |
| Magnesium sulfate                     | Flushing, diaphoresis, nausea, loss of deep-tendon reflexes (serum levels of 9.6 to 12 mg/dL), respiratory paralysis (at serum levels of 12 to 18 mg/dL), cardiac arrest (at serum levels of 24 to 30 mg/dL); when used with calcium channel blockers, suppression of heart rate, contractility, and left ventricular systolic pressure and neuromuscular blockade | Data conflict with regard to effect on perinatal mortality   | Myasthenia gravis   |
| Calcium channel blockers              | Dizziness, flushing, hypotension when used with magnesium sulfate; suppression of heart rate, contractility, and left ventricular systolic pressure and neuromuscular blockade; elevation of hepatic aminotransferase levels   |  | Hypotension, preload-dependent cardiac lesions (e.g., aortic insufficiency)   |
| COX inhibitors                        | Nausea, esophageal reflux, gastritis, and emesis; platelet dysfunction (rarely of clinical significance in patients without an underlying bleeding disorder)   | In utero closure of ductus arteriosus (risk associated with use for >48 hr), PDA in neonate (conflicting data)                               | Platelet dysfunction or bleeding disorder, hepatic or renal dysfunction, gastrointestinal or ulcerative disease, asthma (in women with hypersensitivity to aspirin) |
| Oxytocin-receptor antagonists         | Hypersensitivity injection-site reactions  | For atosiban, an increased rate of fetal or infant death (may be attributable to the lower gestational age of infants in the atosiban group) | None  |
| Nitric oxide donors                   | Dizziness, flushing, hypotension   |  | Hypotension, preload-dependent cardiac lesions (e.g., aortic insufficiency)   |

COX, cyclooxygenase; PDA, patent ductus arteriosus.

block the influx of calcium ions through the cell membrane and also inhibit release of intracellular calcium from the sarcoplasmic reticulum, thus increasing calcium efflux from the cell. The ensuing decrease in intracellular free calcium leads to inhibition of calcium-dependent MLCK-mediated phosphorylation and results in myometrial relaxation. Calcium channel blockers are rapidly absorbed after oral administration. No placebo-controlled trials of calcium channel blockers as tocolytics have been done. **The Cochrane Collaboration meta-analyses support calcium channel blockers as short-term tocolytics, compared with other available agents, because of relatively greater suppression of contractions and fewer side effects than other agents in 12 reported trials.** Rates of birth within 7 days of treatment (relative risk [RR], 0.76; 95% CI, 0.60 to 0.97) and before 34 weeks' gestation (RR, 0.83; 95% CI, 0.69 to 0.99) were significantly reduced with calcium channel blockers, as were the rates of neonatal morbidities that included RDS (RR, 0.63; 95% CI, 0.46 to 0.88), NEC (RR, 0.21; 95% CI, 0.05 to 0.96), IVH (RR, 0.59; 95% CI, 0.36 to 0.98), and jaundice (RR, 0.73; 95% CI, 0.57 to 0.93) when compared with treatment with other tocolytics. Fewer women treated with calcium channel blockers ceased treatment owing to adverse drug reactions (RR, 0.14; 95% CI, 0.05 to 0.36). A recent RCT from Vis and colleagues<sup>53</sup> demonstrated that among women with symptoms of preterm labor and a CL between 10 and 30 mm with a negative FFN, nifedipine and placebo performed comparably with respect to delivery within 7 days. In the nifedipine group, three women (8.1%) delivered within 7 days, compared with one woman (2.8%) in the placebo group (difference -5.3%; one-sided 95% confidence limit, 4.5%). Median gestational ages at delivery

were for nifedipine 37 + 0 weeks' gestation (interquartile range [IQR], 34 + 6 to 38 + 5) and for the placebo 38 + 2 weeks' gestation (IQR, 37 + 0 to 39 + 6) weeks ( $P = .008$ ).

#### MATERNAL EFFECTS

Nifedipine has fewer side effects when compared with  $\beta$ -mimetics and magnesium sulfate. Whereas hypotension occurs frequently with nifedipine, other side effects are more frequent with magnesium and  $\beta$ -mimetics. Nicardipine displayed similar advantages when compared in a randomized trial with magnesium. Pretreatment with IV fluids may reduce the frequency of maternal side effects related to hypotension such as headache (20%), flushing (8%), dizziness, and nausea (6%). Most effects are mild, but serious complications have been reported that include a documented myocardial infarction 45 minutes after the second dose of nifedipine given to a young, healthy woman. **Concomitant or sequential use of calcium channel blockers with  $\beta$ -mimetics is not recommended, nor is concurrent administration of magnesium, owing to reports of skeletal muscle blockade when nifedipine was given with magnesium sulfate.**

#### FETAL EFFECTS

Initial animal studies raised questions of fetal hypotension, but a study of women treated for preterm labor revealed no changes in the fetal middle cerebral artery, renal artery, ductus arteriosus, umbilical artery, or maternal vessels.

#### TREATMENT PROTOCOL

An optimal nifedipine dosing regimen has not been defined. A common approach is to administer an initial loading dose of

20 mg orally, followed by an additional 20 mg orally in 90 minutes. An alternative regimen is to administer 10 mg orally every 20 minutes for up to four doses. If contractions persist, 20 mg can be given orally every 3 to 8 hours for up to 72 hours, with a maximum dose of 180 mg/day. The half-life of nifedipine is approximately 2 to 3 hours, and the duration of action of a single orally administered dose is up to 6 hours. Plasma concentrations peak in 30 to 60 minutes. Nifedipine is almost completely metabolized in the liver and excreted by the kidney.

#### SUMMARY OF TREATMENT WITH CALCIUM CHANNEL BLOCKERS

Nifedipine has been used increasingly as a tocolytic because of its low incidence of significant maternal and fetal side effects and ease of administration. Nifedipine should not be combined with magnesium or  $\beta$ -mimetics, and it should be avoided in the presence of intrauterine infection, maternal hypertension, and cardiac disease. Use should follow published dosage schedules, and the cautions noted should be kept in mind.

#### MAGNESIUM SULFATE

The basis for the clinical use of magnesium sulfate as a labor-inhibiting agent is the observation from the 1960s of a reduction of human uterine myometrial contractility in vivo and in vitro. At a pharmacologic concentration (5 mmol/L), magnesium sulfate inhibits contractile response and decreases intracellular calcium concentration in pregnant human myometrial strips. Despite in vitro observations, the largest placebo-controlled randomized trial of magnesium as a tocolytic failed to demonstrate any benefit over a placebo in prolongation of pregnancy. **A meta-analysis that compared magnesium to controls observed no difference in the risk of birth within 48 hours of treatment for women given magnesium (RR, 0.85; 95% CI, 0.58 to 1.25; 11 trials, 881 women). Magnesium appeared to confer no benefit on the risk of preterm birth (<37 weeks' gestation) or very preterm birth (<34 weeks' gestation).** The risk of death (fetal and pediatric) was higher for infants exposed to magnesium (RR, 2.82; 95% CI, 1.20 to 6.62; 7 trials, 727 infants). The body of available literature fails to support efficacy of magnesium sulfate as a tocolytic agent. Thus in women at 24 to 32 weeks' gestation who are candidates for tocolysis, we recommend that another therapy be used for labor inhibition in women also receiving magnesium sulfate for fetal neuroprotection. Because of the increased risk of maternal complications with the concomitant use of nifedipine and magnesium sulfate, **an agent such as indomethacin may be a reasonable choice for tocolysis in the woman receiving magnesium sulfate for neuroprotection of the fetus.**

#### MATERNAL EFFECTS

Magnesium has a low rate of serious maternal side effects, but flushing, nausea, vomiting, headache, generalized muscle weakness, diplopia, and shortness of breath occur frequently. Chest pain and pulmonary edema have been reported with a frequency similar to that of  $\beta$ -mimetics.

#### NEONATAL EFFECTS

Magnesium crosses the placenta and achieves serum levels comparable to maternal levels, but serious short-term neonatal complications are uncommon. **Lethargy, hypotonia, and respiratory depression may occur.** Prolonged treatment for more than 7 days has been associated with neonatal bone abnormalities. One

small trial suggested that magnesium sulfate may have adverse effects on neonatal and infant morbidity and mortality, but these observations were not confirmed by larger studies that enrolled more than 10 times as many subjects.

**SUMMARY OF TREATMENT WITH MAGNESIUM SULFATE** Magnesium sulfate has historic familiarity, but tocolytic efficacy is not supported by data. However, magnesium may have a beneficial effect on the preterm newborn with respect to reducing the risk of cerebral palsy.

#### CYCLOOXYGENASE INHIBITORS

Prostaglandins are mediators of the final pathways of uterine muscle contraction. Prostaglandins cause an increase in free intracellular calcium levels in myometrial cells and an increased activation of MLCK, resulting in uterine contractions. Myometrial gap-junction formation, an important step in synchronized uterine activity, is enhanced by prostaglandins; given to pregnant women, prostaglandins can ripen the cervix or induce labor, depending on the dosage and route of administration. Prostaglandin synthase, also known as *cyclooxygenase* (COX), converts arachidonic acid to prostaglandin  $G_2$ . **Prostaglandin synthesis is increased when the COX-2 form of this enzyme is induced by cytokines, bacterial products such as phospholipases and endotoxins, and corticosteroids; it is reduced by the inhibition of COX with nonsteroidal antiinflammatory drugs (NSAIDs).** These agents vary in their activity, potency, and side-effect profile. Indomethacin is the NSAID most often used as a tocolytic, although it crosses the placenta. **Unlike aspirin, indomethacin binds reversibly to COX, so that inhibition lasts only until the drug is cleared metabolically.** Umbilical artery serum concentrations equal maternal levels within 6 hours of oral administration. The half-life in the mother is 4 to 5 hours, and in a full-term infant it is 15 hours, but it is significantly longer in preterm infants. The Cochrane review concluded that indomethacin administration was associated with a significant reduction in births before the 37th week of gestation, increased gestational age at birth, and increased birthweight.

#### MATERNAL EFFECTS

Prostaglandin inhibition has multiple side effects because of the abundance of prostaglandin-mediated physiologic functions. Nevertheless, **serious maternal side effects are uncommon when the agent is used in a brief course of tocolysis.** As with any NSAID, gastrointestinal side effects such as nausea, heartburn, and vomiting are common but usually mild. Less common but more serious complications include gastrointestinal bleeding, prolonged bleeding time, thrombocytopenia, and asthma in aspirin-sensitive patients. Prolonged treatment with NSAIDs can lead to renal injury, especially when other nephrotoxic drugs are used. Hypertensive women may rarely experience acute increased blood pressure after indomethacin treatment. The antipyretic effect of an NSAID may obscure a clinically significant fever. Maternal contraindications to indomethacin tocolysis include renal or hepatic disease, active peptic ulcer disease, poorly controlled hypertension, asthma, and platelet disorders.

#### FETAL AND NEONATAL EFFECTS

In actual practice, serious complications to the fetus/newborn with maternal administration of indomethacin have been rare, but risk of injury to the fetus is possible if treatment protocols

are not followed carefully. **Three principal side effects raise concern: (1) in utero constriction of the ductus arteriosus, (2) oligohydramnios, and (3) neonatal pulmonary hypertension.** The ductal constriction occurs because formation of prostacyclin and PGE<sub>2</sub>, which maintain ductal vasodilation, is inhibited by indomethacin. Doppler evidence of ductal constriction was found in 7 of 14 fetuses of women treated with indomethacin between 27 and 31 weeks' gestation, but it resolved within 24 hours after the medication was discontinued. The likelihood of ductal constriction increased from 5% to 10% before 32 weeks to 50% after 48 hours of treatment at 32 to 35 weeks. Ductal constriction is usually transient and responds to discontinuation of the drug, but persistent ductal constriction and irreversible right-sided heart failure have been reported. A review of fetal echocardiographs obtained from 61 women treated with indomethacin for preterm labor found evidence of ductal constriction in 50% of fetuses. A larger study of 124 women given indomethacin for labor inhibition for more than 48 hours revealed a 6.5% frequency of in utero ductal narrowing. **In both of these studies, the ductal narrowing reversed in all fetuses after cessation of medication.**

Oligohydramnios associated with indomethacin tocolysis is due to reduced fetal urine production, which is caused by **the indomethacin-induced reduction of normal prostaglandin inhibition of antidiuretic hormones and the direct effect on fetal renal blood flow.** Prolonged treatment with indomethacin incurs a 7% frequency of oligohydramnios. **These effects are reversible,** but neonatal renal insufficiency and death after several weeks of unmonitored antenatal maternal treatment has been reported.

Primary pulmonary hypertension in the neonate is a potentially fatal illness that has also been associated with prolonged (>48 hr) indomethacin therapy. **Primary neonatal pulmonary hypertension has not been reported within 24 to 48 hours of therapy,** but the incidence may be as high as 5% to 10% with long-term therapy, although a more modern series of longer-term use failed to identify an increased frequency of newborn pulmonary hypertension compared with untreated gestational age-matched controls.

Other complications—including NEC, small bowel perforation, PDA, jaundice, and IVH—have been observed when indomethacin administration was outside of standardized protocols that did not limit the duration of treatment or that used the drug after 32 weeks' gestation. No association with IVH was noted in studies in which standard protocols were used. A review of outcomes of 1621 fetuses treated in utero with indomethacin found no significant differences compared with 4387 infants not exposed.

Sulindac is an NSAID that has less placental transfer than indomethacin, but its tocolytic efficacy has not been studied in large numbers. Because of the effect on fetal urine production and amniotic fluid volume, **indomethacin may be an appropriate tocolytic when preterm labor is associated with polyhydramnios.** Indomethacin has been used to treat preterm labor in women with polyhydramnios and for polyhydramnios without labor. Uterine activity and pain associated with degenerating uterine fibroids in pregnancy also respond well to indomethacin.

#### TREATMENT PROTOCOL FOR INDOMETHACIN TOCOLYSIS

Indomethacin is well absorbed orally. The usual regimen is a 50-mg oral loading dose followed by 25 to 50 mg by mouth

every 6 hours. **Therapy is limited to 2 to 3 days** because of concern about side effects described earlier.

1. Limit use to preterm labor before 32 weeks' gestation in women with normal amniotic fluid volume and normal renal function.
2. Loading dose is 50 mg by mouth.
3. Give 25 mg orally every 6 hours for 48 hours.
4. If the drug is used beyond 48 to 72 hours, amniotic fluid volume should be monitored serially with ultrasound, and ductus arteriosus flow should be evaluated with Doppler echocardiography. If amniotic fluid is significantly reduced or the ductus is narrowed, the drug should be discontinued.
5. Discontinue therapy promptly if delivery seems imminent.
6. Fetal contraindications to the use of indomethacin include renal anomalies, chorioamnionitis, oligohydramnios, ductal-dependent cardiac defects, and twin-twin transfusion syndrome.

#### SUMMARY OF TREATMENT WITH INDOMETHACIN

Indomethacin is an effective tocolytic agent that is generally well tolerated by the mother. **Concern about fetal side effects has appropriately limited use of indomethacin to brief courses of therapy in patients with preterm labor before 32 weeks.**

#### β-MIMETIC TOCOLYTICS

β-Sympathomimetic drugs include terbutaline, ritodrine, and others that have been widely used as tocolytics for many years. Structurally related to epinephrine and norepinephrine, these agents act to relax smooth muscle; for example, in the bronchial tree, blood vessels, and myometrium through stimulation of the β-receptors, which are divided into β<sub>1</sub> and β<sub>2</sub> subtypes. The β<sub>1</sub>-receptors are largely responsible for the cardiac effects, whereas β<sub>2</sub>-receptors mediate smooth muscle relaxation, hepatic glycogen production, and islet cell release of insulin. Stimulation of β-receptors in the heart, vascular system, and liver accounts for the side effects of these drugs.

**The most commonly used β-mimetic in the United States is terbutaline, marketed as a drug for asthma,** but others that include albuterol, fenoterol, hexoprenaline, metaproterenol, nylidrin, orciprenaline, and salbutamol are used in other countries. Ritodrine was approved by the FDA as a parenteral tocolytic in 1980, but it did not achieve wide use because of frequent maternal side effects. Ritodrine is no longer marketed in the United States. Terbutaline has a rapid (3 to 5 minutes) effect when given subcutaneously. Published protocols often use subcutaneous administration, with a usual dose of 0.25 mg (250 μg) every 4 hours. A single subcutaneous dose of terbutaline to arrest contractions during the initial evaluation of preterm contractions may aid in the diagnosis of preterm labor. In one study, women whose contractions persisted or recurred after a single dose were more likely to have true preterm labor than those whose contractions ceased. **The Cochrane Database reported an analysis of 1332 women enrolled into 11 randomized placebo-controlled trials of β-mimetic drugs and found that treated subjects were less likely to deliver within 48 hours (RR, 0.63; 95% CI, 0.53 to 0.75) but not within 7 days.** Although a 48-hour delay in delivery allows sufficient time for in utero transfer and treatment with steroids, perinatal and neonatal death and perinatal morbidity were not reduced in this analysis. Side effects that required change or cessation of treatment were frequent.

### SIDE EFFECTS AND COMPLICATIONS OF $\beta$ -MIMETIC TOCOLYSIS

Maternal side effects of the  $\beta$ -mimetic drugs are common and diverse owing to the abundance of  $\beta$ -receptors in the body. Maternal tachycardia, chest discomfort, palpitation, tremor, headache, nasal congestion, nausea and vomiting, hyperkalemia, and hyperglycemia are significantly more common in women treated with  $\beta$ -mimetics. Most are mild and of limited duration, but serious maternal cardiopulmonary and metabolic complications have been reported.

**Cardiopulmonary Complications of  $\beta$ -Mimetics.** The  $\beta$ -mimetic agents produce a 5 to 10 mm Hg fall in diastolic blood pressure, and the extensive peripheral vasodilation makes it difficult to mount a normal response to hypovolemia. **Signs of excessive blood loss** (e.g., maternal and fetal tachycardia) are masked by  $\beta$ -mimetics, so their use may be dangerous in women with antepartum hemorrhage. The most important steps to prevent cardiac complications are to (1) exclude patients with prior cardiac disease and (2) limit infusion rates so that maternal pulse does not exceed 130 beats/min. Symptomatic cardiac arrhythmias and myocardial ischemia have occurred during  $\beta$ -agonist tocolytic therapy. **Tocolysis should be discontinued and oxygen administered whenever a patient develops chest pain during  $\beta$ -mimetic therapy.** Arrhythmias noted in association with  $\beta$ -mimetic therapy usually respond to discontinuation of the drug and oxygen administration. Baseline or routine electrocardiograms (ECGs) before or during treatment are not helpful. **An ECG is indicated if there is no response to oxygen and cessation of  $\beta$ -mimetic therapy.** Pulmonary edema has been reported with  $\beta$ -mimetic therapy. Restricting the duration of treatment to less than 24 hours, careful attention to fluid status, and detection of complicating conditions such as intrauterine infection may reduce this risk.

**Metabolic Complications.**  $\beta$ -Mimetic agents induce transient hyperglycemia and hypokalemia during treatment. Measurement of glucose and potassium before initiating therapy and, on occasion, during the first 24 hours of treatment, is appropriate to identify significant hyperglycemia ( $>180$  mg/dL) or hypokalemia ( $<2.5$  mEq/L). These metabolic changes are mild and transient, but prolonged treatment beyond 24 hours may induce significant alterations in maternal blood glucose, insulin levels, and energy expenditure. **The risk of abnormal glucose metabolism is further increased by simultaneous treatment with corticosteroids, a common combination for threatened preterm labor.** Other agents should be chosen for women with pregestational diabetes and usually for those with gestational diabetes as well.  $\beta$ -Mimetic treatment in these women requires frequent monitoring and insulin infusion to maintain euglycemia.

**Neonatal Effects.** Neonatal hypoglycemia, hypocalcemia, and ileus may follow treatment with  $\beta$ -mimetics and can be clinically significant if the maternal infusion is not discontinued 2 hours or more before delivery. Long-term data on neurodevelopmental outcomes in humans are lacking.

Protocols for continuous subcutaneous infusion of terbutaline have been reported to have fewer side effects than oral administration but did not improve rates of PTB or perinatal morbidity in randomized placebo-controlled trials. This drug has been the subject of an FDA warning: **"Terbutaline administered by injection or through an infusion pump should not be used in pregnant women for prevention or prolonged (beyond 48**

**to 72 hours) treatment of preterm labor due to the potential for serious maternal heart problems and death. In addition, oral terbutaline tablets should not be used for prevention or treatment of preterm labor."**<sup>54</sup> No placebo-controlled trials that demonstrate effectiveness have been reported since the FDA advisory was issued.

Given their potential for clinically significant side effects and the availability of alternatives, the  **$\beta$ -sympathomimetic agents should not be used in women with known or suspected heart disease, severe preeclampsia or eclampsia, pregestational gestational diabetes requiring insulin, or hyperthyroidism. These drugs are contraindicated when suspected preterm labor is complicated by maternal fever, fetal tachycardia, leukocytosis, or other signs of possible chorioamnionitis.**

**SUMMARY OF TREATMENT WITH  $\beta$ -MIMETIC TOCOLYSIS**  
 $\beta$ -Mimetic drugs were once among the most commonly used tocolytics but have been replaced by agents with better safety and side-effect profiles. Terbutaline has relatively few serious side effects when used as a single subcutaneous injection of 0.25 mg to facilitate maternal transfer or to initiate tocolysis while another agent with a slower onset of action is being given. Long-term oral or subcutaneous treatment has not been shown in controlled trials to reduce prematurity or neonatal morbidity.

### ATOSIBAN AND OTHER TOCOLYTIC AGENTS

Atosiban is a selective oxytocin-vasopressin receptor antagonist. Although commonly used in Europe, it is not available in the United States. In normal parturition, oxytocin stimulates contractions by inducing conversion of phosphatidylinositol to inositol triphosphate, which binds to a protein in the sarcoplasmic reticulum and causes release of calcium into the cytoplasm. A Cochrane review analyzed six randomized trials ( $n = 1695$ ) that compared the oxytocin receptor antagonist atosiban to a placebo. Use of atosiban increased the risk of birth within 48 hours of initiation of treatment (RR, 2.50; 95% CI, 0.51 to 12.35), increased the risk of PTB at less than 28 weeks' gestation (RR, 2.25; 95% CI, 0.80 to 6.35), and increased the risk of PTB at less than 37 weeks' gestation (RR, 1.17; 95% CI, 0.99 to 1.37); however, none of these increases reached statistical significance. All neonatal morbidity and mortality outcomes evaluated were similar in both groups. There was, however, an imbalance in allocation of women with threatened preterm labor under 26 weeks' gestation such that significantly more women in this subgroup were allocated to the atosiban group. In addition, more women in the placebo group than in the atosiban group received rescue treatment, which may have confounded the estimate of the true effects of atosiban when compared with placebo. The use of rescue tocolytics complicated analysis of these trials because the criteria for switching therapies was not strictly defined. Finally, the trial protocol did not define how glucocorticoids should be used, which resulted in a great deal of variation in use among study sites. **The FDA declined to approve the use of atosiban for tocolysis because of concerns about the drug's safety when used in fetuses at less than 28 weeks' gestation.**<sup>55</sup>

Nitric oxide (NO) donors also promote myometrial relaxation. Meta-analysis of trials to compare NO donors to other agents support the notion that NO donors do not delay delivery or improve neonatal outcome when compared with placebo, no treatment, or alternative tocolytics such as ritodrine, albuterol,

and magnesium sulfate. There was, however, a reduction in the number of deliveries prior to 37 weeks' gestation when compared with alternative tocolytics, but the number of deliveries before 32 and 34 weeks' gestation were not influenced. Side effects other than headache were reduced in women who received NO donors rather than other tocolytics. However, women were significantly more likely to experience headache when NO donors had been used.

### Clinical Use of Tocolytic Drugs

Tocolytic therapy is used in several clinical circumstances. In a patient who is in active labor with advanced cervical effacement, the diagnosis is not in question, and the goal is prompt treatment to allow maternal transfer and time for corticosteroids and GBS prophylaxis. In this setting, initial treatment with oral indomethacin or oral nifedipine may be the best choice to stop contractions promptly. Treatment for preterm labor may be continued until contractions have stopped or occur less frequently than four times per hour without additional cervical change, or until a full course of corticosteroids therapy is completed after 48 hours.

### PERSISTENT CONTRACTIONS

**If contractions persist despite therapy, the wisdom of tocolytic treatment should be reevaluated.** The cervix should be reexamined, and if dilation has progressed beyond 4 cm and imminent delivery is thought to be inevitable, tocolytic therapy in most cases should be discontinued. In the setting of progressive preterm labor despite labor inhibition, it is critical to acknowledge the higher probability of placental abruption and/or subclinical chorioamnionitis. Clinical evaluation with focused history, physical examination, and laboratory assessment should be used to address the probability of these conditions.

Some women will have persistent uterine contractions and may exhibit a “nonthreatening” cervical examination that does not change over serial examinations. If a fibronectin swab was collected before therapy was begun, it should be sent for analysis. A positive result is not confirmatory, but a negative fibronectin, if collected before performance of a digital examination, suggests that the risk of imminent delivery is low. Alternatively, a transvaginal cervical ultrasound examination may be performed. A CL of 30 mm or more substantially reduces the likelihood of imminent delivery.

Serum levels are not clinically helpful to adjust the dose of tocolytics. A change to a second agent, or combination therapy with multiple agents, may slow contractions but may also result in increased risks. Combined use of  $\beta$ -mimetics or magnesium sulfate with calcium channel blockers should also be avoided (Box 29-5).

### Care After Acute Treatment for Preterm Labor MAINTENANCE TOCOLYTIC TREATMENT

Continued suppression of contractions after acute tocolysis does not reduce the rate of PTB. Meta-analyses of these data also find no evidence of prolongation of pregnancy or decline in the frequency of PTB.

Posthospitalization surveillance with outpatient monitoring of uterine contractions did not improve the rate of delivery before 37 weeks' gestation, gestational age at delivery, or birth-weight in any of three randomized trials or in a meta-analysis of these. A multicenter randomized trial in which uterine activity was monitored, but in which the data were masked from care

### BOX 29-5 MANAGEMENT OF PERSISTENT CONTRACTIONS DESPITE 12 TO 24 HOURS OF TOCOLYSIS

1. Is subclinical amniotic fluid infection present? Repeat clinical examination, white blood cell counts, and fetal assessment. Consider amniocentesis for glucose, Gram stain, leukocyte esterase, and culture.
2. Is the fetus compromised? Review the fetal heart tracings and, if needed, do a biophysical assessment.
3. Is there evidence of abruption? Is there a suspicion of uterine anomaly with implantation of the placenta on the septum? Evaluate vital signs for evidence of hemodynamic response to blood loss and repeat hemoglobin, hematocrit, and fibrinogen and abdominal sonography for placental implantation site.
4. Is the diagnosis of preterm labor correct? Is the cervix changing? Perform a transvaginal cervical ultrasound to measure cervical length. Send a fibronectin swab.
5. If infection, fetal compromise and abruption can be excluded, stop parenteral tocolysis for 24 hours and observe. Contractions in most patients will stop spontaneously.

providers in one group, also found no improvement in the PTB rate when contraction data were used.

**The duration of hospitalization for an episode of preterm labor varies according to several factors, including the examination of the cervix, ease of tocolysis, gestational age, obstetric history, distance from the hospital, and the availability of home and family support.** Associated risk factors that may complicate or increase the risk of recurrent preterm labor—such as a positive genital culture for *Chlamydia* or gonorrhea, urinary tract infection, and anemia—should be addressed before discharge from hospital care. Social issues such as homelessness, availability of child care, or protection from an abusive partner are important determinants of a patient's ability to adhere to recommendations for medical care, and these issues must be considered before the patient is discharged from the hospital.

### CONDUCT OF LABOR AND DELIVERY FOR THE PRETERM INFANT

**Intrapartum care for women in labor before term is often complicated by conditions that increase the chance of intrapartum fetal compromise such as malpresentation, hypertension, amnionitis, abruption, oligohydramnios, or fetal growth restriction.** When labor is induced preterm for maternal or fetal indications, the lower uterine segment and cervix may not be well prepared for labor, which leads to a prolonged latent phase.

### Intrapartum Assessment of the Preterm Fetus

Intrapartum fetal surveillance has been associated with a significantly lower frequency of intrapartum death and neonatal seizures for preterm infants. **Ominous heart rate tracings in preterm fetuses have the same associations with fetal acidosis as they do later in gestation.** Mean fetal heart rate falls continuously, from 160 beats/min at 22 weeks' gestation to 140 beats/min at term, because of a gradual increase in parasympathetic tone. Fetal heart rate patterns should be considered as representative of well-being in the preterm fetus as they are at term.

## Labor and Delivery

The duration of labor in preterm gestation may be shorter than that of term pregnancy. The active phase of the first stage and the second stage may be particularly brief. Care should be taken to ensure that the fetus does not have a precipitous delivery without control of the fetal head. Prophylactic forceps to “protect” the fetal head are of no benefit. **The neonatal care team should be alerted to the circumstances of a PTB well in advance of the delivery so that appropriate personnel and equipment can be made available.**

## Cesarean Delivery

**Routine cesarean delivery (CD) for all preterm or VLBW infants is not justified.** Trends that favor CD disappear after adjustment for confounding factors. A review of studies of neonatal and maternal morbidities after vaginal versus CD for infants born between 24 and 36 weeks’ gestation found increased maternal morbidity without clear benefit for the infant. Neonatal intracranial hemorrhage occurs as often before and after labor as it does during labor and delivery.

For infants in breech presentation, the reasons for CD are intuitive, particularly to avoid entrapment of the after-coming head and other manipulations that could lead to trauma or hypoxia (see Chapter 17). Older retrospective studies that suggested a benefit of CD led to the current custom of CD for preterm breech fetuses, but data in support of this practice are weak. It is illogical to perform a CD to avoid a traumatic vaginal delivery only to encounter a difficult CD because of an inadequate abdominal or uterine incision. The operation should be conducted to minimize the trauma of delivery through as roomy an incision as is necessary. In a study of delivery mode for high-risk (e.g., with preeclampsia, vaginal bleeding, abnormal heart rate tracing) versus low-risk (e.g., with preterm labor, incompetent cervix) pregnancies with VLBW infants, CD was found to be of no value in the low-risk group but was associated with significantly improved survival rates in the high-risk group. Considering these factors, optimal delivery of the VLBW fetus may at times appropriately lead to a decision to perform a CD without labor. Generally speaking, the appropriate mode of delivery for the preterm fetus ought to be based on similar standards of obstetric indications as at term.

## Delayed Cord Clamping

In December of 2012, ACOG published a committee opinion recommending delayed umbilical cord clamping in preterm infants.<sup>56</sup> This opinion was endorsed by the American Academy of Pediatrics (AAP). The definitions of **early cord clamping and delayed cord clamping are quite varied in the literature. General consensus and review of numerous articles suggest that early cord clamping occurs within 30 seconds of delivery; late cord clamping occurs when the delay is greater than 30 seconds and up to 5 minutes, although most of the benefit occurs within the first 60 to 120 seconds.**<sup>57</sup> Delayed cord clamping (DCC) is associated with substantial benefits in hematologic characteristics. Following DCC, **preterm infants have higher initial hematocrits, higher circulating blood volumes, and higher diastolic blood pressures, and they require less resuscitation in the delivery room.**<sup>58</sup> In addition, DCC has been associated with lower transfusion rates in preterm infants.<sup>59</sup> Although polycythemia and higher bilirubin levels have been

linked to DCC, a statistically significant increased need for phototherapy has not been seen in the preterm population. A paucity of data exists to compare the alternative of umbilical cord milking to DCC. In the only direct comparison study<sup>60</sup> published to date (58 infants enrolled), no difference was noted between milking the cord four times and delaying clamping of the cord for 30 seconds. The published randomized studies on this topic have been relatively small (total of 173 infants randomized to cord milking and either immediate or delayed cord clamping) and thus **milking of the cord cannot be recommended as the standard of care for the preterm infant at this time.** The potential consequences of delaying resuscitation in preterm infants in order to provide DCC is a common concern among neonatal and obstetric providers. However, several studies have demonstrated that these concerns are unfounded. DCC of up to 60 seconds has no deleterious effect in regard to delivery room resuscitation as measured by Apgar scores at 1 and 5 minutes or the need for chest compressions and epinephrine. In fact, **in the VLBW population, DCC reduces the need for any delivery room resuscitation intervention, supplemental oxygen, or bag-mask ventilation.**<sup>61</sup> In addition, no increase in the rate of hypothermia has been noted in infants undergoing DCC.

## PREVENTION OF PRETERM BIRTH

Care of PTB may be described according to the public health model as **tertiary** (treatment initiated *after* the parturitional process has begun to limit perinatal morbidity and mortality), **secondary** (identification and treatment for individuals with increased risk), or **primary** (prevention and reduction of risk in the population). Tertiary care described in the preceding section of this chapter has improved perinatal outcomes but has no effect on the incidence of PTB. Efforts to identify women likely to deliver preterm to reduce or eliminate their risk have not achieved high sensitivity, and, until recently, no effective interventions were available to reduce risk.

Prevention efforts aimed at risk factors have been undertaken with the expectation that PTB would decline in proportion to the contribution of that risk factor as a cause of PTB. The failure of this approach underlies the current understanding of PTB as a syndrome in which multiple factors, known and unknown, contribute to the initiation and progression of preterm parturition. Rather than a distinct entity for which there are specific tests, PTB is more appropriately considered as the result of various pathologic events that affect the timing and progress of parturition. Understanding maternal risk factors, symptoms, and tests as clues to steps in a parturitional sequence that may or may not progress to early delivery, rather than “tests for preterm labor,” brings some clarity to the sometimes confusing literature on this subject.

## Secondary Prevention of Preterm Birth

Identification and elimination or reduction of risk may be applied before and/or after conception.

### Before Pregnancy

Prepregnancy medical risk factors occur in as many as 40% of PTBs, but **preconceptional medical interventions to reduce PTB in these women have been disappointing.** A history of second-trimester loss or PTB is most easily

identified,<sup>3,62</sup> recalling that the risk increases as the gestational age of the previous PTB declines and as the number of PTBs increases. Preconceptional interventions include surgical correction of müllerian anomalies and preconceptional abdominal cerclage. A randomized trial in 1579 women of interconceptional home visits and counseling to reduce LBW and PTB reported no evidence of benefit. Another randomized placebo-controlled trial tested interconceptional antimicrobial treatment in women with a prior early PTB. Subjects were randomly assigned to receive metronidazole and azithromycin or placebo at 3-month intervals between pregnancies, but the recurrence risk of PTB was not improved.

### During Pregnancy

Postconceptional prevention strategies have most often been studied in women with a prior PTB with a major risk factor such as multifetal gestation or bleeding and in women with a sign, symptom, or positive screening test indicative of increased risk. Previous editions of this text have noted the absence of any effective interventions, but recent studies have demonstrated reduced risk in selected populations; for example, in women with a prior PTB and with a short cervix.

### Modification of Maternal Activity

Despite a lack of supporting evidence, bed rest, limited work, and reduced sexual activity are often recommended to reduce the risk of PTB in pregnancies at risk for indicated and spontaneous births. Yost and colleagues found no relationship between coitus and risk of recurrent PTB. **Grobman and coworkers<sup>63</sup> reported no relation between reduced activity and frequency of PTB in nulliparous women with CL less than 30 mm before 24 weeks.**

### NUTRITIONAL SUPPLEMENTS

Supplemental use of omega-3 polyunsaturated fatty acids (PUFAs) has been recommended because populations with a high dietary intake have low rates of PTB, perhaps because omega-3 PUFAs reduce levels of proinflammatory cytokines. European trials of omega-3 supplements and supplemental fish oil found significant reductions in PTB, but a placebo-controlled U.S. trial of supplemental omega-3 PUFAs in women with a prior PTB found no benefit in women who were treated with 17- $\alpha$ -hydroxyprogesterone caproate.<sup>64</sup> Interestingly, women in both arms of this study who consumed more than one fish meal per month had a significantly lower rate of PTB than those who consumed fish once per month or less. **Trials of supplemental vitamins C and E and calcium have not demonstrated a reduction in PTB risk.<sup>65</sup>**

### ENHANCED PRENATAL CARE

Although perhaps helpful in adolescents, programs of enhanced prenatal care that provide social support, home visits, and education have not reduced PTB. Frequent provider-initiated contact for women with a prior PTB also did not decrease recurrent PTB in randomized trials.

However, reduced rates of PTB have been reported for women receiving prenatal care in novel settings: group prenatal care in South Carolina,<sup>66</sup> a regional program to standardize care for an indigent population in Texas,<sup>67</sup> and specialized prematurity clinics in Utah and Ohio<sup>68</sup> for women with a prior PTB have all reported lower rates of premature birth, but all are retrospective and merit confirmation.

### PERIODONTAL CARE

The association of periodontal disease with increased risk of prematurity prompted intensive study of the effects of periodontal care on the rate of PTB. Results have been negative, suggesting shared susceptibility rather than a causal linkage.

### ANTIBIOTIC TREATMENT

Screening and antibiotic treatment of women with abnormal genital flora has been largely ineffective to prevent PTB. Antibiotic treatment for women with a prior PTB who have bacterial vaginosis was associated with reduced risk of recurrent PTB in secondary analyses. Reviews and meta-analyses have also been negative, and a U.S. Preventive Services Task Force review<sup>69</sup> cautioned that there may be “unintended potential for harm” from screening and treatment for bacterial vaginosis in pregnancy. Antibiotic prophylaxis has also been studied in women with positive fetal fibronectin test results. Rates of PTB were actually increased in fibronectin-positive women who received antibiotic treatment. Similar results were reported from a trial of antibiotics in women with *Trichomonas*.

### PROGESTOGENS

Progestogen supplementation for women at risk for PTB has been investigated based on several plausible mechanisms of action, including reduced gap-junction formation and oxytocin antagonism leading to relaxation of smooth muscle, maintenance of cervical integrity, and antiinflammatory effects. Studies performed before 1990 in women with recurrent miscarriage and PTB were reviewed by Keirse,<sup>70</sup> who found “no support for the view that 17- $\alpha$ -hydroxyprogesterone caproate protects against miscarriage, but suggests that it does reduce the occurrence of PTB.” **Subsequent randomized trials have demonstrated an approximately 40% decrease in the rate of PTB in women with a prior PTB and/or a short cervix (<15 to 20 mm before 24 weeks’ gestation) who were treated with either intramuscular 17- $\alpha$ -hydroxyprogesterone caproate 250 mg weekly or with vaginal progesterone suppositories or cream daily between 16 and 36 weeks’ gestation (Table 29-4).<sup>15-17,19,71,72</sup>**

**Several randomized placebo-controlled trials have found that progestogen supplementation does not affect the rate of PTB in women with multifetal gestations, indicating that the**

\*17- $\alpha$ -hydroxyprogesterone caproate.

†Vaginal progesterone in various formulations.

‡Women likely to receive cerclage not enrolled. Mean cervical length at entry was 37 mm.

§Secondary analysis of O’Brien study subjects who later had a short cervix (<28 mm). PTB, preterm birth variably defined.

**mechanism of progesterone's action to reduce risk of PTB in singletons is not related to uterine stretch.**<sup>73-76</sup>

Importantly, the effect of supplemental progesterone compounds is not universally observed in women with a prior PTB, indicating first that some pathways to recurrent PTB are not influenced by this therapy and also that many women with a prior PTB will deliver at term without treatment. The recurrence risk of sPTB without treatment is related to CL at 22 to 24 weeks' gestation and ranges from more than 35% in women whose CL is less than 25 mm to 15% in women with a CL of 25 to 35 mm and to less than 10% in those with a CL above 35 mm. In the only study of women with a previous PTB in which vaginal progesterone did not reduce the risk of recurrent PTB,<sup>16</sup> the mean CL at 18 to 22 weeks' gestation was 37 mm, which suggests that women with a prior PTB who also do not have a short cervix will not benefit from progesterone supplementation. Indeed, a secondary analysis of this study found a reduced risk of PTB in women who later had a short cervix.<sup>15</sup> **Taken together, these studies indicate that a short cervix, rather than prior PTB, is the most appropriate criterion for institution of vaginal progesterone therapy. However, a history of PTB will continue to be an indication for 17- $\alpha$ -hydroxyprogesterone caproate treatment until additional studies demonstrate that such treatment is unnecessary in women with a prior PTB who maintain a normal CL beyond 24 weeks' gestation.**

Trials of progestogens in women with other risk factors, such as a positive fetal fibronectin or bleeding, have not been reported. The mechanism of action is uncertain, but the absence of effect in multifetal gestation coupled with reductions in PTB in women with a short cervix suggest that the pathway may be related primarily to modulation of cervical softening, a conclusion also suggested by basic studies.

**The optimal strategy to identify candidates for progesterone therapy has not been determined.** Universal CL screening of all pregnant women at 18 to 24 weeks' gestation has been proposed based on two favorable cost-effectiveness studies<sup>77,78</sup> and expert opinion,<sup>79</sup> but universal application of any screening test in obstetric care is always accompanied by unanticipated costs and consequences, in this case likely related to reproducibility of cervical sonography and uncertain adherence to recommended treatment protocols.

An alternative list of indications for selective screening for a short cervix with transvaginal ultrasound is shown in [Box 29-6](#). These women are candidates for screening with the expectation that progesterone supplementation will be considered if the CL measurement at 16 to 24 weeks' gestation is 20 mm or less. The value and timing of repeat cervical ultrasound in women with marginal CL measurements is uncertain. The schema suggested is likely to be modified by broader experience with cervical sonographic screening.

### CERVICAL CERCLAGE
