## Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Working together  
to grow libraries in  
developing countries

[www.elsevier.com](http://www.elsevier.com) • [www.bookaid.org](http://www.bookaid.org)

Three of us met on the obstetrics service at The New York Hospital and Cornell University Medical College in 1968. Two of us (J.R.N. and J.L.S.) were residents, and one (S.G.G.) was a medical student. We became friends, and, as our careers moved ahead, we continued to see each other at national meetings. About 35 years ago, at one of these conferences, we were approached by Lynne Herndon, then with Churchill Livingstone, and asked if we would like to collaborate on a new obstetrics book. We were honored to be asked.

We believed a new book was needed and thought that our different areas of interest would complement each other. We decided to prepare a multiple-author textbook, inviting our friends and colleagues to join us. The book was targeted to residents and fellows in training. Of course, we were all in different cities, and this was before the internet, word processors, or fax, so preparing a book like this was a challenge. Yes, it was much more work than we imagined, but it was exciting to read each new chapter and watch the book come together. We were then, and we remain today, extremely thankful to our authors for their outstanding state-of-the-art contributions. Although it has been challenging to keep up with the rapid advances in our field, our authors, including many who have written chapters in every edition, made sure we did.

The first edition of the book was very well received. We were honored by this response and so pleased that the publisher encouraged us to do a second edition, and we accepted. Then a third, a fourth, a fifth, and a sixth followed in the next three decades. Over the years, we invited an outstanding group of editors to join us, and we have had great support from our publishers, now Elsevier.

This seventh edition is the last we will edit. Although we all continue to see patients and teach, we believe the time has come to pass the baton to our colleagues, Dr. Landon, Dr. Galan, Dr. Jauniaux, Dr. Driscoll, Dr. Berghella, and Dr. Grobman. Because *Obstetrics: Normal and Problem Pregnancies* has been the single most important contribution of our professional careers, we are honored they have decided to dedicate this edition to us. We thank them very much, and we thank you, our readers, for your loyalty and support over the years.

# Preface

The seventh edition of *Obstetrics: Normal and Problem Pregnancies* is being delivered to you prematurely! Do we have your attention? Good. We don't mean the book is incomplete. In fact, this edition may have more new information than any we've done before, which is why it is being published just 4 years since the sixth edition, rather than on our usual 5-year cycle. We want to be sure our readers have access to the best, most advanced resource to guide them as they learn and practice obstetrics today. We were able to accomplish this accelerated process thanks to the hard work of our editors, our contributing authors, and our publisher, Elsevier.

As we have done in the past, we surveyed our readers and leaders in the field to assess content that needed to be added and revised. You will find four new chapters in the seventh edition: “[Vaginal Birth After Cesarean Delivery](#),” “[Placenta Accreta](#),” “[Obesity in Pregnancy](#),” and “[Improving Global Maternal Health: Challenges and Opportunities](#).” The first three topics have become more important in our day-to-day obstetric practice, and the chapter on global maternal health is a “must read” for anyone providing obstetric care abroad. In addition to the two appendices on normal values in pregnancy and the anatomy of the pelvis, we have added a third—a glossary of the most frequently used key abbreviations—for easy reference.

We also welcome two new editors to the seventh edition: Drs. Vincenzo Berghella and William Grobman, both recognized leaders in our field who have authored chapters in past editions. We again thank our chapter authors for their outstanding contributions. We welcome nearly 30 new authors, and we recognize six who have written chapters in every edition: Drs. George J. Annas, D. Ware Branch, Mark B. Landon, Adam A. Rosenberg, Philip Samuels, and Baha Sibai. During this past year, we lost a beloved friend and colleague, Sherman Elias, who had coauthored the chapter on legal and ethical issues in obstetric practice with Dr. Annas for the first six editions. Sherman is and will continue to be missed by so many of us.

Readers will find that we have expanded the use of bolded statements and key points to enhance mastery of each chapter. Our chapter on obstetric ultrasound now contains more than 100 images (in print and online), providing an important resource for normal and abnormal fetal anatomy. Our seventh edition's online features include an exciting new resource: videos to accompany several chapters to enhance learning in areas such as cesarean delivery and operative vaginal delivery.

The seventh edition would not have been possible without outstanding support from our publisher, Elsevier, and its expert and dedicated team, Lucia Gunzel, Kate Dimock, and Carrie Stetz, as well as members of our own staff who have provided invaluable editorial and secretarial assistance, including Kenzie Palsgrove and Susan DuPont (Columbus, Ohio), Nancy Schaapveld (Iowa City), and Lisa Prevel (New York).

As noted on the dedication page, this will be the last edition three of us (S.G.G., J.R.N., J.L.S.) will edit. It has been a privilege for us to contribute to this book over the last four decades. We are confident our coeditors will make the book even better, and we wish them great success.

Whether our readers are beginning their careers or have had many years of clinical experience, we hope they will find the seventh edition of this textbook to be a valuable and supportive resource in today's challenging health care climate. And, we hope they appreciate its earlier arrival!

The placenta is a remarkable and complex organ that is still only partly understood. During its relatively short life span, it undergoes rapid growth, differentiation, and maturation. At the same time it performs diverse functions that include the transport of respiratory gases and metabolites, immunologic protection, and the production of steroid and protein hormones. As the interface between the mother and her fetus, the placenta plays a key role in orchestrating changes in maternal physiology that ensure a

successful pregnancy. This chapter reviews the structure of the human placenta and relates this to the contrasting functional demands placed on the organ at different stages of gestation. Because many of the morphologic features are best understood through an understanding of the organ's development, and because many complications of pregnancy arise through aberrations in this process, we approach the subject from this perspective. However, for the purposes of orientation and to introduce

some basic terminology, we first provide a brief description of the macroscopic appearance of the delivered organ, with which readers are most likely to be familiar.

## PLACENTAL ANATOMY

### Overview of the Delivered Placenta

At term, the human placenta is usually a discoid organ, 15 to 20 cm in diameter, approximately 3 cm thick at the center, and weighing on average 450 g. Data show considerable individual variation, and placentae are also influenced strongly by the mode of delivery. **Macroscopically, the organ consists of two surfaces or plates: the chorionic plate, to which the umbilical cord is attached, and the basal plate that abuts the maternal endometrium.** Between the two plates is a cavity that is filled with maternal blood, delivered from the endometrial spiral arteries through openings in the basal plate (Fig. 1-1). This cavity is bounded at the margins of the disc by the fusion of the chorionic and basal plates, and the smooth chorion, or *chorion laeve*, extends from the rim to complete the chorionic sac. The placenta is incompletely divided into between 10 and 40 lobes by the presence of septa created by invaginations of the basal plate. The septa are thought to arise from differential resistance of the maternal tissues to trophoblast invasion and may help to compartmentalize, and hence direct, maternal blood flow through the organ. **The fetal component of the placenta comprises a series of elaborately branched villous trees that arise from the inner surface of the chorionic plate and project into the cavity of the placenta.** This arrangement is reminiscent of the fronds of a sea anemone wafting in the seawater of a rock pool. Most commonly, each villous tree originates from a single-stem villus that undergoes several generations of branching until the functional units of the placenta, the **terminal villi**, are created. These consist of an epithelial covering of trophoblast and a mesodermal core that contains branches of the umbilical arteries and tributaries of the umbilical vein. Because of this repeated

branching, the tree takes on the topology of an inverted wine glass, often referred to as a **lobule**, and two to three of these may “sprout” within a single placental lobe (see Fig. 1-1). As will be seen later, **each lobule represents an individual maternal-fetal exchange unit.** Near term, the continual elaboration of the villous trees almost fills the cavity of the placenta, which is reduced to a network of narrow spaces collectively referred to as the **intervillous space (IVS)**. The maternal blood percolates through this network of channels and exchanges gases and nutrients with the fetal blood that circulates within the villi before draining through the basal plate into openings of the uterine veins. **The human placenta is therefore classified in comparative mammalian terms as being of the villous hemochorial type, although as we shall see, this arrangement only pertains to the second and third trimesters of pregnancy.<sup>1</sup> Prior to that, the maternal-fetal relationship is best described as deciduochoorial.**

### Placental Development

Development of the placenta is initiated morphologically at the time of implantation, when the embryonic pole of the blastocyst establishes contact with the uterine epithelium. At this stage, the wall of the blastocyst comprises an outer layer of unicellular epithelial cells, the trophoblast, and an inner layer of extraembryonic mesodermal cells derived from the inner cell mass; together these layers constitute the chorion. The earliest events have never been observed in vivo for obvious ethical reasons, but they are thought to be equivalent to those that take place in the rhesus monkey.

Attempts have also been made to replicate the situation in vitro by culturing in vitro fertilized human blastocysts on monolayers of endometrial cells. Although such reductionist systems cannot take into account the possibility of paracrine signals that emanate from the underlying endometrial stroma, the profound differences in trophoblast invasiveness displayed by various species are maintained. In the case of the human, the trophoblast

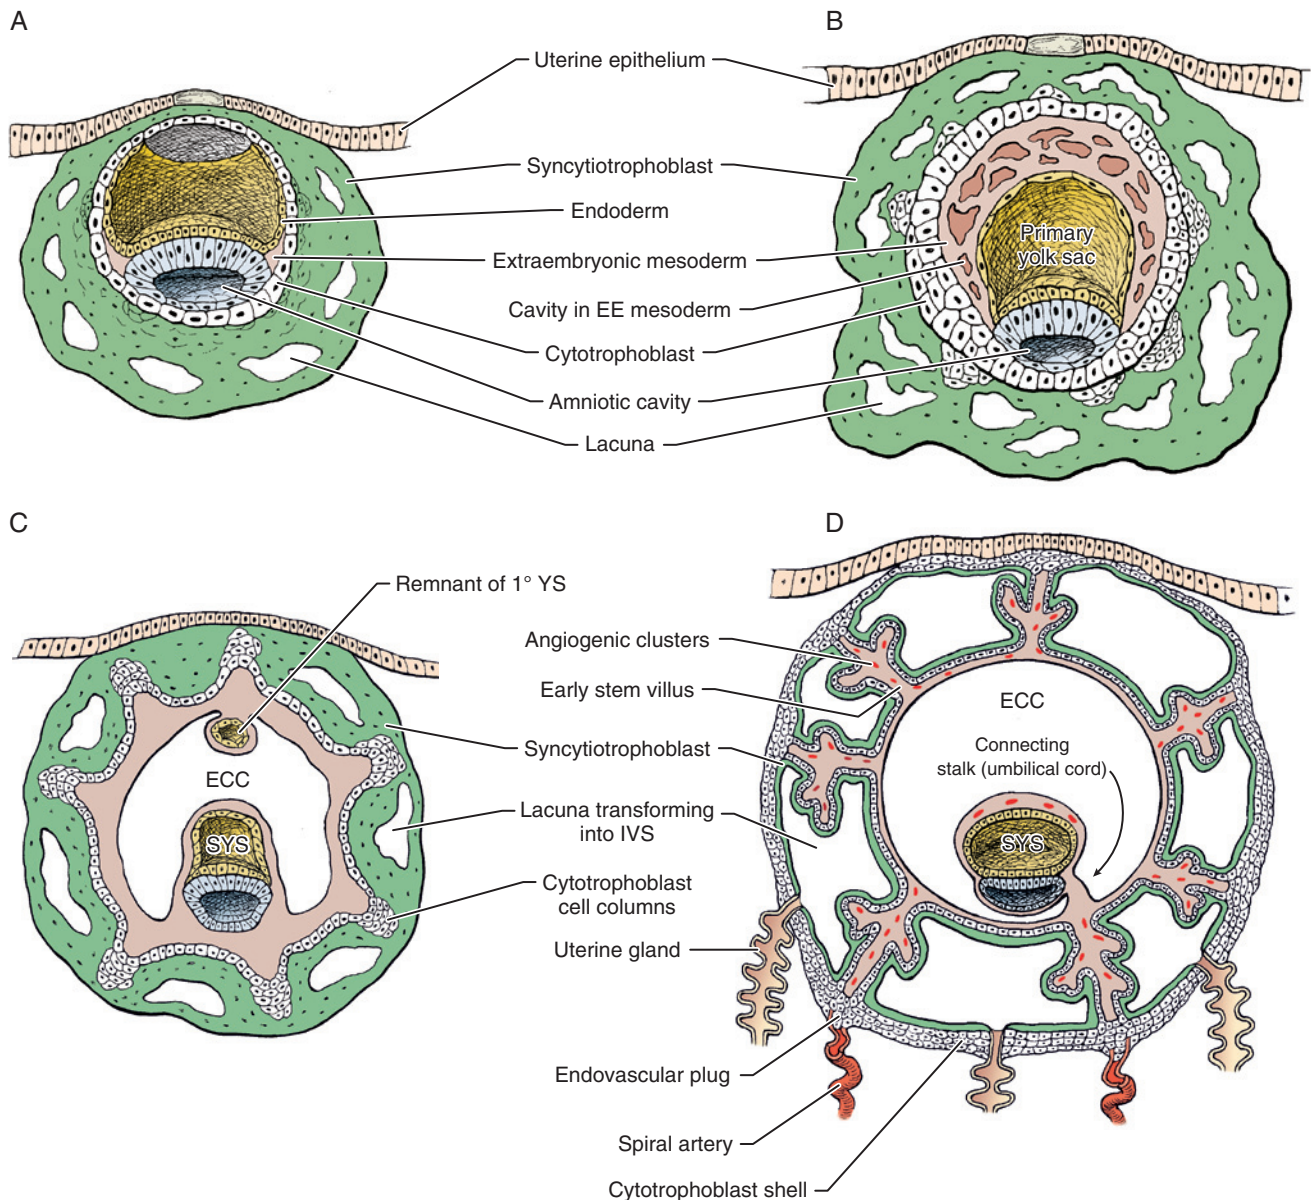

**FIG 1-1** Diagrammatic cross section through a mature placenta shows the chorionic and basal plates that bound the intervillous space. The villous trees arise from stem villi attached to the chorionic plate and are arranged as lobules centered over the openings of the maternal spiral arteries. MC, maternal circulation.

in contact with the endometrium undergoes a syncytial transformation, and tongues of syncytiotrophoblast begin to penetrate between the endometrial cells. No evidence suggests cell death is induced as part of this process, but gradually the conceptus embeds into the stratum compactum of the endometrium.

Recent ultrasound and comparative data indicate that upgrowth and encapsulation by the endometrium may be just as important as trophoblast invasion in this process.<sup>2</sup> The earliest ex vivo specimens available for study are estimated to be around 7 days postfertilization, and in these, the conceptus is almost entirely embedded. A plug of fibrin initially seals the defect in the uterine surface, but by days 10 to 12, the epithelium is restored.

**By the time implantation is complete, the conceptus is surrounded entirely by a mantle of syncytiotrophoblast (Fig. 1-2, A).** This multinucleated mantle tends to be thicker beneath

the conceptus, in association with the embryonic pole, and it rests on a layer of uninucleate cytotrophoblast cells derived from the original wall of the blastocyst. **Vacuolar spaces begin to appear within the mantle and gradually coalesce to form larger lacunae, the forerunners of the IVS.** As the lacunae enlarge, the intervening syncytiotrophoblast is reduced in thickness and forms a complex lattice of trabeculae (see Fig. 1-2, B). Soon after, starting around day 12 after fertilization, the cytotrophoblast cells proliferate and penetrate into the trabeculae. On reaching their tips approximately 2 days later, the cells spread laterally and establish contact with those from other trabeculae to form a new layer interposed between the mantle and the endometrium, the *cytotrophoblastic shell* (see Fig. 1-2, C). Finally, at the start of the third week of development, mesodermal cells derived from the extraembryonic mesoderm invade the trabeculae, bringing with them the hemangioblasts from which the fetal vascular circulation differentiates. The mesoderm

**FIG 1-2** Schematic representation of early placental development between days 9 and 16 postfertilization. ECC, extraembryonic cavity; EE, extraembryonic; IVS, intervillous space; SYS, secondary yolk sac; YS, yolk sac.

cells do not penetrate right to the tips of the trabeculae, and these remain as an aggregation of cytotrophoblast cells—the *cytotrophoblast cell columns*, which may or may not have a covering of syncytiotrophoblast (see Fig. 1-2, C). Proliferation of the cells at the proximal ends of the columns and their subsequent differentiation contribute to expansion of the cytotrophoblastic shell. Toward the end of the third week, the rudiments of the placenta are therefore in place. **The original wall of the blastocyst becomes the chorionic plate, the cytotrophoblastic shell is the precursor of the basal plate, and the lacunae form the IVS (Fig. 1-2, D).** The trabeculae are the forerunners of the villous trees, and repeated lateral branching gradually increases their complexity.

**Initially, villi form over the entire chorionic sac, but toward the end of the first trimester, they regress from all except the deep pole, where they remain as the definitive discoid placenta. Abnormalities in this process may account for the persistence of villi at abnormal sites on the chorionic sac and, hence, the presence of accessory or succenturiate lobes. Also, excessive asymmetric regression may result in the umbilical cord being attached eccentrically to the placental disc.**

### Amnion and Yolk Sac

While these early stages of placental development are taking place, the inner cell mass differentiates and gives rise to the amnion, the yolk sac, and the bilaminar germ disc. The amnion, the yolk sac, and the fluid compartment in which they lie play an important role in the physiology of early pregnancy; their development will be described. The initial formation of these sacs has been controversial over the years, due mainly to the small number of specimens available for study. However, there now appears to be consensus that the amnion extends from the margins of the epiblast layer over the future dorsal surface of the germ disc, whereas the primary yolk sac extends from the hypoblast layer around the inner surface of the trophoblast, separated from it by a loose reticulum thought to be derived from the endoderm. Over the next few days, considerable remodeling of the yolk sac occurs that involves three closely interrelated processes. First, formation of the primitive streak in the germ disc and the subsequent differentiation of definitive endoderm lead to displacement of the original hypoblast cells into the more peripheral regions of the primary yolk sac. Second, the sac greatly reduces in size, either because the more peripheral portion is nipped off, or because it breaks up into a number of vesicles. Third, the reticulum splits into two layers of mesoderm except at the future caudal end of the germ disc, where it persists as a mass; this is the connecting stalk that links the disc to the trophoblast. One layer lines the inner surface of the trophoblast, contributing to formation of the chorion, and the other covers the outer surfaces of the amnion and yolk sac. In between these layers is a large fluid-filled space, the *exocoelomic cavity* (ECC). **The net result of this remodeling is the formation of a smaller secondary yolk sac (SYS); connected to the embryo by the vitelline duct, it floats within the ECC (see Fig. 1-2, D).**

The ECC is a conspicuous feature ultrasonographically that can be clearly visualized using a transvaginal probe toward the end of the third week after fertilization (fifth week of gestational age). Between 5 and 9 weeks of pregnancy, it represents the largest anatomic space within the chorionic sac. **The SYS is the first structure that can be detected ultrasonographically within that space, and its diameter increases slightly**

**between 6 and 10 weeks of gestation to reach a maximum of 6 to 7 mm, and then it decreases slightly.** Histologically, the SYS consists of an inner layer of endodermal cells linked by tight junctions at their apical surface and bearing a few short microvilli. Their cytoplasm contains numerous mitochondria, whorls of rough endoplasmic reticulum, Golgi bodies, and secretory droplets; this gives them the appearance of being highly active synthetic cells. With further development, the epithelium becomes folded to form a series of cyst-like structures or tubules, only some of which communicate with the central cavity. The function of these spaces is not known, although it has been proposed that they serve as a primitive circulatory network in the earliest stages of development because they may contain nonnucleated erythrocytes. On its outer surface, the yolk sac is lined by a layer of mesothelium derived from the extraembryonic mesoderm. This epithelium bears a dense covering of microvilli, and the presence of numerous coated pits and pinocytotic vesicles gives it the appearance of an absorptive epithelium. Although no direct evidence has yet been obtained of this function in the human, transport proteins for glucose and folate have been immunocalized to this layer.<sup>3</sup> Experiments in the rhesus monkey have revealed that the mesothelial layer readily engulfs horseradish peroxidase, and the proposed transport function is reinforced by the presence of a well-developed capillary plexus immediately beneath the epithelium that drains through the vitelline veins to the developing liver.

**However, by week 9 of pregnancy, the SYS begins to exhibit morphologic evidence of a decline in function.** This appears to be independent of the expansion of the amnion, which is gradually drawn around the ventral surface of the developing embryo. As it does this, it presses the yolk sac remnant against the connecting stalk, thus forming the umbilical cord. By the end of the third month, the amnion abuts the inner surface of the chorion, and the ECC is obliterated. The fusion of the amnion and chorion and elimination of the ECC can be seen by ultrasound at around 15 weeks of gestation.

### Maternal-Fetal Relationship During the First Trimester

**For the placenta to function efficiently as an organ of exchange, it requires adequate and dependable access to the maternal circulation. Establishing that access is arguably one of the most critical aspects of placental development, and over recent years, it has certainly been one of the most controversial.** As the syncytiotrophoblastic mantle enlarges, it soon comes in close proximity to superficial veins within the endometrium. These undergo dilation to form sinusoids, which are subsequently tapped into by the syncytium. As a result, maternal erythrocytes come to lie within the lacunae, and their presence has in the past been taken by embryologists as indicating the onset of the maternal circulation to the placenta. If this is a circulation, however, it is entirely one of venous ebb and flow, possibly influenced by uterine contractions and other forces. Numerous traditional histologic studies have demonstrated that arterial connections are not established with the lacunae until much later in pregnancy,<sup>4,5</sup> although the exact timing was not known for many years. The advent of high-resolution ultrasound and Doppler imaging has appeared to answer this question, for in normal pregnancies most observers agree that moving echoes indicative of significant fluid flow cannot be detected within the IVS until 10 to 12 weeks of gestation.

It is now well accepted on the basis of evidence from a variety of techniques that a major change in the maternal circulation to the placenta takes place at the end of the first trimester. First, direct vision into the IVS during the first trimester with a hysteroscope reveals the cavity to be filled with a clear fluid rather than with maternal blood.<sup>6</sup> Second, perfusion of pregnant hysterectomy specimens with radiopaque and other media demonstrates little flow into the IVS during the first trimester, except perhaps at the margins of the placental disc.<sup>4</sup> Third, the oxygen concentration within the IVS is low (<20 mm Hg) prior to 10 weeks of pregnancy, and it rises threefold between weeks 10 and 12.<sup>7</sup> This rise is matched by increases in the mRNA concentrations encoding and in activities of the principal antioxidant enzymes in the placental tissues that confirm a change in oxygenation at the cellular level.<sup>7</sup> The mechanism that underlies this change in placental perfusion relates to the phenomenon of extravillous trophoblast invasion.

### Extravillous Trophoblast Invasion and Physiologic Conversion of the Spiral Arteries

During the early weeks of pregnancy, a subpopulation of trophoblast cells migrates from the deep surface of the cytotrophoblastic shell into the endometrium. Because these cells do not take part in the development of the definitive placenta, they are referred to as *extravillous trophoblast*. Their activities are, however, fundamental to the successful functioning of the placenta, for their presence in the endometrium is associated with the physiologic conversion of the maternal spiral arteries. The cytologic basis of this phenomenon is still not understood, but the net effect is the loss of the smooth muscle cells and elastic fibers from the media of the endometrial segments of the arteries and their subsequent replacement by fibrinoid.<sup>8,9</sup> Some evidence suggests that this is a two-stage process. Very early in pregnancy, the arteries display endothelial basophilia and vacuolation, disorganization of the smooth muscle cells, and dilation. Because these changes are observed equally in both the decidua basalis and parietalis, and because they are also seen within the uterus in cases of ectopic pregnancies, they must be independent of local trophoblast invasion. Instead, it has been proposed that these changes result from activation of decidual renin-angiotensin signaling. Slightly later, during the first few weeks of pregnancy, the invading extravillous trophoblasts become closely associated with the arteries and infiltrate their walls. Further dilation ensues, and as a result, the arteries are converted from small-caliber vasoreactive vessels into funnel-shaped flaccid conduits.

The extravillous trophoblast population can be separated into two subgroups: the *endovascular trophoblast* migrates in a retrograde fashion down the lumens of the spiral arteries, replacing the endothelium; and the *interstitial trophoblast* migrates through the endometrial stroma. In early pregnancy, the volume of the migrating endovascular cells is sufficient to occlude, or plug, the terminal portions of the spiral arteries as they approach the basal plate (Fig. 1-3).<sup>4,5</sup> It is the dissipation of these plugs toward the end of the first trimester that establishes the maternal circulation to the placenta. The mechanism of unplugging of the arteries is unknown at present but could potentially reflect changes in endovascular trophoblast motility or alterations in maternal hemodynamics. Trophoblast invasion is not equal across the implantation site; rather it is greatest in the central region, where it has presumably been established the

longest. It is to be expected, therefore, that the plugging of the spiral arteries will be most extensive in this region, and this may account for the fact that maternal arterial blood flow is most often first detectable ultrasonographically in the peripheral regions of the placental disc.<sup>10</sup> Associated with this blood flow is a high local level of oxidative stress, which can be considered physiologic because it occurs in all normal pregnancies. It has recently been proposed that this stress induces regression of the villi over the superficial pole of the chorionic sac, so forming the chorion laeve (Fig. 1-4).<sup>10</sup>

Under normal conditions, the interstitial trophoblast cells invade as far as the inner third of the myometrium, where they fuse and form multinucleated giant cells. It is essential that the process is correctly regulated; excessive invasion can result in complete erosion of the endometrium and the condition known as *placenta accreta* (see Chapter 21). As they migrate, the trophoblast cells interact with cells of the maternal immune system present within the decidua, in particular macrophages and uterine natural killer (NK) cells. These interactions may play a physiologic role in regulation of the depth of invasion and in the conversion of the spiral arteries. Uterine NK cells accumulate in the endometrium during the secretory phase of the non-pregnant cycle and are particularly numerous surrounding the spiral arteries at the implantation site. Despite their name, no evidence suggests that they destroy trophoblast cells. On the contrary, their cytoplasm contains numerous granules with a diverse array of cytokines and growth factors. Extravillous trophoblast cells express the polymorphic human leukocyte C-antigen (HLA-C) that binds to killer cell immunoglobulin-like receptors (KIRs) on the NK cells. Recent evidence indicates that a degree of activation of the NK cells is necessary for successful pregnancy, most likely because of the release of factors that mediate spiral artery remodeling. Hence, combinations of HLA-C antigen and KIR subtypes that are generally inhibitory are associated with a high risk of pregnancy complications,<sup>11</sup> which emphasizes the importance of immunologic interactions to reproductive success.

Physiologic conversion of the spiral arteries is often attributed with ensuring an adequate maternal blood flow to the placenta, but such comments generally oversimplify the phenomenon. By itself, the process cannot increase the volume of blood flow to the placenta because it only affects the most distal portion of the spiral arteries. The most proximal part of the arteries, where they arise from the uterine arcuate arteries, always remains unconverted, and will act as the rate-limiting segment. These segments gradually dilate in conjunction with the rest of the uterine vasculature during early pregnancy, most probably under the effects of estrogen; as a result, the resistance of the uterine circulation falls, and uterine blood flow increases from approximately 45 mL/min during the menstrual cycle to around 750 mL/min at term or 10% to 15% of maternal cardiac output.

By contrast, the terminal dilation of the arteries will substantially reduce both the rate and pressure with which that maternal blood flows into the IVS. Mathematic modeling has demonstrated that physiologic conversion is associated with a reduction in velocity from 2 to 3 m/sec in the nondilated section of a spiral artery to approximately 10 cm/sec at its mouth.<sup>12</sup> This reduction in the velocity will ensure that the delicate villous trees are not damaged by the momentum of the inflowing blood. Slowing the rate of maternal blood flow across the villous trees will also facilitate exchange, whereas lowering the

**FIG 1-3** During early pregnancy, the tips of the maternal spiral arteries are occluded by invading endovascular trophoblast cells, which impedes flow into the intervillous space. The combination of endovascular and interstitial trophoblast invasion is associated with physiologic conversion of the spiral arteries. Both processes are deficient in preeclampsia, and the retention of vascular smooth muscle may increase the risk of spontaneous vasoconstriction and hence may result in an ischemia-reperfusion type injury to the placenta. MC, maternal circulation.

**pressure in the IVS is important to prevent compression and collapse of the fetal capillary network within the villi.** Measurements taken in the rhesus monkey indicate that the pressure at the mouth of a spiral artery is only 15 mm Hg and within the IVS is on average 10 mm Hg. The pressure within the fetal villous capillaries is estimated to be approximately 20 mm Hg, providing a pressure differential that favors their distension of 5 mm Hg.

Many complications of pregnancy are associated with defects in extravillous trophoblast invasion and failure to establish the maternal placental circulation correctly. In the most severe cases, the cytotrophoblastic shell is thin and fragmented; this is observed in approximately two thirds of spontaneous miscarriages.<sup>13</sup> Reduced invasion may reflect defects inherent in the conceptus, such as chromosomal aberrations, or it may be due to thrombophilia, endometrial dysfunction, or other problems in the mother. The net result is that onset of the maternal circulation is both precocious and widespread throughout the developing placenta, consequent upon absent or incomplete plugging of the maternal arteries.<sup>10</sup> Hemodynamic forces coupled with excessive oxidative stress within the

placental tissues<sup>14</sup> are likely to be major factors that contribute to loss of these pregnancies.

In milder cases, the pregnancy may continue, but it is complicated later by preeclampsia, intrauterine growth restriction (IUGR), or a combination of the two. The physiologic changes are either restricted to only the superficial endometrial parts of the spiral arteries or are absent all together (see Fig. 1-3). In the most severe cases of preeclampsia associated with major fetal growth restriction, only 10% of the arteries may be fully converted, compared with 96% in normal pregnancies.<sup>15</sup> There is still debate as to whether this is due to an inability of the interstitial trophoblast to invade the endometrium successfully, or whether having invaded sufficiently deeply, the trophoblast cells fail to penetrate the walls of the arteries. These two possibilities are not mutually exclusive and may reflect different etiologies.

Whatever the causation, there are several potential consequences to incomplete conversion of the arteries. First, because of the absence of the distal dilation, maternal blood will enter the IVS with greater velocity than normal, forming jetlike spurts that can be detected ultrasonographically. The villous trees are

**FIG 1-4** Onset of the maternal circulation (MC) starts in the periphery of the placenta (arrows), where trophoblast invasion—and hence plugging of the spiral arteries—is least developed. The high local levels of oxidative stress are thought to induce villous regression and formation of the chorion laeve. AC, amniotic cavity; D, decidua; ECC, exocoelomic cavity; P, placenta; M, myometrium; SYS, secondary yolk sac. (Modified from Jauniaux E, Cindrova-Davies T, Johns J, et al. Distribution and transfer pathways of antioxidant molecules inside the first trimester human gestational sac. *J Clin Endocrinol Metab*. 2004;89:1452-1459.)

often disrupted opposite these spurts, which leads to the formation of intervillous blood lakes, and the altered hemodynamics within the IVS result in thrombosis and excessive fibrin deposition. Second, incomplete conversion will allow the spiral arteries to maintain greater vasoreactivity than normal. Evidence from rhesus monkeys and humans shows that spiral arteries are not continuously patent but that they undergo periodic constriction independent of uterine contractions.<sup>10,16</sup> It has recently been proposed that exaggeration of this phenomenon due to the retention of smooth muscle in the arterial walls may lead to a hypoxia-reoxygenation-type injury in the placenta, which culminates in the development of oxidative stress. **Placental oxidative stress is a key factor in the pathogenesis of preeclampsia, and clinical evidence suggests that hypoxia-reoxygenation is a more physiologic stimulus for its generation than simply reduced uterine perfusion.**<sup>17</sup> The third consequence of incomplete conversion is that the distal segments of the arteries are frequently the site of acute atherotic changes.<sup>18</sup> These are likely to be secondary changes, possibly induced by the involvement of these segments in the hypoxia-reoxygenation process or their abnormal hemodynamics; however, if the lesions become occlusive, they will further impair blood flow within the IVS, which contributes to the growth restriction.

### Role of the Endometrium During the First Trimester

Signals from the uterine epithelium and secretions from the endometrial glands play a major role in regulating receptivity

at the time of implantation, but the potential contribution of the glands to fetal development once implantation is complete has largely been ignored. This has been due to the general assumption that once the conceptus is embedded within the uterine wall, it no longer has access to the secretions in the uterine lumen. However, a review of archival placenta in situ hysterectomy specimens has revealed that **the glands discharge their secretions into the IVS through openings in the basal plate throughout the first trimester** (see Fig. 1-2).<sup>19</sup> The secretions are a heterogeneous mix of maternal proteins; carbohydrates, including glycogen; and lipid droplets phagocytosed by the syncytiotrophoblast. Recently, it has been demonstrated that the pattern of sialylation of the secretions changes between the late secretory phase of the nonpregnant cycle and early pregnancy.<sup>20</sup> A loss of terminal sialic acid caps occurs, which will render the secretions more easily degradable by the trophoblast following their phagocytic uptake. The fact that glycodefin, formerly referred to as *PP14* or  $\alpha_2$ -*PEG*, is derived from the glands and yet accumulates within the amniotic fluid with concentrations that peak at around 10 weeks' gestation indicates that the placenta must be exposed to glandular secretions extensively throughout the first trimester.

**Ultrasonographic measurements suggest that an endometrial thickness of 8 mm or more is necessary for successful implantation**, although not all studies have found such an association. Nonetheless, these measurements are in line with observations based on placenta-in-situ specimens, in which an endometrial thickness of over 5 mm was reported beneath the conceptus at 6 weeks of gestation.<sup>21</sup> Gradually, over the remainder of the first trimester, the endometrium regresses so that by 14 weeks of gestation, the thickness is reduced to 1 mm. Histologically, there is also a transformation in the glandular epithelial cells over this period. During early pregnancy, they undergo characteristic hypersecretory morphologic changes, the so-called Arias-Stella reaction,<sup>22</sup> and their cytoplasm contains abundant organelles and large accumulations of glycogen.<sup>19,21</sup> These changes are likely a response to placental lactogens and prolactin from the decidua, which represents a servomechanism by which the placenta induces upregulation of its own nutrient supply. However, by the end of the first trimester, the cells are more cuboidal, and secretory organelles are much less prominent, although the lumens of the glands are still filled with secretions.

**The overall picture is that the glands are most prolific and active during the early weeks of pregnancy, and that their contribution gradually wanes during the first trimester. This would be consistent with a progressive switch from histotrophic to hemotrophic nutrition as the maternal arterial circulation to the placenta is established.** The glands should not be considered solely as a source of nutrients; their secretions are also rich in growth factors such as leukemia inhibitory factor, vascular endothelial growth factor (VEGF), epidermal growth factor, and transforming growth factor beta (TGF- $\beta$ ).<sup>21</sup> Receptors for these factors are present on the villous tissues, so the glands may play an important role in modulating placental proliferation and differentiation during early pregnancy, as in other species. The change in sialylation in early pregnancy will ensure that any of the secretions that gain access to the maternal circulation via the uterine veins will be rapidly cleared in the maternal liver. Hence, a unique proliferative microenvironment can be created within the IVS of the early placenta without placing the mother's tissues at risk of excessive stimulation. Attempts to correlate the

functional activity of the glands with pregnancy outcome have met with mixed success. Thus reduced concentrations of mucin 1, glycodein, and leukemia inhibitory factor have been reported in uterine flushings from women who have suffered repeated miscarriages.<sup>23</sup> However, a recent study has shown no significant association between the expression of these markers within the endometrium and outcome.<sup>24</sup> This difference may reflect impairment in the secretory, rather than the synthetic, machinery of the gland cells, although further work is required to confirm this point.

**From the evidence available, it would appear that the functional importance of the endometrial glands to a successful pregnancy extends well beyond the time of implantation.**

### Topology of the Villous Trees

**One of the principal functions of the placenta is diffusional exchange, and the physical requirements for this impose the greatest influence on the structure of the organ. The rate of diffusion of an inert molecule is governed by Fick's law, so it is proportional to the surface area for exchange divided by the thickness of the tissue barrier. A large surface area will therefore facilitate exchange, and this is achieved by repeated branching of the villous trees.**

The villous trees arise from the trabeculae interposed between the lacunae (see Fig. 1-2) through a gradual process of remodeling and lateral branching. Initially, the different branches have an almost uniform composition, and the villi can be separated only by their relative size and position in the hierarchical branching pattern. At this stage, the mesodermal core is loosely packed, and at the proximal end of the trees, it blends with the extraembryonic mesoderm that lines the ECC. The stromal cells possess sail-like processes that often link together to form fluid-filled channels orientated parallel to the long axis of the villi. Macrophages are often seen within these channels, so it is possible they function as a primitive circulatory system prior to vasculogenesis. In this way proteins derived from the uterine glands could freely pass into the coelomic fluid, and it is notable that the macrophages within the channels are strongly immunoreactive for maternal glycodein<sup>19</sup> secreted from the glands.

Toward the end of the first trimester, the villi begin to differentiate into their principal types. **The connections to the chorionic plate become remodeled to form stem villi, which represent the supporting framework of each villous tree.**<sup>25</sup> These progressively develop a compact fibrous stroma and contain branches of the chorionic arteries and accompanying veins. The arteries are centrally located and are surrounded by a cuff of smooth muscle cells. **Although these have the appearance of resistance vessels, physiologic studies indicate that under normal conditions, the fetal placental circulation operates under conditions of full vasodilation.** Stem villi contain only a few small caliber capillaries, and so they play little role in placental exchange.

After several generations of branching, stem villi give rise to intermediate villi. These are longer and more slender in form and can be of two types: immature and mature. The former are seen predominantly in early pregnancy and represent a persistence of the nondifferentiated form as indicated by the presence of fluid-filled stromal channels. Mature intermediate villi provide a distributing framework, and terminal villi arise at intervals from their surface. Within the core are arterioles and venules

but also a significant number of nondilated capillaries, which suggest a limited capacity for exchange.

**The main functional units of the villous tree are, however, the terminal villi.** There is no strict definition as to where a terminal villus starts, but they are most often short, stubby branches up to 100  $\mu\text{m}$  in length and approximately 80  $\mu\text{m}$  in diameter that arise from the intermediate villi (Fig. 1-5).<sup>25</sup> They are highly vascularized, but by capillaries alone, and they are highly adapted for diffusional exchange, as will be seen later.

This differentiation of the villi coincides temporally with the development of the lobular architecture, and the two processes are most likely interlinked. Lobules can be first identified during the early second trimester, following onset of the maternal circulation, when it is thought hemodynamic forces may shape the villous tree. Convincing radiographic and morphologic evidence shows that maternal blood is delivered into the center of the lobule and that it then disperses peripherally, as in the rhesus monkey placenta.<sup>26</sup> Consequently, it is to be expected that an oxygen gradient will exist across the lobule, and differences in the activities and expression of antioxidant enzymes within the villous tissues suggest strongly that this is the case. Other metabolic gradients (e.g., glucose concentration) may also exist, and together these may exert powerful influences on villous differentiation. Villi in the center of the lobule, where the oxygen concentration will be highest, display morphologic and enzymatic evidence of relative immaturity, and so this is considered to be the germinative zone. By contrast, villi in the periphery of the lobule are better adapted for diffusional exchange.

**Elaboration of the villous tree is a progressive event that continues at a steady pace throughout pregnancy, and by term, the villi present a surface area of 10 to 14 m<sup>2</sup>. This may be significantly reduced in cases of IUGR, although this principally reflects an overall reduction in placental volume rather than maldevelopment of the villous tree.**<sup>27</sup> In cases of preeclampsia alone, villous surface area is normal and is only compromised with associated growth restriction.<sup>27</sup> Attempts have recently been made to monitor placental growth longitudinally during pregnancy using ultrasound. Although the data show considerable individual variability, they indicate that in cases of growth restriction or macrosomia, placental volume is significantly reduced or increased, respectively, at 12 to 14 weeks. **These findings suggest that ultimate placental size has its origins firmly in the first trimester.**

## PLACENTAL HISTOLOGY

The epithelial covering of the villous trees is formed by the syncytiotrophoblast. As its name indicates, this is a true multinucleated syncytium that extends without lateral intercellular clefts over the entire villous surface. In essence, the syncytiotrophoblast acts as the endothelium of the IVS, and everything that passes across the placenta must pass through this layer, either actively or passively. This tissue also performs all hormone synthesis in the placenta, and so a number of potentially conflicting demands are placed upon it.

The syncytiotrophoblast is highly polarized, and one of its most conspicuous features is the presence of a dense covering of **microvilli** on the apical surface. In the first trimester, the microvilli are relatively long (approximately 0.75 to 1.25  $\mu\text{m}$  in length and 0.12 to 0.17  $\mu\text{m}$  in diameter), but as pregnancy advances, they become shorter and more slender, being approximately 0.5 to 0.7  $\mu\text{m}$  in length and 0.08 to 0.14  $\mu\text{m}$  in diameter at term.

**FIG 1-5** Diagrammatic representation of an intermediate villus with terminal villi arising from the lateral surface.

The microvillous covering is even over the villous surface, and measurements of the amplification factor provided vary from 5.2 to 7.7. Many receptors and transport proteins have been localized to the microvillous surface by molecular biologic and immunohistochemical techniques, as will be discussed later. The receptors are thought to reside in lipid rafts, and once bound to their ligand, they migrate to the base of the microvilli, where clathrin-coated pits are present (see Fig. 1-5).<sup>28</sup> Receptor-ligand complexes are concentrated in the pits, which are then internalized. Disassociation of ligands such as cholesterol may occur in the syncytioplasm, whereas other ligands, such as immunoglobulin G, are exocytosed at the basal surface.

Support for the microvillous architecture is provided by a substantial network of actin filaments and microtubules that lie just beneath the apical surface. Also present within the syncytioplasm are numerous pinocytotic vesicles, phagosomes, lysosomes, mitochondria, secretory droplets, strands of endoplasmic reticulum, Golgi bodies, and lipid droplets.<sup>28</sup> **The overall impression is of a highly active epithelium engaged in absorptive, secretory, and synthetic functions. Therefore it is not surprising that the syncytiotrophoblast has a high metabolic rate, consuming approximately 40% of the oxygen taken up by the fetoplacental unit.**<sup>29</sup>

The syncytiotrophoblast is a terminally differentiated tissue; consequently, mitotic figures are never observed within its nuclei. It has been suggested that this condition, which is frequently observed in the fetal cells at the maternal-fetal interface in other species, reduces the risk of malignant transformation in the trophoblast and so protects the mother. Whatever the reason, **the syncytiotrophoblast is generated by the recruitment of**

**progenitor cytotrophoblast cells**, which are uninucleate and lie on a well-developed basement membrane immediately beneath the syncytium. A proportion represents progenitor cells that undergo proliferation, with daughter cells that undergo progressive differentiation.<sup>30</sup> Consequently, a range of morphologic appearances are seen, from cuboidal resting cells with a general paucity of organelles to fully differentiated cells that closely resemble the overlying syncytium.<sup>28</sup> Ultimately, membrane fusion takes place between the two, and the nucleus and cytoplasm are incorporated into the syncytiotrophoblast. Early in pregnancy, the cytotrophoblast cells form a complete layer beneath the syncytium, but as pregnancy advances, the cells become separated and are seen less frequently in histologic sections. In the past this observation was interpreted as being indicative of a reduction in the number of cytotrophoblast cells and therefore a reduction in the proliferative potential of the trophoblast layers. More recent stereologic estimates have revealed a different picture, however, because the total number of these cells increases until term.<sup>31</sup> The apparent decline results from the fact that villous surface area increases at a greater rate, and so cytotrophoblast cell profiles are seen less often in any individual histologic section.

The stimuli that regulate cytotrophoblast cell proliferation are not fully understood. In early pregnancy, prior to 6 weeks, epidermal growth factor (EGF) may play an important role; expression of both the factor and its receptor are localized principally to these cells. EGF is also strongly expressed in the epithelium of the uterine glands,<sup>21</sup> and in the horse, a tight spatial and temporal correlation exists between glandular expression and proliferation in the overlying trophoblast. Later during the first

trimester, insulin-like growth factor II (IGF-II) can be immunolocalized to the cytotrophoblast cells, as can the receptor for hepatocyte growth factor—a powerful mitogen expressed by the mesenchymal cells, which provides the possibility of paracrine control. Environmental stimuli may also be important, and hypoxia has long been known to stimulate cytotrophoblast proliferation in vitro. A greater number of cell profiles are also observed in placentae from high altitudes, where they are exposed to hypobaric hypoxia, and in conditions associated with poor placental perfusion. However, whether this represents increased proliferation or decreased fusion with the syncytiotrophoblast is uncertain.

The factors that regulate and mediate fusion are equally uncertain. Growth factors such as EGF, granulocyte-macrophage colony-stimulating factor (GM-CSF), and VEGF are able to stimulate fusion in vitro, as are the hormones estradiol and human chorionic gonadotropin (hCG). By contrast, TGF- $\beta$ , leukemia inhibitory factor, and endothelin inhibit the process, which suggests that the outcome in vivo depends on a balance between these opposing influences. One of the actions of hCG at the molecular level is to promote the formation of gap junctions between cells, and strong experimental evidence suggests that communication via gap junctions is an essential prerequisite in the fusion process.<sup>32</sup> Whether membrane fusion is initiated at the sites of gap junctions is not known at present, but much interest has been paid recently to other potential mechanisms of fusion. One such is the externalization of phosphatidylserine on the outer leaflet of the cell membrane, although whether this represents part of an apoptotic cascade that is only completed in the syncytiotrophoblast or is inherent to cytotrophoblastic differentiation remains controversial. Another is the expression of human endogenous retroviral envelope proteins HERV-W env and HERV-FRD env, commonly referred to as *syncytin 1* and *syncytin 2*, respectively. The first protein entered the primate genome approximately 25 million years ago, the second over 40 million years ago, and these are considered to have fusogenic and immunomodulatory roles.<sup>33</sup> Expression of syncytin appears to be necessary for syncytial transformation of trophoblast cells in vitro, and ectopic expression in other cell types renders them fusogenic. **Syncytin interacts with the amino acid transporter protein ASCT2, and the expression of both is influenced by hypoxia in trophoblast cell lines in vitro. This could provide an explanation for the increased number of cytotrophoblast cells observed in placentae from hypoxic pregnancies.**

Although it is clear that the cascade of events that control cytotrophoblastic proliferation and fusion has yet to be fully elucidated, it appears to be tightly regulated in vivo. Thus the ratio of cytotrophoblastic to syncytial nuclei remains at approximately 1:9 throughout pregnancy,<sup>31</sup> although it may be perturbed in pathologic cases. Recent evidence from immunohistochemistry and the incorporation of fluorouridine suggests that a constant proportion of the nuclei (approximately 80%) are transcriptionally active across gestation,<sup>34</sup> which enables the tissue to respond more rapidly and independently to challenges. **Nuclei that are transcriptionally inactive are sequestered together into aggregates known as syncytial knots. These nuclei display dense heterochromatin and also show evidence of oxidative changes, which suggests they are aged or damaged in some way.**<sup>35</sup> Syncytial knots become more common in later pregnancy and are taken by pathologists as a marker of syncytial well-being, the so-called Tenney-Parker change.

## Integrity of the Villous Membrane

**One situation that may alter the balance of the two populations of nuclei is damage to the trophoblast layers and the requirement for repair.** Isolated areas of syncytial damage, often referred to as sites of *focal syncytial necrosis*, are a feature of all placentae, although they are more common in those from pathologic pregnancies. Their origin remains obscure but they could potentially arise from altered hemodynamics within the IVS or from physical interactions between villi. One striking example of the latter is the rupture of syncytial bridges that form between adjacent villi and lead to circular defects on the surface 20 to 40  $\mu$ m in diameter. Disruption of the microvillous surface leads to the activation of platelets and to the deposition of a fibrin plaque on the trophoblastic basement membrane. Apoptosis of syncytial nuclei has been reported in the immediate vicinity of such plaques, but whether this reflects cause or effect has yet to be determined. With time, cytotrophoblast cells migrate over the plaque, differentiate, and fuse to form a new syncytiotrophoblastic layer. As a result, the plaque is internalized, and the integrity of the villous surface is restored. In the interim, however, these sites are nonselectively permeable to creatinine and may represent a paracellular route for placental transfer.<sup>36</sup>

In the past, more widespread apoptosis in the syncytiotrophoblast has been reported, with the interpretation that this reflects increased turnover of the trophoblast in pathologic conditions. However, recent research has clarified that although rates of apoptosis are increased in preeclampsia and IUGR, the cell death is confined to the cytotrophoblast cells.<sup>37</sup>

Extensive damage to the syncytiotrophoblast is seen in cases of missed miscarriage, in which complete degeneration and sloughing of the layer can occur.<sup>10,14</sup> Although apoptosis and necrosis are increased among the cytotrophoblast cells, the remaining cells differentiate and fuse to form a new and functional syncytial layer. A similar effect is observed when villi from either first trimester or term placentae are maintained under ambient conditions in vitro.

Thus it is likely that considerable turnover of the syncytiotrophoblast takes place over the course of a pregnancy, although in the absence of longitudinal studies, it is impossible to determine the extent of this phenomenon. Nonetheless, it is clear that the villous membrane cannot be considered an intact physical barrier and that other elements of the villous trees may play important roles in regulating maternal-fetal transfer.

## Placental Vasculature

**The development of the fetal vasculature begins during the third week after conception (the fifth week of pregnancy) with the de novo formation of capillaries within the villous stromal core.** Hemangioblastic cell cords differentiate under the influence of growth factors such as basic fibroblast growth factor and VEGF.<sup>38</sup> By the beginning of the fourth week, the cords have developed lumens, and the endothelial cells become flattened. Surrounding mesenchymal cells become closely apposed to the tubes and differentiate to form pericytes. During the next few days, connections form between neighboring tubes to form a plexus, and this ultimately unites with the allantoic vessels developing in the connecting stalk to establish the fetal circulation to the placenta.

Exactly when an effective circulation is established through these vessels is difficult to determine. First, the connection between the corporeal and extracorporeal fetal circulations is initially particularly narrow, which suggests there can be little

flow. Second, the narrow caliber of the villous capillaries, coupled with the fact that the fetal erythrocytes are nucleated during the first trimester and hence are not readily deformable, will ensure that the circulation presents a high resistance to flow. This is reflected in the Doppler waveform obtained during the first trimester, and the resistance gradually falls as the vessels enlarge over the ensuing weeks.

Early in pregnancy, there are relatively few pericytes, and the capillary network is labile and undergoes considerable remodeling. **Angiogenesis continues until term and results in the formation of capillary sprouts and loops. Both of these processes contribute to the elaboration of terminal villi.<sup>39</sup>** The caliber of the fetal capillaries is not constant within intermediate and terminal villi, and frequently on the apex of a tight bend, the capillaries become greatly dilated and form sinusoids. These regions may help to reduce vascular resistance and facilitate distribution of fetal blood flow through the villous trees.<sup>39</sup> Equally important is the fact that the dilations bring the outer wall of the capillaries into close juxtaposition with the overlying trophoblast. The trophoblast is locally thinned, and as a result, the diffusion distance between the maternal and fetal circulations is reduced to a minimum (see Fig. 1-5). Because of their morphologic configuration, these specializations are referred to as *vasculosyncytial membranes*, and they are considered the principal sites of gaseous and other diffusional exchanges. The arrangement can be considered analogous to that in the alveoli of the lung, where the pulmonary capillaries indent into the alveolar epithelium in order to reduce the thickness of the air-blood diffusion barrier. Thinning of the syncytial layer will not only increase the rate of diffusion into the fetal capillaries, it will also reduce the amount of oxygen extracted by the trophoblast en route. The syncytiotrophoblast is highly active metabolically because of the increased rates of protein synthesis and ionic pumping, but by having an uneven distribution of the tissue around the villous surface, the oxygen demands of the fetus and the placenta can be separated to a large extent.

It is notable that development of vasculosyncytial membranes is seen to its greatest extent in the peripheral regions of a placental lobule, where the oxygen concentration is lowest, and also in placentae from high altitudes. In both instances, it is associated with enlargement of the capillary sinusoids and may be viewed as an adaptive response aimed at increasing the diffusing capacity of the placental tissues. Conversely, an increase in the thickness of the villous membrane is often seen in cases of IUGR and in placentae from cigarette smokers. As mentioned earlier, the hydrostatic pressure differential across the villous membrane is an important determinant of the diameter of the capillary dilations and hence of the villous membrane thickness. Raising the pressure in the IVS not only compresses the capillaries, it also increases the resistance within the umbilical circulation. Both effects will impair diffusional exchange, which highlights the importance of full conversion of the spiral arteries.

**Vascular changes are observed in many complications of pregnancy,<sup>40</sup> where they may underpin changes in the topology of the villous tree. Increased branching of the vascular network is observed in placentae from high altitudes, which causes the terminal villi to be shorter and more clustered than normal. At present, no experimental data indicate that this has any impact on placental exchange; but in theory, this shortening of the arteriovenous pathway may lead to increased efficiency.**

## PLACENTAL PHYSIOLOGY

The placenta provides the fetus with all its essential nutrients, including water and oxygen, and it gives a route for clearance of fetal excretory products in addition to producing a vast array of protein and steroid hormones and factors necessary for the maintenance of pregnancy. In the first trimester, the SYS and the extraembryonic coelom play an important role in protein synthesis and as an additional transport pathway inside the gestational sac. In the last two trimesters, the majority (95%) of maternofetal exchange takes place across the chorioallantoic placenta.

### Physiology of the Secondary Yolk Sac and Exocoelomic Cavity

Now that development of the placenta and the extraembryonic membranes has been covered, we turn to their physiologic roles during pregnancy. Phylogenetically, the oldest membrane is the yolk sac, and the SYS plays a major role in the embryonic development of all mammals. **The function of the yolk sac has been most extensively studied in laboratory rodents. It has been demonstrated that it is one of the initial sites of hematopoiesis, it synthesizes a variety of proteins, and it is involved in maternal-fetal transport.**

The endodermal layer of the human SYS is known to synthesize several serum proteins in common with the fetal liver, such as alpha-fetoprotein (AFP), alpha<sub>1</sub>-antitrypsin, albumin, prealbumin, and transferrin. With rare exceptions, the secretion of most of these proteins is confined to the embryonic compartments, and the contribution of the SYS to the maternal protein pool is limited.<sup>41</sup> This can explain why their concentrations are always higher in the ECC than in maternal serum. AFP is also produced by the embryonic liver from 6 weeks until delivery; it has a high molecular weight ( $\pm 70$  kDa) and, conversely to hCG, is found in similar amounts on both sides of the amniotic membrane. **Analysis of molecular variants of AFP that have an affinity for concanavalin A have demonstrated that AFP molecules within both the coelomic and amniotic fluids are mainly of yolk sac origin, whereas maternal serum AFP molecules are principally derived from the fetal liver.<sup>42</sup>** These results suggest that the SYS also has an excretory function and secretes AFP toward the embryonic and extraembryonic compartments. By contrast, AFP molecules of fetal liver origin are probably transferred from the fetal circulation to the maternal circulation, mainly across the placental villous membrane.

The potential absorptive role of the yolk sac membrane has been evaluated by examining the distribution of proteins and enzymes between the ECC and SYS fluids and by comparing the synthesizing capacity of SYS, fetal liver, and placenta for hCG and AFP.<sup>43</sup> The distribution of the trophoblast-specific hCG in yolk sac and coelomic fluids, together with the absence of hCG mRNA expression in yolk sac tissues, provided the first biologic evidence of its absorptive function. Similarities in the composition of the SYS and coelomic fluids suggest that a free transfer for most molecules occurs between the two corresponding compartments. Conversely, an important concentration gradient exists for most proteins between the ECC and amniotic cavity, indicating that transfer of molecules is limited at the level of the amniotic membrane.

**These findings suggest that the yolk sac membrane is an important zone of transfer between the extraembryonic and**

**embryonic compartments, and that the main flux of molecules occurs from outside the yolk sac—that is, from the ECC—in a direction toward its lumen and subsequently to the embryonic gut and circulation.** The recent identification of specific transfer proteins on the mesothelial covering,<sup>3</sup> and of the multifunctional endocytic receptors megalin and cubilin,<sup>44</sup> lends further support to this concept. When after 10 weeks of gestation, the cellular components of the wall of the SYS start to degenerate, this route of transfer is no longer functional, and most exchanges between the ECC and the fetal circulation must then take place at the level of the chorionic plate.

The development and physiologic roles of the ECC are intimately linked with that of the SYS, for which it provides a stable environment. The concentrations of hCG, estriol, and progesterone are higher in the coelomic fluid than in maternal serum<sup>41</sup> and strongly suggest the presence of a direct pathway between the trophoblast and the ECC. Morphologically, this may be via the villous stromal channels and the loose mesenchymal tissue of the chorionic plate. Protein electrophoresis has also shown that the coelomic fluid results from an ultrafiltrate of maternal serum with the addition of specific placental and SYS bioproducts. For the duration of the first trimester, the coelomic fluid remains straw colored and more viscous than the amniotic fluid, which is always clear. This is mainly due to the higher protein concentration in the coelomic fluid than in the amniotic cavity. The concentration of almost every protein is higher in coelomic fluid than in amniotic fluid, ranging from 2 to 50 times higher depending on the molecular weight of the protein investigated.<sup>41</sup> The coelomic fluid has a very slow turnover, so the ECC may act as a reservoir for nutrients needed by the developing embryo. **These findings suggest that the ECC is a physiologic liquid extension of the early placenta and an important interface in fetal nutritional pathways.** Molecules such as vitamin B<sub>12</sub>, prolactin, and glycodelin (placental protein 14, PP14) are known to be mainly produced by the uterine decida.<sup>41</sup> **This pathway may be pivotal in providing the developing embryo with sufficient nutrients before the intervillous circulation becomes established.**<sup>19</sup>

Some analogies can be drawn between the ECC and the antrum within a developing graafian follicle. It has been suggested that the evolution of the latter was necessary to overcome the problem of oxygen delivery to an increasing large mass of avascular cells. Because the contained fluid has no oxygen consumption, it will permit diffusion more freely than an equivalent thickness of cells. However, because neither follicular nor coelomic fluids contain an oxygen carrier, the total oxygen content must be low. An oxygen gradient will inevitably exist between the source and the target, whether it be an oocyte or an embryo. Measurements in human patients undergoing in vitro fertilization (IVF) have demonstrated that the oxygen tension in follicular fluid falls as follicle diameter, assessed by ultrasound, increases. Thus diffusion across the ECC may be an important route of oxygen supply to the embryo before the development of a functional placental circulation, but it will maintain the early fetus in a low-oxygen environment. This may serve to protect the fetal tissues from damage by O<sub>2</sub> free radicals and may prevent disruption of signaling pathways during the crucial stages of embryogenesis and organogenesis. The presence in the ECC of molecules with a well-established antioxidant role—such as taurine, transferrin, vitamins A and E, and selenium—supports this hypothesis. Associated with this, the low-oxygen environment may also favor the maintenance of “stemness” in embryonic and placental

stem cells. It is notable that the proliferative capacity of the placenta rapidly reduces at the end of the first trimester,<sup>30</sup> which may reflect loss of growth factor stimulation from the endometrial glands or the rise in intraplacental oxygen concentration.

### Placental Metabolism and Growth

**The critical function of the placenta is illustrated by its high metabolic demands. For example, placental oxygen consumption equals that of the fetus, and it exceeds the fetal rate when expressed on a weight basis (10 mL/min/kg).<sup>45</sup> Glucose is the principal substrate for oxidative metabolism by placental tissues. Of the total glucose leaving the maternal compartment to nourish the uterus and its contents, placental consumption may represent up to 70%.** In addition, a significant fraction of placental glucose uptake derives from the fetal circulation. Although one third of placental glucose may be converted to the three-carbon sugar lactate, placental metabolism is not heavily anaerobic. Instead, because the placental tissues are not capable of metabolizing lactate, this may represent a mechanism by which energy resources can be protected for use by the fetal kidneys and liver. During the first trimester, activity is high in the polyol pathways.<sup>46</sup>

These phylogenetically old carbohydrate pathways enable nicotinamide adenine dinucleotide (NAD<sup>+</sup>) and nicotinamide adenine dinucleotide phosphate (NADP<sup>+</sup>) to be regenerated independent of lactate production and thereby permit glycolysis to be maintained under the low-oxygen conditions. **Metabolomic profiling confirms that first-trimester tissues are not compromised energetically, and the ratio of adenosine triphosphate (ATP) to adenosine diphosphate (ADP) is the same at 8 weeks of gestation as it is at term.** The factors that regulate short-term changes in placental oxygen and glucose consumption are uncertain at present, although in pregnancies at high altitudes, the placenta appears to spare oxygen for fetal use at the cost of increased placental utilization of glucose.

The regulation of placental growth is incompletely understood, although dramatic advances have recently been made in the study of imprinted genes. Such genes are expressed in a parent-of-origin manner: paternally expressed genes generally promote placental growth, whereas maternally expressed genes provide restraint. Approximately 100 imprinted genes have been identified at present; these are expressed in the placenta and also in the brain, where they regulate reproductive behaviors such as nest building. Imprinting is achieved through epigenetic mechanisms that are particularly sensitive to environmental factors such as hypoxia, maternal diet, and stress. Perturbations of imprinting therefore represent a possible mechanism linking extrinsic changes to alterations in placental differentiation and function.

**Normal term placental weight averages 450 g, which represents approximately one seventh (one sixth with cord and membranes) of the fetal weight.** Large placentae, either ultrasonographically or at delivery, may prompt investigation into possible etiologies: **increased placental size** has been associated with maternal anemia, fetal anemia associated with erythrocyte isoimmunization, and hydrops fetalis secondary to fetal  $\alpha$ -thalassemia with hemoglobin Bart's. The association of a large placenta with maternal diabetes mellitus is also recognized, possibly a result of insulin-stimulated mitogenic activity or enhanced angiogenesis. Enlarged placentae are also found in cloned animals, presumably because of defects in the expression of imprinted genes, and in animals in which specific gene products have been

deleted. **In humans, an increased ratio of placental size to fetal weight is associated with increased morbidity for the offspring, both in the neonatal period and subsequently.**

An array of growth-promoting peptide hormones (factors) have been characterized in placental tissue at the protein and/or receptor levels. These include the insulin receptor, IGF-I and IGF-II, EGF, leptin, placental growth factor, placental growth hormone, placental lactogen, and a variety of cytokines and chemokines, each of which has been shown to play an important role in fetal/placental development. **IGF-I and IGF-II are polypeptides with a high degree of homology to human proinsulin; both are produced within the placenta and in the fetus and mother, both circulate bound to carrier proteins, and they are 50 times more potent than insulin in stimulating cell growth.** EGF increases RNA and DNA synthesis and cell multiplication in a wide variety of cell types. The integrated physiologic role of these and other potential placental growth factors in regulating placental growth remains to be fully defined; however, the development of null-mutation mouse models for IGF-I, IGF-II, IGF-Ir, and IGF-IIr—as well as for the EGF receptor—have provided evidence in this regard.<sup>47</sup> Specifically, the EGF receptor appears important in placental development, as does IGF-II. Knockout of IGF-II results in diminished placental size, whereas deletion of the *H19* gene that regulates imprinting of the IGF-II clearance receptor results in an increase in placental size.

Conversely, **exposure to chronic hypoxia at high altitudes, nutrient deprivation, infection, and malperfusion due to deficient remodeling of the spiral arteries all lead to a small placenta and fetal IUGR.** Inhibition of protein synthesis through activation of the integrated stress response pathways, formerly referred to as *endoplasmic reticulum stress* or the *unfolded protein response*, and deactivation of the mTOR/AKT pathway appears to be a common feature in many cases.<sup>48</sup> Translational arrest also appears to reduce complexes of the mitochondrial electron transport chain at the protein, but not mRNA, level at high altitudes, which renders ATP levels lower in these placentae compared with sea level controls.<sup>49</sup> Modeling these changes in placental cell lines in vitro leads to a reduction in the rate of cell proliferation. Exposure to exogenous corticosteroid may also result in diminished placental size and represents another pathway through which stress and undernutrition may act.

## Placental Transport

For the bulk of pregnancy, the chorioallantoic placenta is the major site of exchange of nutrients (including oxygen) and of waste products of fetal metabolism (including carbon dioxide) between mother and fetus. As described above, histotrophic nutrition occurs in early pregnancy, and the yolk sac probably contributes to the uptake of nutrients and their transport to the embryo. However, once blood flow to the IVS begins at around 10 weeks of gestation, exchange across the barrier between maternal and fetal circulations within the villi will be predominant, although there may be some limited transfer between maternal blood in the endometrium and the fluid of the amniotic sac. As discussed below, many of the transport mechanisms required to effect exchange are present in the placenta by 10 weeks, and these may be upregulated or downregulated throughout the rest of pregnancy to meet the requirements of fetal growth and homeostasis. The impact of perturbations of nutrient transport on fetal growth has recently been reviewed.<sup>50</sup>

**FIG 1-6** Electron micrograph of human placenta demonstrates the cellular and extracellular components with which solutes must interact in moving from the maternal intervillous space (IVS) to the lumen of the fetal capillary (FC). BCM, basal cell membrane of the syncytiotrophoblast cell; CT, cytotrophoblast; FCE, fetal capillary endothelial cell; LIS, lateral intercellular space of fetal endothelial cell; MPM, microvillous plasma membrane of the syncytiotrophoblast; SC, syncytiotrophoblast. (Courtesy Kent L. Thornburg, PhD, Center for Developmental Health, Oregon Health Science University, Portland.)

For a molecule to reach fetal plasma from maternal plasma and vice versa, it must cross the syncytiotrophoblast, the matrix of the villous core, and the endothelium of the fetal capillary (Fig. 1-6). **The syncytiotrophoblast is the transporting epithelium and is considered to be the major locus of exchange selectivity and regulation. However, both the matrix and endothelium will contribute to the properties of the placenta as an organ of exchange because both contribute to the thickness of the barrier; they may also act as a size filter in that the finite width of the space between the endothelial cells is likely to restrict the diffusion of larger molecules.**

The fact that the syncytiotrophoblast is a true syncytium, with no obvious intercellular or extracellular water-filled spaces, suggests that it forms a tight barrier. However, physiologic data suggest that this is not the case (see below). Nevertheless, regulated exchange most likely occurs predominantly across the two opposing plasma membranes, the *microvillous* (maternal facing) and *basal* (fetal facing) membranes.

**Maternal-fetal exchange across the placenta may occur, broadly, by one of four mechanisms: (1) bulk flow/solvent**

drag, (2) diffusion, (3) transporter-mediated mechanisms, and (4) endocytosis/exocytosis.

### Bulk Flow/Solvent Drag

Differences in hydrostatic and osmotic pressures between the maternal and fetal circulations within the exchange barrier drive water transfer by bulk flow, which drags along dissolved solutes. These solutes are filtered as they move through the components of the barrier. Water movement may be via paracellular channels (see below) or across the plasma membranes. The latter may be enhanced by the presence of aquaporins, integral membrane proteins that form water pores in the plasma membrane.

Hydrostatic pressure gradients will be created by differences in maternal and fetal blood pressure and vascular resistances on the maternal and fetal sides of the placenta. Although the actual pressures are impossible to measure in vivo at this time, evidence suggests that they are lower in the IVS than in the fetal capillaries. Because this would drive water from the fetus to the mother, which is incompatible with fetal growth, clearly a deficit exists in our knowledge and understanding; the assumptions involved in assessing the hydrostatic pressures could simply be wrong. On the other hand, fetal-maternal water transfer driven by hydrostatic pressures may be opposed, and exceeded by, maternal-fetal water transfer driven by osmotic pressure gradients created by the active transport of solute to the fetus across the syncytiotrophoblast. These forces may well be altered as gestation proceeds. Altogether, this is an important area in which further research is required.

### Diffusion

Diffusion of any molecule occurs in both directions across any barrier. When a concentration gradient exists—and/or for charged species, an electrical gradient—one of these unidirectional fluxes (rates of transfer) is greater in one direction than it is in the other so that there is a net flux in one direction. Net flux ( $J_{net}$ ) of solute across the placenta for an uncharged molecule may be described by an adaptation of Fick's law of diffusion:

$$J_{net} = (AD/l)(C_m - C_f) \text{ moles/unit time}$$

where  $A$  is the surface area of the barrier available for exchange,  $D$  is the diffusion coefficient in water of the molecule (smaller molecules will have a larger  $D$ ),  $l$  is the thickness of the exchange barrier across which diffusion is occurring,  $C_m$  is the mean concentration of the molecule in maternal plasma, and  $C_f$  is the mean concentration of solute in the fetal circulation.

Small, relatively hydrophobic molecules such as  $O_2$  and  $CO_2$  will diffuse rapidly across the plasma membranes of the barrier, so their flux is dependent much more on the concentration gradients than on the surface area of the barrier available for exchange or the thickness of the exchange barrier across which diffusion is occurring. Because this concentration gradient is affected predominantly by the blood flows in both circulations, the diffusion of such molecules is said to be *flow limited*. This explains why reductions in uterine or umbilical flow may result in fetal asphyxia and, consequently, growth restriction.

By contrast, hydrophilic molecules such as glucose and amino acids will not diffuse across plasma membranes easily; rather their concentration gradients are maintained, and flux

will be determined predominantly by barrier surface area and thickness. Flux of such “membrane-limited” molecules is not affected by blood flow unless blood flow is dramatically reduced, but it will be altered if abnormal placental development results in reduced surface area of the barrier available for exchange or increased thickness of the barrier; evidence suggests that this occurs in idiopathic IUGR.<sup>27</sup>

In Fick's equation, the term  $AD/l$  is equivalent to what is described as the permeability of a membrane. Measurements of the passive permeability of the placenta have been made in vivo<sup>51</sup> and in vitro<sup>52</sup> utilizing hydrophilic molecules that would be unlikely to be affected by blood flow and which are not substrates for transporter proteins. These measurements show that **an indirect relationship exists between permeability and the molecular size of the hydrophilic tracer**. Such a relationship is explained, most simply, by the presence of extracellular water-filled channels, or pores, across the exchange barrier through which the molecules can diffuse. The existence of this “paracellular permeability pathway” has been controversial because of the syncytiotrophoblast being syncytial, with no obvious paracellular channels. However, transtrophoblastic channels may be present that are not normally visible by electron microscopy. Furthermore, the areas of syncytial denudation that occur in every placenta may provide a route through which molecules may diffuse.<sup>52</sup>

Rates of transfer of hydrophobic molecules by flow-limited diffusion may change over gestation because, as described in previous sections, both uteroplacental and fetoplacental blood flows change. Changes in concentration—and for charged molecules, changes in electrical gradients—between maternal and fetal plasma will also affect rates of transfer. Gestational changes do occur in the maternal and fetal plasma concentrations of solutes, and this affects driving forces. For example, **glucose and amino acid concentrations in maternal plasma increase over gestation, which is due at least in part to the effects of insulin resistance in pregnancy, and of hormones such as human placental lactogen (hPL)**. If expressed across the placental exchange barrier, a maternal-fetal electrical potential difference ( $PD_{mf}$ ) will have an effect on the exchange of ions. In the human, the  $PD_{mf}$  is small but significant between maternal and fetal circulations ( $-2.7 \pm 0.4$  mV fetus negative) in mid gestation<sup>53</sup> and zero or close to it at term.<sup>54</sup> A PD between the mother and the coelomic cavity has been measured in first-trimester pregnancies.<sup>55</sup> No change was apparent in this PD value ( $8.7 \pm 1$  mV fetus negative) between 9 and 13 weeks' gestation, which was somewhat higher than the PD across the syncytiotrophoblast (3 mV) measured using microelectrodes in term placental villi in vitro. The in vitro PD across the microvillous membrane of human syncytiotrophoblast decreases between the early (median,  $-32$  mV) and late first trimester (median,  $-24$  mV), with a small subsequent fall at term ( $-21$  mV). This suggests that as pregnancy progresses, the driving force for cation flux into the syncytiotrophoblast decreases, and for anions it increases.

### Transporter Protein-Mediated Processes

Transporter proteins are integral membrane proteins that catalyze transfer of solutes across plasma membranes at faster rates than would occur by diffusion. Transporter proteins are a large and diverse group of molecules generally characterized by showing substrate specificity. That is, one transporter or class of transporters will predominantly

**transfer one substrate or class of substrates** (e.g., amino acids) **by having appropriate saturation kinetics** (i.e., raising the concentration of a substrate solute will not infinitely increase the rate at which it is transferred on transporters) **and by being competitively inhibitable** (two structurally similar molecules will compete for transfer by a particular transporter protein). **Transporter proteins are found most abundantly in the placenta in the microvillous and basal plasma membranes of the syncytiotrophoblast.** A detailed description of all these is beyond the scope of this chapter but may be found in work by Atkinson and colleagues.<sup>56</sup> **In overview, channel proteins form pores in the plasma membrane and allow diffusion of ions such as  $K^+$  and  $Ca^{2+}$ , and transporters allow facilitated diffusion down concentration gradients, such as the GLUT1 glucose transporter. Exchange transporters, such as the  $Na^+/H^+$  exchanger involved in pH homeostasis of the syncytiotrophoblast and fetus, and cotransporters, such as the system-A amino acid transporter—which cotransports small hydrophilic amino acids such as alanine, glycine, and serine with  $Na^+$ —require the maintenance of an ion gradient through secondary input of energy, often via  $Na^+/K^+$ ATPase. Finally, active transporters directly utilize ATP to transfer against concentration gradients; these include the  $Na^+/K^+$ ATPase and the  $Ca^{2+}$ ATPase, which pumps  $Ca^{2+}$  across the basal plasma membrane from syncytiotrophoblast cytosol toward the fetal circulation.**

Gestational changes in the flux of solutes through transporter proteins could result from changes in the number of transporters in each plasma membrane, their turnover (i.e., the rate of binding to and release from the transporter), or their affinity for solute as well as from changes in the driving forces acting on them, such as electrochemical gradients and ATP availability. A variety of evidence shows that such developmental changes do occur. Using the technique of isolating and purifying microvillous plasma membrane and radioisotopic tracers to measure transport rates in vesicles formed from these membranes, it has been shown that the  $V_{max}$  of the  $Na^+$ -dependent system-A amino acid transporter increases by about fourfold per milligram of membrane protein between the first trimester and term. The activity of the system- $y^+$  cationic amino acid (e.g., arginine, lysine) transporter increases over gestation, whereas the activity of the system- $y^+L$  transporter decreases.<sup>57</sup> This decrease in system- $y^+L$  activity is due to a decrease in the affinity of the transporter for substrate and is accompanied by an increased expression of 4F2hc monomer of the dimer protein.<sup>57</sup> The reason for this decline is not known but could well be associated with a specific fetal need. **Glucose transporter 1 (GLUT1) expression in microvillous membrane increases between the first trimester and term.**<sup>58</sup>  $Na^+/H^+$  exchanger activity is lower in first-trimester microvillous membrane vesicles compared with that at term,<sup>59</sup> a result borne out by studies on the intrasyncytiotrophoblast pH of isolated placental villi from these two stages in gestation. Interestingly, the expression of the NHE1 isoform of this exchanger in the microvillous membrane does not change across gestation, but the expression of both of its NHE2 and NHE3 isoforms increases between weeks 14 and 18 and term.<sup>59</sup> In contrast, no difference is apparent in  $Cl^-/HCO_3^-$  exchanger activity or, by Western blotting, expression of its AE1 isoform between first trimester and term. Our understanding of how these gestational changes are regulated is currently sparse; studies in knockout mice suggest that hormones from the fetus such as IGF-II, which signals demand for the nutrients required

for growth, are important, but much further work is needed in this area.

### Endocytosis/Exocytosis

**Endocytosis is the process by which molecules become entrapped in invaginations of the microvillous plasma membrane of the syncytiotrophoblast,** which eventually pinch off and form vesicles within the cytosol. Such vesicles may diffuse through the intracellular compartment, and if they avoid fusion with lysosomes, they eventually fuse with the basal plasma membrane and undergo exocytosis, releasing their contents into the fetal milieu. **Evidence suggests that immunoglobulin G (IgG) and other large proteins may cross the placenta by this mechanism.**<sup>56,60</sup> Specificity and the ability to avoid lysosomal degradation during the endocytosis phase may be provided by the presence of receptors for IgG in the microvillous membrane invaginations and vesicles. However, this mechanism of transfer and its gestational regulation, if any, is still not well understood.

### A Selective Barrier

In addition to facilitating maternal-fetal transfer, the placenta also acts as a selective barrier that prevents certain substances and maternal hormones from either crossing to the fetus or crossing in an active form. Members of the multidrug-resistance protein (MRP) family, the breast-cancer-resistant protein (BCRP), and P-glycoprotein are present on the apical surface of the syncytiotrophoblast and in the endothelium of the villous capillaries at term. These transporters mediate the efflux of a wide range of anionic and cationic organic compounds in an ATP-dependent manner, and their expression at the mRNA level shows a general increase toward term. **Within the syncytioplasm are a range of cytochrome P450 (CYP) enzymes. Although more restricted than in the liver, placental CYP-mediated metabolism is capable of detoxifying several drugs and foreign chemicals.** Alcohol dehydrogenase is also present, along with glutathione transferase and N-acetyltransferase. This combination of efflux transporters and defensive enzymes provides a degree of protection to the fetus against exposure to potentially noxious xenobiotics, although many drugs and chemicals can still cross and act as teratogens.

The syncytiotrophoblast also expresses the enzyme 11- $\beta$ -hydroxysteroid dehydrogenase 2 (11 $\beta$ -HSD2), which oxidizes maternal cortisol into the inactive metabolite, cortisone. This process allows the fetal hypothalamic-pituitary-adrenal (HPA) axis to develop in isolation from maternal cortisol and also protects the fetal tissues against the growth-inhibitory effects of corticosteroids. However, the activity of placental 11 $\beta$ -HSD2 can be perturbed in pathologic pregnancies associated with growth restriction, and raised fetal levels of cortisol may contribute to the developmental programming of organ systems.

### Substance-Specific Placental Transport Respiratory Gases

**The transfer of the primary respiratory gases, oxygen and carbon dioxide, is likely to be flow limited. Thus, the driving force for placental gas exchange is the partial pressure gradient between the maternal and fetal circulations. Early in gestation, the human embryo develops in a low-oxygen environment. Such an environment appears to be necessary for the avoidance of teratogenesis and the maintenance of stem**

**cell populations.** After about week 10 of gestation, the placenta becomes important as a respiratory organ. Indeed, estimates of human placental diffusing capacities predict that the placenta's efficiency as an organ of respiratory gas exchange allows equilibrium of oxygen and carbon dioxide between the maternal IVS and the fetal capillaries. However, this prediction varies from the observed 10 mm Hg difference in oxygen tension between the umbilical and uterine veins and between the umbilical vein and IVS. By contrast, the  $\text{PCO}_2$  difference from the umbilical to the uterine vein is small (3 mm Hg).  $\text{PO}_2$  differences could be explained by areas of uneven distribution of maternal-to-fetal blood flows or shunting; this limits fetal and maternal blood exchange, a process that may be an active one, as in the lung. The most important contribution, however, is likely the high metabolic rate of the placental tissues. Thus trophoblast cell  $\text{O}_2$  consumption and  $\text{CO}_2$  production lower umbilical vein  $\text{O}_2$  tension and increase uterine vein  $\text{CO}_2$  tension to a greater degree than could be explained by an inert barrier for respiratory gas transfer.

The arteriovenous difference in the uterine circulation and the venoarterial difference in the umbilical circulation widen during periods of reduced blood flow. **Proportionate  $\text{O}_2$  uptake increases and  $\text{O}_2$  consumption remains unchanged over a fairly wide range of blood flows. Thus both uterine and umbilical blood flows can fall significantly without decreasing fetal  $\text{O}_2$  consumption.**<sup>61</sup> Conversely, unilateral umbilical artery occlusion is associated with significant fetal effects.

**Carbon dioxide is carried in the fetal blood both as dissolved carbon dioxide and as bicarbonate. Because of its charged nature, fetal to maternal bicarbonate transfer is limited. However,  $\text{CO}_2$  likely diffuses from fetus to mother in its molecular form, and  $[\text{HCO}_3^-]$  does not contribute significantly to fetal  $\text{CO}_2$  elimination.**

## Glucose

**Placental permeability for D-glucose is at least 50 times greater than the value predicted on the basis of size and lipid solubility.** Specific transporter proteins of the GLUT family are present on both the microvillous and basal membranes of the syncytiotrophoblast, although they are at greater density in the former.<sup>58</sup> This distribution may provide additional uptake capacity to meet the metabolic demands of the syncytium. **The primary human placental glucose transporter is GLUT1, a sodium-independent facilitated transporter, unlike the sodium-dependent transporters found in the adult kidney and intestine.** This transporter is not insulin sensitive. Placental GLUT1 can be saturated at high substrate concentrations; 50% saturation is observed at glucose levels of approximately 5 mM (90 mg/dL). Thus glucose transfer from mother to fetus is not linear, and transfer rates decrease as maternal glucose concentrations increase. This effect is reflected in fetal blood glucose levels following maternal sugar loading. **Modification of transporter expression within the placenta also occurs in response to maternal diabetes.** In this setting, GLUT1 expression is thought to increase on the rate-limiting basal membrane, while it remains constant on the maternal-facing microvillous membrane.<sup>62</sup> Alterations in transporter expression may also depend on gestational stage (e.g., early in pregnancy, GLUT4 may be present within the placenta) and maternal nutrition/placental blood flow. A third transporter, GLUT3, has also been noted in the fetal-facing placental endothelium. Its presence within the syncytiotrophoblast remains controversial.

## Amino Acids

**Amino acid concentrations are generally higher in fetal umbilical cord plasma than in maternal plasma.** Like monosaccharides, amino acids enter and exit the syncytiotrophoblast via specific membrane transporter proteins. These proteins allow amino acids to be transported against a concentration gradient into the syncytiotrophoblast, and subsequently—if not directly—into the fetal circulation.

**Multiple class-specific transporter proteins mediate neutral, anionic, and cationic amino acid transport into the syncytiotrophoblast. These include both sodium-dependent and sodium-independent transporters.**<sup>63</sup> In many cases, amino acid entry is coupled to sodium in cotransport systems located at the microvillous membrane facing the maternal IVS; the system-A amino acid transporter—for which glycine, alanine, and serine are substrates—is a good example of such a cotransport system. As long as an inwardly directed sodium gradient is maintained, trophoblast cell amino acid concentrations will exceed maternal blood levels. **The sodium gradient is maintained by  $\text{Na}^+/\text{K}^+$ ATPase located on the basal or fetal side of the syncytiotrophoblast. In addition, high trophoblast levels of amino acids transported by sodium-dependent transporters can “drive” uptake of other amino acids via transporters that function as “exchangers” (Fig. 1-7).**<sup>63</sup> Examples of these include ASCT1 and  $\gamma^+ \text{LAT}/4\text{F}2\text{HC}$ . Still other transporters function in a sodium-independent fashion. Individual amino acids may be transported by single or multiple transport proteins, and transport systems have been defined in human placenta. A list of the transporters and their changes in IUGR is found in Table 1-1).

SNAT1 and SNAT2, sodium-dependent transporters with activity localized on both the microvillous and basal membranes of the syncytiotrophoblast, are responsible for the system-A transporter activity of the neutral amino acids described above. SNAT4, with similar substrate specificity, is present early in gestation. Other sodium-dependent transport activities localized

to the microvillous membrane include that for β-amino acids such as taurine (TauT) and perhaps glycine transport via system GLY. Sodium-independent transporters that mediate neutral amino acid transfer on the microvillous membrane include system L (LAT-1, 2/4F2HC), which exhibits a high affinity for amino acids with bulky side chains such as leucine, and y<sup>+</sup>LAT/4F2HC, which is capable of transporting both neutral and cationic amino acids such as lysine and arginine. The aforementioned transporters are heterodimeric and require the combination of two distinct proteins with the cell membrane for transport to occur. Cationic amino acids may also be transported by the sodium-independent transport protein CAT1, whereas anionic amino acids (glutamate, aspartate) are transported by the sodium-dependent transport proteins EAAT1 through EAAT4. Basal membrane transport activities are similar; however, a predominance of sodium-independent transport and exchange (e.g., ASCT1) allows flow of amino acids down their concentration gradients into the fetal endothelium/blood space. Although less is known regarding transfer into and out of the fetal endothelium—which, for the most part, abuts the syncytiotrophoblast basal membrane—available studies have verified that these cells also have a complement of amino acid transport proteins.

As implied earlier, **more than one protein may mediate each transport activity within a single tissue.** Examples include EAAT1 through EAAT5, associated with sodium-dependent anionic amino acid transfer; CAT1, CAT2, and CAT2a, associated with system-y<sup>+</sup> activity; and SNAT1, SNAT2, and SNAT4, associated with sodium-dependent transfer of small neutral amino acids. **The reasons that underlie this duplication within the placenta are unclear, but they are more pronounced than in any other organ with the possible exception of the central nervous system.** Certainly, as is the case for the anionic amino acid transporters EAAT1 through EAAT5, differential distribution within various tissue elements plays a role. Differential regulation within single cell types is another likely reason. In isolated trophoblast cells, system-A activity (sodium-dependent transfer of small neutral amino acids) is upregulated by the absence of amino acids partially because of an increase in carrier

affinity. Conversely, increases in trophoblast amino acid concentrations may suppress uptake (transinhibition). These mechanisms serve to maintain constant trophoblast cell amino acid levels during fluctuations in maternal plasma concentrations. **Insulin has also been shown to upregulate this transport activity, as has IGF-I.**

The coordination between placental/fetal metabolism and amino acid transfer is illustrated by the anionic amino acids glutamate and aspartate, which are poorly transported from mother to fetus. **Glutamate, however, is produced by the fetal liver from glutamine and is then taken up across the basal membrane of the placenta. Within the placenta, the majority of glutamate is metabolized and utilized as an energy source.** As a result, sodium-dependent anionic amino acid transfer activity is of particular importance on the basal membrane, as is system-ASC (ASCT1) activity, which is responsible for the uptake of serine—also produced by the fetal liver—into the placenta.

**Lipids**

Esterified fatty acids (triglycerides) are present in maternal serum as components of chylomicrons and very-low-density lipoproteins (VLDLs). Before transfer across the placenta, lipoprotein lipase interacts with these particles and releases free fatty acids, which are relatively insoluble in plasma and circulate bound to albumin owing to their hydrophobic nature. As a result, fatty acid transfer involves dissociation from maternal protein and subsequent association with placental proteins, first at the plasma membrane (FABPpm) and then after transfer into the cell (thought to be via FAT/CD36 and FATP) with intracytoplasmic binding proteins. Transfer out of the syncytiotrophoblast is less well understood but is thought to occur via interaction with FAT/CD36 and FATP, which are present at both the microvillous and basal membrane surfaces. Subsequently, interaction with fetal plasma proteins occurs. Placental fatty acid uptake is in part regulated by peroxisome proliferator-activated receptor γ (PPARγ) and retinoid X receptor (RXR). In turn, long-chain polyunsaturated fatty acids (PUFAs) taken up by the placenta can be metabolized into PPAR ligands, thus affecting the expression of an array of placental genes, including those that influence fatty acid metabolism and transfer. **Fatty acids may also be oxidized within the placenta as a source of energy.** Although precise interactions and mechanisms remain uncertain, it is clear that lipid uptake is of profound importance to fetal development. Targeted deletion of the gene encoding FATP4 (*Slc27a4*), found within the placenta, results in fetal lethality.<sup>64</sup>

Early studies documented that placental fatty acid transfer increases logarithmically with decreasing chain length (C16 to C8) and then declines somewhat for C6 and C4. However, more recent work has clarified the fact **that essential fatty acids are, in general, transferred more efficiently than are nonessential fatty acids.**<sup>65</sup> Of these, docosahexaenoic acid seems to be transferred more efficiently than arachidonic acid; oleic acid is transferred least efficiently. As in the case of amino acids discussed earlier, **the fetus is significantly enriched in long-chain PUFAs compared with the mother.** Such selectivity may also relate to the composition of triglycerides in maternal serum because lipoprotein lipase preferentially cleaves fatty acids in the two positions. In general, **fatty acids transferred to the fetus reflect maternal serum lipids and diet.** Placental fatty transfer has been recently reviewed.<sup>65</sup> **Evidence also suggests that the placental secretion of leptin, a hormone generally secreted by**

**adipocytes, may promote maternal lipolysis, thus providing both placenta and fetus the means by which to ensure an adequate lipid supply.** Another possible mechanism by which lipids may be excreted from the placenta involves the synthesis and secretion of apolipoprotein (apo) B—containing lipoproteins. The relative importance of this pathway in the human placenta is unclear. Placental uptake and excretion of cholesterol is discussed in the section on receptor-mediated endocytosis.

### Water and Ions

**Water transfer from mother to fetus is determined by a balance of osmotic, hydrostatic, and colloid osmotic forces at the placental interface.** Calculation of osmotic pressure from individual solute concentrations is unreliable because osmotic pressure forces depend on the membrane permeability to each solute. Thus sodium and chloride, the principal plasma solutes, are relatively permeable across the placenta and would not be expected to contribute important osmotic effects. As a result, although human fetal plasma osmolality is equal to or greater than maternal plasma osmolality, these measured values do not reflect the actual osmotic force on either side of the membranes.<sup>66</sup> Coupled with findings that hydrostatic pressure may be greater in the umbilical vein than in the IVS, these data do not explain mechanisms for fetal water accumulation. Alternatively, **colloid osmotic pressure differences and active solute transport probably represent the main determinants of net water fluxes—approximately 20 mL/day. It is likely, however, given the large (3.6 L/hr) flux of water between mother and fetus that more active mechanisms, including perhaps controlled changes in end-vessel resistance, play a significant role.** In fact, water flux occurs through both transcellular and paracellular pathways. Water channels (aquaporins 1, 3, 8, and 9) have been identified within the placenta, but their roles relative to water flux within the fetal placental unit have not been discerned.

**In comparison to other epithelia, the specialized placental mechanisms for ion transport are incompletely understood. Multiple mechanisms of sodium transport exist in syncytiotrophoblast membranes** (see Fig. 1-7). The maternal-facing microvillous membrane contains, at a minimum, 1) multiple amino acid cotransporters; 2) a sodium phosphate cotransporter, in which two sodium ions are transported with each phosphate radical; 3) a sodium-hydrogen ion antiporter that exchanges one proton for each sodium ion that enters the cell; and 4) other nutrient transporters. In addition, both sodium and potassium channels have been described. A membrane potential with the inside negative (−30 mV) would promote sodium entry from the IVS, and this probably exists.<sup>67</sup> The fetally directed basal side of the cell contains the  $\text{Na}^+/\text{K}^+$ ATPase. The microvillous or maternal-facing trophoblast membrane has an anion exchanger (AE1) that mediates chloride transit across this membrane in association with  $\text{Cl}^-$  conductance pathways (channels) present in both the microvillous and basal membranes.<sup>68</sup> Paracellular pathways also play an important role. The integration and regulation of these various mechanisms for sodium and chloride transport from mother to fetus is not completely understood; however, accumulating evidence suggests that mineralocorticoids may regulate placental sodium transfer. Further, sodium-hydrogen exchange, mediated by multiple members of the NHE family (NHE1, NHE2, and NHE3), is regulated both over gestation and in response to IUGR, as is expression of  $\text{Na}^+/\text{K}^+$ ATPase.

### Calcium

**Calcium is an essential nutrient for the developing fetus, and ionized calcium levels are higher in fetal than in maternal blood. Higher fetal calcium levels are due to a syncytiotrophoblast basal membrane ATP-dependent  $\text{Ca}^{2+}$  transport system that exhibits high affinity (nanomolar range) for calcium.** Indeed, analogous to amino acid and sodium-hydrogen exchange proteins, multiple isoforms of the plasma membrane calcium ATPase (PMCA) 1 through 4 are expressed within the placenta<sup>69</sup>; the placental expression of PMCA3 has been linked to intrauterine bone accrual. Sodium-calcium exchange (NCX) proteins may also play a role in the extrusion of calcium from the trophoblast—again, multiple isoforms are expressed within the placenta. A variety of calcium channels have been identified in both the apical and basal membranes; TRPV6 plays a significant role in calcium uptake into the syncytiotrophoblast.<sup>69</sup> Intracellular calcium is bound by multiple calcium-binding proteins, which have been identified within the placenta; these include CaBP9k, CaBP28k, CaBP57k, oncomodulin, S-100P, S-100 $\alpha$ , and S-100 $\beta$ . **CaBP9k** in particular is thought to have a regulatory and perhaps rate-limiting role. Calcium transport across the placenta is increased by the calcium-dependent regulatory protein **calmodulin**, regulated by 1,25 dihydroxycholecalciferol, calcitonin, parathyroid hormone–related protein, and parathyroid hormone.

### Placental Nutrient Supply and Intrauterine Growth Restriction

The term *placental insufficiency* has been used as a cause of IUGR but has been poorly understood until recently. It is often taken as being synonymous with *reduced uteroplacental blood flow* or *reduced umbilical blood flow*. Doppler measurements of such blood flows have been of assistance in diagnosing and assessing the severity of IUGR but are limited in value.<sup>70</sup> It is now clear that other variables that determine the capacity of the placenta to supply nutrients may also contribute to IUGR. For example, **in IUGR, the surface area of the exchange barrier is decreased and its thickness decreased,**<sup>27</sup> and such changes are likely to markedly decrease the passive permeability of the placenta. Furthermore, **considerable evidence now shows that the activity and expression of transporter proteins in the syncytiotrophoblast is altered in IUGR.**<sup>71,72</sup> The reported data are summarized in Table 1-1. As can be seen, activity of several transporters decrease, at least one increases, and others show no change at all. This variation in response could reflect whether a change in the placenta is *causative* in IUGR (e.g., the decrease in system-A amino acid transporter activity) or *compensatory* (e.g., the increase in  $\text{Ca}^{2+}$  ATPase activity) and could also reflect differential regulation of the transporters. Understanding these placental phenotypes of IUGR may well give clues to novel means of diagnosing and even treating the condition.

### Vasomotor Control of the Umbilicoplacental Circulation

The placenta represents an extensive extracorporeal vascular bed that must be perfused by the fetal heart. In addition, for efficient exchange, flow in the maternal and placental circulations must be matched as closely as possible. Hence, **there must be local control of vascular resistance within the fetal placental vascular bed.** The principal resistance vessels in the placental circulation are the muscular arteries contained within the stem villi. In the absence of any nerves within the placenta,

**vasomotor control must be performed by local paracrine factors. Nitric oxide, carbon monoxide, and hydrogen sulfide have been identified as having powerful vasodilatory effects.**<sup>73</sup>

It is thought that under normal conditions, the villous vascular bed is fully dilated, and it might constrict under hypoxic conditions to redistribute flow to better perfused areas of the placenta, analogous to the situation in the lung. It is notable that expression of the enzyme cystathionine  $\gamma$ -lyase, which synthesizes hydrogen sulfide, is reduced in the smooth muscle that surrounds the resistance arteries in growth-restricted placentae that display abnormal umbilical artery Doppler waveforms,<sup>73</sup> which suggests it plays an important physiologic role.

### Placental Endocrinology

The human placenta is an important endocrine organ. It signals the presence of the conceptus to the mother in early pregnancy and optimizes the intrauterine environment and maternal physiology for the benefit of fetal growth. **Two major groups of hormones are produced: the steroid hormones, progesterone and the estrogens, and peptide hormones, such as human chorionic gonadotropin (hCG) and hPL.** All are predominantly synthesized in the syncytiotrophoblast, and although the synthetic pathways have been generally elucidated, the factors that regulate secretion are still largely unknown. During early pregnancy, the hormones increase maternal food intake and energy storage, whereas later they mobilize these resources for use by the fetus.

#### Progesterone

**During the first few weeks of pregnancy, progesterone is mainly derived from the corpus luteum; gradually, as the placental mass increases, this organ's contribution becomes dominant with the production of around 250 mg/day of progesterone. The corpus luteum regresses at around 9 weeks, and at that stage, it is no longer essential for the maintenance of a pregnancy.**

Placental synthesis of progesterone begins with the conversion of cholesterol to pregnenolone, as in other steroid-secreting tissues. Placental tissues are poor at synthesizing cholesterol, and so they utilize maternal cholesterol derived from low-density lipoproteins (LDLs) taken up in coated pits on the surface of the syncytiotrophoblast. Conversion of cholesterol to pregnenolone occurs on the inner aspect of the inner mitochondrial membrane, catalyzed by cytochrome P450<sub>scc</sub> (CYP11A1), and in other steroidogenic tissues, the delivery of cholesterol to this site is the principal rate-limiting step in progesterone synthesis. There, delivery is facilitated by the steroidogenic acute regulatory (StAR) protein, which binds and transports cholesterol, but this protein is not present in the human placenta.<sup>74</sup> Instead, a homolog, MLN64, may carry out a similar function; freshly isolated cytotrophoblast cells appear to contain concentrations of cholesterol that are near saturating for progesterone synthesis, which indicates that supply of the precursor is not rate limiting.<sup>75</sup> Side-chain cleavage requires molecular oxygen, but it is unclear whether the conditions that prevail during the first trimester are rate limiting. The rate of production of pregnenolone from radiolabeled cholesterol by placental homogenates in vitro increases throughout the first trimester, and both the concentration and activity of P450<sub>scc</sub> increase in placental mitochondria from the first trimester to term. These changes, coupled with the expansion of the syncytiotrophoblast, most likely account for the increase in progesterone synthesis observed.

Side-chain cleavage also requires a supply of electrons, and this is provided by nicotinamide adenine dinucleotide phosphate (NADPH) through a short electron transport chain in the mitochondrial matrix that involves adrenodoxin reductase and its redox partner adrenodoxin. Preliminary studies in Tuckey's<sup>74</sup> laboratory suggest that the transport of electrons to P450<sub>scc</sub> is rate limiting for the enzyme's activity at mid pregnancy, and so further research on the factors that regulate expression and activity of adrenodoxin reductase during gestation is clearly needed.

The resultant pregnenolone is then converted to progesterone by the enzyme type 1  $3\beta$ -hydroxysteroid dehydrogenase ( $3\beta$ -HSD), principally in the mitochondria. The activity of  $3\beta$ -HSD in placental tissues is significantly higher than that of cytochrome P450<sub>scc</sub>, and so this step is unlikely to ever be rate limiting for the production of progesterone. **Once secreted, the principal actions of the hormone are to maintain quiescence of the myometrium, although it may have immunomodulatory and appetite stimulatory roles as well.** In addition, our new data on the importance of histotrophic nutrition during the first few weeks of pregnancy suggest that **progesterone may be essential to maintain the secretory activity of the endometrial glands.**

#### Estrogens

**The human placenta lacks the enzymes required to synthesize estrogens directly from acetate or cholesterol, and so it uses the precursor dehydroepiandrosterone sulfate (DHEAS) supplied by the maternal and fetal adrenal glands in approximately equal proportions near term.** Following uptake by the syncytiotrophoblast, DHEAS is hydrolyzed by placental sulfatase to dehydroepiandrosterone (DHEA), which is further converted to androstenedione by  $3\beta$ -HSD. Final conversion to estradiol and estrone is achieved by the action of P450 cytochrome aromatase (P450<sub>arom</sub>; CYP19), which has been immunolocalized to the endoplasmic reticulum. The syncytiotrophoblast can also utilize 16-OH DHEAS produced by the fetal liver, converting this to 16 $\alpha$ -OH androstenedione through the action of  $3\beta$ -HSD and then to estriol through the action of P450<sub>arom</sub>. Because approximately 90% of placental estriol production is reliant on fetal synthesis of the precursor 16-OH DHEAS, maternal estriol concentrations have, in the past, been taken clinically as an index of fetal well-being.

Although the synthesis of estrogens can be detected in placental tissues during the early weeks of gestation, secretion significantly increases toward the end of the first trimester. By 7 weeks' gestation, more than 50% of maternal circulating estrogens are of placental origin. Recent analysis of the transcriptional regulation of the *CYP19A1* gene has shown it to be oxygen responsive through a novel pathway that involves the basic helix-loop-helix transcription factor MASH-2.<sup>76</sup> Production of MASH-2 is increased under physiologically low-oxygen conditions and leads to repression of *CYP19A1* gene expression. Hence the change in oxygenation that occurs at the end of the first trimester<sup>7</sup> may stimulate placental production of estrogens.

#### Human Chorionic Gonadotropin

**Human chorionic gonadotropin (hCG) is secreted by the trophoblast at the blastocyst stage and can be detected in the maternal blood and urine approximately 8 to 10 days after fertilization. Its principal function is to maintain the corpus luteum until the placenta is sufficiently developed to take over production of progesterone.** It is a heterodimeric

glycoprotein (approximately 38,000 Da) that consists of  $\alpha$  and  $\beta$  subunits and is principally derived from the syncytiotrophoblast. **The  $\alpha$  subunit is common to that of thyroid-stimulating hormone (TSH), luteinizing hormone (LH), and follicle-stimulating hormone (FSH) and is encoded by a single gene located at chromosome 6q12-21. It is the  $\beta$  subunit that determines the biologic specificity of hCG, and this evolved by a duplication event at the *LHB* gene locus.** Mapping has revealed that in the human, six copies of the CGB gene are located together with a single copy of the *LHB* gene at chromosome 19p13.3. Polymerase chain reaction (PCR)-based techniques have revealed that at least five of the genes, and possibly all six, are transcribed in vivo during normal pregnancy. Most of the steady-state hCG $\beta$  mRNAs are transcribed from *CGB* genes 5, 3, and 8 but with the levels of expression being  $\beta 5 > \beta 3 = \beta 8 > \beta 7, \beta 1/2$ .<sup>77</sup> The  $\beta$  subunits of LH and hCG share 85% amino acid sequence homology and are functionally interchangeable. One of the principal differences between the two is the presence of a 31-amino acid carboxyl-terminal extension in hCG $\beta$  compared with a shorter 7-amino acid stretch in LH $\beta$ . This extension is hydrophilic, contains four *O*-glycosylated serine residues, and is thought to act as a secretory routing signal that targets release of hCG from the apical membrane of the syncytiotrophoblast.

Assembly of hCG involves a complex process of folding, in which a strand of 20 residues of the  $\beta$  subunit is wrapped around the  $\alpha$  subunit, and the two are secured by a disulfide bond. Combination of the subunits occurs in the syncytiotrophoblast prior to the release of intact hCG, and because only limited storage exists in cytoplasmic granules, secretion is largely thought to reflect de novo synthesis. Oxidizing conditions promote combination of the subunits in vitro, most likely through their effects on the disulfide bond, and so the wave of physiologic oxidative stress observed in placental tissues at the transition from the first to second trimesters<sup>7</sup> may influence the pattern of secretion in vivo.

**Concentrations of the hCG dimer in maternal blood rise rapidly during early pregnancy, peak at 9 to 10 weeks, and subsequently decline to a nadir at approximately 20 weeks. The physiologic role of the hCG peak is unknown, and the serum concentration far exceeds that required to stimulate LH receptors in the corpus luteum. In any case, the corpus luteum is coming to the end of its extended life, and so the peak may therefore merely reflect other physiologic events.** Production of the  $\beta$  subunit follows the same pattern, whereas the maternal serum concentration of the  $\alpha$  subunit continues to rise during the first and second trimesters. **Synthesis of the  $\beta$  subunit is therefore considered to be the rate-limiting step.** Early experiments that used primary placental cultures revealed that cyclic adenosine monophosphate (cAMP) plays a key role in the biosynthesis of both subunits, and subsequent work showed it to increase both the transcription and the stability of the  $\alpha$ - and  $\beta$ -mRNAs. The kinetics were different for the two subunits, however, which suggests that the effect occurs through separate pathways or transcription factors. Possible regulatory elements within the  $\alpha$  and  $\beta$  genes were extensively reviewed by Jameson and Hollenberg.<sup>78</sup>

Another theory that has been proposed is that intact hCG may modulate its own secretion in an autocrine/paracrine fashion through the LH/hCG receptor.<sup>79</sup> This G protein-coupled receptor has been identified on the syncytiotrophoblast of the mature placenta and contains a large extracellular domain

that binds intact hCG with high affinity and specificity. However, during early pregnancy, the receptors in the placenta are truncated and probably functionless until 9 weeks. Hence, in the absence of self-regulation, maternal serum concentrations of hCG may rise steeply, until the expression of functional LH/hCG receptors on the syncytiotrophoblast toward the end of the first trimester brings it under control. Reduced synthesis of the functional receptor may underlie the raised serum concentrations of hCG that characterize cases of Down syndrome (trisomy 21).<sup>80</sup>

In addition to changes in the rate of secretion, hCG also exhibits molecular heterogeneity in both its protein and carbohydrate moieties; also, the ratio of the different isoforms secreted changes with gestational age. For the first 5 to 6 weeks of gestation, hyperglycosylated isoforms of the  $\beta$  subunit predominate (hCG-H), resembling the pattern seen in choriocarcinoma.<sup>81</sup> These isoforms are particularly released by extravillous trophoblast, and they stimulate invasion through autocrine/paracrine pathways rather than having traditional endocrine activity. **Reduced levels of hCG-H in the maternal serum have been linked with miscarriage and poor obstetric outcome,<sup>81</sup> and they may reflect impaired development of the extravillous trophoblast. This in turn would lead to deficient spiral artery remodeling.** In normal pregnancies, these hyperglycosylated isoforms decline after the first trimester and are replaced by those that predominate for the remainder of the pregnancy. Midtrimester maternal concentrations of hCG were also found to be raised in a retrospective study of early-onset preeclampsia,<sup>82</sup> and recently a link between the serum concentration and the severity of maternal oxidative stress has been reported.<sup>83</sup> These data reinforce the putative link between the secretion of hCG and the redox status of the trophoblast.

## Placental Lactogen

**Human placental lactogen (hPL), also known as *chorionic somatotropin*, is a single-chain glycoprotein (22,300 Da) that has a high degree of amino acid sequence homology with both human growth hormone (96%) and prolactin (67%).** Therefore it has been suggested that the genes that encode all three hormones arose from a common ancestral gene through repeated gene duplication. Thus **hPL has both growth-promoting and lactogenic effects, although the former are of rather low activity. The hormone is synthesized exclusively in the syncytiotrophoblast and is secreted predominantly into the maternal circulation, where it can be detected from the third week of gestation onward.** Concentrations rise steadily until they plateau at around 36 weeks of gestation, at which time the daily production rate is approximately 1 g. The magnitude of this effort is reflected by the fact that at term, production of hPL accounts for 5% to 10% of total protein synthesis by placental ribosomes, and the encoding mRNA represents 20% of the total placental mRNA.

Little is known regarding the control of hPL secretion in vivo, and maternal concentrations correlate most closely with placental mass. Evidence suggests that calcium influx into the syncytiotrophoblast or an increase in the external concentration in albumin can cause the release of hPL from placental explants in vitro, and this does not appear to be mediated by activation of the inositol phosphate, cAMP, or cyclic guanosine monophosphate (cGMP) pathways.

**The actions of hPL are well defined, both as an appetite stimulant and for its effects on maternal metabolism. It**

**promotes lipolysis, which increases circulating free fatty acid levels, and in the past it was also thought to act as an insulin antagonist, thereby raising maternal blood glucose concentrations. However, it is now thought that placental growth hormone is more important in this respect. Placental lactogen also promotes growth and differentiation of the mammary glandular tissue in anticipation of lactation.**

### Placental Growth Hormone

Placental growth hormone (PGH) is expressed from the hGH-V gene *GH2*, which is in the same cluster as *CSH1*, and it differs from pituitary growth hormone by only 13 amino acids.<sup>84</sup> PGH is secreted predominantly by the syncytiotrophoblast into the maternal circulation in a nonpulsatile manner and cannot be detected in the fetal circulation. Between 10 and 20 weeks of gestation, PGH gradually replaces pituitary growth hormone, which then becomes undetectable until term. **In contrast to hPL, PGH has high growth-promoting but low lactogenic activities.**

Secretion of PGH is not modulated by growth-hormone releasing hormone but rather appears to be rapidly suppressed by raised glucose concentrations both in vivo and in vitro.<sup>84</sup> Through its actions on maternal metabolism, PGH increases nutrient availability for the fetoplacental unit and promotes lipolysis and also gluconeogenesis. **It is also one of the key regulators of maternal insulin sensitivity and IGF-I concentrations. Although IGF-I does not cross into the fetal circulation, it does have a powerful influence on fetal growth through its effects on maternal metabolism, maternal-fetal nutrient portioning, placental transporter expression, and placental growth and blood flow. Circulating levels of PGH correlate with birthweight and are reduced in cases of IUGR.**<sup>84</sup>

### Leptin

Leptin is secreted by adipose tissue and normally feeds back on the hypothalamus to suppress appetite and food intake. However, **pregnancy is a state of central leptin resistance that allows the mother to lay down adipose reserves.** During pregnancy, leptin is secreted in large quantities by the syncytiotrophoblast, regulated in part through hCG and 17 $\beta$ -estradiol.<sup>85</sup> Expression correlates closely with maternal serum concentrations and peaks at the end of the second and during the early third trimesters. The hormone has local stimulatory effects on placental transporter expression and has central effects on appetite.

### Pregnancy-Associated Plasma Protein A

Pregnancy-associated plasma protein A (PAPP-A) is a macromolecular glycoprotein that is increased in the serum of pregnant women from 5 weeks' gestation, and it continuously rises until the end of pregnancy. It is mainly produced by the villous trophoblast and, during pregnancy, its synthesis is upregulated by progesterone. **It is a key regulator of IGF bioavailability, which is essential for normal fetal development, and low maternal serum levels of PAPP-A have been associated with a higher risk of preeclampsia and poor fetal growth during the second half of pregnancy.**<sup>86</sup> Ultrasound measurements of the basal surface area indirectly reflect development of the definitive placenta. The finding of a relationship between basal surface area and PAPP-A levels in maternal serum, and also between basal surface area and birthweight centile, suggests that a combination of these parameters could be useful in identifying

placenta-related disorders from the end of the first trimester of pregnancy.<sup>87</sup>

### Sex Differences in Placental Function

**Increasing evidence suggests sex differences in placental development and function, and in particular to its responses to various stressors.**<sup>72,88</sup> Differences are found in growth factor pathways—with concentrations of IGF-I being higher in the cord blood of female fetuses, whereas the reverse is true for growth hormone—and placental cytokine production. Males grow faster in utero than females but have a smaller placenta in relation to fetal weight, which suggests that the organ is more efficient. However, this may mean that the functional reserve is less and that, as a result, male fetuses are more vulnerable to developmental programming under adverse conditions.<sup>89</sup> Dimorphic patterns of placental gene expression may underlie the greater risk of preeclampsia, growth restriction, and prematurity associated with male babies. For example, in preeclamptic pregnancies, the placentae of boys show significantly higher levels of proinflammatory cytokines and activation of apoptosis, which is associated with more pronounced nuclear factor  $\kappa$ B (NF $\kappa$ B) signaling.<sup>90</sup> This is an area of active research, and greater consideration needs to be paid to the sex of the fetus in future placenta studies.

### SUMMARY

The placenta must be one of the most complex human organs. While growing and differentiating, it performs the functions of many organ systems in the fetus—such as the lungs, kidneys, and liver—that are still immature. Although principally considered an organ of exchange, the placenta also has a major endocrine role. It orchestrates a variety of physiologic responses in the mother that sustain the pregnancy and ensure appropriate allocation of nutrient resources to both parties. Imprinted genes are key players in regulating placental differentiation and function, and their epigenetic status is sensitive to environmental factors. These genes provide a mechanism by which the placenta is able to adapt to meet changing fetal demands and maternal supply. Impaired placental development is frequently associated with fetal growth restriction, and developmental programming of the major organ systems may influence the life-long health of the offspring. Placentation therefore has clinical impact that extends far beyond the 9 months of pregnancy.

### KEY POINTS

- ◆ The mature human placenta is a discoid organ that consists of an elaborately branched fetal villous tree bathed directly by maternal blood of the villous hemochorial type. Normal term placental weight averages 450 g and represents approximately one seventh (one sixth with cord and membranes) of the fetal weight.
- ◆ Continual development throughout pregnancy leads to progressive enlargement of the surface area for exchange (12 to 14 m<sup>2</sup> at term) and reduction in the mean diffusion distance between the maternal and fetal circulations (approximately 5 to 6  $\mu$ m at term).

- ◆ The maternal circulation to the placenta is not fully established until the end of the first trimester; hence organogenesis takes place in a low-oxygen environment of approximately 20 mm Hg, which may protect against free radical-mediated teratogenesis. Uterine blood flow at term averages 750 mL/min, or 10% to 15% of maternal cardiac output.
- ◆ During the first trimester, the uterine glands discharge their secretions into the placental intervillous space and represent an important supply of nutrients, cytokines, and growth factors prior to the onset of the maternal-fetal circulation.
- ◆ The exocoelomic cavity acts as an important reservoir of nutrients during early pregnancy, and the secondary yolk sac is important in the uptake of nutrients and their transfer to the fetus.
- ◆ Oxygen is a powerful mediator of trophoblast proliferation and invasion, villous remodeling, and placental angiogenesis.
- ◆ Ensuring an adequate maternal blood supply to the placenta during the second and third trimesters is an essential aspect of placentation and is dependent upon physiologic conversion of the spiral arteries induced by invasion of the endometrium by extravillous trophoblast during early pregnancy. Many complications of pregnancy, such as preeclampsia, appear to be secondary to deficient invasion.
- ◆ All transport across the placenta must take place across the syncytial covering of the villous tree, the syncytiotrophoblast, the villous matrix, and the fetal endothelium, each of which may impose its own restriction and selectivity. Exchange will occur via one of four basic processes: (1) bulk flow/solvent drag, (2) diffusion, (3) transporter-mediated mechanisms, and (4) endocytosis/exocytosis.
- ◆ The rate of transplacental exchange will depend on many factors, such as the surface area available, the concentration gradient, the rates of maternal and fetal blood flows, and the density of transporter proteins. Changes in villous surface area, diffusion distance, and transporter expression have been linked with IUGR.
- ◆ The placenta is an important endocrine gland that produces both steroid and peptide hormones, principally from the syncytiotrophoblast. Concentrations of some hormones are altered in pathologic conditions—for example, human chorionic gonadotropin in trisomy 21—but in general, little is known regarding control of endocrine activity.

## Acknowledgment

The section on placental metabolism and growth is based on material prepared by Dr. Donald Novak from [Chapter 2](#) of the previous edition of this text.

In obstetric practice, recognition of normal fetal growth, development, and behavior often suggests an expectant management plan. However, abnormalities may require clinical strategies for fetal assessment and intervention. The basic concepts of placental and fetal physiology provide the building blocks necessary for understanding pathophysiology and thus mechanisms of disease. Throughout this chapter, we have reviewed the essential tenets of fetal physiology and have related this information to normal and abnormal clinical conditions.

Much of our knowledge of fetal physiology derives from observations made in mammals other than humans. We have

attempted to include only those observations reasonably applicable to the human fetus and in most instances have not detailed the species from which the data were obtained. Should questions arise regarding the species studied, the reader is referred to the extensive bibliography.

## UMBILICAL BLOOD FLOW

**Fetal blood flow to the umbilical circulation represents approximately 40% of the combined output of both fetal ventricles.**<sup>1</sup> Over the last third of gestation, increases in umbilical blood flow are proportional to fetal growth so that umbilical blood flow remains constant when normalized to fetal weight. Human umbilical venous flow can be estimated through the use of triplex ultrasonography. Although increases in villous capillary number represent the primary contributor to gestation-dependent increases in umbilical blood flow, the factors that regulate this change are unknown; however, a number of important angiogenic peptides and factors, including vascular endothelial growth factor (VEGF), have been identified.<sup>2</sup> Short-term changes in umbilical blood flow are primarily regulated by perfusion pressure. **The relationship between flow and perfusion pressure is linear in the umbilical circulation.** As a result, small (2 to 3 mm Hg) increases in umbilical vein pressure evoke proportional decreases in umbilical blood flow. Because both the umbilical artery and vein are enclosed in the amniotic cavity, pressure changes caused by increases in uterine tone are transmitted equally to these vessels without changes in umbilical blood flow. **Relative to the uteroplacental bed, the fetoplacental circulation is resistant to vasoconstrictive effects of infused pressor agents, and umbilical blood flow is preserved unless cardiac output decreases. Thus despite catecholamine-induced changes in blood flow distribution and increases in blood pressure during acute hypoxia, umbilical blood flow is maintained over a relatively wide range of oxygen tensions.** Endogenous vasoactive autacoids have been identified; nitric oxide may also be important. Endothelin-1, in particular, is associated with diminished fetoplacental blood flow.<sup>3</sup>

## AMNIOTIC FLUID VOLUME

Mean amniotic fluid volume (AFV) increases from 250 to 800 mL between 16 and 32 weeks of gestation. Despite considerable variability, the average volume remains stable up to 39 weeks and then declines to about 500 mL at 42 weeks (Fig. 2-1). Amniotic fluid index (AFI) values across gestation are found in Chapter 35. The origin of amniotic fluid during the first trimester of pregnancy is uncertain. Possible sources include a transudate of maternal plasma through the chorioamnion or a transudate of fetal plasma through the highly permeable fetal skin before keratinization. The origin and dynamics of amniotic fluid are better understood beginning in the second trimester, when the fetus becomes the primary determinant. **AFV is maintained by a balance of fetal fluid production (lung liquid and urine) and fluid resorption (fetal swallowing and flow across the amniotic and/or chorionic membranes to the fetus or maternal uterus; Fig. 2-2).**<sup>4</sup>

The fetal lung secretes fluid at a rate of 300 to 400 mL/day near term. Chloride is actively transferred from alveolar capillaries to the lung lumen, and water follows the chloride gradient. Thus lung fluid represents a nearly protein-free transudate with an osmolality similar to that of fetal plasma. Fetal lung fluid does not appear to regulate fetal body fluid homeostasis, just as fetal intravenous volume loading does not increase lung fluid secretion. Rather, **lung fluid likely serves to maintain lung expansion and facilitate pulmonary growth. Lung fluid must decrease at parturition to provide for the transition to respiratory ventilation.** Notably, several hormones that increase in fetal plasma during labor (i.e., catecholamines, arginine vasopressin [AVP]) also decrease lung fluid production. With the reduction of fluid secretion, the colloid osmotic gradient between fetal plasma and lung fluid results in lung fluid resorption across the pulmonary epithelium and clearance via lymphatics. **The absence of this process explains the increased incidence of transient tachypnea of the newborn, or “wet lung,” in infants delivered by cesarean section in the absence of labor.**

Fetal urine is the primary source of amniotic fluid, and outputs at term vary from 400 to 1200 mL/day. Between 20

**FIG 2-1** Normal range of amniotic fluid volume in human gestation. (From Beall MH, van den Wijngaard JP, van Gemert MJ, Ross MG. Amniotic fluid water dynamics. *Placenta*. 2007;28:816-823.)

and 40 weeks' gestation, fetal urine production increases about tenfold in the presence of marked renal maturation.

The urine is normally hypotonic, and the low osmolality of fetal urine accounts for the hypotonicity of amniotic fluid in late gestation relative to maternal and fetal plasma. Numerous fetal endocrine factors that include AVP, atrial natriuretic factor (ANF), angiotensin II (AII), aldosterone, and prostaglandins can alter fetal renal blood flow, glomerular filtration rate, and urine flow rates.<sup>5</sup> In response to fetal stress, endocrine-mediated reductions in fetal urine flow may explain the association between fetal hypoxia and oligohydramnios. The regulation of fetal urine production is discussed further under “Fetal Kidney” later in this chapter.

**Fetal swallowing is believed to be a major route of amniotic fluid resorption, although swallowed fluid contains a mixture of amniotic and tracheal fluids.** Human fetal swallowing has been demonstrated by 18 weeks' gestation,<sup>6</sup> with daily swallowed volumes of 200 to 500 mL near term. Similar to fetal urine flow, daily fetal swallowed volumes (per body weight) are markedly greater than adult values. With the development of fetal neurobehavioral states, fetal swallowing occurs primarily during active sleep states associated with respiratory and eye movements.<sup>7</sup> Moderate elevations in fetal plasma osmolality increase the number of swallowing episodes and volume swallowed, indicating the presence of an intact thirst mechanism in the near-term fetus.

Because amniotic fluid is hypotonic with respect to maternal plasma, there is a potential for bulk water removal at the amniotic-chorionic interface with maternal or fetal plasma. Although fluid resorption to the maternal plasma is likely minimal, intramembranous flow from amniotic fluid to fetal placental vessels may contribute importantly to amniotic fluid resorption. Thus **intramembranous flow may balance fetal**

**FIG 2-2** Water circulation between the fetus and amniotic fluid. The major sources of amniotic fluid water are fetal urine and lung liquid, and the routes of absorption are through fetal swallowing and intramembranous flow. (From Beall MH, van den Wijngaard JP, van Gemert MJ, Ross MG. Amniotic fluid water dynamics. *Placenta*. 2007;28:816-823.)

### urine and lung-liquid production with fetal swallowing to maintain normal AFVs.

The mechanisms by which water is transferred across the amnion into fetal vessels remains uncertain, but evidence implicates the presence of water channels within the amnion and, as discussed previously, the placental trophoblast and fetal endothelium. Aquaporins 1, 3, 8, and 9 are found within the placenta and fetal membranes. Mice deficient in aquaporin 1 develop polyhydramnios, which suggests an important role for this protein in intramembranous water transfer.<sup>8</sup> Aquaporins 1 and 3, important in transplacental water flow, are regulated by AVP and by cyclic adenosine monophosphate (cAMP), and they show changes in expression throughout gestation.<sup>9</sup>

## FETAL GROWTH AND METABOLISM

### Substrates

**Nutrients are utilized by the fetus for two primary purposes: oxidation for energy and tissue accretion. Under normal conditions, glucose is an important substrate for fetal oxidative metabolism.** The glucose utilized by the fetus derives from the placenta rather than from endogenous glucose production. However, based on umbilical vein–umbilical artery glucose and oxygen (O<sub>2</sub>) concentration differences, glucose alone cannot account for fetal oxidative metabolism. In fact, glucose oxidation accounts for only two thirds of fetal carbon dioxide (CO<sub>2</sub>) production.<sup>10</sup> Thus **fetal oxidative metabolism depends on substrates in addition to glucose.** A large portion of the amino acids taken up by the umbilical circulation are used by the fetus for aerobic metabolism instead of protein synthesis. Fetal uptake for a number of amino acids actually exceeds their accretion into fetal tissues. In addition, other amino acids—notably glutamate—are taken up by the placenta from the fetal circulation and are metabolized within the placenta.<sup>11</sup> **In fetal sheep, and likely in the human fetus as well, lactate also is a substrate for fetal oxygen consumption.**<sup>10</sup> **Thus the combined substrates—glucose, amino acids, and lactate—essentially provide the approximately 87 kcal/kg required daily by the growing fetus.**

Metabolic requirements for new tissue accretion depend on the growth rate and the type of tissue acquired. Although the newborn infant has relatively increased body fat, fetal fat content is low at 26 weeks. Fat acquisition increases gradually up to 32 weeks and rapidly thereafter (about 82 g [dry weight] of fat per week). **Because many of the necessary enzymes for conversion of carbohydrate to lipid are present in the fetus, fat acquisition reflects glucose utilization in addition to placental fatty acid uptake.** In contrast, fetal acquisition of nonfat tissue is linear from 32 to 39 weeks and may decrease to only 30% of the fat-acquisition rate in late gestation (about 43 g [dry weight] per week).

### Hormones

The roles of select hormones in the regulation of placental growth are discussed in [Chapter 1](#). Fetal hormones influence fetal growth through both metabolic and mitogenic effects. **Although growth hormone and growth hormone receptors are present early in fetal life, and growth hormone is essential to postnatal growth, growth hormone appears to have little role in regulating fetal growth.** Instead, changes in insulin-like growth factor (IGF), IGF-binding proteins, or IGF receptors explain the apparent reduced role of growth hormone on fetal

growth. Most if not all tissues of the body produce IGF-I and IGF-II, and both are present in human fetal tissue extracts after 12 weeks' gestation. Fetal plasma IGF-I and -II levels begin to increase by 32 to 34 weeks' gestation. **The increase in IGF-I levels directly correlates with increase in fetal size, and a reduction in IGF-I levels is associated with growth restriction.**<sup>12</sup> **In contrast, no correlation has been found between serum IGF-II levels and fetal growth.** However, a correlation has been noted between small offspring and genetic manipulations that result in decreased IGF-II messenger RNA production. IGF-II knockout mice are small, and knockout of the IGF-II receptor results in fetal overgrowth.<sup>13</sup> Thus tissue IGF-II concentrations and localized IGF-II release may be more important than circulating levels in supporting fetal growth.

IGF binding proteins (IGFBPs) modulate IGF-I and II concentrations in serum, with IGFBP1 having an inhibitory and IGFBP3 a comparatively stimulatory effect. As such, diminished fetal concentrations of IGFBP3 and enhanced concentrations of IGFBP1 have been associated with smaller fetal size.<sup>14</sup>

**A role for insulin in fetal growth is suggested from the increases in body weight and in heart and liver weights in infants of diabetic mothers. Insulin levels within the high physiologic range increase fetal body weight, and increases in endogenous fetal insulin significantly increase fetal glucose uptake. In addition, fetal insulin secretion increases in response to elevations in blood glucose, although the normal rapid insulin response phase is absent.**<sup>15</sup> Plasma insulin levels sufficient to increase fetal growth also may exert mitogenic effects, perhaps through insulin-induced IGF-II receptor binding. Separate receptors for insulin and IGF-II are expressed in fetal liver cells by the end of the first trimester. Hepatic insulin receptor numbers (per gram tissue) triple by 28 weeks, whereas IGF-II receptor numbers remain constant. Thus, although infants of diabetic mothers are at increased risk of cardiac defects, the growth patterns of these infants indicate that insulin levels may be most important in late gestation (see [Chapter 40](#)). Although less common, equally dramatically low birthweights are associated with the absence of fetal insulin. Experimentally induced hypoinsulinemia causes a 30% decrease in fetal glucose utilization and decreases fetal growth.

**As in the adult,  $\beta$ -adrenergic receptor activation increases fetal insulin secretion, whereas  $\beta$ -adrenergic activation inhibits insulin secretion. Fetal glucagon secretion also is modulated by the  $\beta$ -adrenergic system. However, the fetal glycemic response to glucagon is blunted, probably caused by a relative reduction in hepatic glucagon receptors.**

Corticosteroids are essential for fetal growth and maturation, and levels in the fetus rise near parturition in step with maturation of fetal organs such as the lung, liver, kidneys, and thymus and with slowing of fetal growth. Exogenous maternal steroid administration during pregnancy also has the potential to diminish fetal growth in humans and in a variety of other species, perhaps via suppression of the IGF axis.<sup>14</sup> In addition to the insulin-like growth factors, a number of other factors—including epidermal growth factor (EGF), transforming growth factor (TGF), fibroblast growth factor (FGF), and nerve growth factor (NGF)—are expressed during embryonic development and appear to exert specific effects during morphogenesis; for example, EGF has specific effects on lung growth and on differentiation of the secondary palate, and normal sympathetic adrenergic system development is dependent on NGF. However, the specific role of these factors in

regulating fetal growth remains to be defined. **Similarly, the fetal thyroid also is not important for overall fetal growth but is important for central nervous system development.**

Substantial evidence now exists to support the view that several cell-specific growth factors and their cognate receptors play an essential role in placental growth and function in a number of species. Growth factors identified to date include family members of EGF, TGF- $\beta$ , NGF, IGF, hematopoietic growth factors, VEGF, and FGF. The expression, ontogeny, and regulation of most but not all of these growth factors have been explored; in addition, a number of cytokines also play a role in normal placental development. In vitro placental cell culture studies support the concept that **growth factors and cytokines exert their functions locally, promoting proliferation and differentiation through their autocrine and/or paracrine mode of actions.** For example, EGF promotes cell proliferation, invasion, or differentiation depending on the gestational age. Hepatocyte growth factor and VEGF stimulate trophoblast DNA replication, whereas TGF- $\beta$  suppresses cytotrophoblast invasion and endocrine differentiation. In support of local actions, functional receptors for various growth factors have been demonstrated on trophoblast and other cells. Various intracellular signal proteins and transcription factors that respond to growth factors are also expressed in the placenta. A number of elegant studies have identified alterations in growth factors and growth factor receptors in association with placental and fetal growth restriction. Placental defects in growth factor and receptor pathways, explored through the use of transgenic and mutant mice, have provided potential mechanisms for explaining complications of human placental development.<sup>16</sup> **An illustrative example is EGF, a potent mitogen for epidermal and mesodermal cells that is expressed in human placenta. EGF is involved in embryonal implantation, it stimulates syncytiotrophoblast differentiation in vitro, and it modulates production and secretion of human chorionic gonadotropin (hCG) and human placental lactogen (hPL).** The effects of EGF are mediated by EGF-receptor (EGF-R), a transmembrane glycoprotein with intrinsic tyrosine kinase activity. EGF-R is expressed on the apical microvillus plasma membrane fractions from early, middle, and term whole placentae. Placental EGF-R expression is regulated by locally expressed parathyroid hormone-related protein, which is important in placental differentiation and maternal-fetal calcium flux.<sup>17,18</sup> Decreased EGF-R expression has been demonstrated in association with intrauterine growth restriction (IUGR). **Targeted disruption of EGF-R has been shown to result in fetal death as a result of placental defects.**<sup>19</sup> **Overexpression of EGF-R activity results in placental enlargement.**<sup>20</sup>

The EGF family now consists of at least 15 members, many of which have been identified in human placenta. Future studies should reveal whether EGF family members play distinct or overlapping functions in mediating placental growth.

Control of fetal growth may occur via the impact of growth factors/hormones on the placenta or may occur as a direct result of action in and on the fetus. It is clear that nutrition may play a role in these processes. However, the number of genes and gene products known to control or affect fetal growth continues to increase. **Imprinted genes, expressed primarily from maternally or paternally acquired alleles, play a particularly important role in controlling fetal growth.**<sup>21</sup> **Abnormalities in the expression of these genes often result in fetal overgrowth or undergrowth.** Environmental influences, such as alterations in

gene methylation or in modification of histones associated with genes, may further alter gene expression and thus fetal growth, making this a rich area for further exploration.

## FETAL CARDIOVASCULAR SYSTEM

### Development

The heart and the vascular system develop from splanchnic mesoderm during the third week after fertilization. The two primordial heart tubes fuse to form a simple contractile tube early in the fourth week, and the cardiovascular system becomes the first functional organ system. **During weeks 5 to 8, this single-lumen tube is converted into the definitive four-chambered heart through a process of cardiac looping (folding), remodeling, and partitioning.** However, an opening in the interatrial septum, the foramen ovale, is present and serves as an important right-to-left shunt during fetal life.

**During the fourth embryonic week, three primary circulations characterize the vascular system.** The *aortic/cardinal circulation* serves the embryo proper and is the basis for much of the fetal circulatory system. Of note the left sixth aortic (pulmonary) arch forms a connection between the left pulmonary artery and the aorta as the ductus arteriosus. **The ductus arteriosus also functions as a right-to-left shunt by redistributing right ventricular (RV) output from the lungs to the aorta and fetal and placental circulations.** The *vitelline circulation* develops in association with the yolk sac, and although it plays a minor role in providing nutrients to the embryo, its rearrangement ultimately provides the circulatory system for the gastrointestinal (GI) tract, spleen, pancreas, and liver. The *allantoic circulation* develops in association with the chorion and the developing chorionic villi and forms the placental circulation, comprised of two umbilical arteries and two umbilical veins. **In humans, the venous pathways are rearranged during embryonic weeks 4 to 8, and only the left umbilical vein is retained.** Subsequent rearrangement of the vascular plexus associated with the developing liver forms the ductus venosus, a venous shunt that allows at least half of the estimated umbilical blood flow (70 to 130 mL/min/kg fetal weight after 30 weeks' gestation) to bypass the liver and enter the inferior vena cava.<sup>22</sup>

Placental gas exchange provides well-oxygenated blood that leaves the placenta (Fig. 2-3) via the umbilical vein. In addition to the ductus venosus, small branches into the left lobe of the liver and a major branch to the right lobe account for the remainder of the umbilical venous flow. Left hepatic vein blood combines with the well-oxygenated ductus venosus flow as it enters the inferior vena cava. Because right hepatic vein blood combines with the portal vein (only a small fraction of portal vein blood passes through the ductus venosus), right hepatic vein blood is less oxygenated than its counterpart on the left,<sup>22</sup> and a combination of right hepatic/portal drainage with blood returning from the lower trunk and limbs further decreases the oxygen content. Although both ductus venosus blood and hepatic portal/fetal trunk bloods enter the inferior vena cava and the right atrium, little mixing occurs. **This stream of well-oxygenated ductus venosus blood is preferentially directed into the foramen ovale by the valve of the inferior vena cava and the crista dividens on the wall of the right atrium.** This shunts a portion of the most highly oxygenated ductus venosus blood through the foramen ovale with little opportunity for mixing with superior vena cava/coronary sinus

**FIG 2-3** Anatomy of the umbilical and hepatic circulation. Black arrows represent nutrient-rich and oxygen-rich blood. LHV, left hepatic vein; RHV, right hepatic vein. (From Rudolph AM. Hepatic and ductus venosus blood flows during fetal life. *Hepatology*. 1983;3:254-258.)

**FIG 2-4** Anatomy of the fetal heart and central shunts. CA, carotid artery; DA, ductus arteriosus; FA, femoral artery; FO, foramen ovale; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; SVC, superior vena cava; TA, thoracic aorta. (From Anderson DF, Bissonnette JM, Faber JJ, Thornburg KL. Central shunt flows and pressures in the mature fetal lamb. *Am J Physiol*. 1981;241:H60-H66.)

venous return (Fig. 2-4; see also Fig. 2-3). As a result, left atrial filling results primarily from umbilical vein–ductus venosus blood, with a small contribution from pulmonary venous flow. Thus blood with the highest oxygen content is delivered to the left atrium and left ventricle and ultimately supplies blood to the upper body and limbs, carotid and vertebral circulations, and the brain. Inferior vena cava flow is greater than the volume that can cross the foramen ovale. The remainder of the oxygenated inferior vena cava blood is directed through the tricuspid valve (see Fig. 2-3) into the right ventricle (see Fig. 2-4) and is accompanied by venous return from the superior

vena cava and coronary sinus. However, the very high vascular resistance in the pulmonary circulation maintains mean pulmonary artery pressure 2 to 3 mm Hg above aortic pressure and directs most of the RV output through the ductus arteriosus and into the aorta and the fetal and placental circulations.<sup>22</sup>

### Fetal Heart

The adult cardiovascular system includes a high-pressure (95 mm Hg) system and a low-pressure pulmonary circuit (15 mm Hg) driven by the left and right ventricles working in series. Although the ejection velocity is greater in the left ventricle than in the right, equal volumes of blood are delivered into the systemic and pulmonary circulations with contraction of each ventricle. The stroke volume is the volume of blood ejected by the left ventricle with each contraction, and cardiac output is a function of the stroke volume and heart rate ( $70 \text{ mL/beat} \times 72 \text{ beats/min} = 5040 \text{ mL/min}$ ). For a 70-kg adult man, cardiac output averages  $72 \text{ mL/min/kg}$ . In addition to heart rate, cardiac output varies with changes in stroke volume, which in turn is determined by venous return (preload), pulmonary artery and aortic pressures (afterload), and contractility.

In contrast to the adult heart, where the two ventricles pump blood in a series circuit, the unique fetal shunts provide an unequal distribution of venous return to the respective atria, and ventricular output represents a mixture of oxygenated and deoxygenated blood. **Thus the fetal right and left ventricles function as two pumps that operate in parallel, rather than in series, and cardiac output is described as the combined ventricular output.** RV output exceeds 60% of biventricular output<sup>23</sup> and is primarily directed through the ductus arteriosus to the descending aorta (see Fig. 2-4). As a result, placental blood flow, which represents approximately 40% of the combined ventricular output, primarily reflects RV output. Because of the high pulmonary vascular resistance,<sup>23</sup> the pulmonary circulation receives only 5% to 10% of the combined ventricular output. Instead, left ventricular (LV) output is primarily directed through the aortic semilunar valve and aortic arch to the upper body and head. Estimates of fetal LV output average  $120 \text{ mL/min/kg}$  body weight. If LV output is less than 40% of the combined biventricular output,<sup>23</sup> total fetal cardiac output would be above  $300 \text{ mL/min/kg}$ . The distribution of the cardiac output to fetal organs is summarized in Table 2-1,<sup>1</sup> with fetal hepatic distribution reflecting only the portion supplied by the hepatic artery. In fact, hepatic blood flow derives principally from the umbilical vein and to a lesser extent the portal vein,<sup>24</sup> and represents about 25% of the total venous return to the heart.

**The placenta receives approximately 40% of the combined ventricular output, which means the single umbilical vein also conducts this volume of the combined ventricular output toward the fetus.** At least half of the umbilical venous blood bypasses the liver via the ductus venosus, and the remainder traverses the hepatic circulation. The combination of umbilical vein blood, hepatic portal blood, and blood returning from the lower body contributes approximately 69% of the cardiac output that enters the right atrium from the inferior vena cava. Flow across the foramen ovale accounts for approximately one third (27%) of the combined cardiac output.<sup>23</sup> Pulmonary venous return to the left atrium is low and represents approximately 7% of combined ventricular output. Thus the left atrium accounts for only about 34% ( $27\% + 7\%$ ) of the combined ventricular output. Because a volume of inferior vena cava venous return

**TABLE 2-1** DISTRIBUTION OF CARDIAC OUTPUT TO FETAL ORGANS

| ORGAN                  | BIVENTRICULAR CARDIAC OUTPUT (%) |
|------------------------|----------------------------------|
| Placenta               | 40                               |
| Brain                  | 13                               |
| Heart                  | 3.5                              |
| Lung                   | 7                                |
| Liver                  | 2.5 (hepatic artery)             |
| Gastrointestinal tract | 5                                |
| Adrenal glands         | 0.5                              |
| Kidney                 | 2.5                              |
| Spleen                 | 1                                |
| Body                   | 25                               |

Data from Rudolph AM, Heymann MA. Circulatory changes during growth in the fetal lamb. *Circ Res*. 1970;26(3):289.

equivalent to 27% of the combined ventricular output is shunted across the foramen ovale, 42% remains in the right atrium and contributes to RV output. With another 21% from the superior vena cava and 3% from the coronary circulation, RV output accounts for 66% of the combined ventricular output. However, only 7% of RV output enters the pulmonary circulation, leaving 59% entering the aorta via the ductus arteriosus. Similarly, 24% of the combined ventricular output derived from the left ventricle is distributed to the upper body and brain, with approximately 10% combining with RV output in the aorta. Thus 69% of the combined ventricular output reaches the descending aorta, and 40% of this accounts for placental flow, with the remainder distributed to the fetal abdominal organs and lower body.

**Consistent with the greater contribution of the right ventricle to combined ventricular output, coronary blood flow to the myocardium reflects the greater stroke volume of the right side, and RV free wall and septal blood flows are higher than in the left ventricle.<sup>25</sup> It is not surprising then that fetal ventricular wall thickness is greater on the right side relative to the left.** As in the adult, fetal ventricular output depends on heart rate, pulmonary artery and aortic pressures, and contractility. The relationship between mean right atrial pressure (the index often used for ventricular volume at the end of diastole) and stroke volume is depicted in Figure 2-5. The steep ascending limb represents the length–active tension relationship for cardiac muscle in the right ventricle.<sup>26</sup> Under normal conditions, fetal right atrial pressure resides at the break point in this ascending limb, and increases in pressure do not increase stroke volume. Thus **the contribution of Starling mechanisms to increasing right heart output in the fetus is limited. In contrast, decreases in venous return and right atrial pressure decrease stroke volume.** Compared with the left ventricle, the fetal right ventricle has a greater anteroposterior dimension, which increases both volume and circumferential radius of curvature. This anatomic difference increases the radius/wall thickness ratio for the right ventricle and produces increased wall stress in systole and a decrease in stroke volume when afterload increases.<sup>25</sup> Because the right ventricle is sensitive to afterload, a linear inverse relationship exists between stroke volume and pulmonary artery pressure.<sup>26</sup>

The relationship between atrial pressure and stroke volume in the left ventricle is similar to that shown in Figure 2-5 for the right ventricle. Although the break point occurs near the normal

**FIG 2-5** Stroke volume of the fetal right ventricle as a function of mean right atrial pressure. (From Thornburg KL, Morton MJ. Filling and arterial pressures as determinants of RV stroke volume in the sheep fetus. *Am J Physiol*. 1983;244:H656-H663.)

value for left atrial pressure, a small amount of preload reserve remains.<sup>25</sup> In distinction to the fetal right ventricle, the left side is not sensitive to aortic pressure increases. Thus postnatal increases in systemic blood pressure do not decrease LV stroke volume, and LV output increases to meet the needs of the postnatal systemic circulation. Although Starling mechanism–related increases in stroke volume are limited, especially in the right side of the heart, late-gestation fetal heart  $\beta$ -adrenergic receptor numbers are similar to those in the adult, and circulating catecholamine–induced increases in contractility may increase stroke volume by 50%.

**Although the fetal heart rate (FHR) decreases during the last half of gestation, particularly between 20 and 30 weeks, the FHR averages more than twofold above resting adult heart rates.** If analysis is confined to episodes of low heart rate variability, mean heart rate decreases from 30 weeks to term. However, if all heart rate data are analyzed, mean heart rate is stable at 142 beats/min over the last 10 weeks of gestation. Variability in mean heart rate over 24 hours includes a nadir between 2 AM and 6 AM and a peak between 8 AM and 10 AM. Most FHR accelerations occur simultaneously with limb movement, which primarily reflects central neuronal brainstem output. Also, movement-related decreases in venous return and a reflex tachycardia may contribute to heart rate accelerations.<sup>27</sup> **Because ventricular stroke volumes decrease with increasing heart rate, fetal cardiac output remains constant over a heart rate range of 120 to 180 beats/min.** The major effect of this inverse relationship between heart rate and stroke volume is an alteration in end-diastolic dimension. If end-diastolic dimension is kept constant, no fall in stroke volume occurs, and cardiac output increases.

**At birth, major changes in vascular distribution occur with the first breath. Alveolar expansion and the associated increase in alveolar capillary oxygen tension induce a marked decrease in pulmonary microvascular resistance.** This decrease in pulmonary vascular resistance has two effects. First, an accompanying decrease occurs in right atrial afterload and right atrial pressure. Second, the increase in pulmonary flow increases venous return into the left atrium and therefore increases left atrial pressure. The combined effect of these two events is to

increase left atrial pressure above right atrial pressure, which leads to a physiologic closure of the foramen ovale. The return of the highly oxygenated blood from the lungs to the left atrium, left ventricle, and aorta and the decrease in pulmonary vascular resistance, and hence pulmonary trunk pressure, allows backflow of oxygen-rich blood into the ductus arteriosus. **This local increase in ductus arteriosus oxygen tension alters the ductus response to prostaglandins and causes a marked localized vasoconstriction.** Concurrent spontaneous constriction (or clamping) of the umbilical cord stops placental blood flow, reduces venous return, and perhaps augments the decrease in right atrial pressure.

## Regulation of Cardiovascular Function

### Autonomic Regulation

**Through reflex stimulation of peripheral baroreceptors, chemoreceptors, and central mechanisms, the sympathetic and parasympathetic systems have important roles in the regulation of FHR, cardiac contractility, and vascular tone. The fetal sympathetic system develops early, whereas the parasympathetic system develops somewhat later.**<sup>28</sup> Nevertheless, in the third trimester, increasing parasympathetic tone accounts for the characteristic decrease in FHR with periods of reduced FHR reactivity. As evidence, FHR increases in the presence of parasympathetic blockade with atropine. **Opposing sympathetic and parasympathetic inputs to the fetal heart contribute to R-R interval variability from one heart cycle to the next and to basal heart rate variability over periods of a few minutes. However, even when sympathetic and parasympathetic inputs are removed, a level of variability remains.**

Fetal sympathetic innervation is not essential for blood pressure maintenance when circulating catecholamines are present. Nevertheless, fine control of blood pressure and FHR requires an intact sympathetic system. In the absence of functional adrenergic innervation, hypoxia-induced increases in peripheral, renal, and splanchnic bed vascular resistances and blood pressure are not seen.<sup>29</sup> However, hypoxia-related changes in pulmonary, myocardial, adrenal, and brain blood flows occur in the absence of sympathetic innervation, which indicates that both local and endocrine effects contribute to regulation of blood flow in these organs.

Receptors in the carotid body and arch of the aorta respond to pressor or respiratory gas stimulation with afferent modulation of heart rate and vascular tone. Fetal baroreflex sensitivity, in terms of the magnitude of decreases in heart rate per millimeter of mercury increase in blood pressure, is blunted relative to the adult.<sup>30</sup> **However, fetal baroreflex sensitivity more than doubles in late gestation.** Although the set point for FHR is not believed to depend on intact baroreceptors, FHR variability increases when functional arterial baroreceptors are absent.<sup>31</sup> The same observation has been made for fetal blood pressure. Thus fetal arterial baroreceptors buffer variations in fetal blood pressure during body or breathing movements.<sup>31</sup> Changes in baroreceptor tone likely account for the increase in mean fetal blood pressure normally observed in late gestation. In the absence of functional chemoreceptors, mean arterial pressure is maintained<sup>31</sup> while peripheral blood flow increases. Thus peripheral arterial chemoreceptors may be important to maintenance of resting peripheral vascular tone. **Peripheral arterial chemoreceptors also are important components in fetal reflex responses to hypoxia; the initial bradycardia is not seen without functional chemoreceptors.**

## Hormonal Regulation

Adrenocorticotrophic hormone (ACTH) and catecholamines are discussed in the sections that describe the fetal adrenal and thyroid glands later in this chapter.

### ARGININE VASOPRESSIN

**Significant quantities of arginine vasopressin (AVP) are present in the human fetal neurohypophysis by completion of the first trimester. Ovine fetal plasma AVP levels increase appropriately in response to changes in fetal plasma osmolality induced directly in the fetus<sup>32</sup> or via changes in maternal osmolality.<sup>33</sup>** Because of functional high- and low-pressure baroreceptors and chemoreceptor afferents, decreases in fetal intravascular volume or systemic blood pressure<sup>34,35</sup> also increase fetal AVP secretion. Thus in the late-gestation fetus as in the adult, AVP secretion is regulated by both osmoreceptor and volume/baroreceptor pathways. Hypoxia-induced AVP secretion has been demonstrated beyond mid pregnancy of ovine gestation, and reductions in fetal PO<sub>2</sub> of 10 mm Hg (50%) evoke profound increases in fetal plasma AVP levels (about 2 pg/mL to 200 to 400 pg/mL or more). Thus, because fetal AVP responsiveness to hypoxia is augmented relative to the adult (as much as fortyfold), and fetal responsiveness appears to increase during the last half of gestation, **hypoxemia is the most potent stimulus known for fetal AVP secretion.**

**The cardiovascular response pattern to AVP infusion includes dose-dependent increases in fetal mean blood pressure and decreases in heart rate at plasma levels well below those required for similar effects in the adult.** Receptors (V1) distinct from those that mediate AVP antidiuretic effects in the kidney (V2) account for AVP contributions to fetal circulatory adjustments during hemorrhage, hypotension, and hypoxia.<sup>36</sup> Corticotropin-releasing factor (CRF) effects of AVP may contribute to hypoxia-induced increases in plasma ACTH and cortisol levels. In addition to effects on FHR, cardiac output, and arterial blood pressure, AVP-induced changes in peripheral, placental, myocardial, and cerebral blood flows directly parallel the cardiovascular changes associated with acute hypoxia. Because many of these responses are attenuated during AVP receptor blockade, AVP effects on cardiac output distribution may serve to facilitate oxygen availability to the fetus during hypoxic challenges. However, other hypoxia-related responses, including decreases in renal and pulmonary blood flows and increased adrenal blood flow, are not seen in response to AVP infusions.

### RENIN-ANGIOTENSIN II

**Fetal plasma renin levels are typically elevated during late gestation.**<sup>37</sup> A variety of stimuli that include changes in tubular sodium concentration; reductions in blood volume, vascular pressure, or renal perfusion pressure; and hypoxemia all increase fetal plasma renin activity. The relationship between fetal renal perfusion pressure and plasma renin activity is similar to that of adults. Consistent with the effects of renal nerve activity on renin release in adults, fetal renin gene expression is directly modulated by renal sympathetic nerve activity.

**Although fetal plasma AII levels increase in response to small changes in blood volume and hypoxemia, fetal AII and aldosterone levels do not increase in proportion to changes in plasma renin activity. This apparent uncoupling of the fetal renin-angiotensin-aldosterone system and the increase in newborn AII levels may relate to the significant contribution of the placenta to plasma AII clearance in the**

**fetus relative to the adult.** Also, limited angiotensin-converting enzyme (ACE) availability due to reduced pulmonary blood flow and direct inhibition of aldosterone secretion by the normally high circulating ANF levels may contribute. Thus, reductions in AII production and aldosterone responses to AII, augmented AII and aldosterone clearances, and the resulting reductions in AII and aldosterone levels and feedback inhibition of renin may account for the elevated renin and reduced AII and aldosterone levels typically observed during fetal life.

AII infusion increases fetal mean arterial blood pressure. In contrast to AVP-induced bradycardia, fetal AII infusion increases heart rate (after an initial reflex bradycardia) through both a direct effect on the heart and decreased baroreflex responsiveness. Both hormones increase fetal blood pressure similar to the levels seen with hypoxemia. However, AII does not reduce peripheral blood flow, perhaps because circulation to muscle, skin, and bone is always under maximum response to AII, which thereby limits increases in resting tone. AII infusions also decrease renal blood flow and increase umbilical vascular resistance, although absolute placental blood flow does not change. Whereas the adult kidney contains both AII-receptor subtypes ( $AT_1$  and  $AT_2$ ), the  $AT_2$  subtype is the only form present in the human fetal kidney. Maturation differences in the AII receptor subtype expressed would be consistent with earlier studies that demonstrated differing AII effects on fetal renal and peripheral vascular beds. Thus, the receptors that mediate AII responses in the renal and peripheral vascular beds differ during fetal life.

### Fetal Hemoglobin

**The fetus exists in a state of aerobic metabolism, with arterial blood  $PO_2$  values in the 20 to 35 mm Hg range but with no evidence of metabolic acidosis.** Adequate fetal tissue oxygenation is achieved by several mechanisms. Of major importance are the higher fetal cardiac output and organ blood flows. A higher hemoglobin concentration (relative to the adult) and an increase in oxygen-carrying capacity of fetal hemoglobin also contribute. The resulting leftward shift in the fetal oxygen dissociation curve relative to the adult (Fig. 2-6) increases fetal blood oxygen saturation for any given oxygen tension. For example, at a partial pressure of 26.5 mm Hg, adult blood oxygen saturation is 50%, whereas fetal oxygen saturation is 70%. Thus at a normal fetal  $PO_2$  of 20 mm Hg, fetal whole-blood oxygen saturation may be 50%.

**The basis for increased oxygen affinity of fetal whole blood resides in the interaction of fetal hemoglobin with intracellular organic phosphate 2,3-diphosphoglycerate (2,3-DPG).** The fetal hemoglobin (HgbF) tetramer is composed of two  $\alpha$ -chains (identical to adult) and two  $\gamma$ -chains. The latter differ from the  $\gamma$ -chain of adult hemoglobin (HgbA) in 39 of 146 amino acid residues. Among these differences is the substitution of serine in the  $\gamma$ -chain of HgbF for histidine at the  $\beta$ -143 position of HgbA, which is located at the entrance to the central cavity of the hemoglobin tetramer. Due to a positively charged imidazole group, histidine can bind with the negatively charged 2,3-DPG. Binding of 2,3-DPG to deoxyhemoglobin stabilizes the tetramer in the reduced form. Because serine is nonionized and does not interact with 2,3-DPG to the same extent as histidine, the oxygen affinity of HgbF is increased, and the dissociation curve is shifted to the left. If HgbA or HgbF is removed from the erythrocyte and stripped of organic phosphates, the oxygen affinity for both hemoglobins is similar. However, addition of equal amounts of 2,3-DPG to the hemoglobins decreases

**FIG 2-6** Oxyhemoglobin dissociation curves of maternal and fetal human blood at pH 7.4 and 37° C. (Modified from Hellegers AE, Schrufer JJ. Normograms and empirical equations relating oxygen tension, percentage saturation, and pH in maternal and fetal blood. *Am J Obstet Gynecol.* 1961;81:377-384.)

HgbA oxygen affinity (dissociation curve shifts to the right) to a greater extent than for HgbF. Thus, even though overall oxygen affinities are similar, differences in 2,3-DPG interaction result in a higher oxygen affinity for HgbF.

**The proportion of HgbF to HgbA changes between 26 and 40 weeks' gestation. HgbF decreases linearly from 100% to about 70% so that HgbA accounts for 30% of fetal hemoglobin at term.** This change in expression from  $\gamma$ - to  $\beta$ -globulin synthesis takes place in erythroid progenitor cells. Although the basis for this switching is not yet known, our understanding of human globin gene regulation has provided important insights into several fetal hemoglobin disorders, such as the thalassemias and sickle cell anemia. Duplication of the  $\alpha$ -genes on chromosome 16 provides the normal fetus with four gene loci. The genes for the remaining globins are located on chromosome 11 and consist of  $\gamma$ ,  $\delta$ , and  $\beta$ . The two  $\gamma$ -genes differ in the amino acid in position 36, glycine versus alanine. HgbA synthesis is dictated by the  $\gamma$ - and  $\beta$ -genes, HgbF by  $\alpha$  and  $\gamma$ , and HgbA<sub>2</sub> by  $\alpha$  and  $\delta$ . Sequences in the  $\delta$  region may be responsible for the relative expression of the  $\gamma$ -gene such that fetal hemoglobin persists when these are absent.

### FETAL KIDNEY

**Overall fetal water and electrolyte homeostasis is primarily mediated by fetal-maternal exchange across the placenta. However, urine production by the fetal kidney is essential to maintenance of AFV and composition. Although absolute glomerular filtration rate (GFR) increases during the third trimester, GFR per gram of kidney weight does not change because GFR and fetal kidney weight increase in parallel.** The genesis of new glomeruli is complete by about 36 weeks. Subsequent increases in GFR reflect increases in glomerular surface area for filtration, effective filtration pressure, and capillary

filtration coefficient. Although glomerular filtration is related to hydrostatic pressure, and fetal blood pressure increases in the third trimester, both renal blood flow per gram of kidney weight and filtration fraction (GFR/renal plasma flow) remain constant.<sup>38</sup> Newborn increases in filtration fraction parallel increases in arterial pressure, which suggests that the lower hydrostatic pressure within the glomerulus contributes to the relatively low filtration fraction and GFR of the intrauterine kidney.<sup>38</sup> A mild glomerulotubular imbalance may describe the early-gestation fetus. However, renal tubular sodium and chloride reabsorptions increase in late gestation such that glomerulotubular balance is maintained in the third-trimester fetus.<sup>38</sup>

**Although fetal GFR is low, the daily urine production rate is substantial, equaling 60% to 80% of the AFV. The relatively large urine output results from the significant portion of the filtered water (20%) that is excreted in the form of hypotonic urine.** The positive free-water clearance that characterizes fetal renal function originally led to the hypothesis that the fetal kidney lacked AVP receptors. However, ovine fetal renal collecting duct responses to AVP can be demonstrated in the second trimester, which indicates that diminished urine-concentrating ability is not caused by AVP receptor absence. Fetal renal  $V_2$  receptors mediate AVP-induced tubular water reabsorption, and functional  $V_2$  receptors are present in the fetal kidney by the beginning of the last third of gestation.<sup>36</sup> In addition, AVP-induced cAMP production is not different from that of the adult, and AVP-induced apical tubular water channels (aquaporin 2) are expressed in the fetal kidney. In fact, the selective AVP  $V_2$  receptor agonist dDAVP appropriately increases fetal renal water reabsorption without affecting blood pressure or heart rate.<sup>36</sup> Thus  $V_2$  receptors mediate AVP effects on fetal urine production and AFV.<sup>36</sup> Instead, **the reduced concentrating ability of the fetal kidney primarily reflects reductions in proximal tubular sodium reabsorption, short juxtamedullary nephron loops of Henle, and limited medullary interstitial urea concentrations.**

Although fetal plasma renin activity levels are high, effective uncoupling of AII production from plasma renin activity and a high placental clearance rate for AII serve to minimize increases in fetal plasma AII levels. Limiting fluctuations in fetal plasma AII levels may be advantageous for fetal renal function regulation. For example, fetal AII infusion increases fetal mean arterial pressure and renal and placental vascular resistances. In contrast, fetal treatment with the ACE inhibitor captopril increases plasma renin activity and decreases arterial blood pressure, renal vascular resistance, and filtration fraction, and urine flow effectively ceases. Given the potential for AII to decrease placental blood flow, uncoupling of renin-induced angiotensin I production, limited ACE activity, and augmented placental AII clearance may protect the fetal cardiovascular system from large increases in plasma AII levels. Collectively, plasma AII levels appear to be regulated within a very narrow range, and this regulation may be important to overall fetal homeostasis.

**Atrial natriuretic factor (ANF) granules are present in the fetal heart, and fetal plasma ANF levels are elevated relative to the adult. Fetal plasma ANF levels increase in response to volume expansion, and ANF infusion evokes limited increases in ovine fetal renal sodium excretion. Fetal ANF infusion also decreases fetal plasma volume with minimal effect on blood pressure. These observations suggest that ANF actions in the fetus are primarily directed at volume homeostasis and have minimal cardiovascular effects.**

The ability of the fetal kidney to excrete titratable acid and ammonia is limited relative to the adult. In addition, the threshold for fetal renal bicarbonate excretion—defined as the excretion of a determined amount of bicarbonate per unit GFR—is much lower than in the adult. That is, fetal urine tends to be alkaline at relatively low plasma bicarbonate levels, despite the high fetal arterial  $PCO_2$ . Because fetal renal tubular mechanisms for glucose reabsorption are qualitatively similar to those in the adult, fetal renal glucose excretion is limited. In fact, the maximum ability of the fetal kidney to reabsorb glucose exceeds that of the adult when expressed as a function of GFR.

## FETAL GASTROINTESTINAL SYSTEM

### Gastrointestinal Tract

Amniotic fluid contains measurable glucose, lactate, and amino acid concentrations, which raises the possibility that fetal swallowing could serve as a source of nutrient uptake. Fetal swallowing contributes importantly to somatic growth and GI development as a result of the large volume of ingested fluid. **About 10% to 15% of fetal nitrogen requirements may result from swallowing of amniotic fluid protein.<sup>39</sup> Amino acids and glucose are absorbed and utilized by the fetus if they are administered into the fetal GI tract.<sup>40</sup> Furthermore, intragastric ovine fetal nutrient administration partially ameliorates fetal growth restriction induced by maternal malnutrition.<sup>41</sup>**

Further evidence for the role of swallowing in fetal growth results from studies that have demonstrated that impairment of fetal rabbit swallowing at 24 days' gestation (term = 31 days) induces an 8% weight decrease (compared with controls) by 28 days.<sup>42</sup> The fetal GI tract is directly affected, and esophageal ligation of fetal rabbit pups results in marked reductions in gastric and intestinal tissue weight and gastric acidity.<sup>42</sup> Reductions in GI and somatic growth were reversed by fetal intragastric infusion of amniotic fluid.<sup>42</sup> Similarly, esophageal ligation of 90-day ovine fetuses (term = 145 to 150 days) induces a 30% decrease of small intestine villus height<sup>43</sup> and a reduction in liver, pancreas, and intestinal weight.<sup>44</sup>

Although ingestion of amniotic fluid nutrients may be necessary for optimal fetal growth, trophic growth factors within the amniotic fluid also importantly contribute. Thus the reduction in fetal rabbit weight induced by esophageal ligation is reversed by gastric infusion of EGF. Studies in human infants support the association of fetal swallowing and GI growth because upper GI tract obstructions are associated with a significantly greater rate of human fetal growth restriction as compared with fetuses with lower GI obstructions.<sup>45</sup>

Blood flow to the fetal intestine does not increase during moderate levels of hypoxemia. The artery–mesenteric vein difference in oxygen content is also unchanged so that at a constant blood flow, intestinal oxygen consumption can remain the same during moderate hypoxemia. **However, with more pronounced hypoxemia, fetal intestinal oxygen consumption falls as blood flow decreases, and the oxygen content difference across the intestine fails to widen. The result is a metabolic acidosis in the blood that drains the mesenteric system.**

### Liver

Near term, the placenta is the major route for bilirubin elimination. Less than 10% of an administered bilirubin load is excreted in the fetal biliary tree over a 10-hour period; about

**20% remains in plasma. Thus the fetal metabolic pathways for bilirubin and bile salts remain underdeveloped at term.**

The cholate pool size (normalized to body surface area) is one third and the synthetic rate is one half the adult levels. In premature infants, cholate pool size and synthesis rates represent less than half and one third, respectively, of term infant values. In fact, premature infant intraluminal duodenal bile acid concentrations are near or below the level required to form lipid micelles.<sup>46</sup>

The unique attributes of the fetal hepatic circulation were detailed during the earlier discussion of fetal circulatory anatomy. Notably, the fetal hepatic blood supply primarily derives from the umbilical vein. The left lobe receives its blood supply almost exclusively from the umbilical vein (with a small contribution from the hepatic artery), whereas the right lobe receives blood from the portal vein as well. **The fetal liver under normal conditions accounts for about 20% of total fetal oxygen consumption.** Because hepatic glucose uptake and release are balanced, net glucose removal by the liver under normal conditions is minimal. During episodes of hypoxemia,  $\beta$ -adrenergic receptor-mediated increases in hepatic glucose release account for the hyperglycemia characteristic of short-term fetal hypoxemia.<sup>47</sup> **Hypoxia severe enough to decrease fetal oxygen consumption selectively reduces right hepatic lobe oxygen uptake, which exceeds that of the fetus as a whole. In contrast, oxygen uptake by the left lobe of the liver is unchanged.**

## FETAL ADRENAL AND THYROID GLANDS

### Adrenal Glands

**The fetal anterior pituitary secretes ACTH in response to stress, which includes hypoxemia. The associated increase in cortisol exerts feedback inhibition of the continued ACTH response.**<sup>48</sup> In the fetus and adult, proopiomelanocortin post-translational processing gives rise to ACTH, corticotropin-like intermediate lobe peptide (CLIP), and  $\alpha$ -melanocyte-stimulating hormone ( $\alpha$ -MSH). The precursor peptide preproenkephalin is a distinct gene product that gives rise to the enkephalins. Fetal proopiomelanocortin processing differs from the adult. For example, although ACTH is present in appreciable amounts, the fetal pituitary contains large amounts of CLIP and  $\alpha$ -MSH. The fetal ratio of CLIP plus  $\alpha$ -MSH to ACTH decreases from the end of the first trimester to term. Because pituitary corticotropin-releasing hormone (CRH) expression is relatively low until late gestation, AVP serves as the major CRF in early gestation. With increasing gestational age, fetal cortisol levels progressively increase secondary to hypothalamic-pituitary axis maturation. Cortisol is important to pituitary maturation because it shifts corticotrophs from the fetal to the adult type, and it impacts adrenal maturation through regulation of ACTH receptor numbers.<sup>49</sup>

**On a body-weight basis, the fetal adrenal gland is an order of magnitude larger than in the adult. This increase in size is due to the presence of an adrenal cortical definitive zone and a so-called fetal zone that constitutes 85% of the adrenal at birth. Cortisol and mineralocorticoids are the major products of the fetal definitive zone, and fetal cortisol secretion is regulated by ACTH but not human chorionic gonadotropin (hCG). Low-density lipoprotein (LDL)-bound cholesterol (see "Receptor-Mediated Endocytosis and Exocytosis" in Chapter 1) is the major source of steroid precursor in the fetal adrenal. Because the enzyme  $3\alpha$ -hydroxysteroid dehydrogenase is lacking**

in the fetal adrenal, dehydroepiandrosterone sulfate (DHEAS) is the major product of the fetal zone. At mid gestation, DHEAS secretion is determined by both ACTH and hCG. Both fetal ACTH and cortisol levels are relatively low during most of gestation, and no clear correlation has been found between plasma ACTH levels and cortisol production. This apparent dissociation between fetal ACTH levels and cortisol secretion may be explained by 1) differences in ACTH processing, and the presence of the large-molecular-weight proopiomelanocortin processing products CLIP and  $\alpha$ -MSH may suppress ACTH action on the adrenal until late gestation, when ACTH becomes the primary product; 2) fetal adrenal definitive zone ACTH responsiveness may increase; or 3) placental ACTH and/or posttranslational processing intermediates may affect the adrenal response to ACTH.

**Resting fetal plasma norepinephrine levels exceed epinephrine levels approximately tenfold. The fetal plasma levels of both catecholamines increase in response to hypoxemia, and norepinephrine levels are invariably higher than epinephrine levels.** Under basal conditions, norepinephrine is secreted at a higher rate than epinephrine, and this relationship persists during a hypoxemic stimulus. Plasma norepinephrine levels increase in response to acute hypoxemia but decline to remain above basal levels with persistent (>5 min) hypoxemia. In contrast, adrenal epinephrine secretion begins gradually but persists during 30 minutes of hypoxemia. These observations are consistent with independent sites of synthesis and regulation of the two catecholamines.<sup>50</sup> Although the initial fetal blood pressure elevation during hypoxemia correlates with increases in norepinephrine, afterward the correlation between plasma norepinephrine and hypertension is lost.

### Thyroid Gland

The normal placenta is impermeable to thyroid-stimulating hormone (TSH), and triiodothyronine ( $T_3$ ) transfer is minimal.<sup>51</sup> However, appreciable levels of maternal thyroxine ( $T_4$ ) are seen in infants with congenital hypothyroidism (see Chapter 42). **By week 12 of gestation, thyrotropin-releasing hormone (TRH) is present in the fetal hypothalamus, and TRH secretion and/or pituitary sensitivity to TRH increases progressively during gestation. Extrahypothalamic sites, including the pancreas, also may contribute to the high TRH levels observed in the fetus. Measurable TSH is present in the fetal pituitary and serum, and  $T_4$  is measurable in fetal blood by week 12 of gestation.** Thyroid function is low until about 20 weeks, when  $T_4$  levels increase gradually to term. TSH levels rise markedly between 20 and 24 weeks then slowly decrease until delivery. **Fetal liver  $T_4$  metabolism is immature, characterized by low  $T_3$  levels until week 30. In contrast, reverse  $T_3$  levels are high until 30 weeks and decline steadily thereafter until term.**

## FETAL CENTRAL NERVOUS SYSTEM

Clinically relevant indicators of fetal central nervous system function are body movements and breathing movements. Fetal activity periods in late gestation are often termed *active* or *reactive* and *quiet* or *nonreactive*. The *active cycle* is characterized by clustering of gross fetal body movements, a high heart rate variability, heart rate accelerations (often followed by decelerations), and fetal breathing movements. The *quiet cycle* is noted by absence of fetal body movements and a low variability in the fetal heart period. In this context, *fetal heart*

**period variability** refers to deviations in the model heart rate period averaged over short periods (seconds)<sup>52</sup> and is distinct from beat-to-beat variability. In the last 6 weeks of gestation, the fetus is in an active state 60% to 70% of the time. The average duration of quiet periods ranges from 15 to 23 minutes (see Table 4 in Visser and colleagues<sup>52</sup> for a review).

The fetal electrocorticogram shows two predominant patterns: low-voltage, high-frequency and high-voltage, low-frequency electrocortical patterns. *Low-voltage, high-frequency* activity is associated with bursts of rapid eye movement (REM) and fetal breathing movements. Similar to REM sleep in the adult, inhibition of skeletal muscle movement is most pronounced in muscle groups that have a high percentage of spindles. Thus the diaphragm, which is relatively spindle free, is not affected. Fetal body movements during low-voltage electrocortical activity are reduced relative to the activity seen during *high-voltage, low-frequency* electrocortical activity.<sup>53</sup> Polysynaptic reflexes elicited by stimulation of afferents from limb muscles are relatively suppressed when the fetus is in the low-voltage state.<sup>54</sup> Short-term hypoxia<sup>53</sup> or hypoxemia inhibits reflex limb movements, and the inhibitory neural activity arises in the mid-brain area.<sup>54</sup> Fetal cardiovascular and behavioral responses to maternal cocaine use previously have been attributed to reductions in uteroplacental blood flow and resulting fetal hypoxia. However, fetal sheep studies indicate that acute fetal cocaine exposure evokes catecholamine, cardiovascular, and neurobehavioral effects in the absence of fetal oxygenation changes.<sup>55</sup> It is not yet clear whether cocaine-induced reductions in fetal low-voltage electrocortical activity reflect changes in cerebral blood flow or a direct cocaine effect on norepinephrine stimulation of central regulatory centers. However, these observations are consistent with the significant neurologic consequences of cocaine use during pregnancy (see Chapter 55).

**Fetal breathing patterns are rapid and irregular in nature and are not associated with significant fluid movement into the lung.<sup>56</sup> The central medullary respiratory chemoreceptors are stimulated by CO<sub>2</sub>,<sup>57</sup> and fetal breathing is maintained only if central hydrogen ion concentrations remain in the physiologic range. That is, central (medullary cerebrospinal fluid) acidosis stimulates respiratory incidence and depth, and alkalosis results in apnea. Paradoxically, hypoxemia markedly decreases breathing activity, possibly as a result of inhibitory input from centers above the medulla.<sup>58</sup>**

**Glucose is the principal substrate for oxidative metabolism in the fetal brain under normal conditions.** During low-voltage electrocortical activity, cerebral blood flow and oxygen consumption are increased relative to high-voltage values, with an efflux of lactate. During high voltage, the fetal brain shows a net uptake of lactate.<sup>59</sup> The fetal cerebral circulation is sensitive to changes in arterial oxygen content, and despite marked hypoxia-induced increases in cerebral blood flow, cerebral oxygen consumption is maintained without widening of the arterial-venous oxygen content difference across the brain.<sup>60</sup> Increases in CO<sub>2</sub> also cause cerebral vasodilation. However, the response to hypercarbia is reduced relative to that of the adult.

### SUMMARY

The fetus and placenta depend on unique physiologic systems to provide an environment that supports fetal growth and development in preparation for transition to

extrauterine life. Because specific functions of the various physiologic systems are often gestation specific, differences between the fetus and adult of one species are often greater than the differences between systems. Thus the clinician or investigator concerned with fetal life or neonatal transition must fully appreciate these aspects of fetal physiology and their application to their area of study or treatment.

### KEY POINTS

- ◆ Mean amniotic fluid volume increases from 250 to 800 mL between 16 and 32 weeks and decreases to 500 mL at term.
- ◆ Fetal urine production ranges from 400 to 1200 mL/day and is the primary source of amniotic fluid.
- ◆ The fetal umbilical circulation receives approximately 40% of fetal combined ventricular output (300 mL/mg/min).
- ◆ Umbilical blood flow is 70 to 130 mL/min after 30 weeks' gestation.
- ◆ Fetal cardiac output is constant over a heart rate range of 120 to 180 beats/min.
- ◆ The fetus exists in a state of aerobic metabolism, with arterial PO<sub>2</sub> values in the 20 to 25 mm Hg range.
- ◆ Glucose, amino acids, and lactate are the major substrates for fetal oxidative metabolism.
- ◆ Approximately 20% of the fetal oxygen consumption of 8 mL/kg/min is required in the acquisition of new tissue.
- ◆ By week 12 of gestation, thyrotropin-releasing hormone is present in the fetal hypothalamus.
- ◆ Fetal activity periods in late gestation are often termed *active* or *reactive* and *quiet* or *nonreactive*.

## OVERVIEW

Pregnancy is characterized by major adaptations in the maternal anatomy, physiology, and metabolism that are necessary to achieve a successful pregnancy. Hormonal changes significantly alter the maternal physiology and persist throughout both pregnancy and the postpartum period. These adaptations are profound and affect nearly every organ system, and complete understanding of these changes is necessary to differentiate between physiologic alterations and pathology. This chapter describes maternal adaptations in pregnancy and gives specific clinical correlations to describe how these changes may affect care. A complete understanding of these adaptations will also facilitate adequate counseling of patients regarding the physiology that underlies various “normal” symptoms that they may experience.

Many changes in routine laboratory values caused by pregnancy are described in the following text. For a comprehensive review of normal reference ranges for common laboratory tests by trimester, please refer to [Appendix A](#).

## GESTATIONAL WEIGHT GAIN

Pregnancy is generally characterized as a period of weight gain. **Studies on the mean gestational weight gain (GWG) of normal-weight women giving birth to term infants ranged from 22.0 to 36.8 lb during pregnancy.**<sup>1</sup> The recommendations for weight gain during pregnancy have also evolved over time. In the early twentieth century, doctors frequently recommended that women gain between 15 and 20 pounds.<sup>1</sup> However, since that era, our understanding of the contributors to GWG have become more sophisticated, and simultaneously, the body composition of the reproductive-aged population has significantly changed. Thus **we now have more tailored recommendations for GWG that are body mass index (BMI) specific.**<sup>1</sup>

GWG consists of the maternal contribution and the weight of the products of conception. The maternal contribution includes increases in the circulating blood volume, increased mass of the uterus and breasts, increased extracellular fluid, and fat mass accretion.<sup>1</sup> The majority of the accumulated fat mass is subcutaneous, but visceral fat also increases.<sup>2</sup> **The products of conception—the placenta, fetus, and amniotic fluid—comprise approximately 35% to 59% of the total GWG.**<sup>3</sup> The pattern of GWG is most commonly described as sigmoidal with mean weight gains being highest in the second trimester,<sup>4</sup> but the pattern depends on BMI. The Institute of Medicine (IOM) has issued BMI-specific GWG guidelines based upon these BMI differences ([Table 3-1](#)). However, since the publication of these guidelines, emerging evidence suggests that among women who are obese, **adverse pregnancy outcomes may be minimized by limiting GWG even further;** future guidelines may even endorse weight loss.<sup>5,6</sup>

## CARDIOVASCULAR SYSTEM

### Heart

Some of the most profound physiologic changes of pregnancy take place in the cardiovascular system in order to maximize oxygen delivery to both the mother and fetus. The combination of displacement of the diaphragm and the effect of pregnancy on the shape of the rib cage displaces the heart upward and to

the left. The heart also rotates along its long axis, thereby resulting in an increased cardiac silhouette on imaging studies. No change is evident in the cardiothoracic ratio. Other radiographic findings include an apparent straightening of the left-sided heart border and increased prominence of the pulmonary conus. **It is therefore important to confirm the diagnosis of cardiomegaly with an echocardiogram and not simply to rely on radiographic imaging.**

Eccentric cardiac hypertrophy is commonly noted in pregnancy. It is thought to result from expanded blood volume in the first half of pregnancy and progressively increasing afterload in later gestation. These changes, similar to those found in response to exercise, enable the pregnant woman's heart to work more efficiently. Unlike the heart of an athlete that regresses rapidly with inactivity, the pregnant woman's heart decreases in size less rapidly and takes up to 6 months to return to normal.<sup>7</sup>

### Cardiac Output

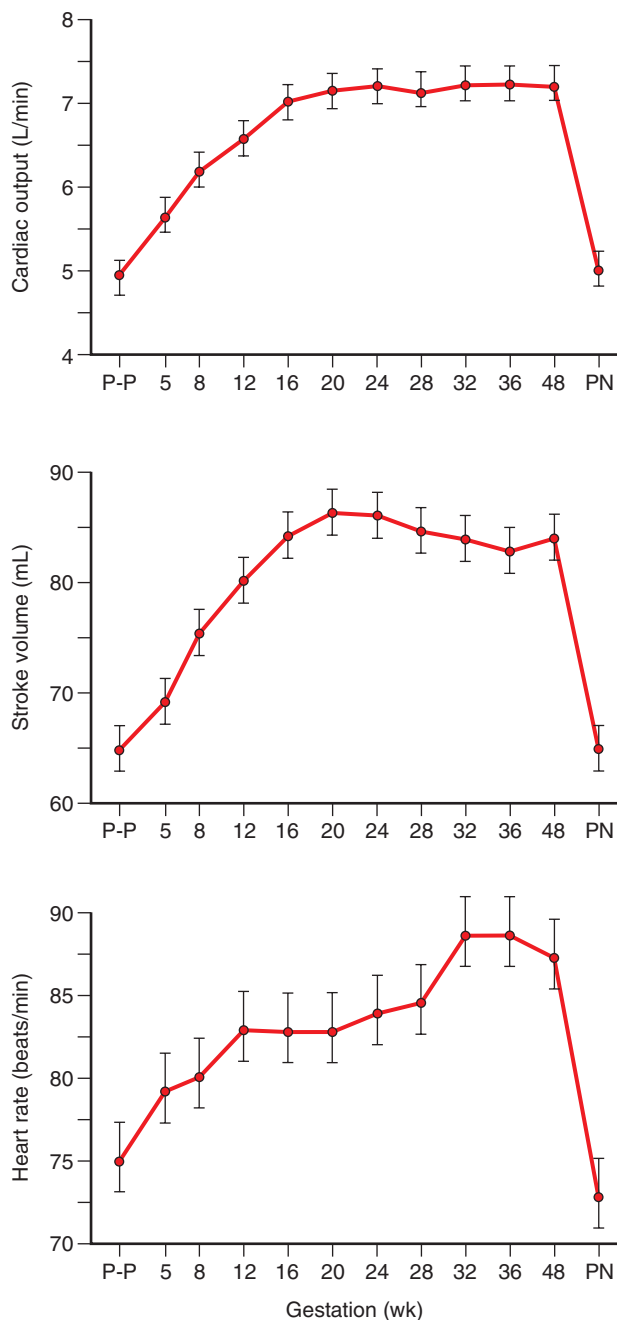

**One of the most remarkable changes in pregnancy is the tremendous increase in cardiac output (CO).** A review of 33 cross-sectional and 19 longitudinal studies revealed that CO increased significantly beginning in early pregnancy and peaked at an average of 30% to 50% above preconceptional values.<sup>8</sup> In a longitudinal study using Doppler echocardiography, CO increased by 50% at 34 weeks from a prepregnancy value of 4.88 to 7.34 L/min ([Fig. 3-1](#)).<sup>8,9</sup> In twin gestations, CO incrementally increases an additional 20% above that of singleton pregnancies. By 5 weeks' gestation, CO has already risen by more than 10%. By 12 weeks, the rise in output is 34% to 39% above nongravid levels, which accounts for about 75% of the total increase in CO during pregnancy. **Although the literature is not clear regarding the exact point in gestation at which CO peaks, most studies point to a range between 25 and 30 weeks.**<sup>9</sup> The data on whether the CO continues to increase in the third trimester are very divergent, with equal numbers of good longitudinal studies showing a mild decrease, a slight increase, or no change.<sup>8</sup> Thus little to no change is likely during this period. This apparent discrepancy appears to be explained by the small number of individuals in each study and the probability that the course of CO during the third trimester is determined by factors specific to the individual.<sup>8</sup> For example, maternal CO in the third trimester is significantly correlated with fetal birthweight and maternal height and weight.<sup>10</sup>

**TABLE 3-1** GESTATIONAL WEIGHT GAIN RECOMMENDATIONS

|  | TOTAL WEIGHT GAIN | MEAN (RANGE) IN LB/WK AFTER FIRST TRIMESTER |
|--|-------------------|---|
| Underweight prepregnancy BMI (<18.5 kg/m <sup>2</sup> )    | 28–40 lb          | 1 (1–1.3)                                   |
| Normal prepregnancy BMI (18.5–24.9 kg/m <sup>2</sup> )     | 25–35 lb          | 1 (0.8–1)                                   |
| Overweight prepregnancy BMI (25.0–29.9 kg/m <sup>2</sup> ) | 15–25 lb          | 0.6 (0.5–0.7)                               |
| Obese prepregnancy BMI (≥30 kg/m <sup>2</sup> )            | 11–20 lb          | 0.5 (0.4–0.6)                               |

BMI, body mass index.

**FIG 3-1** Increase in cardiac output, stroke volume, and heart rate from the nonpregnant state throughout pregnancy. PN, postnatal; P-P, pre-pregnancy. (From Hunter S, Robson S. Adaptation of the maternal heart in pregnancy. *Br Heart J.* 1992;68:540.)

**Most of the increase in cardiac output is directed to the uterus, placenta, and breasts.** In the first trimester, as in the nongravid state, the uterus receives 2% to 3% of CO and the breasts 1%. The percentage of CO that goes to the kidneys (20%), skin (10%), brain (10%), and coronary arteries (5%) remains at similar nonpregnant percentages, but because of the overall increase in CO, this results in an increase in absolute blood flow of about 50%. By term, the uterus receives 17% (450 to 650 mL/min) and the breasts 2%, mostly at the expense of

**FIG 3-2** Effect of position change on cardiac output during pregnancy. \* $P < .05$ . K-C, knee-chest; L.LAT, left lateral; R.LAT, right lateral; SIT, sitting; ST, standing; SUP, supine. (From Clark S, Cotton D, Pivarnik J, et al. Position change and central hemodynamic profile during normal third-trimester pregnancy and postpartum. *Am J Obstet Gynecol.* 1991;164:883.)

a reduction of the fraction of the CO going to the splanchnic bed and skeletal muscle. The absolute blood flow to the liver is not changed, but the overall percentage of CO is significantly decreased.

**Cardiac output (CO) is the product of stroke volume (SV) and heart rate (HR;  $CO = SV \times HR$ ), both of which increase during pregnancy and contribute to the overall rise in CO.** An initial rise in the HR occurs by 5 weeks' gestation and continues until it peaks at 32 weeks' gestation at 15 to 20 beats above the nongravid rate, an increase of 17%. The SV begins to rise by 8 weeks of gestation and reaches its maximum at about 20 weeks at 20% to 30% above nonpregnant values.

Cardiac output in pregnancy depends on maternal position. In a study in 10 normal gravid women in the third trimester, using pulmonary artery catheterization, **CO was noted to be highest in the knee-chest and lateral recumbent positions at 6.9 and 6.6 L/min, respectively.** CO decreased by 22% to 5.4 L/min in the standing position (Fig. 3-2). The decrease in CO in the supine position, compared with the lateral recumbent position, is 10% to 30%. **In both the standing and the supine positions, decreased CO results from a fall in SV secondary to decreased blood return to the heart.** In the supine position, the enlarged uterus compresses the inferior vena cava (IVC), which reduces venous return; before 24 weeks, this effect is not observed. In late pregnancy, the IVC is completely occluded in the supine position, and venous return from the lower extremities occurs through the dilated paravertebral collateral circulation. It is worth noting that whereas the original studies of CO were done with invasive testing, the current accepted practice is to estimate CO in pregnancy using echocardiography.<sup>11</sup>

Despite decreased cardiac output, most supine women are not hypotensive or symptomatic because of the compensated rise in systemic vascular resistance (SVR). However, 5% to 10% of gravidas manifest supine hypotension with symptoms of

dizziness, lightheadedness, nausea, and even syncope. The women who become symptomatic have a greater decrease in CO and blood pressure (BP) and a greater increase in HR when in the supine position than do asymptomatic women. Interestingly, with engagement of the fetal head, less of an effect on CO is seen. The ability to maintain a normal BP in the supine position may be lost during epidural or spinal anesthesia because of an inability to increase SVR. Clinically, the effects of maternal position on CO are especially important when the mother is clinically hypotensive or in the setting of a nonreassuring fetal heart rate tracing. The finding of a decreased CO in the standing position may give a physiologic basis for the finding of decreased birthweight in working women who stand for prolonged periods.<sup>12</sup> In twin pregnancies, CO is notably 15% higher than in singleton pregnancies. This finding is corroborated with findings of increased left atrial diameter in twin pregnancies, indicating volume overload.

### Arterial Blood Pressure and Systemic Vascular Resistance

Blood pressure is the product of cardiac output and systemic vascular resistance ( $BP = CO \times SVR$ ). **Despite the significant increase in cardiac output, the maternal BP is decreased until later in pregnancy as a result of a decrease in SVR that reaches its nadir at midpregnancy and is followed by a gradual rise until term.** Even at full term, SVR remains 21% lower than prepregnancy values in pregnancies not affected by gestational hypertension or preeclampsia.<sup>13</sup> The most obvious cause for the decreased SVR is progesterone-mediated smooth muscle relaxation. However, the exact mechanism for the fall in SVR is poorly understood and likely involves vasorelaxation via the nitric oxide pathway and blunting of vascular responsiveness to vasoconstrictors such as angiotensin II and norepinephrine. **As a result, despite the overall increase in the renin-angiotensin aldosterone system (RAAS), the normal gravida is refractory to the vasoconstrictive effects of angiotensin II.** Gant and colleagues<sup>14</sup> showed that nulliparous women who later develop preeclampsia retain their response to angiotensin II before the appearance of clinical signs of preeclampsia.

Decreases in maternal BP parallel the falling SVR, with initial decreased BP that manifests at 8 weeks' gestation or earlier. Because BP fluctuates with menstruation and is decreased in the luteal phase, it seems reasonable that BP drops immediately in early pregnancy. The diastolic BP and the mean arterial pressure (MAP,  $[2 \times \text{diastolic BP} + \text{systolic BP}]/3$ ) decrease more than the systolic BP, which changes minimally. The overall decrease in diastolic BP and MAP is 5 to 10 mm Hg (Fig. 3-3).<sup>13</sup> **The diastolic BP and the MAP reach their nadir at midpregnancy and return to prepregnancy levels by term. In most studies, they rarely exceed prepregnancy or postpartum values; however, some investigators have reported that at term, the BP is greater than that in matched nonpregnant controls. They have also found that in the third trimester, the BP is higher than prepregnant values.** As noted previously, pregnancy-induced BP changes happen very early, possibly even before the patient realizes that she is pregnant, and therefore even early pregnancy BP assessments may not be consistent with prepregnancy values.<sup>15</sup>

**The position when the BP is taken and what Korotkoff sound is used to determine the diastolic BP are important.**

**FIG 3-3** Blood pressure (BP) trends (sitting and lying) during pregnancy. Postnatal (PN) measures were performed 6 weeks postpartum. (From MacGillivray I, Rose G, Rowe B. Blood pressure survey in pregnancy. *Clin Sci*. 1969;37:395.)

**BP is lowest in the lateral recumbent position, and the BP of the superior arm in this position is 10 to 12 mm Hg lower than that in the inferior arm. In the ambulatory setting, BP should be measured in the sitting position, and the Korotkoff 5 sound should be used.** This is the diastolic BP when the sound disappears, as opposed to the Korotkoff 4, when a muffling of the sound is apparent. In a study of 250 gravidas, the Korotkoff 4 sound could only be identified in 48% of patients, whereas the Korotkoff 5 sound could always be determined. The Korotkoff 4 should only be used when the Korotkoff 5 occurs at 0 mm Hg.<sup>16</sup> Automated BP monitors have been compared with mercury sphygmomanometry during pregnancy, and although they tended to overestimate the diastolic BP, the overall results were similar in normotensive women. Of note in patients with suspected preeclampsia, automated monitors appear increasingly inaccurate at higher BPs.

### Venous Pressure

**Venous pressure in the upper extremities remains unchanged in pregnancy but rises progressively in the lower extremities.** Femoral venous pressure increases from values near 10 cm H<sub>2</sub>O at 10 weeks' gestation to 25 cm H<sub>2</sub>O near term. From a clinical standpoint, this increase in pressure—in addition to the obstruction of the IVC by the expanding uterus—leads to the development of edema, varicose veins, and hemorrhoids and increases the risk for deep venous thrombosis (DVT).

### Central Hemodynamic Assessment

Clark and colleagues studied 10 carefully selected normal women at 36 to 38 weeks' gestation and again at 11 to 13 weeks' postpartum with arterial lines and Swan-Ganz catheterization to characterize the central hemodynamics of term pregnancy (Table 3-2). Newer, noninvasive methods of central hemodynamic monitoring are being developed and validated in the pregnant population. As described earlier, CO, HR, SVR,

**TABLE 3-2** CENTRAL HEMODYNAMIC CHANGES

|  | 11-12 WEEKS<br>POSTPARTUM | 36-38 WEEKS'<br>GESTATION | CHANGE FROM<br>NONPREGNANT STATE |
|--|---------------------------|---------------------------|----------------------------------|
| Cardiac output (L/min)   | 4.3 ± 0.9                 | 6.2 ± 1.0                 | +43%*                            |
| Heart rate (beats/min)   | 71 ± 10.0                 | 83 ± 10.0                 | +17%*                            |

Modified from Clark S, Cotton D, Lee W, et al. Central hemodynamic assessment of normal term pregnancy. *Am J Obstet Gynecol.* 1989;161:1439.

Data are presented as mean ± standard deviation. Although data on pulmonary artery pressures are not presented, they were not significantly different.

\* $P < .05$ .

NS, not significant.

and pulmonary vascular resistance (PVR) change significantly with pregnancy. **In addition, clinically significant decreases occur in colloidal oncotic pressure (COP) and in the COP–pulmonary capillary wedge pressure (PCWP) difference, which explains why gravid women have a greater propensity for developing pulmonary edema with changes in capillary permeability or elevations in cardiac preload. The COP can fall even further after delivery, to 17 mm Hg, and if the pregnancy is complicated by preeclampsia, it can reach levels as low as 14 mm Hg.<sup>17</sup> When the PCWP is more than 4 mm Hg above the COP, the risk for pulmonary edema increases; therefore pregnant women can experience pulmonary edema at PCWPs of 18 to 20 mm Hg, which is significantly lower than the typical nonpregnant threshold of 24 mm Hg.**

### Normal Changes That Mimic Heart Disease

The physiologic adaptations of pregnancy lead to a number of changes in maternal signs and symptoms that can mimic cardiac disease and make it difficult to determine whether true disease is present. Dyspnea is common to both cardiac disease and pregnancy, but certain distinguishing features should be considered. First, the onset of pregnancy-related dyspnea usually occurs before 20 weeks, and 75% of women experience it by the third trimester. **Unlike cardiac dyspnea, pregnancy-related dyspnea does not worsen significantly with advancing gestation. Second, physiologic dyspnea is usually mild, does not stop women from performing normal daily activities, and does not occur at rest. The mechanism for dyspnea of pregnancy is not well characterized but is thought to be secondary to the increased effort of inspiratory muscles.<sup>18</sup>** Other normal symptoms that can mimic cardiac disease include decreased exercise tolerance, fatigue, occasional orthopnea, syncope, and chest discomfort. **Symptoms that should not be attributed to pregnancy and that need a more thorough investigation include hemoptysis, syncope or chest pain with exertion, progressive orthopnea, or paroxysmal nocturnal dyspnea.** Normal physical findings that could be mistaken as evidence of cardiac disease include peripheral edema, mild tachycardia, jugular venous distension after midpregnancy, and lateral displacement of the left ventricular apex.

**Pregnancy also alters normal heart sounds.** At the end of the first trimester, both components of the first heart sound become louder, and exaggerated splitting is apparent. The

second heart sound usually remains normal with only minimal changes. Up to 80% to 90% of gravidas demonstrate a third heart sound (S<sub>3</sub>) after midpregnancy because of rapid diastolic filling. Rarely, a fourth heart sound may be auscultated, but typically phonocardiography is needed to detect this. Systolic ejection murmurs along the left sternal border develop in 96% of pregnancies, and increased blood flow across the pulmonic and aortic valves is thought to be the cause. Most commonly, these are midsystolic and less than grade 3. **Diastolic murmurs have been found in up to 18% of gravidas, but their presence is uncommon enough to warrant further evaluation.** A continuous murmur in the second to fourth intercostal space may be heard in the second or third trimester owing to the so-called mammary souffle caused by increased blood flow in the breast (Fig. 3-4).

Troponin 1 and creatinine kinase-MB levels are tests used to assess myocardial injury in acute myocardial infarction. **Uterine contractions can lead to significant increases in the creatinine kinase-MB level, but troponin levels are not affected by pregnancy or labor.<sup>19</sup>**

### Effect of Labor and the Immediate Puerperium

**The profound anatomic and functional changes in cardiac function reach a crescendo during the labor process. In addition to the dramatic rise in cardiac output with normal pregnancy, even greater increases in cardiac output occur with labor and in the immediate puerperium.** In a Doppler echocardiography study<sup>9</sup> of 15 uncomplicated cases without epidural anesthesia, the CO between contractions increased 12% during the first stage of labor (Fig. 3-5). This increase in CO is caused primarily by an increased SV, but HR may also rise. By the end of the first stage of labor, the CO during contractions is 51% above baseline term pregnancy values (6.99 to 10.57 L/min). Increased CO is in part secondary to increased venous return from the 300- to 500-mL autotransfusion that occurs at the onset of each contraction as blood is expressed from the uterus.<sup>20</sup> Paralleling increases in CO, the MAP also rises in the first stage of labor, from 82 to 91 mm Hg in early labor to 102 mm Hg by the beginning of the second stage. MAP also increases with uterine contractions.

Much of the increase in CO and MAP is due to pain and anxiety. With epidural anesthesia, the baseline increase in CO is reduced, but the rise observed with contractions persists. Maternal posture also influences hemodynamics during labor.

**FIG 3-4** Summary of the findings on auscultation of the heart in pregnancy. MC, mitral closure; TC, tricuspid closure; A2 and P2, aortic and pulmonary elements of the second heart sound. (From Cutforth R, MacDonald C. Heart sounds and murmurs in pregnancy. *Am Heart J*. 1966;71:741.)

**FIG 3-5** Changes in cardiac output during normal labor. (From Hunter S, Robson S. Adaptation of the maternal heart in pregnancy. *Br Heart J* 1992;68:540.)

**Changing position from supine to lateral recumbent increases CO.** This change is greater than the increase seen before labor and suggests that during labor, CO may be more dependent on preload. Therefore it is important to avoid the supine position in laboring women and to give a sufficient fluid bolus before an epidural to maintain an adequate preload.

**In the immediate postpartum period (10 to 30 min after delivery), with a further rise in cardiac output of 10% to 20%, CO reaches its maximum.** This increase is accompanied by a fall in the maternal HR that is likely secondary to increased SV. Traditionally, this rise was thought to be the result of uterine autotransfusion as described earlier with contractions, but the validity of this concept is uncertain. In both vaginal and elective cesarean deliveries, the maximal increase in the CO occurs 10 to 30 min after delivery and returns to the prelabor baseline 1 hour after delivery. **The increase was 37% with epidural anesthesia and 28% with general anesthesia.** Over the next 2 to 4 postpartum weeks, the cardiac hemodynamic parameters return to near-preconceptional levels.<sup>21</sup>

### Cardiac Rhythm

**The effect of pregnancy on cardiac rhythm is limited to an increase in HR and a significant increase in isolated atrial and ventricular contractions.** In a Holter monitor study,<sup>22</sup> 110 pregnant women referred for evaluation of symptoms of palpitations, dizziness, or syncope were compared with 52 healthy pregnant women. Symptomatic women had similar rates of isolated sinus tachycardia (9%), isolated premature atrial complexes (56%), and premature ventricular contractions (PVCs; 49%) but increased rates of frequent PVCs greater than 10/hour (22% vs. 2%,  $P = .03$ ). A subset of patients with frequent premature atrial complexes or PVCs had comparative Holter studies performed postpartum that revealed an 85% decrease in arrhythmia frequency ( $P < .05$ ). This dramatic decline, with patients acting as their own controls, supports the arrhythmogenic effect of pregnancy. In a study of 30 healthy women placed on Holter monitors during labor, a similarly high incidence of benign arrhythmias was found (93%). Reassuringly, the prevalence of concerning arrhythmias was no higher than expected. An unexpected finding was a 35% rate of asymptomatic bradycardia, defined as an HR of less than 60 beats/min in the immediate postpartum period. Other studies have shown that women with preexisting tachyarrhythmias have an increased incidence of these rate abnormalities during pregnancy. **Whether labor increases the rate of arrhythmias in women with cardiac disease has not been thoroughly studied, but multiple case reports suggest labor may increase arrhythmias in these women.**

### HEMATOLOGIC CHANGES

#### Plasma Volume and Red Cell Mass

**Maternal blood volume begins to increase at about 6 weeks' gestation. Thereafter, it rises progressively until 30 to 34 weeks and then plateaus until delivery. The average expansion of blood volume is 40% to 50% (range 20% to 100%).** Women with multiple pregnancies have a larger increase in blood volume than those with singletons. Likewise, volume expansion correlates with infant birthweight, but it is not clear whether this is a cause or an effect. The increase in blood volume results from a combined expansion of both plasma volume and red blood cell (RBC) mass. **The plasma volume begins to**

increase by 6 weeks and expands at a steady pace until it plateaus at 30 weeks' gestation; the overall increase is about 50% (1200 to 1300 mL). The exact etiology of the expansion of the blood volume is unknown, but the hormonal changes of gestation and the increase in nitric oxide (NO) play important roles.

Erythrocyte mass also begins to expand at about 10 weeks' gestation. Although the initial slope of this increase is slower than that of the plasma volume, erythrocyte mass continues to grow progressively until term without plateauing. Without iron supplementation, RBC mass increases about 18% by term, from a mean nonpregnant level of 1400 mL up to 1650 mL. **Supplemental iron increases RBC mass accumulation to 400 to 450 mL, or 30%, and a corresponding improvement is seen in hemoglobin levels. Because plasma volume increases more than the RBC mass, maternal hematocrit falls. This so-called physiologic anemia of pregnancy reaches a nadir at 30 to 34 weeks. Because the RBC mass continues to increase after 30 weeks when the plasma volume expansion has plateaued, the hematocrit may rise somewhat after 30 weeks (Fig. 3-6). The mean and fifth-percentile hemoglobin concentrations for normal iron-supplemented pregnant women are outlined in Table 3-3. A hemoglobin level that reaches its nadir at 9 to 11 g/dL has**

**FIG 3-6** Blood volume changes during pregnancy. RBC, red blood cell. (From Scott DE. Anemia in pregnancy. *Obstet Gynecol Annu.* 1972;1:219-244.)

**TABLE 3-3** HEMOGLOBIN VALUES IN PREGNANCY

| GESTATION (WK) | MEAN HEMOGLOBIN (g/dL) | 5TH PERCENTILE HEMOGLOBIN (g/dL) |
|----------------|------------------------|----------------------------------|
| 12             | 12.2                   | 11.0                             |
| 16             | 11.8                   | 10.6                             |
| 20             | 11.6                   | 10.5                             |
| 24             | 11.6                   | 10.5                             |

| 32             | 12.1                   | 11.0                             |
| 36             | 12.5                   | 11.4                             |
| 40             | 12.9                   | 11.9                             |

From U.S. Department of Health and Human Services. Recommendations to prevent and control iron deficiency in the United States. *MMWR Morb Mortal Wkly Rep.* 1998;47:1.

been associated with the lowest rate of perinatal mortality, whereas values below or above this range have been linked to an increased perinatal mortality.<sup>23</sup>

In pregnancy, erythropoietin levels increase twofold to threefold, starting at 16 weeks, and they may be responsible for the moderate erythroid hyperplasia found in the bone marrow and for the mild elevations in the reticulocyte count. The increased blood volume is protective given the possibility of hemorrhage during pregnancy or at delivery. The larger blood volume also helps fill the expanded vascular system created by vasodilation and by the large, low-resistance vascular pool within the utero-placental unit, thereby preventing hypotension.<sup>18</sup>

**Vaginal delivery of a singleton infant at term is associated with a mean blood loss of 500 mL; an uncomplicated cesarean delivery, about 1000 mL; and a cesarean hysterectomy, 1500 mL.<sup>24</sup> In a normal delivery, almost all of the blood loss occurs in the first hour. Pritchard and colleagues<sup>24</sup> found that over the subsequent 72 hours, only 80 mL of blood is lost. Gravid women respond to blood loss in a different fashion than in the nonpregnant state. In pregnancy, the blood volume drops after postpartum bleeding, but no reexpansion to the prelabor level occurs, and less of a change is seen in the hematocrit. Indeed, instead of volume redistribution, an overall diuresis of the expanded water volume occurs postpartum. After delivery with average blood loss, the hematocrit drops moderately for 3 to 4 days, followed by an increase. By days 5 to 7, the postpartum hematocrit is similar to the prelabor hematocrit. If the postpartum hematocrit is lower than the prelabor hematocrit, either the blood loss was greater than appreciated, or the hypervolemia of pregnancy was less than normal, as in preeclampsia.<sup>24</sup>**

### Iron Metabolism

Iron absorption from the duodenum is limited to its ferrous (divalent) state, the form found in iron supplements. Ferric (trivalent) iron from vegetable food sources must first be converted to the divalent state by the enzyme ferric reductase. If body iron stores are normal, only about 10% of ingested iron is absorbed, most of which remains in the mucosal cells or enterocytes until sloughing leads to excretion in the feces (1 mg/day). Under conditions of increased iron needs, such as during pregnancy, the fraction of iron absorbed increases. After absorption, iron is released from the enterocytes into the circulation, where it is carried bound to transferrin to the liver, spleen, muscle, and bone marrow. In those sites, iron is freed from transferrin and is incorporated into hemoglobin (75% of iron) and myoglobin or is stored as ferritin and hemosiderin. Menstruating women have about half the iron stores of men, with total body iron of 2 to 2.5 g and iron stores of only 300 mg. Before pregnancy, 8% to 10% of women in Western nations have an iron deficiency.

The iron requirements of gestation are about 1000 mg. This includes 500 mg used to increase the maternal RBC mass (1 mL of erythrocytes contains 1.1 mg iron), 300 mg transported to the fetus, and 200 mg to compensate for the normal daily iron losses by the mother. Thus the normal expectant woman needs to absorb an average of 3.5 mg/day of iron. In actuality, the iron requirements are not constant but increase remarkably during the pregnancy from 0.8 mg/day in the first trimester to 6 to 7 mg/day in the third trimester. The fetus receives its iron through active transport via transferrin receptors located on the apical surface of the placental

**FIG 3-7** Histogram of platelet count of pregnant women in the third trimester ( $n = 6770$ ) compared with nonpregnant women ( $n = 287$ ). (From Boehlen F, Hohlfield P, Extermann P. Platelet count at term pregnancy: a reappraisal of the threshold. *Obstet Gynecol.* 2000;95:29.)

syncytiotrophoblast. Holotransferrin is then endocytosed, and the iron is released and follows a similar pattern to reach the fetal circulation. In the setting of maternal iron deficiency, the number of placental transferrin receptors increases so that more iron is taken up by the placenta; however, the capacity of this compensatory mechanism can be inadequate and can result in fetal iron deficiency. Maternal iron deficiency anemia has also been associated with adverse pregnancy outcomes, such as low birthweight infants and preterm birth.<sup>25</sup> For a review on the use of supplemental iron in pregnancy, see [Chapter 44](#).

### Platelets

Before the introduction of automated analyzers, studies of platelet counts during pregnancy reported conflicting results. Even with the availability of automated cell counters, the data on the change in platelet count during pregnancy are still somewhat unclear. Pitkin and colleagues<sup>26</sup> measured platelet counts in 23 women every 4 weeks and found that the counts dropped from  $322 \pm 75 \times 10^3/\text{mm}^3$  in the first trimester to  $278 \pm 75 \times 10^3/\text{mm}^3$  in the third trimester. More recent studies confirm a decline in the platelet count during gestation possibly caused by increased destruction or hemodilution. **In addition to the mild decrease in the mean platelet count, Burrows and Kelton<sup>27</sup> demonstrated that in the third trimester, about 8% of gravidas develop gestational thrombocytopenia with platelet counts between 70,000 and 150,000/ $\text{mm}^3$ . Gestational thrombocytopenia is not associated with an increase in pregnancy complications,<sup>27</sup> and platelet counts return to normal by 1 to 2 weeks postpartum (see [Chapter 44](#)).** Many features of gestational thrombocytopenia are similar to those of mild immune thrombocytopenia, so the etiology may be immunologic.<sup>28</sup> Another hypothesis is that gestational thrombocytopenia is due to exaggerated platelet consumption, similar to that seen in normal pregnancy.<sup>27</sup> Consistent with these findings, Boehlen and associates<sup>29</sup> compared platelet counts during the third trimester of pregnancy with those in nonpregnant controls and showed a shift to a lower mean platelet count and an overall shift to the left of the “platelet curve” in the pregnant women

([Fig. 3-7](#)). This study found that only 2.5% of nonpregnant women have platelet counts less than  $150,000/\text{mm}^3$ , the traditional value used outside of pregnancy as the cutoff for normal, versus 11.5% of gravid women. **A platelet count of less than 116,000/ $\text{mm}^3$  occurred in 2.5% of gravid women; therefore these investigators recommended using this value as the lower limit for normal in the third trimester.** In addition, they suggested that workups for the etiology of decreased platelet count were unneeded at values above this level.<sup>29</sup>

The normal decrease in platelet count is associated with an increase in platelet aggregability. This is evidenced by decreased platelet-function analyzer (PFA-100) values, which signify a decreased time for a platelet plug to occlude an aperture in a collagen membrane and measures the ability of platelets to occlude a vascular breach.<sup>30</sup> **Thus while the number of platelets decreases, platelet function increases to maintain hemostasis.**

### Leukocytes

**The peripheral white blood cell (WBC) count rises progressively during pregnancy.** During the first trimester, the mean WBC count is  $8000/\text{mm}^3$  with a normal range of 5110 to  $9900/\text{mm}^3$ . During the second and third trimesters, the mean is  $8500/\text{mm}^3$  with a range of 5600 to  $12,200/\text{mm}^3$ .<sup>31</sup> In labor, the count may rise to 20,000 to  $30,000/\text{mm}^3$ , and counts are highly correlated with labor progression as determined by cervical dilation. **Because of the normal increase of WBCs in labor, the WBC count should not be used clinically in determining the presence of infection.** The increase in the WBC count is largely due to increases in circulating segmented neutrophils and granulocytes, whose absolute number is nearly doubled at term. The reason for the increased leukocytosis is unclear, but it may be caused by the elevated estrogen and cortisol levels. Leukocyte levels return to normal within 1 to 2 weeks of delivery.

### Coagulation System

**Pregnancy places women at a fivefold to sixfold increased risk for thromboembolic disease (see [Chapter 45](#)).** This greater risk

is caused by increased venous stasis, vessel wall injury, and changes in the coagulation cascade that lead to hypercoagulability. The increase in venous stasis in the lower extremities is due to compression of the IVC and the pelvic veins by the enlarging uterus. **The hypercoagulability is caused by an increase in several procoagulants, a decrease in the natural inhibitors of coagulation, and a reduction in fibrinolytic activity. These physiologic changes provide defense against peripartum hemorrhage.**

Most of the procoagulant factors from the coagulation cascade are markedly increased, including factors I, VII, VIII, IX, and X. Factors II, V, and XII are unchanged or mildly increased, and levels of factors XI and XIII decline. Plasma fibrinogen (factor I) levels begin to increase in the first trimester and peak in the third trimester at levels 50% higher than before pregnancy. The rise in fibrinogen is associated with an increase in the erythrocyte sedimentation rate. In addition, pregnancy causes a decrease in the fibrinolytic system with reduced levels of available circulating plasminogen activator, a twofold to threefold increase in plasminogen activator inhibitor 1 (PAI-1), and a 25-fold increase in PAI-2. The placenta produces PAI-1 and is the primary source of PAI-2.

**Pregnancy has been shown to cause a progressive and significant decrease in the levels of total and free protein S from early in pregnancy, but it has no effect on the levels of protein C and antithrombin III.**<sup>32</sup> The activated protein C (APC)/sensitivity (S) ratio, the ratio of the clotting time in the presence and the absence of APC, declines during pregnancy. The APC/S ratio is considered abnormal if it is less than 2.6. In a study of 239 women,<sup>32</sup> the APC/S ratio decreased from a mean of 3.12 in the first trimester to 2.63 by the third trimester. By the third trimester, 38% of women were found to have an acquired APC resistance, with APC/S ratio values below 2.6. Whether the changes in the protein-S level and the APC/S ratio are responsible for some of the hypercoagulability of pregnancy is unknown. **If a workup for thrombophilias is performed during gestation, the clinician should use caution when attempting to interpret these levels if they are abnormal. Ideally the clinician should order DNA testing for the Leiden mutation instead of testing for APC. For protein-S screening during pregnancy, the free protein-S antigen level should be tested, with normal levels in the second and third trimesters being identified as greater than 30% and 24%, respectively.**<sup>33</sup>

Most coagulation testing is unaffected by pregnancy. The prothrombin time (PT), activated partial thromboplastin time (PTT), and thrombin time all fall slightly but remain within the limits of normal nonpregnant values, whereas the bleeding time and whole blood clotting times are unchanged. Testing for von Willebrand disease is affected in pregnancy because levels of factor VIII, von Willebrand factor activity and antigen, and ristocetin cofactor all increase.<sup>34</sup> Levels of coagulation factors normalize 2 weeks postpartum.

Researchers have found evidence to support the theory that during pregnancy, a state of low-level intravascular coagulation occurs. Low concentrations of fibrin degradation products (markers of fibrinolysis), elevated levels of fibrinopeptide A (a marker for increased clotting), and increased levels of platelet factor 4 and  $\beta$ -thromboglobulin (markers of increased platelet activity) have been found in maternal blood. The most likely cause for these findings involves localized physiologic changes needed for maintenance of the uterine-placental interface.

**TABLE 3-4      REFERENCE RANGES FOR THROMBOELASTOGRAPHY IN PREGNANCY**

|          | AVERAGE | SD   |
|----------|---------|------|
| R        | 6.19    | 1.85 |
| K        | 1.9     | 0.56 |
| $\alpha$ | 69.2    | 6.55 |
| MA       | 73.2    | 4.41 |
| Ly30     | 0.58    | 1.83 |

From Antony K, Mansouri R, Arndt M, et al. Establishing thromboelastography and platelet-function analyzer reference ranges and other measures in healthy term pregnant women. *Am J Perinatol*. 2015;32: 545-554.  
SD, standard deviation.

The complex array of procoagulative changes can be further illustrated via emerging point-of-care analyses, such as thromboelastography and rotational thromboelastography. Briefly, these assays provide a visual and numeric representation of the rate of clot formation and the stability of the clot, which allows a detailed analysis of the expected hypercoagulable state and, if indicated, targets for transfusion.<sup>35</sup> Use of these tests in pregnancy requires caution, however, because physiologic values vary in pregnancy compared with a nonpregnant state; these changes reflect a procoagulative state.<sup>36,37</sup> Reference ranges for pregnancy are shown in Table 3-4.

**RESPIRATORY SYSTEM**

**Upper Respiratory Tract**

During pregnancy, the mucosa of the nasopharynx becomes hyperemic and edematous with hypersecretion of mucus due to increased estrogen. These changes often lead to marked nasal stuffiness and decreased nasal patency; 27% of women at 12 weeks' gestation report nasal congestion and rhinitis, and this increases to 42% at 36 weeks' gestation. This decreased patency can lead to anesthesia complications; in fact, the Mallampati score is demonstrably increased (see Chapter 16).<sup>38</sup> Epistaxis is also common and may rarely require surgery. Additionally, the placement of nasogastric tubes may cause excessive bleeding if adequate lubrication is not used.<sup>18</sup> Polyposis of the nose and nasal sinuses develops in some individuals but regresses postpartum. **Because of these changes, many gravid women complain of chronic cold symptoms. However, the temptation to use nasal decongestants should be avoided because of the risk for hypertension and rebound congestion.**

**Mechanical Changes**

The configuration of the thoracic cage changes early in pregnancy, much earlier than can be accounted for by mechanical pressure from the enlarging uterus. Relaxation of the ligamentous attachments between the ribs and sternum may be responsible. The subcostal angle increases from 68 to 103 degrees, the transverse diameter of the chest expands by 2 cm, and the chest circumference expands by 5 to 7 cm. As gestation progresses, the level of the diaphragm rises 4 cm; however, diaphragmatic excursion is not impeded and actually increases 1 to 2 cm. This increased diaphragmatic excursion is the effect of progesterone, which acts at the level of the central chemoreceptors to increase diaphragmatic effort and results in greater negative inspiratory pressures.<sup>39</sup> **Respiratory muscle function is not affected by pregnancy, and maximal inspiratory and expiratory pressures are unchanged.**

## Lung Volume and Pulmonary Function

The described alterations in chest wall configuration and in the diaphragm lead to changes in static lung volumes. In a review of studies with at least 15 subjects, compared with nonpregnant controls, Crapo<sup>18</sup> found significant changes (Fig. 3-8, Table 3-5). The elevation of the diaphragm decreases the volume of the lungs in the resting state, thereby reducing total lung capacity (TLC) and the functional residual capacity (FRC). The FRC can be subdivided into *expiratory reserve volume* (ERV) and *residual volume* (RV), and both decrease.

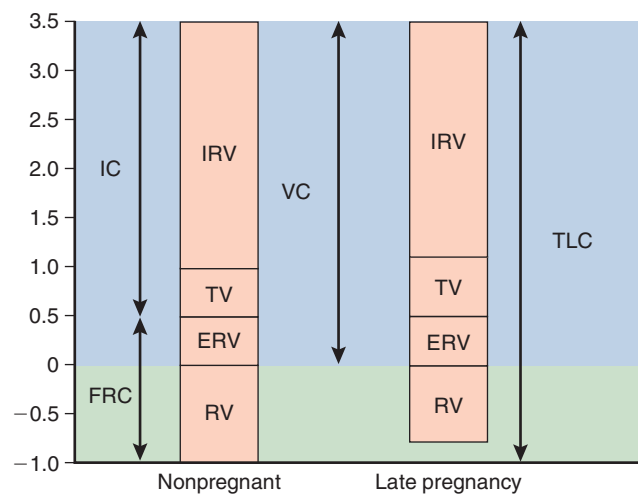

Some spirometric measurements to assess bronchial flow are unchanged in pregnancy, whereas others are altered. Historically, it has been well accepted that the forced expiratory volume in 1 second (FEV<sub>1</sub>) does not change, which suggests that the airway function remains stable. However, FEV<sub>1</sub> may indeed decrease across pregnancy under certain circumstances, such as high altitude. Different studies have observed varied effects on the peak expiratory flow. In a longitudinal study of the peak flow in 38 women from the first trimester until 6 weeks postpartum, peak flows had a statistically significant decrease as gestation progressed, but the amount of the decrease was of questionable

clinical significance.<sup>40</sup> Likewise, a small decline in the peak flow was found in the supine position versus the standing or sitting position. In a similar study of 80 women, peak expiratory flow (PEF) was found to increase progressively after 14 to 16 weeks.<sup>41</sup> Notably, these values were also significantly higher at any time point during pregnancy in parous compared with nulliparous women, which may suggest that this change is permanent.<sup>41</sup> An additional finding of this study was that no differences in forced vital capacity (FVC), FEV<sub>1</sub>, or PEF were noted based on overweight status or excess gestational weight gain. **In summary, both spirometry and peak flowmeters can be used to diagnose and manage respiratory illness, but the clinician should ensure that measurements are performed in the same maternal position.**<sup>40</sup>

## Gas Exchange

**Increasing progesterone levels drive a state of chronic hyperventilation, as reflected by a 30% to 50% increase in tidal volume by 8 weeks' gestation. In turn, increased tidal volume results in an overall parallel rise in minute ventilation, despite a stable respiratory rate** (minute ventilation = tidal volume × respiratory rate). The rise in minute ventilation, combined with a decrease in FRC, leads to a larger than expected increase in alveolar ventilation (50% to 70%). **Chronic mild hyperventilation results in increased alveolar oxygen (PaO<sub>2</sub>) and decreased arterial carbon dioxide (PaCO<sub>2</sub>) from normal levels** (Table 3-6). The drop in the PaCO<sub>2</sub> is especially critical because it drives a more favorable CO<sub>2</sub> gradient between the fetus and mother, which facilitates CO<sub>2</sub> transfer. **The low maternal PaCO<sub>2</sub> results in a chronic respiratory alkalosis.** Partial renal compensation occurs through increased excretion of bicarbonate, which helps maintain the pH between 7.4 and 7.45 and lowers the serum bicarbonate levels. Early in pregnancy, the arterial oxygen (PaO<sub>2</sub>) increases (106 to 108 mm Hg) as the PaCO<sub>2</sub> decreases, but by the third trimester, a slight decrease in the PaO<sub>2</sub> (101 to 104 mm Hg) occurs as a result of the enlarging uterus. This decrease in the PaO<sub>2</sub> late in pregnancy is even more pronounced in the supine position; one study found a further drop of 5 to 10 mm Hg and an increase in the alveolar-to-arterial gradient to 26 mm Hg. Up to 25% of women may exhibit a PaO<sub>2</sub> of less than 90 mm Hg. The mean PaO<sub>2</sub> is lower in the supine position than in the sitting position.<sup>18,42</sup>

As the minute ventilation increases, a simultaneous but smaller increase in oxygen uptake and consumption occurs. Most investigators have found **maternal oxygen consumption to be 20% to 40% above nonpregnant levels. This increase**

occurs as a result of the oxygen requirements of the fetus and placenta and the increased oxygen requirement of maternal organs. With exercise or during labor, an even greater rise in both minute ventilation and oxygen consumption takes place.<sup>18,38</sup> During a contraction, oxygen consumption can triple. As a result of the increased oxygen consumption, and because the FRC is decreased, a lowering of the maternal oxygen reserve occurs. Therefore the pregnant patient is more susceptible to the effects of apnea, such as during intubation, when a more rapid onset of hypoxia, hypercapnia, and respiratory acidosis is seen. Indeed, the desaturation time after thorough preoxygenation is shortened from 9 minutes in the nonpregnant state to 3 minutes in pregnancy.

## Sleep

Pregnancy causes both an increase in sleep disorders and significant changes in sleep profile and pattern that persist into the postpartum period.<sup>43</sup> Pregnancy causes such significant changes that the American Academy of Sleep Medicine has described a specific pregnancy-associated sleep disorder: diagnostic criteria include a complaint of either insomnia or excessive sleepiness with onset during pregnancy. Sleep disturbances are associated with poor health outcomes in the general population, and emerging evidence suggests that abnormal sleep patterns in pregnancy may contribute to certain complications, such as hypertensive disorders and fetal growth restriction.<sup>39,44</sup> It is well known that hormones and physical discomfort affect sleep (Table 3-7). With the dramatic change in hormone levels and the significant mechanical effects that make women more uncomfortable, it is not difficult to understand why sleep is profoundly affected. Multiple authors have investigated the changes in sleep during pregnancy using questionnaires, sleep logs, and polysomnographic studies. From these studies, investigators have shown that **most pregnant women (66% to 94%) report alterations in sleep that lead to the subjective perception of poor sleep quality.** Sleep disturbances begin as early as the first trimester and worsen as the pregnancy progresses.<sup>45</sup> During the third trimester, multiple discomforts occur that can impair sleep: urinary frequency, backache, general abdominal discomfort and contractions, leg cramps, restless legs syndrome (RLS), heartburn, and fetal movement. Interestingly, no changes

**TABLE 3-7** CHARACTERISTICS OF SLEEP IN PREGNANCY

Modified from Santiago J, Nolleto M, Kinzler W. Sleep and sleep disorders in pregnancy. *Ann Intern Med.* 2001;134:396.

\*Rapid eye movement (REM) sleep is important for cognition and makes up 20%-25% of sleep. Stage 1 and 2 non-REM sleep, or light sleep, makes up 55% of sleep. Stage 3 and 4 non-REM sleep, or deep sleep, is important for rest and makes up 20% of sleep.

are seen in melatonin levels, which modulate the body's circadian pacemaker.

In general, **pregnancy is associated with a decrease in rapid eye movement (REM) sleep and a decrease in stage 3 and 4 non-REM sleep.** REM sleep is important for cognitive thinking, and stage 3 and 4 non-REM sleep is the so-called deep sleep that is important for rest. In addition, with advancing gestational age, a decrease in sleep efficiency and continuity and an increase in awake time and daytime somnolence is observed. By 3 months postpartum, the amount of non-REM and REM sleep recovers, but a persistent decrease in sleeping efficiency and nocturnal awakenings occurs, presumably because of the newborn.<sup>43</sup> **Although pregnancy causes changes in sleep, it is important for the clinician to consider other primary sleep disorders that may be unrelated to pregnancy, such as sleep apnea.** The physiologic changes of pregnancy also increase the incidence of sleep-disordered breathing, which includes snoring (in up to 35% of women), upper airway obstruction,<sup>38</sup> and potentially obstructive sleep apnea (OSA). The prevalence of sleep apnea in pregnancy is unknown and has been difficult to determine; the screening questionnaires appear to perform poorly in pregnancy, likely due to the frequency of daytime sleepiness and snoring in pregnancy in the absence of OSA.<sup>46</sup> When it is diagnosed or highly suspected based upon symptoms, OSA appears to increase the risk for intrauterine growth restriction (IUGR) and gestational hypertension via endothelial dysfunction.<sup>44</sup> **Women with excessive daytime sleepiness, loud excessive snoring, and witnessed apneas should be evaluated for OSA with overnight polysomnography. In addition, individuals with known sleep apnea may need repeat sleep studies**

to determine whether changes in treatment are necessary to prevent intermittent hypoxia.<sup>47</sup>

Although the majority of gravidas have sleep problems, most do not complain to their providers or ask for treatment. **Treatment options include improving sleep habits by avoiding fluids after dinner, establishing regular sleep hours, avoiding naps and caffeine, minimizing bedroom noises, and using pillow support.** Other options include relaxation techniques, managing back pain, and use of sleep medications such as diphenhydramine (Benadryl) and zolpidem (Ambien).

Another potential cause of sleep disturbances in pregnancy is the development of restless legs syndrome (RLS) and periodic leg movements during sleep. RLS is a neurosensory disorder that typically begins in the evening and can prevent women from falling asleep. Pregnancy can be a cause of this syndrome, and in one study, up to 34% of gravidas reported symptoms of RLS, although the true prevalence of this disorder during pregnancy is unknown.<sup>48</sup> If treatment is needed, options include improving sleep habits, use of an electric vibrator to the calves, and use of a dopaminergic agent such as levodopa or carbidopa.

## URINARY SYSTEM

### Anatomic Changes

The kidneys enlarge during pregnancy, with the length as measured by intravenous pyelography increasing about 1 cm. This growth in size and weight is due to increased renal vasculature, interstitial volume, and urinary dead space. **The increase in urinary dead space is attributed to dilation of the renal pelvis, calyces, and ureters. Pelvicalyceal dilation by term averages 15 mm (range, 5 to 25 mm) on the right and 5 mm (range, 3 to 8 mm) on the left.**<sup>49</sup>

The well-known dilation of the ureters and renal pelvis begins by the second month of pregnancy and is maximal by the middle of the second trimester, when ureteric diameter may be as much as 2 cm. The right ureter is almost invariably dilated more than the left, and the dilation usually cannot be demonstrated below the pelvic brim. These findings have led some investigators to argue that the dilation is caused entirely by mechanical compression of the ureters by the enlarging uterus and ovarian venous plexus. However, the early onset of ureteral dilation suggests that **smooth muscle relaxation caused by progesterone** plays an additional role. Also supporting the role of progesterone is the finding of ureteral dilation in women with a renal transplant and pelvic kidney. By 6 weeks postpartum, ureteral dilation resolves.<sup>49</sup> A clinical consequence of ureterocalyceal dilation is an increased incidence of pyelonephritis among gravidas with asymptomatic bacteriuria.<sup>50</sup> **In addition, the ureterocalyceal dilation makes interpretation of urinary radiographs more difficult when evaluating possible urinary tract obstruction or nephrolithiasis.**

Anatomic changes are also observed in the bladder. From midpregnancy on, an elevation in the bladder trigone occurs, with increased vascular tortuosity throughout the bladder. This can cause an increased incidence of microhematuria. **Three percent of gravidas have idiopathic hematuria, defined as greater than 1+ on a urine dipstick, and up to 16% have microscopic hematuria.** Because of the increasing size of the uterus, a decrease in bladder capacity develops as pregnancy progresses, accompanied by an increase in urinary frequency, urgency, and incontinence.

### Renal Hemodynamics

Renal plasma flow (RPF) increases markedly from early in gestation and may begin to increase during the luteal phase before implantation.<sup>51</sup> Dunlop showed convincingly that **the effective RPF rises 75% over nonpregnant levels by 16 weeks' gestation (Table 3-8).** The increase is maintained until 34 weeks' gestation, when a decline in RPF of about 25% occurs. The fall in RPF has been demonstrated in subjects studied serially in sitting and left lateral recumbent positions. Like RPF, glomerular filtration rate (GFR), as measured by inulin clearance, increases by 5 to 7 weeks. **By the end of the first trimester, GFR is 50% higher than in the nonpregnant state, and this is maintained until the end of pregnancy.** Three months postpartum, GFR values have declined to normal levels. **This renal hyperfiltration seen in pregnancy is a result of the increase in the RPF.** Because the RPF increases more than the GFR early in pregnancy, the filtration fraction falls from nonpregnant levels until the late third trimester. At this time, because of the decline in RPF, the filtration fraction returns to preconceptional values.

Clinically, GFR is not determined by measuring the clearance of infused inulin (inulin is filtered by the glomerulus and is unaffected by the tubules), but rather by measuring endogenous creatinine clearance. This test gives a less precise measure of GFR because creatinine is secreted by the tubules to a variable extent. Therefore endogenous creatinine clearance is usually higher than the actual GFR. **The creatinine clearance in pregnancy is greatly increased to values of 150 to 200 mL/min (normal, 120 mL/min).** As with GFR, the increase in creatinine clearance occurs by 5 to 7 weeks' gestation and normally is maintained until the third trimester. **GFR is best estimated in pregnancy using a 24-hour urine collection for creatinine clearance.** Formulas used in patients with renal disease that estimate the GFR using serum collections and clinical parameters (which avoid a 24-hour urine collection) are inaccurate in pregnancy and underestimate the GFR.

The increase in the RPF and GFR precede the increase in blood volume and may be induced by a reduction in the preglomerular and postglomerular arteriolar resistance. **Importantly, the increase in hyperfiltration occurs without an increase in glomerular pressure, which if it occurred could have the potential for injury to the kidney with long-term consequences.**<sup>51</sup> Recently, the mechanisms that underlie the marked increase in RPF and GFR have been carefully studied. Although numerous factors are involved in this process, nitric oxide (NO) has been demonstrated to play a critical role in the decrease in renal resistance and the subsequent renal hyperemia. During pregnancy, the activation and expression of the NO synthase is enhanced in the kidneys, and inhibition of NO synthase isoforms has been shown to attenuate the hemodynamic changes within the gravid kidney. Finally, the hormone relaxin appears to be important by initiating or activating some of the effects of NO on the kidney. Failure of this crucial adaptation is associated with adverse outcomes such as preeclampsia and fetal growth restriction (FGR).<sup>52</sup>

**The clinical consequence of glomerular hyperfiltration is a reduction in maternal plasma levels of creatinine, blood urea nitrogen (BUN), and uric acid. Serum creatinine decreases from a nonpregnant level of 0.8 to 0.5 mg/dL by term. Likewise, BUN falls from nonpregnant levels of 13 to 9 mg/dL by term. Serum uric acid declines in early pregnancy**

\*Data from Dunlop W. Serial changes in renal haemodynamics during normal pregnancy. *Br J Obstet Gynaecol.* 1981;88:1.  
<sup>†</sup>Data from Ezimokhai M, Davison J, Philips P, et al. Nonpostural serial changes in renal function during the third trimester of normal human pregnancy. *Br J Obstet Gynaecol* 1981;88:465.

because of the rise in GFR and reaches a nadir by 24 weeks with levels of 2 to 3 mg/dL. After 24 weeks, the uric acid level begins to rise, and by the end of pregnancy, the levels in most women are essentially the same as before conception. The rise in uric acid levels is caused by increased renal tubular absorption of urate and increased fetal uric acid production. **Patients with preeclampsia have elevated uric acid level concentrations; however, because uric acid levels normally rise during the third trimester, overreliance on this test should be avoided in the diagnosis and management of preeclampsia.**

During pregnancy, urine volume is increased, and nocturia is more common. In the standing position, sodium and water are retained; therefore during the daytime, gravidas tend to retain an increased amount of water. At night, while in the lateral recumbent position, this added water is excreted, which results in nocturia. Later in gestation, renal function is affected by position, and the GFR and renal hemodynamics are decreased with changes from lateral recumbency to supine or standing positions.

Renal Tubular Function and Excretion of Nutrients

Despite high levels of aldosterone, which would be expected to result in enhanced urinary excretion of potassium, **gravid women retain about 300 mmol of potassium.**<sup>53</sup> Most of the excess potassium is stored in the fetus and placenta.<sup>53</sup> The mean potassium concentrations in maternal blood are just slightly below nonpregnant levels. The ability of the kidney to conserve potassium has been attributed to increased progesterone levels.<sup>53</sup> For information on the changes in sodium, see the next section, “Body Water Metabolism.”

**Glucose excretion increases in almost all pregnant women, and glycosuria is common.** Nonpregnant urinary excretion of glucose is less than 100 mg/day, but 90% of gravidas with normal blood glucose levels excrete 1 to 10 g of glucose per day. This glycosuria is intermittent and not necessarily related to blood glucose levels or the stage of gestation. Glucose is freely filtered by the glomerulus, and with the 50% increase in GFR, a greater load of glucose is presented to the proximal tubules. A change may occur in the reabsorptive capability of the proximal tubules themselves, but the old concept of pregnancy leading to an overwhelming of the maximal tubular reabsorptive capacity for glucose is misleading and oversimplified. The exact mechanisms that underlie the altered handling of glucose by the proximal tubules appears to be a reduced threshold for glucose resorption via reduced renal glucose transporter expression combined with increased renal blood flow. Aberrations in this mechanism may play a pathophysiologic role in the development of

TABLE 3-9 COMPARISON OF 24-HOUR URINARY PROTEIN AND ALBUMIN EXCRETION

|                    | ≤20 WEEKS (N = 95) | >20 WEEKS (N = 175) | P VALUE |
|--------------------|--------------------|---------------------|---------|
| Protein (mg/24 hr) | 98.1 ± 62.3        | 121.8 ± 71          | .007    |
| Albumin (mg/24 hr) | 9.7 ± 6.2          | 12.2 ± 8.5          | .012    |

gestational diabetes mellitus, and higher thresholds for glucose resorption have been associated with gestational diabetes mellitus.<sup>54</sup> **Even though glycosuria is common, gravidas with repetitive glycosuria should be screened for diabetes mellitus if they have not already been tested.**

**Urinary protein and albumin excretion increase during pregnancy, with an upper limit of 300 mg of proteinuria and 30 mg of albuminuria in a 24-hour period.**<sup>54</sup> Higby and associates<sup>54a</sup> found that the amount of proteinuria and albuminuria increases both when compared with nonpregnant levels and as the pregnancy advances. They collected 24-hour urine samples from 270 women over the course of pregnancy and determined the amount of proteinuria and albuminuria; they found that the amount of protein and albumin excreted in urine did not increase significantly by trimester but did increase significantly when compared between the first and second half of pregnancy (Table 3-9). Similarly, the protein/creatinine ratio increases across pregnancy. **In women who did not have preeclampsia, underlying renal disease, or urinary tract infections, the mean 24-hour urine protein across pregnancy was 116.9 mg, with a 95% upper confidence limit of 260 mg.**<sup>54a</sup> These researchers also noted that patients do not normally have microalbuminuria. **In women with preexisting proteinuria, the amount of proteinuria increases in both the second and third trimesters and potentially in the first trimester.** In a study of women with diabetic nephropathy, the amount of proteinuria increased from a mean of 1.74g ± 1.33 g per 24 hours in the first trimester to a mean of 4.82 ± 4.7 g per 24 hours in the third trimester, even in the absence of preeclampsia.<sup>56</sup> The increase in the renal excretion of proteins is due to a physiologic impairment of the proximal tubular function within the kidney and the increase in the GFR.<sup>55</sup>

Other changes in tubular function include an increase in the excretion of amino acids in the urine and an increase in calcium excretion (see Chapter 39). Also, the kidney responds to the respiratory alkalosis of pregnancy by enhanced excretion

of bicarbonate; however, renal handling of acid excretion is unchanged.

### BODY WATER METABOLISM

The increase in total body water of 6.5 to 8.5 L by the end of gestation represents one of the most significant adaptations of pregnancy. The water content of the fetus, placenta, and amniotic fluid at term totals about 3.5 L. Additional water is accounted for by expansion of the maternal blood volume by 1500 to 1600 mL, plasma volume by 1200 to 1300 mL, and red blood cells by 300 to 400 mL. The remainder is attributed to extravascular fluid, intracellular fluid in the uterus and breasts, and expanded adipose tissue. As a result, **pregnancy is a condition of chronic volume overload with active sodium and water retention secondary to changes in osmoregulation and the renin-angiotensin system.** Increase in body water content contributes to maternal weight gain, hemodilution, physiologic anemia of pregnancy, and the elevation in maternal cardiac output. Inadequate plasma volume expansion has been associated with increased risks for preeclampsia and fetal growth restriction.

### Osmoregulation

Expansion in plasma volume begins shortly after conception, partially mediated by a change in maternal osmoregulation through altered secretion of arginine vasopressin (AVP) by the posterior pituitary. **Water retention exceeds sodium retention; even though an additional 900 mEq of sodium is retained during pregnancy, serum levels of sodium decrease by 3 to 4 mmol/L.** This is mirrored by decreases in overall plasma osmolality of 8 to 10 mOsm/kg, a change that is in place by 10 weeks' gestation and that continues through 1 to 2 weeks postpartum (Fig. 3-9).<sup>25</sup> Similarly, the threshold for thirst and vasopressin release changes early in pregnancy; during gestational weeks 5 to 8, an increase in water intake occurs and results in a transient increase in urinary volume but a net increase in total body water. Initial changes in AVP regulation may be due to placental signals that involve NO and the hormone relaxin. After 8 weeks of gestation, the new steady state for osmolality has been established with little subsequent change in water turnover, resulting in decreased polyuria. Pregnant women perceive fluid challenges or dehydration normally with changes in thirst and AVP secretion, but this occurs at a new, lower "osmostat."

Plasma levels of AVP remain relatively unchanged despite heightened production, owing to a threefold to fourfold increase in metabolic clearance. **Increased clearance results from a circulating vasopressinase synthesized by the placenta that rapidly inactivates both AVP and oxytocin.** This enzyme increases about 300-fold to 1000-fold over the course of gestation proportional to fetal weight, with the highest concentrations occurring in multiple gestations. **Increased AVP clearance can unmask subclinical forms of diabetes insipidus, presumably because of an insufficient pituitary AVP reserve, and it causes transient diabetes insipidus with an incidence of 2 to 6 per 1000.** Typically presenting with both polydipsia and polyuria, hyperosmolality is usually mild unless the thirst mechanism is abnormal or access to water is limited (see Chapter 43).

### Salt Metabolism

Sodium metabolism is delicately balanced and facilitates a net accumulation of about 900 mEq. Sixty percent of the

**FIG 3-9** Plasma osmolality ( $P_{osm}$ ) and plasma sodium ( $P_{Na}$ ) during human gestation ( $n = 9$ ; mean values  $\pm$  standard deviation). Plasma osmolality and urinary concentration and dilution during and after pregnancy: evidence that lateral recumbency inhibits maximal urinary concentrating ability. *Br J Obstet Gynaecol.* 1981;88:472.)

additional sodium is contained within the fetoplacental unit, including amniotic fluid, and is lost at birth. By 2 months postpartum, the serum sodium returns to preconceptional levels. Pregnancy increases the preference for sodium intake, but the primary mechanism is **enhanced tubular sodium reabsorption.** Increased glomerular filtration raises the total filtered sodium load from 20,000 to about 30,000 mmol/day; sodium reabsorption must increase to prevent sodium loss. However, the adaptive rise in tubular reabsorption surpasses the increase in filtered load, which results in an additional 2 to 6 mEq of sodium reabsorption per day. **Alterations in sodium handling represent the largest renal adjustment that occurs in gestation.** Hormonal control of sodium balance is under the opposing actions of the renin-angiotensin-aldosterone system (RAAS) and the natriuretic peptides, and both are modified during pregnancy.

### Renin-Angiotensin-Aldosterone System

**Normal pregnancy is characterized by a marked increase in all components of the RAAS system.** In early pregnancy,

reduced systemic vascular tone attributed to gestational hormones and increased NO production results in decreased mean arterial pressure (MAP). In turn, decreased MAP activates adaptations to preserve intravascular volume through sodium retention.<sup>57</sup> Plasma renin activity, renin substrate (angiotensinogen), and angiotensin levels are all increased a minimum of fourfold to fivefold over nonpregnant levels. Activation of these components of RAAS leads to doubling of aldosterone levels by the third trimester, which increases sodium reabsorption and prevents sodium loss. Despite the elevated aldosterone levels in late pregnancy, normal homeostatic responses still occur to changes in salt balance, fluid loss, and postural stimuli. In addition to aldosterone, other hormones that may contribute to increased tubular sodium retention include deoxycorticosterone and estrogen.

Importantly, whereas pregnant women are responsive to the sodium-retaining effects of mineralocorticoids, they are fairly refractive to their kaliuretic properties. Erhlich and Lindheimer hypothesized that progesterone strongly contributed to potassium homeostasis in pregnancy, and they found that renal potassium excretion was not increased in pregnant women exposed to exogenous mineralocorticoid administration and attributed this to the effects of progesterone.

### Atrial and Brain Natriuretic Peptide

The myocardium releases neuropeptides that serve to maintain circulatory homeostasis. Atrial natriuretic peptide (ANP) is secreted primarily by the atrial myocytes in response to dilation; in response to end-diastolic pressure and volume, the ventricles secrete brain natriuretic peptide (BNP). Both peptides have similar physiologic actions, acting as diuretics, natriuretics, vasorelaxants, and overall antagonists to the RAAS. **Elevated levels of ANP and BNP are found in both physiologic and pathologic conditions of volume overload and can be used to screen for congestive heart failure outside of pregnancy in symptomatic patients.** Because pregnant women frequently present with dyspnea, and many of the physiologic effects of conception mimic heart disease, whether pregnancy affects the levels of these hormones is clinically important. Although ANP levels in pregnancy are variably reported, a meta-analysis<sup>52</sup> showed that ANP levels were 40% higher during gestation and 150% higher during the first postpartum week.

The circulating concentration of BNP is 20% less than that of ANP in normal individuals and has been found to be more useful in the diagnosis of congestive heart failure. Levels of BNP are reported to increase significantly in the third trimester of pregnancy compared with first-trimester levels ( $21.5 \pm 8$  pg/mL vs.  $15.2 \pm 5$  pg/mL) and are highest in pregnancies complicated by preeclampsia ( $37.1 \pm 10$  pg/mL). In pregnancies with preeclampsia, higher levels of BNP are associated with echocardiographic evidence of left ventricular enlargement. **Whereas the BNP levels are increased during pregnancy, in preeclampsia, the mean values are still lower than the levels used to screen for cardiac dysfunction ( $>75$  to  $100$  pg/mL). Therefore BNP can be used to screen for congestive heart failure in pregnancy (see Chapter 37).**<sup>58</sup>

### Clinical Implications of Pregnancy-Related Renal and Urologic Changes

The normal pregnancy-related changes in the kidneys and urinary tract can have profound clinical implications. From 2%

**to 8% of pregnancies are complicated by asymptomatic bacteriuria, and risk is increased among multiparous women; those of a low socioeconomic class; and women with diabetes, sickle cell disease, and history of previous urinary tract infections. Although this prevalence is approximately equivalent to that in the nonpregnant population, in pregnancy, 30% of these progress to pyelonephritis.** This rate is three to four times higher in pregnancy compared with that of nonpregnant controls; overall, 1% to 2% of all pregnancies are complicated by urinary tract infections.<sup>59</sup> For this reason, many providers screen pregnant women for bacteriuria at every clinical encounter. Asymptomatic bacteriuria and symptomatic urinary tract infections are treated to prevent subsequent progression to pyelonephritis and the accompanying maternal and fetal morbidity (see Chapter 54).

Many pregnant women report urinary frequency and nocturnal voiding that start as early as the first trimester, and 60% describe urinary urgency, 10% to 19% develop urge incontinence, and 30% to 60% develop stress incontinence. In a longitudinal cohort study of 241 women, the onset of stress urinary incontinence during the first pregnancy was found to carry an increased risk of long-term symptoms. The rate of urinary incontinence at the 12-year mark was ultimately lower in women who had resolution of their symptoms postpartum (57%) compared with those who did not (91%).<sup>60</sup>

## ALIMENTARY TRACT

### Appetite

In the absence of nausea or “morning sickness,” women who eat according to appetite will increase food intake by about 200 kcal/day by the end of the first trimester. **The recommended dietary allowance calls for an additional 300 kcal/day, although in reality, most women make up for this with decreased activity.** Energy requirements vary depending on the population studied, teenage status, and level of physical activity. The sense of taste may be blunted in some women, which can lead to an increased desire for highly seasoned food. **Pica**, a bizarre craving for strange foods, is relatively common among gravidas, and a history of pica should be sought in those with poor weight gain or refractory anemia. Examples of pica include the consumption of clay, starch, toothpaste, and ice.

### Mouth

The pH and the production of saliva are probably unchanged during pregnancy. Ptyalism, an unusual complication of pregnancy, most often occurs in women suffering from nausea and may be associated with the loss of 1 to 2 L of saliva per day. Most authorities believe ptyalism actually represents inability of the nauseated woman to swallow normal amounts of saliva rather than a true increase in the production of saliva. A decrease in the ingestion of starchy foods may help decrease the amount of saliva. No evidence suggests that pregnancy causes or accelerates the course of dental caries; however, the gums swell and may bleed after tooth brushing, giving rise to the so-called gingivitis of pregnancy. At times, a tumorous gingivitis may occur that presents as a violaceous pedunculated lesion at the gum line that may bleed profusely. Called *epulis gravidarum*, or *pyogenic granulomas*, these lesions consist of granulation tissue and an inflammatory infiltrate (see Chapter 51).

Importantly, up to 40% of pregnant women have periodontal disease. Although it has been linked to preterm birth, more recent data and a report by the American College of Obstetricians and Gynecologists (ACOG)<sup>61</sup> suggest evidence is insufficient to show an association between periodontal infection and preterm birth and that no evidence supports improvement in outcomes following dental treatment during pregnancy. However, for general health and well-being, counseling on good oral habits in pregnancy is recommended.

## Stomach

In pregnancy, the tone and motility of the stomach and gastroesophageal (GE) sphincter are decreased, probably because of the smooth muscle-relaxing effects of progesterone and estrogen. Nevertheless, scientific evidence in regard to delayed gastric emptying is inconclusive. **Although gastric emptying does not appear to be delayed in pregnancy, compared with nonpregnant controls, an increased delay is seen in labor with the etiology ascribed to the pain and stress of labor.**

**Pregnancy reduces the risk for peptic ulcer disease, but it increases GE reflux disease and dyspepsia in 30% to 50% of individuals.**<sup>62</sup> This apparent paradox can be partially explained by physiologic changes in the stomach and lower esophagus. The increase in GE reflux disease is multifactorial and is attributed to esophageal dysmotility caused by gestational hormones, gastric compression from the enlarged uterus, and a decrease in the pressure of the GE sphincter. Estrogen may also lead to increased reflux of stomach acids into the esophagus and may be the predominant cause of reflux symptoms. Theories proposed to explain the decreased incidence of peptic ulcer disease include increased placental histaminase synthesis with lower maternal histamine levels; increased gastric mucin production, which protects the gastric mucosa; reduced gastric acid secretion; and enhanced immunologic tolerance of *Helicobacter pylori*, the infectious agent that causes peptic ulcer disease (see [Chapter 48](#)).

## Intestines

**Perturbations in the motility of the small intestines and colon are common in pregnancy and result in an increased incidence of constipation in some and diarrhea in others.** Up to 34% of women in one study noted an increased frequency of bowel movements, perhaps related to increased prostaglandin synthesis. The prevalence of constipation appears to be higher in early pregnancy: 35% to 39% of women report constipation in the first and second trimesters, but only 21% report it in the last trimester. The motility of the small intestines is reduced in pregnancy, with increased oral-cecal transit times. No studies on the colonic transit time have been performed, but limited information suggests reduced colonic motility. Although progesterone has been thought to be the primary cause of the decrease in gastrointestinal (GI) motility, newer studies show that estrogen-induced nitric oxide released from nerves that innervate the GI tract results in relaxation of the GI tract musculature.<sup>62</sup> Absorption of nutrients from the small bowel is unchanged, with the exception of increased iron and calcium absorption, but the increased transit time due to decreased motility allows for more efficient absorption. In addition, both water and sodium absorption in the colon are increased.

The enlarging uterus displaces the intestines and, most importantly, moves the position of the appendix. Thus the presentation, physical signs, and type of surgical incision are affected in

the management of appendicitis. Portal venous pressure is increased in pregnancy, which leads to dilation wherever there is portosystemic venous anastomosis; this includes not only the GE junction but also the hemorrhoidal veins, the dilation of which results in the common complaint of hemorrhoids.

With the prevalence of obesity in today's society, it is becoming more common to care for women with a history of bariatric surgery. Such surgeries are performed in women with a body mass index (BMI) of 40 kg/m<sup>2</sup> or greater or 35 kg/m<sup>2</sup> with comorbidities. It is important to be aware of the nutritional deficiencies that can accompany such surgery. These include protein, iron, vitamins B<sub>12</sub> and D, and calcium.<sup>63</sup> Additionally, practitioners should exercise caution when prescribing nonsteroidal antiinflammatory drugs (NSAIDs) to patients with smaller gastric pouches because the risk of gastric ulceration increases because of the reduced absorptive surface in these patients.

## Gallbladder

Because of progesterone, the rate at which the gallbladder empties is much slower. After the first trimester, the fasting and residual volumes of the gallbladder are twice as great. In addition, the biliary cholesterol saturation is increased, and the chenodeoxycholic acid level is decreased.<sup>64</sup> This change in the composition of the bile fluid favors the formation of cholesterol crystals, and with incomplete emptying of the gallbladder, the crystals are retained and gallstone formation is enhanced. Furthermore, the progesterone acts to inhibit smooth muscle contraction of the gallbladder, thereby predisposing to formation of sludge or gallstones. **By the time they deliver, up to 10% of women have gallstones on ultrasonographic examination;** however, only 1 in 6000 to 1 in 10,000 pregnancies ultimately require cholecystectomy.<sup>65</sup>

## Liver

The size and histology of the liver are unchanged in pregnancy. However, many clinical and laboratory signs usually associated with liver disease are present. Spider angiomas and palmar erythema caused by elevated estrogen levels are normal and disappear soon after delivery. **Although total body protein increases, serum albumin and total protein levels fall progressively during gestation as a result of hemodilution. By term, albumin levels are 25% lower than nonpregnant levels. In addition, serum alkaline phosphatase activity rises during the third trimester to levels two to four times those of non-gravid women.** Most of this increase is caused by placental production of the heat-stable isoenzyme and not from the liver. The serum concentrations of many proteins produced by the liver increase. These include elevations in fibrinogen, ceruloplasmin, transferrin, and the binding proteins for corticosteroids, sex steroids, and thyroid hormones.

**With the exception of alkaline phosphatase, the other liver function tests are unaffected by pregnancy, including serum levels of bilirubin, aspartate aminotransferase (AST), alanine aminotransferase (ALT),  $\gamma$ -glutamyl transferase (GGT), 5'-nucleotidase, creatinine phosphokinase, and lactate dehydrogenase.** In some studies, the mean levels of ALT and AST are mildly elevated but still fall within normal values. Levels of creatinine phosphokinase and lactate dehydrogenase can increase with labor, and pregnancy may be associated with mild subclinical cholestasis that results from the high

concentrations of estrogen. Reports on serum bile acid concentrations are conflicting: some studies show an increase, whereas others show no change. **The fasting levels are unchanged, and the measurement of a fasting level appears to be the best test for diagnosing cholestasis of pregnancy.**<sup>66</sup> Cholestasis results from elevated levels of bile acids and is associated with significant pruritus, usually mild increases of ALT and AST, and an increased risk for poor fetal outcomes (see [Chapter 47](#)).

### Nausea and Vomiting of Pregnancy

**Nausea and vomiting, or so-called morning sickness, complicates up to 70% of pregnancies. Typical onset is between 4 and 8 weeks' gestation with improvement before 16 weeks; however, 10% to 25% of women still experience symptoms at 20 to 22 weeks' gestation, and some women will have symptoms throughout the gestation.**<sup>67</sup> Although the symptoms are often distressing, simple morning sickness seldom leads to significant weight loss, ketonemia, or electrolyte disturbances. The cause is not well understood, although relaxation of the smooth muscle of the stomach probably plays a role. Elevated levels of human chorionic gonadotropin (hCG) may be involved. However, a good correlation between maternal hCG concentrations and the degree of nausea and vomiting has not been observed. Similarly, minimal data exist to show the etiology is associated with higher levels of estrogen or progesterone. Interestingly, pregnancies complicated by nausea and vomiting generally have a more favorable outcome than those without such symptoms.<sup>67</sup> Treatment is largely supportive and consists of reassurance, avoidance of foods found to trigger nausea, and frequent small meals. Eating dry toast or crackers before getting out of bed may be beneficial. **ACOG states that the use of either vitamin B<sub>6</sub> alone or in combination with doxylamine (Unisom) is safe and effective and should be considered a first line of medical treatment.**

A recent review of alternative therapies to antiemetic drugs found that acupressure, wristbands, or treatment with ginger root may be helpful. For details on hyperemesis gravidarum, please see [Chapter 6](#).

## ENDOCRINE CHANGES

### Thyroid

**Thyroid diseases are common in women of childbearing age (see [Chapter 42](#)). However, normal pregnancy symptoms mirror those of thyroid disease, which makes it difficult to know when screening for thyroid disease is appropriate. In addition, the physiologic effects of pregnancy frequently make the interpretation of thyroid tests difficult.** Therefore it is important for the obstetrician to be familiar with the normal changes in thyroid function that occur. Recent data have shown that the correct and timely diagnosis and treatment of thyroid disease is important to prevent both maternal and fetal complications.

Despite alterations in thyroid morphology, histology, and laboratory indices, pregnant women remain euthyroid. The thyroid gland does increase in size but not as much as was commonly believed. **If adequate iodine intake is maintained, the size of the thyroid gland remains unchanged or undergoes a small increase that can be detected only by ultrasound.** The World Health Organization (WHO) recommends that iodine intake be increased in pregnancy from 100 mg/day to 150 to 200 mg/day. In an iodine-deficient state, the thyroid gland is up

to 25% larger, and goiters occur in 10% of women.<sup>68</sup> Histologically, an increase in thyroid vascularity occurs during pregnancy with evidence of follicular hyperplasia. **The development of a clinically apparent goiter during pregnancy is abnormal and should be evaluated.**

During pregnancy, serum iodide levels fall because of increased renal loss. In addition, in the latter half of pregnancy, iodine is also transferred to the fetus, which further decreases maternal levels; these alterations cause the thyroid to synthesize and secrete thyroid hormone actively.<sup>68</sup> However, at least one investigator has reported that in iodine-sufficient regions, the concentration of iodide does not decrease. Although increased uptake of iodine by the thyroid occurs in pregnancy, pregnant women remain euthyroid by laboratory evaluation.

**Total thyroxine (TT4) and total triiodothyronine (TT3) levels begin to increase in the first trimester and peak at midgestation as a result of increased production of thyroxine-binding globulin (TBG).** The increase in TBG is seen in the first trimester and plateaus at 12 to 14 weeks' gestation. The concentration of TT4 increases by a factor of about 1.5 in parallel with the TBG from a normal range of 5 to 12 mg/dL in nonpregnant women to 9 to 16 mg/dL during pregnancy. **Only a small amount of TT4 and TT3 is unbound, but these free fractions—normally about 0.04% for T4 and 0.5% for T3—are the major determinants of whether an individual is euthyroid.** The extent of change in free T4 and T3 levels during pregnancy has been controversial, and the discrepancies in past studies have been attributed to the techniques used to measure the free hormone levels. **The current best evidence is that the free T4 levels rise slightly in the first trimester and then decrease so that by delivery, the free T4 levels are 10% to 15% lower than in nonpregnant women; however, these changes are small, and in most gravidas, free T4 concentrations remain within the normal nonpregnant range (Fig. 3-10).**<sup>68</sup> In clinical practice, the free T4 level can be measured using either the free thyroxine index (FTI) or estimates of free T4.

**FIG 3-10** Relative changes in maternal thyroid function during pregnancy. hCG, human chorionic gonadotropin; T<sub>4</sub>, thyroxine; TBG, thyroxine-binding globulin; TSH, thyroid-stimulating hormone. (From Burrow G, Fisher D, Larsen P. Maternal and fetal thyroid function. *N Engl J Med* 1994;331:1072.)

These tests use immunoassays that do not measure the free T4 directly and may be less accurate in pregnancy because they are TBG dependent. **The FTI is a more accurate method for measuring free T4, and the currently used estimates for free T4 may incorrectly diagnose women as hypothyroid in the second and third trimesters; however, other authors have shown that these free T4 estimates are accurate.**<sup>69</sup> Free T3 levels follow a similar pattern as free T4 levels.

**Thyroid-stimulating hormone (TSH) concentrations decrease transiently in the first trimester and then rise to prepregnant levels by the end of this trimester. TSH levels then remain stable throughout the remainder of gestation.**<sup>69</sup> The transient decrease in TSH coincides with the first-trimester increase in free T4 levels, and both appear to be caused by the thyrotropic effects of hCG. Women with higher peak hCG levels have more TSH suppression. TSH and hCG are structurally very similar, and they share a common  $\alpha$ -subunit and have a similar  $\beta$ -unit. **It has been estimated that a 10,000-IU/L increment in circulating hCG corresponds to a mean free T4 increment of 0.6 pmol/L (0.1 ng/dL) and in turn lowers TSH by 0.1 mIU/L.**<sup>68,70</sup> These investigators measured TSH levels during successive trimesters of pregnancy in a large group of women and found that TSH was suppressed below normal in 18% in the first trimester, 5% during the second trimester, and 2% in the third trimester. In the first two trimesters, the mean hCG level was higher in women with suppressed TSH levels.<sup>71</sup> It appears that hCG has some thyrotropic activity, but conflicting data on the exact role of hCG in maternal thyroid function remain.<sup>68</sup> **In some women, the thyrotropic effects of hCG can cause a transient form of hyperthyroidism called *transient gestational thyrotoxicosis* (see Chapter 42).**

The influence of maternal thyroid physiology on the fetus appears much more complex than previously thought. Whereas the maternal thyroid does not directly control fetal thyroid function, the systems interact through the placenta, which regulates the transfer of iodine and a small but important amount of thyroxine to the fetus. It was previously thought that little if any transplacental passage of T4 and T3 occurred. **It is now recognized that T4 crosses the placenta, and in early pregnancy, the fetus is critically dependent on the maternal T4 supply for normal neurologic development.**<sup>72</sup> However, as a result of the deiodinase activity of the placenta, a large percentage of T4 is broken down before transfer to the fetus. **The human fetus cannot synthesize thyroid hormones until after 12 weeks' gestation, and any fetal requirement before this time is totally dependent on maternal transfer.** Even after the fetal thyroid is functional, the fetus continues to rely to some extent on a maternal supply of thyroxine. Like T4, thyrotropin-releasing hormone crosses the placenta; TSH does not.

Neonates with thyroid agenesis or a total defect in thyroid hormone synthesis have umbilical cord thyroxine levels between 20% and 50% of those in normal infants, which demonstrates that the placenta is not impermeable to T4. In women who live in iodine-deficient areas, maternal hypothyroidism is associated with neonatal hypothyroidism and defects in long-term neurologic function and mental retardation termed *endemic cretinism*. These abnormalities can be prevented if maternal iodine intake is initiated at the beginning of the second trimester. **Haddow and coworkers<sup>73</sup> have found that maternal hypothyroidism during pregnancy results in slightly lower intelligence quotient (IQ) scores in children tested at ages 7 to 9 years. These**

**findings have resulted in controversy over whether all pregnant women should be screened for subclinical hypothyroidism, which has an incidence of 2% to 5%. Position statements from various organizations are currently contradictory. The Endocrine Society recommends universal screening, whereas ACOG does not support this position (Committee Opinion No. 381).** The Maternal-Fetal Medicine Unit Network is currently conducting a randomized trial to investigate the long-term downstream effects (children's intellectual development at 5 years of age) of subclinical hypothyroidism in pregnancy.

Because iodine is actively transported across the placenta and the concentration of iodide in the fetal blood is 75% that of the maternal blood, the fetus is susceptible to iodine-induced goiters when the mother is given pharmacologic amounts of iodine. **Similarly, radioactive iodine crosses the placenta, and if given after 12 weeks' gestation when the fetal thyroid is able to concentrate iodine, profound adverse effects can occur.** These include fetal hypothyroidism, mental retardation, attention-deficit disorder, and a 1% to 2% increase in the lifetime cancer risk.

The American Academy of Pediatrics (AAP) recently released a policy statement urging all pregnant and breastfeeding women to take a supplement with adequate levels of iodine in order to optimize fetal neurocognitive development and to decrease vulnerability to certain environmental pollutants. Even mild iodine deficiency in pregnancy is associated with decreased IQ scores. The National Academy of Sciences and American Thyroid Association recommend 290  $\mu$ g of daily iodine intake.<sup>74</sup> In order to achieve this, most women require supplementation with 150  $\mu$ g of iodine daily. Currently, only 15% to 20% of pregnant and breastfeeding mothers take supplemental iodine.

## Adrenals

Increased steroid production is essential in pregnancy to meet the need for an increase in maternal production of estrogen and cortisol and the fetal need for reproductive and somatic growth development. **Pregnancy is associated with marked changes in adrenocortical function with increased serum levels of aldosterone, deoxycorticosterone, corticosteroid-binding globulin (CBG), adrenocorticotrophic hormone (ACTH), cortisol, and free cortisol, causing a state of physiologic hypercortisolism (see Chapter 43 and Appendix A).**<sup>75</sup> Although the combined weight of the adrenal glands does not increase significantly, expansion of the zona fasciculata, which primarily produces glucocorticoids, is observed. The plasma concentration of CBG doubles because of hepatic stimulation by estrogen by the end of the sixth month of gestation, compared with nonpregnant values; this results in elevated levels of total plasma cortisol. **The levels of total cortisol rise after the first trimester, and by the end of pregnancy, they are nearly three times higher than nonpregnant values and reach levels in the range seen in Cushing syndrome.** The diurnal variations in cortisol levels may be partly blunted but are maintained, and the highest values occur in the morning.

Only free cortisol, the fraction of cortisol not bound to CBG, is metabolically active; however, direct measurements are difficult to perform. Urinary free cortisol concentrations, the free cortisol index, and salivary cortisol concentrations—all of which reflect active free cortisol levels—are elevated after the first trimester. In a study of 21 uncomplicated pregnancies, urinary free cortisol concentration doubled from the first to the third trimester. Although the increase in total cortisol concentrations can be

explained by the increase in CBG, this does not explain the higher free cortisol levels. The elevation in free cortisol levels seems to be caused in part by a marked increase in corticotropin-releasing hormone (CRH) during pregnancy, which in turn stimulates the production of ACTH in the pituitary and from the placenta. **Outside of pregnancy, CRH is mainly secreted from the hypothalamus. During pregnancy, CRH is also produced by the placenta and fetal membranes and is secreted into the maternal circulation.** First-trimester values of CRH are similar to prepregnant levels, followed by an exponential rise in CRH during the third trimester predominantly as a result of the placental production. CRH and ACTH concentrations continue to rise in the third trimester despite the increased levels of total and free cortisol levels, which supports the theory that an increase in CRH drives the increased levels of cortisol seen in pregnancy. Furthermore, significant correlation is observed between the rise in CRH levels and maternal ACTH and urinary free cortisol concentrations. Other possible causes for the hypercortisolism include delayed plasma clearance of cortisol as a result of changes in renal clearance, pituitary desensitization to cortisol feedback, or enhanced pituitary responses to corticotropin-releasing factors such as vasopressin and CRH.<sup>75</sup>

Although the levels of cortisol are increased to concentrations observed in Cushing syndrome, little clinical evidence is present for hypercortisolism during pregnancy with the exception of weight gain, striae, hyperglycemia, and tiredness. **The diagnosis of Cushing syndrome during pregnancy is difficult because of these changes; this is discussed further in Chapter 43.**

Like aldosterone, deoxycorticosterone (DOC) is a potent mineralocorticoid. Marked elevations in the maternal concentrations of DOC are present by midgestation and reach peak levels in the third trimester. In contrast to the nonpregnant state, plasma DOC levels in the third trimester do not respond to ACTH stimulation, dexamethasone suppression, or salt intake.<sup>75</sup> These findings suggest that an autonomous source of DOC, specifically the fetoplacental unit, may be responsible for the increased levels. Dehydroepiandrosterone sulfate levels are decreased in gestation because of a marked rise in the metabolic clearance of this adrenal androgenic steroid. Maternal concentrations of testosterone and androstenedione are slightly higher; testosterone is increased because of an elevation in sex hormone-binding protein, and androstenedione rises because of an increase in its synthesis.

## Pituitary

The pituitary gland enlarges by approximately one third in pregnancy, principally because of proliferation of prolactin-producing cells in the anterior pituitary (see Chapter 43). **The enlargement of the pituitary gland and subsequent increased intrasellar pressure make it more susceptible to alterations in blood supply and hypotension and increases the risk for postpartum infarction (Sheehan syndrome) should a large maternal blood loss occur.**<sup>76</sup>

Anterior pituitary hormone levels are significantly affected by pregnancy. **Serum prolactin levels begin to rise at 5 to 8 weeks' gestation and by term are 10 times higher.** Consistent with this, the number of lactotroph (prolactin-producing) cells increases dramatically within the anterior lobe of the pituitary from 20% of the cells in nonpregnant women to 60% in the third trimester. In the second and third trimesters, the decidua is a source of much of the increased prolactin production. Despite the increase, prolactin levels remain suppressible by

bromocriptine therapy.<sup>77</sup> **The principal function of prolactin in pregnancy is to prepare the breasts for lactation** (see Chapter 24). In nonlactating women, the prolactin levels return to normal by 3 months postpartum. In lactating women, the return to baseline levels takes several months, with intermittent episodes of hyperprolactinemia in conjunction with nursing. **Maternal follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are decreased to undetectable levels as a result of feedback inhibition from the elevated levels of estrogen, progesterone, and inhibin.** Maternal pituitary growth hormone production is also suppressed because of the action of the placental growth hormone variant on the hypothalamus and pituitary; however, the serum levels of growth hormone increase as a result of the production of growth hormone from the placenta.

The hormones produced by the posterior pituitary are also altered, and the changes in arginine vasopressin (AVP) were discussed earlier in this chapter under "Osmoregulation." Oxytocin levels increase throughout pregnancy, and they rise dramatically and peak in the second stage of labor.

## PANCREAS AND FUEL METABOLISM

### Glucose

Pregnancy is associated with significant physiologic changes in carbohydrate metabolism. This allows for the continuous transport of energy, in the form of glucose, from the gravid woman to the developing fetus and placenta. Pregnancy taxes maternal insulin and carbohydrate physiology, and in all pregnancies, some deterioration in glucose tolerance occurs. In most women, only mild changes take place. In others, pregnancy is sufficiently diabetogenic to result in gestational diabetes mellitus. Overall, **pregnancy results in fasting hypoglycemia, postprandial hyperglycemia, and hyperinsulinemia.**<sup>78</sup> To accommodate the increased demand for insulin, hypertrophy and hyperplasia of the insulin-producing  $\beta$ -cells occur within the islets of Langerhans in the maternal pancreas. For a complete review of the physiologic changes in glucose metabolism, please see Chapter 40.

### Proteins and Lipids

**Amino acids are actively transported across the placenta for the fetus to use for protein synthesis and as an energy source.** In late pregnancy, the fetoplacental unit contains about 500 mg of protein.<sup>6,79</sup> During pregnancy, fat stores are preferentially used as a substrate for fuel metabolism, and thus protein catabolism is decreased. Dietary protein is used efficiently in pregnancy as has been shown by measuring nitrogen balance at multiple points throughout gestation and finding an increased nitrogen balance toward the end of pregnancy.

**Plasma lipids and lipoproteins increase in pregnancy. A gradual twofold to threefold rise in triglyceride levels occurs by term, and levels of 200 to 300 mg/dL are normal. Total cholesterol and low-density lipoprotein levels are also higher such that by term, a 50% to 60% increase is observed.** High-density lipoprotein (HDL) levels initially rise in the first half of pregnancy and then fall in the second half. By term, HDL concentrations are 15% higher than nonpregnant levels. Triglyceride concentrations return to normal by 8 weeks postpartum even with lactation, but cholesterol and low-density lipoprotein (LDL) levels remain elevated (Fig. 3-11). Women with preexisting hyperlipidemia can have a transient worsening of their lipid

**FIG 3-11** Triglycerides (upper panel) and cholesterol (lower panel) in plasma and in lipoprotein fractions before, during, and after pregnancy. HDL, high-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein. (From Salameh W, Mastrogiannis D. Maternal hyperlipidemia in pregnancy. *Clin Obstet Gynecol*. 1994;37:66.)

profiles accentuated by the necessity for discontinuing medications such as HMG-CoA reductase inhibitors (statins).

The mechanisms for the pregnancy-induced changes in lipids are not completely understood but appear to be partly caused by the elevated levels of estrogen, progesterone, and human placental lactogen. The rise in LDL is associated with placental steroidogenesis, and the pattern of LDL variation in pregnancy can be used to predict long-term predisposition to atherogenesis.<sup>79</sup> In a study of parity and carotid atherosclerosis in 1005 women over a 6-year period, a significant relationship was found between the progression of carotid atherosclerosis and parity, even after controlling for traditional risk factors. This suggests that pregnancy itself may present an increased risk of subsequent development of atherosclerosis.

## SKELETON

### Calcium Metabolism

Pregnancy was initially thought to be a state of “physiologic hyperparathyroidism” with maternal skeletal calcium loss needed to supply the fetus with calcium. However, most fetal calcium needs are met through a series of physiologic changes in calcium metabolism without long-term consequences to the maternal skeleton.<sup>80</sup> This allows the fetus to accumulate 21 g

**FIG 3-12** The longitudinal changes in calcium and calcitropic hormone levels that occur during human pregnancy. Normal adult ranges are indicated by the shaded areas. 1,25-D, 1,25-dihydroxyvitamin D; PTH, parathyroid hormone. (From Kovacs CS, Kronenberg HM. Maternal-fetal calcium and bone metabolism during pregnancy, puerperium, and lactation. *Endocr Rev*. 1997;18:832.)

(range of 13 to 33 g) of calcium—80% of this during the third trimester, when fetal skeletal mineralization is at its peak. Calcium is actively transported across the placenta. Surprisingly, calcium is excreted in greater amounts by the maternal kidneys so that by term, calciuria is doubled.

**Maternal total calcium levels decline throughout pregnancy.** The fall in total calcium is caused by the reduced serum albumin levels that result in a decrease in the albumin-bound fraction of calcium. However, the physiologically important fraction, serum ionized calcium, is unchanged and constant (Fig. 3-12).<sup>80</sup> Therefore the actual maternal serum calcium levels are maintained, and the fetal calcium needs are met mainly through increased intestinal calcium absorption. Calcium is absorbed through the small intestines, and its absorption is doubled by 12 weeks' gestation, with maximal absorption in the third trimester.<sup>80</sup> The early increase

in absorption may allow the maternal skeleton to store calcium in advance of the peak third-trimester fetal demands. Although most fetal calcium needs are met by increased absorption of calcium, accumulating data confirm that at least some calcium resorption from maternal bone occurs to help meet the increased fetal demands in the third trimester. These data are compatible with the hypothesis that physiologic mechanisms exist to ensure an adequate supply of calcium for fetal growth and milk production without sole reliance on the maternal diet. Maternal serum phosphate levels are similarly unchanged.<sup>80</sup>

Older studies showed an increase in maternal parathyroid hormone (PTH) levels. In more recent prospective studies, all using newer assays, maternal levels of PTH were not elevated and actually remained in the low-normal range throughout gestation.<sup>80</sup> Therefore pregnancy is not associated with relative hyperparathyroidism (see [Chapter 42](#)).

Vitamin D is a prohormone derived from cholesterol, and it occurs in two main nutritional forms: D3 (cholecalciferol), which is generated in the skin, and D2 (ergocalciferol), which is derived from plants and is absorbed in the gut. **Serum levels of 25-hydroxyvitamin D (25[OH]D) increase in proportion to vitamin D synthesis and intake. Levels of 25[OH]D represent the best indicator of vitamin D status.**<sup>81</sup> 25[OH]D is furthered metabolized to 1,25-dihydroxyvitamin D or active vitamin D. Levels of 1,25-dihydroxyvitamin D increase overall in pregnancy, and prepregnancy levels double in the first trimester and peak in the third trimester. Levels of 25[OH]D do not change in pregnancy unless vitamin D intake or synthesis is changed. The increase in 1,25-dihydroxyvitamin D is secondary to increased production by the maternal kidneys and potentially the fetoplacental unit and is independent of PTH control, and this increase is directly responsible for most of the increase in intestinal calcium absorption. See [Chapter 42](#) for further information on calcium homeostasis.

**The estimated prevalence of vitamin D deficiency in pregnancy in the United States may be as high as 50%. Controversy exists over recommendations to institute universal screening during pregnancy by measuring serum levels of 25[OH]D. Levels less than 32 ng/mL indicate vitamin D deficiency, with recommendations to increase vitamin D supplementation if such a deficiency is diagnosed.**<sup>81</sup> Results from a cohort study found that maternal vitamin D deficiency was associated with impaired lung development, neurocognitive difficulties, increased risk of eating disorders, and lower peak bone mass. Calcitonin levels also rise by 20% and may help protect the maternal skeleton from excess bone loss.<sup>80</sup>

### Skeletal and Postural Changes

The effect of pregnancy on bone metabolism is complex, and evidence of maternal bone loss during pregnancy has been inconsistent, with various studies reporting bone loss, no change, and even gain. Whether pregnancy causes bone loss is not the primary question; instead, the critical question is whether pregnancy and lactation have a long-term risk for causing osteoporosis later in life. **Pregnancy is a period of high bone turnover and remodeling.**<sup>82</sup> **Both pregnancy and lactation cause reversible bone loss, and this loss is increased in women who breastfeed for longer intervals. Studies do not support an association between parity and osteoporosis later in life.** Additionally, in a comparison of female twins discordant for parity, pregnancy and lactation were found to have no detrimental effect on long-term bone loss.

Bone turnover appears to be low in the first half of gestation; it increases in the third trimester, which corresponds to the peak rate of fetal calcium needs, and it may represent turnover of previously stored skeletal calcium.<sup>80</sup> Markers of both bone resorption (hydroxyproline and tartrate-resistant acid phosphatase) and bone formation (alkaline phosphatase and procollagen peptides) are increased during gestation. A change in the micro-architectural pattern of bone with no change in overall bone mass has been described, and this pattern seems to result in a framework more resistant to the bending forces and biomechanical stresses needed to carry a growing fetus. Multiple studies that measure bone density during pregnancy have shown that bone loss occurs only in the trabecular bone and not cortical bone. Older reports indicate that the cortical bone thickness of long bones may even increase with pregnancy.

**Although bone loss occurs in pregnancy, the occurrence of osteoporosis during or soon after pregnancy is rare. Whether additional calcium intake during pregnancy and lactation prevents bone loss is controversial. Most current studies indicate that calcium supplementation does not decrease the amount of bone loss, although maternal intake of 2 g per day or greater is modestly protective. This is greater than the recommended dietary allowance of 1000 to 1300 mg/day during pregnancy and lactation.** Additionally, women on medications known to be associated with bone loss, such as heparin or steroids, may require increased doses of calcium.<sup>83</sup>

**Pregnancy results in a progressively increasing anterior convexity of the lumbar spine (lordosis).** This compensatory mechanism keeps the woman's center of gravity over her legs and prevents the enlarging uterus from shifting the center of gravity anteriorly. The unfortunate side effect of this necessary alteration is low back pain in two thirds of women, with the pain described as severe in one third. Because the ligaments of the pubic symphysis and sacroiliac joints loosen, some have hypothesized that this increase in joint laxity is secondary to increased relaxin, whereas others have found no correlation throughout gestation. **Marked widening of the pubic symphysis occurs by 28 to 32 weeks' gestation, with the width increasing from 3 to 4 mm to 7.7 to 7.9 mm.** This commonly results in pain near the symphysis that is referred down the inner thigh with standing and may result in a maternal sensation of snapping or movement of the bones with walking.

### SKIN

During pregnancy, physiologic alterations take place in the skin, nails, and hair (see [Chapter 51](#)). Increased cutaneous blood flow allows heat to dissipate and is responsible for the "glow" of pregnancy. Hyperpigmentation is also observed in about 90% of women, likely due to increased melanocyte-stimulating hormone and estrogen. This hyperpigmentation accentuates the areola, genital skin, and linea alba in addition to scars and freckles, and it results in melasma, also known as the *mask of pregnancy*. Many women also notice hirsutism and thickening of scalp hair during pregnancy, which commonly sheds about 1 to 5 months postpartum and is the result of a prolonged anagen phase followed by a large proportion of follicles entering the telogen phase simultaneously.<sup>84</sup> During pregnancy, the nails can develop brittleness, leukonychia, transverse grooving, subungual hyperkeratosis, and distal onycholysis.<sup>84</sup> **The high estrogen state of pregnancy also enhances the appearance of telangiectasias and palmar erythema.**<sup>84</sup>

## CENTRAL NERVOUS SYSTEM

Whereas central nervous system complaints such as headache and problems with attention are common in pregnancy, few intrinsic changes occur in the central nervous system. Volumetric magnetic resonance imaging (MRI) has demonstrated decreased brain size in healthy women over the course of pregnancy, with a return to baseline by 6 months postpartum; the etiology and significance of these changes are unclear. Volumetric assessment of the pituitary gland, however, reveals that it increases in size and volume, as discussed earlier in this chapter. Changes in vessel-wall integrity predispose to aneurysm rupture; increased relaxin, for example, upregulates collagenase and collagen remodeling.<sup>85</sup> In addition, the risk of subarachnoid hemorrhage is increased fivefold in pregnancy.

## EYES

Pregnancy is associated with ocular changes, most of which are transient. The two most significant of these are increased thickness of the cornea and decreased intraocular pressure.<sup>86</sup> Corneal thickening is apparent by 10 weeks' gestation and may cause problems with contact lenses. **Corneal changes persist for several weeks postpartum, and patients should be advised to wait before obtaining a new eyeglass or contact prescription.** Concomitant visual changes are also frequent with a reported incidence of 25% to 89%.<sup>84</sup> The majority of these women had changes in their visual acuity and refractive error, as well as a myopic shift (i.e., they became more far-sighted), from pregravid levels with a return to baseline vision postpartum.<sup>70</sup> Because of these transient alterations in the eye, pregnancy is considered by most to be a contraindication to photorefractive keratectomy, and it has been recommended that pregnancy be avoided for 1 year after such surgery. Intraocular pressure falls by about 10%, and individuals with preexisting glaucoma typically improve.<sup>87</sup> Pregnancy either does not change or minimally decreases visual fields. Therefore any complaints of visual field changes are atypical and need evaluation. Similarly, visual changes such as a loss of vision or "dark floaters" are also atypical and may signify retinal detachment or posterior reversible encephalopathy syndrome, and such changes require evaluation.

## BREASTS

Pregnancy-related breast changes begin in the first trimester and continue throughout pregnancy. For a complete review on normal development and physiologic changes of the breast in pregnancy, please see [Chapter 24](#).

## LOWER REPRODUCTIVE TRACT

### Vagina

Nearly every organ system changes during pregnancy to promote pregnancy maintenance or to prepare for parturition. In the vagina, increased vascularity and hyperemia develop in the skin of the vulva and the mucosa of the vagina, which may cause a bluish discoloration of the vulva, cervix, and vagina as described by Chadwick in 1887 and Jacquemin in 1836.<sup>88</sup> Progesterone increases venous distensibility which, combined with the mechanical effects of the uterus and the increased circulating blood volume, may result in the appearance or worsening of

varicose veins in the vulva. The connective tissue underlying the vaginal epithelium also relaxes, and the muscle fibers thicken.<sup>88</sup> The vaginal mucosa itself increases in thickness, and the epithelial cells acquire a characteristic oval form. Estradiol rises across gestation, which leads to increased glycogen levels, namely in the epithelial cells. This glycogen is metabolized into lactic acid, which causes the vaginal pH to decrease. This lactic acid appears to primarily be a byproduct of lactobacilli,<sup>86</sup> which dominate the vaginal flora in pregnancy,<sup>71,89-92</sup> as will be discussed in the microbiome section of this chapter. **Thus it is a combination of hormonal and microbiotic changes that contribute to alterations in the vagina.**

### Cervix

During pregnancy, the cervix undergoes a reversible transformation from a closed, rigid, nondistensible structure charged with maintaining a pregnancy to a soft, distensible, nearly indistinguishable ring of tissue capable of stretching to permit the passage of a term fetus. **Unlike the body of the uterus, cervical tissue comprises little smooth muscle; the major component is connective tissue, which consists of collagen, elastin, proteoglycans, and a cellular portion.**<sup>92</sup> Changes in the collagen structure and glycosaminoglycans, which are under hormonal control, contribute to the successful softening and dilation of the cervix.<sup>92</sup> Following delivery, this tissue is repaired to allow subsequent pregnancies.

During pregnancy, the cervix also produces copious amounts of mucus that is thicker and more acidic during pregnancy owing to the effects of progesterone. This mucus is rich in matrix metalloproteinases, which change in composition as pregnancy progresses as their role shifts from cervical remodeling to sentinels against ascending infection.<sup>93</sup> Levels of immunoglobulin G (IgG)—and, to a lesser extent, IgA—increase during pregnancy. IgG levels are highest in the first trimester and subsequently decrease in the second and third trimesters, whereas IgA levels remain relatively constant. Because peak levels of IgG and IgA during all trimesters of pregnancy significantly exceed levels in all phases of the menstrual cycle, it has been postulated that this enhancement may result from increased estrogen and progestin levels. Expression of particular interleukins correlates with immunoglobulin levels but also appears to be influenced by the vaginal microbial composition with decreased *Lactobacillus* species associated with increased cervical interleukin 8 (IL-8), a proinflammatory cytokine.

## MICROBIOME

**The human microbiome encompasses the totality of the microbes living on and within our bodies. The microbes and their human hosts have co-evolved as a physiologic community comprised of unique, body-site specific niches, meaning that the composition of microbes present at any body site is distinct from other body sites.** These microbes generally form a symbiotic relationship with their human hosts, although exceptions do exist. The microbiome of healthy nonpregnant women was described in 2012.<sup>94,95</sup> More recent work has demonstrated that the microbiome of specific body sites change during pregnancy.<sup>71,91,96</sup> **The body site-specific changes in the microbiome during pregnancy may serve to maintain pregnancy, prepare the body for parturition, or establish the neonatal microbiome at the time of parturition.** This emerging field poses exciting questions for the mechanisms of not only

**FIG 3-13** This principal coordinate analysis (PCoA) plot demonstrates the degree to which each woman's vaginal microbiome differs from the microbiome of other women's vaginas. Here, nonpregnant women are shown in blue, and pregnant women are shown in green with different vaginal sites indicated by the shades of blue or green. Visually apparent clustering is seen based upon pregnancy status (pregnant vs. nonpregnant), whereas the vaginal site contributed less to cluster formation. (From Aagaard K, Riehle K, Ma J, et al. A metagenomic approach to characterization of the vaginal microbiome signature in pregnancy. *PLoS One*. 2012;7(6):e36466.)

preterm birth but also the nature of the interaction between microbes and their human hosts in general.

### Vaginal Microbiome

As discussed previously in this chapter, the estrogen-induced increase in glycogen is metabolized into lactic acid by *Lactobacillus*, which decreases the pH of the vagina and fosters further *Lactobacillus* growth. The presence of lactobacilli has long been noted to increase as gestational age advances, but since the advent of metagenomics (detailed microbiome analysis), more specific compositional changes have been noted.

The microbiome of the vagina in pregnancy has decreased diversity (alpha diversity) and decreased richness (less different species present).<sup>71</sup> As recently demonstrated, the composition of the microbiome is also different (Fig. 3-13). **Whereas the number of genera and species present decreased, a subsequent dominance by several genera was apparent, notably *Lactobacillus*. The particular species enriched—*L. jensenii*, *L. johnsonii*, or *L. crispatus*—is of probable biologic significance.**<sup>71</sup> For example, *L. jensenii* anaerobically metabolizes glycogen, which is increased with the rising estrogen levels and thereby contributes to the acidic vaginal environment. Additionally, *L. jensenii* may have surface-associated proteins that inhibit sexually transmitted infections, including infection by *Neisseria gonorrhoeae*; thereby *L. jensenii* may help prevent preterm birth. Both *L. jensenii* and *L. crispatus* are strong hydrogen peroxide producers and have been hypothesized to protect against bacterial vaginosis, which has been posited as a risk factor for preterm birth and human immunodeficiency virus (HIV) infection.<sup>97,98</sup>

One of the predominant species in the GI tract of neonates, *L. johnsonii*, is also enriched in the vaginal microbiome during pregnancy. It is able to survive passage through the acidic stomach and can colonize the lower GI tract; it secretes antimicrobial bacteriocins, which can kill *Enterococcus* species<sup>99</sup>; and it is associated with increased mucus thickness in the stomach.<sup>100</sup> Thus it may be important for establishing the neonatal GI microbiome.

### Gut Microbiome

Pregnancy is also characterized by changes in the gut microbiota. Over the course of gestation, the bacterial load of the intestines is reported to increase, and the composition also changes. One study found that the diversity within an individual (alpha diversity) decreased with advancing gestation, but diversity between individuals (beta diversity) increased. These changes occurred in parallel with an overall increase in Proteobacteria and a decrease in *Faecalibacterium*. An abundance of Proteobacteria is often associated with inflammatory conditions, and *Faecalibacterium* has antiinflammatory effects; taken together, **the stool in the third trimester of pregnancy resembles stool from inflammatory disease states.** One study inoculated mice with the stool of women in their first and third trimesters of pregnancy and found that stool from the third trimester induced higher levels of inflammation, adiposity, and glucose intolerance in the mice than stool from the first trimester of pregnancy. **Thus pregnancy is associated with changes in the gut microbiome that resemble proinflammatory and prodiabetogenic states.** However, these changes may promote energy storage and fetal growth.

### Placental Microbiome

Contrary to the commonly held belief that the upper reproductive tract and placenta are sterile, evidence has been mounting that microbiota are present even in the absence of clinically evident intraamniotic infection.<sup>96,101-103</sup> One recent study that utilized detailed metagenomic analytic methods not only identified bacteria in healthy term deliveries, it found that the **composition of the microbiome was different among women with term versus preterm birth and was also different among women with or without a remote antenatal infection, such as pyelonephritis.**<sup>96</sup> This study also found that the particular composition of the bacteria present in the placenta most closely resembled the oral microbiome and did not resemble the vaginal or skin microbiome. This implies that the bulk of the bacteria isolated were neither contaminants nor ascending infections but may have arrived in the placenta via hematogenous spread from the oral cavity.<sup>96</sup> Together these findings may explain the proposed link between periodontal disease and preterm birth.

#### SUMMARY

In conclusion, the physiologic changes of pregnancy overall serve to support and maintain the pregnancy in a manner that encompasses almost every organ system from head to toe. Some of these shifts lead to symptoms that can be worrisome to patients, and the role of the practitioner is to discern whether symptoms reflect normal physiologic changes or more concerning pathology. Lastly, the role of microbes in maintaining, or perhaps disrupting, the pregnancy is an emerging field; within a few years, the depth and breadth of the relationship between humans and their microbiomes will likely be further elucidated.

#### KEY POINTS

- ◆ The “healthy” amount of weight to gain during pregnancy is BMI specific.
- ◆ Maternal cardiac output increases 30% to 50% during pregnancy. Supine positioning and standing are both

associated with a fall in cardiac output, which is highest during labor and in the immediate postpartum period.

- ◆ As a result of the marked fall in systemic vascular resistance and pulmonary vascular resistance, PCWP does not rise despite an increase in blood volume.
- ◆ Maternal BP decreases early in pregnancy. The diastolic BP and the mean arterial pressure reach a nadir at mid-pregnancy (16 to 20 weeks) and return to prepregnancy levels by term.
- ◆ Maternal plasma volume increases 50% during pregnancy. Red blood cell volume increases about 18% to 30%, and the hematocrit normally decreases during gestation but not below 30%.
- ◆ Pregnancy is a hypercoagulable state that is accompanied by increases in the levels of most of the procoagulant factors and decreases in the fibrinolytic system and in some of the natural inhibitors of coagulation.
- ◆ PaO<sub>2</sub> and PaCO<sub>2</sub> fall during pregnancy because of increased minute ventilation. This facilitates transfer of CO<sub>2</sub> from the fetus to the mother and results in a mild respiratory alkalosis.
- ◆ BUN and creatinine normally decrease during pregnancy as a result of the increased glomerular filtration rate.
- ◆ Plasma osmolality decreases during pregnancy as a result of a reduction in the serum concentration of sodium and associated anions. The osmolality set points for AVP release and thirst are also decreased.
- ◆ Despite alterations in thyroid morphology, histology, and laboratory indices, the normal pregnant woman is euthyroid, with levels of free T<sub>4</sub> within nonpregnant norms.
- ◆ Pregnancy is associated with a peripheral resistance to insulin, primarily mediated by tumor necrosis factor alpha and human placental lactogen. Insulin resistance increases as pregnancy advances; this results in hyperglycemia, hyperinsulinemia, and hyperlipidemia in response to feeding, especially in the third trimester.
- ◆ Physiologic changes in the vagina interact with the vaginal microbiome to protect against infection and promote pregnancy maintenance.

## Acknowledgment

This chapter is based on the contribution by Dr. Michael C. Gordon in the three previous editions.

**Pregnancy poses unique immunologic challenges to the mother, who must become tolerant to a genetically foreign fetus yet remain immunocompetent to fight infection.** Immunology is one of the fastest moving fields in medical science with many recent advances in the understanding of immunologic changes in pregnancy. The study of maternal-fetal immunology was initially driven by a desire to understand how such a paradoxical feat could occur naturally. Sir Peter Medawar<sup>1</sup> suggested several possibilities to explain fetal tolerance by the mother, including anatomic separation of the fetus and mother, antigenic immaturity of the fetus, and immunologic inertness of the mother. Over time, research has revealed that none of these explanations were adequate for several reasons. First, maternal and fetal cells were discovered to come into contact with each other throughout pregnancy; therefore neither the mother nor the fetus is truly anatomically separated from the other.<sup>2-4</sup> Small populations of fetal cells in the mother and maternal cells in the fetus can persist for decades after pregnancy, which is known as **microchimerism (Mc)**.<sup>5</sup> Secondly, the fetus is not antigenically immature. Fetal immune cells in the skin can elicit potent immune responses.<sup>6</sup> Other fetal immune cells become highly specialized to suppress the fetal immune system and prevent reactivity toward maternal microchimeric cells that enter the fetus.<sup>7</sup> Finally, the mother is not immunologically inert; maintaining the ability to recognize pathogens and fight infection is paramount to her survival during pregnancy. Instead, the maternal immune system has developed an elaborate strategy to become more flexible to what she considers “self” during pregnancy in order to prevent immunologic attack of the fetus.<sup>8,9</sup> The study of pregnancy immunology has revealed many fascinating mechanisms at work to achieve and maintain fetal tolerance during pregnancy while still allowing for normal immune defense.

In this chapter, we focus on describing pregnancy immunology as it relates to normal pregnancy and obstetric complications. In some perinatal conditions, the study of pregnancy immunology is central to the discovery of better diagnostic strategies and therapies. For example, preterm labor associated with infection is characterized by immunologic proteins in the blood, amniotic fluid, and vaginal fluid, which are thought to play a major role in triggering labor.<sup>10-12</sup> Understanding the functions of the immune system and individual immune cells as they relate to maternal tolerance of the fetus, preterm birth, preeclampsia, pregnancy loss, and common perinatal infections will allow the clinician to gain a deeper appreciation for normal and abnormal pregnancy.

## IMMUNE SYSTEM OVERVIEW: INNATE AND ADAPTIVE IMMUNITY

The immune system is classically divided into two arms, the **innate (Fig. 4-1)** and **adaptive (Fig. 4-2)** immune systems. Each arm of the immune system fights infection by a slightly different and complementary method. Both systems have several important mechanisms to prevent maternal immunity from targeting and killing the fetus, yet the immune system must remain competent to overcome an infection to preserve the mother's life. Achieving a balance between controlling normal immune responses and maintaining immune function is a major challenge of pregnancy.

**The innate immune system uses fast, nonspecific methods of pathogen detection to prevent and control an initial**

**infection. Innate immunity consists of immune cells such as macrophages, dendritic cells (DCs), natural killer (NK) cells, eosinophils, and basophils.** In pregnancy, these cells have been implicated in preterm labor, preeclampsia, maternal-fetal tolerance, and intrauterine growth restriction (IUGR). Many of these cells identify pathogens through pattern-recognition receptors (PRRs) that recognize common pathogen structures such as lipoteichoic acid and lipopolysaccharide (LPS), constituents of the cell walls of gram-positive and gram-negative bacteria. PRRs include the macrophage mannose receptor and Toll-like receptors (TLRs), a large family of PRRs likely responsible for the earliest immune responses to a pathogen.<sup>13</sup> TLR activation is often triggered by components of bacterial cell walls, which initiate a signaling cascade that leads to release of cytokines. **Cytokines** are small immunologic proteins implicated in the pathogenesis of preterm labor. Another component of innate immunity is **complement**, a system of plasma proteins that coat pathogen surfaces with protein fragments to target them for destruction.

In many cases, innate immune defenses are effective in combating pathogens. Sometimes, pathogens may evolve more rapidly than the hosts they infect, or they evade innate immune responses, like seasonal influenza viruses. The adaptive immune system must then act to control infection. **Adaptive immunity results in the clonal expansion of lymphocytes (T cells and B cells) and antibodies against a specific antigen. Although slower to respond, adaptive immunity targets specific components of a pathogen and is capable of eradicating an infection that has overwhelmed the innate immune system.** Adaptive immunity also requires presentation of antigen by specialized antigen-presenting cells (APCs), production and secretion of stimulatory cytokines, and ultimately, amplification of antigen-specific lymphocyte clones (T cells and B cells). These memory T and B cells provide lifelong immunity to the specific antigen.

## INNATE IMMUNITY: FIRST LINE OF HOST DEFENSE

Epithelial surfaces of the body are the first defenses against infection. Mechanical epithelial barriers to infection include ciliary movement of mucus and epithelial cell tight junctions that prevent microorganisms from easily penetrating intercellular spaces. Chemical mechanisms of defense include enzymes (e.g., lysozyme in saliva, pepsin), low pH in the stomach, and antibacterial peptides (e.g., defensins in the vagina) that degrade bacteria.

**After a pathogen enters the tissues, it is often recognized and killed by phagocytes, a process mediated by macrophages and neutrophils. TLRs, a family of PRRs on the surface of macrophages and other innate immune and epithelial cells, represent a primary mechanism of pathogen detection.** TLR activation results in secretion of cytokines that initiate inflammatory responses. Nucleotide-binding oligomerization domain receptors (NOD-like receptors, NLRs) are also PRRs, and they operate inside the cell to recognize pathogen structures once they have entered the cell through phagocytosis or via pores. NLRs can cooperate with TLRs to initiate or regulate an inflammatory or apoptotic response. Cytokines and chemokines such as interleukin-8 (IL-8) are released after activation of PRRs to recruit neutrophils to sites of inflammation; they also coordinate many immune functions that include cell activation,

**INNATE IMMUNITY**

- First line of host defense to infection
- Rapid response
- Nonspecific recognition of broad classes of pathogens
- Preexisting effector cell population (*no amplification required*)
- Inability to discriminate self vs. non-self; only recognizes pathogens

**A. Cells****B. Pattern Recognition Receptors:** Recognize common microbial patterns and structures

**C. Complement System:** Plasma proteins that cooperate to facilitate destruction of pathogens**D. Induced Innate Immune Responses**

**FIG 4-1** The innate immune system. This system acts as the first line of host defense and consists of immune cells (**A**), the pattern-recognition receptors that target common pathogen structures (**B**), the complement system (**C**), and induced innate immune responses (**D**). The toll-like receptors and their common ligands are listed because they act as the principal immune sensors of pathogens (**B**). Complement activation may occur through three different initiating pathways that converge with production of the C3 convertase and generation of the terminal complement proteins (**C**). As a result of activation of these components of the innate immune system, neutrophils may be recruited to the site of infection, and cytokines and chemokines may be produced (**D**).

## ADAPTIVE IMMUNITY

- Activated when innate immune defenses overwhelmed
- Delayed response
- Specific recognition of small protein peptides
- Requires amplification of lymphocyte clones
- Ability to discriminate self from non-self

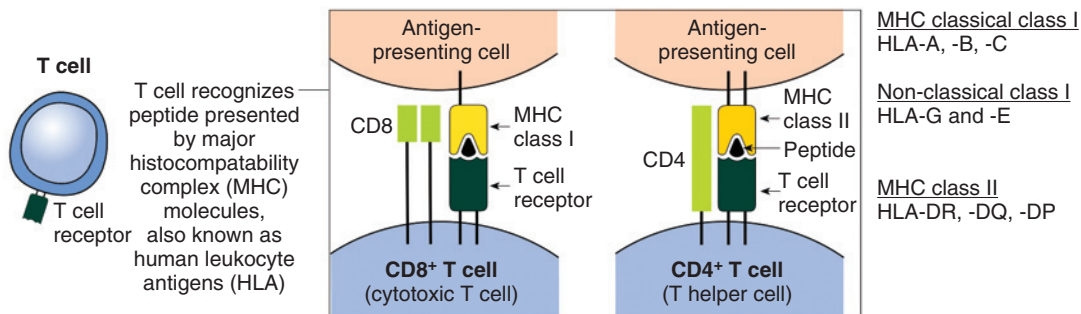

### A. B Cells Receptors and Antibodies

#### Antibody types

- IgA high in:
  - Breast milk
  - Vaginal fluid
  - Gut
- IgD
  - Surface Ig on naive B cells
- IgE
  - Involved in allergic responses
- IgG
  - Most abundant Ig
  - Crosses placenta
  - Involved in immunologic memory
- IgM
  - Involved in primary B cell responses

### B. T Cells and T Cell Receptors

### C. T Helper Type 1 (T<sub>H</sub>1) and Type 2 (T<sub>H</sub>2) Responses

- T helper type 1 response activates macrophages
- Associated cytokines:
  - IFN- $\gamma$
  - IL-12
  - TNF- $\alpha$
  - IL-18
- Induced by *Listeria monocytogenes* and may contribute to intrauterine fetal death

- T helper type 2 response activates B cells
- Associated cytokines:
  - IL-4
  - IL-6
  - IL-5
  - IL-13
- Cytokines with anti-inflammatory properties
  - IL-10
  - TGF- $\beta$
- Thought to dominate over TH1 responses in pregnancy

**FIG 4-2** The adaptive immune system acts to control infection that has overwhelmed the innate immune system and is also important in transplant rejection and tumor killing. B cells secrete antibodies to protect the extracellular spaces of the body from infection and assist in the activation of helper T (CD4<sup>+</sup>) cells (A). Different classes of antibodies reflect structural variations that allow antibodies to be targeted to different bodily compartments and serve slightly different functions. The first step in T-cell activation occurs when the T-cell receptor recognizes a complex of peptides presented by a major histocompatibility (MHC) molecule (B). A CD4<sup>+</sup> T cell recognizes peptide presented by MHC class II, and a CD8<sup>+</sup> T cell interacts with peptides presented by MHC class I. Peptides may be presented by many different types of the listed MHC class I or class II molecules. After activation, the CD4<sup>+</sup> T cell (or helper T cell) may either activate macrophages through a helper T-cell type 1 response or activate B cells through the helper T-cell type 2 response (C).

replication, and differentiation. **Proinflammatory cytokines have been described in the mother and fetus and in the amniotic fluid of women with preterm labor and intraamniotic infection.**<sup>10,11</sup>

### Antimicrobial Peptides

Antimicrobial peptides are secreted by neutrophils and epithelial cells to kill bacteria by damaging pathogen membranes. **Defensins are a major family of antimicrobial peptides that protect against bacterial, fungal, and viral pathogens.** Neutrophils secrete  $\alpha$ -defensins, and epithelial cells in the gut and lung secrete  $\beta$ -defensins. Both  $\alpha$ - and  $\beta$ -defensins are temporally expressed by endometrial epithelial cells during the menstrual cycle.<sup>14</sup> Susceptibility to upper genital tract infection may be related in part to the decreased expression of antimicrobial peptides in response to hormonal changes during the menstrual cycle. Many other tissues of the female reproductive tract and the placenta secrete defensins, including the vagina, cervix, fallopian tubes, decidua, and chorion. **Elevated concentrations of vaginal and amniotic fluid defensins have been associated with intraamniotic infection and preterm birth.**

### Macrophages

Macrophages mature from circulating monocytes that leave the circulation to migrate into tissues throughout the body. **Macrophages have critical scavenger functions that likely help to prevent bacteria from establishing an intrauterine infection during pregnancy.** Macrophages are one of the most abundant immune cell types in the placenta and can directly recognize, ingest, and destroy pathogens. Pathogen recognition may occur through PRRs such as TLRs, scavenger receptors, and mannose receptors. Macrophages also internalize pathogens or pathogen particles through phagocytosis, macropinocytosis, and receptor-mediated endocytosis. Multiple receptors on the macrophage can induce phagocytosis, including the mannose receptor, scavenger receptor, CD14, and complement receptors. Macrophages also release many bactericidal agents after ingesting a pathogen, such as oxygen radicals, nitric oxide, antimicrobial peptides, and lysozyme.

**Uterine macrophages represent up to one third of the total leukocytes in pregnancy-associated tissue during the later parts of pregnancy and perform many critical functions to support the pregnancy.** Macrophages are a major source of inducible nitric oxide synthetase, a rate-limiting enzyme for nitric oxide production. During pregnancy, nitric oxide is thought to relax uterine smooth muscle, and uterine nitric oxide synthetase activity and expression decreases before parturition. Uterine macrophages are also a major source of prostaglandins, inflammatory cytokines, and matrix metalloproteinases that are prominent during term and preterm parturition. Throughout pregnancy, macrophages are also in close proximity to invading trophoblasts that establish placentation. Placental growth involves trophoblast remodeling and programmed cell death (apoptosis). Macrophages in the placenta phagocytose apoptotic trophoblast, which also programs the macrophage to release antiinflammatory cytokines (e.g., IL-10) promoting fetal tolerance.

### Natural Killer Cells

The NK cell has important functions during pregnancy and becomes the most abundant leukocyte in the pregnant uterus.

**NK cells differ from T and B cells in that they do not express clonally distributed receptors for foreign antigens and can lyse target cells without prior sensitization.** The phenotype of decidual NK (dNK) cells is different from that of NK cells in peripheral blood, which seems to correlate with different primary functions. Most NK cells in blood (90%) have low CD56 and high CD16 expression (CD56<sup>dim</sup>/CD16<sup>bright</sup>); in the uterine decidua, dNK cells have high CD56 expression (CD56<sup>bright</sup>). The level of CD56 expression determines whether an NK cell has a primary cytolytic (CD56<sup>dim</sup>) or cytokine-producing (CD56<sup>bright</sup>) function. **During pregnancy, dNK cells are the predominant decidual immune cell with peak levels (~85%) in early pregnancy that gradually decline by mid gestation but that remain at approximately 50% of total decidual immune cells.**<sup>15</sup> **In addition, dNK cells are thought to play a major role in the remodeling of the spiral arteries to establish normal placentation.** Mice with genetically defective or low numbers of dNK cells fail to undergo spiral artery remodeling and normal development of the decidua, which are critical processes for normal placentation (see Chapter 1).<sup>16,17</sup> This defect is corrected with administration of interferon- $\gamma$  (IFN- $\gamma$ ), a prominent NK cell cytokine, which suggests that dNK cells play an important role in the angiogenesis necessary for trophoblast invasion. The cytolytic activity of dNK cells is low and is further inhibited by interactions with human leukocyte antigen G (HLA-G).<sup>18,19</sup>

### Toll-Like Receptors

TLRs are a recently discovered large family of PRRs on macrophages and many other cell types that play a key role in innate immunity.<sup>13</sup> **TLRs are now recognized as the principal early sensors of pathogens that can activate both the innate and adaptive immune system.** Ten functional toll homologues are found in humans, and they recognize a wide range of pathogen ligands (see Fig. 4-1, B). TLR4 is a TLR that recognizes LPS from gram-negative bacteria, which triggers a signaling cascade that leads to cytokine gene expression (Fig. 4-3). TLR4 is expressed on macrophages, dendritic cells, endothelium, and numerous epithelial tissues. TLR2 recognizes motifs from gram-positive bacteria, including lipoteichoic acid and peptidoglycan. Several bacteria evade TLR recognition by producing proteins or LPS mutants that interfere with TLR signaling. For example, *Yersinia pestis*—the bacteria responsible for plague—expresses a tetraacylated LPS that is poorly recognized by TLR4 and results in TLR4 antagonism. *Brucella abortus*, known to induce recurrent abortion in cattle, produces at least two proteins that are potent inhibitors of TLR signaling, which gives the bacteria a survival advantage in evading immune detection.<sup>20</sup>

Expression of both TLR2 and TLR4 has been demonstrated in the placenta, and first-trimester trophoblast cells express both TLR2 and TLR4.<sup>21</sup> Activation of TLR2 triggers Fas-mediated apoptosis, whereas TLR4 activation induces proinflammatory cytokine production. The immunologic capability of first-trimester trophoblast cells to recognize pathogens and induce apoptosis suggests that innate immunity may be an important placental mechanism for triggering spontaneous abortion. TLR4 is also expressed in villous macrophages, villous and extravillous trophoblast, and the amniochorion. Expression of TLR4 and TLR2 increases in the chorioamniotic membranes of women with intraamniotic infection and also in term labor. Although intrauterine injection of LPS induces preterm birth in many

**FIG 4-3** Toll-like receptor 4 (TLR4) recognition of lipopolysaccharide (LPS). Recognition of LPS by TLR4 occurs through several steps. (1) LPS is released from intact or lysed bacteria. (2) LPS binds to LPS-binding protein (LBP). (3) The LPS-LBP complex is recognized by a cell surface receptor complex TLR4, CD14, and MD-2. Binding of LPS-LBP to the TLR4-CD14-MD-2 receptor recruits the intracellular adapter molecule, myeloid differentiation factor 88 (MyD88). Binding of MyD88 promotes the association of IL-1 receptor-associated protein kinase 4 (IRAK). Next, tumor necrosis factor receptor-associated kinase 6 (TRAF6) initiates a signaling cascade that results in degradation of IκB, which releases nuclear factor κB (NF-κB), a transcription factor, into the cytoplasm. (4) NF-κB translocates into the nucleus and activates cytokine gene expression. Although the figure depicts TLR4 activation in a macrophage, many other immunologic and epithelial cells express TLR4 and induce cytokine production (5) through this mechanism.

murine and nonhuman primate models, administration of LPS to TLR4 mutant mice or LPS blockade with a TLR4 antagonist does not result in preterm delivery.<sup>22,23</sup> This finding suggests that TLR4 is required for LPS-induced preterm birth in mice and that it is an important driver of the inflammatory cascade that results from intraamniotic infection.

**Maturation of TLR expression in the fetal membranes over time may explain the tendency for infection-associated preterm births to occur no earlier than the late second or early third trimester.**<sup>24</sup> Although TLR4 is expressed in the cytoplasm of amniotic epithelium in the first trimester, not until 25 weeks is there TLR4 expression on the apical membrane, which is in contact with amniotic fluid and potential pathogens.<sup>25</sup> A similar ontogeny in TLR4 expression is seen in the fetal lung. When mouse fetal lung is exposed to LPS on fetal day 14 (term is 20 days), TLR4 expression and cytokines are undetectable. By day 17, TLR4 is expressed and an acute cytokine response occurs in fetal lungs. TLR4 likely controls the magnitude of the LPS-induced cytokine response during the perinatal period, and TLR4 placental expression is dependent on gestational age.

## Complement System

**An important component of the innate immune system is the complement system, which consists of a large number of plasma proteins that cooperate to destroy and facilitate the removal of pathogens** (see Fig. 4-1, C). Complement proteins are detected in the amniotic fluid during intraamniotic infection, and regulation of complement is necessary to protect placental and fetal tissues from inflammation and destruction. The nature of the initial pathogen trigger determines one of three activation pathways: 1) classic, 2) alternate, and 3) lectin-binding pathways. For example, the *classic pathway* of complement activation is triggered when the complement protein C1q binds to antigen-antibody complexes on the surface of pathogens. This binding then results in a series of activation and amplification steps that result in production of the membrane

attack complex (MAC), which creates a pore in the pathogen membrane and leads to cell lysis. Formation of the MAC is an important mechanism of host defense against *Neisseria* species. Genetic deficiencies in C5-C9 complement proteins have been associated with susceptibility to *N. gonorrhoeae* and *N. meningitidis*.

Regulatory proteins exist to protect cells from the deleterious effects of complement and are expressed on the placental membranes. Placental tissues at the maternal-fetal interface strongly express several negative regulators of complement activation, including CD59 (MAC antagonist), membrane cofactor protein, and decay-accelerating factor (inhibitor of C3 and C5 convertases).<sup>26,27</sup> Whether these regulatory proteins might become overwhelmed during an intraamniotic infection, leading to weakening of the membranes by complement proteins, is unknown.

## Cytokines

**The release of cytokines and chemokines by macrophages and other immune cells represents an important induced innate immune response** (Table 4-1; see Fig. 4-1, D). Activated macrophages secrete cytokines—IL-1β, IL-6, IL-12, and tumor necrosis factor alpha (TNF-α)—that initiate inflammatory responses to control infections. **These cytokines are often referred to as *proinflammatory* because they mediate fever, lymphocyte activation, tissue destruction, and shock.** Higher levels of several cytokines and chemokines have been implicated in the increased morbidity and mortality with influenza during pregnancy. In lung homogenates of infected pregnant mice, levels of IL-6 and IL-8; regulated on activation, normal T-cell expressed and secreted (RANTES [CCL5]); and monocyte chemoattractant protein 1 (MCP-1 [CCL2]) were higher after infection with the 2009 H1N1 influenza virus strain. Dramatic elevations in IL-6 have also been implicated in deaths, such as in the 1918 influenza virus, with an estimated mortality in pregnancy of 27%.<sup>28</sup> An increase in cytokine levels is likely not the only explanation for increased morbidity and mortality from

**TABLE 4-1** CYTOKINES AND THEIR PRIMARY ACTIONS IN REGULATING IMMUNE AND INFLAMMATORY RESPONSE

| CYTOKINE                           | PRODUCED BY                     | PRIMARY ACTION  |
|------------------------------------|---------------------------------|---|
| Interferons                        | Monocytes and macrophages       | Produced in response to viruses, bacteria, parasites, and tumor cells<br>Action includes killing tumor cells and inducing secretion of other inflammatory cytokines<br>One of the first cytokines to appear during an inflammatory response |
| Interleukin-1                      | Monocytes and macrophages       | Induces fever; costimulator of CD4 <sup>+</sup> helper T cells  |
| Interleukin-2                      | Activated T cells               | Primary growth factor and activation factor for T cells and natural killer cells  |
| Interleukin-4                      | CD4 <sup>+</sup> helper T cells | B-cell growth factor for antigen-activated B cells  |
| Interleukin-6                      | Monocytes and macrophages       | Regulates growth and differentiation of lymphocytes and growth factor for plasma cells<br>and induces the synthesis of acute-phase reactants by the liver   |
| Interleukin-8                      | Monocytes                       | Chemoattractant for neutrophils   |
| Interleukin-10                     | CD4 <sup>+</sup> helper T cells | Suppresses production of interferon, suppresses cell-mediated immunity, enhances humoral immunity   |
| Transforming growth factor $\beta$ | T cells and monocytes           | Inhibits the proliferation of lymphocytes   |

influenza infection during pregnancy. Recently, enhanced NK- and T-cell responses to influenza vaccination in pregnant women were reported, which suggests that robust cellular immune responses also play a role.<sup>29</sup>

During normal pregnancy, many cytokines become repressed with advancing gestation, including IFN- $\gamma$ , vascular endothelial growth factor (VEGF), MCP-1 (CCL2), and eotaxin. TNF- $\alpha$  and granulocyte colony-stimulating factor (G-CSF) levels increase slightly with advancing gestation, which is surprising because both have been linked to proinflammatory responses, and maintaining uterine quiescence during pregnancy is thought to require repression of inflammation. **Proinflammatory cytokines such as IL-1 $\beta$ , TNF- $\alpha$ , and IL-6 have also been identified in the amniotic fluid, maternal and fetal blood, and vaginal fluid of women with intraamniotic infection at much higher levels than that observed during normal pregnancy.<sup>10-12,30</sup> These cytokines not only serve as a marker of intraamniotic infection, they may trigger preterm labor and lead to neonatal complications. The fetal inflammatory response syndrome describes the connection between elevated proinflammatory cytokines in fetal blood, preterm labor, and increased adverse fetal outcomes (see Chapter 29).<sup>30</sup>**

The relative contribution of individual cytokines and chemokines to preterm labor was studied in a unique nonhuman primate model. Preterm labor was induced by intraamniotic infusions of IL-1 $\beta$  and TNF- $\alpha$  but not by IL-6 or IL-8. IL-1 $\beta$  stimulated preterm labor in all cases and was associated with an intense contraction pattern.<sup>31</sup> TNF- $\alpha$  induced a variable degree of uterine activity characterized as preterm labor in some animals or as a uterine contraction pattern of moderate intensity. Despite prolonged elevations in amniotic fluid levels, neither IL-6 nor IL-8 induced an increase in uterine contractions until near term. **These results suggest a primary role for IL-1 $\beta$  and TNF- $\alpha$  in the induction of infection-associated preterm birth.** Recent data suggest that parturition and prostaglandin mRNA expression was delayed in IL-6 null mutant mice by 1 day compared with wild-type mice.<sup>32</sup> Furthermore, LPS did not induce preterm birth in IL-6–null mutant mice, in contrast to wild-type mice. **Together, these data indicate that IL-6 plays a role in triggering normal parturition, perhaps in activation of labor pathways.**

Investigation of the individual effect of a single cytokine on pregnancy or complications of pregnancy in humans has

proved challenging for several reasons. Many cytokines tend to be functionally redundant, with one cytokine compensating for the absence of another. Second, multiple cytokine receptors (i.e., interleukin-1 [IL-1] receptor antagonist, IL-18 binding protein) modulate similar cytokine effects. New families of decoy or silent cytokine receptors and suppressors of cytokine signaling have also been discovered in the placenta and amniotic fluid. Finally, molecular variants of cytokines may act as receptor antagonists. Therefore **individual cytokine effects during pregnancy must be interpreted in the context of cytokine receptors, receptor antagonists, silent cytokine receptors, and suppressors of cytokine signaling.**

### Chemokines

**Chemokines are a class of cytokines that act primarily as chemoattractants that direct leukocytes to sites of infection.** These chemotactic agents constitute a superfamily of small (8 to 10 kDa) molecules that can be divided into three groups—C, CC, and CXC—based on the position of either one or two cysteine residues located near the amino terminus of the protein. IL-8, CCL2 (also known as MCP-1), and RANTES (CCL5) are a few examples of chemokines. CXC chemokines, such as IL-8, bind to CXC receptors (CXCRs) and are important for neutrophil activation and mobilization. **Increases in IL-8 levels have been described in the amniotic fluid, maternal blood, and vaginal fluid with infection-associated preterm birth.<sup>33</sup> IL-8 and CCL2 have also been implicated in uterine stretch-induced preterm labor thought to occur in multiple gestation.<sup>34</sup>**

Some chemokine receptors are used as a coreceptor for the viral entry of the human immunodeficiency virus (HIV; see Chapter 53). The two major chemokine co-receptors for HIV are CXCR4 and CCR5, both of which are expressed on activated T cells. CCR5 is also expressed on DCs and macrophages, which allows HIV to infect these cell types. Rare resistance to HIV infection was discovered to correlate with homozygosity for a nonfunctional variant of CCR5 caused by a gene deletion in the coding region. The gene frequency for this CCR5 variant is highest in Northern Europeans but has not been detected in many black or Southeast Asian populations, in whom the prevalence of HIV infection is high. CCR3 is another chemokine coreceptor for HIV that is expressed by microglia, and it can be used by some HIV strains to infect the brain.

## ADAPTIVE IMMUNITY

The function of the adaptive immune system is to eliminate infection as the second line of immune defense and to provide increased protection against reinfection through immunologic “memory.” Adaptive immunity comprises primarily B cells and T cells (lymphocytes), which differ from innate immune cells in several important respects, including the mechanism for pathogen recognition and lymphocyte activation. Targeting a specific pathogen component in an immune response is a critical feature of the adaptive immune system and is necessary, in most cases, for resolution of the infection. However, achieving this specificity requires generation of an incredible diversity of T-cell receptors (TCRs) and B-cell receptors (BCRs). This creates the potential for self-antigens to be mistakenly targeted, resulting in an autoimmune response. Self-reactive T cells and B cells are thought to either undergo apoptosis in the thymus or to be regulated in the periphery. A small population of regulatory T cells contributes to peripheral regulatory mechanisms to prevent autoimmune responses and is discussed specifically in reference to mechanisms of fetal tolerance.

### Major Histocompatibility Complex

Discriminating cells that are “self” from those that are “nonself” is a critical function of the immune system to determine which cells should be destroyed and which to leave alone. In pregnancy, this process must be carefully regulated to prevent the killing of fetal cells, which express paternal genes that appear foreign to the maternal immune system; this in effect expands the maternal immune system’s definition of “self” to include the fetus. **The ability of a lymphocyte to distinguish self from nonself is based on the expression of unique major histocompatibility complex (MHC) molecules on a cell’s surface, which present small peptides from within the cell.** MHC molecules are highly polymorphic proteins produced by a cluster of genes on the short arm of chromosome 6. This gene complex is classically divided into two distinct regions referred to as *class I* and *class II*. **Class I contains classical transplantation HLA genes (e.g., *HLA-A*, *-B*, and *-C*) and nonclassical HLA genes distinguished by more limited polymorphism (e.g., *HLA-G*, *-E*, and *-F*). Class II contains polymorphic genes that are often matched for transplantation, including those of the *HLA-DR*, *-DQ*, and *-DP* families of genes.** Reduced HLA matching is associated with graft rejection after transplantation through activation of T cells. This system differs significantly from the innate immune system, in which recognition of MHC is not necessary for pathogen destruction.

### Humoral Immune Responses: B Cells and Antibodies

The function of B cells is to protect the extracellular spaces (e.g., plasma, vagina) in the body through which infectious pathogens usually spread (see Fig. 4-2, A). B cells mainly fight infection by secreting antibodies, also called *immunoglobulins*. Many similarities are found between B and T lymphocytes. Like T cells, B cells also undergo clonal expansion after antigen stimulation and can be identified by a variety of specific cell surface markers (e.g., CD19, CD20, and BCR antigens). Activated B cells may proliferate and differentiate into antibody-secreting plasma cells. **Antibodies control infection by several**

**mechanisms that include neutralization, opsonization, and complement activation.** *Neutralization* of a pathogen refers to the process of antibody binding, which prevents the pathogen from binding to a cell surface and internalizing. Alternatively, antibodies that coat the pathogen may enhance phagocytosis, also referred to as *opsonization*. Antibodies may also directly activate the classical complement pathway. **Activation of the B cell drives the B cell to proliferate and differentiate into an antibody-secreting plasma cell.**

Recently it was discovered that profound changes occur in many types of B cells during pregnancy.<sup>35</sup> Immature B cells that are the precursors to antigen-specific mature B cells are significantly reduced with advancing gestation in the maternal bone marrow, blood, and spleens of pregnant mice. **Lymphopoiesis of B cells is reduced during pregnancy, which may be mediated by the normal pregnancy rise in estradiol.**<sup>36</sup> Estradiol reduces levels of IL-17, a critical factor necessary for B-cell production in the bone marrow.<sup>37</sup> This reduction in immature B cells is further potentiated during the second half of pregnancy by the antigen-induced deletion of immature B cells.<sup>38</sup> Although immature B cells are reduced during pregnancy, the number of mature B cells is significantly increased. Surprisingly, an increased number of mature B cells are found in the lymph nodes that drain the uterus.<sup>35</sup> **Overall, pregnancy is associated with profound changes in the numbers of B cells in several compartments.**

**Autoantibodies produced by B cells against angiotensin receptor I, known as *AT1-AA*, are thought to play a role in inducing hypertension and proteinuria in women with preeclampsia and fetal growth restriction.**<sup>39,40</sup> *AT1-AA* is present in 70% to 95% of women with preeclampsia, and antibody titer is correlated with disease severity.<sup>41</sup> *AT1-AA* can bind to endothelial and placental cells in vitro to induce oxidative stress and cytokine and endothelin production.<sup>42,43</sup> Transfer of these autoantibodies from women with preeclampsia can also induce hypertension and proteinuria in pregnant mice.<sup>39</sup> Although a wide spectrum of immunologic abnormalities is found in preeclampsia, **the concept that an autoantibody can cause disease in pregnancy is well established.** For example, Graves disease is the most common causes of thyrotoxicosis in pregnancy (see Chapter 42). More than 80% of individuals with Graves disease have anti-thyroid stimulating hormone (TSH) receptor autoantibodies. B cells are likely beneficial in establishing fetal tolerance but may also contribute to the pathogenesis of certain obstetric complications, such as preeclampsia.

### Antibody Isotypes

**Antibodies share the same general structure produced by the interaction and binding of four separate polypeptides (Fig. 4-4). These include two identical light (L) chains (23 kDa) and two identical heavy (H) chains (55 kDa).** The composition of the H chain determines the antibody isotype, function, and distribution in the body. In humans, there are five types of H chains—designated mu (M), delta (D), gamma (G), alpha (A), and epsilon (E)—that correspond to the five major antibody isotypes (immunoglobulin M [IgM], IgD, IgG, IgA, and IgE). To effectively combat extracellular pathogens, antibodies must be specialized to cross epithelia into different bodily compartments. In fact, antibodies are made in several distinct classes or isotypes (i.e., IgM and IgG) that vary in their composition. Naïve B cells express only IgM and IgD. Activated B cells undergo isotype switching, a process that produces different

**FIG 4-4** Structure of immunoglobulin. Immunoglobulins are produced by B cells to neutralize foreign substances, such as bacteria and viruses. They are large, Y-shaped proteins found in the serum and plasma. CH, constant domain of the heavy chain; CL, constant domain of the light chain; VH, variable domain of the heavy chain; VL, variable domain of the light chain.

antibody isotypes specialized for different functions and areas of the body.

**The first antibody to be produced during an immune response is IgM because it is expressed before isotype switching.** The serum concentration of IgM is 50 to 400 mg/dL, with a circulation half-life of 5 days. IgM antibodies are low in affinity, but the antibodies form pentamers that compensate by binding at multiple points to the antigen. **IgM is highly efficient at activating the complement system, which is critical during the earliest stages of controlling an infection.** Other isotypes dominate in the later stages of antibody responses.

**IgG represents about 75% of serum immunoglobulin in adults and is further divided into four subclasses: IgG1, IgG2, IgG3, and IgG4. Two subtypes of IgG, IgG1 and IgG3, are efficiently transported across the placenta and are important in conferring humoral immune protection for the fetus after birth.** The smaller size of IgG and its monomeric structure allows it to easily diffuse into extravascular sites. In mice, the level of IgG3 and IgM increase in early pregnancy but decline as pregnancy advances.<sup>35</sup>

**IgA is the predominant antibody class in epithelial secretions from the vagina, intestine, and lung.** IgA forms dimers and mainly functions as a neutralizing antibody. As a secreted antibody, IgA is not in close contact with either phagocytes or complement and, therefore, is less efficient in opsonization and complement activation. **IgA is the principal antibody in breast milk, which provides the neonate with humoral immunity from the mother (see Chapter 24). Neonates are particularly susceptible to infectious pathogens through their intestinal mucosa, and IgA is highly effective in neutralizing these bacteria and toxins.** Epidemiologic studies indicate that deaths from diarrheal diseases could be reduced between 14- and 24-fold by breastfeeding, owing in part to the maternal-infant transmission of IgA.<sup>44</sup> Levels of IgA rise toward the end of pregnancy in pregnant mice.<sup>35</sup>

IgE has the lowest concentration in serum of all the antibodies but is bound efficiently by mast cell receptors. IgE binding of antibody triggers the mast cell to release granules, which results in an allergic response. Prenatal maternal exposure to allergens may have an effect on IgE in the fetus at birth; concentration of house dust mite allergens has been correlated in a dose-dependent manner with total IgE measured in neonatal heel capillary blood. IgE also plays a prominent role in immune responses to eukaryotic parasites.

## T CELLS

**When pathogens replicate inside cells (all viruses, some bacteria and parasites), they are inaccessible to antibodies and must be destroyed by T cells. T cells are lymphocytes responsible for the cell-mediated immune responses of adaptive immunity, which require direct interactions between T lymphocytes and cells bearing the antigen that the T cells recognize.** Common to all mature T cells is the TCR complex. T cells develop a vast array of antigen specificity through a series of TCR gene rearrangements, and many aspects of TCR rearrangements are similar to those that produce antibody specificity. For example, during viral replication inside a host cell, viral antigen is expressed on the surface of the infected cell. T cells, along with HLA, then recognize these foreign antigens. HLA class I molecules present peptides from proteins in the cytosol, which may include degraded host or viral proteins. HLA class II molecules bind peptides derived from proteins in intracellular vesicles and thus display peptides that originate from pathogens in macrophage vesicles internalized by phagocytic cells and from B cells.

A variety of T cells are recognized based on their expression of different cell surface markers (i.e., CD2, CD3, CD4, CD8). **Cytotoxic T cells kill infected cells directly and express a variety of cell surface antigen and specific receptors, including CD8. Helper T cells activate B cells and express CD4.** Cytotoxic and helper T cells recognize peptides bound to proteins of two different classes of HLA molecules (see Fig. 4-2, B). APCs will present antigen to CD8<sup>+</sup> T cells in the context of MHC class I molecules (e.g., HLA-A). In contrast, antigen-presenting cells that present antigens with MHC class II molecules (e.g., HLA-DR) interact with T cells bearing CD4.

**HIV uses multiple strategies to disable T-cell responses, mainly by targeting CD4<sup>+</sup> T cells.** Targeting viral infection to CD4<sup>+</sup> T cells allows the virus to control and ultimately destroy this important T-cell subset. HIV destroys CD4<sup>+</sup> T cells through direct viral killing, which lowers the apoptosis threshold of infected cells, and through CD8<sup>+</sup> T cells that recognize viral peptides on the CD4<sup>+</sup> T-cell surface. CD8<sup>+</sup> T cells likely contain the infection but are unable to eradicate the virus. Viral mutants produced during one of the earliest steps of viral infection may contribute to the escape of virus-infected cells from CD8<sup>+</sup> T-cell killing. HIV also has an error-prone reverse transcriptase that copies the viral RNA genome into DNA, making “mistakes” that lead to production of viral variants. The presentation of peptides from HIV variants by CD4<sup>+</sup> T cells may also interfere and downregulate the CD8<sup>+</sup> T-cell response to the original (wild-type) virus. Finally, the HIV negative-regulation factor gene (*nef*) downregulates expression of MHC class II and CD4, which decreases the presentation of viral antigens on the cell surface.

## Helper T-Cell Subsets

CD4<sup>+</sup> T cells were originally classified into T-helper 1 (Th1) and T-helper 2 (Th2) subsets depending on whether their main function involved cell-mediated responses and selective production of IFN- $\gamma$  (Th1) or humoral-mediated responses with production of IL-4 (Th2). The number of subsets identified continues to expand and now includes regulatory T cells (T<sub>REG</sub>), Th17, follicular helper T cells (T<sub>FH</sub>), Th22, and Th9. The most well-characterized subsets are Th1 and Th2. **The Th1 subset is important in the control of intracellular bacterial infections such as *Mycobacterium tuberculosis* and *Chlamydia trachomatis*.** Intracellular bacteria survive because the vesicles they occupy do not fuse with intracellular lysosomes, which contain a variety of enzymes and antimicrobial substances. Th1 cells activate macrophages to induce fusion of their lysosomes with vesicles that contain the bacteria. Th1 cells also release cytokines and chemokines that attract macrophages to the site of infection, like IFN- $\gamma$ , TNF- $\alpha$ , IL-12, and IL-18. Th2 immune responses are mainly responsible for activating B cells by providing a critical “second signal.” Th2 cells produce cytokines that include IL-4, -5, -6, -10, and -13 and transforming growth factor beta (TGF- $\beta$ ). Although CD4<sup>+</sup> T cells can be described in a discrete manner using named subsets like Th1 or Th2, overlap between the functions of these cells is likely.

## REGULATORY T CELLS

T<sub>REG</sub> cells are now recognized as master regulators of the immune system, a feat they accomplish by downregulating antigen-specific T-cell responses to diminish tissue damage during inflammation and to prevent autoimmunity.<sup>45</sup> The most well-defined “naturally occurring” T<sub>REG</sub> cells express CD4 and CD25 (CD4<sup>+</sup>, CD25<sup>+</sup>), but other “suppressor” T cell populations can be generated in vitro (e.g., Tr1, Th3). Although CD4<sup>+</sup>CD25<sup>+</sup> cells were originally thought to also be defined by Forkhead box p3 (Foxp3) expression, this population now appears to be more complex and sometimes expresses other regulatory factors. **T<sub>REG</sub> cells are unique among the many mechanisms identified to maintain tolerance of the fetus, because fetal antigen-specific T<sub>REG</sub> cells are maintained in the maternal circulation after delivery, which may benefit the next pregnancy (see “Maternal Tolerance of the Fetus”).**<sup>46</sup> Human chorionic gonadotropin (hCG) acts as a chemoattractant for T<sub>REG</sub> to the maternal-fetal interface, and in the mouse this stimulates T<sub>REG</sub> frequency and suppressive activity.<sup>47</sup> Similarly, the number of B<sub>REG</sub> cells and B<sub>REG</sub> secretion of IL-10 increased when co-cultured with hCG.<sup>48</sup> In this way, hCG may act as an

early critical regulator of fetal tolerance by stimulating the populations and suppressive activity of T<sub>REG</sub> and B<sub>REG</sub> cells.

**The function of T<sub>REG</sub> cells during pregnancy may be critical for fetal tolerance but could also underlie the unique susceptibility of pregnant women to *Listeria monocytogenes* (see Chapter 54).** Pathogen-specific CD8<sup>+</sup> T cells confer protection against *L. monocytogenes*. T<sub>REG</sub> cells act to suppress the function of CD8<sup>+</sup> T cells, which is necessary for fetal tolerance, but secondarily disrupt maternal immunity toward *L. monocytogenes*, which is necessary for bacterial eradication.<sup>49,50</sup> Infection also reduces the suppressive activity of T<sub>REG</sub>, which may increase inflammation at the maternal-fetal interface and may promote bacterial invasion into the placenta and the fetus. Although trophoblast cells are resistant to *L. monocytogenes* in vitro, the placenta becomes highly infected in vivo, perhaps because of the immunosuppressive actions of T<sub>REG</sub> cells. **Once infected, the placenta acts as a reservoir of *L. monocytogenes*, which continually releases bacteria into the maternal circulation and propagates the infection, preventing bacterial clearance until the placenta is expelled.**<sup>51</sup> In contrast, *Plasmodium* infection increases T<sub>REG</sub> activation and suppressive activity during pregnancy, which may allow for host evasion and further parasite replication. The role of T<sub>REG</sub> cells in pregnancy may explain the unique susceptibility of pregnant women to certain perinatal infections.

## FETAL IMMUNE SYSTEM

Descriptions of the development of the fetal immune system are relatively limited, but sufficient information exists to determine that the fetus, even very early in gestation, has innate immune capacity.<sup>52,53</sup> Acquired immunity, particularly the capacity to produce a humoral response, develops more slowly and is not completely functional until well after birth. Many of the immune protective mechanisms that are present to protect the fetus from both pathogens and maternal immune recognition occur at the maternal-fetal interface. Fortunately, abnormalities of normal immune development are relatively rare. However, when they do occur, they can have profound effects on newborn and child health. Some of the more common immunodeficiencies are listed in Table 4-2.

Fetal thymic development begins with a primordial thymus at about 7 weeks' gestation. The thymus is first colonized with cells from the fetal liver at 8.5 to 9.5 weeks' gestation. These cells express primitive (CD34) and early T-cell surface antigen (CD7). Between 12 and 13 weeks, cells within the fetal liver and spleen express the TCR. By 16 weeks' gestation, the fetal

**TABLE 4-2** COMMON IMMUNE DEFECTS

| COMMON NAME                             | DEFECT  | CELLS AFFECTED                 | COMMENTS  |
|---|---|--------------------------------|---|
| X-SCID                                  | Common $\gamma$ chain of IL-2 receptor  | T cells and NK cells           | X-linked recessive and most common form of SCID, accounting for about 45%-50% of cases            |
| ADA-SCID                                | Defect in purine metabolism leading to abnormal accumulation of adenosine   | T cells, B cells, and NK cells | Autosomal recessive affecting both male and female infants; accounts for about 20% of SCID cases  |
| Jak-3 deficiency                        | Mutation on chromosome 19 of Janus kinase 3 activated by cytokine binding to the common $\gamma$ chain of the IL-2 receptor | T cells and NK cells           | Autosomal recessive, affecting both male and female infants; accounts for about 10% of SCID cases |
| Hyper-IgM syndrome, autosomal recessive | Defect in CD40 ligand (T cell) and CD40 (B cell) signaling, resulting in the inability of immunoglobulin class switching    | Elevated IgM                   | X-linked and autosomal recessive  |

ADA-SCID, adenosine deaminase severe combined immunodeficiency; Ig, immunoglobulin; IL-2, interleukin 2; NK, natural killer; X-SCID, X-linked severe combined immunodeficiency.

thymus has distinct cortical and medullary regions suggestive of functional maturity, and this is confirmed by the brisk response to allogeneic and mitogen stimulation. Functionally, fetal T cells show proliferative capacity very early in gestation. Stimulation by phytohemagglutinin of fetal T cells in vitro can be demonstrated as early as 10 weeks. Allogeneic responses in mixed lymphocyte culture can be detected in cells obtained from fetal liver as early 9.5 weeks and are consistently seen at 12 weeks' gestation. The fetal immune system generates T<sub>REG</sub> cells within lymph nodes in response to maternal microchimeric cells, which is further evidence that fetal T cells are functional and must be regulated to prevent an immune response.<sup>7</sup>

The ontogeny of fetal B-cell development in many ways parallels the development of T cells, and early pre-B cells (CD19 and CD20) are identified by cell surface markings in the fetal liver by 7 to 8 weeks' gestation.<sup>54</sup> Ultimately, these cells are produced in the fetal bone marrow when the marrow becomes the primary hematopoietic organ in the second trimester. Surface expression of IgM can be noted as early as 9 to 10 weeks. Cells in the fetal circulation express the common B-cell antigens (CD20) by 14 to 16 weeks' gestation, and secretion of IgM has been noted as early as 15 weeks. The level of IgM continues to increase and reaches normal postnatal levels by 1 year of age. The appearance of surface IgG and IgA is noted in fetal B cells at 13 weeks with secretion of IgG at 20 weeks' gestation. Postnatal levels of immunoglobulin are not reached until about 5 years of age.

**The neonatal immune system has unique challenges at the time of birth when the newborn is no longer protected from pathogens by the placenta and maternal immune system.** A puzzling observation has been that neonatal T cells could become functionally activated in vitro, yet the neonate is profoundly susceptible to systemic infection, as evidenced by the high rates of infection-related neonatal deaths in low- and middle-income countries.<sup>55</sup> To investigate the basis for neonatal susceptibility to infection, a mouse model of *L. monocytogenes* was used in which neonates have diminished survival and bacterial counts are a thousandfold higher than in adults.<sup>56</sup> Interestingly, transfer of adult immune cells from splenocytes into the neonates resulted in diminished cytokine production by the adult cells; when the neonatal immune cells were transferred into the adult, the neonatal cells demonstrated greater cytokine production. These results suggested active suppression of the immune response within the neonate, which was identified to reside within a population of fetal red blood cells (CD71<sup>+</sup>), making an enzyme called *arginase*. Destruction of the CD71<sup>+</sup> cells allowed the neonate to defend itself against *Escherichia coli* and *L. monocytogenes*, but the fetal intestine was found to be inflamed. **CD71<sup>+</sup> cells appear to protect the neonate from excessive inflammation that would occur from commensal microbes during bacterial colonization of the gut at the expense of impairing neonatal immunity to systemic infections.** An understanding of the basis for neonatal susceptibility to infection may allow for therapeutic strategies.

### Cord Blood Transplantation

**Fetal blood contains a high number of hematopoietic stem cells as well as naïve T cells and NK cells, which makes it an ideal source of cells for hematopoietic cell transplantation.** In 1988, the first hematopoietic cell transplant was carried out in a child with Fanconi anemia using a cord blood sample from an HLA-identical sibling. Today, more than 30,000 cord blood transplantations have been performed, and obstetricians are

often asked to collect umbilical cord blood remaining in the placenta after cord clamping. Cord blood is typically collected into closed-system bags or syringes that contain anticoagulation additives. The average volume per collection is about 75 mL of cord blood, which is processed to deplete red blood cells and then cryopreserved for later use. Cord blood samples are processed at either private or public cord blood banks. Specimens banked at private cord blood banks will be reserved for the donor family, with an estimated need for use between 1 per 1000 and 1 per 200,000.<sup>57</sup> Samples donated to public cord blood banks are processed, HLA typed, and entered into the National Marrow Donor Program, where they are made available to any individual who requires bone marrow transplantation. The major advantage of public banks is that samples are available to ethnic groups, which traditionally have difficulty finding a suitable HLA-matched donor (e.g., Native Americans, Asian/Pacific Islanders, and African Americans). **The American Congress of Obstetricians and Gynecologists (ACOG) recommends that if a patient requests information regarding collection and banking of umbilical cord blood, balanced and accurate information regarding the advantages and disadvantages of public versus private banking should be provided. Private umbilical cord blood banking is cost effective only for children with a very high likelihood of needing a stem cell transplant.**

Cord blood specimens were initially used only in children because of the reduced number of CD34<sup>+</sup> cells that were present in the donor specimen. As use increased, even in the setting of less than ideal HLA matching, engraftment success was accompanied by a reduction in the frequency of severe (grades 3 and 4) graft-versus-host disease (GVHD). Because of the success noted in children, cord blood specimens are now commonly used in adults. **Double-unit cord blood transplantation is standard practice at many centers and appears to be associated with a lower risk of disease relapse.**<sup>58</sup> After engraftment, usually only one donor source predominates, and the recipient does not develop multisource mixed chimerism. At the present time, the need for autologous cord blood cells is limited. In 2010, more than 450,000 cord blood units were banked worldwide with donor registries present in nearly all regions of the world (47 registries in Europe, 9 in North America, 2 in Africa, 11 in Asia, and 2 in Australia). Umbilical cord blood units are shared internationally, and approximately 40% are matched to a donor across an international border. **The obstetrician-gynecologist can play an important role in improving the availability of cord blood units internationally by encouraging pregnant women to donate to a public cord blood bank.**

### MATERNAL TOLERANCE OF THE FETUS

**Pregnancy is a unique immunologic phenomenon in which the normal immune rejection of foreign tissues does not occur.** The maternal immune system clearly recognizes fetal cells as foreign,<sup>59</sup> and about 30% of primiparous and multiparous women develop antibodies against the inherited paternal HLA of the fetus.<sup>60</sup> The continued presence of these antibodies does not appear to be harmful to the fetus. Persistent fetal cells in the mother may play a role in maintaining the levels of these antibodies because in some women, the antibodies persist, whereas in others they disappear. Formation of IgG antibodies against inherited paternal HLA antigens is associated with the presence of primed cytotoxic T lymphocytes specific for these HLA

antigens. Maternal T lymphocytes specific for fetal antigens exist during pregnancy but appear to be hyporesponsive.<sup>9,61</sup> The normal growth and development of the fetus despite maternal immune recognition requires several maternal and fetal adaptations that in most women allow pregnancy to be carried uneventfully to term.

**Achieving fetal tolerance requires changes to maternal immunity in multiple locations and by many different cell types because maternal and fetal cells are in direct contact with each other (Fig. 4-5).** The syncytiotrophoblast, the outermost layer of chorionic villi, is in direct contact with maternal blood in the intervillous space. Extravillous trophoblast in the decidua is in contact with many different maternal cells, including macrophages, dNK cells, and T cells. Endovascular trophoblast replaces endothelial cells in the maternal spiral arteries and is in direct contact with maternal blood. Fetal and maternal macrophages are also in close contact in the chorion layer of the fetal membranes. **A final and critical interface is within the secondary lymphoid organs (lymph nodes and spleen), where shed fetal trophoblast debris from the placenta comes into contact with maternal immune cells.**<sup>62</sup> A series of studies using a murine model with a unique fetal antigen demonstrated that secondary lymphoid organs are the primary site of fetal and placental alloantigen presentation by maternal, not fetal, APCs.<sup>58,63,64</sup> Maternal recognition of fetal alloantigens likely begins before pregnancy in the lymph nodes that drain the uterus after intercourse with genital tract exposure to seminal fluid.<sup>64</sup> **In summary, the complex nature of the cells and the many locations of the maternal-fetal interface necessitate a number of different immune mechanisms to prevent fetal rejection.** We describe many of the well-known mechanisms of fetal tolerance with a focus on T<sub>REG</sub> cells because of recent exciting studies that implicate their critical role.

## Tolerance Through Regulation of Maternal T Cells

**Maternal T cells acquire a state of tolerance for fetal alloantigens during pregnancy.** This has been elegantly demonstrated in female mice sensitized to known paternal antigens before pregnancy.<sup>9,61</sup> During pregnancy, the female mice became tolerant to the same paternal antigens expressed by the fetus that were previously recognized and destroyed. **Several mechanisms exist to suppress maternal T-cell responses.** Activated maternal T cells may be deleted, killed, or become anergic in several ways. Suppression of T-cell activation by maternal T<sub>REG</sub> cells is a focus of this section, but other mechanisms to regulate T-cell activation also occur, including chemokine gene silencing in decidual stromal cells, upregulation of a T-cell immunoinhibitory receptor (programmed death 1 [PD-1]), enzymatic depletion of tryptophan (indoleamine 2,3-dioxygenase [IDO]), and the presence of Fas ligand (FasL) and B7-family molecules (B7-DC, B7-H2, B7-H3) on placental trophoblast.<sup>63,65-67</sup> The importance of suppressing maternal T cells to prevent fetal rejection is evident by the multiple mechanisms used both in the periphery and at the maternal-fetal interface.

**T<sub>REG</sub> cells suppress antigen-specific immune responses and are elevated in the maternal circulation of women and mice during pregnancy.**<sup>68</sup> Outside of pregnancy, T<sub>REG</sub> cells (CD4<sup>+</sup>, CD25<sup>+</sup>) act mainly to prevent autoimmune responses from occurring when self-reactive T cells escape from the thymus during normal T-cell development. In mice, depletion of CD25<sup>+</sup> T<sub>REG</sub> cells resulted in fetal resorptions from allogeneic matings.<sup>69,70</sup>

In a mouse model of spontaneous abortion, transfer of T<sub>REG</sub> cells from mice with a normal pregnancy could also prevent abortion in the mice that were otherwise destined to abort. In women with recurrent spontaneous abortion and preeclampsia, decreased numbers of CD4<sup>+</sup>CD25<sup>+</sup> T<sub>REG</sub> cells are present, which suggests a connection between these conditions and T<sub>REG</sub> activity. The mechanism of T<sub>REG</sub> suppression of T-cell responses is unknown but may involve either direct cell contact or production of anti-inflammatory cytokines such as IL-10 and TGF- $\beta$ .

**Pregnancy selectively drives expansion of maternal T<sub>REG</sub> cells (>100-fold), which are maintained after delivery and are rapidly expanded in a subsequent pregnancy.<sup>46</sup> This preexisting pool of fetal-specific maternal T<sub>REG</sub> cells is poised to impart tolerance and benefit the next pregnancy.**

T<sub>REG</sub> cells may be generated through several mechanisms. Before conception, T<sub>REG</sub> cells may be induced after exposure to seminal fluid.<sup>71</sup> During pregnancy, induction of peripheral T<sub>REG</sub> cells may occur through immature DC exposure to fetal antigens shed into the maternal circulation from the placenta (see “[Amelioration of Rheumatoid Arthritis in Pregnancy](#)”).<sup>8,72</sup> Estrogen has also been shown to increase proliferation of T<sub>REG</sub> cells, and the higher levels of estrogen in pregnancy may drive expansion of this cell population during pregnancy.

**A specific gene called *conserved noncoding sequence 1* (CNS1) confers the ability to generate T<sub>REG</sub> cells in the periphery and has been identified as a critical evolutionary step in allowing for pregnancy to occur in mammals with a placenta.**<sup>73</sup> T<sub>REG</sub> cells can be made in two locations, which are now thought to also inform their function: production in the thymus (thymic T<sub>REG</sub>; tT<sub>REG</sub>) mediates tolerance to self-antigens, and induction in the periphery (peripheral T<sub>REG</sub>; pT<sub>REG</sub>) occurs in response to commensal bacteria, food, or pregnancy.<sup>74</sup> In a mouse model, pT<sub>REG</sub> cells specific for a fetal alloantigen were found to accumulate in the placenta.<sup>73</sup> Deletion of the *CNS1* gene in female mice resulted in abortion (fetal resorption) with immune cell infiltration of the placenta and defective remodeling of the uterine spiral arteries. Interestingly, in syngeneic matings (breeding pairs with the same genetic background), deletion of the *CNS1* gene was not associated with fetal abortion. This suggests that pT<sub>REG</sub> cells are critical in achieving fetal tolerance with maternal-fetal HLA disparity. *CNS1* is highly conserved in eutherian (placental) mammals (i.e., humans, dolphins, elephants) but is absent from noneutherian mammals (platypus, wallaby) and nonmammals (zebrafish) that lack a placenta.<sup>73</sup> **This evidence suggests that *CNS1* is a critical gene that allows for the evolution of a placenta in eutherian mammals.**

## Tolerance Through Regulation of Maternal B Cells

Several mechanisms act to protect the fetus from an antibody-mediated attack. First, immature B cells are partially deleted in the spleen and bone marrow during the second half of pregnancy in mice.<sup>38</sup> Secondly, the combination of reduced immature B cells and depletion of the IDO enzyme acts to prevent differentiation of B cells in a mouse model.<sup>75</sup> IDO is also depleted at the maternal-fetal interface, which may have a dual role in suppressing both B- and T-cell responses (see “[Maternal Tolerance of the Fetus](#)”). Levels of B-cell activating factor of the tumor necrosis factor family (BAFF) are reduced during pregnancy; BAFF acts to costimulate B cells and to promote proliferation.<sup>35</sup> Finally, a special class of B cells is upregulated during pregnancy;

### Maternal T and B cells

- hCG stimulates proliferation of  $B_{REG}$  and  $T_{REG}$  cells and acts as a chemoattractant for  $T_{REG}$  to maternal-fetal interface
- Induction of fetal-specific  $T_{REG}$  cells in the uterine draining lymph nodes after exposure to seminal fluid
- Pregnancy induces expansion of maternal  $T_{REG}$  cells, which are sustained postpartum and rapidly expanded in the next pregnancy
- Upregulation of PD-1 on maternal T cells
- CNS1 (Foxp3 enhancer) enables generation of maternal  $T_{REG}$  in periphery
- $B_{REG}$  (B10) cells produce IL-10

### Maternal-Fetal Interface, Decidua, Villous and Extravillous Trophoblast

- Limited expression of polymorphic HLA by extravillous trophoblast (e.g. HLA-G, HLA-E)
- B7 family molecules (B7-DC, B7-H2, B7-H3)
- Tryptophan depletion
- Epigenetic silencing of chemokine genes in decidual stromal cells
- Secretion of FasL by villous trophoblast
- Decoy receptors and non-death domain containing TNF receptors
- Syncytiotrophoblast sloughing releases apoptotic cells containing fetal antigens that induce a "tolerogenic" DC phenotype
- Negative regulators of complement activation (e.g. CD59)
- Suppression of Th1 & activation of Th2
- Secretion of IL-10
- Few numbers of DC in decidua
- Cytolytic function of dNK cells is low and further inhibited by HLA-G

### Peripheral Lymphoid Organs

### Lymph Nodes and Spleen

- Persistent fetal antigen presentation by lymph node resident DC to  $CD8^+$  T cells induces tolerance
- Partial deletion of maternal B cells specific for fetal antigens in spleen and bone marrow

### Fetal Immunity

- Production of  $T_{REG}$  cells in fetal lymph nodes specific for maternal microchimeric cells
- Neonatal  $CD71^+$  cells expressing arginase-2 suppress inflammation associated with rapid gut colonization with commensal microbes after birth

**FIG 4-5** Mechanisms that promote maternal-fetal tolerance. Many different mechanisms and cell types have been identified that prevent rejection or dangerous immune responses during pregnancy. We have illustrated some of these mechanisms that operate within the maternal-fetal interface, maternal B- and T-cell populations, secondary lymphoid organs, and the fetus. The term *maternal-fetal interface* may refer to several locations where maternal and fetal cells come into direct contact, including the decidua and the intervillous space.

these are called *regulatory B cells* ( $B_{\text{REG}}$  or B10), and they act to downregulate immune responses, mainly through the production of antiinflammatory cytokines (e.g., TGF- $\beta$ , IL-10).<sup>76-79</sup> **An important cofactor for  $B_{\text{REG}}$  cells is hCG, and the rise of hCG in early pregnancy is likely to stimulate proliferation of  $B_{\text{REG}}$  cells to support early tolerance of the fetus.**<sup>48</sup>

### Tolerance Through Dendritic Cells and Antigen Presentation

Dendritic cells (DCs) present antigen to naïve T cells and initiate T-cell expansion and polarization to foreign antigens, which could represent a problem for fetal tolerance. Fortunately, DCs are relatively rare in the decidua, which would effectively limit the ability to initiate a T-cell response to fetal antigens encountered at this maternal-fetal interface.<sup>80</sup> Despite the scarcity of DCs at the maternal-fetal interface, fetal antigens are detected in mice throughout all secondary lymphoid organs (spleen, lymph nodes). Antigens from the fetus are presented exclusively by maternal APCs; this is quite different than the case of a transplanted organ, in which either donor or host APCs are capable of presenting antigens and initiating T-cell responses.<sup>58</sup> Fetal antigens come mainly from apoptotic trophoblast debris that results from normal placental growth. An interesting mechanism to promote fetal tolerance occurs through the uptake of fetal antigens by follicular DCs that results in a prolonged period (weeks to months) of fetal antigen presentation.<sup>81</sup> Several waves of bone marrow-derived DCs sample the fetal antigens presented by follicular DCs and subsequently represent these antigens to maternal CD8<sup>+</sup> T cells, which induces deletion of CD8<sup>+</sup> T cells. In this case, tolerance and T-cell deletion is likely induced for two reasons. First, fetal antigens are mainly derived from apoptotic cells, which induce tolerogenic responses after uptake by DCs.<sup>82</sup> Secondly, the continuous nature of fetal antigen presentation mediated by follicular DCs is a powerful signal to induce T-cell tolerance.<sup>83</sup> Although follicular DCs were thought to only play a role in the regulation of B-cell immunity, evidence now suggests that the long-term nature of antigen presentation by these cells is a significant factor in shaping peripheral T-cell tolerance to fetal antigens.

### Tolerance Through Human Leukocyte Antigens

Fetal trophoblast cells are in direct contact with maternal blood and should be at risk for maternal immunologic rejection. **The expression of MHC molecules by fetal trophoblast cells is limited to class I antigens—primarily class Ib HLA-G, HLA-E, and HLA-F—all of which have limited polymorphisms.** The exception to this rule of limited genetic variability is the expression of HLA-C, a class Ia molecule that is highly polymorphic, expressed primarily by extravillous trophoblast, and is thought to interact with dNK cells to facilitate uterine spiral artery remodeling.<sup>84</sup> **Expression of HLA-G by fetal trophoblast cells is thought to protect the invasive cytotrophoblast from killing by dNK cells and is also thought to contain placental infection.** HLA-G also inhibits macrophage activation through ILT-4, an inhibitory receptor. Through interactions with dNK cells, HLA-G likely contributes to normal pregnancy by maintenance of immune tolerance at the maternal-fetal interface. However, other mechanisms must also contribute to this process because normal pregnancies in women and fetuses that lack a functional HLA-G gene (HLA-G null) have been described.<sup>85</sup>

### Tolerance Through Regulation of Complement, Chemokines, and Cytokines

**Local inhibition of complement in the placenta may be important in preventing fetal rejection or preterm labor, particularly in the setting of inflammation or infection.** In a murine model of abortion induced by antiphospholipid antibodies, protection against abortion was conferred by antagonizing factor B, an alternative complement component. Defects of placental formation were also observed in a murine model associated with activation of the alternative complement pathway and maternal C3. Finally, several negative regulators of complement are expressed by trophoblast cells, including CD59 (MAC antagonist), membrane cofactor protein, and decay accelerating factor (inhibitors of C3 and C5 convertases).<sup>27</sup> When a negative regulator of murine complement (*Crry*) was genetically ablated, embryo survival was compromised and placental inflammation was observed.<sup>86</sup> C3 activation plays a major role in fetal rejection in this model because the embryos survived when genetically deficient *Crry* mice were mated to C3-deficient mice. **Several studies suggest that inhibition of complement activation may contribute significantly to fetal tolerance, particularly in the setting of inflammation.**

Expression of chemokines and some cytokines at the maternal-fetal interface could be dangerous for the fetus because these small proteins may be inflammatory and may attract immune cells. **Regulation of chemokine expression (CXCL9, CXCL10, CXCL11, CCL5) by decidual stromal cells in mice was found to prevent the accumulation of T cells in the decidua after an inflammatory challenge.**<sup>67</sup> Chemokine expression was effectively silenced by epigenetic changes that involve histone repressor marks on chemokine gene promoters that appeared after transformation of endometrial stromal cells into decidual stromal cells. T cells are known to be relatively rare in decidua, which may be the result of a lack of chemokine production by decidual stromal cells.

Whether a change in the T-helper cytokine profile plays a role in fetal tolerance remains controversial.<sup>87</sup> It was originally thought that a Th2-type immune response might predominate during pregnancy, a theory based on the adverse effects of Th1 cytokines on murine pregnancy and weakened immunity during pregnancy to intracellular infections that require Th1 cytokine activity.<sup>88-90</sup> IL-10 is a Th2 cytokine that is elevated during pregnancy, and it is known to downregulate Th1 cytokine production to prevent fetal resorption in mice genetically predisposed to abortion. In a study of women with a history of recurrent spontaneous abortion, maternal cytokine profiles of stimulated peripheral blood mononuclear cells were compared between women who had a successful pregnancy and those who had a spontaneous abortion. Increased Th2 cytokines were associated with a successful pregnancy, and elevated Th1 cytokines were associated with a spontaneous abortion. Although several studies have reported a Th2-type profile in the blood of healthy pregnant women, not all studies supported the Th2 bias.<sup>91,92</sup> **Most studies have noted suppression of Th1 and activation of Th2 cytokine profiles in the blood of women with a normal pregnancy, and this effect may be more pronounced at the maternal-fetal interface. Interestingly, the Th1 cytokine profile is activated in preterm labor.**

### Fetal Rejection

The idea that loss of maternal-fetal tolerance may contribute to unexplained preterm fetal death or spontaneous preterm birth

is emerging. **Unexplained preterm fetal death has been linked to a loss of fetal tolerance and chronic chorioamnionitis, which describes an influx of T cells into the fetal membranes.**<sup>93</sup> *Chronic chorioamnionitis* is an unusual pathologic diagnosis in the placenta, and it differs significantly from *acute chorioamnionitis*, which refers to neutrophilic infiltration into the membranes that often occurs in the setting of placental infection. **In chronic chorioamnionitis, a large number of CD3+ and CD8+ T cells are found in the fetal membranes in addition to some CD4+ T cells.** In a case series of 30 women with an unexplained preterm fetal death, chronic chorioamnionitis was diagnosed significantly more often in fetal death cases than in preterm birth controls (60% vs. 38%). In addition, maternal anti-HLA class II seropositivity was significantly higher in women with a fetal death than in women after live birth (36% vs. 11%). A similar pattern of immunologic changes associated with a maternal antifetal response was identified in women with spontaneous preterm birth, which included a significantly higher frequency of chronic chorioamnionitis, maternal anti-HLA class I seropositivity, and complement (C4d) deposition along the umbilical vein endothelium. These observations suggest that a maternal antifetal immune response similar to allograft rejection is common in cases of unexplained fetal death and spontaneous preterm birth. **The conclusion that maternal tolerance of the fetus can be impaired is also supported by recent observations and hypotheses surrounding perinatal infections (e.g., *L. monocytogenes*) through an infection-associated reduction in T<sub>REG</sub> leading to maternal T-cell infiltration of the placenta.**<sup>50</sup> **Once maternal-fetal tolerance is sufficiently impaired to allow maternal T cells into the placenta, inflammation can then facilitate pathogenic invasion of the fetus and fetal death.**

## SOLID ORGAN TRANSPLANTATION IN PREGNANCY

Women with a solid organ transplant present many interesting questions as to how tolerance is maintained for the fetus and the transplanted organ during pregnancy.<sup>94</sup> Although it was classically thought that the placenta served as an impenetrable barrier between mother and fetus, we now know that bidirectional cell trafficking occurs routinely between the mother and the fetus.<sup>3</sup> Thus in nearly every pregnancy, cells that originate from the fetus can be found in the mother, and conversely, cells that originate from the mother can be found in the fetus. The long-term persistence of fetal cells in the mother and maternal cells in her progeny leads to the coexistence of at least two cell populations in a single person and is referred to as *microchimerism (Mc)*. **A pregnant woman with a solid organ transplant has at least three, and possibly more, sources of Mc that include fetal Mc, maternal Mc from her own mother's cells that entered when she was a fetus, and cells from the donor allograft.** APCs in the pregnant woman, the donor organ, and the microchimeric cell populations can all present antigens from each other, which results in at least 16 combinations of antigens and APCs.<sup>94</sup>

**Maintaining tolerance to all of these cell populations is a formidable task, and in a few instances, it has been documented to fail, which results in transplant rejection during pregnancy or postpartum.** In two women with a history of cardiac transplant, HLA class II antibodies to fetal antigens developed during pregnancy and then cross-reacted with the

transplanted organ, culminating in graft rejection. In the first case, cardiac rejection occurred 3 months postpartum in a woman who had otherwise been on a stable immunosuppressant regimen for 17 years.<sup>95</sup> HLA typing on the baby and the baby's father determined that paternal antigens presented by the fetus were likely to have triggered rejection. A second case of cardiac rejection linked to pregnancy occurred after an 8-week miscarriage in a woman 6 years after her transplantation.<sup>96</sup> A deeper understanding of the mechanisms of fetal tolerance and allograft rejection during and after pregnancy will lead to further advances in identifying pregnant women at unique risk for rejection during pregnancy.

**Remarkably, uterine transplantation has now been performed in at least 11 women, and one live birth has been reported following transplantation.**<sup>97</sup> In women with a history of uterine transplantation, menstruation has been reported to resume in the recipient as early as 43 days after transplant. Rejection episodes have been reported and were reversed successfully by corticosteroids. The woman who achieved a live birth underwent single embryo transfer 1 year after transplantation and was maintained on tacrolimus, azathioprine, and corticosteroids throughout pregnancy; corticosteroids were also used to reverse one episode of mild rejection that was diagnosed during the pregnancy. Blood flow through the uterine vessels and fetal growth were both normal throughout the pregnancy; however, preeclampsia developed at 31 weeks' gestation, and a cesarean delivery was performed because of an abnormal fetal heart rate tracing. The infant was born with an appropriate birthweight (1775 g) and excellent Apgar scores (9, 9, 10). Although uterine transplantation was once thought impossible, it has now been shown to withstand the challenge of pregnancy.

## AMELIORATION OF RHEUMATOID ARTHRITIS IN PREGNANCY

**Pregnancy has a remarkable effect on the disease course of some autoimmune inflammatory diseases, such as rheumatoid arthritis (RA) and multiple sclerosis, that results in a temporary amelioration or remission of symptoms** (see Chapter 46).<sup>98</sup> RA is characterized by a symmetric inflammatory arthritis that causes pain, stiffness, and swelling of multiple joints. **Nearly three quarters of pregnant women with RA experience improvement in symptoms during the second and third trimesters with a return of symptoms postpartum.** Early hypotheses to explain this phenomenon focused on the role of sex hormones; cortisol and placental gamma globulin were rejected as potential therapies after studies that tested each could not mimic the effect of pregnancy on RA. Interestingly, the odds that pregnancy will result in amelioration of symptoms are not related to disease severity, duration, maternal age, or rheumatoid factor positivity.<sup>8</sup> Instead, amelioration of RA symptoms was observed significantly more often in women carrying a fetus with different paternally inherited HLA class II antigens from those of the mother.<sup>99</sup> This is strong evidence that fetal genetics and the maternal immune response to paternal (fetal) HLA antigens play a role in the pregnancy-induced remission of RA.

**We have previously hypothesized that amelioration of RA occurs as a secondary benefit from the maternal T- and B-cell tolerance that develops to release of fetal antigens during pregnancy, which is coupled to normal placental growth.**<sup>8,100</sup> As the placenta grows, apoptotic syncytiotrophoblast cells (the

outer epithelial lining of the chorionic villi) are shed into the maternal blood. This process starts in the first trimester and by the third trimester results in gram quantities of fetal debris entering the maternal circulation daily. Fetal antigens are present in this apoptotic debris, including fetal minor histocompatibility antigens.<sup>72</sup> Phagocytosis of this debris by maternal immature DCs would result in presentation of fetal antigens to maternal T cells. As the antigens came from apoptotic cells, the immature DCs would change to a “tolerogenic” phenotype specialized to promote induction of T<sub>REG</sub>, T-cell deletion, and anergy toward the presented fetal antigen. **Amelioration of RA could occur through the simultaneous presentation of fetal and self HLA (RA-associated) peptides by tolerogenic DCs and downregulation of maternal T-cell immunoreactivity.**

Supportive evidence for this theory comes from studies of both murine and human pregnancy. Murine studies demonstrate maternal T-cell deletion, anergy, and induction of T<sub>REG</sub> to fetal antigens.<sup>9,46,61</sup> **Maternal-fetal HLA disparity is the strongest predictor of RA amelioration/remission in human pregnancy.**<sup>99</sup> Induction and suppressive activity of T<sub>REG</sub> cells is impaired in syngeneic versus allogeneic murine pregnancy, which suggests that maternal-fetal HLA disparity is important in the degree of maternal T-cell tolerance achieved. Finally, a significant correlation has been found between levels of human fetal DNA (representing the quantity of placental debris in maternal circulation) and changes in RA activity during pregnancy.<sup>9,99</sup>

### SUMMARY

Adaptations of the maternal immune system to tolerate the fetus during pregnancy are remarkable. No other condition in medicine allows foreign tissue to be so readily accepted and tolerated. We have gained tremendous insight into how maternal immunity adapts to the challenge of protecting the fetus from immunologic attack, but further research is necessary to understand how these mechanisms operate during normal and abnormal pregnancy. Preeclampsia and preterm labor are obstetric conditions with known abnormalities of the maternal immune system. The potential to make breakthroughs in these areas through the study of immunology in pregnancy is enormous.

### KEY POINTS

- ◆ The innate immune system uses fast, nonspecific methods of pathogen detection to prevent and control an initial infection and includes macrophages, NK cells, the complement system, and cytokines. Macrophages have critical scavenger functions that likely help to prevent bacteria from establishing an intrauterine infection during pregnancy. Decidual NK (dNK) cells are thought to play a major role in remodeling of the spiral arteries to establish normal placentation.
- ◆ Proinflammatory cytokines such as IL-1 $\beta$ , TNF- $\alpha$ , and IL-6 have been identified in the amniotic fluid, maternal and fetal blood, and vaginal fluid of women with intraamniotic infection at much higher levels than those

observed during normal pregnancy. These cytokines not only serve as a marker of intraamniotic infection, they trigger preterm labor and can lead to neonatal complications.

- ◆ Adaptive immunity results in the clonal expansion of lymphocytes (T cells and B cells) and an increase in antibodies against a specific antigen. Although slower to respond, adaptive immunity targets specific components of a pathogen and is capable of eradicating an infection that has overwhelmed the innate immune system.
- ◆ The function of B cells is to protect the extracellular spaces in the body (e.g., plasma, vagina) through which infectious pathogens usually spread by secreting antibodies (immunoglobulins). Antibodies control infection by several mechanisms, including neutralization, opsonization, and complement activation. Autoantibodies produced by B cells against angiotensin receptor I (AT1-AA) are thought to play a role in inducing hypertension and proteinuria in women with preeclampsia and intrauterine fetal growth restriction.
- ◆ When pathogens replicate inside cells (all viruses, some bacteria and parasites), they are inaccessible to antibodies and must be destroyed by T cells. A variety of T cells are recognized based on their expression of different cell surface markers that include those of CD8<sup>+</sup> (effector or cytotoxic T cells), CD4<sup>+</sup> (helper T cells), and CD4<sup>+</sup>CD25<sup>+</sup> (T<sub>REG</sub> cells). CD8<sup>+</sup> T cells kill cells directly, whereas helper T cells activate B cells to produce antibodies. T<sub>REG</sub> cells are now recognized as master regulators of the immune system that work by downregulating antigen-specific T-cell responses to diminish tissue damage during inflammation and to prevent autoimmunity.
- ◆ The fetal immune system, even very early in gestation, has innate immune capacity. Acquired immunity, particularly the capacity to produce antibodies, develops more slowly and is not completely functional until well after birth. CD71<sup>+</sup> cells appear to protect the neonate from excessive inflammation that would occur from commensal microbes during bacterial colonization of the gut at the expense of impairing neonatal immunity to systemic infections.
- ◆ Fetal blood contains a high number of hematopoietic stem cells, making it an ideal source of cells for hematopoietic stem cell transplantation. The estimated need for the use of privately banked cord blood is between 1 in 1000 and 1 in 200,000, which is cost effective only for children with a very high likelihood of needing a transplant.
- ◆ Maintaining tolerance to the fetus requires several immunologic mechanisms, both at the maternal-fetal interface and in the maternal periphery. A critical interface is within the secondary lymphoid organs (lymph nodes and spleen), where fetal antigens are presented to maternal immune cells. Some of these mechanisms include generation of paternal-specific T<sub>REG</sub> and B<sub>REG</sub> cells in the maternal periphery, T-cell deletion, tryptophan depletion, presence of FasL or TNF-related apoptosis-inducing ligand/Apo-2L (TRAIL) on tropho-

blast cells, HLA-G expression by the placenta, and inhibition of complement activation by the placenta.

- ◆ Among the many mechanisms identified to maintain tolerance of the fetus, T<sub>REG</sub> cells are unique because fetal antigen-specific T<sub>REG</sub> cells are maintained after delivery, which may benefit the next pregnancy. T<sub>REG</sub> cells suppress antigen-specific immune responses and are elevated in the maternal circulation of women and mice during pregnancy. Pregnancy selectively drives expansion of maternal T<sub>REG</sub> cells (>100-fold), which are maintained after delivery and are rapidly expanded in subsequent pregnancies. In addition, hCG acts as a chemoattractant for T<sub>REG</sub> to the maternal-fetal interface and, in the mouse, stimulates T<sub>REG</sub> cell numbers and their suppressive activity.
- ◆ Unexplained preterm fetal death has been linked to a loss of fetal tolerance and chronic chorioamnionitis, which refers to an influx of T cells into the fetal membranes. A related observation in mice connects maternal T-cell infiltration of the placenta with a loss of maternal T<sub>REG</sub> cells and perinatal death during infection with *L. monocytogenes*.
- ◆ A pregnant woman with a solid organ transplant has at least three and possibly more sources of small foreign cell populations (Mc) to which she must maintain tolerance: fetal Mc, maternal Mc (her own mother's cells that entered when she was a fetus), and cells from the donor allograft. In a few cases, transplant rejection has been linked to antifetal antibodies that developed during pregnancy.
- ◆ Remarkably, uterine transplantation has now been performed in at least 11 women with one live birth reported following transplantation.
- ◆ Pregnancy has a remarkable effect on the disease course of some autoimmune or inflammatory diseases, such as RA and multiple sclerosis, that results in a temporary amelioration or remission of symptoms. Amelioration of RA during pregnancy may occur as a secondary benefit from the maternal T- and B-cell tolerance that develops to fetal antigens during pregnancy.

Perinatal care has progressed remarkably from its original focus on maternal mortality, which approximated 1% per pregnancy in the early 1900s. Following the tremendous strides in reducing maternal morbidity and mortality, obstetric care has made great advances in regard to optimization of fetal and neonatal health, including the diagnosis, prevention, and treatment of congenital malformations; the reduction in infectious diseases; and improvements in sequelae of prematurity. It is now commonplace to deliver infants who would not have survived childbirth or the neonatal period in previous eras. For example, low birthweight (LBW) premature infants routinely survive beyond a weight of 400 to 500 g. Conversely, large for gestational age (LGA) infants

are often delivered by cesarean section, avoiding the potential trauma of labor. As we now examine the long-term consequences associated with this improved survival, as well as the effects of treatment aimed at improving outcomes (e.g., maternal glucocorticoids), we have begun to recognize long-term health effects of perinatal influences in adults. **An understanding of the developmental origins of adult health and disease provides an appreciation of the critical role of perinatal care and may ultimately guide our treatment paradigms.**

The concept of developmental origins of adult disease should not be surprising to obstetricians. Teratogenesis represents perhaps the most acute consequence of developmental effects.

In the late 1950s, thalidomide was marketed as both a sedative and a morning sickness prescription for pregnant women. Although the drug was not actively marketed in the United States for lack of Food and Drug Administration (FDA) approval, more than 2.5 million tablets were distributed to private physicians in the United States. Thalidomide was widely used in Europe and was included in some 50 over-the-counter products for a diversity of indications. Thalidomide-induced limb malformations are now well recognized. Notably, similar to mechanisms of developmental programming discussed below, thalidomide may induce its teratogenic effects through epigenetic mechanisms. As described by Stephens and colleagues,<sup>1</sup> thalidomide likely binds to promotor sites of insulin-like growth factor and fibroblast growth factor as well as downstream signaling genes that regulate angiogenesis. The resulting inhibition of angiogenesis truncates limbs during development. As will be discussed below, **a variety of mechanisms may “program” the phenotype of the offspring via aberrations in cellular signaling or epigenetic function.**

Whereas the short-term consequences of thalidomide were rapidly recognized, longer-term programming effects of diethylstilbestrol (DES) were slow to be identified. Prior to FDA approval in 1947, DES was used off label to prevent adverse pregnancy outcomes in women with a history of miscarriage. Despite a double-blind trial in the early 1950s that demonstrated no benefit of taking DES during pregnancy,<sup>2</sup> DES continued to be given to pregnant women throughout the 1960s. It was not until 1971 that the FDA advised against the use of DES in pregnant women in response to a report that demonstrated the link between DES and vaginal clear cell adenocarcinoma in girls and young women. Similar to thalidomide, it is now recognized that the oncogenic and teratogenic effects of in utero DES exposure may be mediated via epigenetic

mechanisms. As reported by Bromer and colleagues,<sup>3</sup> in utero DES exposure results in hypermethylation of the *HOXA10* gene, which regulates uterine organogenesis. Thus both the short-term anatomic defects associated with thalidomide and the delayed oncogenic effects associated with DES are examples of developmental origins of adult disease mediated via epigenetic effects.

This chapter will review the consequences and mechanisms of these prenatal and neonatal influences on developmental programming. We will primarily focus on the associations demonstrated in human studies, utilizing evidence from case reports, epidemiologic studies, and meta-analyses. We selectively discuss evidence from animal models that confirm the phenotype or suggest pathogenic pathways and potential mechanisms.

## EPIGENETICS AND PROGRAMMING

Epigenetics is a genetic process that switches genes on and off in response to external or environmental factors. The essential concept of **“gestational programming” signifies that the nutritional, hormonal, and metabolic environment provided by the mother permanently alters organ structure, cellular responses, and gene expression that ultimately impact the metabolism and physiology of her offspring (Fig. 5-1).** Further, these effects vary and are dependent upon the developmental period, and as such, rapidly growing fetuses and neonates are more vulnerable. The programming events may have immediate effects—for example, impairment of organ growth at a critical stage—whereas other programming effects are deferred until expressed by altered organ function at a later age. In this instance, the question is about how the memory of early events is stored and later expressed despite continuous cellular replication and replacement. This may be mediated through epigenetic

**FIG 5-1** Impact of gestational programming on organ systems.

**FIG 5-2** DNA methylation. **A**, Methylation by DNA methyltransferases at CpG islands. **B**, DNA demethylation relaxes chromatin structure, which allows histone acetylation and the binding of transcriptional complexes.

control of gene expression, which involves modification of the genome without altering the DNA sequence.

**Epigenetic phenomena are fundamental features of mammalian development that cause heritable and persistent changes in gene expression without altering DNA sequence.** Epigenetic regulation includes changes in the DNA methylation pattern and modifications of chromatin packaging via posttranslational histone changes.

**DNA methylation represents a primary epigenetic mechanism.** The DNA of the early embryo is hypomethylated, and with progressive increases in DNA methylation in response to environmental signals, organogenesis and tissue differentiation occur. DNA methylation typically occurs on cytosine bases that are followed by a guanine, termed *CpG dinucleotides*. The methylation by a DNA methyltransferase leads to recruitment of methyl-CpG binding proteins, which induce transcriptional silencing both by blocking transcription factor binding and by recruiting transcriptional corepressors or histone-modifying complexes. Anomalous DNA methylation in normally hypomethylated CpG-rich regions of gene promoters is associated with inappropriate gene silencing (e.g., cancer). It is during embryogenesis and early postnatal life that DNA methylation patterns are fundamentally established and are imperative for silencing of specific gene regions, such as imprinted genes and repetitive nucleic acid sequences. The epigenome is reestablished at specific stages of development, making it a prime candidate as the basis for fetal programming. As such, **changes in epigenetic markers are associated with inflammation and multiple human diseases, including many cancers and neurologic disorders.** Because methylation requires the nutrient supply and enzymatic transfer of methyl groups, it is plausible that in utero nutritional, hormonal, or other metabolic cues alter the timing and direction of methylation patterns during fetal development (Fig. 5-2).

**Another essential mechanism of gene expression and silencing is the packaging of chromatin into open (euchromatic) or closed (heterochromatic) states, respectively. Chromatin consists of DNA packaged around histones into a nucleoprotein complex.** Posttranslational modification of histone tails through acetylation, methylation, phosphorylation, ubiquitination, and SUMOylation can alter histone interaction with DNA and recruit proteins (e.g., transcriptional factors) that alter chromatin conformation. Histone tail acetylation by histone acetyltransferases promotes active gene expression,

**FIG 5-3** DNA methylation, histone modification, and noncoding RNA.

whereas histone tail deacetylation by histone deacetylases (HDACs) is associated with gene silencing (Fig. 5-3). Histone methylation can either repress or activate transcription depending on which lysine is methylated. For example, trimethylation of histone H3 at lysine 4 (H3K4me3) is associated with active gene transcription, whereas dimethylation of histone H3 at lysine 9 (H3K9me2) is associated with transcriptional silencing.<sup>4</sup> Histone modifications and DNA methylation patterns are not exclusively independent, and thus they can reciprocally regulate one another's state.

**Finally, noncoding RNAs (ncRNAs) are emerging as a potential third epigenetic mediator.** The ncRNAs are transcribed from DNA but are not translated into proteins, and they function to regulate gene expression at the transcriptional

and posttranscriptional level. The three major short ncRNAs (<30 nucleotides) associated with gene silencing are microRNAs (miRNAs), short inhibitory RNAs (siRNAs), and piwi-interacting RNAs (piRNAs).<sup>5</sup> Long ncRNAs (>200 nucleotides) play a regulatory role during development and exhibit cell type-specific expression. Whereas these ncRNAs are usually associated with regulation of gene expression at the translational level, recent work suggests they may be involved in DNA methylation as well, thereby further regulating transcription of their targets.

**Both human and animal studies provide evidence of epigenomic modulation by the maternal milieu; importantly, they implicate it in the transmission of gestational programming effects to multiple generations.**<sup>6</sup>

## FETAL NUTRITION AND GROWTH

**Nutrition is unquestionably one of the cornerstones of health.** More importantly, **good evidence suggests that appropriate nutritional supplementation before conception and during pregnancy may reduce the risk of some birth defects** (see [Chapters 6](#) and [7](#)). Perhaps the most convincing argument that can be made for the need to consider maternal nutrition as a critical modulator of embryonic development is the observation that maternal iodine supplementation has eradicated the occurrence of **iodine deficiency–induced cretinism** and other iodine deficiency–associated developmental defects. In addition, adverse maternal nutrition—which has an immediate and visible impact on the outcome of pregnancy—is seen in the case of **folate deficiency and spina bifida**. Similarly, maternal polymorphisms in the genes of folate metabolism are also associated with intrauterine growth restriction (IUGR) and abnormalities that include cleft palate and heart defects. In addition to its critical role in the conversion of homocysteine to methionine, the functional mechanism for folate likely involves epigenetic effects, because **folate generates the principal methyl donor (s-adenosyl methionine [SAME]) that participates in methylation of DNA and histones.**

Animal studies have also irrevocably shown the importance of a mother's diet in shaping the epigenome of her offspring. A classic example is that of permanent hypomethylation of certain regions of the genome as a result of deficient folate or choline (methyl donors) during late fetal or early postnatal life. Specifically, in viable yellow agouti mice, when the agouti gene is completely unmethylated, the mouse has a yellow coat color and is obese and prone to diabetes and cancer. When the agouti gene is methylated, as in normal mice, the coat color is brown and the mouse has a low disease risk. Although both the fat yellow and skinny brown mice are genetically identical, the former exhibits an epigenetic “mutation.”<sup>7</sup>

Although teratogenesis, structural malformations, and even oncogenic risks can be linked to developmental insults, it is only recently that the epidemic of metabolic syndrome has been attributed, in part, to consequences of fetal and newborn development. **Obesity now represents a major public health problem and health epidemic** (see [Chapter 41](#)). As recently reported, the adverse consequences of obesity are projected to overwhelm the beneficial effects of reduced smoking in the United States and have resulted in an actual *decline* in life expectancy. In the United States, 69% of adults are *overweight* (body mass index [BMI] from 25 to 30 kg/m<sup>2</sup>), and 35% are *obese* (BMI ≥30 kg/m<sup>2</sup>). Of concern to obstetricians is a marked and continuing increase in the prevalence of obesity among pregnant

women, a factor associated with both obstetric complications and high-birthweight newborns, a known risk factor for childhood obesity. Whereas the epidemic of obesity in the United States was originally attributed to changes in the work environment, a surplus of high calories, inexpensive food, and a lack of childhood exercise, it is now recognized that **the risks of obesity in metabolic syndrome can be markedly influenced by early life events, particularly prenatal and neonatal growth and environmental exposures.** In the early 1990s, Barker and Hales<sup>8</sup> brought attention to this with epidemiologic studies demonstrating that **nutritional insufficiency during embryonic and fetal development resulted in latent disease, including obesity, in adulthood.** A series of studies have demonstrated a marked increase in deaths from coronary heart disease and adult hypertension in association with small for gestational age (SGA) newborns. In addition, investigators observed impaired glucose tolerance and diabetes in association with LBW.

Whereas the incidence of growth restriction has risen in the United States due in part to medical complications such as hypertension and multiple gestations, an approximate 25% increase in the incidence of high-birthweight (HBW) babies has also been seen during the past decade. Epidemiologic studies have confirmed that **the relationship between birthweight and adult obesity, cardiovascular disease, and insulin resistance is in fact a U-shaped curve, with increasing risks at both the low and high ends of the birthweight spectrum.** Importantly, the sequelae of programming do *not* occur as a threshold response associated with either very low or very high birthweight, rather they represent a continuum of risk for adult disease in relation to variance from an ideal newborn birthweight.

As will be described below, these studies have spawned a burst of epidemiologic and mechanistic studies of the developmental origins of adult diseases. The original focus on cardiovascular disease and metabolic syndrome has been extended to a diversity of adult diseases—including cancer and diseases that affect the kidneys, lungs, and immune system—and also with learning ability, mental health, and aging. Thus **the field of developmental origins of adult disease has grown from considering short-term toxic or teratogenic effects to looking at long-term adult sequelae of low or high birthweight and, more recently, at the impact of environmental toxins** (e.g., bisphenol A [BPA]). In addition to these influences, other factors that include maternal stress, preterm delivery, and maternal glucocorticoid therapy, among others, may significantly impact adult health and disease.

## ENERGY-BALANCE PROGRAMMING

As noted above, epidemiologic studies demonstrate that the *metabolic syndrome*—a cluster of conditions that include obesity, hypertension, dyslipidemia, and impaired glucose tolerance—may be a result in part of the effects of LBW. Ultimately, **obesity results from an imbalance in energy intake and expenditure as regulated by appetite, metabolism, adipogenic propensity, and energy utilization.** In 1992, Hales and Barker<sup>8</sup> proposed the “**thrifty phenotype hypothesis**” and suggested that **in response to an impaired nutrient supply in utero, the growing fetus adapts to maximize metabolic efficiency because it will increase survival likelihood in the postnatal environment.** This adaptation would be beneficial in response to environmental cycles of famine and drought, in which reduced maternal—and thus fetal—nutrient supply would likely be replicated in the subsequent extrauterine environment. Numerous studies have

demonstrated the **increased risk of obesity associated with LBW**. In addition to obesity, **LBW appears to predispose to excess central adiposity, a phenotype specifically associated with risk for cardiovascular disease**.

Although the long-term effects of LBW are linked to adult obesity, several studies have demonstrated important effects of **newborn or childhood catch-up growth among the LBW infants**. Those infants who are born small and remain small in comparison to their peers exhibit a lower risk of obesity and metabolic syndrome than those born small who catch up and exceed normal weights through infancy or early adolescence. These findings, replicated in animal models, have great significance for neonatal and childhood care. For example, a major goal of the treatment for premature LBW infants is the achievement of a minimum weight satisfactory for hospital discharge at birth. **Contrary to current practice, it may be advisable to limit rapid weight gain in the neonatal period. Importantly, breastfeeding results in a lower obesity risk compared with formula feeding.**<sup>9</sup> Breastfeeding may have advantages over formula feeding in both nutrient and hormone composition as well as in the natural limitations that prevent overfeeding.

As discussed above, programming effects of birthweight simulate a U-shaped curve because LGA infants also are at an increased risk of adult cardiovascular disease and diabetes. Understandably, LGA infants are often born to obese women, who frequently express glucose intolerance or insulin resistance and who often consume high-fat Western diets prior to and throughout pregnancy. Studies demonstrate that each of these risks—**obesity, glucose intolerance, and a high-fat diet—and their outcomes (LGA) may individually contribute to the programming of adult obesity**. When combined with variations in maternal feeding and different childhood diets, it is understandable that epidemiologic studies have not yet determined which of these factors is paramount in programming mechanisms. As discussed below, animal models demonstrate programming effects independently associated with each of these risks.

Animal models of LBW that have used a variety of methods—such as maternal nutrient restriction (global or specific), uterine artery ligation, and glucocorticoid exposure, among others—have effectively demonstrated increased adult adiposity. Similar to human studies, the propensity to obesity is particularly evident in LBW newborns who exhibit postnatal catch-up growth.<sup>10</sup> Studies primarily on rodents and sheep have provided important insights into the underlying mechanisms of programmed obesity, which include lasting changes in proportions of fat and lean body mass, central nervous system appetite control, adiposity structure and function, adipokine secretion and regulation, and energy expenditure.

Animal models of overnutrition mimic the modern dietary intake of high-fat, high-carbohydrate diets. Maternal obesity and high-fat, high-carbohydrate diets also result in increased adult programmed adiposity, notably via mechanisms that impact appetite and adipose tissue.<sup>11</sup>

### Programming by Environmental Agents

Increasing human exposure to a wide range of industrial and agricultural chemicals has been well recognized. The Centers for Disease Control and Prevention (CDC) reported significant human exposure to endocrine-disrupter chemicals (EDCs), including those that act via estrogen receptors (eEDCs). BPA is a nearly ubiquitous monomer plasticizer. The consistent findings

**FIG 5-4** Bisphenol A levels during pregnancy.

of elevated BPA levels indicates continued routine exposure of adults and children. BPA is measurable in breast milk (1.1 ng/mL), maternal (1 to 2 ng/mL) and fetal serum (0.2 to 9.2 ng/mL), amniotic fluid (8.3 to 8.7 ng/mL), and placental tissues (1.0 to 104.9 ng/mL; Fig. 5-4).<sup>12</sup> BPA pharmacokinetics are similar in women, female monkeys, and rodents.<sup>13</sup> BPA metabolism includes conjugation and clearance as BPA-glucuronide and BPA-sulfate, with most BPA found recovered in urine. Because the fetus and newborn have reduced conjugation capacity, BPA elimination is likely prolonged. Furthermore, the well-documented fetal swallowing of amniotic fluid recirculates BPA excreted in fetal urine. These findings explain, in part, the elevated fetal serum and amniotic fluid BPA levels.

**Higher BPA urinary concentrations are associated with increased adiposity at 9 years of age,<sup>14</sup> and BPA levels are associated strongly with levels of the adipokines adiponectin and leptin.** Thus BPA exposure and maternal obesity may act synergistically to program obesity in the offspring. Epidemiologic studies support the association of human developmental EDC exposure and obesity in later life. Prenatal and early life polychlorinated biphenyl (PCB) exposure is associated with increased male and female weight at puberty. In utero exposure to hexachlorobenzene is linked to overweight children at age 6 years, and organochlorine pesticides are positively associated with BMI.<sup>15</sup>

The programming effects of BPA exposure are likely diverse; human epidemiologic studies have associated maternal BPA urinary concentrations with hyperactivity, aggression, anxiety, and depression, with effects more apparent in female offspring. Among inner-city children, prenatal BPA exposure is linked to altered emotional behavior such that males were more aggressive and females were less anxious or depressed.<sup>16</sup>

Animal models of BPA exposure indicate that BPA-programmed obesity mechanisms include changes in adipogenesis and neurogenesis. In vitro studies reveal marked embryologic effects of BPA that include alterations in cell differentiation. The proadipogenic effects of environmental obesogens have been well documented; recent studies have demonstrated effects on adipocyte generation that resulted in an increased number, differentiation, and lipogenic function with potential epigenetic effects that traverse generations. In rats, prenatal BPA increased

adipogenesis in females at weaning in association with overexpression of several lipogenic genes (*C/EBP $\alpha$* , *PPAR $\gamma$* , *SREBP1*, lipoprotein lipase, fatty acid synthase, and stearyl-CoA desaturase-1).<sup>17</sup> In samples from children, low-dose BPA increased the mRNA expression and enzymatic activity of 11 $\beta$ -hydroxysteroid dehydrogenase type 1 (11 $\beta$ -HSD1) in omental adipose tissue and visceral adipocytes, consistent with BPA-induced acceleration of adipogenesis. At environmentally relevant doses, BPA inhibits adiponectin and stimulates release of inflammatory adipokines, including interleukin 6 (IL-6) and tumor necrosis factor alpha (TNF $\alpha$ ) from human adipose tissue.

In addition to adipogenic effects, recent EDC studies indicate neurodevelopmental effects of BPA. **Low-dose maternal BPA exposure has been shown to accelerate neurogenesis and neuronal migration in mice and results in aberrant neuronal network formation.** As a consequence of accelerated neurogenesis, maternal BPA reduces the fetal neural stem/progenitor cell population at embryonic day 14.5.<sup>18</sup> Maternal BPA exposure may ultimately program offspring appetite development; BPA upregulates critical mouse embryonic genes associated with appetite pathway neurogenesis, and in vitro BPA stimulates proliferation of neuroprogenitor cells.

BPA effects have been demonstrated both histologically and behaviorally. Prenatal and neonatal BPA exposure induces dysfunction of the hippocampal cholinergic system. Prenatal BPA may also alter development of dopamine and N-methyl-D-aspartate (NMDA) systems in association with offspring anxious behaviors and cognitive deficits as well as serotonergic systems that regulate mood. **Gender-specific effects are well documented; in utero BPA exposure has been found to alter offspring rat brain structure and behavior, including sexually dimorphic behaviors, with effects more apparent in females than in males.** Male mice offspring demonstrated increased aggression and memory impairment in addition to increased brain expression of estrogen receptors alpha and beta during early life. In studies of primates, prenatal BPA was found to alter male cynomolgus monkey offspring sexual behavior. As noted earlier, these effects have been identified in human offspring as well.<sup>16</sup>

### Mechanisms of Programmed Obesity: Appetite and Adiposity

The hypothalamic regulation of appetite and satiety function develops in utero in precocial species, those in which the young are relatively mature as newborns. In the rat and in humans, although neurons that regulate appetite and satiety become detectable in the fetal hypothalamus early in gestation, the functional neuronal pathways form during the second week of postnatal life in the rat and likely during the third trimester in humans. Notably, the obesity gene product leptin, which is synthesized primarily by adipose tissue and the placenta, is a critical neurotrophic factor during development. In contrast to the adult, in which leptin acts as a satiety factor, fetal/neonatal leptin promotes the development of satiety pathways. In leptin-deficient (*ob/ob*) mice, satiety pathways are permanently disrupted and demonstrate axonal densities one third to one fourth that of controls.<sup>19</sup> Treatment of *adult* *ob/ob* mice with leptin does not restore satiety projections, but leptin treatment of *newborn* *ob/ob* mice does rescue the neuronal development,<sup>19</sup> indicating the critical role of leptin during the perinatal period.

**Early-life leptin exposure is likely a putative programming mechanism in SGA and LGA human newborns.** In LBW

**FIG 5-5** Leptin secreted by adipose tissue and insulin secreted by the pancreas suppress neuropeptide Y (NPY) and increase proopiomelanocortin (POMC). 3V, third ventricle; AgRP, agouti gene-related protein; ARC, arcuate nucleus; LHA, lateral hypothalamic area; NTS, nucleus of the solitary tract; PVN, paraventricular nucleus.

human offspring, leptin levels are low at delivery, and cord blood levels reflect neonatal fat mass. In contrast to the low serum levels of leptin in SGA newborns, LGA infants have elevated leptin levels. Obese pregnant mothers further have elevated leptin levels related to maternal adiposity, and breast milk leptin levels also reflect maternal fat mass.

**Leptin binding to its receptor activates proopiomelanocortin (POMC) neurons and downstream anorexigenic pathways. Obesity is often associated with leptin resistance, which results in an inability to balance food intake with actual energy needs.** The leptin pathway is counterregulated by the orexigenic neuropeptide Y (NPY; Fig. 5-5). Impaired leptin signaling could result in increased expression of NPY, which would promote increased nutrient intake while decreasing overall physical activity. In LBW newborns, appetite dysregulation has been demonstrated as a key predisposing factor for the obese phenotype.<sup>20</sup> Studies on LBW offspring specifically indicate dysfunction at several aspects of the satiety pathway, as evidenced by reduced satiety and cellular signaling responses to leptin.<sup>21</sup> Recent studies have demonstrated an upregulation of the hypothalamic nutrient sensor nicotinamide adenine dinucleotide (NAD)-dependent deacetylase sirtuin 1 (SIRT1), a factor that epigenetically regulates gene transcription of factors critical to neural development. Importantly, neuronal stem cells from rodent SGA fetuses and newborns demonstrate reduced growth and impaired differentiation to neurons and glial cells.<sup>22</sup> Thus impaired neuronal development, and ultimately reduced satiety pathways, may be a consequence of a reduction in neural stem cell growth potential and reduced leptin-mediated neurotrophic stimulation during periods of axonal development.

**FIG 5-6** Transcriptional regulation of adipogenesis. C/EBP, CCAAT/enhancer binding protein; PPAR: peroxisome proliferator-activated receptor; RXR, retinoic X receptor; SREBP, sterol regulatory element-binding protein.

In addition to appetite/satiety dysfunction, **mechanisms that regulate adipose tissue development and function (lipogenesis) may be a key factor in the development of programmed obesity.** Increase in adipose tissue mass or adipogenesis occurs primarily during prenatal and postnatal development, although some adipogenesis continues throughout adulthood. The process of adipogenesis requires highly organized and precisely controlled expression of a cascade of transcription factors within the preadipocyte (Fig. 5-6), and this process is regulated by hormones, nutrients, and epigenetic factors. Of note, LBW offspring show a paradoxical increased expression of the principal adipogenic transcription factor, peroxisome proliferator-activated receptor gamma (PPAR $\gamma$ ), and of hypertrophic adipocytes with increased propensity for fat storage, as evidenced by increased lipogenesis and de novo fatty acid synthesis. **In accordance with this, LBW preadipocytes exhibit early differentiation and premature induction of adipogenic genes.**<sup>23,24</sup> **Because the signaling pathways of adipogenesis and lipogenesis are upregulated prior to the development of obesity, they may be among the crucial contributory factors that predispose to programmed obesity.** Furthermore, cellular studies indicate that in LBW infants, adipocytes at birth have fundamental traits identical to those seen with thiazolidine (PPAR agonist) treatment; that is, the adipocytes are more insulin sensitive and demonstrate increased glucose uptake and thereby facilitate increased lipid storage within the adipocytes. Thus early activation of PPAR or its downstream targets could promote the storage of lipids and thereby increase the risk of obesity. This concept reverberates with studies on maternal exposure to PPAR agonists, which induces fetal mesenchymal stem cells along the adipocyte lineage and causes a reduction in the osteogenic potential in these cells, resulting in greater fat mass in adult offspring.<sup>25</sup> The role of stem cell precursor programming in metabolic disease pathways in response to maternal nutrient supply is an intriguing area for understanding developmental plasticity and potential preventive therapeutic strategies. Also, **the potential transdifferentiation of white adipose tissue toward a brown-fat phenotype, which can expend energy via thermogenesis, offers an alternative preventive strategy for programmed obesity.**

Offspring born to obese rat dams fed a high-fat diet also demonstrate increased food intake, adiposity, and circulating leptin levels and impaired glucose homeostasis dependent upon the period of exposure.<sup>11</sup> In addition, these offspring have an activated adipose tissue renin-angiotensin system that partly

contributes to their hypertensive phenotype.<sup>26</sup> The underlying phenotype appears to be similar to that of LBW infants, with altered appetite regulation, enhanced adipogenesis, and reduced energy expenditure. Nonetheless, salient mechanistic differences exist, such as increased proliferation of appetite-stimulating or orexigenic neurons in the fetus, the inability of elevated leptin to downregulate NPY, and decreased PPAR $\gamma$  corepressors.

### Hepatic Programming

In conjunction with the increased incidence of childhood and adolescent obesity, **children and adolescents now have an increased risk of developing nonalcoholic fatty liver disease (NAFLD), or nonalcoholic steatohepatitis, and type 2 diabetes.** Type 2 diabetes has increased tenfold in some regions of the United States during the past decade, and the prevalence is particularly high in adolescent Native Americans, approaching rates of 6%. NAFLD, as determined by elevated serum aminotransferase, may occur in up to 10% of obese adolescents in the United States, although studies using ultrasonographic measures of fatty liver have estimated rates of up to 25% to 50% of obese adolescents. As a reflection of the severity of the metabolic syndrome, **cases of cirrhosis associated with NAFLD in obese children have been described recently.** Further evidence suggests that obesity can potentiate additional insults to the liver, such as with alcohol and hepatitis C infection.

Men and women with reduced abdominal circumference at birth, potentially reflecting reduced hepatic growth during fetal life, have elevated serum cholesterol and plasma fibrinogen. Similarly, **poor weight gain in infancy is associated with altered adult liver function,** reflected by elevated serum total and low-density lipoprotein (LDL) cholesterol and increased plasma fibrinogen concentrations.<sup>27</sup> Although human studies have focused on the diagnosis and consequences of NAFLD in obese children and adolescents, animal studies (described below) indicate the early expression of fatty liver in fetuses exposed to maternal high-fat diets that were not LGA. Consequently, **a heretofore undiagnosed increase in liver adiposity may exist among normal-weight offspring of mothers exposed to Western, high-fat diets.**

Animal models of both maternal nutrient restriction and nutrient excess demonstrate the presence of NAFLD, alterations in liver structure, and changes in key metabolic transcription factors and enzymes involved in glucose-lipid homeostasis in offspring. Specifically, maternal protein restriction during a rat pregnancy shifts the enzyme setting of the liver in favor of

**FIG 5-7** Mechanisms for nonalcoholic hepatic steatosis (nonalcoholic fatty liver disease [NAFLD]) include (1) increased fatty acid uptake by the liver and increased triglyceride synthesis; (2) increased de novo lipogenesis; (3) decreased fatty acid oxidation; (4) decreased very-low-density lipoprotein (VLDL) secretion, preventing release of fatty acid from the liver; and (5) hepatic insulin resistance, which promotes lipogenesis and gluconeogenesis and inhibits lipolysis.

glucose production, rather than glucose utilization, as evidenced by increased phosphoenolpyruvate carboxykinase and decreased glucokinase enzyme activities in offspring. Furthermore, these key hepatic enzymes of glucose homeostasis retain the ability to respond to the challenge of a high-fat, high-calorie diet but with an altered “set point” of regulation. Moreover, because these enzymes are predominantly located in different metabolic zones of the liver (glucokinase in the perivenous and phosphoenolpyruvate carboxykinase in the periportal zone), these altered activities have been attributed to clonal expansion of the periportal and contraction of the perivenous cell populations.<sup>28</sup>

Five potential mechanisms lead to abnormal hepatic lipid metabolism and NAFLD (Fig. 5-7). On a molecular level, PPAR transcription factors are implicated in regulating lipid metabolism. PPAR $\alpha$  in particular is predominantly expressed in the liver and regulates genes involved in fatty acid oxidation. Although PPAR $\gamma$  is expressed at very low levels in the liver, PPAR $\gamma$  agonists have been shown to ameliorate NAFLD in a rat model.<sup>29</sup> In addition, PPAR $\alpha$  and PPAR $\gamma$  modulate the inflammatory response, and PPAR activators have been shown to exert antiinflammatory activities in various cell types by inhibiting the expression of acute-phase proteins, such as C-reactive protein (CRP).<sup>30</sup> CRP is produced by hepatocytes in response to tissue injury, infection, and inflammation and is moderately elevated in obesity, metabolic syndrome, diabetes, and NAFLD. Rat studies have demonstrated NAFLD and elevated hepatic CRP levels in LBW adult offspring associated with reduced expression of hepatic PPAR $\gamma$  and PPAR $\alpha$ .<sup>31</sup> PPAR transcription factors and their coregulator peroxisome proliferator-activated receptor gamma coactivator (PGC-1 $\alpha$ ) are in turn regulated by SIRT1, which is a nutrient sensor that has epigenetic effects. Consistent with reduced PPAR $\alpha$ , LBW offspring have reduced hepatic SIRT1 activity and PGC-1 $\alpha$  expression, which likely promotes hepatic lipogenesis and suppresses hepatic lipolysis.<sup>32</sup> Similar changes of reduced hepatic SIRT1 activity and PGC-1 $\alpha$  expression are observed in offspring from maternal high-fat diet and obese pregnancies.<sup>33</sup>

## Pancreatic Programming

Although programmed adult obesity or diet-induced obesity may be attributed to the etiology of insulin resistance, studies in humans and animals indicate that **in utero nutrition and environmental exposures directly impact the pancreas**. Alterations of pancreatic  $\beta$ -cell mass by maternal malnutrition was demonstrated in the mid 1960s. Whereas LGA human neonates have pancreatic  $\beta$ -cell hyperplasia and increased vascularization, SGA infants have reduced plasma insulin concentrations and pancreatic  $\beta$ -cell numbers.<sup>34</sup> Consistent with the adverse effects of rapid catch-up growth, the greatest insulin resistance is observed in individuals who are LBW but develop adult obesity.<sup>35</sup> **In humans, growth in utero is directly associated with fetal insulin levels. Importantly, beyond the regulation of glucose uptake, insulin has important developmental functions in systems that include skeletal and connective tissues and neural development.**

These extremes of weight are critical because the risk of insulin resistance in adult life is twofold greater among men who weighed less than 8.2 kg at 1 year of age and in those who weighed 12.3 kg or more.<sup>36</sup> A link has also been found between reduced early growth and proinsulin concentrations, suggesting that pancreatic tissue or function may be impaired, whereas other studies have suggested that fetal programming may alter the structure or function of insulin-sensitive target tissues.

Dependent upon the prevalence of obesity, **approximately 25% of individuals with normal glucose tolerance have insulin resistance similar to that seen in type 2 diabetes, but they compensate for this with enhanced insulin secretion.** These individuals are at increased risk to develop overt diabetes. Studies of fetal programming have focused upon the finding that birthweight and newborn plasma glucose levels are directly correlated in normal pregnancies and in those complicated by diabetes. Far less focus has been paid to levels of amino acids in maternal or fetal blood, although amino acids are also major determinants of fetal growth.

In addition to low and high birthweight, recent studies suggest that **antenatal exposure to betamethasone may result in insulin resistance in adult offspring.** A 30-year follow-up of a double-blind, placebo-controlled randomized trial of antenatal betamethasone for the prevention of neonatal respiratory distress syndrome demonstrated **no differences in body size, blood lipids, blood pressure, or cardiovascular disease among those exposed to betamethasone or placebo. However, offspring exposed to betamethasone demonstrated higher plasma insulin concentrations at 30 min in a 75 g oral glucose tolerance test, and lower glucose concentrations were observed at 120 min.**<sup>37</sup> The authors suggest that antenatal exposure to betamethasone may result in insulin resistance in adult offspring. A further study of 20-year-old offspring demonstrated significantly reduced blood pressure in betamethasone-exposed offspring.<sup>38</sup> In view of these findings, the authors recommend that obstetricians utilize a single course, rather than multiple courses, of antenatal glucocorticoids.

Various animal models of maternal diabetes, nutritional manipulation—both underfeeding and overfeeding—and uterine ligation all have reported altered  $\beta$ -cell growth, disturbances in insulin secretion, and long-term effects on insulin sensitivity. **Reduced  $\beta$ -cell growth and insulin secretion have been observed in LBW offspring,<sup>39</sup> whereas accelerated  $\beta$ -cell mass and excess insulin secretion was observed in offspring of**

**obese pregnant women.**<sup>40</sup> Despite differing nutrition and growth, both led to  $\beta$ -cell failure, tissue-specific insulin resistance, and development of diabetes in the adult offspring. This phenomenon has been attributed to developmental epigenetic regulation. The  $\beta$ -cell transcription factor pancreatic duodenal homeobox 1 (*PDX1*) is critical for  $\beta$ -cell development, and progressive silencing of *Pdx-1* expression has been observed in  $\beta$ -cells isolated from LBW offspring. Importantly, this silencing corresponds with persistent altered epigenetic regulation of the *PDX1* gene. Additionally, increased circulating lipids can induce  $\beta$ -cell apoptosis via endoplasmic reticulum stress pathways. Interestingly, *Pdx-1* is protective against pancreatic endoplasmic reticulum stress in response to high-fat feeding in rodents. Whereas obesity in pregnancy can increase pancreatic fat deposition in rodent models, whether this in turn leads to permanent changes in gene expression as observed in the growth-restricted fetus remains unknown.

**The transgeneration diabetogenic effect is evident: maternal gestational diabetes and the resultant intrauterine hyperglycemia can transmit the diabetogenic phenotype to a subsequent generation.**<sup>41</sup> Consequently, the incidence of mothers who exhibit gestational diabetes has increased.<sup>42</sup> Similar to humans, rat models of maternal diabetes demonstrate a transgeneration diabetogenic effect. Female offspring of diabetic mothers develop gestational diabetes and induce the effect in their fetuses and thereby in the next generation. Notably, intrauterine hyperglycemia alters imprinted gene expression in sperm.<sup>43</sup>

### Cardiac Programming

In addition to the aforementioned glucocorticoid effects on insulin resistance, **evidence suggests that maternal betamethasone treatment of preterm infants is associated with long-term adverse cardiac outcomes, including hypertrophic cardiomyopathy.**<sup>44</sup> Animal models discussed below confirm the association of fetal cortisol exposure with increased left ventricular cardiomyocyte size. A reduction in cardiomyocyte number through either reduced cellular proliferation or increased apoptosis appears to be a central feature. Because cardiomyocytes are highly differentiated and rarely replicate after birth, their inappropriate prenatal reduction is likely to result in a permanent loss of myocardial functioning units and an increased susceptibility to cardiac hypertrophy and ischemic heart disease. Confounding the direct association, **left ventricular hypertrophy also has been reported in growth-restricted infants.** Recent studies have suggested that maternal vitamin D deficiency may program long-term vulnerability to cardiovascular disease via effects on the fetal renin-angiotensin system and altered cardiomyocyte growth.

Similar to programming of the metabolic syndrome, extensive epidemiologic data have demonstrated **the association of birth-weight with adult coronary heart disease.** Slow growth during fetal life and infancy followed by accelerated weight gain in childhood predisposes to adult coronary heart disease in both men and women.<sup>45</sup> **The association between LBW and coronary heart disease has been replicated among men and women throughout North America, the Indian subcontinent, and Europe.**

As a result of similar pathophysiologic mechanisms, **a strong interaction of these risk factors exists with stroke.** However, the impact of programming is again evident in the marked differences in adult phenotype dependent upon fetal and childhood

environments. In a study of over 2000 people within the Helsinki birth cohort, two different paths of early growth preceded the development of hypertension in adult life.<sup>46</sup> **Small body size at birth and low weight gain during infancy followed by a rapid gain in BMI during childhood was associated with an increase in coronary heart disease as adults.** In contrast, **LBW in utero and throughout infancy followed by a persistent small body size at adolescence resulted in an increased risk of stroke and an atherogenic lipid profile.** These two different paths of growth may lead to hypertension via altered biologic processes. Although restriction of rodent weight gain following LBW prevents an obese phenotype, significant atherogenic and pancreatic abnormalities are present, and these offspring exhibit markedly elevated cholesterol levels and insulin deficiency.<sup>47</sup> These results, in both humans and animals, indicate that preventive strategies may be elusive; **prevention of LBW, rather than modulation of infant growth rates, is key.**

In addition to the effect of fetal nutrient exposure on cardiac development, significant mechanisms of vasculogenesis underlie the programming of hypertension. These may include modifications in arterial elastin and stiffness and in the size of the arterial and capillary beds.<sup>48</sup> Although no direct evidence suggests that elastin synthesis is impaired in the developing large arteries of human fetuses whose growth is restricted, children with a single umbilical artery demonstrate striking asymmetry in the compliance of their iliac arteries at 5 to 9 years of age. Importantly, **preterm birth also significantly affects the elastin content and viscoelastic properties of the vascular extracellular matrix in human arteries.** Inadequate elastin synthesis during early development may cause a permanent increase in arterial stiffness in adulthood, leading to hypertension and cardiovascular disease.<sup>49</sup>

Although this chapter does not seek to review all toxic teratogenic exposures, **prenatal cocaine exposure has been demonstrated to have significant effects on cardiac function in offspring.** Cocaine exposure results in an increased rate of neonatal arrhythmia and transient cardiac ST elevations. Although a blinded cross-sectional study did not demonstrate any significant differences in human left ventricular cardiac function, prenatal cocaine exposure did result in changes in diastolic filling in neonates with the degree of change correlated to the degree of cocaine exposure. Some changes persisted to the age of 26 months, particularly in those infants exposed to high levels of cocaine in utero. The mechanisms of these cocaine effects may relate to the inhibition of dopamine, serotonin, and norepinephrine reuptake. In addition to direct effects, the impact of cocaine on the programming of cardiac function may be mediated via the autonomic nervous system. Some studies, although not all, have demonstrated an alteration in resting heart rate and heart rate variability. A well-performed investigation revealed a dose-dependent effect of fetal cocaine on neonatal heart rate at 4 to 8 weeks of age, although the duration of this effect is unknown.<sup>50</sup> Further effects on static stress, renal sympathetic activity, and heart rate variability confirm the effects of cocaine on the developing cardioregulatory systems. Taken in sum, these studies suggest that **fetal cocaine exposure has at least a short-term impact, and potentially a longer-term impact, on cardiac function in humans.**

Although no clear epidemiologic evidence links prenatal hypoxia and adult cardiovascular disease, animal models suggest an effect of hypoxia on adult cardiac function. Chronic hypoxia during the course of pregnancy also results in LBW newborns with altered myocardial structure and altered heart development.

Antenatal hypoxia causes pulmonary vascular remodeling during fetal life that results in pulmonary vascular disease (i.e., hypertension) in newborns.<sup>51</sup> Hypoxia-mediated responses act in part via hypoxia inducible factor (HIF) regulating multiple genes, including vascular endothelial growth factor (VEGF), and downstream inflammatory responses.<sup>52</sup> Among other effects, prolonged hypoxia in utero suppresses fetal cardiac function, alters cardiac gene expression, increases myocyte apoptosis, and results in a premature exiting of the cell cycle by cardiomyocytes in addition to myocyte hypertrophy.<sup>53</sup>

### Osteoporosis Programming

Recent evidence indicates that **fetal and neonatal life may be a critical factor in the development of osteoporosis**, a disease typically associated with aging. In considering the major determinants of bone mass in later life, the most critical issues are 1) peak bone mass achieved during the third decade of life and 2) the rate of bone loss following this period. Thus **bone mass in the elderly is largely determined by peak bone mass that occurs much earlier in life**. Several epidemiologic studies have demonstrated that LBW and weight at 1 year are directly correlated with reduced bone marrow content and bone mineral density.<sup>54</sup> Consistent with these findings, poor childhood growth was associated with an increased risk of hip fracture in elderly adults.

**The mechanisms by which the fetal and neonatal period can influence peak bone mineral content include the interaction of vitamin D and calcium and additional factors such as fetal and neonatal growth hormone, cortisol, and insulin-like growth factor 1 (IGF-1).** An undernourished fetus deprived of calcium may upregulate vitamin D activity in an attempt to increase calcium availability. Although more than 60% of peak bone mass is gained during puberty, a growing body of evidence suggests that a substantial proportion of peak bone mass is determined by growth earlier in life. Additional maternal factors may influence neonatal bone mineral content. **Low maternal fat stores, maternal smoking or increased physical exercise in late pregnancy, and low maternal birthweight all predict lower whole-body bone marrow content in the neonate.**<sup>55</sup> Breastfed children initially have lower bone mass than bottle-fed children but may ultimately accrue greater bone mass by 8 years. In rats, maternal diet modulation or uterine artery ligation affects the bone structure of offspring. As adults, these offspring had lower serum 25-hydroxy vitamin D levels and lower bone mineral content and bone area, which was also associated with changes in their growth plates. This is consistent with the nutritional programming of the skeletal growth trajectory and complements the epidemiologic evidence for programming of osteoporosis in humans.

### Brain Programming

Cerebral function and development during the critical fetal/neonatal window is highly complex; therefore it is understandable that a number of stressors during early life would impact a variety of areas, including cognition and behavior, dysfunction of which could lead to anxiety and even addictive behavior. **In utero exposure to cocaine, and perhaps methamphetamine, demonstrates a number of cerebral effects.**<sup>56</sup> Children exposed to prenatal cocaine evidence a significant impact on behavior (aggression), attention-deficit/hyperactivity disorder (ADHD), substance abuse (e.g., cigarettes), and impaired language.<sup>56</sup> Additional studies have suggested potential impairment of

intelligence quotient (IQ), cognition, motor function, and school performance. Understandably, windows of exposure and dose-dependent responses are difficult to quantify. Nevertheless, a number of studies have suggested that **heavy cocaine use is related to worse outcome in regard to behavior, language, and IQ.**<sup>56</sup> Studies of neuroimaging have demonstrated significant alterations in the specific volumes of brain regions among cocaine-exposed children when assessed as children, adolescents, and adults. Studies of diffusion tensor imaging and functional magnetic resonance imaging (MRI) reveal increased creatine in the frontal white matter, a potential sign of abnormal energy metabolism.<sup>57</sup> Cocaine-exposed children exhibit greater activation in the white inferior frontal cortex and the caudate nucleus during response inhibition, suggesting that **prenatal cocaine may affect the development of brain systems involved in the regulation of attention and response inhibition.**<sup>56</sup>

Considering other substances of abuse, among children exposed to methamphetamine, magnetic resonance spectroscopy demonstrated increases in total creatine in the basal ganglia, again indicative of possible alterations in cellular energy metabolism.<sup>58</sup> Neuroimaging of children exposed to opiates in utero further reveal smaller intracranial and brain volumes, including a smaller cerebral cortex, amygdala, brainstem, and cerebellar white matter among other areas. This is consistent with **animal studies, which indicate that prenatal nicotine or cocaine exposure targets specific neurotransmitter receptors in the fetal brain and elicits abnormalities in cell proliferation and differentiation and thus leads to reduced neurogenesis and altered synaptic activity.**<sup>59</sup> The underlying mechanism may involve increased apoptosis of neuronal cells.

### MATERNAL STRESS AND ANXIETY

Although the effects of maternal substance abuse may be a direct impact of the specific drug-receptor interaction, the commonality of behavioral effects in the offspring suggests that disruption in the fetal neuroendocrine environment—potentially associated with increased fetal adrenocorticotrophic hormone (ACTH)/cortisol—may impact fetal/neonatal brain development. In view of these findings, extensive epidemiologic investigation has been focused on maternal stress and anxiety. During the second trimester, increased maternal anxiety has been associated with lower neonatal dopamine and serotonin levels, greater right frontal electroencephalogram (EEG) activation, and lower vagal tone. In late pregnancy, maternal anxiety has been associated with increased salivary cortisol levels among 10-year-old children, suggesting that maternal anxiety during pregnancy programs the offspring's stress responsiveness. In a recent study, **neonates of mothers with high anxiety demonstrated altered auditory evoked responses, which suggests differences in attention allocation.** In addition to chronic maternal anxiety, acute stress responses during pregnancy may include death of close relatives, natural disasters, and maternal neuropsychiatric conditions. Many of these stress exposures have significant impact, with potential neurodevelopmental consequences for the offspring. **Children of mothers with posttraumatic stress disorder (PTSD) during pregnancy display altered cortisol levels accompanied by signs of behavioral distress during the first 9 months of life.**<sup>60</sup>

**The role of the maternal hypothalamic-pituitary-adrenal (HPA) axis is recognized as contributing to maternal stress-mediated effects on fetal development.** Although the

developing fetus is normally protected from high levels of circulating maternal cortisol by the placental enzyme 11 $\beta$ -hydroxysteroid dehydrogenase type 2 (11 $\beta$ -HSD2), which metabolizes cortisol to inactive cortisone, downregulation of placental 11 $\beta$ -HSD2 may occur in response to drug exposure, maternal diet, and obstetric conditions that include preeclampsia, preterm birth, and IUGR.<sup>61</sup> **A reduction in placental 11 $\beta$ -HSD2 may thus increase fetal exposure to maternal cortisol levels and may have secondary effects on brain maturation and development.** Among pregnant women who undergo amniocentesis, a strong correlation exists between maternal plasma and amniotic fluid cortisol levels indicative of fetal levels. The correlation with maternal anxiety suggests that measures of amniotic fluid cortisol may serve as an index for fetal hormone exposure.

Psychiatric disorders seen in the offspring of pregnancies associated with maternal stress may be a consequence of cortisol binding to select brain regions during development. Notably, most fetal tissues express glucocorticoid receptors from mid gestation onward. It is well established that steroid hormones in the fetus are involved in organ development and maturation, such as of the brain, heart, lungs, gastrointestinal (GI) tract, and kidneys. Glucocorticoids may impact diverse gene expression via epigenetic mechanisms that include DNA methylation, histone acetylation, and miRNA.<sup>62</sup> Of note, the hippocampus, which is critical for learning and memory, has extensive glucocorticoid receptors. Although not studied in humans, glucocorticoid exposure in rat dams results in a reduction in the volume and number of cells in the nucleus accumbens, a central limbic nucleus critical to reward circuitry.<sup>63</sup> These findings may provide a mechanism by which maternal stress or substance abuse contributes to offspring addictive behavior, which represents a dysfunction of the limbic system.

The effects of maternal stress may extend beyond fetal/neonatal neurologic and behavioral issues. Maternal prenatal anxiety and stress predicted a significant adverse effect on illness in the infant and also predicted antibiotic use,<sup>64</sup> whereas a wide range of prenatal stressors were associated with morbidity in childhood. Specifically, **prenatal anxiety has been associated with childhood asthma, whereas stress-related maternal factors have been linked to increased eczema during early childhood.**

**A generational effect of fetal programming and the HPA axis is suggested by findings that LBW babies have elevated cortisol concentrations in umbilical cord blood and have elevated urinary cortisol secretion in childhood.**<sup>65</sup> Nilsson and colleagues<sup>66</sup> demonstrated a continuous relationship between size at birth and stress susceptibility, whereas other studies have found that cortisol responses to stress were significantly and inversely related to birthweight. Similarly, in regard to physiologic responses, LBW is associated with increased blood pressure and heart rate responses to psychologic stressors in women but not in men.

In corroboration of the human data, findings from experiments with rodent models show that prenatal stress, such as restraint and administration of exogenous glucocorticoids, not only impairs cognition and increases anxiety and reactivity to stress but also alters brain development.<sup>67</sup> Furthermore, prenatal stress increases sensitivity to nicotine and other addictive drugs. Interestingly, **maternal nurturing impacts the offspring's epigenome and behavior.** In rats, maternal nurturing behavior altered the offspring epigenome at a glucocorticoid receptor gene

promoter in the hippocampus. As a result, highly nurtured rat pups demonstrated less anxiety than those that received minimal nurturing.

More recent studies of nonhuman primates implicate chronic consumption of a high-fat diet during pregnancy in increased anxious behavior in offspring. This behavior is thought to be caused by perturbations in the fetal brain serotonergic-melanocortin pathways.<sup>68</sup>

## GLUCOCORTICIDS AND PREMATURITY

Although glucocorticoid therapy for the preterm infant has made a significant contribution to the reduction of neonatal respiratory distress syndrome, intraventricular hemorrhage, and infant mortality, the tendency has been for clinicians to utilize multiple courses of glucocorticoids. Studies that have examined the impact of human perinatal glucocorticoid exposure have demonstrated that **children exposed to dexamethasone during preterm gestation who were born at term have increased emotionality, general behavioral problems, and impairments in verbal working memory.**<sup>64</sup> Further, **offspring of women given multiple doses of antenatal glucocorticoids have reduced head circumference and significantly increased aggressive violent behavior and attention deficits.**<sup>69</sup> These findings suggest that fetal exposure to pharmacologic glucocorticoid levels during critical developmental periods, prior to the normal increase seen in the term newborn, may have adverse consequences, including to the programming of the offspring's HPA axis. Preterm babies exposed to antenatal betamethasone had a lower salivary cortisol response to a heel stick than matched controls at 3 to 6 days after delivery.<sup>70</sup> Additional studies demonstrate that antenatal corticosteroids are associated with suppressed cortisol responses to corticotrophin-releasing hormone (CRH) during the immediate neonatal period. Salivary cortisol responses to immunization at 4 months of age were significantly correlated with the mean plasma cortisol in the first 4 weeks of life independent of maternal glucocorticoid exposure. It is notable that preterm infants have a similar spectrum of developmental and behavioral problems as do babies whose mothers have experienced extreme stress or anxiety during pregnancy, and both groups demonstrate increased levels of attention deficit, hyperactivity, anxiety, and depression.

Although premature exogenous glucocorticoid exposure via maternal administration has consequences, **it should be recognized that if actually delivered preterm, infants are exposed to increased endogenous cortisol prior to the time at which they would normally experience this increase—that is, at term.** Several studies demonstrate that LBW is associated with increased resting heart rate and fasting plasma cortisol concentrations in adulthood. Among preterm babies born at less than 32 weeks, newborn plasma cortisol levels are four to seven times higher than the fetal levels would be at the same gestational age. As the elevated levels persist through 4 weeks of age, they likely result from a combination of both the acute antenatal steroids and postnatal endogenous glucocorticoid exposure. Whether a consequence of prematurity or perhaps of premature cortisol exposure, preterm infants—especially those born prior to 28 weeks' gestation—have significant neurologic impairments, including visual-motor coordination when measured at 8 years of age. **In view of these consequences of exogenous and endogenous glucocorticoids, maternal glucocorticoid use**

**should be directed only at those infants most likely to benefit and those most likely to deliver preterm.**

Whereas the effects of glucocorticoids on programming brain development and organ maturation is well accepted, it is less well recognized that glycyrrhiza—a natural constituent of licorice—may also impact fetal programming by disrupting cortisol metabolism. Glycyrrhiza inhibits placental 11 $\beta$ -HSD2 and thus results in a potential increased transmission of maternal cortisol to the fetal compartment. In a study of Finnish children at 8 years of age, those with **high exposure to glycyrrhiza from maternal licorice ingestion had significant deficits in verbal and visual spatial abilities and in narrative memory, and they had significant increases in externalizing symptoms and in aggression-related problems.** These effects on cognitive performance appear to be related to the degree of licorice consumption.<sup>71</sup> In addition to licorice, glycyrrhiza is often used as a flavoring in candies, chewing gum, herbal teas, alcoholic and nonalcoholic drinks, and herbal medications. Although these results suggest that exposure to glycyrrhiza should be limited during pregnancy, it more importantly indicates the diversity of foods and drugs that can impact fetal development and programming, perhaps through effects on fetal cortisol exposure.

As adults, prematurely born infants also display abnormalities of insulin resistance, elevated blood pressure, and abnormal retinal vasculature. Although much attention has been focused on the effects of LBW on the programming of metabolic syndrome, a study of 49-year-old Swedish men demonstrated that systolic and diastolic blood pressures were inversely correlated with gestational age, rather than birthweight, independent of current BMI. Similar results have been demonstrated in women born preterm. An intergenerational effect may occur because consequences of elevated blood pressure and abnormal vascularization among women may have a subsequent impact on future pregnancies. Thus **women who were born before 37 weeks of gestational age demonstrate a 2.5-fold increased risk of developing gestational hypertension in their own pregnancies.**<sup>72</sup>

In a recent study from western North Carolina, boys and girls aged 9 through 16 were tested for depression in relation to birthweight and additional prenatal and perinatal factors. **LBW predicted depression in adolescent girls** (38.1% vs. 8.4% among girls with normal birthweight) but not boys. In addition, **LBW was associated with an increased risk of social phobia, posttraumatic stress symptoms, and generalized anxiety disorder—all of which were far more common in girls than in boys.**<sup>73</sup> Further studies have demonstrated that LBW is associated with an increased risk of schizophrenia, ADHD, and eating disorders. These findings are consistent with animal studies that indicate gender-specific effects of developmental programming.

## IMMUNE FUNCTION

**Prenatal stress may influence the developing immune system, particularly as related to asthma and atopic diseases.** Maternal nervousness during gestation correlates with elevated immunoglobulin E (IgE) levels in cord blood and may predict atopic diseases in early childhood. Importantly, pregnant women with prenatal stress have elevated proinflammatory cytokine levels,<sup>74</sup> which may impact the risk of allergy in childhood. Although these findings suggest that *enhanced* immunologic responses may occur following maternal stress, LBW may be associated with

*reduced* inflammatory responses that contribute to increased morbidity. Young adults born during seasonal famine and likely growth restricted were more likely to die of infectious diseases. These infants demonstrated reduced thymic size and altered patterns of T-cell subsets with a lower CD4/CD8 ratio, suggestive of lower thymic output. Interestingly, Hartwig and colleagues<sup>75</sup> reported that the likelihood of asthma and eczema at the age of 14 years was significantly increased in children of mothers who had experienced adverse life events during the second half of gestation, but a greater increase was found if this occurred in mothers without asthma compared with mothers who had asthma. Postpartum maternal influences also may contribute because mothers of these infants express lower levels of maternal breast milk interleukin 7 (IL-7), a putative thymic trophic factor. In support of the impaired inflammation response among LBW infants, antibody **responses to typhoid vaccination are positively associated with birthweight.** These findings suggest that **atopy-related immune function may be enhanced in either LBW offspring or offspring associated with maternal prenatal stress, although LBW may well result in significant impairment in offspring infectious disease-related immune function.** The consequences of LBW and reduced immune function may be a critical factor that predisposes to infant mortality in developing countries.

Much as perinatal factors can influence immunity, mothers who are allergic have lower interferon- $\gamma$  responses during pregnancy, which has been postulated to influence the cytokine milieu of the fetus.<sup>76</sup> Similarly, maternal asthma during pregnancy is associated with fetal growth restriction and preterm birth. Placental expression of proinflammatory placental cytokines is significantly increased in pregnancies complicated by mild asthma, although only in the presence of a female fetus.<sup>77</sup> Significant evidence shows that **both the maternal allergic phenotype and the maternal environmental exposures during pregnancy affect the risk of subsequent allergic disease in childhood.** Evidence indicates that maternal allergy is a recognized risk factor for allergic disease. In regard to maternal environmental exposures, a number of factors may influence fetal immune development and allergic outcomes. Although evidence is inconsistent and mechanisms are unclear, several studies have demonstrated that a Mediterranean diet may protect against early childhood wheezing.<sup>78</sup> Other studies have explored the effects of folate supplementation, polyunsaturated fatty acids, antioxidants, and a range of vitamins and micronutrients, although again with a lack of consistency.

Interestingly, recent evidence suggests that **maternal exposure to microbes may influence fetal immune competence.** Exposure in utero to a farming environment has been demonstrated to protect against the development of childhood asthma and eczema.<sup>79</sup> Similar results have demonstrated that farming environments alter the expression of innate immune genes and modify umbilical cord IgE levels. Some studies,<sup>80,81</sup> although not all,<sup>82,83</sup> suggest an association between cesarean delivery and chronic immune disorders, particularly childhood asthma. Because the newborn GI flora is markedly affected by elective cesarean delivery, it is possible that changes in the microbiome may influence early development or maturation of diverse immune systems.

In contrast to the potential beneficial effect of microbial exposure, maternal cigarette smoking increases the risk of asthma in the offspring. This likely occurs via an allergic sensitization rather than by the classic direct pulmonary effects of cigarette

smoke. Animal studies also support the premise that innate immune function can be programmed as a result of perinatal challenges to the immune system during development. In rats, administration of bacterial endotoxin, lipopolysaccharide (LPS), to neonates influences the adult neuroimmune response to a second LPS challenge, in part through the HPA axis.<sup>84</sup> In addition, undernutrition—particularly during prenatal and postnatal periods—affects immune competence of offspring by increasing basal inflammation and also reducing cytokine induction in response to inflammatory stimuli.

Potentially confounding the association of cigarette smoking is a finding that children with a smaller head circumference at 10 to 15 days of age had a markedly increased odds ratio for wheezing at 7 years of age. Thus **factors that determine fetal growth may also be associated with wheezing in childhood.** Children with both small and large head circumferences at birth, consistent with both undernutrition and overnutrition, have increased atopic sensitization and elevated serum IgE at ages 5 to 7 years.<sup>85</sup> Large head circumference at birth has previously been reported to be marked by elevated IgG levels in adulthood and a risk of asthma in adolescence. The relationship of developmental origins to childhood asthma is complex because several asthma phenotypes are possible, including those associated with atopy compared with those associated with acute childhood viral infection. Although both of these diseases exhibit childhood wheezing and/or immune modulation, they likely have significant alterations in predisposition. Because asthma is associated with an exaggerated type 2 helper T cell (TH2) response to both allergic and nonallergic stimuli, it has been proposed that genes involved in IgE synthesis and airway remodeling have failed to be silenced during early infancy. In utero programming of these genes may result in the predisposition to allergic responses.

## OTHER PROGRAMMING

### Endocrine Programming

Low birthweight may also be associated with additional endocrine disorders that affect gonadal and adrenal axes. **Reduced fetal growth results in exaggerated adrenarche, early puberty, and small ovarian size with the subsequent development of ovarian hyperandrogenism.**<sup>86</sup> Children born SGA may have puberty at a normal age or even earlier but appear to exhibit a more rapid progression, which compromises adult ovarian function.<sup>87</sup> Compared with average for gestational age (AGA) girls, SGA girls displayed increased baseline estradiol, stimulated estradiol, and 17-hydroxyprogesterone at the beginning of puberty, whereas LBW is associated with precocious puberty in girls.<sup>86</sup> Among LBW girls, those who demonstrate postnatal catch-up growth have greater fat mass and more central fat. Whether this suggests that early puberty is a consequence of hyperandrogenism or hyperinsulinism associated with the central adiposity is uncertain. Importantly, **children who present with precocious puberty, particularly those with a history of LBW, have an increased risk of developing ovarian hyperandrogenism and other features of polycystic ovary syndrome (PCOS) during or soon after menarche.**<sup>86</sup> Growth restriction may thus program adrenal function and induce permanent changes in ovarian morphology and function in utero, contributing to PCOS in adult life.

Despite the association with PCOS, women born during a famine do not appear to have differences in fertility rates as measured by age at first pregnancy, completed family size, and

interpregnancy interval. Recent studies have suggested that the cohort of offspring from the Dutch famine may even have an increased fertility compared with controls.<sup>88</sup> Furthermore, despite the impact on puberty, **LBW does not appear to advance the age of menopause in women.**<sup>89</sup> There is evidence, however, of an increased prevalence of anovulation in adolescent girls born SGA compared with controls (40% vs. 4%),<sup>90</sup> although this may be a consequence of obesity-associated endocrine perturbations. These findings suggest that the effects of maternal nutritional status during pregnancy on reproductive performance of offspring are relatively small.

In the female rat, pubertal timing and subsequent ovarian function is influenced by the animal's nutritional status in utero, with both maternal caloric restriction and a high-fat maternal diet resulting in the early onset of puberty. However, the former leads to a reduction in progesterone levels, whereas the latter causes elevated progesterone concentrations in adult offspring. In sheep, reduced lifetime reproductive capacity has been demonstrated in ewes born to mothers undernourished during late pregnancy or in the first months of life. Similarly, in rodents, maternal undernutrition causes premature reproductive senescence via alteration of the hypothalamic-pituitary-gonadal axis,<sup>91</sup> whereas maternal obesity and a high-fat diet result in increased ovarian apoptosis and follicular growth in the adult offspring.<sup>92</sup> Prenatal exposure to testosterone impairs female reproductive capacity in sheep, and prepubertal administration of estradiol disrupts ovarian cyclicity in adult rats. Furthermore, animals that receive an excess of thyroxine during the neonatal period exhibit changes in the pituitary-hypothalamic responses linked to the secretion of thyroid-stimulating hormone (TSH) in later life.

### Sexuality Programming

The following discussion is not meant to imply disease states or opine on issues of normalcy of sexuality but rather to discuss the developmental processes that result in adult sexual orientation. Among males, sexual orientation is largely dichotomous (heterosexual, homosexual), although bisexual orientation among women is likely more prevalent. A genetic component for sexual orientation is evident from studies that demonstrate an increased rate of homosexuality among relatives of homosexuals. Twin studies report moderate heritability of sexual orientation,<sup>93</sup> although advances have been limited in the identification of specific genetic loci responsible for sexual orientation. **Significant research demonstrates a major role for gonadal steroidal androgens in regulating sexual dimorphism in the brain and subsequent behavior.** Animal studies confirm that hormonal signals that operate during critical periods may have programming effects on sexuality. The classic example of such a phenomenon is the exposure of female rats at a critical period of fetal life to a single exogenous dose of testosterone, which permanently reoriented sexual behavior. A similar dose of testosterone in 20-day-old females had no effect. Thus, a critical time exists at which the animal's sexual physiology is sensitive and can be permanently changed.<sup>94</sup> Based upon early animal models, initial studies resulted in what is likely an oversimplified theory: relative overexposure of females to androgens may contribute to female homosexuality, and underexposure to prenatal androgens in men may contribute to male homosexuality. Using a proxy marker of prenatal hormonal androgen exposure, the ratio of the second to fourth finger lengths, several studies have demonstrated that homosexual women have

significantly masculine measurements compared with heterosexual women, although one study reported no difference. A further proxy marker is otoacoustic emissions (OAEs), which represent sounds emitted by the cochlea, which are more numerous in females than in males. Significant evidence suggests that OAEs are influenced by prenatal androgen exposure, with evidence that females with male co-twins have a masculinized OAE pattern. Despite the tendency for homosexual women to be exposed to more prenatal androgens than heterosexual women, overlap is considerable between the two female groups, indicating that prenatal androgens do not act in isolation.<sup>95</sup> Reports among heterosexual and homosexual men are inconclusive in regard to proxy markers.

In contrast to the stronger correlation of female versus male homosexuality with measures of prenatal androgen exposure, birth order impacts more significantly among males. **The fraternal birth order effect indicates that homosexual men have a greater number of older brothers than heterosexual men do, with the estimated odds of being homosexual increasing by 33% with each older brother.**<sup>95</sup> Of note, homosexual males with older brothers have significantly lower birthweights compared with heterosexual males with older brothers.<sup>96</sup> These findings may suggest an interaction of birthweight and additional developmental factors. Several investigators have proposed a role of immunization of mothers to male-linked androgens, which results in maternal Y-chromosome linked antibodies that may act on male-differentiating receptors within the fetal brain.<sup>91</sup> Further studies demonstrate sexual orientation–related neuronal variation that includes hypothalamic and selected cortical regions. Despite these associations, **little conclusive understanding exists of specific neurodevelopmental mechanisms that produce homosexuality or heterosexuality.** However, emerging evidence suggests that prenatal exposure to EDCs affects neural circuits at the hypothalamus-pituitary axis, impacts fetal testicular development, masculinizes genitalia in females, feminizes yolk production (vitellogenesis) in males, and alters sex and social behavior.<sup>97</sup>

## Renal Programming

In humans, the total number of nephrons ranges between approximately 600,000 and slightly over one million, although the factors that determine an individual's glomerular number are unknown. Nephrogenesis occurs up to approximately 36 weeks' gestation, and both genetic and environmental effects alter or regulate the number of nephrons. From a genetic perspective, **select genes that regulate renal signaling and transcription permutation have been associated with renal hypoplasia. Thus most congenital renal anomalies have an inheritable component.**

**Environmental exposures and stresses are well demonstrated to alter nephron number.** Autopsies of newborns and children have demonstrated a marked association between LBW and reduced nephron number.<sup>98</sup> Importantly, **low glomerular number and high glomerular size have been associated with the development of hypertension, cardiovascular diseases, and an increased susceptibility to renal disease in later life.** Reduced nephron number as a result of developmental programming may result in single nephron glomerular hyperfiltration. The compensatory glomerular hypertrophy, which maintains normal glomerular filtration rate (GFR), ultimately may cause glomerular sclerosis and nephron loss and can contribute to later hypertension and chronic renal disease.

Reduced nephron number beginning in the fetal/neonatal period may have effects different from that of adult nephrectomy. In sheep, fetal unilateral nephrectomy at 110 days gestation leads to subsequent hypertension.<sup>99</sup> Similarly, unilateral nephrectomy in the neonatal rat results in adult hypertension and impaired renal function. These findings differ from observations after human nephrectomy performed in adults (e.g., renal transplant donors), in whom hypertension generally does develop. The mechanisms that contribute to hypertension resulting from reduced glomerular number that occurs during fetal and neonatal life are unclear, but they indicate that **the developmental impact on nephron number may play an important role in programmed hypertension.** These include the role of specific genes and growth factors involved in this process, the paired box 2 gene (*PAX2*) and glial cell–derived neurotrophic factor (GDNF) as well as apoptotic markers and signaling pathways.

In view of the contribution of renal disease to hypertension, it is notable that **very LBW infants exhibit a high rate of hypertension during adolescence.**<sup>100</sup> Preterm children also demonstrate a higher prevalence of hypertension, as do AGA and SGA offspring.<sup>101</sup> Among black Americans in the southeastern United States and among Australian aboriginals, LBW is associated with adult-onset renal disease.<sup>98</sup> As a marker of impending renal disease, microalbuminuria is more than twofold greater in SGA offspring at a young adult age than that occurring in AGA offspring, although not all studies demonstrate this effect. Nutritional insults seen in SGA, LBW, and premature births are perhaps associated with excess glucocorticoid exposure and secondarily reduced glomerular number. Paradoxically, autopsy studies indicate that the number of renal podocytes in full-term newborns is significantly lower than in preterm fetuses. It is unknown whether this is a pathologic process related to continued adverse exposures (e.g., drugs, maternal diet) during intrauterine life that results in renal podocyte demise or a normal physiologic process (e.g., apoptosis).

Pregnant patients are also exposed to a variety of **nephrotoxic drugs, including nonsteroidal antiinflammatory drugs (NSAIDs), ampicillin/penicillin, and aminoglycosides. NSAIDs may lead to renal hypoperfusion during critical nephrogenic periods, resulting in cystic changes in developing nephrons**<sup>102</sup> and acute or chronic renal failure in preterm newborns. The impairment in renal development that results from angiotensin-converting enzyme (ACE) inhibitors is well documented, likely a result of the critical role of angiotensin in nephrogenesis.

Although less is known regarding offspring of pregnancies complicated by diabetes, exposure to transiently high blood glucose concentrations may reduce nephron development in rat pups. In humans, increased urinary albumin excretion has been demonstrated in adult offspring of Pima Indian mothers with diabetes, suggesting an early glomerular injury.<sup>103</sup> Notably, individuals with a history of hypertension had only 50% as many nephrons as those without hypertension.<sup>104</sup> The nephron number in adult kidneys is correlated to birthweight, with each kilogram increase in birthweight associated with an additional 250,000 nephrons.<sup>98</sup> However, these studies could not differentiate age or disease-related loss of nephrons compared with developmental origins. Reduced nephron number has been demonstrated in the absence of hypertension, indicating that additional processes of programmed hypertension may occur independently of a reduction in nephron number. **Whether a reduced nephron**

number is etiologic of hypertension, a consequence of hypertension, or a coincident finding may depend upon the individual.

### SUMMARY

As we continue to learn of the significance and mechanisms of developmental programming of adult health and disease, the critical consequences of developmental windows are increasingly recognized. Programming effects may affect development by altering organ size, structure, or function. Cellular signaling mechanisms and increasingly recognized epigenetic consequences may be highly dependent upon the magnitude of the exposure and the window of exposure during embryogenesis or organogenesis. Most importantly, we are only beginning to recognize how consequences of prophylactic treatments may alter programmed phenotypes. Certainly, it appears there is no single mechanism, nor one single developmental window, that affects each organ or system development. Consequently, the ultimate management of fetuses and newborns is likely to be individualized rather than universal. We hope to develop a greater understanding of the relative risks and benefits of current day obstetric decisions, including repeated doses of maternal glucocorticoids, advantages versus disadvantages of early delivery of SGA fetuses, use of oral hypoglycemic agents that cross the placenta, and many other management dilemmas.

### KEY POINTS

- ◆ Maternal influences on the in utero environment (nutrition, hormonal, metabolic, stress, environmental toxins, and drugs) are critical determinants of fetal growth and influence a wide variety of metabolic, developmental, and pathologic processes in adulthood.
- ◆ Both ends of the growth spectrum (i.e., both low and high birthweight) are associated with increased risk of adult obesity, metabolic syndrome, cardiovascular disease, insulin resistance, and neuroendocrine disorders.
- ◆ The mechanisms that link early developmental events to the later manifestation of disease states involve “programmed” changes in organ structure, cellular responses, gene expression, the epigenome, and/or stem cells.
- ◆ Gestational programming events may have immediate effects or are deferred and expressed at a later age, with potential transmission to multiple generations.
- ◆ Transmission of gestational programming effects to multiple generations may occur via epigenomic modulation that causes heritable and persistent changes in gene expression without altering the DNA sequence.
- ◆ Prenatal care is evolving to provide essential goals of optimizing maternal, fetal, and neonatal health to prevent or reduce adult-onset diseases.
- ◆ Guiding policy regarding optimal pregnancy nutrition and weight gain, management of low and high fetal-weight pregnancies, use of maternal glucocorticoids, and newborn feeding strategies, among others, have yet to comprehensively integrate the long-term consequences on adult health.

## PRENATAL CARE: CHANGING THE PARADIGM TO INCLUDE THE LIFE-COURSE PERSPECTIVE

Pregnancy and childbirth are major life events. Preconception and prenatal care are not only part of the pregnancy continuum that culminates in delivery, the postpartum period, and

parenthood, they should also be considered in the context of women's health throughout the life span.<sup>1,2</sup> This chapter will review pertinent considerations for prenatal care using the broader definitions espoused by the U.S. Public Health Service and the American College of Obstetricians and Gynecologists (ACOG).<sup>3,4</sup> Specifically, prenatal care should consist of a series of interactions with caretakers, defined as *visits* and *contacts*, that

includes three components: 1) early and continuing risk assessment, 2) health promotion, and 3) medical and psychosocial interventions and follow-up.<sup>5</sup> The overarching objective of prenatal care is to promote the health and well-being not only of the pregnant woman, fetus, and newborn but also of the family. Hence, **the breadth of prenatal care does not end with delivery but rather includes preconception care and postpartum care that extends up to 1 year after the infant's birth.**<sup>4</sup> Importantly, this introduces the concept of interconception care and the notion that almost all health care interactions with reproductive-age women (and men) are opportunities to assess risk; promote healthy lifestyle behaviors; and identify, treat, and optimize medical and psychosocial issues that could impact pregnancy and the lifetime health of the mother and child.

### Definition and Goals of Care

National and international societies have recognized the importance of the continuum of preconception, prenatal, and interconception care as a comprehensive public health priority across the life span, beginning as early as adolescence, for multiple reasons.<sup>6-9</sup> **The aim of preconception care is to promote the health of women before conception in order to reduce preventable adverse pregnancy outcomes by facilitating risk screening, health promotion, and effective interventions as part of routine health care.**<sup>6</sup> As defined by the Centers for Disease Control and Prevention (CDC), it includes “interventions that aim to identify and modify biomedical, behavioral, and social risks to a woman's health or pregnancy outcome through prevention and management, emphasizing those factors which must be acted on before conception or early in pregnancy to have maximal impact.”<sup>6</sup> **Interconception care is defined as care provided between delivery and the beginning of the woman's next pregnancy.** The term *interconception health* has limited familiarity among many medical providers, with *preconception care* being the term used more often in medical circles to refer to care that can maximize parental health *before* pregnancy. The term *interconception health* was coined by the CDC as a strategy to optimize parental health between pregnancies by addressing disease processes, health behaviors, and environmental hazards causally associated with infant mortality and other adverse pregnancy outcomes. **During the interconception period, intensive interventions are provided to women who have had a previous pregnancy that ended in an adverse outcome** (i.e., fetal loss, preterm birth [PTB], low birth-weight [LBW], birth defects, or infant death).<sup>10</sup> Many medical conditions among reproductive-age women frequently become apparent during pregnancy and may contribute to negative birth outcomes in the infant. Hence, interconception care typically refers to enhanced interventions after an adverse pregnancy outcome.<sup>11,12</sup> However, for purposes of this discussion, preconception and interconception care are essentially interchangeable.

### Evidence and Rationale for Paradigm Shift

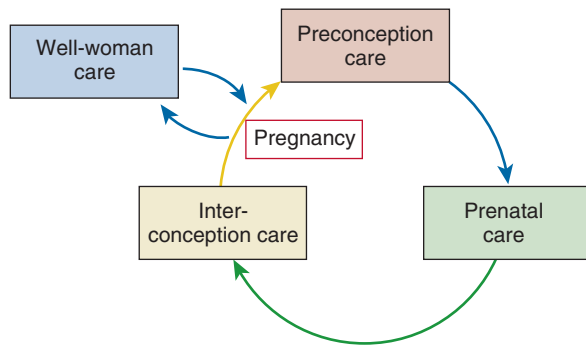

The evidence and rationale for providing these services are multiple. First, increasing evidence suggests that human health status in adulthood is dictated by microenvironmental and macroenvironmental conditions around the time of conception (fetal programming of adult disease; see Chapter 5). Hence, the first prenatal visit may be too late to address modifiable behaviors that could optimize not only pregnancy outcome but the

health of the child and future adult.<sup>13-15</sup> A second significant contribution to adverse pregnancy outcome is related to congenital anomalies, PTB, and LBW. Children born with these conditions contribute significantly to neonatal and infant mortality as well as to family and society health care costs. **Patients who present at their first prenatal visit, even as early as the first trimester, are often too late to initiate behaviors or therapeutic interventions to prevent developmental abnormalities or mitigate risk for LBW and potential preterm delivery.** Third, almost half of pregnancies are mistimed, unplanned, or unwanted such that women may not be at optimal health or practicing ideal health behaviors at the time of conception, and this is particularly true for adolescents and/or low-income women.<sup>16-18</sup> Fourth, the proportion of women who delay childbearing or get pregnant with significant medical conditions is increasing, and specific opportunities exist to optimize fertility and pregnancy outcomes as it relates to medication management for those planning pregnancy.<sup>6,15,20-23</sup> **Specifically, for those planning pregnancy, preconception/interconception visits provide an opportunity for teachable moments, and data suggest couples planning pregnancy are more likely to change behaviors.**<sup>12,15,24,25</sup> Hence, although the functional set of services provided during preconception care, prenatal care, and interconception care are distinct and should be individualized for the patient, operationally—and perhaps politically—these clinical visits should be viewed as a continuum of comprehensive women's health services provided across a woman's life span, from menarche to menopause or sterilization.<sup>7,12,26,27</sup> Finally, national surveys reveal that 84% of reproductive-age women (18 to 44 years) have had a health care visit within the past year, which suggests significant opportunity to provide preconception counseling, yet data indicate this is not being done.<sup>27</sup> Although primary care settings and the well-woman visit are an ideal time to provide these services, all health care practitioners—including but not limited to nutritionists, pharmacists, nurses, midwives, physicians in family practice, obstetrician-gynecologists, and medical subspecialists—should approach every health care encounter with a reproductive-age woman as an opportunity to maximize her health and that of her future offspring by asking two simple questions: 1) Are you pregnant or planning to become pregnant? 2) If not, what are you doing to keep from becoming pregnant?

Collectively, these questions are a great segue to the ultimate question: What is your reproductive life plan? The answers to these questions will guide the subsequent health care interaction and appropriate preconception or interconception counseling and any intervention.<sup>11</sup>

### Components of Preconception Care and Well-Woman Visits

A pregnancy or the desire to become pregnant is the sentinel event in differentiating preconception, interconception, and well-woman care (Fig. 6-1). **Preconception care is included as a preventive health service in well-woman visits covered by the Patient Protection and Affordable Care Act.**<sup>27</sup> Barriers to more widespread utilization of preconception care include lack of provider knowledge and training about essential components of preconception care across all specialties.<sup>8</sup> Although multiple checklists and online assessments exist, a detailed description provided by the Select Panel on Preconception Care as part of the CDC work groups and the corresponding rationale and evidence rating scale has been published, along with a recent

**FIG 6-1** The fluid interconnections among preconception care, postpartum/interconception care, and well-woman care.

update of published validated tools.<sup>28,29</sup> The strategy is similar to most health care interactions: the provider asks screening questions in regard to personal and family history and exposures, undertakes health promotion (counseling for risk reduction), and provides treatment and/or intervention if specific conditions are identified. Table 6-1 lists representative examples of potential topic areas pertinent for a preconception care visit, and it gives examples of medical conditions that could be optimized prior to conception, assuming pregnancy is planned. Ideally, a checklist or questionnaire should be completed prior to seeing the clinician, and the patient would raise questions or ask for clarification as required. Online and interactive modules are also available, and inclusion in electronic medical records (EMRs) and sharing across clinical sites should be encouraged.<sup>30</sup> Perhaps

**TABLE 6-1** PERTINENT TOPICS FOR PRECONCEPTION/INTERCONCEPTION COUNSELING AND OF MEDICAL CONDITIONS THAT CAN BE OPTIMIZED WHEN PREGNANCY IS PLANNED

| CLINICAL CONDITION                                 | COMMENT  |
|--|--|
| <b>General Health</b>                              |  |
| Age  | <p>&lt;18 years: Teenage pregnancy is associated with adverse maternal and familial consequences and increased risk of preterm birth.</p> <p>&gt;18 to 34 years: This is the ideal age group, especially if part of the reproductive life plan.</p> <p>&gt;35 years: Increased genetic risks; increase in complications, risk of cesarean delivery, obstetric morbidity, and mortality; general health, not age, should guide recommendations for pregnancy.</p> |
| Weight   | <p><b>Underweight:</b> Advise weight gain before conceiving and/or greater weight gain with pregnancy.</p> <p><b>Overweight:</b> Advise weight loss before conceiving; increased BMI is associated with multiple adverse outcomes that include pregnancy loss, stillbirth, diabetes, preeclampsia, and cesarean delivery.</p>  |
| <b>Psychiatric/ Neurologic</b>                     |  |
| Depression, anxiety                                | Adjust medications to those most favorable to pregnancy at the lowest possible dose; counsel about fetal echocardiography and neonatal withdrawal syndrome for some medications; reassure that risk/benefit profile favors treatment.  |
| Seizure disorders                                  | Start folic acid 4 mg when considering pregnancy to decrease risk of NTD; if no seizure in 2 yr, consider trial off medication; adjust medications to those most favorable to pregnancy to avoid risk of dysmorphic structural malformation syndromes; close serum monitoring is required during pregnancy; reassure that risk/benefit profile favors treatment.   |
| Migraines  | Migraine pattern can change with pregnancy. Most migraine-specific medications are not contraindicated.  |
| <b>Cardiac</b>                                     |  |
| Congenital cardiac disease or valve disease        | Coordinate with cardiologist; pregnancy may be contraindicated with some conditions depending on severity (NYHA classification) or medications needed.   |
| Coronary artery disease                            | Coordinate with cardiologist.  |
| Hypertension                                       | Adjust medications to optimize blood pressure. Discontinue ACE inhibitors and ARBs; these drugs are associated with congenital abnormalities.  |
| <b>Respiratory</b>                                 |  |
| Asthma   | Optimize treatment regimen per stepped protocol; if steroid dependent, use early ultrasound to evaluate for fetal cleft; advise patients at increased risk for gestational diabetes that medications, including steroids, are not contraindicated; emphasize that benefits of treatment exceed risks.  |
| <b>Gastrointestinal</b>                            |  |
| Inflammatory bowel disease                         | Optimize treatment regimen, advise that it is ideal to conceive while in remission; some medications have absolute versus relative contraindications.  |
| <b>Genitourinary</b>                               |  |
| Uterine malformations                              | Coordinate with reproductive endocrinologist if indicated.   |
| <b>Metabolic/Endocrine</b>                         |  |
| Diabetes   | Achieve euglycemia before conception (hemoglobin A <7%); dose-dependent relationship regarding risk of congenital anomalies with medications; with type 1 and longstanding type 2 diabetes, insulin therapy is best; sulfonylureas are usually reserved for gestational diabetes mellitus.   |
| <b>Hematologic</b>                                 |  |
| Sickle cell/thalassemia                            | Genetic counseling; advise sickle cell patient that crises can be exacerbated by pregnancy, and a risk of preterm birth/low birthweight is present.  |
| History of DVT/PE, known hereditary thrombophilias | Risk of recurrent DVT/PE requires prophylaxis during pregnancy   |
| <b>Infectious</b>                                  |  |
| STIs, TORCH, parvovirus                            | Establish risk factors, counsel to avoid infection, and treat as appropriate.  |
| <b>Rheumatologic</b>                               |  |
| SLE  | It is ideal to conceive while SLE is in remission; some medications may be contraindicated.  |
| <b>Genetic</b>                                     |  |
| Known genetic disorder in patient or partner       | Genetic counseling, medical records to confirm diagnosis, and evaluation are warranted for prenatal diagnosis or assisted reproduction to avoid inheritance risk based on parents preferences and values.  |

ACE, angiotensin-converting enzyme; ARB, angiotensin II receptor blockers; BMI, body mass index; DVT, deep vein thrombosis; NTD, neural tube defect; NYHA, New York Hospital Association; PE, pulmonary embolism; STI, sexually transmitted infection; SLE, systemic lupus erythematosus; TORCH, toxoplasmosis, other infections, rubella, cytomegalovirus, herpes.

the most essential component of the preconception or well-woman visit that needs more consistent and widespread implementation and dissemination is the development and documentation of an individual's reproductive life plan.

### Reproductive Life Plan: Definition

**Files and associates<sup>11</sup> have defined a *reproductive life plan* as a “set of personal goals regarding the conscious decision about whether or not to bear children” and ideally, such a plan outlines a strategy to achieve those goals.** Certain key elements should be considered when developing or discussing a reproductive life plan. These include 1) the desire or lack of desire to have children; 2) parental ages; 3) maternal health and coexisting medical conditions; 4) the desired number of children and anticipated spacing of children, taking into consideration ideal birth-spacing intervals, maternal age, and likelihood of fertility; 5) risk tolerance, such as for genetic or medical/obstetric complications; 6) family history; and 7) life context (age, school, career, partner, readiness for childbearing). Importantly, **reproductive life plans should be individualized, iterative, and addressed initially at menarche, confirmed or modified at subsequent health encounters by all care providers, and retired with menopause or sterilization.** Files and colleagues<sup>11</sup> have provided an algorithm and guidelines for developing a reproductive life plan, and convenient online tools have been designed for women contemplating pregnancy.<sup>31-32</sup> Unfortunately, studies indicate that even when women have achieved the pregnancy intention stage of readiness, many are still practicing preconception behaviors associated with poor pregnancy outcomes, such as poor diet (overweight or underweight), smoking, and binge drinking; this suggests a greater need for both one-on-one provider-patient interactions and more pervasive social media messages.<sup>12,26,33</sup> Research has demonstrated that patients want to be told this information from their providers, and many will respond favorably.<sup>34</sup> Further, sharing this information in groups, community settings, and in the presence of the partner has been shown to increase effectiveness.<sup>26</sup> Importantly, reproductive life plans should not be limited to reproductive-age women—the concept is pertinent for adolescent boys and men as well. **If conception is not anticipated within the year, an obvious discussion/intervention includes effective contraception options.**

**When specific conditions are detected and pregnancy is not recommended or intended, reliable contraception should be prescribed, and the importance of compliance should be strongly reinforced.** Data suggest that many women with complex medical problems who are advised against pregnancy conceive unintentionally and/or do not use contraception because of low perceived risk of conceiving.<sup>33,35</sup> If pregnancy is desired, in addition to screening and encouraging healthy behaviors, interventions to optimize the medical condition and adjust medications to profiles favorable for pregnancy should occur (see Table 6-1 for medical conditions and interventions common for preconception care and pregnancy).

## PRECONCEPTION HEALTH COUNSELING

### Maternal Age

The average maternal age at first birth has increased steadily over the last three decades in developed countries. **In 1970, the average age of first childbirth was 24.3, compared with 27.8 in 2009, the most recent year for which comparable**

**international data are available.**<sup>36</sup> The United States has one of the lowest average maternal ages at first birth (25 years), whereas British and German women are delaying motherhood longer than anywhere else in the world (30 years). Advanced maternal age (AMA) is a contributing factor to maternal mortality. Maternal mortality is defined and the causes are described in Chapter 57.

### Advanced Maternal Age

**With advancing maternal age comes an increased likelihood of preexisting chronic medical diseases such as arthritis, hypertension, and diabetes.**<sup>37-42</sup> The national Maternity Experiences Survey of the Canadian Perinatal Surveillance System<sup>42</sup> found that nulliparous women aged 35 years and over are significantly more likely to have had a miscarriage or infertility treatment, to request or be offered a cesarean delivery (CD), and to have a higher rate of CD than primiparous women aged 20 to 29 years, but they are not at higher risk for PTB, LBW, or small-for-gestational-age (SGA) infants. Overall, maternal age seems to have little impact on the rate of obstetric complications in women in their fourth decade of life. However, women aged 50 years or more are at increased risk for preeclampsia and gestational diabetes mellitus (GDM), and the vast majority of them can expect to deliver via CD.<sup>37-42</sup> A recent population-based register study found that a maternal age of 30 years or older was associated with the same number of additional cases of fetal deaths as those with comorbid overweight or obesity.<sup>43</sup>

Many nulliparous women age 40 and over require artificial reproductive technology (ART) to become pregnant. For ART singleton pregnancies, most studies have demonstrated a similar age- and parity-adjusted risk of pregnancy-induced hypertension and GDM in in vitro fertilization (IVF) and in controls.<sup>44</sup> In older women, ART techniques may require oocyte donation, which has been associated with increased risks of preeclampsia and premature labor. A recent meta-analysis<sup>45</sup> has found that the overall rate of preeclampsia after oocyte donation is approximately 22%. Furthermore, as a result of ART, the twin birth rate to women aged 40 to 44 nearly doubled between 1990 and 2001, and that of triplets increased fourfold in women 35 years and older between 1975 and 1998.<sup>46</sup> Within this context, in particular in older women with a preexisting medical condition, a multidisciplinary approach involving a maternal-fetal medicine specialist and an obstetrician should be started prior to conception.

### Teen Pregnancies

Before the development of effective methods of female contraception, such as oral contraception and intrauterine devices (IUDs), and before access of women to education, late-teenage first pregnancy was common around the world. Not surprisingly, pregnancy in the late teenage years and early twenties is not associated with a major increase in pregnancy complications. A recent Swedish survey has found that adolescents are more likely to be delivered vaginally than older women and that the risks of placenta previa, postpartum hemorrhage (PPH), and perineal rupture are lower for adolescents than for adult women.<sup>47</sup> Neonates of teenage mothers have less fetal distress and meconium aspiration but have greater risk of being delivered prematurely. **This higher risk of prematurity has been consistently reported by other authors and seems to be the only significant obstetric risk of late teen pregnancy.**<sup>48</sup> However, in modern Western societies, adolescent pregnancy is often unplanned and unwanted

and has a negative impact on the physical, emotional, educational, and economic condition of the pregnant teenager. In particular, **adolescent parenthood is associated with a range of adverse outcomes for young mothers, including mental health problems such as depression, substance abuse, and posttraumatic stress disorder (PTSD).**<sup>49</sup> Teen mothers are also more likely to be impoverished and to reside in communities and families that are socially and economically disadvantaged, which could be one of the factors that contributes to their higher risk of delivering prematurely.

In middle- and low-income countries, higher risks of preterm delivery have also been demonstrated for adolescent mothers aged 10 to 19 years (see [Chapter 57](#)). In addition, their risk of eclampsia, puerperal endometritis, emergency CD, PPH, and systemic infections is higher compared with mothers aged 20 to 24 years.<sup>50</sup> These worldwide consistent trends stress the important role of health care workers not only in providing guidance for teenagers and their parents, but also serving as health policy advocates to influence school and community leadership to ensure that all teenagers receive sound sex education in school programs and that family planning agencies are permitted to counsel teenagers and provide contraception services that include medications and devices.

### Body Mass Index

Abnormal maternal weight is an increasingly common complication in developed and developing countries and affects an increasing number of women of reproductive age. Maternal obesity has become a global issue associated with obstetric, surgical, and anesthetic risks and increased risk for acute and chronic diseases, both in the mother and in the child; it also affects the economic productivity of individuals in the society and creates an additional cost burden on the health care system (see [Chapter 41](#)). Anorexia and bulimia nervosa, once thought to be rare eating disorders, have also been increasing because of cultural pressure on the drive for thinness in developed countries in contrast to longstanding food deprivation in developing countries.

### Weight Gain

Weight gain during pregnancy has been shown to be an important predictor of pregnancy outcome (see [Chapter 7](#)). Maternal weight gain correlates with fetal weight gain and is, therefore, closely monitored. Too little weight gain should lead to an evaluation of nutritional factors and an assessment of associated fetal growth. Excess weight gain is one of the first signs of fluid retention, but it may also reflect increased dietary intake or decreased physical activity.

In the United States, the total weight gain recommended in pregnancy is 11 to 16 kg (25 to 35 lb) for women at a healthy weight.<sup>51</sup> Underweight women can gain up to 18 kg (40 lb), but overweight women should limit weight gain to 7 kg (15 lb), although they do not need to gain any weight if they are morbidly obese.<sup>52</sup> At term, the typical woman gains about 3 to 4 kg (7 to 9 lb) from increased tissue fluid volume and fat, 1.5 to 2 kg (3 to 4 lb) from increased blood volume, 0.5 to 1 kg (1 to 2 lb) from breast enlargement, 1 kg (2 lb) from enlargement of the uterus, 1 kg or 1 L (2 lb) from amniotic fluid, 2.7 to 3.6 kg (6 to 8 lb) for the fetus, and 0.5 to 1 kg (1 to 2 lb) of placental weight. Usually, 1.4 to 2.7 kg (3 to 6 lb) are gained in the first trimester, and 0.2 to 0.6 kg (0.5 to 1 lb) per week are gained during the last two trimesters of pregnancy.

If the patient does not show a 4.5 kg (10 lb) weight gain by mid pregnancy, her nutritional status should be reviewed. Inadequate weight gain is associated with an increased risk of an LBW infant. Inadequate weight gain seems to have its greatest effect in woman at a healthy weight or those who are underweight before pregnancy. Underweight mothers must gain more weight during pregnancy to produce infants of normal weight. In overweight and obese women, weight loss or gain of 11 lb (5 kg) or less is associated with increased risk of an SGA infant and decreased neonatal fat mass, lean mass, and head circumference.<sup>53</sup>

**When excess weight gain is noted, patients should be counseled to avoid foods that are high in fats and carbohydrates, to limit sugar intake, and to increase their physical activity.** Rapid weight gain requires an assessment for fluid retention. Factors that contribute to excessive weight gain during pregnancy include high fat and low fiber intake, high carbohydrate or sugar intake, and decreased physical activity during pregnancy. Several small studies suggest that monitoring weight gain, quantity of food consumed, and physical activity combined with behavioral counseling can limit weight gain during pregnancy and promote postpartum weight loss. However, larger randomized controlled trials are needed to demonstrate long-term effectiveness.<sup>54</sup>

Dietary and lifestyle interventions in pregnancy can reduce maternal gestational weight gain and improve outcomes for both mother and baby.<sup>55</sup> **Among the interventions, those based on diet are the most effective and are associated with reductions in maternal gestational weight gain and improved obstetric outcomes.**

**Weight gain and weight retention after pregnancy is a risk factor for subsequent obesity.**<sup>23,56</sup> Thus postpartum weight loss should be encouraged. Women who resumed their prepregnancy weight by 6 months postpartum gained only 2.4 kg (5 lb) over the next 10 years compared with 8.3 kg (18 lb) for women who retained weight after delivery.<sup>57</sup> Weight retention between the first and second pregnancy is associated with an increased risk for perinatal complications, even in underweight and normal-weight women.<sup>58</sup>

Stabilizing interpregnancy weight appears to be an important target in order to avoid adverse perinatal outcomes in a second pregnancy. Although clinicians have focused on teaching women that appropriate weight gain is important for pregnancy, the concomitant importance of postpartum weight loss has not been given equal attention.<sup>24,59,60</sup> A recent meta-analysis on the effect of diet, exercise, or both for weight reduction in women after childbirth has found that both diet and exercise together and diet alone help women lose weight after childbirth.<sup>61</sup> The authors also concluded that this needs confirmation in large trials of high methodologic quality.

### Overweight and Obesity

Sixty-five percent of Americans are overweight (body mass index [BMI]  $\geq 25$  kg/m<sup>2</sup>) or obese (BMI  $\geq 30$  kg/m<sup>2</sup>).<sup>62</sup> Pregestational weight gain or obesity and excessive gestational weight gain are now well-established independent risk factors for maternal-fetal complications and long-term risks in adult life for the child. The selected risks include increased miscarriage, congenital anomalies, hypertensive disorders, GDM, macrosomia, and delivery complications that include instrumental delivery, shoulder dystocia, emergency CD, PPH, venous thromboembolism (VTE), anesthetic complications, and wound infections.<sup>63,64</sup> In

overweight and obese women, the adjusted odds ratio (OR) is 2.04 (95% confidence interval [CI], 1.41-2.95) for cesarean delivery for an interpregnancy weight retention of 2 or more BMI units.<sup>65</sup> Being overweight or obese before pregnancy is also associated with a higher risk of fetal loss.<sup>66</sup> In women who are overweight or obese at 18 years, losing 4 kg or more before pregnancy is associated with a lower risk of fetal loss.<sup>66</sup>

Maternal obesity is a key predictor of childhood obesity and metabolic complications in adulthood. The children of women who are overweight or obese during pregnancy are also at increased risk for cognitive deficits, externalizing problems (particularly attention-deficit/hyperactivity disorder), and internalizing psychopathology in childhood and adolescence.<sup>67</sup>

Emerging evidence supports the role of first microbial contacts in promoting and maintaining a balanced immune response in early life, and recent findings suggest that microbial contact begins prior to birth and is shaped by the maternal microbiota (see Chapter 3). Although the mechanisms remain unclear, post-natal maturation of immune regulation seems to be largely driven by exposure to microbes, and the gastrointestinal tract is the largest source of microbial exposure.<sup>68</sup> Early exposures that impact the intestinal microbiota are associated with the development of childhood diseases that may persist into adulthood such as asthma, allergic disorders (atopic dermatitis, rhinitis), chronic immune-mediated inflammatory diseases, type 1 diabetes, obesity, and eczema.<sup>68,69</sup> Breast milk samples from obese mothers tend to contain a different and less diverse bacterial microbiota compared with milk from those at a healthy weight.<sup>70</sup> The gut microbiome can rapidly respond to altered diet, potentially facilitating the diversity of human dietary lifestyles.<sup>65</sup> Alterations in the bacterial composition of the mother have been shown to affect the development and function of the gastrointestinal tract of her offspring.<sup>68,69</sup> Thus prepregnancy strategies to modify the microbiota of future mothers may prove to be a safe and effective target for interventions to decrease the risk of allergic and noncommunicable diseases in future generations.

### Underweight

Prepregnancy underweight and insufficient gestational weight gain have been considered as individual risk factors for the occurrence of miscarriage, PTB, intrauterine growth restriction (IUGR), and hypertensive disorders.<sup>71</sup> A recent systematic review and meta-analysis<sup>72</sup> has shown that the birthweight of children of mothers with anorexia nervosa is lower by 0.19 kg compared with children of mothers at a healthy weight. A population study from the same authors has also shown that eating disorders are associated with increased odds of receiving fertility treatment and subsequent twin births.<sup>73</sup> Women with anorexia nervosa were more likely to have an unplanned pregnancy and to have mixed feelings about the unplanned pregnancy.

In underweight women and in those at a healthy weight, the risk for macrosomia can be halved if women lost more than 1 BMI unit between pregnancies, but at the same time, the risk for LBW doubled.<sup>65</sup>

### Pregnancy After Bariatric Surgery

Pregnancy after bariatric surgery appears to effectively reduce the risk of complications such as fetal macrosomia, GDM, and hypertensive disorders of pregnancy (see Chapters 25 and 41).<sup>74-77</sup> Women who become pregnant after bariatric surgery may constitute a unique obstetric population with an increased

risk of severe deficiencies in iron, vitamin A, vitamin B<sub>12</sub>, vitamin K, folate, and calcium; these deficiencies can result in both maternal complications such as severe anemia and fetal complications such as congenital abnormalities, IUGR, and failure to thrive.<sup>76</sup> Less invasive techniques, such as laparoscopic adjustable gastric banding, do not appear to increase the rate of small neonates seen with other bariatric surgery procedures.<sup>77</sup> Close supervision before, during, and after pregnancy following bariatric surgery and nutrient supplementation adapted to the patient's individual requirements can help to prevent nutrition-related complications and can improve maternal and fetal health in this high-risk obstetric population.

### Infections and Immunizations

**Primary care, preventative health, and well-women visits are ideal settings in which to screen and counsel women about sexually transmitted infections (STIs) such as syphilis, gonorrhea, chlamydia, and human immunodeficiency virus (HIV) in addition to toxoplasmosis, other infections, rubella, cytomegalovirus, and herpes (TORCH) infections. It is also an ideal time to confirm and update immunization status** (see Chapters 52, 53, and 54). Patients who are sexually active should be counseled about the importance of condoms to prevent STIs (irrespective of other contraceptive methods), and they should be screened for STIs based on age and geographic prevalence as per national guidelines.<sup>78,79</sup>

Toxoplasmosis screening based on risk factors may be indicated at this time because approximately one fourth of the U.S. population is infected.<sup>80</sup> Patients who have negative screens are at risk for congenital toxoplasmosis and should be counseled to avoid risks such as contact with infected cats and ingestion of raw or undercooked meat. Immunocompetent patients who screen positive can be reassured of low risk with regard to fetal loss or stillbirth; although rare, reports of congenital infection after previous infection have been described.<sup>81</sup> A prospective analysis of the population risks and benefits to substantiate routine screening for and education about toxoplasmosis has not been done in the United States. However, proponents argue a theoretic benefit based on treatment availability, extrapolated epidemiologic data from some European countries (France, Belgium, Austria) where screening is widespread, and the prevalence of congenital infection comparable to other congenital diseases that are currently screened for by mandate, such as phenylketonuria and congenital hypothyroidism.<sup>82</sup> The screening for toxoplasmosis could be performed once at the beginning of pregnancy to provide patients with the information on measures to prevent acquiring the infection during pregnancy, such as avoiding raw vegetables and meat or freezing meat before consumption.

Approximately 50% to 80% of reproductive-age women have evidence of prior cytomegalovirus (CMV) infection, and susceptible women (e.g., child care workers and women with small children in day care) should be counseled about the importance of hand hygiene after contact with toys, saliva, and urine as a preventive measure. Risk of vertical transmission is more likely after primary infection, and current treatment options are limited. Routinely screening for CMV to enhance awareness and encourage prevention practices in at-risk mothers is performed in a few European countries (France, Belgium) but is currently not endorsed in the United States.<sup>83</sup> Likewise, women with primary or recurrent herpes should be informed about the benefits of prophylactic antiviral suppression in the third trimester

to decrease risk of vertical transmission and the need for cesarean delivery.<sup>84</sup>

**All reproductive-age women should be current with immunizations recommended by the Advisory Committee on Immunization Practices (ACIP) and the CDC.<sup>85</sup> This is the time to draw and document protective titers for rubella, varicella, and hepatitis B and to immunize the susceptible patient.** Patients should use contraception for up to 3 months following immunizations with live vaccines. If the woman conceives and is expected to deliver during flu season, she should be counseled to receive the influenza vaccine to decrease disease severity for her. She should be given the tetanus, diphtheria, and pertussis (Tdap) vaccine in late pregnancy (27 to 36 weeks) to provide passive immunity for the newborn.<sup>85</sup>

### Genetic and Family History

**The time to screen appropriate populations for genetic disease-carrier status and multifactorial congenital malformations or familial diseases with major genetic components is before pregnancy. If patients screen positive, referral for genetic counseling is indicated, and consideration of additional preconception options may be warranted** including donor egg or sperm, ART after preimplantation selection, prenatal genetic testing after conception, or adoption (see Chapter 10).<sup>86</sup> Certain diseases may be related to race/ethnicity or geographic origin. Patients of African, Asian, or Mediterranean descent should be screened for the various heritable hemoglobinopathies (sickle cell disease,  $\alpha$ - and  $\beta$ -thalassemia). Patients of Jewish and French-Canadian heritage should be screened for Tay-Sachs disease, Canavan disease, and cystic fibrosis. In the United States, it has been suggested that cystic fibrosis screening be offered to all couples planning a pregnancy or seeking prenatal testing.<sup>87</sup> Resolution of these issues during the preconception period is much easier and less hurried without the time limits placed by an advancing pregnancy. The age of the father is also important because genetic, structural, behavioral, or cognitive risks to the child may exist when the father is older; this emphasizes the importance of a reproductive life plan for men as well as women.<sup>88,89</sup>

### Substance Abuse and Other Hazards

In the general population, fetal and neonatal exposures to drugs and other toxins are often the consequence of the lifestyle choices of the parents, with exposure to tobacco smoke and alcohol among the most pervasive and easily documented. **Smoking and use of alcohol and drugs by pregnant women are all harmful to the developing fetus, but because these substances are often used in combination, teasing apart the specific contributions of each substance to adverse child outcomes can prove difficult when analyzing epidemiologic data** (see Chapter 8). Overall, the risks to the neonate include IUGR, birth defects, altered neuropsychological behavior, and, for some drugs, withdrawal symptoms. Subsequent behavior, development, and neurologic function may also be impaired by behaviors that occurred during the preconception period. Consideration of socioeconomic inequalities in unplanned pregnancy is important in assessing the impact of a specific toxic substance on the developing fetus, because exposure may precede pregnancy recognition. A U.S. study of reproductive-age nonpregnant women looked at the prevalence of behavioral risk factors individually and in combination.<sup>90</sup> One third of the women had at least one risk factor, and 19% had

two or more risk factors, which confirms the opportunity for preconception care to mitigate outcomes.<sup>90</sup>

### Active and Passive Smoking

In many countries, smoking has replaced poverty as the most important risk factor for PTB, IUGR, and sudden infant death syndrome (SIDS).<sup>91</sup> Cigarette smoke contains scores of toxins that exert a direct effect on placental and fetal cell proliferation and differentiation.<sup>92</sup> The use of or exposure to tobacco products by pregnant women is associated more specifically with placenta previa, placental abruption, placenta accreta, pregnancy bleeding of unknown origin, and preterm premature rupture of membranes. Smoking is linked to a reduction of weight, fat mass, and most anthropometric parameters in the fetus; in the placenta, it is linked with alterations in protein metabolism and enzyme activity.<sup>92</sup> The transplacental induction of genetic alterations by tobacco smoke carcinogens and their implication to childhood diseases remain poorly understood.<sup>93</sup> However, epidemiologic studies support a relationship between maternal smoking during pregnancy and adverse neurobehavioral effects for her offspring later in life.<sup>94</sup> Prenatal exposure to tobacco seems to increase the risks for cognitive deficits, attention-deficit/hyperactivity disorder, conduct disorder, criminality in adulthood, and a predisposition in the offspring to start smoking and to abuse alcohol. A direct, specific action on the developing human brain is plausible during the major part of prenatal life because the nicotinic receptors are already present in the brain during the first trimester. The long-term effects of passive and active smoking during pregnancy on childhood or adulthood diseases, including respiratory and cardiovascular disease and cancer, are only starting to emerge from large epidemiologic studies.<sup>93</sup>

In spite of these well-established negative consequences, epidemiologic studies have shown that, depending on the patient population, **20% to 50% of pregnant women smoke or are exposed to passive smoking.** In many industrialized countries, prevalence rates of women actively smoking appear to have peaked and have begun to decline, whereas in other countries, smoking is becoming increasingly common among young women.<sup>91</sup> Smoking during pregnancy has been linked to high health care costs, and it accounted for approximately \$250 million in direct medical costs each year in the United States at the end of the last decade.<sup>95,96</sup> The complications with the largest smoking-attributable cost were LBW and lower respiratory tract infection. More than a decade ago, it was calculated that an annual drop of 1 percentage point in smoking prevalence among pregnant women would prevent the delivery of 1300 LBW infants and would save \$21 million in direct medical costs during the first year of the program.<sup>96</sup> Smoking during pregnancy has been recognized as the most important modifiable risk factor associated with adverse perinatal outcomes. **Because most of the placental and fetal damage is done in the first trimester of pregnancy, helping women to quit smoking before conceiving should be a primary objective in prepregnancy counseling.**

### Alcohol

**Alcohol is a well-established teratogen, and alcohol used during pregnancy can lead to fetal alcohol syndrome (FAS), which includes specific morphologic features, such as microcephaly, and long-term abnormal neuropsychological outcomes. The main issue with alcohol use during pregnancy is**

**that no amount of alcohol consumption has been found to be safe during pregnancy;** this can explain the blanket policy advice of many national departments of health that support total alcohol abstinence during pregnancy. There is no doubt that heavy or binge drinking is detrimental to fetal development in utero and that it has long-term negative effects on the offspring's cognition and behavior. A systematic review<sup>97</sup> of obstetric outcomes that included miscarriage, stillbirth, IUGR, prematurity, SGA infants, and birth defects including FAS found no convincing evidence of the adverse effects of prenatal alcohol exposure at low to moderate levels of exposure. A recent systematic review of child neuropsychological outcomes found a detrimental association between moderate prenatal alcohol exposure and child behavior and between mild-to-moderate prenatal alcohol exposure and child cognition.<sup>98</sup> A recent prospective follow-up study has also shown that intake of 15 to 21 drinks per week on average prior to pregnancy is not associated with abnormal neurophysiological outcome at 5 years of age, but intake of 22 or more drinks per week is associated with lower intelligence quotient (IQ) and lower attention scores.<sup>99</sup> These data support the concept of prepregnancy support to reduce or quit alcohol consumption for women planning a pregnancy. Regular screening for alcohol use should be carried out using such tools as the Tolerance-Annoyance, Cut-Down, Eye-Opener (T-ACE) questionnaire<sup>100</sup> (see Chapter 8) or other simple screening tools, and appropriate directed therapy should be made available to those women who screen positive.

### Other Substance Abuse

Substance abuse in pregnancy (see Chapter 55) has increased over the past three decades, and it has been recently estimated that approximately 225,000 infants yearly in the United States are exposed prenatally to illicit substances.

*Cannabis* is the most commonly used illicit substance in the United States, predominantly for its pleasurable physical and psychotropic effects. Four states and the District of Columbia have now made recreational use of *Cannabis* legal, and this topic has gained national attention. It has been shown that *Cannabis* use can lead to IUGR and withdrawal symptoms in the neonate. **A recent case-control study has also found that *Cannabis* use, cigarette smoking, illicit drug use, and apparent exposure to second-hand cigarette smoke separately or in combination during pregnancy were associated with an increased risk of stillbirth.** In longitudinal studies, fetal *Cannabis* exposure has been associated with negative effects on intellectual outcome.

Cocaine use in pregnancy can lead to spontaneous abortion, PTB, placental abruption, and preeclampsia. Although fetal cocaine exposure has been linked to numerous abnormalities in arousal, attention, and neurologic and neurophysiological function, most such effects appear to be self-limited and restricted to early infancy and childhood. Neonatal issues include poor feeding, lethargy, and seizures.

**Poor obstetric outcomes can be up to six times higher in patients who abuse opiates such as heroin and methadone.** Opiate exposure elicits a well-described withdrawal syndrome that affects central nervous, autonomic, and gastrointestinal systems; this effect is most severe among methadone-exposed infants.

Amphetamine use can lead to congenital anomalies and other poor obstetric outcomes. Methamphetamine use in particular is an escalating problem worldwide because it is the only illegal substance that can be made from legally obtained

over-the-counter cold medications. It is a powerful stimulant with a long half-life that crosses the placenta and concentrates in breast milk. Although evidence of an increased risk of congenital anomalies has been inconsistent, studies have consistently demonstrated an association between amphetamines and late/no prenatal care, maternal psychiatric disorders, homelessness, IPV, LBW and SGA infants, IUGR, neonatal intensive care unit (NICU) admissions, and childhood neurodevelopmental abnormalities. Maternal deaths from severe hypertension, tachycardia, and cardiac decompensation have also been reported.

Mothers who use illicit drugs require specialized prenatal care, and the neonate may need extra supportive care. Once recognized, a specialized approach can lead to improved maternal and neonatal outcomes. A similar multidisciplinary approach that includes access to rehabilitation centers is essential to help future mothers with an addiction quit before starting a pregnancy.

### Intimate Partner Violence

Violence against women is increasingly recognized as a problem that should be addressed, and reports suggest that abuse occurs during 3% to 8% of pregnancies. Questions that address personal safety and violence should be included during the prenatal period, and tools such as the Abuse Assessment Score are recommended.

### Mercury Exposure

**Data regarding the accumulation of mercury in fish has led to warnings advising pregnant women to avoid or decrease fish consumption.** In the United States, all 50 states have recommended limits on the ingestion of locally caught fish for pregnant women and children. Mercury is neurotoxic and has been associated with a dose-dependent impact on neurologic development. Approximately 5% to 8% of pregnant women may have mercury levels above the recommended amount, and increased awareness of the risks associated with mercury has led to decreased consumption or elimination of fish from the diets of many pregnant women. Unfortunately, the harms of mercury are counterbalanced by the benefits of omega-3 fatty acids found in fish that include decreased LBW and PTB, an increase in visual acuity, and higher performance on developmental tests and higher IQ scores in offspring. It is unclear whether dietary supplements are similarly beneficial because the stability and bioavailability varies and has not been well characterized. The U.S. Environmental Protection Agency (EPA) has attempted to clarify these mixed messages by recommending that reproductive-age women, pregnant women, and children eat a variety of fish two or three times a week (4 to 6 oz per serving) but that they should avoid eating fish with a high mercury content (king mackerel, shark, swordfish, and tilefish).

### Occupational Hazards and Environmental Exposures

Occupational hazards should be identified. If a patient works in a laboratory with chemicals or in agriculture around a lot of pesticides, for example, she should be advised to identify potential reproductive toxins and limit her exposure. This is an active area of research, and several online resources are available for information about potential environmental and occupational teratogens. Patients whose occupations require heavy physical exercise or excess stress should be informed that they may need to decrease such activity later in pregnancy because both have been associated with an increased risk of PTB and reduced fetal growth in observational studies.

## ENVIRONMENTAL EXPOSURES

A study based on the National Health and Nutrition Examination Survey demonstrated that all pregnant women are exposed to and have detectable levels of chemicals that can be harmful to reproduction or human development. Because exposure to environmental agents can be mitigated or prevented, it is important for women to be made aware of known toxic substances and to be informed as to how to access resources to gain additional information. Environmental contributors to reproductive health begin in utero and are influenced by social, physical, nutritional, and chemical agents. Lead has historical significance, but more recent concerns are related to mercury, phthalates, perchlorates, pesticides, and bisphenol A (BPA; see Chapter 8). These agents are considered endocrine-disrupting chemicals that interfere with cellular proliferation or differentiation and result in altered metabolic, hormonal, or immunologic capabilities. For example, pesticides are used widely in agriculture and household settings, with an estimated 1.2 billion lb per year of active ingredients used in the United States. These chemicals have been associated with impaired cognitive development and fetal growth and increased risk of childhood cancers. BPA is commonly found in plastics used for food and beverage products and packaging and has been associated with recurrent miscarriages and aggression and hyperactivity in girls. Primary care physicians can play an important role by providing guidance to women about how to avoid toxic exposures at home and in the community, and they can help educate patients by referring them to online resources.

## Screening for Chronic Disease, Optimizing Care, and Managing Medication Exposure

Clear evidence shows that for some conditions—such as diabetes mellitus, phenylketonuria, and inflammatory bowel disease—medical disease management before conception can positively influence pregnancy outcome. Medical management to normalize the intrauterine biochemical environment should be discussed with the patient, and appropriate management plans should be outlined before conception; advice can also be given about avoiding specific medications in the first trimester (e.g., isotretinoin). Table 6-1 gives examples of general health and medical conditions by organ system that can be optimized by preventing pregnancy until it can be planned and then adjusting medication type or dose to minimize teratogenicity or impact on neonatal development.

## PRENATAL CARE

### Components of Prenatal Care

Recent guidelines to address the content and efficacy of prenatal care have focused on the medical, psychosocial, and educational aspects of the prenatal care system. Prenatal care satisfies the definition of primary care from the Institute of Medicine as “integrated, accessible health care services by clinicians who are accountable for addressing a large majority of personal health care needs, developing a sustained partnership with patients, and practicing in the context of family and community.” Prenatal care satisfies other criteria for primary care in that it is comprehensive and continuous and offers coordinated health care. Hence, prenatal care provides additional opportunities to advance wellness and prevention. It is another opportunity to introduce and reinforce habits, knowledge, and life-long skills in self-care, health education, and wellness to inculcate

principles of routine screening, immunization, and regular assessment for psychological, behavioral, and medical risk factors. Phelan<sup>24</sup> argues that clinicians are not taking advantage of pregnancy as a “teachable moment”—a naturally occurring life transition that motivates people to spontaneously adopt risk-reducing behaviors. If health and habits are not optimized during the preconception period, pregnancy qualifies as a teachable moment because it meets the following criteria proposed by McBride<sup>25</sup> and colleagues:

- Perception of personal risk and outcome expectancies is increased.
- The perceptions are associated with strong affective or emotional responses.
- The event is associated with a redefinition of self-concept or social role.

Education about pregnancy, childbearing, and childrearing is an important part of prenatal care, as are detection and treatment of abnormalities. However, more recently, contemporary models of prenatal and childbirth education have been criticized because research has not shown a strong association between class attendance and childbirth experiences or parenting expectations. In fact, among first-time mothers, a decline in childbirth class attendance has been observed, from 70% in 2002 to 56% in 2005.

## High-Tech Versus Low-Tech Care

Historically, the primary goal of prenatal care was to minimize maternal and neonatal mortality. However, new technology has been introduced to assess the fetus antepartum that includes electronic fetal monitoring, sonography, prenatal diagnosis, and other in utero interventions with the fetus emerging as a patient in utero. Prevention of morbidity and mortality is now the goal. This has made the task of prenatal care more complex because mother and fetus now require an increasingly sophisticated level of care. At the same time, pregnancy is basically a physiologic process, and the healthy pregnant patient may not benefit from application of advanced technology; that is, she may receive poor quality care as a result of misuse or overutilization of the health care system.

Prenatal care can be provided at a variety of sites that range from the patient's home to the physician or midwife's private office to a public health or hospital clinic. Obstetricians must optimize their efforts by resourceful use of other professionals and support groups that include nutritionists, childbirth educators, public health nurses, nurse practitioners, family physicians, nurse midwives, and specialty medical consultants. Most pregnant women who are healthy and have normal pregnancies can be followed by an obstetric team that includes nurses, nurse practitioners, and nurse-midwives in addition to the obstetrician. These women should be cared for by practitioners who have adequate time to spend on patient education and parenting preparation, while physicians can appropriately concentrate on complicated problems that require their medical skills. This also provides for improved continuity of care, which is recognized as extremely important for patient satisfaction.

No prospective controlled trials have demonstrated the efficacy of prenatal care overall. Two documents that have addressed the content and efficacy of prenatal care have suggested changes in the current prenatal care system. Since publication of these recommendations, several well-designed randomized clinical trials and cost-benefit analyses have been reported using alternative visit schedules. No difference was evident in outcomes for

patients who underwent a reduced frequency of visits as measured by rates of PTB and LBW, and the reduced frequency model was shown to be cost effective. Although fewer visits were associated with decreased maternal satisfaction with care, as well as increased maternal anxiety, studies support the concept of reduced antenatal visits for selected women.

Efficacy of prenatal care also depends on the quality of care provided by the caretaker. If a blood pressure is recorded as “elevated,” and no therapeutic maneuvers are recommended, the outcome will remain unchanged. Recommendations must be made and must be carried out by the patient, whose compliance is essential to alter outcome. Using national survey data, Kogan and colleagues reported that women received only 56% of the procedures and 32% of the advice recommended as part of prenatal care content, whereas poor women and black women received even fewer of the recommended interventions. Site of care was also an important determinant, suggesting that infrastructure must be geared to address population-specific needs.

### Risk Assessment

The concept of risk in obstetrics can be examined at many levels. **All the problems that arise in pregnancy, whether common complaints or more hazardous diseases, convey some risk to the pregnancy depending on how they are managed by the patient and her care provider. Risk assessment has received detailed attention in the past. It has been shown that most women and infants who suffer morbidity and mortality will come from a small segment of those with high-risk factors; by reassessing risk factors before pregnancy, during pregnancy, and again in labor, the ability to identify those at highest risk increases.** Most of the emphasis for screening, risk assessment, and associated trials for therapeutic interventions have focused primarily on preeclampsia and PTB prevention. Table 6-2 lists representative examples of other clinical conditions that have been proposed to be included as part of routine screening and risk assessment during the antepartum period since 1989. Although commonly included as part of current routine screening programs, few of these screening programs were implemented as a result of evidence-based criteria, such as

those proposed by the U.S. Preventive Services Task Force (USPSTF). Most have been utilized as a result of expert or consensus opinion, cost-benefit, or risk-management decisions.

### Initial Prenatal Visit

It is important to individualize patient care and to be thorough. Therefore the initial visit should include a detailed history along with physical and laboratory examinations.

### Social and Demographic Risks

Low socioeconomic status should be identified, and attempts to improve nutritional and hygienic measures should be undertaken. Appropriate referral to federal programs—such as for the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC)—and to public health nurses can have real benefits. If a patient has a history of a previous neonatal death, stillbirth, or PTB, records should be carefully reviewed so that the correct diagnosis is made and recurrence risk is appropriately assessed. A history of drug abuse or recent blood transfusion should be elicited. The history of medical illnesses should be detailed, and records should be obtained if possible. A rapid procedure for diagnosing mental disorders in primary care may be useful in pregnancy. If appropriate, patients should be screened and treated for depression.

### Medical Risk

Family history of diabetes, hypertension, tuberculosis, seizures, hematologic disorders, multiple pregnancies, congenital abnormalities, and reproductive loss should be elicited. Often, a family history of mental retardation, birth defects, or genetic traits is difficult to elicit without formal genetic counseling or questionnaires; nonetheless, these areas should be emphasized at the initial history. **A better history may be obtained if patients are asked to fill out a preinterview questionnaire or history form.** Any significant maternal cardiovascular, renal, or metabolic disease should be defined. Infectious diseases such as urinary tract disease, syphilis, tuberculosis, or herpes genitalis should be identified. Surgical history with special attention to any abdominal or pelvic operations should be noted. A history of previous cesarean delivery should include indication, type of uterine

incision, and any complications; in addition, a copy of the surgical report may be informative. Allergies, particularly drug allergies, should be prominent on the problem list.

### Obstetric Risk

**Previous obstetric and reproductive history is essential to optimizing care in subsequent pregnancies.** The gravidity and parity should be noted with the outcome for each prior pregnancy recorded in detail. Previous miscarriages and documentation about the gestational age at the time of the loss is important; these not only confer risk and anxiety for another pregnancy loss, they can be associated with an increased risk for genetic disease and PTB.

Previous preterm delivery is strongly associated with recurrence; therefore it is important to delineate the events that surrounded the PTB. Did the membranes rupture before labor? Were painful uterine contractions present? Was there any bleeding? Were any fetal abnormalities evident? What was the neonatal outcome? All these questions are vital in determining the etiology and prognosis of the condition, although specific recommendations will vary and the efficacy of routine prevention programs is not clear. In patients with a previous premature delivery from preterm labor or premature rupture of the membranes (PROM), progesterone administration reduces the risk of recurrence. Cervical insufficiency and uterine anomalies are all conditions that may be known from a previous pregnancy.

**After all the specific inquiries, it is recommended that the patient be asked a few simple questions: What important items haven't I asked? What concerns or questions do you have? Leaving time for open-ended questions is the best way to complete the initial visit.**

### Physical and Laboratory Evaluation

Physical examination should include a general physical examination and a pelvic examination. Baseline height and weight, pre-pregnancy weight, and vital signs are recorded. Any physical finding that might have an impact on pregnancy or that might be affected by pregnancy should be defined. It is particularly important to perform and record a complete physical examination at this initial visit because in the absence of specific problems or complaints, less emphasis will be placed on nonobstetric portions of the examination as pregnancy progresses. Documentation of baseline vital signs, cardiac examination, and other physical findings is important prior to the expected physiologic changes that will occur over time.

A pelvic examination should be performed in early pregnancy. Cervical cytology, if indicated, and testing for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are done. Bacterial vaginosis should be recognized. Bimanual exam should focus on the uterine size and the presence of palpable adnexal masses. The cervix should be carefully palpated, and any deviation from normal should be noted. Clinical pelvimetry should be performed with the clinical impression of adequacy noted (see Chapter 12). The exam may be limited by examiner skill and patient variation (e.g., obesity). Most practitioners perform an ultrasound in the first and/or second trimester, which confirms dating and should also evaluate for the presence of uterine or adnexal pathology. A detailed description of gestational age determination utilizing ultrasound is provided in Chapter 9.

Basic laboratory studies are routinely performed. Some studies need not be repeated if recent normal values have been obtained,

such as at a visit following a preconceptional visit or a recent gynecologic or infertility examination. Blood studies should include Rh type and screening for irregular antibodies, hemoglobin level, or hematocrit and serologic tests for syphilis and rubella. A urine sample should be obtained and tested for abnormal protein and glucose levels. Screening for asymptomatic bacteriuria has been traditionally done by urine culture, but screening may be simplified by testing for nitrites and leukocyte esterase. Tuberculosis screening should also be performed in areas of disease prevalence. Multiple options exist for aneuploidy screening and/or diagnosis depending on when women present for prenatal care (see Chapter 10).

The laboratory evaluations outlined above are the minimum standard tests; specific conditions will require further evaluation. A history of thyroid disease will lead to thyroid function testing. Anticonvulsant therapy requires measurement of blood levels of medication to determine if the appropriate dose is being used. The importance of compliance with dosing and serial evaluation of serum blood levels should be emphasized; for example, both thyroid medications and anticonvulsant levels are sensitive to the physiologic expansion of blood volume and metabolic changes that occur during pregnancy. Adequacy of hormone replacement and/or drug levels will need to be monitored throughout pregnancy. Identification of problems on screening (e.g., anemia, abnormal glucose screen) will mandate further testing. If not done before conception, screening for varicella has been suggested for women with no known history of chickenpox. The ACOG has recommended routine screening of all pregnant women for hepatitis B. In addition, HIV screening should also be offered because maternal therapy with azidothymidine (AZT) can reduce vertical transmission (see Chapter 53). Hepatitis C and CMV screening should be considered for at-risk populations. Recommendations for the content of prenatal care are summarized in Table 6-3. Note that these recommendations are drawn from various sources; most are based on expert opinion, and although similar, they are not entirely in agreement with regard to all recommendations.

### Repeat Prenatal Visits

A plan of visits is outlined to the patient. **Traditionally, this has been every 4 weeks for the first 28 weeks of pregnancy, every 2 to 3 weeks until 36 weeks, and weekly thereafter if the pregnancy progresses normally.** The U.S. Public Health Service suggested that this number of visits can be decreased—especially in parous, healthy women—and studies suggest that this can be done safely. If any complications are present, the intervals can be increased appropriately. For example, patients with hypertensive disease or those at risk for preterm delivery may require weekly visits.

At regular visits, the patient is weighed, the blood pressure is recorded, and the presence of edema is evaluated (see “**Intercurrent Problems**” below). Fundal height is regularly measured with a tape measure, fetal heart tones are recorded, and fetal position is noted. The goal of subsequent pregnancy visits is to assess fetal growth and maternal well-being. **In addition, at each prenatal visit, time should be allowed ask the patient whether she has any problems or questions. Family members should be encouraged to come to prenatal visits, ask questions, and participate to the degree that the patient wishes.**

In patients at risk of prematurity, or in those with a short cervix noted during an ultrasound, frequent cervical checks or sonographic evaluation of cervical length may reveal premature

| <b>Urine</b>                      |              |                   |       |       |    |    |    |    |    |    |
| Dipstick                          | X            |                   |       |       |    |    |    |    |    |    |
| Protein                           | X            |                   |       |       |    |    |    |    |    |    |
| Sugar                             | X            |                   |       |       |    |    |    |    |    |    |
| Culture                           |              | X                 |       |       |    |    |    |    |    |    |
| <b>Infections</b>                 |              |                   |       |       |    |    |    |    |    |    |
| Rubella titer                     | X            |                   |       |       |    |    |    |    |    |    |
| Syphilis test                     | X            |                   |       |       |    |    |    |    |    |    |
| Gonococcal culture                | X            | X                 |       |       |    | X  |    |    |    |    |
| Hepatitis B                       | X            |                   |       |       |    |    |    |    |    |    |
| HIV (offered)                     | X            | X                 |       |       |    |    |    |    |    |    |
| Toxoplasmosis                     | X            |                   |       |       |    |    |    |    |    |    |
| Illicit drug screen (offered)     | X            |                   |       |       |    |    |    |    |    |    |
| Genetic screen                    | X            |                   |       |       |    |    |    |    |    |    |

\*Includes preconception visit.

†If preconception care has preceded.

GDM, gestational diabetes mellitus; HIV, human immunodeficiency virus; MSAFP, maternal serum  $\alpha$ -fetoprotein.

dilation or effacement that can be treated with progesterone suppositories or cerclage (see [Chapters 28 and 29](#)).

Further laboratory evaluations are routinely performed at 28 weeks, when the hemoglobin or hematocrit, Rh type and screen for antibodies, serologic test for syphilis, and possibly HIV testing can be repeated. If the patient is Rh negative and unsensitized, she should receive Rhesus immune globulin (RhIG) prophylaxis at this time (see [Chapter 34](#)). A glucose screening test for diabetes is also appropriately performed at this time (see [Chapter 40](#)), and some clinicians advocate routine fetal movement counting using a movement chart (see [Chapter 11](#)). At 36 weeks, a repeat hematocrit, especially in those women with anemia or those at risk for peripartum hemorrhage (multipara, repeat CD), may be performed. Group B *Streptococcus* (GBS) screening should be done at 35 to 36 weeks with consideration given to possible intrapartum prophylaxis. Also, appropriate cultures for the pathogens responsible for STIs (*N. gonorrhoeae* and *C. trachomatis*) should be obtained as indicated in the third trimester based on geographic prevalence rates and demographic risk factors.

After 41 weeks from the last menstrual period, the patient should be entered into a screening program for fetal well-being, which may include electronic monitoring tests or ultrasound

evaluation (see [Chapter 11](#)). If labor has not occurred by 41 to 42 weeks, induction should be recommended (see [Chapter 36](#)).

### Intercurrent Problems

It is the practice in prenatal care to evaluate the pregnant patient for the development of certain important complications. Inherent in these checks is surveillance for intervening problems, an important one being preeclampsia. Blood pressure will change physiologically in response to pregnancy, but development of hypertension must be recognized so that evaluation, treatment, or hospitalization can be promptly initiated (see [Chapter 31](#)).

Dependent edema is physiologic in pregnancy, but generalized or facial edema can be a first sign of disease. It is critical here, as in all areas, for the practitioner to understand the normal changes associated with pregnancy in order to accept and explain these (see [Chapter 3](#)) but also to aggressively manage any abnormal changes.

Proteinuria reflects urinary tract disease, generally either from infection or glomerular dysfunction and possibly as a result of preeclampsia. The degree of proteinuria should be quantitated in a 24-hour urine collection. Any urinary tract infection should be treated because **asymptomatic bacteriuria is a risk factor for pyelonephritis and PTB**.

Fetal, placental, or amniotic fluid abnormalities are often first detected by deviation from the clinical expectation. In some conditions, the risk of fetal anomaly will be so high as to prompt baseline screening or testing (e.g., sonography, fetal echocardiography, prenatal karyotype). At other times, risk only becomes evident during the course of prenatal care. Growth restriction and macrosomia can often be suspected clinically, usually on the basis of an abnormality in fundal growth. For the patient who has a history of these conditions or other predisposing factors such as hypertension, renal disease, or diabetes, particular vigilance is in order. Alteration in amniotic fluid, too much or too little, can sometimes be detected clinically based on a uterine size/date discrepancy. In addition to maternal conditions, abnormalities in amniotic fluid volume (see [Chapter 35](#)) may be caused by fetal disease that can be defined using sonography and that may alter management of the pregnancy; for example, prompt delivery or therapeutic amnioreduction may be considered.

### Common Patient-Centered Issues

Although not exhaustive, this section includes common issues or concerns likely to be raised by the patient at some point during successive prenatal visits. The practitioner should be prepared to address these as part of the health education, promotion, and prevention goals of each patient.

#### Nutrition During Pregnancy

[Chapter 7](#) provides a detailed description of diet guidelines for weight gain. In addition, iron and vitamin supplementation, including folic acid supplementation, are also discussed in that chapter.

#### Activity and Employment

Most patients are able to maintain their normal activity levels in pregnancy. Mothers tolerate pregnancy with considerable physical activity, such as looking after small children, working, and routine exercise; however, **heavy lifting and excessive physical activity should be avoided**. Modification of activity level as the pregnancy progresses is seldom needed, except if the mother's job involves physical danger. Recreational exercises should be encouraged, such as those available in prenatal exercise classes. The importance of physical activity cannot be overstressed. Unfortunately, many women are routinely told to decrease their physical activity, even though research on moderate aerobic activity shows no negative impact on pregnancy outcomes. In the absence of medical or obstetric complications, **current ACOG recommendations advocate for 30 minutes or more of moderate exercise daily**. A Cochrane review of aerobic exercise in pregnancy indicated improved maternal fitness, but evidence is insufficient to determine whether maternal or neonatal risks or benefits exist.

Previously sedentary women with no medical contraindications can start with 15 minutes of continuous exercise three times per week and work toward a goal of 30 minutes four times per week. With regard to exercise intensity, a good rule of thumb is the so-called talk test; that is, if the exercising woman cannot maintain a conversation (perceived moderate intensity), she is probably overexercising. Studies suggest that women who engage in regular recreational activity have less GDM, less preeclampsia, and less low back and pelvic pain. The patient should be counseled to discontinue activity whenever she experiences discomfort.

**If the job presents hazards no greater than those encountered in daily life, healthy pregnant women may work until their delivery.** Strenuous physical exercise, standing for prolonged periods, and work on industrial machines in addition to other adverse environmental factors may be associated with increased risk of poor pregnancy outcome, and these should be modified as necessary.

#### Travel

**A pregnant woman should be advised against prolonged sitting during car or airplane travel because of the risk of venous stasis and possible thromboembolism.** The usual recommendation is a maximum of 6 hours per day driving, stopping at least every 2 hours for 10 minutes to allow the patient to walk around and increase venous return from the legs. Hydration and support stockings are also recommended.

The patient should be instructed to wear her seatbelt during car travel but to wear it under the abdomen as pregnancy advances (see [Chapter 26](#)). It may also be helpful to take pillows along to increase comfort. If the patient is traveling a significant distance, it might be helpful for her to carry a copy of her medical record with her should an emergency arise in a strange environment. She should also become familiar with the medical facilities in the area or perhaps obtain the name of a local obstetrician should a problem occur.

#### Nausea and Vomiting in Pregnancy

Nausea and vomiting are common in pregnancy and affect approximately 75% of pregnancies. **Hyperemesis gravidarum is an extreme form characterized by vomiting, dehydration, and weight loss that frequently results in hospitalization.** The exact etiology of hyperemesis gravidarum is unknown, but it is believed to be related to a product of the placenta and is correlated with human chorionic gonadotropin (hCG) and estradiol concentrations. Twin and sibling studies suggest a genetic component, whereas epidemiologic risk factors include younger age, low prepregnancy body mass, female fetus, history of motion sickness or migraines, and *Helicobacter pylori* infection. Smoking and obesity are associated with a *decreased* risk of hyperemesis. If hyperemesis gravidarum occurs in a first pregnancy, the recurrence risk is approximately 15%, although this may be reduced if there is a change in paternity.

Women with hyperemesis gravidarum can have transient laboratory abnormalities that may include suppressed thyroid-stimulating hormone (TSH) or elevated free thyroxine (see [Chapter 42](#)). They can also have elevated liver enzymes and bilirubin, higher levels of amylase and lipase, and altered electrolytes (loss of sodium, potassium, and chloride). Women with severe hyperemesis can develop rare, severe complications such as Wernicke encephalopathy, beriberi, central pontine myelinolysis, peripheral neuropathy, and hepatic or renal failure. Similarly, severe vomiting has been associated with Mallory-Weiss tears, esophageal rupture, pneumomediastinum, and retinal detachment.

Fetal effects of hyperemesis gravidarum are unclear. In general, if the problem is corrected or resolves and the patient is able to gain weight, there are no consequences. However, if the woman has poor weight gain (<15 lb), the fetus is at increased risk for LBW and PTB.

Treatment of hyperemesis gravidarum is primarily symptomatic. No evidence is available to support an ideal diet in these cases, but women are frequently advised to eat small meals that

favor proteins over carbohydrates and liquids over solids. Women admitted to the hospital typically require intravenous (IV) hydration, and most recommend initial supplementation with thiamine (100 mg) for 3 days to prevent the possibility of Wernicke encephalopathy. Three randomized controlled trials suggest a benefit of vitamin B<sub>6</sub> in reducing nausea. If symptoms persist, adding an antihistamine may be beneficial. In addition to antihistamines, benzamides, phenothiazines, butyrophenones, type 3 serotonin receptor antagonists, and corticosteroids have all been used in the treatment of hyperemesis. Although anecdotally successful, the evidence of efficacy from randomized trials is inconclusive. This is important to consider given that some of the agents can cause adverse reactions that include but are not limited to extrapyramidal symptoms, anxiety, and depression. Ginger is an alternative therapy that has been successful in treating the nausea and vomiting of pregnancy.

In rare instances, patients do not respond to treatment, are unable to tolerate oral intake, and cannot maintain their weight or continue to lose weight. **These patients may benefit from enteral or parenteral nutrition**, although significant complications have been described with parenteral nutrition that include thrombophlebitis and death from infection or pericardial tamponade. A recent study by Holmgren and colleagues described maternal and neonatal outcomes from 94 patients admitted with hyperemesis gravidarum and treated with medications, but only as compared with a nasogastric tube (NGT) or a peripherally inserted central catheter (PICC); they found no difference in gestational age, mean birthweight, or Apgar scores, but an increased risk of NICU admissions was reported in the PICC line group (9.1% vs. 4.1% or 0%). Of patients managed with medication, 7% (3/42) had an adverse reaction from the medication that resolved after treatment, whereas 11% (2/19) of patients had the NGT dislodge, and 64% (21/33) of patients with a PICC line required treatment for infection, thromboembolism, or both. Based on their findings and those of others, the authors suggested that PICC lines should be avoided.

Finally, some patients who fail treatment opt to terminate their pregnancy, although the exact incidence is unknown; a web-based survey of over 800 women who agreed to be part of a hyperemesis gravidarum registry noted that 15% had at least one termination, and 6% had more than one termination as a direct or indirect result of severe hyperemesis gravidarum. These women felt they were too sick to care for their family or themselves, or they were concerned about the potential adverse consequences of hyperemesis gravidarum on their baby. Further, these women indicated that health care providers were uncaring or did not appear to understand or acknowledge how sick they were, which suggests that further education within the medical community about the physical and psychological burden of hyperemesis gravidarum is needed.

### Heartburn

Heartburn is a common complaint in pregnancy because of relaxation of the esophageal sphincter (see [Chapter 3](#)). Overeating contributes to this problem, therefore the patient who experiences postprandial heartburn should be advised to save part of her meal for later and to not eat immediately before lying down. Pillows to prop up the upper body at bedtime may help. If necessary, antacids may be prescribed. Liquid antacids coat the esophageal lining more effectively than do tablets. In a subset of patients, H<sub>2</sub> receptor blockers may be helpful (see [Chapter 48](#)).

### Backache

Back pain is a common complaint in pregnancy that affects over 50% of women. Numerous physiologic changes of pregnancy likely contribute to the development of back pain including ligament laxity related to relaxin and estrogen, weight gain, hyperlordosis, and anterior tilt of the pelvis; these altered biomechanics lead to mechanical strain on the lower back. **Backache can be prevented to a large degree by avoidance of excessive weight gain and a regular exercise program before pregnancy.** Exercises to strengthen back muscles can also be helpful. Posture is important, and sensible shoes should be worn, not high heels. Scheduled rest periods with elevation of the feet to flex the hips may be helpful. Other successful treatment modalities that have been described include nonelastic maternity support binders, acupuncture, aquatic exercises, and pharmacologic regimens that incorporate acetaminophen, narcotics, prednisone, and rarely, antiprostaglandins (if remote from term).

### Sexual Activity

Generally speaking, in the absence of any known contraindications, no restrictions need to be placed on sexual intercourse. However, the patient should be advised that pregnancy may cause changes in comfort and sexual desire. Frequently, increased uterine activity is noted after sexual intercourse; it is unclear whether this is due to breast stimulation, female orgasm, or prostaglandins in male ejaculate. In a survey of 425 primiparous women, Fox and colleagues reported that over 60% of women reported sexual activity in the third trimester, and up to one-third engaged in sexual activity within 2 days of delivery. Studies suggest that sexual activity during pregnancy is rarely discussed, although most women feel the need to receive more information. For women at risk for preterm labor or those with a history of previous pregnancy loss and who note increased uterine activity after sex, use of a condom or avoidance of sexual activity may be recommended.

### Prepared Parenthood and Support Groups

**Routine classes on newborn child care and parenting should be part of the prenatal care program.** Many parents are completely unprepared for the myriad changes in their lives, and some idea of what to expect is beneficial. As pregnancy progresses, challenging needs can arise. Support groups for families with genetic or medical conditions, such as Down syndrome or skeletal dysplasias, or preterm infants and maternal support groups for mothers of twins or triplets and for women who have had cesarean delivery have all shown that they can meet the special needs of these parents. Unsuccessful pregnancies lead to special problems and needs for which social workers, clergy, and specialized support groups can be invaluable. Miscarriage, stillbirth, and infant death are particularly devastating events best managed by a team approach with special attention given to the grieving process. Referral to such groups as Compassionate Friends of Miscarriage, Infant Death, and Stillbirth is recommended. Careful evaluation and follow-up for depression should be part of the routine pregnancy postpartum care (see [Chapter 23](#)).

### Prenatal Record

**The prenatal care record should describe the comprehensive care provided and should allow for systematic documentation of coordinated services.** One such example is the antepartum record designed by ACOG. Many of the advances in risk

assessment and perinatal regionalization result directly from widespread implementation of this record. Most electronic medical record (EMR) systems have attempted to capture the important components, but they are limited in the degree to which different EMR systems can interrelate with each other. Technology allows sophisticated recording, display, and retrieval—often computer based—of prenatal care records, but quality relies on accurate, consistent compiling and concurrent recording of the information. The record must be complete yet simple, directive but flexible, and at the same time legible, transmittable, and able to display necessary data rapidly. Some data exist regarding the quality of documentation in prenatal/intrapartum records as it relates to billing diagnosis, but little data is available regarding the quality of documentation in EMRs. Implementation of the International Classifications of Diseases may help, but this has yet to be determined. European nations often have one record for uniform care, and many health care systems have adopted records to permit internal consistency. Commonly used records accurately reflect the following:

1. Demographic data, obstetric history
2. Medical and family history, including genetic screening
3. Baseline physical examination with emphasis on the gynecologic examination
4. Menstrual history, especially last normal menstrual period (LMP), with documentation of established due date and reference criteria for dating if that was done with something other than LMP
5. Record of individual visits
6. Routine laboratory data (e.g., Rh, GBS, Rapid Plasma Reagin Test [RPR], rubella, hepatitis, and HIV)
7. Problem list
8. Space for special notations and plans (e.g., planned trial of labor after cesarean [TOLAC; see [Chapter 20](#)], repeat CD, tubal ligation)

These records must be made available to consultants, and they should be available at the facility where delivery is planned. If transfer is expected, a copy of the prenatal record should accompany the patient.

### Prenatal Education

In general, it is believed that patient education leads to better self-care, and pregnancy is no exception. Efforts to improve understanding, involvement, and satisfaction with pregnancy and the perinatal period are increasing. In this area more than any other, the options for paramedical support have expanded. Practitioners and patients have access to a vast array of support personnel (e.g., doulas) and groups to assist and advise in the pregnancy and subsequent parenthood. Group prenatal care has recently been initiated and has been associated with improved patient satisfaction. Patients should be educated about care options and should be allowed to participate in decision making.

## POSTPARTUM CARE

### Components of the Postpartum Visit

Postpartum care is covered in detail in [Chapter 23](#); however, it should be stressed that a key element in ensuring the optimal interconception period is by encouraging and reinforcing the importance of keeping the postpartum appointment. Most patients should be seen approximately 6 weeks postpartum, sooner for complicated deliveries and cesarean deliveries. The goal of this visit is to evaluate the physical,

psychosocial, and mental well-being of the mother; to provide support and referral for breastfeeding; and to initiate or encourage compliance with the preferred family planning option and preconception care for the next pregnancy. Depending on the mother's education and insurance status, the likelihood of attending the postpartum visit ranges from 77% to 95%. Data suggest that maternal health after pregnancy is associated with improved child health, and so increasing compliance with postpartum visits has been identified as both a national and international public health priority.

### Birth Spacing

**An important goal of the postpartum visit and interconception care is to encourage birth spacing—specifically, to educate women about the importance of waiting at least 24 months to conceive again. This interconception interval has been associated with decreased risk of PTB/LBW and decreased risk for uterine rupture among women attempting a vaginal birth after a cesarean delivery (VBAC).**

An estimated one in three pregnancies in the United States occurs within 18 months of a previous birth, 1 in 2 occurs within 18 to 59 months, and 1 in 6 occurs after 60 months or more. *Short birth spacing*, defined as 18 months or less, was found to be strongly linked to unintended pregnancies and age, specifically teenagers (between 15 and 19 years old at the time of conception) and women whose first conception was after the age of 30. For women who do wait the recommended interval, using the most efficacious contraceptive method in light of their medical comorbidities is critical to optimize the interconception period because 49% of pregnancies are unplanned. For example, an estimated 26% to 41% percent of postpartum women have intercourse before their 6-week postpartum visit, 41% by 6 weeks, 65% by 8 weeks, and 78% by 12 weeks. Whether they had complications during the birth was a significant factor in how long they waited. **Educating women on the most appropriate contraception based on medical conditions and discharging patients with an effective contraception method is essential to assist women in achieving the recommended 24-month interval.**

Specific nutritional recommendations such as calcium, folate, or iron supplementation vary during the interconception period depending on whether the woman is breastfeeding or anemic or has had any other complications. In general, most women are nutrient depleted post partum, and a daily prenatal vitamin should be continued for at least 8 weeks after delivery. Further, attention should be directed toward counseling about the common tendency and known hazards of weight retention.

Recent systematic reviews have demonstrated the benefits of postpartum psychosocial support for early detection and prevention of maternal depression as well as for decreased newborn readmissions. Psychosocial support can be provided by clinicians or trained lay personnel.

### Counseling Regarding Medical Conditions and Obstetric Complications

Finally, follow-up is needed for medical complications such as heart disease, hypertension, diabetes, and depression—conditions that may have been exacerbated by pregnancy—as well as thyroid disease and epilepsy, conditions in which postpartum medication adjustments may be required. One focus of interconception care is on medical complications that were present during pregnancy. Chronic diseases such as

diabetes, hypertension, obesity, and depression may first become apparent during prenatal care. Lack of access to routine well-woman and medical care contribute to a disproportionate number of pregnancy complications among minority women and those of low socioeconomic status. Medical complications during pregnancy may also account for the increasing rate of cesarean delivery and also of LBW/PTB, the most common cause of infant deaths. A history of a previous pregnancy outcome is an important predictor of future reproductive risk. However, **many women with adverse pregnancy outcomes do not receive targeted interventions to reduce risks during future pregnancies.** Women with a history of PTB, preeclampsia, and GDM should be informed that they are at increased risk of recurrence with subsequent pregnancies in addition to being at risk for subsequent development of hypertension and cardiovascular disease. Likewise, women with GDM are at increased risk of developing type 2 diabetes. Patients should be counseled to inform all subsequent health care providers of these prior medical conditions that occurred during pregnancy.

Pregnancy complications, both maternal and fetal/newborn, should be reviewed, and recurrence risk should be discussed along with any potential interventions considered. For example, cesarean delivery has a high likelihood of repeating; therefore the risks, benefits, and alternatives should be addressed, and this discussion should include the type of uterine incision used, any abnormal placentation, and the possibility of a TOLAC. If childbirth was traumatic, the clinician should be alert for signs or symptoms of depression or PTSD. Women with preeclampsia

or chronic hypertension should be advised to start a low-dose aspirin regimen after 12 weeks' gestation in their next pregnancy. To prevent recurrence, women with preterm deliveries should be counseled to seek care early to discuss treatment options, which may include progesterone therapy or cerclage based on clinical history.

### COMING FULL CIRCLE: COMPONENTS OF INTERCONCEPTION CARE AND WELL-WOMAN VISITS

As noted throughout this chapter, the specific components of preconception, postpartum, and interconception care and the well-woman visit overlap conceptually to the point of redundancy. However, on a pragmatic basis, much work needs to be done relative to dissemination of good information and implementation of quality care. Models to incorporate interconception care into health programs for women are limited but are currently being investigated. The most common settings have focused on low-income and minority populations as a potential intervention to eliminate their disparate maternal and birth outcomes.

One example of the implementation of interconception care was in Chicago among low-income black women with a prior adverse pregnancy outcome. This program, Interconception Care Period (ICCP), focused on the integration of social services, family planning, and medical care provided through a team approach (Table 6-4). The planned delivery of

**TABLE 6-4** INTERCONCEPTION CARE RESOURCES

| RESOURCE  | DESCRIPTION AND LINK  |
|---|---|
| Interconception Care Project of California  | The Interconception Care Project is a collection of recommendations to improve and promote the interconception health of women by maximizing care provided during the postpartum visit. A panel of obstetric and health experts developed evidence-based postpartum clinical management algorithms and companion patient education materials based on the 21 most common pregnancy and delivery complications identified using ICD-9 discharge code data in California. The algorithms are designed to guide risk assessment, management, and counseling based on risk of adverse pregnancy outcome and/or maternal/neonatal complications in order to improve the mother's health and reduce risks in future pregnancies. Patient handouts were developed (English and Spanish) that offer explanations of the condition and treatment options; they discuss self-care strategies to improve the health of the woman, her baby, and any future pregnancies ( <a href="http://www.everywomancalifornia.org">www.everywomancalifornia.org</a> ). |
| Planning for a Healthy Future: Algorithm for Providers Caring for Women of Childbearing Age | Wisconsin Association for Perinatal Care (WAPC) developed a program to put the life course approach to women's health into action. Health care providers can use the algorithm to integrate preconception and interconception care into well-woman care and to identify areas of risk of which a woman may not be aware. Links to other WAPC preconception health resources are also available.<br><a href="http://www.perinatalweb.org/major-initiatives/reducing-infant-mortality/resources">http://www.perinatalweb.org/major-initiatives/reducing-infant-mortality/resources</a>  |
| March of Dimes Screening and Counseling Checklist   | Patients are given the checklist at the reception desk and are asked to fill it out before seeing the provider. Providers can use this one-page summary to initiate discussions about preconception care. This list offers a series of essential questions that help providers develop good clinical management plans.<br><a href="http://www.healthteamworks.org/guidelines/preconception.html">www.healthteamworks.org/guidelines/preconception.html</a>  |
| Smiles for Life: Women's Oral Health Curriculum   | Addresses the importance of oral health before, during, and after pregnancy and includes information on the prevalence of oral disease during pregnancy, its consequences for both mothers and children, and a review of dental treatment guidelines for pregnant women.<br><a href="http://www.smilesforlifeoralhealth.org/buildcontent.aspx?ut=560&amp;pagekey=61366&amp;cbreceipt=0">www.smilesforlifeoralhealth.org/buildcontent.aspx?ut=560&amp;pagekey=61366&amp;cbreceipt=0</a>  |
| Preconception and Interconception Care Guideline  | Colorado Department of Public Health developed guidelines designed to assist clinicians providing preconception and interconception care. The guidelines were adapted from the <i>American Journal of Obstetrics and Gynecology Supplement</i> , December 2008, and CDC Proceedings of the Preconception Health and Health Care Clinical, Public Health, and Consumer Workgroup Meetings, June 2006.<br><a href="http://www.healthteamworks.org/guidelines/preconception.html">http://www.healthteamworks.org/guidelines/preconception.html</a>   |
| Before, Between, and Beyond Pregnancy   | The National Preconception/Interconception Care Clinical Toolkit was designed to help primary care providers, their colleagues, and their practices incorporate preconception health into the routine care of women of childbearing age.<br><a href="http://beforeandbeyond.org/toolkit">http://beforeandbeyond.org/toolkit</a>   |
| Guidelines for Preconception and Interconception Care: Specific Health Conditions           | This concise pocket-sized brochure highlights common medical disorders and includes patient counseling recommendations, confirmatory tests, and contraindicated medications (if not using contraception) as well as recommended contraception for high-risk medical diseases.<br><a href="http://www.everywomancalifornia.org/files.cfm?filesID=531">www.everywomancalifornia.org/files.cfm?filesID=531</a>   |

interventions based on a woman's unique interconceptional health needs was often replaced by efforts to address the woman's socioeconomic needs. Although medical care remained important, participants viewed themselves as healthy and did not view medical care as a priority; in addition, women's perceptions of contraceptive effectiveness were not always aligned with clinical knowledge.

Since 2005, all 97 federal Healthy Start Programs—initiated in 1991 to address the factors that contribute to the high infant mortality rate in the United States, particularly among populations with disproportionately high rates of adverse perinatal health outcomes—have been required to include an interconception care component. Recommendations for health care providers to address interconception medical conditions have been developed and range from algorithms to toolkits; [Table 6-4](#) gives resources for additional interconception care.

In summary, the traditional approach to improving perinatal outcomes has focused on prenatal care once a woman is already pregnant. **However, the fact is that birth outcomes and maternal outcomes have not significantly improved in the past 40 years. This, coupled with new knowledge that maternal complications during pregnancy and postpartum and newborn complications are associated with long-term health outcomes for both the mother and child, requires that the health care system reframe the approach to providing care to women. Hence, the life-course perspective was proposed.** The improvement of maternal health before conception and in the interconception interval can reduce prematurity and LBW and can subsequently improve the health of infants, and it can maximize the health of mothers and children for generations to come.

### KEY POINTS

- ◆ The breadth of prenatal care does not end with delivery but rather includes both preconception and postpartum care, which extends up to 1 year after the infant's birth. Importantly, this introduces the concept of interconception care and the principle that almost all health care interactions with reproductive-age women (and men) are opportunities to assess risk, promote healthy lifestyle behaviors, and identify and treat medical and psychosocial issues that could impact pregnancy and the life-time health of the mother and child.
- ◆ *Interconception care* is defined as care provided between the end of a woman's pregnancy to the beginning of her next pregnancy. During the interconception period, intensive interventions are provided to women who have had a previous pregnancy that ended in an adverse outcome (i.e., fetal loss, PTB, LBW, infant death, or birth defect).
- ◆ A *reproductive life plan* is a "set of personal goals regarding the conscious decision about whether or not to bear children." Ideally, it outlines a plan to achieve those goals. Reproductive life plans should be individualized, iterative, and addressed initially at menarche, confirmed or modified at subsequent health encounters by all care providers, and retired with menopause or sterilization.
- ◆ When specific conditions are detected such that pregnancy is not recommended or intended, reliable contraception should be prescribed, and the importance of compliance should be reinforced. Many women with complex medical problems who are advised against pregnancy conceive unintentionally and/or do not use contraception because of a low perceived risk of conceiving.
- ◆ Age, weight (BMI), and changes in weight during pregnancy and over time impact pregnancy outcome and long-term maternal health.
- ◆ Primary care, preventative health, and well-women visits are ideal times to screen and counsel patients about STIs and TORCH infections and to confirm and/or update immunization status.
- ◆ All reproductive-age women should be current with immunizations as recommended by ACIP and the CDC. This is the time to draw and document protective titers for rubella, varicella, and hepatitis B and to immunize the susceptible patient.
- ◆ The time to screen appropriate populations for genetic disease-carrier status, congenital malformations, or familial diseases with major genetic components is *before* pregnancy. If patients screen positive, referral for genetic counseling is indicated because consideration of additional preconception options may be warranted.
- ◆ Smoking and alcohol and drug use by pregnant women are all harmful to the developing fetus, but because these substances are often used in combination, teasing apart the specific contributions of each substance to adverse child outcomes can prove difficult. Overall, the risks to the neonate include IUGR, birth defects, altered neuropsychological behavior, and for some drugs, withdrawal symptoms. Subsequent behavior, development, and neurologic function may also be impaired from health problems that started during the preconception period.
- ◆ A study based on the National Health and Nutrition Examination Survey demonstrated that all pregnant women are exposed to and have detectable levels of chemicals that can be harmful to reproduction or human development. Because exposure to environmental agents can be mitigated or prevented, it is important for women to be made aware of known toxic substances and to inform them as to how to access resources to gain additional information.
- ◆ Clear evidence shows that for some conditions—such as diabetes mellitus, phenylketonuria, and inflammatory bowel disease—medical disease management before conception can positively influence pregnancy outcome. Medical management should be discussed with the patient, and appropriate management plans should be outlined before conception. Advice should also be given about specific medications to avoid during the first trimester (e.g., isotretinoin).
- ◆ All the problems that arise in pregnancy, whether common complaints or more hazardous diseases, convey some risk to the pregnancy that will depend on how these problems are managed by the patient and her care provider. It has been shown that most women and infants who suffer morbidity and mortality will come from a small segment of women with high-risk factors; by reassessing risk factors before and during pregnancy

and again in labor, the ability to identify those at highest risk improves.

- ◆ A key element to ensure the optimal interconception period is to encourage and reinforce the importance of keeping the postpartum appointment. Most patients should be seen approximately 6 weeks post partum, sooner for complicated or cesarean deliveries. The goal of this visit is to evaluate the physical, psychosocial, and mental well-being of the mother; to provide support and referral for breastfeeding; to initiate or encourage compliance with the preferred family planning option; and to initiate preconception care for the next pregnancy.
- ◆ An important goal of the postpartum visit and interconception care is to encourage birth spacing—specifically, to educate women about the importance of waiting at least 24 months after delivery to conceive again because this interval has been associated with a decreased risk of preterm birth and low birthweight, and it decreases the risk for uterine rupture among women who attempt a vaginal birth after a cesarean delivery.

## OVERVIEW

In light of the obesity epidemic, the concept of eating for two during pregnancy has come under great scrutiny in recent years. Despite public health efforts to promote weight loss, the number of reproductive-age women who are overweight (body mass index [BMI] >25.0 to 29.9 kg/m<sup>2</sup>) has remained stable at

approximately 30%. Of more concern is the twofold increase in obesity (BMI ≥30 kg/m<sup>2</sup>) from 13% to 35% in the same population (Fig. 7-1).<sup>1</sup> **This increase in obesity disproportionately affects minority populations, such as Hispanics and blacks, and especially women.**<sup>2</sup> The increased rates of obesity are attributed to numerous factors that include increased consumption of nonnutritious foods and decreased physical activity. In pregnancy, excessive gestational weight gain increases the risk of higher BMI in a subsequent pregnancy.

**Excessive weight gain during pregnancy significantly increases the risk of postpartum weight retention and contributes to the accretion of excess adipose tissue in the fetus.** Additionally, obesity poses specific risks to the process of labor and delivery and to fetal outcomes. Obesity, however, is not the only concern in the management of nutrition during pregnancy. The importance of adequate nutrition is also a critical issue during pregnancy, and deficiency or excess of various nutrients can have both short- and long-term consequences to the mother and her fetus. In this chapter we address the specific nutrient requirements during pregnancy, recommendations for weight gain, and other special concerns regarding nutrition and pregnancy.

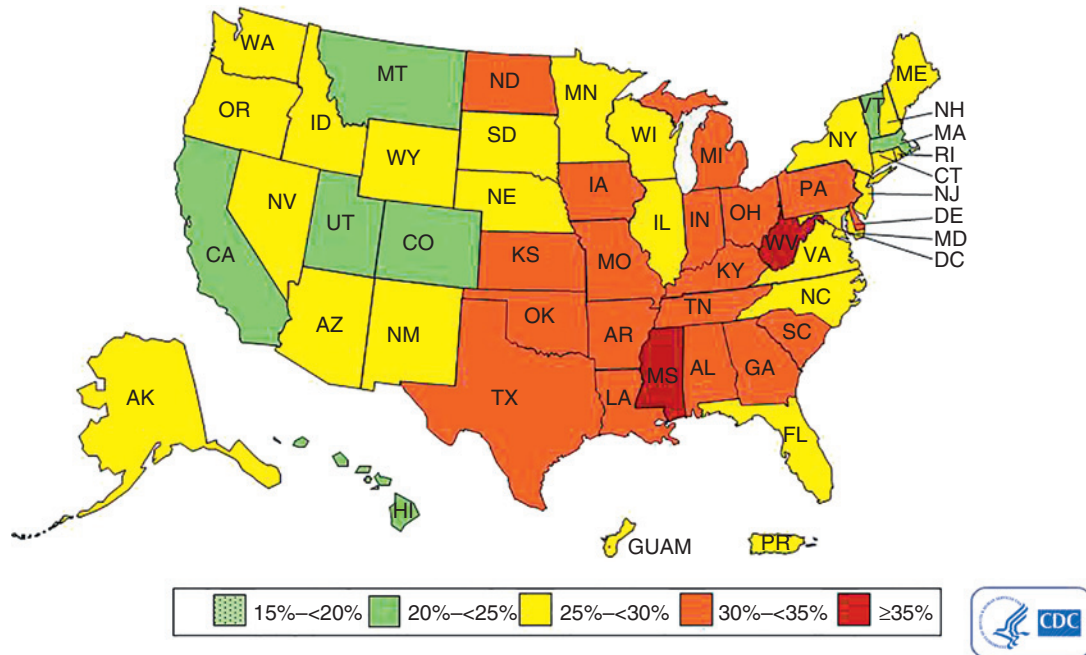

## INTEGRATING NUTRITION INTO THE OBSTETRIC HISTORY

Every woman should have the opportunity to meet with a health care provider for a prepregnancy history and physical examination that includes a nutritional assessment. **The purpose of this assessment is to identify the quality of a patient's diet and to assess any nutritional risk factors that could jeopardize her health or the health of her developing baby.** Adequate intake

### Prevalence\* of Self-Reported Obesity Among U.S. Adults by State and Territory, BRFSS, 2013

\*Prevalence estimates reflect BRFSS methodological changes started in 2011. These estimates should not be compared to prevalence estimates before 2011.

**FIG 7-1** Adult obesity in the United States in 2013. (From Behavioral Risk Factor Surveillance System [BRFSS], Centers for Disease Control and Prevention. Available at <http://www.cdc.gov/obesity/data/prevalence-maps.html>.)

of nutrients supports the developing fetus, reduces fetal risk, and improves pregnancy outcomes.<sup>3</sup> During the nutritional assessment, the patient's medical history, weight status, dietary intake, and laboratory data should be reviewed. The medical history will identify maternal risk factors for nutritional deficiencies and chronic diseases with nutritional implications (e.g., absorption, eating, and metabolic disorders; infections; inflammatory bowel disease; diabetes mellitus; phenylketonuria; sickle cell trait; and renal disease).

Pertinent dietary information includes appetite, meal patterns, dieting regimens, cultural or religious dietary practices, dietary restrictions, food allergies, cravings, and aversions. Information about abnormal eating practices such as bingeing, purging, laxative or diuretic use, or pica—eating nonfood items (ice, detergent, starch)—should be ascertained.

During the assessment, other relevant information includes the habitual use of caffeine-containing beverages or sugary soft drinks, tobacco, alcohol, recreational drugs, vitamins, and herbal supplements.<sup>4</sup> Specifically asking about nutritional supplements is critically important because many patients do not consider these items to be “medications” and thus will not volunteer that these are being used. **A patient's diet can be assessed by asking about intake over the previous 24 hours or by administering a diet history questionnaire in the waiting room.**

Nutrition-related complications during a prior pregnancy are also important to assess. Gestational weight gain in previous pregnancies and history of hyperemesis, gestational diabetes, anemia, and pica should be determined (see [Chapters 6 and 40](#)). **Women with a short interpregnancy interval (e.g., <1 year between pregnancies) may have depleted nutrient reserves,**

**which is associated with increased preterm birth, intrauterine growth restriction (IUGR), and maternal morbidity and mortality.<sup>5,6</sup>**

In addition to the medical history, the social history may provide key information regarding the patient's nutritional risk. For example, some work environments adversely impact dietary intake because they may not provide adequate time to eat balanced meals, or they allow access to food that is only marginally nutritious. Women with lower socioeconomic status often need support to obtain nutritious food, and referral to food-assistance programs may be appropriate (e.g., Women, Infants, and Children Program [WIC]).

Many women are receptive to nutritional counseling just prior to or during pregnancy, making this an opportune time to encourage the development of good nutrition and physical activity practices aimed at preventing future medical problems such as obesity, diabetes, hypertension, and osteoporosis.<sup>3</sup> Pregnant women found to be at risk may benefit from a referral to a registered dietitian as shown in [Table 7-1](#).

### MATERNAL WEIGHT GAIN RECOMMENDATIONS

In 1990 the Institute of Medicine (IOM) first published recommendations on weight gain during pregnancy.<sup>7</sup> The guidelines were proposed to address many issues regarding the role of nutrition in pregnancy, including the prevention of small-for-gestational-age (SGA) and growth-restricted neonates. As noted previously, the obesity rate has surged in recent decades. As such, in 2009, the IOM updated the 1990 guidelines regarding weight

**TABLE 7-1** SITUATIONS IN WHICH CONSULTATION WITH A REGISTERED DIETITIAN IS ADVISABLE

- Pregnancy involves multiple gestations (twins, triplets).
- Gestations are frequent (less than a 3-month interpregnancy interval).
- Tobacco, alcohol, or drug use (chronic medicinal or illicit) is occurring.
- Severe nausea and vomiting (hyperemesis gravidarum) is a problem.
- Eating disorders are present, including anorexia, bulimia, and compulsive eating.
- Weight gain is inadequate during pregnancy.
- Pregnancy occurs in adolescence.
- Eating is restrictive (vegetarianism, macrobiotic, raw food, vegan).
- Food allergies or food intolerances are present.
- Gestational diabetes mellitus (GDM) or history of GDM is involved.
- Patient has a history of low-birthweight babies or other obstetric complications.
- Social factors are present that may limit appropriate intake (e.g., religion, poverty).

gain in pregnancy. In contrast to the 1990 recommendations, these guidelines consider both the short- and long-term outcome for the pregnant woman and her child. Additionally, because of the great importance of achieving appropriate pregravid weight, the 2009 guidelines emphasize that women begin pregnancy at a healthy weight. Lastly, the guidelines call for individualized preconceptional, prenatal, and postpartum care to help women attain healthy weight gain and return to a healthy pregravid weight after delivery.<sup>8</sup>

Many general recommendations exist regarding diets for pregnant women to avoid problems such as excessive gestational weight gain and potential complications such as gestational diabetes and fetal overgrowth. These diets vary from those high in complex carbohydrates and low in fats<sup>9</sup> to those low on the glycemic index<sup>10</sup> to diets high in probiotics.<sup>11</sup> Whereas all of these diets may offer some theoretic advantage, presently none can be endorsed as optimal. **Consuming healthy food is the goal to meet the IOM gestational weight guidelines and address the individual needs of the patient.**

### Low or Underweight Preconception Body Mass Index

The 2009 IOM guidelines are based upon the World Health Organization (WHO) classifications to define underweight, normal weight, overweight, and obese patients (Table 7-2). *Underweight* is classified as a BMI below 18.5 kg/m<sup>2</sup>. **Based on the available data, there is strong support that women with**

**low pregnancy BMI and low gestational weight gain have an increased risk (<10%) for having SGA infants, preterm birth, and perinatal mortality.**<sup>12</sup> In contrast, excessive gestational weight gain for women with a low pregravid BMI increases risk of large-for-gestational-age (LGA) neonates and for increased maternal weight retention postpartum (Fig. 7-2; also see Chapters 6 and 41).<sup>13</sup>

### Overweight and Obese Prepregnancy Body Mass Index

**Approximately 60% of reproductive-age women are overweight (BMI >25 kg/m<sup>2</sup>), and of these, 50% are obese (BMI >30 kg/m<sup>2</sup>).** Another 8% have severe obesity, with a BMI greater than 40 kg/m<sup>2</sup>. Obesity poses a multitude of threats related to pregnancy: antepartum risks include spontaneous abortion, congenital anomalies, preterm birth, gestational diabetes, hypertension, and preeclampsia; during labor, risk of shoulder dystocia and cesarean delivery are higher; and postpartum risks include thromboembolic events, anemia, and incision-site infections (see Chapters 6 and 41).<sup>14</sup>

**The 2009 IOM guidelines recommend that overweight women with a singleton pregnancy gain a total of 15 to 25 lb during pregnancy (compared with 25 with 35 lb for normal-weight women). Obese women are advised to gain only 11 to 20 lb during the course of their pregnancy.** These recommendations were based primarily on class I obesity because data are limited regarding weight gain recommendations for each class of obesity. As such, the IOM guidelines do not differentiate between class I obesity (BMI 30 to 34.9 kg/m<sup>2</sup>), class II obesity (BMI 35 to 39.9 kg/m<sup>2</sup>), and class III obesity (BMI ≥40 kg/m<sup>2</sup>).<sup>15,16</sup> The 11 to 20 lb gestational weight gain for obese patients primarily represents the obligatory weight gain of pregnancy. This includes approximately 12 to 14 lb of water, 2 lb of protein, and a variable amount of adipose tissue (Table 7-3).

Some authors have recommended less gestational weight gain for obese class II and III women to decrease neonatal morbidity.<sup>17</sup> Whereas others have noted an increased risk of SGA babies with decreased lean body mass, as well as decreased fat mass, in overweight and obese women with inadequate gestational weight gain.<sup>18</sup>

## MATERNAL WEIGHT GAIN RECOMMENDATIONS FOR SPECIAL POPULATIONS

### Multiple Gestations

For twin pregnancies, the IOM recommends a gestational weight gain of 37 to 54 lb for women of normal weight, 31 to 50 lb for overweight women, and 25 to 42 lb for obese women (Table 7-4). For triplet and higher-order gestations, the data on ideal gestational weight gain are insufficient; thus no specific recommendations exist for these.<sup>15</sup>

### Adolescents

**Approximately 17% of teenage girls ages 12 through 19 are obese in America, and these obese teens face the same obstetric risks that adult obese women face.** Because 80% of teen pregnancies are unintended, the ability of an obstetrician to discuss preconception nutrition concerns with an obese teen is nearly impossible. Thus efforts should be made during the early prenatal care visits to emphasize the importance of appropriate gestational weight gain and adequate nutrition. Studies have

**FIG 7-2** Adjusted absolute risks for infants small for gestational age (solid circle) and large for gestational age (open circle) and for emergency cesarean delivery (solid triangle) and postpartum weight retention of  $\geq 5$  kg (open triangle) according to prepregnancy body mass index (in kg/m<sup>2</sup>) and gestational weight gain categories of the World Health Organization. Gestational weight gain categories are low (<10 kg), medium (10–15 kg), high (16–19 kg), and very high ( $\geq 20$  kg). (Modified from Nohr EA, Vaeth M, Baker JL, et al. Combined associations of pre-pregnancy body mass index and gestational weight gain with the outcome of pregnancy. *Am J Clin Nutr*. 2008;87:1750.)

**TABLE 7-3** OBLIGATORY COMPONENTS OF WEIGHT GAIN DURING PREGNANCY

|   | GRAMS      |
|---|------------|
| <b>Protein</b>                            |            |
| Fetus                                     | 420        |

specific racial or ethnic groups, or in those who smoke cigarettes. The IOM guidelines recognize that each of these special groups may possibly benefit from specific gestational weight gain guidelines, but the available evidence is insufficient to make recommendations.

## MATERNAL NUTRIENT NEEDS: CURRENT RECOMMENDATIONS

### Energy

Energy expenditure consists of four basic components: (1) resting metabolic rate (RMR); (2) the thermic effect of food (TEF), or diet-induced thermogenesis; (3) the thermic effect of energy (TEE); and (4) adaptive, or facultative, thermogenesis. RMR is the amount of energy, or calories, used at rest and accounts for approximately 60% of total energy expenditure in healthy people. TEF is the caloric cost of eating, digesting, absorbing, resynthesizing, and storing food and accounts for

**FIG 7-3** Components of energy expenditure. (From Catalano PM, Holtenbeck C. Energy requirements in pregnancy. *Obstet Gynecol Surv.* 1992;47:368.)

about 5% to 10% of total energy expenditure. TEE is quite variable and in sedentary individuals may account for only 15% to 20% of total energy expenditure. *Adaptive thermogenesis*, or *facultative thermogenesis*, refers to adaptations by an organism to adjust to environmental changes, such as overfeeding or underfeeding, as well as to alterations in ambient temperature. Adaptive thermogenesis accounts for no more than 10% of RMR and varies by individual (Fig. 7-3).

**The total maternal energy requirement for a full-term pregnancy is estimated at 80,000 kilocalories (kcal). This accounts for the increased metabolic activity of the maternal and fetal tissues as well as for the growth of the fetus and placenta.** Maternal energy needs are increased to support the maternal cardiovascular, renal, and respiratory systems. Basal requirements can be determined based on maternal age, stature, activity level, preconception weight, BMI, and gestational weight gain goals. Daily caloric requirements have been estimated by the WHO by dividing the gross energy cost of pregnancy (80,000 kcal) by the approximate duration of pregnancy (250 days after the first month), producing an average additional 300 kcal/day for the entire pregnancy. During the first trimester, total energy expenditure does not change greatly, and weight gain is minimal assuming the woman began her pregnancy without depleted body reserves. Therefore additional energy intake is recommended primarily in the second and third trimesters. During the second trimester, a pregnant woman should consume an additional 340 kcal/day above the nonpregnant energy requirement, and in the third trimester, the additional caloric requirement is 452 kcal/day.<sup>20</sup>

However, a series of prospective studies were conducted in the late 1980s and 1990s to assess energy expenditure in pregnancy. Many of these studies obtained baseline data prior to a planned pregnancy and incorporated measurements such as estimates of body composition, energy intake in the diet, RMR, standard measures of exercise, and activity diaries. These studies showed that the energy cost of pregnancy is much lower than previously estimated.<sup>21-25</sup>

The introduction of the doubly labeled water method has allowed researchers to estimate total energy expenditure in the free-living state. In well-nourished women, RMR usually begins to rise soon after conception and continues to rise until delivery. However, considerable interindividual variation is apparent. In healthy, well-nourished women, the average increases in RMR above prepregnancy values are 4.5%, 10.8%, and 24.0% for the first, second, and third trimesters, respectively.

Pregnancy induces changes in fuel utilization. **Later in pregnancy, the basal or fasting contribution of carbohydrates to oxidative metabolism increases. Fetal growth and lactation are dependent on energy preferentially derived from carbohydrates.**<sup>26</sup>

## Proteins

Additional protein is required during pregnancy for fetal, placental, and maternal tissue development. During the course of the pregnancy, an average of 925 g of protein are stored, which is required for the tissue development. **Maternal protein synthesis increases to support expansion of the blood volume, uterus, and breast tissue.** Fetal and placental proteins are synthesized from amino acids supplied by the mother. Protein recommendations are therefore increased from 46 g/day for an adult, nonpregnant woman to 71 g/day during pregnancy. This represents a change in protein recommendation from 0.8 g/kg/day for nonpregnant women to 1.1 g/kg/day during pregnancy.<sup>20</sup>

## Omega-3 Fatty Acids

Polyunsaturated fatty acids (PUFAs) are an essential component of neural tissue and are found in high concentrations in membrane phospholipids of the gray matter and the retina. These critically important fatty acids cannot be synthesized by the body and thus must be consumed in the diet as either linoleic or  $\alpha$ -linolenic acid. After ingestion,  $\alpha$ -linolenic acid is converted to its biologically active forms, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). The amount of fatty acids that are transported to the fetus depends both on maternal dietary intake and placental function. With n-3 PUFA supplementation, randomized, placebo-controlled studies have shown a positive relationship between maternal intake and umbilical cord concentrations.<sup>27</sup>

The best dietary sources for PUFAs are seafood—namely, oily fish such as salmon, sardines, and anchovies—as well as oils from some plants, such as flax seeds and walnuts.<sup>28,29</sup> **The Food and Drug Administration (FDA) recommends that pregnant women consume 200 to 300 mg/day of DHA, which can be achieved by consuming 1 to 2 servings (8 to 12 ounces) of fish per week. However, the average pregnant or lactating woman consumes only 52 mg/day of DHA and 20 mg/day of EPA.**<sup>30</sup> For those women with insufficient seafood consumption, alternate sources of DHA include fish oil supplements (150 to 1200 mg/day), enhanced prenatal vitamins (200 to 300 mg/day), DHA-enriched eggs (up to 150 mg/egg), and the plant oils listed above.<sup>31</sup> Regarding seafood consumption, the American College of Obstetricians and Gynecologists (ACOG) encourages women who are pregnant, planning to become pregnant, or breastfeeding to follow the updated FDA recommendations to **avoid fish with the highest mercury concentration, specifically tilefish, shark, swordfish, and king mackerel. They should also limit consumption of white albacore tuna to 6 oz/week.**<sup>32</sup>

During the third trimester of pregnancy and the first 2 years of infancy, brain development occurs rapidly, and DHA supplementation has been well studied during this period.<sup>33</sup> **The best evidence in support of PUFA supplementation comes from studies that show a positive relationship between PUFA supplementation and neurodevelopmental outcomes in children.**<sup>34,35</sup> Results of randomized, controlled trials have generally supported these findings. For example, one study used cod liver

oil supplementation from 18 weeks gestational age until 12 weeks postpartum and found children's mental processing scores at 4 years of age correlated significantly with maternal intake of DHA.<sup>35</sup> However, other randomized, controlled trials have found no difference in cognitive and language scores between offspring of women supplemented with fish oil during pregnancy and those who received placebo.<sup>36</sup> A recently published follow-up study showed that at 18 months of age, children of mothers who were supplemented with 800 mg of DHA during pregnancy showed no difference in mean cognitive, language, or motor scores, although fewer children in the DHA group had delayed development compared with controls.<sup>37</sup>

In addition to the well-studied effects of PUFA on fetal brain development, much interest has been paid to other potential benefits of DHA supplementation during pregnancy. For instance, dietary supplementation with PUFA has been promoted as a means to prolong gestation and prevent prematurity. This hypothesis originated after an epidemiologic study compared the diets of women in Denmark to those of the Faroe Islanders, and researchers noted that the seafood-based diet of the island population was associated with higher birthweight (+225 g) at term.<sup>38</sup> This association spawned subsequent research; however, a **Maternal Fetal Medicine Network trial did not find evidence that fish oil supplementation decreased the risk of preterm delivery in high-risk patients.**<sup>39</sup> However, moderate fish intake of up to three meals/week before 22 weeks gestation was associated with a decreased risk of preterm birth.<sup>40</sup> Although older trials of PUFA supplementation purported an increase in birthweight because of prolonged gestational age,<sup>41</sup> more recent trials have reported a *decrease* in birthweight after adjusting for gestational age.<sup>42,43</sup> Thus at present, evidence is insufficient to recommend PUFA supplementation as a means to reduce the risk of preterm birth.

## VITAMIN AND MINERAL SUPPLEMENTATION GUIDELINES

### Dietary Reference Intakes

To address the changing nutritional needs of the American population, the Food and Nutrition Board of the IOM established the first Dietary Reference Intakes (DRIs) in 1997. These values moved beyond the traditional Recommended Daily Allowances (RDAs) to focus on the prevention of chronic disease, and **the DRIs provide a range for safe and appropriate intake, as well as tolerable upper limit, based on the available research. The DRIs include four dietary reference values for every life stage and gender group.** These include (1) estimated average requirement, (2) recommended dietary allowance, (3) adequate intake, and (4) tolerable upper intake level (UL). At present, DRIs have been established for vitamin A, the carotenoids, the B vitamins, vitamin C, vitamin D, vitamin K, folate, calcium, choline, chromium, copper, fluoride, iodine, iron, magnesium, manganese, molybdenum, phosphorus, biotin, pantothenic acid, selenium, and zinc. Recommendations regarding the intake of other nutrients will be available over the next decade as the scientific evidence is evaluated (Table 7-5).<sup>44</sup>

### Tolerable Upper Intake Level

The UL is the highest level of daily nutrient intake that is unlikely to pose risks of adverse health effects to almost all (97% to 98%) of the individuals in a specified life stage and gender group (see Table 7-5).

Routine vitamin/mineral supplementation for women who report appropriate dietary intake and demonstrate adequate weight gain (without edema) is not mandatory. However, **most health care providers prescribe a prenatal vitamin and mineral supplement because many women do not meet their nutritional requirements during the first trimester, especially with regard to folic acid and iron.**

## Vitamins

### Vitamin A

Vitamin A is a fat-soluble vitamin that exists in various compounds, including retinal, retinyl esters, retinol, and retinoic acid. Retinoic acid is the most active form of vitamin A. Retinol is considered preformed vitamin A. In plants, vitamin A exists in its precursor forms, such as provitamin A, carotenoids (e.g. beta-carotene), and cryptoxanthin. Vitamin A is required for cell differentiation, regulation of gene expression, and for the development of the vertebrae, spinal cord, limbs, heart, eyes, and ears.

Severe vitamin A deficiency is rare in the United States, and an adequate intake of vitamin A is readily available in a healthy diet. Women with lower socioeconomic status, however, may consume diets with inadequate amounts of vitamin A. Vitamin A deficiency during pregnancy weakens the immune system, increases risk of infection, and has been linked with night blindness. However, increasing dietary intake of vitamin A is advised, rather than supplementation, because excess retinol intake is a known human teratogen. Excess vitamin A causes abnormalities of the cranial neural crest cells, resulting in cardiac and craniofacial defects that include microcephaly.<sup>45</sup>

The DRI for vitamin A during pregnancy is 770 µg/day, and the tolerable UL has been established at 3000 µg/day.<sup>46</sup> **Over-the-counter multivitamin supplements may contain excessive doses of vitamin A and therefore should be discontinued during pregnancy. Additionally, topical creams that contain retinol derivatives, commonly used to treat acne, should be avoided during pregnancy and in women trying to conceive.**

### Vitamin D

Vitamin D intake is essential for proper absorption of calcium, normal bone health, and skeletal homeostasis. **During pregnancy, vitamin D is also critically important for fetal growth and development as well as for regulation of genes associated with normal implantation and angiogenesis.** Low maternal vitamin D status has been associated with reduced intrauterine long-bone growth, shorter gestation, congenital rickets, and fractures in the newborn. Low maternal vitamin D status may also have consequences for fetal imprinting that may affect neurodevelopment, immune function, and chronic disease susceptibility soon after birth and later in life.

Maternal vitamin D status may also be an independent risk factor for preeclampsia, and supplementation may be helpful in preventing this complication and in promoting neonatal well-being.<sup>47</sup> However, these data come from observational studies, and prospective cohort studies have not found an association.<sup>48</sup> A recent multicenter European trial examined whether vitamin D supplementation (1600 IU/day) can improve maternal glucose metabolism.<sup>49</sup>

The recommended intake of vitamin D during pregnancy and lactation is 600 IU/day.<sup>50</sup> Recent studies have shown that low maternal vitamin D levels are common during pregnancy, even in patients who take daily prenatal vitamins that contain 400 IU

**TABLE 7-5** DIETARY REFERENCE INTAKES: RECOMMENDED DAILY INTAKES FOR INDIVIDUALS

| VITAMIN/MINERAL              | AGE (YR) | NONPREGNANT | PREGNANT | UPPER INTAKE LEVELS |
|------------------------------|----------|-------------|----------|---------------------|
| Vitamin A (μg)               | <18      | 700         | 750-1200 | 2800                |

DRI's are included for calcium, phosphorous, magnesium, vitamin D, and fluoride (1997); for thiamin, riboflavin, niacin, vitamins B<sub>6</sub> and B<sub>12</sub>, folate, pantothenic acid, biotin, and choline (1998); for vitamins C and E, selenium, and the carotenoids (2000); for vitamins A and K, arsenic, boron, chromium, copper, iodine, iron, manganese, molybdenum, nickel, silicon, vanadium, and zinc (2001); and for calcium and vitamin D (2011). Reports were accessed April 24, 2015; available online at <http://www.iom.edu/Activities/Nutrition/SummaryDRIs/DRI-Tables.aspx>.

ND, not determined.

of vitamin D. Lee and colleagues<sup>51</sup> found that 50% of mothers and 65% of newborns infants were significantly vitamin D deficient at the time of birth despite daily supplementation with 400 IU of vitamin D and drinking two glasses of vitamin D fortified milk. Poor vitamin D status is also significantly more common among black pregnant women.<sup>52,53</sup>

**Vitamin D supplementation is advised for women who are strict vegetarians, those with limited exposure to sunlight, and those who avoid dairy foods. To evaluate vitamin D levels during a preconception or prenatal visit, serum 25-hydroxy-D levels should be evaluated.** Most experts agree that 20 ng/mL (50 nmol/L) are needed daily for optimal bone health. Supplementation with 1000 to 4000 IU per day of vitamin D is safe during pregnancy.<sup>54</sup>

### Vitamin C

Vitamin C, also known as *ascorbic acid*, is a water-soluble vitamin and antioxidant that functions to reduce free radicals and also aids in procollagen formation. Adequate vitamin C is also needed for iron uptake. Women who smoke have an increased need for vitamin C. Current recommendations indicate that pregnant women should consume 85 mg/day rather than the 75 mg/day recommended for nonpregnant adult women. The increased requirement protects against depleted plasma vitamin C levels and ensures that adequate vitamin C is transported to the developing fetus. No human studies have been done to examine the effects of large doses of vitamin C on fetal growth and development. Because it is known that vitamin C is actively transported from the maternal to the fetal circulation, a tolerable upper intake has been set at 1800 to 2000 mg/day.<sup>55</sup>

**The hypothesis that oxidative stress contributes to development of preeclampsia has spurred interest in the use of antioxidants for prevention of the disease. However, several large, randomized placebo-controlled studies and a Cochrane review have shown no benefit.<sup>56</sup> Thus supplementation with antioxidant vitamins C and E for the prevention of preeclampsia is *not* recommended.<sup>57</sup>**

### Vitamin B<sub>6</sub>

Vitamin B<sub>6</sub>, also known as *pyridoxine*, is a water-soluble B-complex vitamin that serves as a coenzyme in protein, carbohydrate, and lipid metabolism. Vitamin B<sub>6</sub> is involved in the synthesis of heme compounds and aids in the formation of maternal and fetal red blood cells, antibodies, and neurotransmitters. **Research shows that supplemental vitamin B<sub>6</sub> is**

**effective at relieving nausea and vomiting during pregnancy.<sup>58</sup>**

Whereas a recent Cochrane review of hyperemesis protocols could not draw firm conclusions about the efficacy of vitamin B<sub>6</sub>, evidence was sufficient for ACOG to support monotherapy with B<sub>6</sub> as a first-line treatment to reduce nausea and vomiting (10 to 25 mg three times a day).<sup>59,60</sup> Because excessive amounts of vitamin B<sub>6</sub> can cause numbness and nerve damage, the tolerable upper intake level for pregnant women was established at 100 mg/day.

### Vitamin K

Vitamin K, a fat-soluble vitamin, is required for synthesis of clotting factors II, VII, IX, and X. Transportation of vitamin K from mother to fetus is limited; nevertheless, significant bleeding problems in the fetus are rare. However, newborn infants are often functionally deficient in vitamin K and receive parenteral supplementation at birth. The DRI for vitamin K is 90 mg for pregnant and nonpregnant women; the tolerable UL has not been established.<sup>55</sup>

### Folate

Folate and its metabolically active form tetrahydrofolate function as coenzymes in one-carbon transfer reactions for the synthesis of nucleic acids and several amino acids. **Therefore adequate levels of dietary folate are important for fetal and placental development and are needed to support rapid cell growth, replication, cell division, and nucleotide synthesis.<sup>61</sup>** Because embryonic neural tube closure is complete by 18 to 28 days after conception, it is critical that pregnant women consume adequate folate before and during the first 4 weeks of embryologic development (6 weeks gestational age by last menstrual period [LMP]). Demand for folate is also increased during the second and third trimesters to support maternal erythropoiesis.

Unfortunately, folate deficiency is the most prevalent vitamin deficiency during pregnancy.<sup>62</sup> Folate deficiency in humans is attributed to suboptimal dietary intake, behavioral and environmental factors, and genetic defects. Humans cannot synthesize folate and are therefore entirely dependent on dietary sources or supplements to meet their requirements. In 1992, the U.S. Centers for Disease Control and Prevention (CDC) recommended that all women of childbearing age take 400 µg/day of supplemental folate to ensure the presence of adequate folate levels when pregnancy occurs, whether intended or not.<sup>63</sup> **The DRI for folate in women of childbearing age is 400 µg/day;**

for pregnant women it is 600 µg/day. The tolerable UL for folate has been established at 1000 µg/day. Additionally, evidence suggests that the long-term use of oral contraceptives inhibits folate absorption and enhances folate degradation in the liver.<sup>64</sup> Therefore folate stores may be more rapidly depleted in women who have used oral contraceptives, which may lead to a higher incidence of folate deficiency in such women if they become pregnant.

FOLATE AND NEURAL TUBE DEFECTS

Neural tube defects (NTDs) occur in 1.4 to 2 per 1000 pregnancies and are second only to cardiac anomalies in terms of the most common congenital malformations worldwide.<sup>65</sup> Prevalence varies according to race and ethnicity. Hispanic women have the highest rates, whereas black women and Asian women have the lowest rates.<sup>66</sup> Women who have had a previous pregnancy affected by an NTD or who are personally affected by an NTD are at a higher risk (2% to 3%).<sup>67</sup> A family history of a close family member (sibling, niece, or nephew) with an NTD raises a woman's risk of an affected pregnancy to approximately 1%, as does maternal diabetes or the consumption of certain antiepileptic medications such as valproic acid or carbamazepine. A higher risk of NTDs is also associated with increased maternal weight.<sup>68</sup> However, 95% of children with NTDs are born to couples without any family history of NTDs.<sup>69</sup>

The etiology of NTDs is thought to be insufficient folate intake coupled with the increased folate demands of pregnancy. A genetic defect in the production of enzymes involved in folate metabolism has also been linked to NTDs.<sup>62</sup> The neural tube is formed very early in pregnancy, between 18 and 28 days post conception. Defects in the formation of the neural tube include the absence of brain formation (anencephaly), defects in the closure of the lower tube (spina bifida), and open NTDs (meningoceles and myoceles). **The early formation and the detrimental effects of folate deficiency on neural tube formation are the basis behind the recommendation that folate supplementation begin prior to conception and be continued at least through the first trimester of pregnancy.**<sup>70</sup>

FOLATE SUPPLEMENTATION

Several randomized, controlled, and observational trials have shown that periconceptional and early pregnancy consumption of folate supplements can reduce a woman's risk for having an infant with an NTD by as much as 50% to 70%.<sup>62</sup> Since the U.S. government began the Folate Fortification Program in 1998, cereals, pastas, rice, and breads have been fortified with folate, and NTD rates have declined.<sup>66</sup> Using data from eight population-based birth defect surveillance systems with prenatal diagnosis of NTDs, the CDC reported that the prevalence of NTDs in the United States declined from an estimated 4000 cases between 1995 and 1996 to 3000 cases from 1999 through 2000.<sup>71</sup> This 26% decrease in NTD-affected pregnancies highlights the success of this public health policy. Using a similar level of folate fortification, a Canadian study showed a 46% reduction in the prevalence of NTDs.<sup>72</sup> The higher baseline rate of NTDs compared with the United States might explain the greater risk reduction.

In women with a previous pregnancy affected by an NTD, research has shown that supplementation with 4000 µg/day (4 mg/day of folate initiated at least 1 month prior to attempting to conceive and continued throughout the first trimester of pregnancy reduced the risk of a repeat NTD

TABLE 7-6      DIAGNOSIS OF ANEMIA IN PREGNANCY

| Hemoglobin (g/dL) | <11             | 10.5             | <11             |
| Hematocrit (%)    | <33             | 32               | <33             |

Data from U.S. Centers for Disease Control and Prevention ([www.cdc.gov](http://www.cdc.gov)).

by 72%.<sup>61</sup> Whereas no definitive evidence proves that other high-risk groups such as close family members of affected individuals, diabetics, or women on antiepileptic medications will benefit from higher levels of supplementation, many experts recommend a higher dose of folate—at least 1000 µg/day—before conception and in early pregnancy. For these women, a separate folate supplement should be prescribed; additional doses of multivitamins should not be used. Additional daily multivitamin consumption could lead to toxicity of other vitamins, particularly vitamin A, which is teratogenic to the developing fetus.<sup>63</sup>

Minerals

Iron

Iron is an essential component of hemoglobin production, and requirements increase significantly during pregnancy. **Additional iron is needed to expand maternal red cell volume by 20% to 30%, and iron is also required for fetal and placental tissue production.** Throughout pregnancy, an additional 450 mg of iron is delivered to the maternal marrow, and 250 mg of iron is depleted from blood loss during delivery. It is estimated that approximately 1000 mg of iron is required during pregnancy. The DRI has been established at 27 mg/day in pregnancy, compared with 18 mg/day for nonpregnant women. The tolerable upper intake for iron has been established at 45 mg/day.<sup>46</sup>

Maintaining adequate iron stores is important but difficult for many women during pregnancy. According to the CDC, screening for anemia should take place prior to pregnancy and during the first, second, and third trimesters in high-risk individuals, as shown in Table 7-6. Iron deficiency anemia increases the risk of maternal and infant death, preterm delivery, and low neonatal birth weight. Anemia also negatively impacts normal infant brain development and function. The prevalence of iron deficiency in pregnancy is higher in black women, low-income women, teenagers, women with less than a high school education, and women with multiple gestations.<sup>73</sup>

As shown in Table 7-6, hemoglobin less than 11 g/dL or hematocrit below 33% in the first or third trimester indicates anemia. Hemoglobin less than 10.5 g/dL or hematocrit below 32% in the second trimester also indicates anemia.

Additional laboratory findings include microcytic hypochromic anemia with evidence of depleted iron stores, low plasma iron levels, high total iron-binding capacity, and low serum ferritin levels. Ferritin levels less than 10 to 15 µg/L have the highest sensitivity and specificity for diagnosing iron deficiency in the anemic patient.

Prenatal care providers generally recommend daily iron supplementation with 30 mg of elemental iron in the form of simple salts beginning around the twelfth week of pregnancy for women who have normal preconception hemoglobin measurements (Table 7-7).<sup>74</sup> For women who are pregnant with multiples or for those with low preconception hemoglobin levels, a supplement of between 60 and 100 mg/day of elemental

**TABLE 7-7 ORAL IRON SUPPLEMENTS**

| ORAL SUPPLEMENT   | ELEMENTAL IRON  |
|-------------------|-----------------|
| Ferrous fumarate  | 106 mg/tablet   |
| Ferrous sulfate   | 65 mg/tablet    |
| Ferrous gluconate | 28-36 mg/tablet |

Data from the American College of Obstetricians and Gynecologists. ACOG Practice Bulletin No. 95: Anemia in pregnancy. *Obstet Gynecol.* 2008;112(1):201-207.

iron is recommended until hemoglobin concentrations have normalized, after which supplementation can be decreased to 30 mg/day.<sup>75</sup>

For women with severe iron deficiency, those who cannot tolerate oral iron, or those with malabsorption syndromes, parenteral iron can be used. Parenteral iron is especially valuable for increasing hemoglobin levels faster than oral iron. One randomized, controlled trial of oral versus intravenous (IV) iron sucrose showed that IV iron significantly increased hemoglobin levels after both 5 and 14 days, whereas women treated with an oral supplement showed no improvement. However, by day 40, no significant difference between the hemoglobin levels of the two groups was noted.<sup>76</sup>

Iron supplements may produce gastrointestinal (GI) side effects, namely constipation and nausea, which should be taken into account when prescribing the course of treatment. Deferring supplementation until the second trimester, when iron requirements increase and nausea has waned, may be helpful to improve adherence. Nausea resulting from iron supplements can be minimized by taking the supplement following a meal; however, this may decrease total iron absorption. Recommending bulk laxatives and/or stool softeners when prescribing iron supplements may also improve adherence.

Antacids impair iron absorption and should not be taken concurrently; this is of particular importance during the third trimester, when gastroesophageal reflux is common. Iron is better absorbed if the maternal diet contains adequate amounts of vitamin C. Occasionally, pregnant women develop pica and ingest nonfood substances such as clay, dirt, or ice. Iron deficiency has been postulated to cause pica, but certain cultural influences may also lead to these practices. Pregnant women with iron deficiency should be questioned about ingestion of these nonfood substances, and women experiencing pica should be tested for iron deficiency. Pica is mostly of concern if it prevents the mother from consuming nutrient-rich foods or if the materials she consumes contain toxic components.

### Calcium

Large quantities of calcium are essential for the development of the fetal skeleton and tissues and for hormonal adaptations during pregnancy. These include changes in calcium regulatory hormones that affect intestinal absorption, renal reabsorption, and bone turnover of calcium. The presence of 1,25(OH)<sub>2</sub>D<sub>3</sub> stimulates increased intestinal absorption of calcium during the second and third trimesters, which protects maternal bone while meeting fetal calcium requirements. In contrast to maternal iron and folate stores, which are relatively small and easily depleted, maternal calcium stores are large and are mostly stored skeletally, allowing for easy mobilization. Fetal calcium needs are highest during the third trimester, when the fetus utilizes an average of 300 mg/day in response to the increased maternal 1,25(OH)<sub>2</sub>D<sub>3</sub>. Studies suggest that inadequate calcium during pregnancy is

associated with gestational hypertension, preterm delivery, and preeclampsia.<sup>77,78</sup>

The DRI for calcium in pregnant women 19 to 50 years old is 1000 mg/day, and it is 1300 mg/day for adolescent females ages 9 to 19. Adolescents may need additional calcium during pregnancy because their own bones still require calcium deposition to ensure adequate bone density. The tolerable upper intake for calcium during pregnancy is 2500 mg/day.<sup>79</sup> Obtaining adequate dietary calcium is difficult for many women before and during pregnancy, and supplementation may be needed, especially for black, Hispanic, and Native American women. Consuming at least three servings of dairy foods every day, including calcium-fortified juices and beverages, can help meet these requirements. Women who limit their intake of dairy foods because of lactose intolerance may be able to tolerate yogurt and cheese on a daily basis but may also require a supplement. Calcium carbonate, gluconate, lactate, or citrate may provide 500 to 600 mg/day of calcium to account for the difference between the amount of calcium required and that consumed. **The standard prenatal vitamin typically contains 150 to 300 mg per tablet.** Multivitamins marketed to the nonpregnant population generally have less than 200 mg per tablet. Calcium is thought to be absorbed in doses of 600 mg at one time, making it unlikely that pregnant women would reach the upper tolerable limit.

The data concerning the role of calcium in preventing pregnancy-induced hypertension or preeclampsia remain controversial. Whereas calcium supplementation has been shown to decrease blood pressure and preeclampsia in smaller studies, larger trials have failed to show an effect.<sup>78,80</sup> Evidence has shown that calcium supplementation reduces the risk of developing hypertension during pregnancy but only in women who did not have adequate calcium intake prior to supplementation.<sup>63</sup> It is prudent to ensure women are meeting their calcium requirements for their age and to stress the importance of adequate calcium intake before and during pregnancy.

### Zinc

Zinc is involved in catalytic, structural, and regulatory functions for nucleic acid and protein metabolism. More than 100 enzymes require zinc, and maternal zinc deficiency can lead to prolonged labor, IUGR, teratogenesis, and embryonic or fetal death.<sup>52</sup> The DRI for pregnant women is 11 mg/day and may be higher for vegetarians or vegans because phytates from whole grains and beans bind with zinc and can reduce absorption. The tolerable upper intake for zinc has been established at 40 mg/day for both pregnant and nonpregnant women. Pregnant women who eat well-balanced diets do not typically require zinc supplementation. However, if a woman is prescribed more than 60 mg/day of elemental iron, zinc supplementation is recommended because iron competes with zinc for absorption.

### Choline

Choline is an essential nutrient needed for cell signaling and structural cell membrane integrity. It is critical for stem cell proliferation and apoptosis. Demand for choline is high during pregnancy because maternal choline is transported to the fetus to aid in brain and spinal cord development.<sup>81</sup> Adequate choline is needed for normal fetal neural development and function, and it is essential for memory.<sup>82</sup> Choline is derived not only from the diet but also from de novo synthesis. The current recommendation for choline during pregnancy is 450 mg/day, and it

is 550 mg/day for breastfeeding mothers. Dietary sources of choline include eggs (126 mg/egg), tofu (100 mg/3 oz), lean beef (67 mg/3 oz), Brussels sprouts (62 mg/cup cooked), cauliflower (62 mg/¾ cup cooked), navy beans (48 mg/½ cup cooked), peanut butter (20 mg/2 tablespoons), and skim milk (38 mg/cup).

## NUTRITION-RELATED PROBLEMS DURING PREGNANCY

### Nausea and Vomiting

During pregnancy, nausea and vomiting commonly occur between 5 and 18 weeks of gestation and typically improve by 16 to 18 weeks. As many as 15% to 20% of women experience these symptoms until the third trimester, and 5% of women suffer these up until delivery. Between 50% and 90% of women have some degree of nausea with or without vomiting, but only a small percentage of these require hospitalization for severe hyperemesis gravidarum.<sup>83</sup> **Women with hyperemesis may vomit multiple times throughout the day, lose more than 5% of their prepregnancy body weight, and usually require hospitalization for dehydration and electrolyte replacement.**

The causes of pregnancy-related nausea and vomiting are unclear but may be related to increased levels of human chorionic gonadotropin (hCG), which doubles every 48 hours in early pregnancy and peaks at about 12 weeks gestation. Studies show that women are more likely to have nausea or vomiting during pregnancy if they (1) are pregnant with twins or higher multiples; (2) have a history of nausea and vomiting in a previous pregnancy; (3) have a history of nausea or vomiting as a side effect of taking birth control pills; (4) have a history of motion sickness; (5) have a relative (mother or sister) who had morning sickness during pregnancy; or (6) have a history of migraine headaches.

Strategies for managing nausea and vomiting during pregnancy are shown in [Box 7-1](#). **After following these recommendations, vitamin B<sub>6</sub> (10 to 25 mg three times daily) can be considered as first-line treatment for nausea and vomiting during pregnancy.** Ginger and acupuncture may also be helpful to treat nausea during pregnancy.<sup>58,84</sup>

#### BOX 7-1 STRATEGIES FOR MANAGING NAUSEA, VOMITING, HEARTBURN, AND INDIGESTION IN PREGNANCY

- Eat small, low-fat meals and snacks (fruits, pretzels, crackers, nonfat yogurt).
- Eat slowly and frequently.
- Avoid strong food odors by eating room temperature or cold foods and using good ventilation while cooking.
- Drink fluids between meals rather than with meals.
- Avoid foods that may cause stomach irritation such as spearmint, peppermint, caffeine, citrus fruits, spicy foods, high-fat foods, or tomato products.
- Wait 1-2 hours after eating a meal before lying down.
- Take a walk after meals.
- Wear loose-fitting clothes.
- Brush teeth after eating to prevent symptoms.

Courtesy Lisa Hark, PhD, RD.

### Heartburn and Indigestion

Heartburn and indigestion affect two thirds of pregnant women and are usually caused by gastric content reflux that results from both lower esophageal pressure and decreased motility secondary to increased progesterone.<sup>84</sup> Limited gastric capacity due to a shift of organs to accommodate the growing fetus contributes to these symptoms in the third trimester of pregnancy. Strategies for managing heartburn and indigestion are also shown in [Box 7-1](#).

### Constipation

Fifty percent of pregnant women experience constipation at some point during their pregnancy, which is often associated with straining, hard stools, and incomplete evacuation rather than infrequent defecation. Constipation during pregnancy is associated with smooth muscle relaxation, an increase in water reabsorption from the large intestine, and slower GI motility. Pregnant women often note overall GI discomfort, a bloated sensation, an increase in hemorrhoids and heartburn, and decreased appetite. Constipation can also be aggravated by iron supplements. Strategies for managing constipation during pregnancy are shown in [Box 7-2](#).

### Food Contamination

Both the pregnant woman and her unborn fetus are more susceptible to food poisoning secondary to hormonal changes associated with pregnancy. **Pathogens of special concern during pregnancy include *Listeria monocytogenes*, *Toxoplasma gondii*, *Salmonella* species, and *Campylobacter jejuni*.** These organisms can cross the placenta and therefore pose a risk of foodborne infection to the developing fetus.<sup>85</sup> To avoid listeriosis, pregnant women should be advised to wash vegetables and fruits well; cook all meats to minimum safe internal temperatures; avoid processed, precooked meats (cold cuts, smoked seafood, pâté) and soft cheeses (brie, blue cheese, Camembert, and Mexican *queso blanco* [white cheese]); and only consume dairy products that have been pasteurized. All foods should be handled in a sanitary and appropriate manner to prevent bacterial contamination. Toxoplasmosis can be passed to humans by water, dust, and soil or by eating contaminated foods, and cats are the main host of *T. gondii*. Toxoplasmosis most often results from eating raw or uncooked meat, unwashed fruits and vegetables, and by cleaning a cat's litter box or handling contaminated soil. *Salmonella* and *Campylobacter* can be found in raw, unpasteurized milk; raw or undercooked meat and poultry; eggs,

#### BOX 7-2 STRATEGIES FOR MANAGING CONSTIPATION IN PREGNANCY

- Increase fluid intake by drinking water, herbal teas, and noncaffeinated beverages.
- Increase daily fiber intake by eating high-fiber cereals, whole grains, legumes, and bran.
- Use a psyllium fiber supplement (e.g., Metamucil).
- Increase consumption of fresh, frozen, or dried fruits and vegetables.
- Participate in moderate physical activity such as walking, swimming, or yoga.
- Take stool softeners in conjunction with iron supplementation.

Courtesy Lisa Hark, PhD, RD.

salads, cream desserts, and dessert fillings; and untreated water. To avoid infection, pregnant women should wash their hands often, especially after handling animals or working in the garden, and they should avoid undercooked food and unpasteurized juices. All surfaces that come into contact with raw meat, fish, or poultry should also be washed with hot soapy water.<sup>85</sup>

Food contaminated with heavy metals can also produce devastating neurotoxic and teratogenic effects in the developing fetus that may result in miscarriage, stillbirth, premature labor, or other fetal complications.<sup>86</sup> In particular, case reports of teratogenicity or embryotoxicity have been reported with exposure to methyl mercury, lead, cadmium, nickel, and selenium. Mercury can be removed from vegetables by peeling them or by washing them well with soap and water. All dairy foods and juices consumed during pregnancy should be pasteurized.<sup>87-89</sup>

## SPECIAL NUTRITIONAL CONSIDERATIONS DURING PREGNANCY

### Caffeine

Caffeine is metabolized slowly in pregnancy and passes readily through the placenta to the fetus. **Moderate caffeine intake is common during pregnancy, however, women who are pregnant or trying to become pregnant should limit their caffeine intake to no more than 200 mg/day**, the equivalent of one 12-ounce cup of coffee. Other sources of caffeine include teas, hot cocoa, chocolate, energy drinks, coffee ice cream, and soda. Many studies have looked for a correlation between high caffeine intake and miscarriage, preterm birth, and IUGR. Review of the available literature reveals that moderate caffeine consumption (<200 mg per day) is not a major contributing factor to miscarriage or preterm birth.

### Vegetarian and Vegan Diets

Balanced vegetarian diets—those that exclude meat, fish, and poultry but still include dairy and eggs—have not been linked to any significant health effects during pregnancy.<sup>90</sup> Research from vegetarian populations worldwide reveals that macronutrient intake of pregnant vegetarians is similar to that of pregnant nonvegetarians, except that vegetarians consume less protein and more carbohydrates. **Vegan diets—those that exclude all animal products, including eggs and dairy—may provide insufficient iron, essential amino acids, trace minerals (zinc), vitamin B<sub>12</sub>, vitamin D, calcium, and PUFAs to support normal embryonic and fetal development. Thus it is recommended that patients who follow a vegan diet meet with a dietitian early during the pregnancy to analyze their nutritional intake and assess any necessary supplementation that should be added.** For example, fortified vegetarian food products are now widely available and include some nondairy milk with added calcium and vitamin D, meat substitutes that contain protein, and fortified juice and breakfast cereals.<sup>90</sup>

### Herbal Supplements

Because of the unregulated nature of herbal supplements, they are generally not recommended for consumption during pregnancy. In addition, data are sparse regarding their use during pregnancy, and the strength and purity of supplements can vary widely among products and manufacturers. Despite this, the consumer market for complementary and alternative treatments continues to grow. Studies have shown that pregnant women often choose herbal supplements because their use represents a

holistic approach to health and overall wellness. The best-studied herb in the pregnancy literature is ginger, which has been used for centuries for nausea and vomiting.<sup>91</sup> Experts recommend a trial of 250 mg capsules three times daily or consumption of ginger tea. **Whereas countless other herbs and supplements certainly hold potential benefits, more research is needed before any of these supplements can be safely recommended in pregnancy.**

## KEY POINTS

- ◆ Pregnant women may need as much as an additional 300 kcal/day for the entire pregnancy, but requirements may be significantly less and vary among individuals.
- ◆ The Institute of Medicine recommendations for gestational weight gain for women are set by weight category: underweight (BMI <18.5; 28 to 40 lb), normal weight (BMI 18.5 to 24.9; 25 to 35 lb), overweight (BMI 25.0 to 29.9; 15 to 35 lb), and obese (BMI >30; 11 to 20 lb).
- ◆ Protein requirements during pregnancy increase from 0.8 g/kg/day for nonpregnant women to 1.1 g/kg/day during pregnancy.
- ◆ The daily recommended intake for folate in women of childbearing age is 400 µg/day; for pregnant women, it is 600 µg/day. Women whose fetuses are at high risk of a neural tube defect should be prescribed a higher dose of folate (4 mg/day) both before conception and in early pregnancy.
- ◆ Iron supplementation is often prescribed during pregnancy because of the (20% to 30%) expanded maternal red cell mass as well as for fetal and placental tissue production. Iron supplements can cause GI side effects such as constipation.
- ◆ Vitamin D supplementation is often required during pregnancy in women with specific dietary preferences or for those with minimal exposure to sunlight. To evaluate vitamin D concentrations before and during pregnancy, check serum 25(OH)D levels and aim for concentrations of 25(OH)D of greater than 20 nmol/L. The DRI for vitamin D is 600 IU/day in all pregnant and reproductive-age women.
- ◆ The DRI for calcium in nonpregnant and pregnant women 19 to 50 years of age is 1000 mg/day, and it is 1300 mg/day for females 9 to 19 years of age.
- ◆ Many common GI problems during pregnancy—such as heartburn, nausea and vomiting, and constipation—are improved with proper nutritional counseling.

## OVERVIEW

The placenta allows the transfer of many drugs and dietary substances. Lipid-soluble compounds readily cross the placenta, and water-soluble substances pass less well the greater their molecular weight. The degree to which a drug is bound to plasma protein also influences the amount of drug that is free to cross the placenta. **Virtually all drugs cross the placenta to some degree, with the exception of large molecules such as heparin and insulin.**

Developmental defects in humans may result from genetic, environmental, or unknown causes. Approximately 25% are unequivocally genetic in origin; drug exposure accounts for only 2% to 3% of birth defects. Approximately 65% of defects are of unknown etiology, but most are thought to be combinations of genetic and environmental factors.

**The incidence of major malformations in the general population is 2% to 3%.<sup>1</sup>** A *major malformation* is defined as one that is incompatible with survival, such as anencephaly; one that requires major surgery for correction, such as cleft palate or congenital heart disease; or one that produces major dysfunction, such as mental retardation. If minor malformations are also included, such as ear tags or extra digits, the rate may be as high as 7% to 10%. The risk of malformation after exposure to a drug must be compared with this background rate.

Species specificity is marked in drug teratogenesis. For example, thalidomide was not found to be teratogenic in rats and mice but is a potent human teratogen. However, it was thought that the original animal studies were flawed because subsequent studies found teratogenicity in mice, rats, rabbits, and monkeys. Animal studies can be used to estimate human risk in about 24% of drugs.

The Teratology Society suggested abandoning the U.S. Food and Drug Administration (FDA) letter classification,<sup>2</sup> and 20 years later, this has finally occurred. The categories implied that risk increases from category A to X. However, the drugs in different categories may pose similar risks but be in different categories based on risk/benefit considerations. The categories create the impression that drugs within a category present similar risks, whereas the category definition permits inclusion in the same category of drugs that vary in type, degree, or extent of risk, depending on potential benefit. The risks and benefits of a drug's use in pregnancy are described in this chapter.

**The categories were designed for prescribing physicians and not to address inadvertent exposure. For example, isotretinoin and oral contraceptives were both category X based on lack of benefit for oral contraceptives during pregnancy, yet oral contraceptives do not have any teratogenic risk with inadvertent exposure.** When counseling

patients or responding to queries from physicians, we recommend using specific descriptions from teratogen information databases (Box 8-1).

**The classic teratogenic period is from day 31 after the last menstrual period (LMP) in a 28-day cycle to 71 days from the LMP (Fig. 8-1). During this critical period, organs are forming, and teratogens may cause malformations that are usually overt at birth.** Timing of exposure is important. Administration of drugs early in the period of organogenesis affects the organs developing at that time, such as the heart or neural tube. Closer to the end of the classic teratogenic period, the ear and palate are forming and may be affected by a teratogen.

#### BOX 8-1 TERATOGEN INFORMATION DATABASES

- **Reproductive Toxicology Center (REPROTOX).** 7831 Woodmont Avenue, Suite 375, Bethesda, MD 20814; phone 301-514-3081; [www.reprotox.org](http://www.reprotox.org)
- **Organization of Teratology Information Services (OTIS).** Medical Center, 200 W. Arbor Drive, #8446, San Diego, CA 92103-9981; phone 886-626-6847; [www.otispregnancy.org](http://www.otispregnancy.org)

**Before day 31, exposure to a teratogen produces an all-or-none effect.** With exposure around conception, the conceptus usually either does not survive or survives without anomalies. Because so few cells exist in the early stages, irreparable damage to some may be lethal to the entire organism. If the organism remains viable, however, organ-specific anomalies are not manifested because either repair or replacement will occur to permit normal development. However, a similar insult at a later stage may produce organ-specific defects.

#### BASIC PRINCIPLES OF TERATOLOGY

To understand the etiology of birth defects, it is important to enumerate the principles of abnormal development, or teratogenesis. **Wilson's six general principles of teratogenesis<sup>3</sup> provide a framework for understanding how structural or functional teratogens may act.** Each principle is covered here.

#### Genotype and Interaction With Environmental Factors

**The first principle is that susceptibility to a teratogen depends on the genotype of the conceptus and on the manner in which the genotype interacts with environmental factors.** This is perhaps most clearly shown by experiments in which different genetic strains of mice have varied greatly in their susceptibility

**FIG 8-1** Gestational clock showing the classic teratogenic period. LMP, last menstrual period. (From Blake DA, Niebyl JR. Requirements and limitations in reproductive and teratogenic risk assessment. In: Niebyl JR, ed. *Drug Use in Pregnancy*, 2nd ed. Philadelphia: Lea & Febiger; 1988:2.)

to teratogens that lead to oral clefts. Some of the variability in responses to human teratogens, such as to anticonvulsant drugs such as valproic acid and hydantoin, probably relates to genotype of the embryo. The increasing complexity of these potential interactions is illustrated by a series of elegant studies by Muselman and colleagues.<sup>4</sup>

### Timing of Exposure

**The second principle is that susceptibility of the conceptus to teratogenic agents varies with the developmental stage at the time of exposure.** This concept of *critical stages of development* is particularly applicable to alterations in structure. **Most structural defects occur during the second to the eighth weeks of development after conception, during the embryonic period.** For such defects, it is believed that a critical stage in the developmental process exists after which abnormal embryogenesis cannot be initiated. For example, neural tube defects (NTDs) result from the failure of the neural tube to close. Given that this process occurs between 22 and 28 days postconception, any exogenous effect on development must be present at or before this time. The neural tube has five distinct closure sites that may respond differentially to agents and may respond differently in timing. Investigations of thalidomide teratogenicity have clearly shown that the effects of the drug differ as a function of the developmental stage at which the pregnant woman took the drug.

### Mechanisms of Teratogenesis

**The third principle is that teratogenic agents act in specific ways—that is, via specific mechanisms—on developing cells and tissues in initiating abnormal embryogenesis (pathogenesis).** Teratogenic mechanisms are considered separately below.

### Manifestations

**The fourth principle is that irrespective of the specific deleterious agent, the final manifestations of abnormal development are malformation, growth restriction, functional disorder, and death.** The manifestation is thought to depend largely on the stage of development at which exposure occurred; a teratogen may have one effect if exposure occurs during embryogenesis and another if the exposure is during the fetal period. *Embryonic exposure* is likely to lead to structural abnormalities or embryonic death; *fetal exposure* is likely to lead to functional deficits or growth restriction.

Despite the importance of teratogen timing on specificity of anomalies, a general pattern usually emerges with respect to any given teratogen. This will be evident throughout this chapter as we consider various agents. If no pattern is evident for a purported teratogen, it increases the suspicion that any purported association is spurious, and the observation reflects confounding variables not recognized and, hence, not taken into account.

### Agent

**The fifth principle is that access of adverse environmental influences to developing tissues depends on the nature of the influence (agent).** This principle relates to such pharmacologic factors as maternal metabolism and placental passage. Although most clearly understood for chemical agents or drugs, the principle also applies to physical agents such as radiation or heat. For an adverse effect to occur, an agent must reach the conceptus, either indirectly through maternal tissues or directly by traversing the maternal body.

### Dose Effect

**The final principle is that manifestations of abnormal development increase in degree from the no-effect level to the lethal level as dosage increases.** This means that the response (e.g., malformation, growth restriction) may be expected to vary according to the dose, duration, or amount of exposure. For most human teratogens, this dose response is not clearly understood, but along with the principle of critical stages of development, these concepts are important in supporting causal inferences about human reproductive hazards. Data regarding in utero exposure to ionizing radiation clearly show the importance of dose on observed effects. The potential complexity of relationships between dose and observed effects for teratogens has been noted.

## EPIDEMIOLOGIC APPROACHES TO BIRTH DEFECTS

Teratogens and reproductive toxicants have been identified and are being sought in various ways. Here we enumerate most common approaches, their strengths, and their pitfalls.

### Case Reports

**Many known teratogens and reproductive toxicants were identified initially through case reports of an unusual number of cases or a constellation of abnormalities.** These have often come from astute clinicians who observed something out of the ordinary. Although the importance of astute observations of abnormal aggregations of cases or patterns of malformations must be recognized, we cannot rely on such methods for identifying health hazards. Furthermore, etiologic speculations based on case reports or case series usually do not lead to a causal agent and are often false-positive speculations. **Whereas case reports may identify a new teratogen, they can never provide an estimate of the risk of disease after exposure.**

### Descriptive Studies

**Descriptive epidemiologic studies provide information about the distribution and frequency of some outcome of interest, resulting in rates of occurrence that can be compared among populations, places, or times.** Defining the population at risk is the first step, and this can be done geographically, such as residents within a state, or medically, such as patients at a particular hospital. Definition of the population at risk includes the period under consideration. The population at risk constitutes the *denominator* for calculating rates of the occurrence of outcomes of interest.

The second step in a descriptive study is to determine the *numerator* for calculating rates for comparison. This involves two important concepts: *case definition*, or what defines a case to be counted, and *case ascertainment*, or how cases are to be identified.

Relevant examples of descriptive studies are surveillance programs. An at-risk population is identified and then followed over time to detect outcomes of interest, and cases are included in the database. Surveillance programs can develop baseline data and subsequently permit early recognition of potential problems based on ongoing data collection and analysis. **Birth defect surveillance monitoring systems (BDSMSs) are designed to identify cases that occur in a defined population, usually by reviewing vital records or hospital record abstracts or charts.** In the past 20 years, a dramatic increase has been seen in the

number of state-based birth defect surveillance systems, and approximately half the states now have some type of BDSMS. These programs conduct routine reviews of occurrence rates of specific malformations and attempt to identify increases in rates or clusters of cases.

### Case-Control Studies

**In a case-control study design, groups of individuals (cases) with some outcome or disease of interest (e.g., a congenital malformation) are compared with controls with regard to a history of one or more exposures.** This is the most widely used approach in reproductive outcomes research. Controls are ideally as similar as possible to the cases except of course lacking the outcome of interest. After cases and controls have been identified, the hypothesis to be tested is whether these two groups differ in exposure as well as outcome. How accurately exposure and its timing are determined may vary greatly among studies, but in any study, the same methods must be used to establish the exposure of both cases and controls.

Case-control studies are advantageous in testing outcomes of infrequent occurrence. This can be conducted relatively rapidly and inexpensively. A disadvantage is the potential for several important types of bias, including bias in recalling exposure, in selecting appropriate controls, and in ascertaining cases.

These problems can be addressed in part by use of two control groups, one “normal” and the second “abnormal.” Any of several abnormal controls seem equally useful (e.g., infants with mendelian or chromosomal disorders as well as infants with no specific malformations).<sup>5</sup> In the former, mothers have incentive to recall, but teratogenesis is not the etiology. Ideally, case-control studies of potential teratogens should follow descriptive studies. After suspecting on the basis of case observations that thalidomide was teratogenic, Lenz<sup>6</sup> conducted a case-control study. **The association between valproic acid use and spina bifida was also verified by case-control studies.**<sup>7</sup>

### Cohort Studies

In cohort studies, groups are defined by the presence or absence of exposure to a given factor and then are followed over time and compared for rates of occurrence (i.e., incidence rates) of the outcome of interest. Cohort studies have three advantages: (1) the cohort is classified by exposure before the outcome is determined, thereby eliminating exposure recall bias; (2) incidence rates can be calculated among those exposed; and (3) multiple outcomes can be observed simultaneously.

**Cohort studies, often called *prospective studies*, require that groups differing in exposure be followed through time with outcomes observed; therefore these studies tend to be time consuming and expensive.** In addition, occurrence rates for many adverse reproductive outcomes, such as congenital malformations, are low; thus large samples must be followed for a considerable period of time. Two main types of cohort studies have been developed, those that identify a cohort and follow it into the future (*concurrent* cohort study) and those that identify a cohort at some time in the past and follow it to the present (*nonconcurrent* or *historical* cohort study). In both cases, risks of adverse outcomes are compared between groups. **Cohort studies enable investigators to calculate incidence rates that provide a measure of risk of an outcome after the exposure.** Risk in the exposed group can be compared with risk in an unexposed group. Most frequently, the ratio of the incidence rate among the exposed to the rate among the unexposed is determined. This

ratio, referred to as *relative risk*, is a measure of how much the presence of exposure increases the risk of the outcome.

In *historical prospective studies*, the study begins by identifying groups who differ in terms of some past exposure, and these are followed to the present to determine outcomes; exposure groups are defined before outcomes are known. A major advantage is that although the time frame is prospective, investigators do not have to follow the cohort into the future and wait for events to occur. A disadvantage is that these studies require the ability to determine exposure status retrospectively.

### Clinical Trials

**Ideally, analytic studies—case control or cohort—are followed by a randomized clinical trial in which the efficiency of a prevention or treatment regimen is evaluated; that is, subjects are randomly assigned to different treatment groups.** The individuals should be as similar as possible in terms of unknown factors that may affect the response before they are randomly assigned to the treatment groups to receive the different regimens.

Clinical trials of both NTD recurrence<sup>8</sup> and occurrence<sup>9</sup> have shown a protective effect of periconceptional folic acid supplementation, findings that have led to key public health recommendations regarding the use of folic acid to reduce the risk of these often devastating defects.

## MEDICAL DRUG USE

Patients should be educated about drug alternatives to cope with tension, aches and pains, and viral and other medical illnesses during pregnancy. The risk/benefit ratio should justify the use of a particular drug, and the minimum effective dose should be used. Because long-term effects of drug exposure in utero may not be revealed for many years, caution with regard to the use of any drug in pregnancy is warranted. Also, some drug doses may have a significant effect on the concentrations of analytes routinely used in serum screening for aneuploidy and NTDs.<sup>10</sup> Methadone has been reported to increase screen-positive results for trisomy 18, and screen-positive rates for NTDs were higher for those on corticosteroids, antibiotics, and antidepressants.<sup>10</sup>

### Effects of Specific Drugs

#### Estrogens and Progestins

**Studies have not confirmed any teratogenic risk for oral contraceptives or progestins.** A meta-analysis of first-trimester sex hormone exposure revealed no association between exposure and fetal genital malformations. However, because of the medicolegal climate and the conflicting past literature, it is wise to exclude pregnancy before giving progestins to an amenorrheic patient.

#### Androgenic Steroids

**Androgens may masculinize a developing female fetus.** Danazol has been reported to produce clitoral enlargement and labial fusion when given inadvertently for the first 9 to 12 weeks after conception (Fig. 8-2) in 23 of 57 female infants exposed.

#### Spermicides

The once touted increased risk of abnormal offspring in mothers who had used spermicides for contraception has not been confirmed. **A meta-analysis of reports of spermicide exposure concludes that the risk of birth defects is not increased.**<sup>11</sup>

**FIG 8-2** Perineum of a female fetus exposed to danazol in utero. (From Duck SC, Katayama KP. Danazol may cause female pseudohermaphroditism. *Fertil Steril*. 1981;35:230.)

### Antiepileptic Drugs

**Women with epilepsy who take antiepileptic drugs (AEDs) during pregnancy have approximately double the general population risk of malformations in offspring.** Compared with the general risk of 2% to 3%, the risk of major malformations in women with epilepsy who take AEDs is about 5%, especially cleft lip with or without cleft palate and congenital heart disease. **Valproic acid and carbamazepine each carry approximately a 1% risk of NTDs and other anomalies.** Valproic acid monotherapy significantly increases risk for spina bifida (odds ratio [OR] 12.7), atrial septal defect (2.5), cleft palate (5.2), hypospadias (4.8), polydactyly (2.2), and craniosynostosis (6.8).<sup>12</sup> A high daily dose or a combination of two or three drugs increases the chance of malformations.

Holmes and colleagues<sup>13</sup> screened 128,049 pregnant women at delivery to identify three groups of infants: those exposed to AEDs, those unexposed to AEDs but with a maternal history of seizures, and those unexposed to AEDs with no maternal history of seizures (control group). The infants were examined systematically for the presence of malformations. The combined frequency of anticonvulsant embryopathy was higher in 223 infants exposed to one AED than in 508 control infants (20.6% vs. 8.5%; OR, 2.8; 95% confidence interval [CI], 1.1-9.7). The frequency was also higher in 93 infants exposed to two or more AEDs than in the controls (28.0% vs. 8.5%; OR, 4.2; 95% CI, 1.1-5.1). The greater the number of AEDs, the higher the risk of malformation. The 98 infants whose mothers had a history of epilepsy but who took no AEDs during the pregnancy did not have a higher frequency of abnormalities than the control infants.

Phenytoin decreases folate absorption and lowers serum folate, which has been implicated in birth defects. Therefore folic acid supplementation should be given to these mothers, but this may require adjustment of the AED. Although women with

**FIG 8-3** Facial features of the fetal hydantoin syndrome. Note broad, flat nasal ridge; epicanthic folds; mild hypertelorism; and wide mouth with prominent upper lip. (Courtesy Dr. Thaddeus Kelly, Charlottesville, VA.)

epilepsy were not included in the Medical Research Council study, most authorities would recommend 4 mg/day folic acid for high-risk women. One study suggested that folic acid at doses of 2.5 to 5 mg daily could reduce birth defects in the offspring of women who take AEDs.<sup>14</sup>

**Fewer than 10% of offspring show the fetal hydantoin syndrome, which consists of microcephaly, growth deficiency, developmental delays, mental retardation, and dysmorphic craniofacial features (Fig. 8-3).** In fact, the risk may be as low as 1% to 2% above background. Although several of these features are also found in other syndromes, such as fetal alcohol syndrome, more common in the fetal hydantoin syndrome are hypoplasia of the nails and distal phalanges (Fig. 8-4) and hypertelorism. Carbamazepine is also associated with an increased risk of a dysmorphic syndrome.<sup>15</sup> A genetically determined metabolic defect in arene oxide detoxification in the infant may increase the risk of a major birth defect. Epoxide hydrolase deficiency may indicate susceptibility to fetal hydantoin syndrome.<sup>16</sup>

In a follow-up study of long-term effects of antenatal exposure to phenobarbital and carbamazepine, no neurologic or behavioral differences were noted between the two groups. However, children exposed in utero to phenytoin scored 10 points lower on IQ tests than children exposed to carbamazepine and non-exposed controls. At 3 years of age, children who had been exposed to valproate in utero had significantly lower IQ scores than those exposed to other antiepileptic drugs; therefore **valproate should not be used as a first-choice drug in women of reproductive age.** Also, prenatal exposure to phenobarbital decreased verbal IQ scores in adult men.

Lamotrigine exposures have been compiled in a voluntary registry established by the manufacturer, GlaxoSmithKline. After 1558 exposures in the first trimester, no increased risk of birth defects overall has been observed.<sup>17</sup> Of 1532 infant exposures to newer-generation antiepileptic drugs, 1019 were to lamotrigine, and 3.7% had major birth defects. Of 393 infants exposed to oxcarbazepine, the rate was 2.8%, and for 108 exposed to topiramate, the rate was 4.6%. None of these differences were statistically different from controls. Valproic acid carries significantly higher risks than lamotrigine or carbamazepine.<sup>18</sup> One study suggested a fivefold increased risk of cleft lip and/or cleft palate with use of topiramate.<sup>19</sup> In general, polytherapy exposure is associated with some poorer outcomes in neuropsychological or developmental testing.<sup>20</sup> Minimizing the dose during pregnancy is also critical in preventing birth defects.<sup>21</sup>

Some women may have taken AEDs for a long period without reevaluation of the need for continuation of the drugs. For patients with idiopathic epilepsy who have been seizure free for

2 years and who have a normal electroencephalogram (EEG), it may be safe to attempt a trial of withdrawal of the drug before pregnancy.

**Most authorities agree that the benefits of AEDs during pregnancy outweigh the risks of discontinuation of the drug if the patient is first seen during pregnancy.** Continuing AEDs depends on the type of seizures, seizure control, adverse effects of the AED regimen, and patient adherence. Adherence can be determined by measuring a serum concentration of the AED. If the level is low or undetected and the patient is seizure free, AED therapy may not be required. Because the albumin concentration falls in pregnancy, the total amount of phenytoin measured is decreased because it is highly protein bound. However, the level of free phenytoin, which is the pharmacologically active portion, is unchanged.

Pediatric care providers need to be notified at birth when a patient has been on anticonvulsants because this therapy can affect vitamin K–dependent clotting factors in the newborn.

### Isotretinoin

**Isotretinoin is a significant human teratogen.** This drug is marketed as Accutane for treatment of cystic acne, and it unfortunately has been taken by women who were not planning pregnancy.<sup>22</sup> Long-acting reversible contraception such as an intrauterine device (IUD) or an etonogestrel implant (Nexplanon) are recommended. Isotretinoin is labeled as contraindicated in pregnancy (FDA category X) with appropriate warnings that a negative pregnancy test is required before therapy. Of 154 exposed human pregnancies, 21 cases of birth defects, 12 spontaneous abortions, 95 elective abortions, and 26 normal infants were reported in women who took isotretinoin during early pregnancy. **The risk of structural anomalies in patients studied prospectively is now estimated to be about 25%, and an additional 25% have mental retardation alone.** The malformed infants have a characteristic pattern of craniofacial, cardiac, thymic, and central nervous system (CNS) anomalies that include microtia/anotia (small/absent ears; Fig. 8-5), micrognathia, cleft palate, heart defects, thymic defects, retinal or

**FIG 8-4** Hypoplasia of toenails and distal phalanges. (From Hanson JW, Smith DW. Fetal hydantoin syndrome. *Lancet* 1976;1[7961]:186.)

**FIG 8-5** Infant exposed to isotretinoin (Accutane) in utero. Note high forehead, hypoplastic nasal bridge, and abnormal ears. (From Lot IT, Bocian M, Pribam HW, Leitner M. Fetal hydrocephalus and ear anomalies associated with use of isotretinoin. *J Pediatr*. 1984;105:598.)

optic nerve anomalies, and CNS malformations that include hydrocephalus.<sup>22</sup> Microtia is rare as an isolated anomaly yet appears commonly as part of the retinoic acid embryopathy. Cardiovascular defects include great vessel transposition and ventricular septal defects (VSDs).

Unlike vitamin A, isotretinoin is not stored in tissue. Therefore a pregnancy after discontinuation of isotretinoin is not at risk because the drug is no longer detectable in serum 5 days after its ingestion. **In 88 pregnancies prospectively ascertained after discontinuation of isotretinoin, no increased risk of anomalies was noted.** Topical tretinoin has not been associated with any teratogenic risk.

### Vitamin A

No evidence suggests that vitamin A or  $\beta$ -carotene is teratogenic in normal doses. The vitamin A levels in prenatal vitamins (5000 IU/day) have not been associated with any documented risk. **Eighteen cases of birth defects have been reported after exposure to levels of 25,000 IU or more of vitamin A during pregnancy.** Vitamin A in doses greater than 10,000 IU/day was shown to increase the risk of malformations in one study but not in another.

### Psychoactive Drugs

**No clear risk has been documented for most psychoactive drugs with respect to overt birth defects.** However, effects of chronic use of these agents on the developing brain in humans is difficult to study, and so a conservative attitude is appropriate. Lack of overt defects does not exclude the possibility of behavioral teratogenesis, and neonatal withdrawal may occur. However, untreated depression carries risks also.

### TRANQUILIZERS

Conflicting reports of the possible teratogenicity of the various tranquilizers, including meprobamate and chlordiazepoxide, have appeared, but in prospective studies no increased risk of anomalies has been shown.

A fetal benzodiazepine syndrome has been reported in seven infants of 36 mothers who regularly took benzodiazepines during pregnancy. However, the high rate of abnormality occurred with concomitant alcohol and substance abuse and may not have been caused by the benzodiazepine exposure. In most clinical situations, however, the risk/benefit ratio does not justify the use of benzodiazepines in pregnancy. Use of diazepam in labor has been associated with neonatal hypotonia, hypothermia, and respiratory depression.

### LITHIUM

In the International Register of Lithium Babies, 217 infants were listed as exposed at least during the first trimester of pregnancy, and 25 (11.5%) were malformed. Eighteen had cardiovascular anomalies, including six cases of the rare Ebstein anomaly, which occurs in only 1 in 20,000 in the nonexposed population. Of 60 unaffected infants who were followed to age 5 years, no increased mental or physical abnormalities were noted compared with unexposed siblings.

However, two other reports suggest bias of ascertainment in the registry and a risk of anomalies much lower than previously thought. A case-control study of 59 patients with Ebstein anomaly showed no difference in the rate of lithium exposure in pregnancy from a control group of 168 children with neuroblastoma.<sup>23</sup> **A prospective study of 148 women exposed to**

**lithium in the first trimester showed no difference in the incidence of major anomalies compared with controls.**<sup>24</sup>

One fetus in the lithium-exposed group had Ebstein anomaly, and one infant in the control group had a VSD. The authors concluded that lithium is not a major human teratogen. **Nevertheless, we recommend that women exposed to lithium be offered ultrasound and fetal echocardiography.**

Lithium is excreted more rapidly during pregnancy, thus serum lithium levels should be monitored. Perinatal effects of lithium have been noted and include hypotonia, lethargy, and poor feeding in the infant. Also, complications similar to those seen in adults taking lithium have been noted in newborns, including goiter and hypothyroidism.

Two cases of polyhydramnios associated with maternal lithium treatment have been reported. Because nephrogenic diabetes insipidus has been reported in adults taking lithium, the presumed mechanism of this polyhydramnios is fetal diabetes insipidus. **Polyhydramnios may be a sign of fetal lithium toxicity.**

It is usually recommended that drug therapy be changed in pregnant women taking lithium to avoid fetal drug exposure. Tapering over 10 days delays the risk of relapse. However, discontinuing lithium is associated with a 70% chance of relapse of the affective disorder in 1 year as opposed to 20% in those who remain on lithium. **Discontinuation of lithium may pose an unacceptable risk of increased morbidity in women who have had multiple episodes of affective instability. These women should be offered appropriate prenatal diagnosis with ultrasound, including fetal echocardiography.** Lithium may be withheld for 24 to 48 hours before delivery to reduce neonatal complications and reduce infant hospital stays.<sup>25</sup>

### ANTIDEPRESSANTS

Imipramine was the original tricyclic antidepressant (TCA) claimed to be associated with cardiovascular defects, but the number of patients studied remains small. Of 75 newborns exposed in the first trimester, six major defects were observed—three cardiovascular—and neonatal withdrawal has been observed.

Amitriptyline has been more widely used, and the majority of the evidence supports its safety. In the Michigan Medicaid study, 467 newborns had been exposed during the first trimester, with no increased risk of birth defects.

**No increased risk of major malformations has been found after first-trimester exposure to fluoxetine in several studies.**<sup>26</sup>

**However, one recent study showed a twofold increased risk of VSDs.**<sup>27</sup> Chambers and associates found more minor malformations and perinatal complications among infants exposed to fluoxetine throughout pregnancy, but this study is difficult to interpret because the authors did not control for depression. When a group whose mothers received tricyclic agents was used as a control for depression, infants exposed to fluoxetine in utero did not appear to have more minor malformations or perinatal complications. One study suggested an increased risk of low-birthweight infants with higher doses of fluoxetine (40 to 80 mg) throughout pregnancy.

Nulman evaluated the neurobehavioral effects of long-term fluoxetine exposure during pregnancy and found no abnormalities among 228 children aged 16 to 86 months (average age, 3 years). Theoretically, some psychiatric or neurobehavioral abnormality might occur as a result of exposure, but it would

be very difficult to ascertain because of all of the confounding variables.

Current data on other selective serotonin reuptake inhibitor (SSRI) exposures show no consistent teratogenic risk.<sup>28</sup> Citalopram is transferred across the placenta the most, followed by fluoxetine. The lowest transfer is found with sertraline, followed by paroxetine,<sup>29</sup> although **two studies found an increased risk of cardiac defects after exposure to paroxetine.**<sup>27</sup> A recent large, population-based cohort study suggested no substantial increased risk of cardiac defects attributable to antidepressant use in the first trimester.<sup>30</sup> One study showed a twofold increased risk of NTDs after citalopram.<sup>27</sup>

Studies have described neonatal withdrawal in the first 2 days after in utero exposure to these drugs.<sup>31</sup> Infants exposed during pregnancy exhibited more tremulousness and sleep changes at 1 to 2 days of age. However, no abnormalities were found when children were examined at ages of 16 to 86 months after prolonged exposure during pregnancy.

A sixfold increased risk of persistent pulmonary hypertension (PPH) in newborns has been reported in infants exposed to SSRIs after 20 weeks of pregnancy,<sup>32</sup> raising the absolute risk from 1 to 2 per 1000 in unexposed infants to 6 to 12 per 1000 in exposed infants. Another study did not confirm this finding but did confirm a fivefold increased risk of PPH with cesarean section before labor.<sup>33</sup> Exposure to SSRIs in the first trimester did not increase the risk of miscarriage.<sup>34</sup> No major malformations have been reported in 133 infants exposed to bupropion.<sup>35</sup>

**When considering the use of antidepressant drugs during pregnancy, it should be noted that among women who maintained their medication throughout pregnancy, 26% relapsed**

**compared with 68% who discontinued medication.**<sup>36</sup> Also, **fetal alcohol spectrum disorders were 10 times more common in SSRI-exposed offspring than in unexposed offspring.** Therefore controversy exists as to whether the risks of antidepressants outweigh the benefits, and counseling may be as effective as drug therapy.<sup>37</sup>

### Anticoagulants

Warfarin has been associated with chondrodysplasia punctata, which is similar to the genetically determined Conradi-Hünermann syndrome. **Warfarin embryopathy occurs in about 5% of exposed pregnancies and includes nasal hypoplasia, bone stippling seen on radiologic examination, ophthalmologic abnormalities including bilateral optic atrophy, and mental retardation (Fig. 8-6).** Ophthalmologic abnormalities and mental retardation may occur even with use only beyond the first trimester. **The risk for pregnancy complications is higher when the mean daily dose of warfarin is more than 5 mg.**

The alternative drugs, heparin and enoxaparin, do not cross the placenta because they are large molecules with a strong negative charge. **Because heparin does not have an adverse effect on the fetus when given in pregnancy, it should be the drug of choice for patients who require anticoagulation, except in women with artificial heart valves.** However, therapy with 20,000 U/day for more than 20 weeks has been associated with bone demineralization, and 36% of patients had more than a 10% decrease from baseline bone density to postpartum values. The risk of spine fractures was 0.7% with low-dose heparin and 3% with a high-dose regimen. Heparin can also cause thrombocytopenia.

**FIG 8-6** Warfarin embryopathy. Note small nose with hypoplastic bridge. (From Shaul W, Hall JG. Multiple congenital anomalies associated with oral anticoagulants. *Am J Obstet Gynecol.* 1977;127:191.)

**Low-molecular-weight heparins (LMWHs) may have substantial benefits over standard unfractionated heparin (UFH).** The molecules are still relatively large and do not cross the placenta, plus the half-life is longer, which allows for once-daily administration. **However, enoxaparin is cleared more rapidly during pregnancy, so twice-daily dosing is advised.** LMWHs have a much more predictable dose-response relationship, which obviates the need for monitoring of partial thromboplastin time. The risk of heparin-induced thrombocytopenia and clinical bleeding at delivery is lower, but studies that suggest less risk of osteoporosis are preliminary.

**Women with mechanical heart valves, especially the first-generation valves, require warfarin anticoagulation because heparin is neither safe nor effective.** Heparin treatment is associated with more thromboembolic complications and more bleeding complications than warfarin therapy.

The risks of heparin during pregnancy may not be justified in patients with only a single remote episode of thrombosis in the past. Certainly, conservative measures should be recommended, such as elastic stockings and avoidance of prolonged sitting or standing.

### Thyroid and Antithyroid Drugs

Propylthiouracil (PTU) and methimazole both cross the placenta and may cause some degree of fetal goiter. In contrast, the thyroid hormones triiodothyronine and thyroxine cross the placenta poorly, so that fetal hypothyroidism produced by antithyroid drugs cannot be corrected satisfactorily by administration of thyroid hormone to the mother. Thus the goal of such therapy during pregnancy is to keep the mother slightly hyperthyroid to minimize fetal drug exposure. By the third trimester, 30% of women no longer need antithyroid medication.<sup>38</sup>

**Methimazole has been associated with scalp defects in infants and choanal or esophageal atresia<sup>38</sup>** as well as a higher incidence of maternal side effects. However, PTU and methimazole are equally effective and safe for therapy of hyperthyroidism. **Still, in 2009 the FDA released a black box warning highlighting serious liver injury with PTU treatment, to a greater extent than methimazole. The Endocrine Society is now advocating treatment with PTU only during the first trimester and switching to methimazole for the remainder of the pregnancy.**<sup>39,40</sup>

Radioactive iodine (<sup>131</sup>I or <sup>125</sup>I) administered for thyroid ablation or for diagnostic studies is not concentrated by the fetal thyroid until after 12 weeks of pregnancy. Thus with inadvertent exposure before 12 weeks, no specific risk to the fetal thyroid results from <sup>131</sup>I or <sup>125</sup>I administration.

The need for thyroxine increases in many women with primary hypothyroidism when they are pregnant, as reflected by an increase in serum thyroid-stimulating hormone (TSH) concentrations.<sup>41</sup> Because hypothyroidism in pregnancy may adversely affect the fetus, possibly by increasing prematurity, it is prudent to monitor thyroid function throughout pregnancy and to adjust the thyroid dose to maintain a normal TSH level. **It is recommended that women with hypothyroidism increase their levothyroxine dose by approximately 30% as soon as pregnancy is confirmed (two extra doses each week) and then have dosing adjustments based on TSH levels.**<sup>41</sup>

Topical iodine preparations are readily absorbed through the vagina during pregnancy, and transient hypothyroidism has been demonstrated in the newborn after exposure during labor.

### Digoxin

In 194 exposures, no teratogenicity of digoxin was noted. Blood levels should be monitored in pregnancy to ensure adequate therapeutic maternal levels.

Digoxin-like immunoreactive substances may be mistaken in assays for fetal concentrations of digoxin. In one study of fetuses with cardiac anomalies, no difference was found in the immunoreactive digoxin levels whether the mother had received digoxin or not. In hydropic fetuses, digoxin may not easily cross the placenta.

### Antihypertensive Drugs

**For treatment of chronic hypertension in pregnancy,  $\alpha$ -methyldopa has been widely used.** Although postural hypotension may occur, no unusual fetal effects have been noted. Hydralazine is used frequently in pregnancy, and no teratogenic effect has been observed. For more on antihypertensive drugs, see Chapter 31.

### SYMPATHETIC BLOCKING AGENTS

Propranolol is a  $\beta$ -adrenergic blocking agent in widespread use for various indications, for which no evidence of teratogenicity has been found. Bradycardia has been reported in the newborn as a direct effect of a dose of the drug given to the mother within 2 hours of delivery.

Several studies of propranolol use in pregnancy show an increased risk of intrauterine growth restriction (IUGR) or at least a skewing of the birthweight distribution toward the lower range. Ultrasound monitoring of exposed patients is prudent. Studies from Scotland suggest improved outcome with the use of atenolol to treat chronic hypertension during pregnancy.

Calcium channel blockers such as nifedipine have been widely used for chronic hypertension in pregnancy without evidence of teratogenicity. Magnesium sulfate should be used with caution in women taking these agents.

### ANGIOTENSIN-CONVERTING ENZYME INHIBITORS AND ANGIOTENSIN RECEPTOR BLOCKERS

Fetal exposure to angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) in the first trimester has not been associated with an increased risk of birth defects. **ACE inhibitors such as enalapril and captopril and angiotensin II receptor antagonists such as valsartan can cause fetal renal tubular dysplasia in the second and third trimesters, leading to oligohydramnios, fetal limb contractures, craniofacial deformities, and hypoplastic lung development.** Fetal skull ossification defects have also been described. **For these reasons, women taking these medications who plan pregnancy should be switched to other agents.**

### Antineoplastic Drugs and Immunosuppressants

**Mycophenolate mofetil carries a moderate teratogenic risk.**<sup>42</sup> Frequent features include microtia or anotia, cleft lip and/or palate, heart defects, and dysmorphic facial features. The numbers are too small to determine the actual rate of malformations.

**Methotrexate, a folic acid antagonist, appears to be a human teratogen, although experience is limited.** Infants of three women known to have received methotrexate in the first trimester of pregnancy had multiple congenital anomalies, including cranial defects and malformed extremities. Of eight women inadvertently treated with methotrexate after

misdiagnosis of ectopic pregnancy, two infants were severely malformed, three patients miscarried, and three chose to terminate the pregnancies.<sup>43</sup> Eight normal infants were delivered to seven women treated with methotrexate in combination with other agents after the first trimester. When low-dose oral methotrexate (7.5 mg/week) was used for rheumatoid disease in the first trimester, five full-term infants were normal and three patients experienced spontaneous abortions.

Azathioprine has been used by patients with renal transplants or systemic lupus erythematosus. The frequency of anomalies in 375 women treated in the first trimester was not increased. Some infants had leukopenia, some were small for gestational age (SGA), and the others were normal.

No increased risk of anomalies in fetuses exposed to cyclosporine in utero has been reported. An increased rate of prematurity and growth restriction has been noted, but it is difficult to separate the contributions of the underlying disease and the drugs given to these transplant patients. The B-cell line may be depleted more than the T-cell line, and one author recommends that infants exposed to immunosuppressive agents be followed for possible immunodeficiency.

Eight malformed infants have resulted from first-trimester exposure to cyclophosphamide, but these infants were also exposed to other drugs or radiation. Low birthweight may be associated with use after the first trimester, but this may also reflect the underlying medical problem.

Chloroquine is safe in doses used for malarial prophylaxis, and no increased incidence of birth defects was reported among 169 infants exposed to 300 mg once weekly. However, after exposure to larger antiinflammatory doses (250 to 500 mg/day), two cases of cochleovestibular paresis were reported.<sup>44</sup> No abnormalities were noted in 114 other infants.

No association was found between administration of tumor necrosis factor (TNF) inhibitors infliximab or adalimumab and congenital anomalies.<sup>45</sup>

When cancer chemotherapy must be used during embryogenesis, the rate of spontaneous abortion and major birth defects is increased. Later in pregnancy, the risk of stillbirth and IUGR is greater, and myelosuppression is often present in the infant.

## Antiasthmatics

### TERBUTALINE

Terbutaline has been widely used in the treatment of preterm labor. It is more rapid in onset, has a longer duration of action than epinephrine, and is preferred for asthma in the pregnant patient. No risk of birth defects has been reported with terbutaline, although long-term use has been associated with an increased risk of glucose intolerance.

### CROMOLYN SODIUM

Cromolyn sodium may be administered in pregnancy, and the systemic absorption is minimal. Teratogenicity has not been reported in humans.

### ISOPROTERENOL AND METAPROTERENOL

When isoproterenol and metaproterenol are given as topical aerosols for the treatment of asthma, the total dose absorbed is usually not significant. With oral or intravenous (IV) doses, however, the cardiovascular effects of the agents may decrease uterine blood flow. For this reason, they should be used with caution. No teratogenicity has been reported.

## CORTICOSTEROIDS

All steroids cross the placenta to some degree, but prednisone and prednisolone are inactivated by the placenta. When prednisone or prednisolone is given to a pregnant woman, the concentration of active compound in the fetus is less than 10% of that in the mother. Therefore these agents are the drugs of choice for treating medical diseases such as asthma. Inhaled corticosteroids are also effective therapy, and very little drug is absorbed. When steroid effects are desired in the fetus to accelerate lung maturity, betamethasone and dexamethasone are preferred because these are minimally inactivated by the placenta. **A meta-analysis of exposure to corticosteroids in the first trimester showed an odds ratio of 3.0 for cleft lip and/or cleft palate.**

## IODIDE

Iodide, such as that found in a saturated solution of potassium iodide (SSKI) expectorant, crosses the placenta and may produce a fetal goiter large enough to produce respiratory obstruction in the newborn (Fig. 8-7). Before a pregnant patient is advised to take a cough medicine, the clinician should be sure to ascertain that it does *not* contain iodide.

## Antiemetics

Remedies suggested to help nausea and vomiting in pregnancy without pharmacologic intervention include eating crackers at the bedside on first awakening in the morning (before getting out of bed), getting up very slowly, omitting iron tablets, consuming frequent small meals, and eating protein snacks at night. **None of the current medications used to treat nausea and vomiting have been found to be teratogenic except possibly methylprednisolone used before 10 weeks of gestation.**

## VITAMIN B<sub>6</sub>

Vitamin B<sub>6</sub> (pyridoxine) 25 mg three times a day has been reported in two randomized placebo-controlled trials to be effective for treating the nausea and vomiting of pregnancy. In several other controlled trials, no evidence of teratogenicity was found.

## DOXYLAMINE

Delayed-release doxylamine 10 mg plus pyridoxine 10 mg (Diclegis) is effective and well tolerated.<sup>46</sup> It has been approved by the FDA for NVP.

**Doxylamine is an effective antihistamine for nausea and vomiting of pregnancy and can be combined with vitamin B<sub>6</sub> to produce a therapy similar to Diclegis.** Vitamin B<sub>6</sub> (25 mg) and doxylamine (25 mg) at bedtime plus 12.5 mg doxylamine (one-half tablet) with vitamin B<sub>6</sub> (25 mg) in the morning and afternoon is an effective combination.

## MECLIZINE

In one randomized, placebo-controlled study, meclizine gave significantly better results than placebo, and prospective clinical studies have provided no evidence that meclizine is teratogenic in humans. In 1014 patients in the Collaborative Perinatal Project and in an additional 613 patients from the Kaiser Health Plan, no teratogenic risk was found.

## DIMENHYDRINATE

No teratogenicity has been noted with dimenhydrinate, but a 29% failure rate and a significant incidence of side effects, especially drowsiness, has been reported.

**FIG 8-7** Iodide-induced neonatal goiter. **A**, Appearance on the first day of life. **B**, Appearance at 2 months of age. (From Senior B, Chernoff HL. Iodide goiter in the newborn. *Pediatrics*. 1971;47:510.)

### DIPHENHYDRAMINE

In 595 patients treated in the Collaborative Perinatal Project, no teratogenicity was noted with diphenhydramine. However, drowsiness can be a problem.

### PHENOTHIAZINES

Teratogenicity does not appear to be a problem with the phenothiazines when evaluated as a group. In the Kaiser Health Plan Study, 976 patients were treated, and in the Collaborative Perinatal Project 1309 patients were treated; in both studies, no evidence of association between these drugs and malformations was noted. In 114 mothers treated with promethazine and in 877 mothers given prochlorperazine, no increased risk of malformations was found.

### METOCLOPRAMIDE

**Of 3458 infants exposed to metoclopramide during the first trimester, no increased risk of malformations, low birth-weight, or preterm delivery was reported.**<sup>47</sup>

### ONDANSETRON

Ondansetron is no more effective than promethazine, but it is less sedating.<sup>48</sup> It has not been associated with a significant risk of adverse fetal outcomes.<sup>49</sup> One study showed no increased risk of birth defects after ondansetron exposure.<sup>49</sup> However, a larger study<sup>50</sup> found a doubling in the prevalence of heart defects in exposed children.

In a double-blind randomized trial, ondansetron and metoclopramide demonstrated similar antiemetic effects, but the overall profile of adverse effects was better with ondansetron.<sup>51</sup>

### METHYLPREDNISOLONE

Forty patients with hyperemesis who were admitted to the hospital were randomized to oral methylprednisolone or oral promethazine, and methylprednisolone was more effective.<sup>52</sup> In a larger study in which all patients received promethazine and metoclopramide, methylprednisolone did not reduce the need for rehospitalization. Methylprednisolone should be used only after 10 weeks of pregnancy because of the potential risk of cleft lip and/or cleft palate.

### GINGER

**Ginger has been used with success for treating nausea, vomiting, and hyperemesis in the outpatient setting.** A significantly greater relief of symptoms was found after ginger treatment than with placebo. Patients took 250-mg capsules containing powdered ginger root four times a day.

### Acid-Suppressing Drugs

The use of cimetidine, omeprazole, and ranitidine has not been found to be associated with any teratogenic risk in 2261 exposures.<sup>53</sup> Of an additional 3651 infants exposed to proton-pump inhibitors in the first trimester, no increased risk of birth defects was reported.<sup>54</sup> Drugs taken in the study were mostly omeprazole but also included lansoprazole, esomeprazole, and pantoprazole.

### Antihistamines and Decongestants

No increased risk of anomalies has been associated with most of the commonly used antihistamines, such as chlorpheniramine. However, in one study, terfenadine was associated with an

increased risk of polydactyly. Astemizole did not increase the risk of birth defects in 114 infants exposed in the first trimester. However, an association between exposure to antihistamines during the last 2 weeks of pregnancy and retrolental fibroplasia in premature infants has been reported.

An increased risk of birth defects was noted with phenylpropanolamine exposure in the first trimester, specifically ear defects and pyloric stenosis.<sup>55</sup> In one retrospective study, an increased risk of gastroschisis was associated with first-trimester pseudoephedrine use. Phenylephrine has been associated with endocardial cushion defects.<sup>55</sup> Use of these drugs for trivial indications should be discouraged because long-term effects are unknown. If decongestion is necessary, topical nasal sprays will result in a lower dose to the fetus than systemic medication.

Patients should be educated that antihistamines and decongestants are only symptomatic therapy for the common cold and have no influence on the course of the disease. Other remedies should be recommended, such as use of a humidifier, rest, and fluids. If medications are necessary, combinations with two drugs should not be used if only one drug is necessary. If the diagnosis is truly an allergy, an antihistamine alone will suffice.

### Antibiotics and Antiinfective Agents

Because pregnant patients are particularly susceptible to vaginal yeast infections, antibiotics should be used only when clearly indicated. Therapy with antifungal agents may be necessary during or after the course of therapy.

#### PENICILLINS

Penicillin, ampicillin, and amoxicillin are safe in pregnancy. In the Collaborative Perinatal Project, 3546 mothers took penicillin derivatives in the first trimester of pregnancy with no increased risk of anomalies. Of 86 infants exposed to dicloxacillin in the first trimester, no increase in birth defects was reported.

Clavulanate is added to penicillin derivatives to broaden their antibacterial spectrum. Of 556 infants exposed in the first trimester, no increased risk of birth defects was observed. Amoxicillin/clavulanate was studied in randomized controlled trials (RCTs) as a potential therapy for chorioamnionitis in women with preterm premature rupture of membranes (PPROM). During this trial, amoxicillin/clavulanate was compared with both placebo and erythromycin. An increased incidence of necrotizing enterocolitis was found in the amoxicillin/clavulanate group when compared with both the placebo and erythromycin groups. It has been suggested that amoxicillin/clavulanate selects for specific pathogens, which leads to abnormal microbial colonization of the gastrointestinal tract and ultimately to the initiation of necrotizing enterocolitis. **Therefore amoxicillin/clavulanate should be avoided in women at risk for preterm delivery.**

#### CEPHALOSPORINS

In a study of 5000 Michigan Medicaid recipients, a suggestion of possible teratogenicity (25% increased birth defects) was found with cefaclor, cephalexin, and cephradine but not with other cephalosporins. However, another study of 308 women exposed in the first trimester showed no increase in malformations, therefore the consensus is that these drugs are safe.

#### SULFONAMIDES

Among 1455 human infants exposed to sulfonamides during the first trimester, no teratogenic effects were noted. However,

the administration of sulfonamides should be avoided in women deficient in glucose-6-phosphate dehydrogenase (G6PD) because dose-related hemolysis may occur.

Sulfonamides cause no known damage to the fetus in utero because the fetus can clear free bilirubin through the placenta. However, these drugs might theoretically have deleterious effects if they were to be present in the blood of the neonate after birth. Sulfonamides compete with bilirubin for binding sites on albumin and thus raise the levels of free bilirubin in the serum and increase the risk of hyperbilirubinemia in the neonate. Although this toxicity occurs with direct administration to the neonate, kernicterus in the newborn following in utero exposure has not been reported.

#### SULFAMETHOXAZOLE WITH TRIMETHOPRIM

Trimethoprim is often given with sulfa to treat urinary tract infections. However, one unpublished study of 2296 Michigan Medicaid recipients suggested an increased risk of cardiovascular defects after exposure in the first trimester. **In one retrospective study of trimethoprim with sulfamethoxazole, the odds ratio for birth defects was 2.3, whereas in another study it was 2.5 to 3.4.**

#### NITROFURANTOIN

Nitrofurantoin is used in the treatment of acute uncomplicated lower urinary tract infections, as well as for long-term suppression, in patients with chronic bacteriuria. Nitrofurantoin is capable of inducing hemolytic anemia in patients deficient in G6PD. However, hemolytic anemia in the newborn as a result of in utero exposure to nitrofurantoin has not been reported.

No reports have associated nitrofurantoin with congenital defects. In the Collaborative Perinatal Project, 590 infants were exposed—83 in the first trimester—with no increased risk of adverse effects. In another study<sup>56</sup> in 1334 women exposed in the first trimester, no increase in malformations was reported. Use in the last 30 days before delivery was associated with increased risk of neonatal jaundice.

#### TETRACYCLINES

**Tetracyclines readily cross the placenta and are firmly bound by chelation to calcium in developing bone and tooth structures. This produces brown discoloration of the deciduous teeth, hypoplasia of the enamel, and inhibition of bone growth. The staining of the teeth takes place in the second or third trimesters of pregnancy, whereas bone incorporation can occur earlier.** Depression of skeletal growth was particularly common among premature infants treated with tetracycline. **First-trimester exposure to doxycycline is not known to carry any risk. First-trimester exposure to tetracyclines was not found to have any teratogenic risk in 341 women in the Collaborative Perinatal Project or in 174 women in another study. Alternative antibiotics are currently recommended during pregnancy.**

#### AMINOGLYCOSIDES

Streptomycin and kanamycin have been associated with congenital deafness in the offspring of mothers who took these drugs during pregnancy. Ototoxicity was reported with doses as low as 1 g of streptomycin twice a week for 8 weeks during the first trimester. Of 391 mothers who had received 50 mg/kg of kanamycin for prolonged periods during pregnancy, nine children (2.3%) were found to have hearing loss.

Nephrotoxicity may be greater when aminoglycosides are combined with cephalosporins. Neuromuscular blockade may be potentiated by the combined use of aminoglycosides and curariform drugs. Potentiation of magnesium sulfate–induced neuromuscular weakness has also been reported in a neonate exposed to magnesium sulfate and gentamicin.

Other than ototoxicity, no known teratogenic effect has been associated with aminoglycosides in the first trimester. In 135 infants exposed to streptomycin in the Collaborative Perinatal Project, no teratogenic effects were observed. Among 1619 newborns whose mothers were treated for tuberculosis with multiple drugs, including streptomycin, the incidence of congenital defects was the same as in a healthy control group.

### ANTITUBERCULOSIS DRUGS

No evidence suggests any teratogenic effect of isoniazid, para-aminosalicylic acid, rifampin, or ethambutol.

### ERYTHROMYCIN

No teratogenic risk of erythromycin has been reported. In 79 patients in the Collaborative Perinatal Project and 260 in another study, no increase in birth defects was noted.

### CLARITHROMYCIN

Of 122 first-trimester exposures, no significant risk of birth defects was reported with clarithromycin.

### FLUOROQUINOLONES

The quinolones (ciprofloxacin and norfloxacin) have a high affinity for bone tissue and cartilage and may cause arthralgia in children. However, no malformations or musculoskeletal problems were noted in 38 infants exposed in utero in the first trimester, in 132 newborns exposed in the first trimester in the Michigan Medicaid data, or in 200 other first trimester exposures.

### METRONIDAZOLE

**Studies have failed to show any increase in the incidence of congenital defects among the newborns of mothers treated with metronidazole during early or late gestation.** Among 1387 prescriptions filled, no increase in birth defects could be determined. A meta-analysis confirmed lack of teratogenic risk.

### Antiviral Agents

The Acyclovir Registry has recorded 756 first-trimester exposures with no increased risk of abnormalities in the infants.<sup>57</sup> Among 1561 pregnancies exposed to acyclovir, 229 exposed to valacyclovir, and 26 exposed to famciclovir—all in the first trimester—no increased risk of birth defects was found.<sup>58</sup> The Centers for Disease Control and Prevention (CDC) recommends that pregnant women with disseminated infection (e.g., herpetic encephalitis or hepatitis or varicella pneumonia) be treated with acyclovir.

### LINDANE

After application of lindane to the skin, about 10% of the dose used can be recovered in the urine. Toxicity in humans after use of topical 1% lindane has been observed almost exclusively after misuse and overexposure to the agent. Although no evidence of specific fetal damage is attributable to lindane, the agent is a potent neurotoxin, and its use during pregnancy should be limited. Pregnant women should be cautioned about

shampooing their children's hair because absorption could easily occur across the skin of the hands. An alternate drug for lice is usually recommended, such as pyrethrins with piperonyl butoxide.

### Antiretroviral Agents

**Zidovudine (ZDV) should be included as a component in the antiretroviral regimen whenever possible because of its record of safety and efficacy.** In a prospective cohort study, children exposed to ZDV in the perinatal period through Pediatric AIDS Clinical Trials Group Protocol 076 were studied up to a median age of 4.2 years. No adverse effects were observed in these children. The International Antiretroviral Registry was established in 1989 to detect any major teratogenic effect of the antiretroviral drugs. Through January 2004, more than 1000 pregnancies had first-trimester exposures to ZDV and lamivudine, and no increase in teratogenicity was reported.

Concerns have been raised regarding the use of other antiretroviral therapies. Efavirenz is not recommended during pregnancy because of reports of significant malformations in monkeys who received efavirenz during the first trimester and also three case reports of fetal NTDs in women who received the drug.<sup>59</sup> In 2001, Bristol-Myers Squibb issued a warning advising against the use of didanosine and stavudine in pregnant women after cases of lactic acidosis were reported, some of which were fatal. These two drugs should only be used if no other alternatives are available.

### Antifungal Agents

Nystatin is poorly absorbed from intact skin and mucous membranes, and topical use has not been associated with teratogenesis. Clotrimazole or miconazole use in pregnancy is not known to be associated with congenital malformations. However, in one study, a statistically significant increase in risk of first-trimester abortion was noted after use of these drugs, but these findings were considered not to be definitive evidence of risk. Of 2092 newborns exposed in the first trimester in the Michigan Medicaid data, no increased risk of anomalies was found.

Limb deformities were reported in three infants exposed to 400 to 800 mg/day of fluconazole in the first trimester. However, in systematic studies of 460 patients who received a single 150-mg dose of fluconazole, no increased risk of defects was observed.<sup>60</sup> In one registry study,<sup>61</sup> fluconazole was associated with an increased risk of Tetralogy of Fallot.

### Drugs for Induction of Ovulation

In more than 2000 exposures, no evidence of teratogenic risk of clomiphene has been noted, and the percentage of spontaneous abortions is close to the expected rate. Although infants are often exposed to bromocriptine in early pregnancy, no teratogenic effects have been observed in more than 1400 pregnancies.

### Mild Analgesics

Some pains during pregnancy justify the use of a mild analgesic. However, pregnant patients should be encouraged to use non-pharmacologic remedies such as local heat and rest.

### ASPIRIN

No evidence suggests any teratogenic effect of aspirin taken in the first trimester. **Aspirin does have significant perinatal effects, however, because it inhibits prostaglandin synthesis. Uterine contractility is decreased, and patients taking aspirin**

**in analgesic doses have delayed onset of labor, longer duration of labor, and an increased risk of a prolonged pregnancy.**

**Aspirin also decreases platelet aggregation, which can increase the risk of bleeding before as well as at delivery.** Platelet dysfunction has been described in newborns within 5 days of ingestion of aspirin by the mother. Because aspirin causes permanent inhibition of prostaglandin synthetase in platelets, the only way for adequate clotting to occur is for more platelets to be produced.

Multiple organs may be affected by chronic aspirin use. Of note, prostaglandins mediate the neonatal closure of the ductus arteriosus. In one case report, maternal ingestion of aspirin close to the time of delivery was related to closure of the ductus arteriosus in utero.

### ACETAMINOPHEN

Acetaminophen has also shown no evidence of teratogenicity.<sup>62</sup> With acetaminophen, inhibition of prostaglandin synthesis is reversible; thus once the drug has cleared, platelet aggregation returns to normal. **In contrast to aspirin, bleeding time is not prolonged with acetaminophen,** and the drug is not toxic to the newborn. Thus if a mild analgesic or antipyretic is indicated, acetaminophen is preferred over aspirin.

Patients should be counseled on the risks associated with taking excessive amounts of acetaminophen. Doses of greater than 4 g daily (8 extra strength acetaminophen, 12 regular strength acetaminophen) are associated with liver fibrosis, leading to cirrhosis and liver failure. These deleterious effects are only effectively managed by liver transplantation. Patients should understand the doses of acetaminophen in all the products taken for pain. Combination products that contain acetaminophen may be overlooked in calculating the total daily dose, leading to unintentional overdose.

### NONSTEROIDAL ANTIINFLAMMATORY AGENTS

No evidence of teratogenicity has been reported for other nonsteroidal antiinflammatory drugs (NSAIDs such as ibuprofen, naproxen, diclofenac, and piroxicam).<sup>63,64</sup> Chronic use may lead to oligohydramnios, and constriction of the fetal ductus arteriosus or neonatal pulmonary hypertension, as has been reported with indomethacin, might occur.

### CODEINE

In the Collaborative Perinatal Project, no increased relative risk of malformations was observed in 563 codeine users. In one recent study, maternal treatment with opioid analgesics was associated with an increased risk of heart defects, spina bifida, and gastroschisis. **Codeine can cause addiction and newborn withdrawal symptoms if used to excess perinatally.**

### SUMATRIPTAN

Of 479 exposures to sumatriptan in the first trimester,<sup>65</sup> 4.6% of infants had birth defects—not significantly different from the nonexposed population. **For women whose severe headaches do not respond to other therapy, sumatriptan may be used during pregnancy.**<sup>66</sup>

### BISPHOSPHONATES

The bisphosphonate drug class represents a group of medications used for treating a variety of bone disorders, including osteoporosis and Paget disease, and for controlling excess blood calcium

in the setting of cancer or after chemotherapy administration. A published review of case reports for the bisphosphonate drug class—which includes alendronate, ibandronate, risedronate, etidronate, pamidronate, tiludronate, and zoledronic acid—in both short- and long-term use showed no serious fetal or neonatal adverse effects. Marginal decreases in gestational age, birthweight, and neonatal abnormalities may be attributed to bisphosphonate use. The decision to continue bisphosphonate use in pregnancy is based on the patient's duration and amount of osteopenia or osteoporosis. Patients should also be counseled on appropriate calcium supplementation and the use of vitamin D, which can mitigate the risk of bone-related issues.<sup>67</sup>

## DRUGS OF ABUSE

### Tobacco and Nicotine Products

Sorting out potential confounding factors is complicated when comparing smokers with nonsmokers. However, smoking is associated with a fourfold increase in small size for gestational age as well as an increased prematurity rate. **The higher perinatal mortality rate associated with smoking is attributable to an increased risk of abruptio placentae, placenta previa, premature and prolonged rupture of membranes, and IUGR.** The risks of complications and of the associated perinatal loss rise with the number of cigarettes smoked. Discontinuation of smoking during pregnancy can reduce the risk of both pregnancy complications and perinatal mortality, especially in women at high risk for other reasons. Maternal passive smoking was also associated with a twofold risk of low birthweight at term in one study (see Chapter 6).

A positive association has also been found between smoking and sudden infant death syndrome (SIDS) and increased respiratory illnesses in children. In such reports, it is not possible to distinguish between apparent effects of maternal smoking during pregnancy and smoking after pregnancy, but both may play a role.

The spontaneous abortion rate for smokers may be up to twice that of nonsmokers, and abortions associated with maternal smoking tend to have a higher percentage of normal karyotypes and occur later than those with chromosomal aberrations.

### Smoking Cessation During Pregnancy

Tobacco smoke contains nicotine, carbon monoxide, and thousands of other compounds. Although nicotine is the mechanism of addiction to cigarettes, other chemicals may contribute to adverse pregnancy outcomes. For example, carbon monoxide decreases oxygen delivery to the fetus, whereas nicotine decreases uterine blood flow.

Nicotine withdrawal may first be attempted with *nicotine fading*, switching to brands of cigarettes with progressively less nicotine over a 3-week period. Exercise may also improve quitting success rates. **Nicotine medications are indicated for patients with nicotine dependence,** defined as smoking more than one pack per day, smoking within 30 minutes of getting up in the morning, or prior withdrawal symptoms. Nicotine medications are available as patches, gums, or inhalers. **Although the propriety of prescribing nicotine during pregnancy might be questioned, cessation of smoking eliminates many other toxins, including carbon monoxide; nicotine blood levels are not increased over that of smokers.** In a randomized trial,<sup>68</sup> adding a nicotine patch to behavioral cessation support did not increase the rate of abstinence from smoking until delivery.

Compliance was low, and fewer than 10% of women in both groups used patches for more than 1 month.

Congenital anomalies occurred in five of 188 infants of women treated with bupropion during the first trimester of pregnancy—not a significant difference from the number expected. No data are available on the safety of varenicline use in pregnancy.<sup>69</sup> However, both of these medications have recently had product warnings mandated by the FDA about the risk of psychiatric symptoms and suicide associated with their use.

## Alcohol

Fetal alcohol syndrome (FAS) has been reported in the offspring of alcoholic mothers and includes the features of gross physical retardation with onset prenatally and continuing after birth (Fig. 8-8).

In 1980, the Fetal Alcohol Study Group of the Research Society on Alcoholism proposed criteria for the diagnosis of FAS. At least one characteristic from each of the following three categories had to be present for a valid diagnosis of the syndrome:

1. Growth retardation before and/or after birth
2. Facial anomalies including small palpebral fissures; indistinct or absent philtrum; epicanthic folds; flattened nasal bridge; short nose length; thin upper lip; low-set, unparallel ears; and retarded midfacial development
3. Central nervous system dysfunction including microcephaly, varying degrees of mental retardation, or other evidence of abnormal neurobehavioral development such as attention-deficit/hyperactivity disorder (ADHD)

**The full syndrome occurs in 6% of infants of heavy drinkers, and less severe birth defects and neurocognitive deficits occur in a larger proportion of children whose mothers drank heavily during pregnancy.**

Jones and colleagues compared 23 chronically alcoholic women with 46 controls and compared the pregnancy outcomes

of the two groups. Among the alcoholic mothers, perinatal deaths were about eight times more frequent. Growth restriction, microcephaly, and IQ below 80 were considerably more frequent in alcoholic women than among the controls. Overall outcome was abnormal in 43% of the offspring of the alcoholic mothers compared with 2% of the controls.

Ouellette and associates addressed the risks of smaller amounts of alcohol. Nine percent of infants of abstinent or rare drinkers and 14% of infants of moderate drinkers were abnormal—not a significant difference. **In heavy drinkers (average daily intake of 3 oz of 100-proof liquor or more), 32% of the infants had anomalies.** The aggregate pool of anomalies, growth restriction, and an abnormal neurologic examination was found in 71% of the children of heavy drinkers, twice the frequency in the moderate and rarely drinking groups. In this study, an increased frequency of abnormality was not found until 45 mL of ethanol daily (equivalent to three drinks) were exceeded. The study of Mills and Graubard also showed that total malformation rates were not significantly higher among offspring of women who had an average of less than one drink per day or one to two drinks per day than among nondrinkers. Genitourinary malformations increased with increasing alcohol consumption, however, so the possibility remains that for some malformations, no safe drinking level exists.

**Heavy drinking remains a major risk to the fetus, and reduction even in midpregnancy can benefit the infant.**<sup>70</sup> An occasional drink during pregnancy carries no documentable risk, but no level of drinking is known to be safe (see Chapter 6).

Sokol and colleagues have addressed history taking for prenatal detection of risky drinking. Four questions help differentiate patients who drink sufficiently to potentially injure the fetus (Box 8-2). The patient is considered at risk if more than two drinks are required to make her feel “high.” The probability of risky drinking increases to 63% for those who respond positively to all four questions.

**FIG 8-8** Fetal alcohol syndrome. **A**, At birth. **B**, At 5 years. **C**, At 8 years. Note the short palpebral fissures, short nose, hypoplastic philtrum, thinned upper lip vermilion, and flattened midface. (From Streissguth AP. CIBA Foundation Monograph 105. London: Pitman; 1984.)

### BOX 8-2 T-ACE QUESTIONS FOUND TO IDENTIFY WOMEN DRINKING SUFFICIENTLY TO POTENTIALLY INJURE THE FETUS\*

- T** How many drinks does it take to make you feel high?  
How many drinks can you hold? (*tolerance*)
- A** Have people *annoyed* you by criticizing your drinking?
- C** Have you felt you ought to *cut down* on your drinking?
- E** Have you ever had to drink first thing in the morning to steady your nerves or to get rid of a hangover? (*eye opener*)

From Sokol RJ, Martier SS, Ager JW. The T-ACE questions: practical prenatal detection of risk-drinking. *Am J Obstet Gynecol.* 1989;160:863.

\*Two points are scored as a positive answer to the tolerance question and one point each is scored for the other three. A score of 2 or more correctly identified 69% of risk drinkers.

### Cannabis

No significant teratogenic effect of *Cannabis* has been documented, but the data are insufficient to say that no risk is present. One study that found a mean 73-g decrease in birthweight associated with *Cannabis* use validated exposure with urine assays rather than relying on self-reporting. Other studies have not shown an effect on birthweight or length. Behavioral and developmental alterations have been observed in some studies but not in others.

### Cocaine

A serious difficulty in defining the effects of cocaine on the infant is the frequent presence of many confounding variables in the population using cocaine. These mothers often abuse other drugs, smoke, have poor nutrition, fail to seek prenatal care, and live under poor socioeconomic conditions. All of these factors are difficult to take into account in comparison groups. Another difficulty is the choice of outcome measures for infants exposed in utero. The neural systems likely to be affected by cocaine are involved in neurologic and behavioral functions not easily quantitated by standard infant development tests.

**Cocaine-using women have a higher rate of spontaneous abortion than controls. Other studies have suggested an increased risk of congenital anomalies after first-trimester cocaine use, most frequently those of the cardiac and central nervous systems.** In the study of Bingol and colleagues, the malformation rate was 10% in cocaine users, 4.5% in “polydrug users,” and 2% in controls. MacGregor and associates reported a 6% anomaly rate compared with 1% for controls.

Cocaine is a CNS stimulant that has local anesthetic and marked vasoconstrictive effects. Not surprisingly, **abruptio placentae has been reported to occur immediately after nasal or IV administration.**<sup>71</sup> Several studies have also noted increased stillbirths, preterm labor, premature birth, and SGA infants with cocaine use.

**The most common brain abnormality in infants exposed to cocaine in utero is impairment of intrauterine brain growth as manifested by microcephaly.**<sup>72</sup> In one study, 16% of cocaine-exposed newborns had microcephaly compared with 6% of controls. Somatic growth is also impaired, and so the growth restriction may be symmetric or characterized by a relatively low head circumference/abdominal circumference ratio. Multiple other neurologic problems have been reported after cocaine exposure in addition to dysmorphic features and neurobehavioral abnormalities.

Aside from causing congenital anomalies in the first trimester, cocaine has been reported to cause fetal disruption, presumably as a result of interruption of blood flow to various organs. Bowel infarction has been noted with unusual ileal atresia and bowel perforation. Limb infarction has resulted in missing fingers in a distribution different from the usual congenital limb anomalies. CNS bleeding in utero may result in porencephalic cysts.

### Narcotics and Methadone

Menstrual abnormalities, especially amenorrhea, are common in heroin abusers, although these symptoms are not associated with the use of methadone. Medical intervention is more likely to involve methadone maintenance, with the goal being a dose of approximately 20 to 40 mg/day. The dose should be individualized at a level sufficient to minimize the use of supplemental illicit drugs, which represent greater risk to the fetus than even the higher doses of methadone required by some patients. Manipulation of the dose in women maintained on methadone should be avoided in the last trimester because of an association with increased fetal complications and deaths attributed to fetal withdrawal in utero. Because management of narcotic addiction during pregnancy requires a host of social, nutritional, educational, and psychiatric interventions, these patients are best managed in specialized programs. Buprenorphine is also an acceptable treatment, and infants exposed to this drug required less morphine and had shorter hospital stays and shorter duration of treatment for neonatal abstinence syndrome than did infants exposed to methadone. However, women on buprenorphine were more likely to discontinue treatment.

**The pregnancy of the narcotic addict is at increased risk for abortion, prematurity, and growth restriction. Withdrawal should be watched for carefully in the neonatal period.**<sup>73</sup>

### Caffeine

**No evidence of teratogenic effects of caffeine in humans has been found.** The Collaborative Perinatal Project showed no increased incidence of congenital defects in 5773 women taking caffeine in pregnancy, usually in a fixed-dose analgesic medication. The average cup of coffee contains about 100 mg of caffeine, and a 12 oz can of soda contains about 50 mg. Some conflicting evidence exists concerning the association between heavy ingestion of caffeine and increased pregnancy complications. Early studies suggested that the intake of greater than seven to eight cups of coffee per day was associated with low-birthweight infants, spontaneous abortions, prematurity, and stillbirths. However, these studies were not controlled for the concomitant use of tobacco and alcohol. **In one report that controlled for smoking and other habits, demographic characteristics, and medical history, no relationship was found between malformations, low birthweight, or short gestation and heavy coffee consumption.** When pregnant women consumed more than 300 mg of caffeine per day, one study suggested an increase in term low-birthweight infants less than 2500 g at greater than 36 weeks.

Concomitant consumption of caffeine with cigarette smoking may increase the risk of low birthweight. Maternal coffee intake decreases iron absorption and may contribute to maternal anemia.

Two other studies have shown conflicting results. One retrospective investigation that reported a higher risk of fetal loss was biased by ascertainment of the patients at the time of fetal loss because these patients typically have less nausea and would be expected to drink more coffee. A prospective cohort study found

no evidence that moderate caffeine use increased the risk of spontaneous abortion or growth restriction. Measurement of serum paraxanthine, a caffeine metabolite, revealed that only extremely high levels are associated with spontaneous abortions.

**The American College of Obstetricians and Gynecologists (ACOG) concluded that moderate caffeine consumption (less than 200 mg/day) does not appear to be a major contributing factor in miscarriage or preterm birth, but the relationship to growth restriction remains undetermined.**<sup>74</sup> High caffeine intake may or may not be related to miscarriage, and so limiting intake to 200 mg/day seems prudent.<sup>74</sup>

### Aspartame

The major metabolite of aspartame is phenylalanine,<sup>75</sup> which is concentrated in the fetus by active placental transport. Sustained high blood levels of phenylalanine in the fetus as seen in maternal phenylketonuria (PKU) are associated with mental retardation in the infant. However, within the usual range of aspartame ingestion in normal individuals, peak phenylalanine levels do not exceed normal postprandial levels, and even with high doses, phenylalanine concentrations are still very far below those associated with mental retardation. These responses have also been studied in women who are obligate carriers of PKU, and their levels are still normal. **Thus it seems unlikely that aspartame during pregnancy would cause any fetal toxicity.**

## DRUGS IN BREAST MILK

Many drugs that are not usually of clinical significance to the infant can be detected in breast milk at low levels. The rate of transfer into milk depends on the lipid solubility, molecular weight, degree of protein binding, degree of ionization of the drug, and the presence or absence of active secretion. Nonionized molecules of low molecular weight, such as ethanol, cross easily. If the mother has unusually high blood concentrations, such as with increased dosage or decreased renal function, drugs may appear in higher concentrations in the milk.

The amount of drug in breast milk is a variable fraction of the maternal blood level, which itself is proportional to the maternal oral dose. Thus the dose to the infant is usually subtherapeutic, approximately 1% to 2% of the maternal dose on average. This amount is usually so trivial that no adverse effects are noted. In the case of toxic drugs, however, any exposure may be inappropriate. Allergy may also exist or may be initiated. Long-term effects of even small doses of drugs may yet be discovered. Also, drugs are eliminated more slowly in the infant with immature enzyme systems. Short-term effects of most maternal medications on breastfed infants are mild and pose little risk to the infants. Because the benefits of breastfeeding are well known, the risk of drug exposure must be weighed against these benefits.

With drug administration in the immediate few days postpartum, before lactation is fully established, the infant receives only a small volume of colostrum; thus little drug is excreted into the milk. It is also helpful to allay the fears of patients undergoing cesarean deliveries that analgesics or other drugs administered at this time might have some adverse effects on the infant because no adverse effects have been shown. For drugs that require daily dosing during lactation, knowledge of pharmacokinetics in breast milk may minimize the dose to the infant. For example, dosing immediately after nursing decreases the neonatal exposure because the blood level will be at its nadir just before the next dose.

**Short-term effects, if any, of most maternal medications on breastfed infants are mild and pose little risk to the infants.**<sup>76</sup>

Of 838 breastfeeding women, 11.2% reported minor adverse reactions in the infants, but these reactions did not require medical attention. In 19%, antibiotics caused diarrhea; in 11%, narcotics caused drowsiness; in 9%, antihistamines caused irritability; and in 10%, sedatives, antidepressants, or antiepileptics caused drowsiness.<sup>76</sup>

The American Academy of Pediatrics has reviewed drugs in lactation<sup>77,78</sup> and now refers providers to LactMed (<http://toxnet.nlm.nih.gov>) for effects of specific drugs.

## Drugs Commonly Listed as Contraindicated During Breastfeeding

### Cytotoxic Drugs That May Interfere With Cellular Metabolism of the Nursing Infant

Cyclosporine, doxorubicin, and cyclophosphamide might cause immune suppression in the infant, although data are limited with respect to these drugs. In general, the potential risks of the drugs would outweigh the benefits of continuing nursing.<sup>78</sup>

After oral administration to a lactating patient with choriocarcinoma, methotrexate was found in milk in low but detectable levels. Most individuals would elect to avoid any exposure of the infant to this drug. However, in environments in which bottle feeding is rarely practiced or presents practical or cultural difficulties, therapy with this drug would not in itself appear to constitute a contraindication to breastfeeding.

### Drugs of Abuse for Which Adverse Effects on the Infant During Breastfeeding Have Been Reported

Drugs of abuse such as amphetamines, cocaine, heroin, LSD, and phencyclidine are all contraindicated during breast feeding because they are hazardous to the nursing infant and to the health of the mother.<sup>78</sup>

### Radioactive Compounds That Require Temporary Cessation of Breastfeeding

The American Academy of Pediatrics<sup>78</sup> suggests consultation with a nuclear medicine physician so that the radionuclide with the shortest excretion time in breast milk can be used for lactating patients. The mother can attempt to store breast milk before the study, and she should continue to pump to maintain milk production but should discard the milk during therapy. The physician may reassure the patient by assessing the radioactivity of the milk before nursing is resumed. **Radiopharmaceuticals require variable intervals of interruption of nursing.**

## Drugs for Which the Effect on Nursing Infants Is Unknown but May Be of Concern

This category includes several classes of psychotropic drugs, amiodarone (associated with hypothyroidism), lamotrigine (potential for therapeutic serum concentration in the infant), metoclopramide (potential dopaminergic blocking, but no reported detrimental effects), and metronidazole.<sup>78</sup>

Antianxiety, antidepressant, and antipsychotic agents are sometimes given to nursing mothers. Although no data are available about adverse effects in infants exposed to these drugs through breast milk, they could theoretically alter CNS function.<sup>78</sup> Some psychoactive drugs have been reported to appear in breast milk in levels that approach clinical significance (10% or more). These include bupropion, fluoxetine, citalopram, sertraline, and venlafaxine.<sup>78</sup> Fluoxetine is excreted in breast milk

**FIG 8-9** Effect of sertraline on platelet 5-hydroxytryptamine levels in four breastfed infants and their mothers. (From Epperson CN, Anderson GM, McDougle CJ. Sertraline and breast-feeding. *N Engl J Med*. 1997;336:1189.)

at low levels, so the infant receives approximately 6.7% of the maternal dose.<sup>79</sup> The level in the breastfed newborn is certainly lower than the level during pregnancy.

**Sertraline causes a decline in 5-hydroxytryptamine levels in mothers but not in their breastfed infants.<sup>80</sup> This implies that the small amount of drug the infant ingests in breast milk is not enough to have a pharmacologic effect (Fig. 8-9). Infants of mothers taking psychotropic drugs should be monitored for sedation during use and for withdrawal after cessation of the drug.**

A bigger problem is postpartum depression exacerbated by fatigue, and **the benefits of nursing should be weighed against the negative effect on bonding that would result from untreated postpartum depression.**

Temporary cessation of breastfeeding after a single dose of metronidazole may be considered. Its half-life is such that interruption of lactation for 12 to 24 hours after single-dose therapy usually results in negligible exposure to the infant. However, no adverse effects in infants have been reported.

### Drugs Associated With Significant Effects in Some Nursing Infants That Should Be Given to Nursing Mothers With Caution

#### BROMOCRIPTINE

Bromocriptine is an ergot alkaloid derivative. Because it has an inhibitory effect on lactation, it should be avoided unless the mother has taken it during the pregnancy.

#### ERGOTAMINE

Ergotamine is used by some for migraine headache, and it has been associated with vomiting, diarrhea, and convulsions in the infant. Administration of an ergot alkaloid for the treatment of uterine atony does not contraindicate lactation.

#### LITHIUM

Breast milk levels of lithium are one third to one half of the maternal serum levels, and the infant's serum levels while nursing are much lower than the fetal levels that occur when the mother takes lithium during pregnancy. The benefits of breastfeeding must be weighed against the theoretic effects of small amounts of the drug on the developing brain.<sup>78</sup>

### Maternal Medication Usually Compatible With Breastfeeding

#### NARCOTICS, SEDATIVES, AND ANTICONVULSANTS

In general, no evidence of adverse effect is noted with most of the sedatives, narcotic analgesics, and anticonvulsants. Patients may be reassured that in normal doses, carbamazepine, phenytoin, magnesium sulfate, codeine, morphine, and meperidine do not cause any obvious adverse effects in breastfed infants because the dose detectable in the breast milk is approximately 1% to 2% of the mother's dose, which is sufficiently low to have no significant pharmacologic activity.

Although the short-term use of codeine by a breastfeeding mother appears to be harmless, in one case, a mother was breastfeeding while taking codeine and acetaminophen for episiotomy pain. On day 7, the infant was lethargic and had difficulty feeding, and the infant died on day 13. The mother was an ultra-rapid metabolizer who converted codeine to morphine at a rapid rate. The milk level of morphine was 87 ng/mL, whereas the infant's level was 70 ng/mL.<sup>81</sup> Because a mother's status is rarely known, the use of any codeine product should be restricted to less than 2 days.

With diazepam, the milk/plasma ratio at peak dose is 0.68, with only small amounts detected in the breast milk. In two lactating patients who took carbamazepine while nursing, the concentration of the drug in the breast milk at 4 and 5 weeks postpartum was similar—about 60% of the maternal serum level. Accumulation does not seem to occur, and no adverse effects were noted in either infant.

#### COLD PREPARATIONS

Although studies are not extensive, no harmful effects have been noted from antihistamines or decongestants. Less than 1% of a pseudoephedrine dose or triprolidine dose ingested by the mother is excreted in the breast milk.

#### ANTIHYPERTENSIVES

##### THIAZIDES

After a single 500-mg oral dose of chlorothiazide, no drug was detected in breast milk. In one mother taking 50 mg of hydrochlorothiazide daily, the drug was not detectable in the nursing infant's serum, and the infant's electrolytes were normal. Thiazide diuretics may decrease milk production in the first month of lactation.

##### β-BLOCKERS

Propranolol is excreted in breast milk, with milk concentrations after a single 40-mg dose less than 40% of peak plasma concentrations. Thus an infant consuming 500 mL/day of milk would ingest an amount that represents approximately 1% of a therapeutic dose, which is unlikely to cause any adverse effect.

Atenolol is concentrated in breast milk to about three times the plasma level. One case was reported in which a 5-day-old term infant had signs of β-adrenergic blockade with bradycardia (80 beats/min) with the breast milk dose calculated to be 9% of

the maternal dose. Adverse effects in other infants have not been reported. Because milk accumulation occurs with atenolol, infants must be monitored closely for bradycardia. Propranolol is a safer alternative.

Clonidine concentrations in milk are almost twice the maternal serum levels. Neurologic and laboratory parameters in the infants of treated mothers are similar to those of controls.

#### ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Captopril is excreted into breast milk in low levels, and no effects on nursing infants have been observed.

#### CALCIUM CHANNEL BLOCKERS

Nifedipine is excreted into breast milk at a concentration of less than 5% of the maternal dose, and verapamil is excreted at an even lower level. Neither have caused adverse effects in the infant.

#### ANTICOAGULANTS

Most mothers who require anticoagulation may continue to nurse their infants with no problems. Heparin does not cross into milk and is not active orally.

At a maternal dose of warfarin of 5 to 12 mg/day in seven patients, no warfarin was detected in breast milk or in infant plasma. This low concentration is probably because warfarin is 98% protein bound, and the milk would contain an insignificant amount of drug to exert an anticoagulant effect.<sup>82</sup> Another report confirmed that warfarin appears only in insignificant quantities in breast milk.<sup>83</sup> The oral anticoagulant bishydroxycoumarin was given to 125 nursing mothers with no effect on the infants' prothrombin times and no hemorrhages. **Thus with careful monitoring of maternal prothrombin time, so that the dosage is minimized, and of neonatal prothrombin times to ensure lack of drug accumulation, warfarin may be safely administered to nursing mothers.**

#### CORTICOSTEROIDS

Prednisone enters breast milk in an amount not likely to have any deleterious effect. In a study of seven patients, 0.14% of a sample was secreted in the milk in the subsequent 60 hours, a negligible quantity. Even at 80 mg/day, the nursing infant would ingest less than 0.1% of the dose, less than 10% of its endogenous cortisol.

#### DIGOXIN

Digoxin enters breast milk in a small amount because of significant maternal protein binding. In 24 hours, an infant would receive about 1% of the maternal dose. No adverse effects in nursing infants have been reported.

#### ANTIBIOTICS

Penicillin derivatives are safe in nursing mothers. With the usual therapeutic doses of penicillin or ampicillin, no adverse effects are noted in the breastfed infants. In susceptible individuals or with prolonged therapy, diarrhea and candidiasis are concerns.

Dicloxacillin is 98% protein bound. If this drug is used to treat breast infections, very little will get into the breast milk, and nursing may be continued.

Cephalosporins appear only in trace amounts in milk. In one study, after cefazolin 500 mg was administered intramuscularly three times a day, no drug was detected in breast milk. After 2 g of cefazolin was administered intravenously, the infant was exposed to less than 1% of the maternal dose.

Tooth staining or delayed bone growth from tetracyclines have not been reported after the drug was taken by a breastfeeding mother. This finding is probably because of the high binding of the drug to calcium and protein, limiting its absorption from the milk. The amount of free tetracycline available is too small to be significant.

Sulfonamides only appear in small amounts in breast milk and are ordinarily not contraindicated during nursing. However, the drug is best avoided in premature, ill, or stressed infants in whom hyperbilirubinemia may be a problem, because the drug may displace bilirubin from binding sites on albumin. On the other hand, sulfasalazine was not detected in the breast milk of a mother taking this drug.<sup>84</sup>

Gentamicin is transferred into breast milk, and half of nursing newborn infants have the drug detectable in their serum. The low levels detected would not be expected to cause clinical effects.

Nitrofurantoin is excreted into breast milk in very low concentrations. In one study, the drug could not be detected in 20 samples from mothers receiving 100 mg four times a day.

Erythromycin is excreted into breast milk in small amounts, although no reports of adverse effects on infants exposed to erythromycin in breast milk have been noted. Azithromycin also appears in breast milk in low concentrations. Clindamycin is excreted into breast milk in low levels, and nursing is usually continued during administration of this drug.

There are no reported adverse effects on the breastfed infant when isoniazid is administered to nursing mothers, and its use is considered to be compatible with breastfeeding.<sup>78</sup>

#### ACYCLOVIR

Acyclovir is compatible with breastfeeding. If a mother takes 1 g/day, the infant receives less than 1 mg/day—a very low dose.

#### ANTIFUNGAL AGENTS

No data are available on the effects of nystatin, miconazole, or clotrimazole in breast milk. However, with only small amounts absorbed vaginally and poor oral bioavailability, this would not be expected to be a clinical problem. Infant exposure to ketoconazole in human milk was 0.4% of the therapeutic dose, again unlikely to cause adverse effects.

#### ORAL CONTRACEPTIVES

Estrogen and progestin combination oral contraceptives cause dose-related suppression of milk production. Oral contraceptives that contain 50 µg or more of estrogen during lactation have been associated with shortened duration of lactation, decreased milk production, decreased infant weight gain, and decreased protein content of the milk. Lactation is inhibited to a lesser degree if the pill is started about 3 weeks postpartum and with lower doses of estrogen than 50 µg. Although the magnitude of the change is low, it still may be of nutritional importance, particularly in malnourished mothers.

An infant who consumes 600 mL of breast milk daily from a mother using an oral contraceptive that contains 50 µg of ethinylestradiol receives a daily dose in the range of 10 ng of the estrogen. The amount of natural estradiol received by infants who consume a similar volume of milk from mothers not using oral contraceptives is estimated at 3 to 6 ng during anovulatory cycles and 6 to 12 ng during ovulatory cycles. No consistent long-term adverse effects on growth and development have been described.

Evidence indicates that norgestrel is metabolized, rather than accumulated, by infants, and to date, no adverse effects have been identified as a result of progestational agents taken by the mother. ACOG recommends placement of the etonogestrel contraceptive implant 4 weeks or more after childbirth. Progestin-only contraceptives do not cause alteration of breast milk composition or volume, making them ideal for the breastfeeding mother. When the infant is weaned, the mother should be switched to combined oral contraceptives for maximum contraceptive efficacy.

### ALCOHOL

Alcohol levels in breast milk are similar to those in maternal blood. If a moderate social drinker had two cocktails and had a blood alcohol concentration of 50 mg/dL, the nursing infant would receive about 82 mg of alcohol, which would produce insignificant blood concentrations. No evidence suggests that occasional ingestion of alcohol by a lactating mother is harmful to the breastfed infant. However, one study showed that ethanol ingested chronically through breast milk might have a detrimental effect on motor development but not mental development.<sup>85</sup> Also, alcohol in breast milk has an immediate effect on the odor of the milk, and this may decrease the amount of milk the infant consumes.<sup>86</sup>

### PROPYLTHIOURACIL

Propylthiouracil (PTU) is found in breast milk in small amounts. If the mother takes 200 mg of PTU three times a day, the child would receive 149 µg daily, or the equivalent of a 70-kg adult receiving 3 mg/day. Several infants studied up to 5 months of age show no changes in thyroid parameters. **Lactating mothers on PTU can thus continue nursing with close supervision of the infant.** PTU has been preferred over methimazole because of its high protein binding (80%) and lower breast milk concentrations. However, recently it has been observed that liver injury is higher with PTU than with methimazole, but no cases of liver damage in infants of nursing mothers taking PTU have been reported.

### H2-RECEPTOR BLOCKERS

In theory, H2-receptor antagonists such as ranitidine and cimetidine might suppress gastric acidity and cause CNS stimulation in the infant, but these effects have not been confirmed. The American Academy of Pediatrics now considers H2-receptor antagonists to be compatible with breastfeeding. Famotidine, nizatidine, and roxatidine are less concentrated in breast milk and may be preferable in nursing mothers.

### CAFFEINE

**Caffeine has been reported to have no adverse effects on the nursing infant, even if the mother consumes five cups of coffee per day.** In one study, the milk level contained 1% of the total dose 6 hours after coffee ingestion, which is not enough to affect the infant. In another report, no significant difference in 24-hour heart rate or sleep time was observed in nursing infants when their mothers drank coffee for 5 days or abstained for 5 days.<sup>87</sup>

### TOBACCO

Nicotine and its metabolite cotinine enter breast milk. Infants of smoking mothers achieve significant serum concentrations of nicotine even if they are not exposed to passive smoking;

exposure to passive smoking further raises the levels of nicotine. Women who smoke should be encouraged to stop during lactation as well as during pregnancy.

## OCCUPATIONAL AND ENVIRONMENTAL HAZARDS

### Ionizing Radiation

The general hazards of radiation exposure are well known. To provide counseling in specific clinical situations, key variables are dose, timing, and temporal sequence.

#### Acute Exposure

Systematic studies of atomic bomb survivors in Japan showed conclusively that in utero exposure to high-dose radiation increased the risk of microcephaly and mental and growth restriction in the offspring. Distance from the hypocenter—the area directly beneath the detonated bomb—and gestational age at the time of exposure were directly related to microcephaly and mental and growth restriction in the infant. **The greatest number of children with microcephaly, mental retardation, and growth restriction were in the group exposed at 15 weeks' gestation or earlier.** Exposures were calculated by the distance of the victims from the epicenter. Microcephaly and mental retardation were associated with ionizing radiation at doses of 50 rads or greater, with 20 rads being the lowest dose at which microcephaly was observed. It is noteworthy that radiation from the atomic bomb blast differs from the low linear transfer of filtered radiation used in diagnostic studies.

Although teratogenic effects have been found in several organ systems of animals exposed to acute, high-dose radiation, the only structural malformations reported among humans exposed prenatally are those mentioned earlier. Using data from animals and from outcomes of reported human exposures at various times during pregnancy, Dekaban<sup>88</sup> constructed a timetable for extrapolating acute, high-dose radiation (>250 rad) to various reproductive outcomes in humans. Similarities between animal and known human effects support Dekaban's proposal.

**Effects of chronic low-dose radiation on reproduction have not been identified in animals or humans.** Increased risk of adverse outcomes was not detected among animals with continuous low-dose exposure (<5 rad) throughout pregnancy. The National Council for Radiation Protection<sup>89</sup> concluded that exposures less than 5 rads were not associated with increased risk of malformations.

Exposures are expressed in Gray (Gy) increments: 1 Gy equals 1000 mGy equals 100 rads (Table 8-1). Thus 10 mGy equals 1 rad. **Fortunately, virtually no single diagnostic test produces a substantive risk.** Table 8-1 shows mean and maximum fetal exposure. Only multiple computed tomography (CT) scans and fluoroscopies would lead to cumulative exposures of 100 mGy or 10 rads. Internal exposures are 50% less than maternal surface doses.

Female frequent flyers or aircraft crew members may be exposed to radiation during frequent, long, high-altitude flights. The Federal Aviation Administration (FAA) recommends that exposure be limited to 1 mSv (0.1 rad) during the pregnancy.<sup>90</sup>

Therapeutic exposures for maternal thyroid ablation with I<sup>131</sup> are rare, but they can cause fetal thyroid damage after 12 weeks of pregnancy.

**TABLE 8-1** APPROXIMATE FETAL DOSES FROM COMMON DIAGNOSTIC PROCEDURES

| EXAMINATION                          | MEAN (mGY) | MAXIMUM (mGY) |
|--------------------------------------|------------|---------------|
| <b>Conventional Radiography</b>      |            |               |

| Pelvis                               | 25         | 79            |

From Lowe SA: Diagnostic radiography in pregnancy: risks and reality. *Aust N Z J Obstet Gynaecol*. 2004;44:191.

10 mGY = 1 rad.

## Mutagenesis

Mutagenic effects in the offspring of irradiated women may be manifested years after the birth of the infant. Mutagenic effects presumably explain the 50% increased risk of leukemia in children exposed in utero to radiation during maternal pelvimetry examinations compared with nonirradiated controls. However, the clinical consequence is almost nil. The absolute risk is approximately 1 in 2000 for exposed versus 1 in 3000 for unexposed children.

Lowe<sup>89</sup> estimates one additional cancer death per 1700 exposures of 10 mGy (1 rad). If it were to be recommended that pregnancies be terminated whenever exposure from diagnostic radiation occurred because of the increased probability of leukemia in the offspring, 1699 exposed pregnancies would have to be terminated to prevent a single case of leukemia. Radiation exposures should be minimized, but fear of radiation should never preclude a necessary diagnostic procedure. A consent form has been developed for use with pregnant women.<sup>91</sup>

Questions have also been raised about potential risks to children associated with paternal occupational exposure to low-dose radiation. A case-control study by Gardner and colleagues in the area around the Sellafield Nuclear Facility in the United Kingdom found a statistically significant association between paternal preconception radiation dose and childhood leukemia risk. A similar association had been observed between paternal preconception radiation and risk in workers at the Hanford nuclear facility in the United States. The finding regarding childhood leukemia risk is a particularly contentious issue, contradicting studies of the children born to atomic bomb survivors who do not show genetic effects, such as increased risks of childhood cancers. A study in the vicinity of nuclear facilities in Ontario also failed to demonstrate an association between childhood leukemia risk and paternal preconceptional radiation exposure.

## Video Display Terminals

Concern about video display terminals (VDTs) linked to adverse reproductive outcomes now seems unwarranted. Early concern grew out of reports of spontaneous abortion clusters among

groups of women who used VDTs at work; some reported clusters included birth defects. Since then, numerous reassuring papers have been published on this topic, along with a number of reviews.<sup>92</sup> **VDT use does not increase the risk of adverse reproductive outcomes.**

## Lead

Twenty-five years of public health efforts have produced a striking reduction in lead exposure in the United States. The average blood lead level has decreased to less than 20% of levels measured in the 1970s. However, elevated blood lead (>20 µg/dL) has a higher incidence among immigrants to Southern California. In Los Angeles, 25 of the 30 cases of elevated blood lead occurred in immigrants.

High lead concentration in maternal blood is associated with an increased risk of delivery of an SGA infant. The frequency of preterm birth was also almost three times higher among women who had umbilical cord levels greater than or equal to 5.1 µg/dL, compared with those who had levels below that cutoff. One study in Norway found an increased risk of low birthweight and also NTDs.<sup>93</sup>

Lead poisoning was reported after a pregnant woman ingested *Garbhpal ras*, an Asian Indian health supplement that contained extremely high levels of lead.<sup>94</sup>

Asking pregnant women about risk factors for lead exposure can aid in assessing prenatal exposure risk. A questionnaire that gathered information on housing conditions, smoking status, and consumption of canned foods had a sensitivity of 89.2% and a negative predictive value of 96.4%.<sup>95</sup> Consumption of calcium and avoidance of the use of lead-glazed ceramics resulted in lowering of blood lead, especially in pregnant women of low socioeconomic status in Mexico City.

Because the nervous system may be more susceptible to the toxic effects during the embryonic and fetal periods than at any other time of life, and because maternal and cord blood lead concentrations are directly correlated, lead concentrations in blood should not exceed 25 µg/dL in women of reproductive age.<sup>96</sup>

**Ideally, the maternal blood lead level should be less than 10 µg/dL to ensure that a child begins life with minimal lead exposure. A dose-response relationship is strongly supported by numerous epidemiologic studies of children showing a reduction in IQ with increasing blood lead concentrations above 10 µg/dL.** Of note, these studies measured blood lead concentrations over time (often 2 years or more) and reported averaged values. **Other neurologic impairments associated with increased blood lead concentrations include ADHD, hearing deficits, and learning disabilities; shorter stature has also been noted.** Thus for public health purposes, childhood lead poisoning has been defined as a blood lead level of 10 µg/dL or higher.

In occupational settings, federal standards mandate that women should not work in areas where air lead concentrations can reach 50 µg/cm because this can result in blood concentrations above 25 to 30 µg/dL.<sup>97</sup> Subtle but permanent neurologic impairment in children may occur at lower blood lead concentrations.

## Mercury in Fish

Fish and shellfish are an important part of a healthy diet, but some large fish contain significant amounts of mercury. **Mercury in high levels may harm an unborn baby or young child's developing nervous system.**<sup>98</sup>

**Pregnant women, those who may become pregnant, and nursing mothers should avoid shark, swordfish, king mackerel, and tile fish because they contain high levels of mercury.**<sup>99</sup>

Consumption of up to 12 oz a week of shrimp, canned light tuna, salmon, pollock, and catfish—all of which are very low in mercury—is considered safe. Albacore (white) tuna and tuna steaks have more mercury than canned light tuna, but 6 oz per week are allowed.

### OBSTETRICIAN'S ROLE IN EVALUATING DRUG AND REPRODUCTIVE RISKS IN AND BEYOND THE WORKPLACE

Clinical questions about adverse reproductive outcomes of potential drug teratogens or environmental or occupational exposures are difficult to answer, and answers are seldom as clear cut as the obstetrician would like. Even if the exposure were known, often no study of similar exposure with a sufficient sample size is available. Without this, a physician cannot give a reliable estimate of risk.

For drugs and other exposures discussed in this chapter, the threshold is unknown below which no adverse reproductive outcome can be expected. Except for ionizing radiation, maximum recommended exposure levels are difficult to quantify. When available, epidemiologic studies often have limitations in design, execution, analysis, and interpretation. Thus the questions must often be answered on the basis of reasoned judgments in the face of inadequate data.

In addition to traditional genetic referral sources, a variety of teratology information services and computer databases are available to physicians who counsel pregnant women (see Box 8-1). The options include personal computer software (e.g., Grateful Med) and CD-ROM copies in medical libraries or leased from commercial versions. Information is available from a TOXNET representative through the National Library of Medicine Specialized Information Services (<http://sis.nlm.nih.gov/>).

The National Library of Medicine (NLM) maintains several files on the TOXNET database system, including reproductive and developmental toxicology information in bibliographic or text form. Examples include Developmental and Reproductive Toxicology, GEN-TOX (genetic toxicology), LactMed, and the Environmental Mutagen Information Center. Other very useful sources are Reprotox (<http://reprotox.org>) and TERIS (<http://depts.washington.edu/%7Eterisweb/teris/index.html>). The book by Briggs and Freeman, *Drugs in Pregnancy and Lactation*, tenth edition (2014), is now available both in print and online. The online version is updated quarterly.

### SUMMARY

Many medical conditions during pregnancy and lactation are best treated initially with nonpharmacologic remedies. Before a drug is administered in pregnancy, the indications should be clear and the risk/benefit ratio should justify drug use. If possible, therapy should be postponed until after the first trimester. In addition, patients should be cautioned about the risks of social drug use such as smoking, alcohol, and illicit drug use during pregnancy. Most drug therapy does not require cessation of lactation, because the amount excreted into breast milk is sufficiently small as to be pharmacologically insignificant.

### KEY POINTS

- ◆ The critical period of organ development extends from day 31 to day 71 after the first day of the last menstrual period.
- ◆ Infants of epileptic women taking certain anticonvulsants, such as valproic acid, have double the rate of malformations of unexposed infants; the risk of fetal hydantoin syndrome is less than 10%.
- ◆ The risk of malformations after in utero exposure to isotretinoin is 25%, and an additional 25% of infants have mental retardation.
- ◆ Heparin is the drug of choice for anticoagulation during pregnancy except for women with artificial heart valves, who should receive coumadin despite the 5% risk of warfarin embryopathy.
- ◆ Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers can cause fetal renal failure in the second and third trimesters, leading to oligohydramnios and hypoplastic lungs.
- ◆ Vitamin B<sub>6</sub> 25 mg three times a day is a safe and effective therapy for first-trimester nausea and vomiting; doxylamine 12.5 mg three times a day is also effective in combination with B<sub>6</sub>.
- ◆ Most antibiotics are generally safe in pregnancy, although aminoglycosides are known to be ototoxic. Trimethoprim may carry an increased risk in the first trimester, and tetracyclines taken in the second and third trimesters may cause tooth discoloration in offspring.
- ◆ Aspirin in analgesic doses inhibits platelet function and prolongs bleeding time, increasing the risk of peripartum hemorrhage.
- ◆ Fetal alcohol syndrome occurs in infants of mothers who drink heavily during pregnancy. A safe level of alcohol intake during pregnancy has not been determined.
- ◆ Cocaine has been associated with increased risk of spontaneous abortions, abruptio placentae, and congenital malformations, in particular, microcephaly.
- ◆ Most drugs are safe during lactation because subtherapeutic amounts, approximately 1% to 2% of the maternal dose, appear in breast milk. Only short-term (<2 days) use of codeine is safe during breastfeeding.
- ◆ Only a small amount of prednisone crosses the placenta, so it is the preferred corticosteroid for most illnesses. In contrast, betamethasone and dexamethasone readily cross the placenta and are preferred for acceleration of fetal lung maturity.
- ◆ Exposure to high-dose ionizing radiation during gestation causes microcephaly and mental retardation; however, diagnostic exposures below 5 rads do not pose increased teratogenic risks.
- ◆ Lead levels in blood have decreased in recent years in all except immigrant populations, making it easier to achieve blood levels below 25 µg/dL in women of reproductive age; this low level minimizes fetal growth restriction.
- ◆ Mercury in high levels deleteriously affects the fetal nervous system. For this reason pregnant and nursing women should avoid shark, swordfish, king mackerel, and tile fish; exposures to mercury can further be limited by restricting ingestion of certain other seafood (shrimp, canned tuna, salmon, pollock, catfish) to 12 oz/week.

# Obstetric Ultrasound: Imaging, Dating, Growth, and Anomaly

DOUGLAS S. RICHARDS

## Overview 160

### Biophysics of Ultrasound 161

#### Optimizing the Ultrasound Image 161

Frequency 161

Power 161

Gain 161

Attenuation 161

Focus 162

Depth and Zoom 163

### Special Ultrasound

#### Modalities 163

M-Mode 163

Color and Pulse-Wave Doppler 164

Three-Dimensional Ultrasound 165

### Scanning Technique 166

Orientation 166

Angle of Insonation 166

Using Natural Windows 167

## First-Trimester Ultrasound 168

First-Trimester Normal Findings 168

First-Trimester Abnormal Findings 169

### Second- and Third-Trimester Ultrasound 170

Types of Examinations 170

Qualifications for Performing and Interpreting Diagnostic Ultrasound Examinations 171

### Components of the Examination 171

Cardiac Activity 171

Number of Fetuses 171

Presentation 171

Amniotic Fluid Volume 171

Placenta and Umbilical Cord 173

Uterus and Adnexa 174

Anatomic Survey 176

Documentation 176

Cleaning and Disinfection of Probes 176

## Ultrasound for Determining Gestational Age 176

Standard Measurements 177

Gestational Age Determination 177

When to Use Ultrasound Dating 180

### Safety of Ultrasound 182

Quantifying Machine Power Output 182

### Ultrasound Diagnosis of Malformations 183

Ultrasound as a Screening Tool for Birth Defects 183

Screening for Aneuploidy 184

Screening for Anomalies With the Standard Ultrasound Examination 185

### Clinical Value of Birth Defect Screening 189

### "Entertainment" Ultrasound Examinations 189

## KEY ABBREVIATIONS

## OVERVIEW

Over the past several decades, the clinical use of ultrasound imaging in obstetrics has expanded remarkably. It is now considered by many to be the most valuable diagnostic tool in the field. Ultrasound was first used clinically in pregnancy in the

early 1960s to measure the biparietal diameter (BPD)—the distance between spikes on an oscilloscope screen. Since then, the technology has progressed to the point that even relatively inexpensive ultrasound machines yield detailed real-time images of the fetus. This chapter addresses general aspects of ultrasound in pregnancy as well as the use of ultrasound to diagnose birth

defects. More detailed discussions of other specific pregnancy problems that include ultrasound assessment—such as multiple gestation, third-trimester bleeding, and cervical insufficiency—are covered in other chapters.

## BIOPHYSICS OF ULTRASOUND

**The underlying basis of ultrasound image production relies on the piezoelectric effect: when electrical impulses are applied to certain ceramic crystals, mechanical oscillations are induced.** Conversely, induced vibrations of piezoelectric crystals generate a detectable electric current. In diagnostic ultrasound applications, the ultrasound machine sends an electric signal of the desired frequency to piezoelectric crystals embedded in the ultrasound probe. When the probe is placed in contact with a patient's skin, the skin and underlying tissues begin to vibrate, generating a sound or pressure wave. As this pulse of energy encounters an interface between materials of different impedance, a small amount of the energy is reflected as an echo. The pulses that return to the patient's skin cause the crystals in the probe to vibrate, which generates an electric current that is passed back to the ultrasound machine. The pulses of energy emitted are very brief—about 1  $\mu$ sec. The number of pressure peaks produced in 1 sec is the frequency of the sound waves. **Ultrasound machines used in obstetrics operate at frequencies between about 2 and 9 MHz. Sound frequencies above 20 KHz cannot be detected by the human ear, hence the term *ultrasound*.** Between each emitted sound pulse, the probe “listens” for an echo. **Because of this alternating send-recvie function, the piezoelectric crystal serves as both the transmitter and receiver of the ultrasonic waves.**

To produce an image, the ultrasound machine must sense the intensity and the time elapsed from the sending to the receipt of the returning echoes. **Highly reflective tissues, such as bone, generate relatively more intense echoes.** The deeper an object lies, the longer it will take for the return echo to be registered. Because the velocity of sound in tissues is known, the return time can be used to calculate the distance of the object from the transducer. Intensity and depth characteristics are registered in the machine's computer memory, and this information is then used by the computer to activate pixels on the monitor with the appropriate location and intensity.

Modern ultrasound probes used in obstetrics have a curved face in which are embedded a row of crystals. The linear arrangement of the crystals on the probe allows the mechanical oscillations generated by each crystal to be combined into to a wedge-shaped beam. A two-dimensional (2-D) image of the scan plane is then displayed with the curved shape of the probe face at the top of the screen. With endovaginal probes, the crystals are mounted on a smaller surface with a tighter curvature.

## OPTIMIZING THE ULTRASOUND IMAGE

### Frequency

As noted above, ultrasound transducers are designed to operate at a certain frequency or over a range of frequencies. Lower-frequency sound waves penetrate tissues better but cannot achieve the same resolution as higher-frequency probes. However, if too high a frequency for a certain patient is used, the lack of penetration severely degrades the images. **Thus the highest frequency probe that allows adequate penetration should be used. This usually depends on the thickness of the patient's**

**abdominal wall. For obese patients, a lower-frequency probe must be chosen. The frequency used for most general purpose transabdominal obstetric probes is about 3 to 5 MHz.** A lower-frequency transducer (2 to 2.25) may be needed to provide adequate resolution in obese patients. When available, a higher-frequency probe that operates at 5 MHz or above is useful in selected patients. Higher-end probes now operate at a range of frequencies, thus one transducer may operate at 2 to 5 MHz and another at 5 to 8 MHz. **Because penetration of the maternal abdominal wall is not an issue, transvaginal probes usually operate at a frequency of 5 to 10 MHz.** Most quality ultrasound machines now have a feature called *tissue harmonic imaging*. With this modality, a standard frequency (e.g., 3 MHz) is transmitted and propagated in the usual manner. Because a relatively low-frequency wave is emitted, good penetration is preserved. However, in the receive part of the cycle, the ultrasound machine listens for the reflection of the first harmonic wave (e.g., 6 MHz). This higher-frequency wave only has to travel one direction, thus some of the resolution benefit of high-frequency scanning is retained. This process also reduces noise in the image by removing various forms of artifact, making cystic structures appear free of echoes. Harmonic imaging often significantly improves image quality and should be used liberally when available.

### Power

Ultrasound machines have the capability of delivering varying amounts of voltage to the transducer elements. Increasing the power output increases the amplitude of energy waves in the ultrasound beam and results in stronger returning echoes. This can improve the signal-to-noise ratio and can improve imaging capabilities. However, energy is required to create oscillations in the molecules of insonated tissues. Because this energy is absorbed into the tissues, delivering an unnecessarily high energy dose raises safety concerns. The safety of diagnostic ultrasound will be discussed later in this chapter.

### Gain

**Signals from the weak echoes returning to the transducer elements must be amplified before being used for display.**

This amplification process is referred to as *gain*. Because of attenuation, echoes returning from deeper within the body have a lower intensity, and the machine must boost the amplification from these echoes. This built-in processing feature is known as *time-gain compensation* (TGC), meaning that echoes with a greater time delay automatically have greater amplification. The amount of amplification, or gain, can be controlled by the sonographer in two ways, with the gain control knob or the TGC controls. The gain control knob adjusts the overall gain up or down, so the brightness of the image can be changed to optimize visualization of anatomic details. When an image is too bright or too dark, much diagnostic information is lost (Fig. 9-1). Because tissue characteristics vary from patient to patient, penetration of sound waves at different depths may vary, so the gain at different depths may be adjusted. This is done using the TGC controls, a set of sliders on the instrument control panel (Figs. 9-2 and 9-3). A uniform scale across the brightness values should be sought.

### Attenuation

**Attenuation of ultrasound waves is affected by the medium through which the sound waves pass. Virtually no pulses pass**

**FIG 9-1** **A**, In this image the overall gain is too low, yielding a dark image. **B**, This image has too much gain. In both cases, diagnostic detail is lost.

**FIG 9-2** **A** shows the slide bars that comprise the time-gain compensation controls. In this case, the fact they are lined up in the center indicates that no adjustment for different depths was needed (**B**).

through gas. This is why there must be a coupling agent (e.g., ultrasound gel) applied between the transducer face and the patient's skin. For several reasons, ultrasound waves lose intensity as they pass through tissues. The pressure waves gradually diverge from the central beam and are scattered by reflection from small structures within the tissue, and part of the sound energy is absorbed within tissues. Some tissues, such as bone, strongly attenuate sound waves. The thicker the tissues through which sound waves must pass before arriving at the target, the more the attenuation and the greater the difficulty in retrieving

good information from the echoes. Because of attenuation, obstetric ultrasound imaging is greatly affected if the patient is obese. In patients with a thick, dense abdominal wall, image quality is greatly reduced. In such patients, attention to equipment controls and scanning technique is essential.

### Focus

A linear array transducer makes an ultrasound beam by firing a row of crystals placed along the surface of the probe. When adjacent crystals fire, the pressure waves reinforce one another

**FIG 9-3** Incorrect time-gain compensation settings (**A**). The slide bars are inappropriately shifted to the left in the near field, making the corresponding area of the image too dark (**B**).

**FIG 9-4** Ultrasound image before zoom is applied. The area within the dotted lines should be expanded to fill the entire screen.

by a process called **constructive interference**. This phenomenon creates the central ultrasound beam that extends out from the probe. Electronic control of the timing and order that crystals are activated can work to focus this beam at the region of interest within the tissues. **Image resolution is optimal when the structure of interest lies within this zone of optimal focus, which can be adjusted by the sonographer.**

### Depth and Zoom

When scanning, the sonographer should strive to cone down the view to best demonstrate important structures without filling the screen with irrelevant material. The depth control can be used to simply crop extraneous structures at the bottom of the image. The zoom control is a little more sophisticated; it magnifies a box within the image rather than just removing information from the bottom of the image (Figs. 9-4 and 9-5).

**Proper depth and zoom are important for several reasons. Most importantly, limiting the size of the scanned area allows**

**FIG 9-5** Appearance after zoom is applied. Compared with Figure 9-4, the cardiac structures are more easily seen. Additionally, because a smaller area was being scanned, the frame rate increased from 25 to 58 frames per second.

**a higher frame rate and resolution. Additionally, homing-in on the area of interest draws attention to important detail within that scanned area.**

## SPECIAL ULTRASOUND MODALITIES

### M-Mode

For most obstetric applications, the familiar 2-D gray-scale real-time ultrasound is used. This is formally known as *B-mode ultrasound*. Another ultrasound modality that is available on most machines is referred to as *M-mode ultrasound* (“motion mode”). M-mode ultrasound shows changes along a single ultrasound beam over time. The depth of the echo-producing structures is shown on the y-axis, and time is shown on the x-axis. M-mode is useful for documenting the presence of fetal cardiac

**FIG 9-6** M-mode application in an 8-week fetus. The row of dots in the left panel indicates the line of information, in this case cardiac pulsations, being displayed over time in the right panel. M-mode is preferred to Doppler for documenting fetal viability before 10 weeks. Note the prominent brain vesicle in the fetal head, a normal finding.

**FIG 9-7** M-mode ultrasound with the cursor through the heart valves. In any ultrasound exam, it is important to have a permanent record showing fetal viability. M-mode is convenient for this purpose and can be used to determine the fetal heart rate.

activity (Figs. 9-6 and 9-7), and **M-mode is also sometimes used for specialized echocardiography applications.**

### Color and Pulse-Wave Doppler

Over the past 25 years, Doppler ultrasound imaging has assumed a key role in obstetrics. With this modality, the ultrasound machine detects shifts in the frequency of echoes returning from a specific location in the image. **This frequency shift, the Doppler shift, is caused by motion of the insonated material toward or away from the transducer.** Doppler ultrasound is primarily used to demonstrate the presence, direction, and velocity of blood flow. The machine displays moving blood as color superimposed on the 2-D gray-scale image. By convention,

flow toward the ultrasound transducer is displayed in red and flow away is displayed in blue. Pulse-wave Doppler continuously measures the relative velocity of flow within a designated gate inside a vessel. **Flow velocity waveforms are used to calculate the systolic/diastolic (S/D) ratio, the pulsatility index, and the resistance index.**

**These indexes are primarily used to assess downstream resistance in the vessel being interrogated.** In pregnancies with fetal growth restriction, the flow within the umbilical artery is used to assess placental function (Fig. 9-8). **For some applications, the absolute flow velocity is needed. For example, when screening for fetal anemia, the peak flow velocity in the fetal middle cerebral artery is measured, as this correlates**

**FIG 9-8** Color and spectral Doppler evaluation of the umbilical artery. In the left panel, the coiling arteries and vein are shown. Red indicates flow toward the transducer and blue is flow away. The sample gate for the pulse Doppler is superimposed. On the right is the result of the pulse Doppler, depicting a normal flow velocity waveform.

**FIG 9-9** Color and spectral Doppler interrogation of the middle cerebral artery. Abnormally high peak velocity is an indicator of moderate to severe fetal anemia. Because the actual velocity is being measured, the angle of insonation should line up with the vessel.

**with the degree of fetal anemia.** To give meaningful results, it is absolutely essential that the angle of insonation ( $\theta$ ) must be in line with the direction of blood flow (Fig. 9-9). Most ultrasound machines are equipped with the technology to allow the sonologist to autocorrect the angle of insonation when the optimal angle cannot be obtained.

### Three-Dimensional Ultrasound

High-performance computers have allowed the development of ultrasound machines and probes that can acquire, process, and display a three-dimensional (3-D) volume, as opposed to the single plane displayed with 2-D ultrasound. To obtain this volume, the transducer uses an internal mechanical sweep mechanism that summates contiguous 2-D planes. This volume

**FIG 9-10** Three-dimensional image shows bilateral cleft lip. Images such as this can be helpful for counseling patients.

data can either be stored for analysis or updated and displayed on a continuous basis. Adding a real-time updating of a rendered image is commonly referred to as *four-dimensional ultrasound*.

**For diagnosing certain birth defects, 3-D ultrasound may be useful.** Information from an acquired volume may be processed in such a way that the fetal surface is displayed in a lifelike manner. Surface abnormalities, such as facial clefts, can be well demonstrated with this approach (Fig. 9-10).<sup>1</sup> In addition, 3-D images can be more readily understood by patients and other professionals who will participate in care of the baby.

Software available for use with 3-D ultrasound machines can manipulate stored volume data off-line to show any desired plane through the scanned area. Some of these planes may be difficult to obtain with standard 2-D imaging. Storage of a volume of data also allows retrospective generation of 2-D images from different planes than were originally recorded. This

**FIG 9-11** Transabdominal sagittal view of the uterus. The uterine fundus and cervix are labeled. By convention, the right side of the ultrasound screen corresponds to the inferior aspect of the patient.

could be a powerful tool for review of ultrasound exams. Another feature of 3-D ultrasound is its ability to calculate tissue and fluid volumes. For example, lung volume measurements have been used to predict pulmonary hypoplasia.<sup>2</sup>

**Despite the demonstrated capabilities of 3-D ultrasound, no proof exists of an advantage of this technology over standard 2-D imaging for prenatal diagnosis. A 2009 American College of Obstetricians and Gynecologists (ACOG) practice bulletin states that “three-dimensional ultrasonography may be helpful in diagnosis as an adjunct to, but not a replacement for, two dimensional ultrasonography.”<sup>3</sup>**

## SCANNING TECHNIQUE

### Orientation

The sonographer starts the exam by exposing the patient's skin over the entire uterus and liberally applying warmed coupling gel. An appropriate probe is selected, and a preliminary survey of the entire uterine contents and adnexa is performed. Before going any further, it is a good idea to **document fetal cardiac activity**. Images are frozen and recorded liberally. Almost all machines have a **cine loop** feature in which a few seconds of sequential images are saved so that the sonographer can scroll backward if the desired image was missed.

**Every effort should be made to perform the scan with the sonographer and the patient in standard positions.** In most settings, the ultrasound machine and the sonographer are on the patient's right, with the sonographer comfortably seated facing the head of the patient. **The probe is held in such a way that the image on the screen is properly oriented. By convention, the probe surface is shown at the top of the screen. For sagittal views, the right of the screen corresponds to the inferior aspect of the patient (Fig. 9-11). For transverse views, the patient's right is shown on the left of the screen.** With transvaginal ultrasound, transverse views also show the patient's right side to the left of the screen. In transvaginal sagittal views, “up” is to the left of the screen (i.e., toward the bladder), and “down” (toward the sacrum) is to the right of the screen (Fig. 9-12). Ultrasound transducers have a notch or ridge that demarcates the side of the probe that will correspond to the left side of the monitor. Thus with transabdominal work, this mark would be

**FIG 9-12** Transvaginal sagittal view showing proper orientation. The left of the screen is “up” on the patient, that is, toward the bladder (BI). The probe tip (Pr), fetal head (FH), cervix (Cx), placenta (PI), and rectum (R) are labeled. Note how transvaginal ultrasound provides the ultimate “window,” showing very clear views of structures close to the vaginal apex. Also note the presence of vasa previa.

toward the patient's head for sagittal views and toward the patient's right for transverse views. With transvaginal scanning, the mark is up for sagittal views and to the patient's right for transverse views. Thus in going from sagittal to transverse, the probe is always rotated counterclockwise, and the clinician goes clockwise to move from transverse to sagittal.

If the sonographer sits or stands on the wrong side of the patient or holds the probe backward, standard orientation of the images is difficult to maintain. A “backward” image is clearly unacceptable for diagnostics and for documentation. Also, a casual approach to probe orientation will prevent the sonographer from developing the hand-eye coordination needed to quickly and accurately steer the probe.

**To establish the position of the fetus, the orientation of the probe must obviously be correct.** This is important not only when deciding whether the fetus is cephalic or breech but also when determining the right and left side of the fetus. For example, when the image shows the fetal spine to the right side of the uterus, the fetal left will be up in a cephalic presentation and down with a breech. The sonographer should not depend on the side of the stomach or axis of the heart to define the position of the fetus because these structures are not always in a normal position.

### Angle of Insonation

There is often a best angle from which to view aspects of the intrauterine contents and fetal structures. For example, transverse views of the kidneys are best obtained from a directly anterior or posterior direction. With a lateral view, one kidney is shadowed by the spine (Fig. 9-13). Sliding the transducer across the mother's abdomen to change the angle of insonation by 90 degrees corrects this problem. Sometimes, significant pressure with the transducer is needed to get the probe into position for optimal visualization. If the fetal position precludes clear visualization of a structure, a good strategy is to move forward with the examination and come back to the troublesome area. The fetus will often have moved in such a way that adequate views can be obtained.

**FIG 9-13** **A**, Shadowing by the spine precludes visualization of the left kidney. **B**, By sliding the transducer to a different location on the maternal abdominal wall, a more favorable angle of insonation is possible. The spine (Sp), right kidney (RK), and left kidney (LK) are labeled.

**FIG 9-14** **A**, Scan through the pannus of the abdominal wall. **B**, By moving the probe into the relatively thinner area near the maternal umbilicus, the resolution improved dramatically. A similar result can be obtained when scanning below the pannus in the suprapubic area. Of course, when an object of interest is in the maternal pelvis, transvaginal ultrasound provides an even better window (see Fig. 9-12). This fetus has truncus arteriosus (Tr).

### Using Natural Windows

As previously noted, increasing the power of ultrasound impulses can overcome some of the effects of attenuation in maternal tissues. Although it is tempting to use higher-power settings for obese patients, other methods should be attempted first. As a starting point, the proper probe frequency and gain setting should be used. **Even more effective, however, is to avoid**

**attenuation altogether by scanning through one of the natural “windows” in the maternal abdominal wall.** The abdominal wall thickness in obese women is substantially less near the umbilicus (Fig. 9-14) and in the suprapubic area. **To a lesser extent, thickness is also decreased lateral to the central pannus.** Using these windows can often improve the quality of images dramatically. Of course, in early pregnancy or when

structures of interest are low in the pelvis, the problem of attenuation is reduced considerably by the use of an endovaginal probe (see Fig. 9-12). The reduction of attenuation with transvaginal ultrasound allows the use of a higher-frequency probe, which usually results in excellent resolution. **Another natural window is amniotic fluid, and scanning through amniotic fluid improves the image quality below or deep to the amniotic fluid.** This is especially true for imaging the surface of the fetus. A full bladder provides a window to structures low in the maternal pelvis. However, scanning with a full maternal bladder has significant disadvantages; not only is it uncomfortable for the patient, it also artificially elongates the cervix and may distort the apparent relationship of the cervix and placenta. Fortunately, this is no longer necessary because transvaginal ultrasound can provide superior views to structures in the maternal pelvis.

### FIRST-TRIMESTER ULTRASOUND

**Transvaginal ultrasound is almost always superior to transabdominal ultrasound for evaluation very early in pregnancy.** Because the distance between the probe and pregnancy structures is often just a few centimeters, attenuation of sound waves is minimal, and high-frequency probes may be used. As previously noted, this allows better resolution of detail. Although an acceptable first-trimester scan can usually be completed transabdominally, it is often helpful to use transvaginal ultrasound as a supplement to or replacement for transabdominal ultrasound. **In general, structures are visible one week earlier with transvaginal ultrasound. At about 10 to 12 weeks' gestation, the uterus has grown enough—and the fetus is far enough away from the transducer—that advantages of transvaginal scanning are lost.** Even if a structure of interest is low in the uterus, lack of maneuverability of the probe tip may make it difficult or impossible to obtain images through the desired fetal plane. Because of this limitation and the need for a precise midsagittal plane, measurement of the fetal nuchal translucency as part of the first-trimester aneuploidy screen is almost always done transabdominally.

Transvaginal ultrasound is well accepted by most patients and can be accomplished with minimal discomfort. In some clinics, women are given the option of inserting the probe themselves.

### First-Trimester Normal Findings

Both ACOG and the American Institute of Ultrasound Medicine (AIUM) have defined the essential components of a first-trimester scan. Knowledge of the time at which embryonic structures normally appear is important for identifying pathologic pregnancies. For the reasons noted earlier, it will be assumed that transvaginal ultrasound is being used for this discussion.

The gestational sac can usually be seen at 4 weeks, the yolk sac at 5 weeks (Fig. 9-15), and the fetal pole with cardiac activity by 6 weeks. Cardiac activity can be seen simultaneously with the appearance of a fetal pole as a pulsation at the lateral aspect of the yolk sac. **Because pulse or color Doppler carry higher energy, which theoretically could be harmful during embryogenesis (before 10 menstrual weeks),<sup>4</sup> M-mode ultrasound is used to document cardiac activity during this time** (see Fig. 9-6). Starting at 7 weeks, the embryo has grown to the point that recognizable features, such as a cephalic pole, can be seen. As shown in Figure 9-6, a prominent midline brain vesicle can be seen at this time. **The cerebral falx is visible at 9 weeks, and the appearance and disappearance of physiologic gut**

**FIG 9-15** This image shows a normal 7-week gestational sac with the yolk sac (YS) and adjacent fetal pole (FP). Calipers show the measurement to establish the gestational age. CRL, crown-rump length.

**FIG 9-16** Nine-week fetus showing the physiologic gut herniation (curved arrow). Note also how the amnion (straight arrow) has not yet fused to the chorion at the uterine wall.

**herniation are noted between 8 and 11 weeks (Fig. 9-16). In the course of this physiologic process, the bowel is seen to lie within the umbilical cord and does not float freely. Obviously, the diagnosis of an abdominal wall defect should be made with caution at this age.** The stomach can consistently be seen by 11 weeks. If conditions are favorable, it is often possible to also visualize the bladder and kidneys at 11 weeks. At about 12 weeks, using color Doppler, the two umbilical arteries can often be identified as they course around the bladder. The fetal heart rate is initially quite slow, averaging 110 beats/min at 6 weeks,<sup>5</sup> then it increases steadily to a mean peak of 157 beats/min at 8 weeks. When the fetal position is favorable, transvaginal ultrasound has the potential for giving good views of the fetal cardiac anatomy in most patients at 13 weeks.<sup>6</sup> Until 13 to 16 weeks' gestation, the amnion has not fused to the chorion and is seen as a separate membrane (see Fig. 9-16). **Until 12 weeks, the crown-rump length (CRL) should be measured for gestational age determination.** Care should be taken to measure

**FIG 9-17** **A**, Image of the fetus is cut obliquely, and the crown-rump length is inappropriately short. It is measured correctly in **B**. The difference in the calculated gestational age from these two measurements was 5 days. The normal brain vesicle (asterisk) is noted.

the full length of the fetus. The gestational age can be significantly underestimated if an oblique plane is used (Fig. 9-17).

### First-Trimester Abnormal Findings

**Spontaneous abortion occurs in 15% of clinically established pregnancies. When cardiac activity has been demonstrated, the miscarriage rate is reduced to 2% to 3% in asymptomatic low-risk women.**<sup>7</sup> It is important to note, however, that in some groups at high risk for miscarriage—such as women over the age of 35 years who are undergoing infertility treatments—early visualization of cardiac activity does not provide quite as much reassurance. In one study that involved such women, the miscarriage rate in asymptomatic women was still 16% after a heartbeat was documented.<sup>8</sup> **In younger women who present with bleeding, only 5% miscarry if the ultrasound is normal and shows a live embryo.**<sup>9</sup> If an intrauterine clot is present (Fig. 9-18), coexistent with an otherwise normal-appearing pregnancy, the miscarriage rate is 15%.<sup>9</sup>

In the majority of pregnancies destined to abort, the embryo does not develop, and ultrasound shows an empty gestational sac (Fig. 9-19). Such a pregnancy is termed an *anembryonic gestation*. When a failed pregnancy is suspected based on clinical or sonographic grounds, patients and clinicians alike are anxious to determine viability as soon as possible. However, the potential for great harm is obvious if a pregnancy is incorrectly deemed to be a failed pregnancy, and a desired pregnancy is interrupted. There have been cases in which a premature diagnosis of a failed pregnancy was made, medical evacuation of the uterus was unsuccessfully attempted, and the fetus was subsequently found to be viable. Because no significant medical risk attends waiting for certainty when a failed pregnancy is suspected, a cautious approach is always advisable. **Criteria for deciding that a pregnancy of uncertain viability is in fact a failed pregnancy**

**FIG 9-18** This patient presented with vaginal bleeding. A subchorionic clot (CI) was present in the lower uterine segment. This patient carried the pregnancy successfully. The fetus (Fe) and placenta (PI) are shown.

should be set to virtually eliminate the possibility of a false-positive diagnosis. A multispecialty panel from the Society of Radiologists in Ultrasound panel recommended criteria to achieve this end.<sup>10</sup> These include (1) the presence of a fetus with a CRL of more than 7 mm and no heartbeat, (2) the absence of an embryo when the mean sac diameter is greater than 25 mm, (3) the absence of an embryo with a heartbeat more than 2 weeks after a scan showed a gestational sac without a yolk sac, and (4) the absence of an embryo with a heartbeat more than 11 days after a gestational sac with a

**FIG 9-19** Irregular gestational sac from an anembryonic gestation.

**FIG 9-20** Compared with Figure 9-15, the yolk sac in this image is relatively large for the gestational age. An embryo was never seen with this pregnancy.

**yolk sac was seen.** Similar but less stringent criteria that are suspicious for a pregnancy failure are described in the same report. Other signs that indicate a possible failed pregnancy include an enlarged yolk sac ( $>7$  mm; Fig. 9-20) or less than 5 mm difference between gestational sac diameter and the CRL of the embryo. **If there are borderline findings and uterine evacuation is being considered, it is prudent to repeat the ultrasound in 7 to 10 days to be absolutely sure that a viable pregnancy is not interrupted.**<sup>10</sup> Although a quantitative human chorionic gonadotropin (hCG) value that does not show an appropriate rise may indicate an abnormal pregnancy, a decision to medically or surgically evacuate an intrauterine failed pregnancy should be based on abnormal ultrasound findings.

**First-trimester ultrasound findings predictive of a chromosomal abnormality include a thick nuchal translucency, absent nasal bone, abnormally fast or slow fetal heart rate, and some structural malformations.**<sup>11</sup> The first-trimester aneuploidy screen will be discussed in detail in Chapter 10.

### BOX 9-1 SUGGESTED COMPONENTS OF THE STANDARD OBSTETRIC ULTRASOUND PERFORMED IN THE SECOND AND THIRD TRIMESTERS

- Standard biometry
- Fetal cardiac activity (present or absent, normal or abnormal)
- Number of fetuses (if multiples, document chorionicity, amnionicity, comparison of fetal sizes, estimation of amniotic fluid normality in each sac, and fetal genitalia)
- Presentation
- Qualitative or semiquantitative estimate of amniotic fluid volume
- Placental location, especially its relationship to the internal os, and placental cord insertion site
- Evaluation of the uterus that includes fibroids, adnexal structures, and the cervix
- Cervix when clinically appropriate and technically feasible
- Anatomic survey to include:
  - Head and neck
    - Cerebellum
    - Choroid plexus
    - Cisterna magna
    - Lateral cerebral ventricles
    - Midline falx
    - Cavum septum pellucidum
    - Fetal lip
    - Nuchal skin fold may be helpful for aneuploidy risk
  - Chest
    - Four-chamber view of the heart
    - Outflow tracts (if possible)
  - Abdomen
    - Stomach (presence, size, and situs)
    - Kidneys
    - Bladder
    - Umbilical cord insertion into the abdomen
    - Number of umbilical cord vessels
  - Spine
  - Extremities (presence or absence of legs and arms)
  - Gender

## SECOND- AND THIRD-TRIMESTER ULTRASOUND

### Types of Examinations

The AIUM, in conjunction with ACOG and the American College of Radiology (ACR), have defined a set of criteria for standard obstetric ultrasound examinations performed in the second and third trimesters.<sup>3,12</sup> **Components of a standard obstetric examination are shown in Box 9-1.** A complete description of the AIUM and ACOG guidelines can be found in the listed references.

These guidelines recognize that not all ultrasound examinations have the same purpose. For this reason, types of fetal

sonographic evaluations have been defined. Components of the first-trimester ultrasound examination were described previously. A **standard** second- or third-trimester examination (current procedural terminology [CPT] code 76805), as defined in [Box 9-1](#), can be performed by any appropriately qualified sonographer. **It is recognized that certain scans, termed *specialized examinations* (CPT code 76811), are more complex than the complete standard examinations performed in the course of routine pregnancy care. This designation and billing code are intended to be used for referral practices with special expertise in the identification of and counseling on fetal anomalies.** Other specialized examinations may include fetal Doppler ultrasonography and fetal echocardiography.<sup>3</sup> Follow-up examinations are needed for many obstetric conditions; these are termed **repeat** examinations (CPT 76816).

**Another examination category is the *limited examination* (CPT 76815). Limited ultrasound examinations, also performed by a trained sonographer, are used to obtain a specific piece of information about the pregnancy.** Examples of this type of examination include the determination of fetal lie or assessment of amniotic fluid volume. **The importance of restricting limited examinations to those cases in which a complete examination has previously been performed should be self-evident.** Consider the consequence if a brief ultrasound is done and critically important information is missed, such as a serious malformation in the fetus. Unfortunately, it is all too common for practitioners to perform limited examinations in a manner inconsistent with good medical practice. For example, in some clinics, practitioners perform an ultrasound at the first prenatal visit to document viability but do not measure the fetus or record the results of the examination. Such a practice can create problems later in pregnancy when the gestational age is in doubt.

**All the aspects of the standard obstetric examination listed in [Box 9-1](#) are important for clinical management and should not be neglected. It is clearly unacceptable for an ultrasound exam to miss such conditions as placenta previa, multiple gestation, or an ovarian tumor.** The diagnosis and management of these and other conditions are discussed in detail elsewhere in this book, but a brief description of the importance of the components of the standard ultrasound examination will be given here.

### Qualifications for Performing and Interpreting Diagnostic Ultrasound Examinations

Most ultrasound exams in the United States are performed by professionals who are credentialed by the American Registry of Diagnostic Medical Sonography (ARDMS). Individuals with these credentials have had extensive education and testing to ensure their competency. A physician then generates a report based on the images and information obtained by the sonographer. When appropriate, the physician may personally perform or repeat parts of the exam. **The AIUM has published guidelines on the training and experience needed for physicians to perform or interpret ultrasound examinations.**<sup>13</sup> In brief, these guidelines recommend that licensed physicians have completed an equivalent of 3 months training dedicated to ultrasound in the context of an approved residency, fellowship, or other postgraduate training. In the absence of a formal training program, physicians can qualify through having 100 American Medical Association (AMA) category I credits dedicated to diagnostic ultrasound. In addition to participation in either a formal training program or by taking postgraduate courses, physicians should

have been involved with the performance, evaluation, and interpretation of at least 300 appropriately supervised sonograms. The full text of the guidelines is in the referenced document.

## COMPONENTS OF THE EXAMINATION

### Cardiac Activity

Obviously, the presence or absence of cardiac activity should be documented. As noted previously, after about 6 weeks' gestation, the diagnosis of fetal life is rarely difficult. Even though fetal death may be obvious with B-mode imaging, **confirming the absence of a heartbeat with color or pulse-wave Doppler is recommended.** Absence of color signal in the fetal chest, contrasted with the demonstration of flow in the surrounding uterine tissues, can increase the confidence that fetal death has indeed occurred. Throughout pregnancy, an abnormally fast, slow, or irregular heartbeat can be detected by visual inspection with gray-scale ultrasonography. The abnormal rate can be quantified and documented with M-mode or pulse-wave Doppler ultrasound.

### Number of Fetuses

**When a multiple pregnancy is diagnosed, the number of amnions and chorions should always be determined** (see [Chapter 32](#)). **Determination of chorionicity is most easily accomplished in early pregnancy. The presence of unlike sex twins, separate placentae, or a thick membrane dividing the sacs with a twin peak or "lambda sign" all indicate the presence of two chorions** (see [Fig. 9-3](#)). **It is well-recognized that the level of fetal risk is much higher when fetuses share chorions, and the risk is extremely high if there is a single amnion.**<sup>14</sup> Monochorionic pregnancies require early referral for a specialized ultrasound. **In all twin pregnancies, periodic ultrasound examinations should be performed to assess fetal growth.** Twins are at significantly increased risk for growth abnormalities, and it is not possible to assess the growth of the twins individually by abdominal palpation.

### Presentation

The assessment of presentation is not merely a matter of determining whether the fetus is head down or breech. A more precise ultrasound analysis of presentation is important in certain circumstances. If a transverse lie is diagnosed, it is important to diagnose whether the fetus is back down (i.e., back toward the cervix) because this may require a vertical incision for cesarean delivery. If the patient has preterm labor or ruptured membranes, a back-up transverse lie indicates a high risk for cord prolapse. The attitude of the fetal head, especially a face presentation, can be important in assessing progress in labor. In cases of marked caput or molding in late labor, it is often difficult to determine the position of the fetal head by palpation of the cranial sutures. Under these circumstances, ultrasound can be used to readily identify fetal cranial landmarks to clarify the position of the fetal head.<sup>15</sup>

### Amniotic Fluid Volume

Every ultrasound examination should include an assessment of the amniotic fluid volume (see [Chapter 35](#)). It is acceptable for an experienced examiner to make this determination subjectively.<sup>12</sup> However, to aid in communication and to provide criteria for management protocols, semiquantitative methods have been devised. **A popular method is the amniotic fluid index**

**FIG 9-21** These sonographic images show the deepest vertical pocket in each of the four quadrants of the uterus. The sum of the measurements of these pockets is the amniotic fluid index.

**FIG 9-22** An ultrasound image showing polyhydramnios. The distance between the anterior and posterior uterine walls was 9 cm.

(AFI), the sum of the measurements of the deepest vertical pocket of fluid in each of the uterine quadrants (Fig. 9-21). The limits of the quadrants are the maternal midline and a horizontal line through the maternal umbilicus. Each pocket should measure at least 1 cm in width.<sup>16</sup> The line between the calipers should not cross through loops of cord or fetal parts.

Polyhydramnios and oligohydramnios can be defined either by an AFI outside of a fixed range, usually defined as greater than 24 cm or less than 5 cm, respectively.<sup>17</sup> A simpler semi-quantitative method is to diagnose *polyhydramnios* when the single deepest pool measures greater than 8 cm (Fig. 9-22)<sup>18</sup> and *oligohydramnios* when the shallowest pool measures less than 2 cm in two dimensions.<sup>16</sup>

The actual volume of amniotic fluid can be determined by dye-dilution techniques performed at the time of amniocentesis. The semiquantitative ultrasound methods described previously correlate somewhat with actual fluid volume, but their accuracy for predicting abnormal fluid volume is limited.<sup>18</sup>

### Oligohydramnios

The complete absence of amniotic fluid before labor can indicate fetal malformations, rupture of the membranes, or placental insufficiency. A deficit of amniotic fluid that occurs before the mid second trimester can result in the oligohydramnios sequence, which includes pulmonary hypoplasia, fetal deformations, and flexion contractures of the extremities. The outcome with anhydramnios depends on the cause and the gestational age at which it is first present. Fetal malformations that cause absence of fluid usually involve the urinary tract. These may include complete bladder outlet obstruction or bilateral renal anomalies in which no urine is produced. Examples include bilateral renal agenesis, bilateral multicystic dysplastic

kidneys, or autosomal-recessive polycystic kidney disease. **The development of lethal pulmonary hypoplasia when the cause of mid second trimester oligohydramnios is other than a urinary tract malformation is not as predictable.**

For many years, it has been recognized that less extreme alterations of amniotic fluid volume can be important. Chamberlain and associates<sup>19</sup> found that with less than a 1-cm pocket of fluid, perinatal mortality increased fortyfold. The incidence of intrauterine growth restriction (IUGR) was also much higher when this degree of oligohydramnios was found. These findings and those of other investigators led to the recognition that oligohydramnios can be an important sign of placental insufficiency, and amniotic fluid volume assessment became part of the biophysical profile (see Chapter 11). Because of the association between oligohydramnios and fetal compromise, it became common practice to deliver the baby when the AFI was less than 5. More recently, it has been shown that isolated ultrasound-diagnosed oligohydramnios is not as predictive of perinatal outcome as was previously thought.<sup>20</sup> In 2014, ACOG recommended using a deepest vertical pocket of 2 cm or less as the definition of oligohydramnios by which clinical management decisions should be made. This method is simpler than the AFI, and more importantly, it has been shown to reduce the rate of obstetric interventions for oligohydramnios with no difference in perinatal outcomes compared with using an AFI of less than 5.<sup>21</sup>

### Polyhydramnios

Polyhydramnios has been classified as *mild* if the AFI is more than 24 cm, or the deepest pocket is more than 8 cm; it is considered *moderate* with an AFI greater than 30 cm, or when the deepest pocket is more than 12 cm; and it is *severe* when the AFI is greater than 35 cm or the deepest pocket is more than 16 cm.<sup>22</sup> Severe polyhydramnios may be indicative of a fetal problem and requires specialized ultrasound to determine the etiology. It is often caused by malformations that can greatly affect neonatal management or prognosis. For many of these conditions, the excess amniotic fluid is a result of poor fetal swallowing because of neurologic abnormalities, genetic syndromes, or gastrointestinal (GI) malformations. **The chance of a malformation or genetic syndrome being present with mild, moderate, or severe polyhydramnios is approximately 8%, 12%, and 30%, respectively.**<sup>23</sup> **The chance of a fetus with polyhydramnios having aneuploidy is 10% when other anomalies are present.** Other serious causes of severe polyhydramnios include twin-to-twin transfusion syndrome and fetal hydrops. An association has been found between polyhydramnios and fetal macrosomia, and maternal diabetes mellitus is present in about 5% of cases.<sup>23</sup> Mild polyhydramnios may simply be a variant of normal, and it often resolves spontaneously. **With polyhydramnios, an increase in preterm birth is observed when the patient has diabetes (22%) or the fetus has anomalies (39%) but not when it is idiopathic.**<sup>24</sup> No studies have researched whether antepartum testing is helpful, although polyhydramnios is listed as an indication for antepartum testing in an ACOG technical bulletin.<sup>21</sup> When polyhydramnios persists, follow-up ultrasound exams are appropriate to assess fetal growth and amniotic fluid volume.

### Placenta and Umbilical Cord

One of the principal advantages of routine ultrasound is that serious problems of placentation—such as placenta previa,

**FIG 9-23** Sagittal transabdominal view of the lower uterus and cervix. The relationship between the edge of the placenta and cervix is unclear, and placenta previa cannot be accurately diagnosed.

**FIG 9-24** Sagittal transvaginal view of the same patient. Marginal placenta is clearly visible, and the edge of the placenta (Plac edge) extends 1.5 cm over the internal os (Int cx os). Calipers are not shown.

placenta accreta, and vasa previa—can be diagnosed in a timely manner (see Chapter 18). At the time of the routine screening ultrasound (beyond 18 weeks), it should be determined whether the placenta covers the internal cervical os. If the placenta and the cervix are not seen clearly, or if it appears that the edge of the placenta is close to the cervix, vaginal ultrasound should be used liberally to clarify this relationship (Figs. 9-23 and 9-24).<sup>25</sup>

The terms *complete* and *partial placenta previa* originated from a time when the relationship of the placenta to the partially dilated cervix was determined by digital examination. Because the internal cervical os is not typically dilated at the time of ultrasound, these definitions are confusing and often uninformative. For this reason, a joint statement by the major ultrasound and obstetric societies in the United States<sup>16</sup> and a policy statement by the Society of Obstetricians and Gynaecologists of Canada<sup>26</sup> recommended a classification that retains only the terms *placenta previa* and *low-lying placenta*. The distance

**FIG 9-25** Sagittal transvaginal image showing vasa previa. An umbilical vessel (UV) passes over the internal os of the cervix (Cx). In this case, a velamentous cord insertion was evident, and this vessel passed over the cervix running from the cord insertion to the placenta.

that the edge of the placenta covers or ends short of the internal cervical os should be measured and reported. This quantitative description is much more helpful than a report of “complete” or “partial” previa for predicting the future placental position and in planning management. **For pregnancies greater than 16 weeks, if the placental edge ends 2 cm or more from the cervix, the placental location should be reported as normal. If the placental edge is less than 2 cm from the internal os but not covering the internal os, the placenta should be labeled as low lying, and follow-up ultrasonography is recommended at 32 weeks’ gestation.**<sup>16</sup>

Between 18 and 23 weeks’ gestation, the edge of the placenta extends to or covers the internal os of the cervix in about 2% of patients.<sup>27</sup> However, most cases of placenta previa diagnosed early in pregnancy resolve as pregnancy progresses. The rate of persistence of placenta previa depends on the degree of overlap. When the degree of overlap is 15 mm or greater, 19% persist as placenta previa, whereas if the overlap is 25 mm or greater, 40% remain.<sup>27</sup> Another study found that when placenta previa is present at 15 to 19 weeks, only 12% persist.<sup>28</sup> **The rate of persistence gradually increases as the gestational age advances, up to 73% if placenta previa is present at 32 to 35 weeks.** This study also showed that the degree of overlap was helpful in predicting persistence. These results suggest that **repeated ultrasound examinations should be performed until the placenta moves well away from the cervix or until it becomes clear that the previa will persist.** If the placenta previa persists, ultrasound can be very valuable in planning delivery.

**The diagnosis of vasa previa is critical because the recognition of this finding at the time of a screening ultrasound greatly affects the chance of fetal survival.**<sup>29</sup> **The fetal mortality rate is high when vasa previa is not diagnosed before labor.** Conversely, early diagnosis and aggressive obstetric management of patients with vasa previa almost always results in a live baby born in good condition. The fetal vessels that cover the cervix may not be readily apparent with a routine transabdominal screening examination; therefore a high index of suspicion should be maintained. Transvaginal color Doppler ultrasound should be strongly considered in any case of velamentous cord insertion, a succenturiate lobe, or when portions of umbilical

cord are noted to be low in the uterus (Fig. 9-25). The sonographer should also be aware that when placenta previa “resolves,” branches of the umbilical vessels on the chorionic plate may still course over the cervix as placental villi degenerate beneath them, resulting in vasa previa. Identifying the cord insertion onto the placenta eliminates the possibility of velamentous cord insertion, but it does not exclude vasa previa from the other placental abnormalities. **Documentation of the cord insertion onto the placenta is good practice, and it is recommended when technically possible.**<sup>16</sup>

In addition to determining the placenta’s location, its appearance should be assessed. Many changes observed in the placenta are related to calcification, fibrosis, and infarction. The general trend is for these changes to become more apparent as pregnancy progresses, but their clinical significance is unclear. It has recently been recognized that a “globular” placenta, with a narrow base compared with height, is associated with an increased rate of IUGR, fetal death, and other complications.<sup>30</sup>

The sonographer should confirm that there are two arteries and a vein in the umbilical cord.<sup>16</sup> In late pregnancy, this can be ascertained by looking at a transverse cut of the cord in a free loop. In the second trimester, two umbilical arteries are most easily confirmed by identifying the vessels with color Doppler as they course around the fetal bladder (Fig. 9-26). **A single umbilical artery is present in about 0.5% of all newborns. Because of the increased incidence of associated malformations, especially those that involve the kidneys and heart, this finding should prompt a detailed fetal survey.** Fetuses with a single umbilical artery have a 20% chance of growth restriction. Additionally, the rate of polyhydramnios, abruption, placenta previa, structural placental abnormalities, cesarean delivery, low Apgar scores, and fetal death are all increased.<sup>31</sup>

## Uterus and Adnexa

With any obstetric ultrasound, including those performed in the first trimester, the adnexal and uterine morphology should be evaluated. Many women enter pregnancy without being aware that they have fibroids or a müllerian malformation. Fibroids are usually readily apparent with transvaginal or transabdominal ultrasound. **A common pitfall is to confuse uterine contractions, which are commonly present in the second trimester, with fibroids (Fig. 9-27). Contractions have a more lenticular shape and blend with the surrounding myometrium, whereas fibroids usually are spherical with distinct borders and a whorled internal echo texture.** Pedunculated fibroids, even large ones, can be missed if the sonographer does not examine areas around the periphery of the uterus. Most studies have shown a higher rate of pregnancy complications when fibroids are present. However, the odds ratios are typically modest and of limited clinical importance.<sup>32</sup> It is difficult to predict how fibroids will affect an individual patient’s pregnancy because the number, size, and location can vary markedly. **Ultrasound mapping of fibroids can help in making a delivery plan.** Although large fibroids that fill the pelvis may preclude vaginal birth, it is usually prudent to not predict early in the pregnancy the need for cesarean delivery. Fibroids can rise out of the pelvis, leaving a relatively clear lower uterine segment. **Because multiple fibroids in the lower uterus can greatly complicate the performance of a low transverse cesarean delivery, ultrasound may help predict the need for a classical incision.** Studies with serial ultrasound exams have had conflicting results in regard to the growth of fibroids during pregnancy.<sup>33,34</sup>

**FIG 9-26** **A**, Umbilical vein (UV) and a single umbilical artery (UA) are shown in a transverse section of a free loop of cord. **B**, A transverse view of the fetal pelvis, using color Doppler, clearly shows the normal paired umbilical arteries coursing around the bladder (Bl). It is often easier to document the umbilical arteries in early pregnancy with this color Doppler method.

**FIG 9-27** **A**, Two fibroids are shown that are round and well circumscribed. **B**, Uterine contraction is lenticular in shape and does not have a clear border. Contractions such as this are very common in the second trimester.

### Cervix

It has been clearly documented that a short cervix, as measured with transvaginal ultrasound, is associated with an increased risk of preterm birth in both high- and low-risk patients (see [Chapters 28](#) and [29](#)). Intervention with a cervical cerclage has been shown to improve outcome in patients with a prior spontaneous preterm birth who have a short cervix in a subsequent pregnancy.<sup>35</sup> **Treatment of low-risk women who have a short cervix with vaginal progesterone has also been shown to be reduce the rate of preterm birth.**<sup>36</sup> However, the value of universal screening is unproven, and ACOG currently does

**not recommend this practice.**<sup>3</sup> The lower limit of normal for cervical length in the mid second trimester is 25 mm. When the routine 18- to 20-week transabdominal ultrasound shows a length less than this, referral for a specialized exam is appropriate.

### Adnexa

**It is important for a complete obstetric ultrasound to include an assessment of the adnexa.** Normal-sized ovaries may be difficult or impossible to see in the second or third trimester because of shielding by bowel. In a study of sonographic

**FIG 9-28** Transabdominal and transvaginal images of an ovarian dermoid. **A**, An 8-week pregnancy with the uterus (Ut) demarcated in the transabdominal image. **B**, Using transvaginal ultrasound, the mass fills the entire field of view. Characteristic irregular mixed solid and cystic areas with highly echogenic nodules (arrows) are seen within the dermoid. To see the pelvic structures clearly with transabdominal ultrasound, the maternal bladder (Bl) must be very full. Although this provides a good window, the structures of interest are pushed away from the probe, which limits resolution. In contrast, the probe is less than 1 cm from the mass when vaginal ultrasound is used.

visualization of normal ovaries, Shalev and coworkers<sup>37</sup> found that although both ovaries were visible in almost all first-trimester scans, both ovaries were visible in only 16% of second- and third-trimester scans, and in 60% of these, neither ovary was seen. However, in most cases when a significant tumor is present, it will be visible. The sonographic appearance of an adnexal mass discovered during pregnancy guides decision making regarding the need for surgical removal. **Masses that consist of simple cysts usually represent benign processes and do not require removal during pregnancy.** Masses with features of malignancy—such as large size, multiple cystic cavities, thick septa, internal papillae, or solid areas—require careful evaluation and may require operative removal. The most common neoplasms in pregnancy are benign cystic teratomas (Fig. 9-28). These can usually be identified by their sonographic characteristics.

### Anatomic Survey

**Systematic evaluation of fetal anatomy is critical. It is a good idea to proceed with an examination in a consistent order so that important parts are not forgotten.** Although many well-recognized maternal risk factors exist for congenital anomalies, 90% of birth defects occur in fetuses of low-risk women.<sup>3</sup> For this reason, it is important that anyone who performs obstetric ultrasound have familiarity with the appearance of normal fetal anatomy in order to recognize deviations from normal. As mentioned previously, although more advanced detailed sonograms (specialized examinations) are appropriate for patients with identified risk factors, **all standard examinations should include a full anatomic survey.** An overview of some of the more common fetal malformations that can be recognized at the time of a standard ultrasound examination is presented later in this chapter.

**When components of the standard second- or third-trimester ultrasound examination cannot be obtained**

**because of maternal obesity, unfavorable fetal position, or other technical factors, this should be documented in the report. In such patients, it is reasonable to repeat the ultrasound in 2 to 4 weeks. If a second attempt is unsuccessful, no further exams to attempt better visualization are necessary.**<sup>3,16</sup>

### Documentation

A report for any ultrasound exam should list the indication. Documentation of ultrasound findings is important not only for good patient care but also for quality review and legal defense. **AIUM guidelines in regard to record keeping state, “Adequate documentation of the study is essential for high-quality patient care. This should include a permanent record of the sonographic images, incorporating whenever possible ... measurement parameters and anatomic findings.”**<sup>3,12</sup>

### Cleaning and Disinfection of Probes

To avoid transmitting disease from one patient to another, **proper cleansing and disinfecting of probes is important.**<sup>3</sup> With a transabdominal probe, it is sufficient to simply wipe the probe clean with a disposable antiseptic paper towelette. Transvaginal probes should be covered during use with a disposable latex or nonlatex cover. Following the exam, the probe should be cleaned with running water or a damp cloth. It is then important that chemical high-level disinfection be carried out as per the probe manufacturer’s recommendations.

## ULTRASOUND FOR DETERMINING GESTATIONAL AGE

**Determination of the correct gestational age is one of the most important aspects of prenatal care.** Making correct management decisions for conditions such as preterm labor, prolonged and postterm pregnancy, and preeclampsia depends heavily on knowledge of the gestational age of the fetus. Without

early confirmation of the estimated date of delivery (EDD), it is very difficult to diagnose growth disorders in the fetus. Biochemical screening for open fetal defects and chromosomal anomalies likewise requires accurate dating. **For these and other reasons, it has become routine in developed countries to offer at least one ultrasound examination in the first half of pregnancy to accurately establish the gestational age.**<sup>3</sup>

### Standard Measurements

Ian Donald first demonstrated the clinical use of ultrasound in obstetrics in the early 1960s with the measurement of the BPD. Since that time, a large number of publications have correlated this parameter with gestational age. The BPD can first be measured from 12 to 13 weeks' gestation, when the skull has become ossified. Other standard measurements that include the femur length (FL), abdominal circumference (AC), and head circumference (HC) can also be made starting in the late first trimester.

With transvaginal ultrasound, the embryo can be measured when it is only a few millimeters long, between 5 and 6 weeks' gestation. From 6 to 10 weeks' gestation, the maximal length of the embryo is measured. After about 10 weeks, the head, trunk, and extremities are visible, and the measurement is literally from the well-visualized crown to the rump.<sup>38</sup> Views of the CRL such as those shown in [Figure 9-29](#) are obtained. **Because the fetus is often in a flexed position ([Fig. 9-30](#)), the CRL becomes less accurate after the first trimester and should not be used after it reaches 84 mm (14 weeks of gestation).**<sup>39</sup>

It is possible to measure virtually any body part of the fetus. However, a standard set of measurements has been accepted as being the most useful for gestational age prediction. After the first trimester, these include the BPD, HC, AC, and FL. Unless these are measured according to standard criteria ([Box 9-2](#)), their value in defining the age or growth of a fetus is limited. Optimal views for obtaining measurements are shown in [Figures 9-31 to 9-35](#). Common errors to be avoided are also shown. With practice, a sonographer learns to slide the transducer to the proper position on the maternal abdominal wall then angulate and rotate the transducer until the precise plane for biometry or anatomic assessment is obtained. In time, making these adjustments becomes second nature.

**FIG 9-29** Measurement of the crown-rump length (CRL). This is a sagittal view of the fetus with the crown of the head to the right and the rump to the left.

### Gestational Age Determination

**In very early pregnancy, the gestational sac diameter can give a fairly close approximation of the gestational age.** The mean sac diameter increases by about 1 mm per day, and the gestational age (in days) can be figured by adding 30 to the mean sac diameter (in millimeters).<sup>40</sup> Because the range of error in age prediction from sac measurement is significantly greater than for the CRL and other standard measurements, the sac

#### BOX 9-2 DESCRIPTION OF IMAGES FOR FETAL BIOMETRY

##### Head

- Image is from side not front or back.
- Head is oval rather than round.
- Midline structures are centered not displaced to the side.
- Measure at the level of thalamus and cavum septum pellucidum.
- Image should not include the top of the orbits or any part of the brainstem or cerebellum.
- Measure outer edge of the proximal skull to the inner edge of the distal skull.
- Head circumference is measured at the level of the biparietal diameter, around the outer perimeter of the skull.

##### Abdomen

- Abdomen is nearly round, not oval or squashed.
- Obtain a true transverse image not oblique.
- Images of ribs should be similar on both sides.
- Measure at the level where the umbilical vein joins the portal sinus.
- Calipers are all the way to the skin surface not at the rib, liver, or spine edge.

##### Femur

- Femur should be perpendicular to direction of insonation.
- Ends should be sharply visible not tapered or fuzzy.
- The measurement should exclude the distal epiphysis.

**FIG 9-30** This is an inappropriate image for obtaining the crown-rump length (CRL) because the flexed position of the fetus gives a falsely low measurement.

**FIG 9-31** Image of the fetal head for biparietal diameter and head circumference measurements. The cavum septum pellucidum (CSP) and the thalami (Thal) are indicated. Criteria for an appropriate image are listed in [Box 9-2](#).

**FIG 9-33** Proper image for measurement of the abdominal circumference (AC). Criteria for an appropriate image are listed in [Box 9-2](#). The umbilical vein (UV) is seen at the level of the portal sinus. The stomach (St) and spine (Sp) are also labeled.

**FIG 9-32** Examples of inappropriate head views for biparietal diameter and head circumference (HC) measurements. **A**, The transducer is rotated in such a way that the image includes the cerebellum. **B**, The head is imaged from the back and not from the side. **C**, The scan plane goes through the head obliquely. Note how the brain structures are asymmetric. **D**, This true axial image is too high on the head. The cavum septum pellucidum is not seen.

**FIG 9-34** Examples of abdominal views that are inappropriate for abdominal circumference measurements. **A**, This true axial image is too low on the abdomen. The umbilical vein is seen close to the anterior abdominal wall. **B**, This is an oblique cut through the abdomen. Note the asymmetric appearance of the ribs. **C**, The abdomen is overly compressed because the sonographer has applied too much pressure to the maternal abdominal wall. **D**, The transducer is rotated in such a way that an oblong view of the abdomen is obtained. This gives an artificially elongated anterior-posterior dimension.

size should not be used as the final gestational age determinant.<sup>3</sup> **The measurement of the early embryo, either as the maximal embryo length or CRL, is commonly accepted as the best sonographic method for gestational age determination.** Using a static scanner in pregnancies dated by “good” menstrual dates, Robinson and Fleming<sup>41</sup> found that the 95% confidence intervals for gestational age prediction using the CRL was  $\pm 4.7$  days. Later studies, in which gestational age was determined by in vitro fertilization, showed an even smaller random error.<sup>42</sup> **The high accuracy of ultrasound dating of early embryos is explained by their relatively large weekly percentage change in size and the fact that very little variation is seen among early embryos in their growth rates. The variability of gestational age estimations increases with advancing gestation.**<sup>3,39</sup>

The 95% confidence intervals for gestational age prediction using the BPD as a single parameter between 14 and 21 weeks is  $\pm 7$  days.<sup>43</sup> In a study of pregnancies dated by in vitro

fertilization, Chervenak and colleagues<sup>44</sup> found that in this period of pregnancy, all of the single parameters considered (BPD, HC, and FL) performed quite well: 95% confidence intervals for the gestational age ranged between  $\pm 7.5$  days for the HC and  $\pm 8.7$  days for the FL. Composite gestational age assessment using mathematic modeling from multiple parameters is now the most accepted method of ultrasound dating after the first trimester.<sup>39</sup> **The studies previously cited show that gestational age calculation using a combination of standard parameters before 22 weeks is accurate to within  $\pm 7$  days and is comparable to CRL measurement in the first trimester. For this reason, it is not necessary to refer a patient for ultrasound in the first trimester for the sole purpose of obtaining optimal dates.**<sup>45</sup>

As pregnancy progress beyond 22 weeks, variability in fetal size increases considerably, and ultrasound prediction of gestational age becomes progressively less accurate. In

**FIG 9-35** In the left image, the entire diaphysis of the femur is not clearly shown. This will give an inappropriately short measurement. The ends should be distinct, as shown in the image on the right. FL, femur length.

one study, the composite gestational age assessment at 24 to 30 weeks had a variability ( $\pm 2$  standard deviations) of 1.8 weeks, and after 30 weeks, the variability was 2 to 3 weeks.<sup>38</sup> These variability figures represent a statistical description of the variability of the gestational age calculations in the studied population. In the third trimester, growth disorders in fetuses are relatively common and can bring about marked size variation. For this reason, **the obstetrician must exercise caution when basing management decisions on third-trimester ultrasound dates.**

**When to Use Ultrasound Dating**

Since the time of Nägele in the early 1800s, obstetric providers have routinely used menstrual dates for determining the EDD. **Agreement is near universal that in pregnancies in which the menstrual dates are uncertain or thought to be unreliable because of a history of uncertain recall, irregular cycles, recent hormonal contraception use, or an abnormally light last menstrual period (LMP), dates derived from ultrasound biometry are preferred.**<sup>3,16,39</sup> Because variations in timing of ovulation even with a certain LMP have never been shown to be less than the variation in age assessment from ultrasound,<sup>16</sup> it could be argued that dating can be best be established by ultrasound measurements, ignoring menstrual dates. Nevertheless, all recent guidelines on establishing gestational age include references to menstrual dates. **In a 2014 reaffirmation of a 2009 ACOG practice bulletin,<sup>3</sup> it was suggested that ultrasound dates should take precedence over the menstrual dates if an ultrasound performed in the first trimester is more than 7 days different or an ultrasound exam before 20 weeks is discrepant by more than 10 days.** A joint committee opinion issued in 2014 from ACOG, AIUM, and the Society for Maternal-Fetal Medicine (SMFM) entitled “Method for Estimating Due Date” made very specific recommendations that extend through the entire pregnancy (Table 9-1).<sup>39</sup> **Importantly, the committee opinion and the 2009 ACOG practice bulletin**

**TABLE 9-1**      CIRCUMSTANCE IN WHICH ULTRASOUND GESTATIONAL AGE DETERMINATION SHOULD TAKE PRECEDENCE OVER “GOOD” MENSTRUAL DATES

| GESTATIONAL AGE (WEEKS) | USE ULTRASOUND DATES IF DISCREPANCY IS: |
|-------------------------|---|
| Less than 8 6/7         | >5 days                                 |
| From 9 0/7 to 15 6/7    | >7 days                                 |

| From 22 0/7 to 27 6/7   | >14 days                                |
| Greater than 28 0/7     | >21 days                                |

From American College of Obstetricians and Gynecologists. Committee opinion no 611: method for estimating due date: *Obstet Gynecol.* 2014;124:863-866.

**both note that in the third trimester aberrant growth is relatively common, so changing certain menstrual dates in favor of a late ultrasound date risks missing the presence of a significant growth disorder, and decisions about changing dates require careful consideration and close surveillance.**<sup>3,39</sup>

**Assessing Fetal Growth**

The first ultrasound examination is generally considered to be a dating examination; that is, the measurements are used to determine the gestational age. An accurate knowledge of gestational age determined or confirmed by the first ultrasound examination forms the basis for subsequent clinical and sonographic assessments of fetal growth. **Because insufficient or excessive growth can be associated with significant fetal morbidity, recognition of growth abnormalities is one of the primary aims of prenatal care and is an important aspect of ultrasound examinations.** In most obstetric practices, growth ultrasound examinations are obtained when abdominal palpation and fundal height measurements raise the suspicion of abnormal growth.<sup>46</sup> A lagging fundal height, combined with the

knowledge of clinical risk factors for IUGR, is commonly used as a “screening test” for insufficient fetal growth, whereas ultrasound is considered the “diagnostic test.” This scheme for the prenatal detection of growth-restricted fetuses has met with mixed results. Although some studies have shown sensitivities for the detection of small for gestational age (SGA) fetuses with fundal height to be as low as 15%,<sup>46</sup> others suggest a 65% to 85% sensitivity and 96% specificity.<sup>47</sup> The positive predictive value of a lagging fundal height for diagnosing IUGR has been reported to be 50%. Schemes for the antenatal diagnosis of small fetuses may perform significantly better if clinical risk factors are taken into account.<sup>48,49</sup>

Serial ultrasound examinations have been shown to be superior to physical examination for diagnosing insufficient growth.<sup>50</sup> For this reason, some have advocated a routine third-trimester ultrasound examination to screen for growth abnormalities even in low-risk pregnancies. Studies have shown, however, that this policy has little or no impact on perinatal morbidity and mortality.<sup>47,51</sup> **Because of the high cost and unproven benefit of such a screening program, routine ultrasound examinations for growth are generally not a part of prenatal care in the United States. However, it is still accepted that ultrasound should be ordered when clinical examination is suspicious and when significant risk factors for a growth abnormality are present.** Such risk factors include diabetes mellitus, maternal hypertension, a previous small or large baby, multiple gestation, or poor maternal weight gain. A risk-based approach is particularly appropriate in cases such as multiple gestation or marked maternal obesity, in which clinical evaluation of fetal size is difficult or impossible.<sup>16,47</sup>

### Estimating Fetal Weight

A large number of formulas for calculating the estimated fetal weight (EFW) have been proposed. The most popular of these have been compiled in a review by Nyberg and colleagues.<sup>40</sup> **All incorporate the abdominal circumference because this is the standard measurement most susceptible to the variations in fetal soft tissue mass.** Although the AC alone is a fairly good marker for detecting abnormal fetal growth, the addition of other standard measurements to estimated weight formulas increases their accuracy.<sup>52</sup> **It has been shown that the addition of measurements beyond the standard set (BPD, HC, AC, and FL) does not significantly improve weight estimations. It appears that the error inherent in obtaining the basic measurements, especially the AC, is great enough to obscure any refinement in accuracy that might be gained from additional measurements.**

Many studies have been done to evaluate the accuracy of ultrasound for predicting birthweight.<sup>40</sup> It has been claimed in some publications that one formula is better than another when statistically significant differences in accuracy are seen. However, the differences in accuracy are usually of limited clinical significance, and no formula has been consistently shown to be superior to another.<sup>53</sup>

When scans are done by well-trained sonographers, most studies show a mean absolute error in weight prediction of about 8% to 10% of the actual birthweight. Overall, 74% of infants have a birthweight within 10% of ultrasound estimates.<sup>54</sup> In 5% of cases, the deviation is greater than 20%.<sup>47</sup>

**It is often assumed that ultrasound is more objective than clinical examination and that ultrasound estimates of fetal weight are therefore more reliable. Surprisingly, most studies**

**have not shown this to be true.** In a review by Sherman and colleagues<sup>55</sup> of 12 studies in which ultrasound was compared with clinical examination for weight estimation, ultrasound was found to be clearly superior in only one, and it involved a subgroup of patients with birthweights less than 2500 g. In three studies, clinical estimates were superior, and in the remaining eight, the two methods either were equivalent or had mixed results depending on the specific formula used. Interestingly, one study<sup>55</sup> showed that a term parous woman in labor is about as accurate in predicting the birthweight as clinical estimation by a physician or a sonographic estimate. Although it has not been proven, it is reasonable to assume that ultrasound measurements, fetal palpation, and maternal characteristics can complement one another. When the discrepancy between modalities is marked, the clinician should be prompted to reassess the results of each method. Strategies aimed at improving the performance of ultrasound for estimating fetal weight—for example, using formulas based on subpopulations of fetuses, such as those who are preterm or are thought to be small or large for gestational age—have not shown a clinically important improvement in the accuracy of weight estimates compared with traditional “one-size-fits-all” formulas.<sup>56</sup>

### Diagnosing Abnormal Growth

The most accepted way of diagnosing abnormal growth in a fetus is to calculate the EFW using standard ultrasound measurements and then compare the estimated weight with an accepted standard. Several of these are in common use in currently available ultrasound software.

**If the EFW is less than the 10th or greater than the 90th percentile, the fetus is said to be small or large for the gestational age.**<sup>47,57</sup> Defining abnormal growth using these percentile cutoffs includes many babies who are healthy but are constitutionally large or small. Using a more restrictive definition, such as a birthweight less than the 3rd or greater than the 97th percentile, is more predictive of a poor neonatal outcome. Of course, using these criteria would fail to detect many less severely affected fetuses. Additionally, some infants have a birthweight within the normal range but have not grown to their genetic potential. For this reason, some investigators have argued that individual birthweight percentile limits that incorporate such characteristics as maternal weight, height, ethnic group, parity, and fetal sex should be used.<sup>58</sup> Claussen and colleagues<sup>59</sup> found that about one fourth of fetuses judged to be abnormally small using conventional limits were within normal limits with adjusted percentiles. Conversely, one fourth of babies identified as small or large with adjusted percentiles would have been missed by conventional assessment. In another study from the same institution, it was demonstrated that the risk for stillbirth, neonatal death, and low Apgar scores can be better predicted by the customized weight percentiles. However, the use of customized formulas has not been shown to improve outcomes and are not in common use.<sup>47</sup>

### Growth Restriction

**In 1977, Campbell and Thoms<sup>60</sup> described the HC/AC ratio as a useful marker for detecting fetal growth restriction** (see Chapter 33). This was based on the observation that growth of the soft tissues in the fetal abdomen is more likely to be compromised than the head when nutritional deprivation is an issue. This understanding led to the concept that *asymmetric growth restriction* is virtually pathognomonic of nutritional

deprivation, whereas *symmetric growth restriction* signifies an underlying condition such as aneuploidy. This categorization has some utility, but it should be recognized that a great deal of overlap exists between body ratios of fetuses whose growth is restricted from either nutritional or intrinsic factors. However, because a very high HC/AC ratio is uncommon in normal fetuses, such a ratio points away from constitutional smallness. Additionally, it has been shown in newborns that a low weight/length ratio is associated with an increase in several markers of morbidity even if the birthweight is greater than the 10th percentile; this perhaps indicates these infants also experienced growth restriction.<sup>61</sup> Currently, no consensus has been reached concerning the level of surveillance appropriate for a fetus with a high HC/AC ratio but normal estimated weight.

**When a patient presents late for prenatal care and the gestational age is uncertain, diagnosis of a growth disorder is particularly difficult. In these cases, a high or low HC/AC ratio can raise the suspicion of a growth disorder.** Other ultrasound findings may be useful to help confirm the suspicion. For example, IUGR is often associated with oligohydramnios, abnormal umbilical artery Doppler flow studies, or an abnormal-appearing placenta. Macrosomic fetuses may demonstrate obviously thickened subcutaneous fat pads. In suspected cases, as long as the fetus is stable, serial ultrasound examinations to evaluate growth are appropriate. **Repeated ultrasound exams for growth should be performed at least 2 to 4 weeks apart.** A shorter interval makes it difficult to tell if apparent trends are due to the real growth or variations in the measurement technique.<sup>3</sup> The rate of growth can be valuable for predicting adverse outcome. Formulas that define rates of normal growth have been published, but most clinicians rely on an observation of progressively increasing or decreasing weight percentiles to evaluate the severity of an ongoing growth disorder.

### Macrosomia

**The term macrosomia implies growth beyond a specific weight, usually 4000 or 4500 g.** Morbidity is increased for infants who weigh 4000 to 4500 g compared with the general population, and risks increase sharply above 4500 g. **Large cohort studies support 4500 g as an EFW above which a fetus should be considered macrosomic.**<sup>57</sup> **The absolute error of ultrasound-estimated fetal weight is increased with macrosomia. When the birthweight exceeds 4500 g, only 50% of fetuses weigh within 10% of the ultrasound-derived estimate.**<sup>54</sup>

It has been hoped by many that ultrasound could aid in the difficult decisions faced by obstetricians when macrosomia is suspected. Because difficult delivery from shoulder dystocia can lead to permanent neurologic injury in the fetus, this is one of the most feared complications in obstetrics (see Chapter 17). Unfortunately, ultrasound for fetal weight estimation has proved to be of limited usefulness for the prevention of shoulder dystocia and other complications associated with fetal macrosomia.

In a review of 4480 deliveries by Gonen and colleagues,<sup>62</sup> ultrasound ordered because of a clinical suspicion of macrosomia only detected 17% of the infants who weighed over 4500 g, and only 1 of the 23 infants who weighed over 4500 g had a brachial plexus injury. Additionally, 93% of infants who had shoulder dystocia weighed less than 4500 g. **For these reasons, clinical investigators have concluded that most cases of injury that result from shoulder dystocia cannot be predicted by ultrasound and that if cesarean delivery were routinely performed when macrosomia was suspected, the rate of cesarean delivery would be increased with very little benefit.**

## SAFETY OF ULTRASOUND

Since diagnostic ultrasound was introduced for clinical use, attention has appropriately been given to ensuring its safety. It has been recognized that the energy from sound waves is converted into heat as sound waves are attenuated. **Mechanical energy from the sound waves can cause the formation of microbubbles, resulting in a phenomenon called cavitation.** Because cavitation occurs only under high ultrasound intensities where air is present, it is not of significant concern with diagnostic ultrasound of the fetus.

### Quantifying Machine Power Output

As of 1976, trials had indicated that no clinically significant biologic effects were apparent from diagnostic ultrasound. It was subsequently recognized that it would be impractical to repeat safety studies for each new generation of ultrasound machines operating with different modalities and power outputs. The U.S. Food and Drug Administration (FDA) decided that approval for equipment marketed after 1976 would require acoustic outputs less than that of equipment that existed at that time, which was 94 mW/cm<sup>2</sup> spatial-peak temporal-average (SPTA). However, it has become apparent that improvements in ultrasound imaging can be obtained in some cases with higher power levels than is allowed under this regulation. The FDA agreed to relax this standard if machines provided users with real-time information that indicates the potential for fetal harm from the higher-power outputs now allowed. An **output display standard** was adopted that showed the required information on the ultrasound monitor. The numbers pertinent to users of obstetric ultrasound are the thermal indexes for soft tissue (TIs) and bone (Tlb). **The thermal index denotes the potential for increasing the temperature of tissue being insonated with that power output.** It is determined by the settings and ultrasound modalities being used. A thermal index (TI) of 1.0 indicates that given certain conditions, the temperature of the tissue may be increased by 1° C. Because little bone formation occurs in the first trimester, the TIs is more relevant. Later in pregnancy, as ossification occurs, sound waves have a greater impact on bone, so the Tlb becomes more important. If the output display standard is followed, the new regulations allow the ultrasound intensity to be as high as 720 mW/cm<sup>2</sup>. Machines that do not have the output display still must operate with a maximal sound intensity of less than 94 mW/cm<sup>2</sup>.

A 2008 official statement from the AIUM<sup>63</sup> on ultrasound bioeffects states that no effects have been observed from unfocused beam SPTA intensities below 100 mW/cm<sup>2</sup> or TI values less than 2. In 2009, the World Health Organization (WHO) sponsored a systematic review and meta-analysis to evaluate the safety of human exposure to ultrasonography in pregnancy. This study showed no adverse maternal or perinatal effects, impaired physical or neurologic development, increased risk for malignancy in childhood, subnormal intellectual performance, or mental diseases. This analysis concluded that according to the available evidence, exposure to diagnostic ultrasonography during pregnancy appears to be safe.<sup>64</sup> **Taking into account the many studies that have been done to date, an official statement from the AIUM on prudent use and clinical safety states, “No independently confirmed adverse effects caused by exposure from present diagnostic ultrasound instruments have been reported in human patients in the absence of contrast agents.”**<sup>65</sup> Nevertheless, researchers in the field caution about the possibility that unrecognized harm exists. For this

reason, the AIUM position remains that ultrasound should be used by qualified health professionals to provide medical benefit to the patient. **In another official statement, the AIUM propounds the ALARA principle (as low as reasonably achievable).<sup>66</sup> This means that the potential benefits and risks of each examination should be considered, and equipment controls should be adjusted to reduce as much as the possible the acoustic output from the transducer.**

In general, ultrasound energy and the potential for temperature elevation become progressively greater from B-mode to color Doppler to spectral Doppler. For this reason, M-mode ultrasound is preferred for documenting fetal viability in the first trimester (see Fig. 9-7).<sup>4</sup> However, Doppler modes should be used liberally to confirm fetal death.

## ULTRASOUND DIAGNOSIS OF MALFORMATIONS

Over the past few decades, a large number of publications have described the ultrasound diagnosis of fetal malformations. A catalog of the diseases now considered detectable with prenatal ultrasound is beyond the scope of this chapter. This section addresses the use of ultrasound as a general screening test for malformations, discusses the role of ultrasound in aneuploidy screening, and describes the relatively common birth defects that may be diagnosed with a standard ultrasound examination.

### Ultrasound as a Screening Tool for Birth Defects

With improvements of ultrasound equipment in the last few decades, many patients and clinicians have come to assume an ultrasound exam will likely detect all serious fetal anomalies. Indeed, in the 1980s and early 1990s, several individual centers reported detection rates of greater than 75% in referral and low-risk patients. **However, serious questions in regard to the sensitivity of routine ultrasound exams in more general settings were raised by a large multicenter randomized trial published in 1993, the Routine Antenatal Diagnostic Imaging With Ultrasound Study (RADIUS).<sup>67</sup> This randomized trial included standardized ultrasound exams of over 15,000 women between 16 and 20 weeks' gestation and then again at 31 to 33 weeks. Patients were selected to be at low risk for pregnancy complications. In this study, only 17% of major anomalies were diagnosed by ultrasound prior to 24 weeks' gestation, and only 35% were detected overall. The study's authors concluded that routine ultrasound to screen for birth defects in low-risk women was not efficacious. A subsequent large study of ultrasound screening for birth defects, the Eurofetus study,<sup>68</sup> included over 200,000 women screened with routine ultrasound in 61 hospital units in 14 European countries. In contrast to the low rate of detection of anomalies in the RADIUS trial, 61% of malformed fetuses were detected. The sensitivity was higher for major malformations (74%), and a significant difference in detection rates was found according to the particular malformation or organ system involved. Defects of the central nervous system and urinary tract were detected 88% of the time, whereas only 18% of cases of cleft lip and palate were diagnosed. Ultrasound identified 18% of minor musculoskeletal malformations and 21% of minor cardiac malformations, and sensitivities were 74% and 39% for major anomalies of these two organ systems.**

The nature of the population being screened and the thoroughness of postnatal ascertainment of birth defects also affect

the sensitivity of ultrasound for detecting defects. **The detection rate has been shown to be higher in high-risk populations screened at centers with extensive experience at diagnosing birth defects.** In studies that did not include rigorous prospective neonatal evaluation, subtle anomalies may not have been noted, and a sonographic "miss" of these defects would not be counted. This would give a falsely optimistic detection rate. **The gestational age at which ultrasound is performed can influence the sensitivity of anomaly screening.** Whereas many defects can now be recognized in the late first trimester (e.g. anencephaly and large abdominal wall defects), most are not visible until later. Some defects may become more readily apparent late in pregnancy. Although multiple exams in each pregnancy would undoubtedly increase the detection rate of malformations, resource and financial constraints make this impractical.

**Summarizing the results of large studies and systematic reviews, the report of the 2014 National Institute of Child Health and Human Development (NICHD) Workshop on Fetal Imaging concluded that the range of detection rates for anomalies overall is wide, from 16% to 44% prior to 24 weeks of gestation, with a detection rate of 84% for major and lethal anomalies.<sup>16</sup>**

**In the hands of a well-trained examiner, the detection rate of some anomalies should approach 100%.** For example, anencephaly, abdominal wall defects, and anomalies that involve an abnormal accumulation of fluid within a body cavity (e.g., hydronephrosis or hydrocephalus) will rarely be missed. The fact that spina bifida, which itself may be difficult to see, is almost always accompanied by easily recognized intracranial findings makes the detection rate of this defect quite high. The growing awareness that a screening ultrasound should include not only the four-chamber view of the heart (Fig. 9-36) but also views of the outflow tracts (Figs. 9-37 and 9-38) has resulted in a significant increase in the detection rate of heart defects. DeVore<sup>69</sup> reviewed three studies from the 1990s in which only the four-chamber view was obtained as part of a screening ultrasound in low-risk populations. Only 8 of 151 cases were identified with the four-chamber screening, giving a detection rate of 5%. In contrast, a 2006 Norwegian study<sup>70</sup> of over 30,000 unselected patients used not only the four-chamber view but also the great vessel views and showed a 57% prenatal detection rate of heart defects. **Because of studies that show the importance of outflow tract visualization for the detection of many heart defects, ACOG and the AIUM now recommend that attempts should be made to obtain these views in all second- and third-trimester scans.<sup>3,12</sup>**

It is well recognized that adequate training is essential to the proper performance and interpretation of obstetric ultrasound exams. In the RADIUS trial, the detection rate for anomalies was almost three times higher when the exams were performed at a tertiary center compared with a general practice setting (13% vs. 35%), presumably because of greater experience of sonographers at the tertiary centers. **To maintain acceptable levels of sensitivity, compliance with the AIUM guidelines for training and experience is important.**

It is generally agreed that the most cost-effective approach for screening low-risk pregnancies is to perform a standard examination between 18 and 20 weeks. At this gestational age, adequate visualization of major organs is possible for most women. In some, because of an unusually thick or dense maternal abdominal wall or unfavorable fetal position, completion of the anatomic survey is suboptimal, and a follow-up scan may be helpful.<sup>3,16</sup>

**FIG 9-36** Normal four-chamber cardiac images from the apex (*left*) and lateral views (*right*). The apex (Ap) and left ventricle (LV) are labeled.

**FIG 9-37** Left ventricular outflow tract view. The left ventricle (LV) and ascending aorta (Asc Ao) are indicated.

**FIG 9-38** Right ventricular outflow tract view. The main pulmonary artery (MPA) arises from the right ventricle (RV) and crosses anterior to the ascending aorta (Ao) before bifurcating.

False-positive results must be taken into account when considering the effectiveness of ultrasound screening for birth defects. **Falsely abnormal results can cause patients and families considerable anguish and result in unnecessary follow-up tests.** Fortunately, in both the RADIUS and the Eurofetus trials, fewer than one in 500 women was erroneously told that her healthy fetus had a malformation.<sup>67,68</sup> However, of the nearly 3000 suspected malformations in the Eurofetus study, 10% were false-positive diagnoses, and 6% involved fetuses in which an initial concern was resolved on a subsequent ultrasound exam.

## Screening for Aneuploidy

### First Trimester

As has been previously discussed in this chapter, ultrasound assessment is an important part of first-trimester aneuploidy screening (see [Chapter 10](#)). **The most important sonographic component of first-trimester screening is the nuchal translucency measurement (Fig. 9-39).** The presence or absence of a

### visible nasal bone is another important ultrasound finding.

Other ultrasound findings have been described, such as reverse ductus venosus flow and tricuspid regurgitation, but they are not in general use.<sup>71</sup> Criteria are rigorous for appropriate nuchal translucency and nasal bone images, and individuals who wish to perform the ultrasound component of the first-trimester screen must be certified to do so.

### Second Trimester

As is discussed in [Chapter 10](#), well-established screening tests exist for fetal aneuploidy; however, the role of ultrasound in aneuploidy screening is less straightforward. Starting in 1985, a number of “**soft markers**,” as opposed to actual birth defects, were found to have an association with Down syndrome. **These include a thick nuchal fold, short nasal bone, cerebral ventriculomegaly, short femur or humerus, echogenic intracardiac focus, echogenic bowel, and pelviectasis (Fig. 9-40, e-Figs. 9-1 and 9-2).** It has been shown that these markers

**e-FIG 9-1** Midabdominal axial view of fetus with trisomy 21 showing echogenic bowel (*arrows*). The stomach (St) and spine (Sp) are labeled.

**e-FIG 9-2** Midabdominal axial view of renal pelviectasis. The anterior-posterior measurement of the renal pelvis (calipers) is used to define the limits of normal and to follow progression. LT, left; RT, right.

**FIG 9-39** Midsagittal view of a 12-week fetus showing the nuchal translucency (NT) and nasal bone (NB).

**FIG 9-40** Axial image of a fetus with trisomy 21, showing a thick posterior nuchal fold (calipers).

perform poorly as individual predictors of Down syndrome. However, using likelihood ratios for each marker, they can be used in combination to calculate a formal risk adjustment for the presence of trisomy 21.<sup>72</sup> **In spite of the well-documented association between these markers and trisomy 21, the ultrasound at 18 to 20 weeks should not be considered an adequate screening test. A patient who desires such screening should be encouraged to use better-defined and well-established screening methods, which may include first-trimester screening, the quad screen, or cell-free DNA testing.**

Not infrequently, these soft markers are seen incidentally at the time of the screening exam at 20 weeks. The NICHD workshop on fetal imaging made recommendations on how to proceed in this circumstance.<sup>16</sup> It concluded that an echogenic intracardiac focus has such a small likelihood ratio that it does not significantly change the prior risk and can thus be ignored. The presence of other soft markers should prompt referral for a targeted ultrasound and other aneuploidy screening tests. Whenever a structural anomaly is identified, a finding that is not just a soft marker, invasive prenatal diagnosis should be offered.<sup>71</sup>

## Screening for Anomalies With the Standard Ultrasound Examination

As previously noted, specific components should be evaluated in the course of a standard ultrasound exam performed in the second or third trimesters (see Box 9-1).<sup>3,16</sup> Careful attention to each of these components will allow detection of many, if not most, serious birth defects. In the following sections, normal structures will be demonstrated, and the alterations expected with different birth defects will be shown. The conditions described are those for which the general obstetrician should have familiarity and that might reasonably be detected with a standard screening ultrasound examination. Ultrasound images of most of these conditions are found in the online version of this book.

### Head and Neck

#### GENERAL APPEARANCE

On axial views, the head should have an oval appearance. Elongation of the head, termed *dolichocephaly*, is often caused by lateral compressive forces associated with oligohydramnios, especially if the fetus is in a breech presentation. An abnormally round shape, termed *brachycephaly*, can be an important indicator of fetal abnormalities, especially holoprosencephaly and aneuploidies (e-Fig. 9-3).

#### NEURAL TUBE DEFECTS

**Anencephaly is often first suspected when a proper image for measuring the BPD cannot be obtained.** The absence of the cranial vault can be diagnosed after 10 weeks' gestation. Although the skull is missing, lobulated disorganized brain tissue can be prominent between 9 and 11 weeks. This tissue degenerates by 15 weeks, leaving the characteristic appearance in which there is no cortex or cranium and the fetal eyes appear at the top of an intact lower face (e-Figs. 9-4 and 9-5). Meningocele that extends varying distances from the base of the skull down the neck and body may be present along with anencephaly. Fetuses with anencephaly do not swallow normally, so polyhydramnios commonly develops in pregnancies that are allowed to continue.

**Whenever a normal calvarium is absent, especially if there are additional clefts or amputations in the fetus, a careful search should be made for strands of membranes attached to the fetus, which are diagnostic of the amniotic band sequence.** When major skull deficits are caused by amniotic bands, typically some cerebral cortex remains (e-Fig. 9-6), although this is not the case with anencephaly.

**Encephalocele is the least common type of neural tube defect and is manifested by a protrusion of the meninges, and sometimes brain tissue, through a midline defect in the cranium.** Ultrasound shows a midline sac protruding through the skull, most often in the occiput (e-Fig. 9-7). The outcome with encephalocele is very poor if brain tissue is present within the encephalocele sac or other significant associated anomalies are apparent. When the defect is isolated with no brain involvement, most children have a good neurologic outcome.

The sensitivity of ultrasound for diagnosing spina bifida increased dramatically in the 1980s when it was discovered that fetuses with this condition have readily apparent secondary changes in the brain and skull.<sup>73</sup> **These include frontal narrowing of the skull (the "lemon" sign; e-Fig. 9-8), ventriculomegaly, and an abnormal cerebellum and posterior fossa. The cerebellum is deformed and drawn backward to obliterate**

**e-FIG 9-3** Marked brachycephaly. Note the nearly round outline of the calvarium. This fetus has a triploid karyotype with Dandy-Walker syndrome. A posterior fossa cyst (*asterisk*) and widely separated cerebellar hemispheres (*arrows*) are evident.

**e-FIG 9-4** Anencephaly. In this sagittal view of a 16-week fetus, absence of the normal cranial structures above the level of the face and orbits (Orb) is apparent.

**e-FIG 9-5** Coronal view of the fetal face with anencephaly. The typical "frog eyes" appearance is shown. The fetal chin (Ch) and orbits (Or) are labeled.

**e-FIG 9-6** Acrania resulting from amniotic bands. The fetal face is seen in a semicoronal view with the chin (Ch) and one of the orbits labeled. A large portion of the cerebral cortex developed with no brain covering. An amniotic band (AB) is indicated.

**e-FIG 9-7** Occipital meningocele protruding through a defect (*curved arrows*) in the occipital bone. This defect was associated with a large posterior fossa cyst (PFC) and dilation of the lateral ventricles (L).

**e-FIG 9-8** Transverse view of the head of a fetus with spina bifida. In addition to the "lemon sign," with indentation of the frontal bones (*arrowheads*), this image also demonstrates mildly dilated lateral ventricles (*arrows*). The choroid plexus (CP) is also shown.

the posterior fossa. This finding, the **Arnold-Chiari type II malformation**, is referred to as the *banana sign* (e-Figs. 9-9 and 9-10).

### CYSTIC HYGROMA

A **cystic hygroma** is a loculated accumulation of fluid in the skin of posterior neck (e-Fig. 9-11). In fetuses with this finding, edema may be widespread and is often associated with severe hydrops. These fetuses do not survive into the third trimester. **When a cystic hygroma is present, the chance is more than 60% that the fetus has a chromosome abnormality, most commonly Turner syndrome.**<sup>74</sup>

### CLEFT LIP AND PALATE

A coronal view of the fetal face is usually readily obtainable (e-Fig. 9-12). e-Figure 9-13 shows the presence of cleft lip, and 3-D views of a cleft lip (see Fig. 9-10) can help patients understand the nature of the fetal deformity. **Approximately two-thirds of those with cleft lip also have cleft palate**, which may be demonstrated with oblique views that show a defect in the maxillary ridge (e-Fig. 9-14). An isolated cleft palate is rarely diagnosed with prenatal ultrasound.

### MICROGNATHIA

A midsagittal view of the face is the best for the detection of micrognathia (e-Fig. 9-15), which may be an important marker for genetic syndromes such as trisomy 18. **Severe hypoplasia of the mandible, such as that seen with Pierre-Robin sequence, can cause breathing difficulties at birth; therefore prenatal diagnosis is invaluable in planning proactively for management of the neonate.**

### CEREBELLUM AND CISTERNA MAGNA

The cerebellum and posterior fossa should always be visualized to diagnose spina bifida, as described above, and the Dandy-Walker malformation. In the latter condition, a posterior fossa cyst is present that is continuous with the fourth ventricle; also apparent are complete or partial absence of the cerebellar vermis and varying degrees of hydrocephalus (e-Fig. 9-16 and Video 9-1). About 50% of affected fetuses have other intracranial malformations, 35% have extracranial abnormalities, and 15% to 30% have aneuploidy.<sup>75</sup> Many infants with Dandy-Walker syndrome die after birth, usually as a result of associated malformations; the majority of survivors have some degree of mental handicap.

### CHOROID PLEXUS

Cysts within the choroid plexus are noted in approximately 1% of normal fetuses (e-Fig. 9-17). They generally are benign and resolve before 26 weeks' gestation without sequelae. Because their presence indicates a sevenfold increase in risk that the fetus has trisomy 18, referral for a specialist ultrasound is indicated.<sup>16</sup> **In a fetus without trisomy 18, a choroid plexus cyst is not considered significant, and no further follow-up is needed.**<sup>16,76</sup>

### LATERAL VENTRICLES

*Hydrocephalus* is a general term used to describe a head in which the cerebral ventricles are dilated. Many causes are possible and include spina bifida; stenosis of the aqueduct of Sylvius; normal pressure hydrocephalus; agenesis of the corpus callosum; fetal toxoplasmosis, other infections, rubella, cytomegalovirus, and herpes simplex (TORCH) infections (see Chapters 52 and 53);

and other serious developmental malformations of the brain. In some cases, particularly those caused by aqueductal stenosis, the head can be markedly enlarged. The lateral and third ventricles may be very dilated with marked thinning of the cerebral cortex (e-Fig. 9-18). **With atraumatic delivery and appropriate neurosurgical treatment, more than half of infants with aqueductal stenosis survive, but about 75% of survivors have moderate to severe developmental delay.**<sup>77</sup> **The degree of hydrocephalus and the thickness of the remaining cerebral cortex are weak predictors of the neurologic outcome.**

The appearance of the choroid plexus can assist in the diagnosis of less obvious hydrocephalus. With hydrocephalus, the choroid plexus—which usually fills this portion of the lateral ventricle from side to side (e-Fig. 9-19)—appears compressed and “dangles” (e-Fig. 9-20). The accepted upper limit of the transverse diameter of the lateral ventricles at the atrium is 10 mm. **When the ventricles measure between 10 and 12 mm, the chance of a normal neurologic outcome is 96%, and it is 86% with a measurement between 12 and 15 mm.**<sup>78</sup> Whenever any degree of hydrocephalus is seen, a careful search for other malformations is essential, because their presence strongly influences the prognosis. Agenesis of the corpus callosum should be considered when modest ventricular dilation is primarily confined to the posterior horns (e-Fig. 9-21). Although fetuses with spina bifida usually have dilation of the lateral ventricles, the head size is usually not increased.<sup>79</sup>

A unilateral cystic lesion adjacent to the cerebral cortex most likely represents an arachnoid cyst (e-Fig. 9-22). These generally are associated with a good prognosis but can reach considerable size and can cause symptoms such as seizures or hydrocephalus. Porencephalic cysts are unilateral cystic lesions in the brain that have a much worse outcome. These arise from intracerebral infarcts or hemorrhages with subsequent liquefaction of the brain tissue or clot (e-Fig. 9-23). The resultant cystic cavity within the brain parenchyma may be in communication with the subarachnoid space or a cerebral ventricle.

### MIDLINE FALX

**Absence or abnormality of midline structures of the brain should point to a diagnosis of holoprosencephaly.** This condition results from incomplete division of the cerebral hemispheres. With the *alobar* form of holoprosencephaly, the head is usually small and brachycephalic. No midline echo divides the cerebral cortex, and a single crescent-shaped ventricle lies anterior to the bulbous-appearing thalamus (e-Fig. 9-24). Many fetuses with holoprosencephaly have facial abnormalities that may include hypotelorism or cyclopia, facial clefts, absent nose or single nostril, and presence of a proboscis above or between the eyes. Chromosome abnormalities, especially trisomy 13, and other malformations are present in one third of these cases. **Regardless of the karyotype or presence of other malformations, alobar holoprosencephaly is associated with a dismal neurologic prognosis, and death almost always occurs either before or shortly after birth.** When partial division of the brain is evident, the fetus may have *semilobar* (e-Fig. 9-25) or *lobar* holoprosencephaly, both of which have a somewhat more favorable prognosis.

### Chest

#### CHEST MASSES

Displacement of the heart away from the midline is often a sign of a diaphragmatic hernia or a lung mass such as congenital pulmonary adenomatoid malformation (CPAM) or pulmonary

**e-FIG 9-9** Normal cerebellum. The two cerebellar hemispheres are indicated by the arrowheads. The cisterna magna (CM) is the fluid-filled space posterior to the cerebellum. PF, posterior fossa.

**e-FIG 9-10** Transverse view through the head of a fetus with lumbar spina bifida. This fetus clearly has an Arnold Chiari type II malformation. The cerebellar hemispheres (*arrowheads*) are elongated and drawn back to fill the posterior fossa. Compare this to the image of the normal cerebellum and posterior fossa in [e-Figure 9-9](#). This distorted appearance of the cerebellum is called the "banana sign."

**e-FIG 9-11** Large posterior nuchal cystic hygroma, outlined by arrowheads.

**e-FIG 9-12** Coronal view of the lower fetal face showing a normal mouth (UL is the upper lip, LL is the lower lip) and tip of the nose.

**e-FIG 9-13** Midline cleft lip (*asterisk*) in a fetus with holoprosencephaly. This is a coronal view through the lower fetal face with the lower lip (LL), tip of the nose (No), and eye indicated. This view is easy to obtain in almost all fetuses by rotating the ultrasound transducer 90 degrees from the plane used to obtain the biparietal diameter, then sliding the transducer forward to the face.

**e-FIG 9-15** Sagittal view of a fetal face showing micrognathia. The small mandible is indicated by the arrowhead.

**e-FIG 9-14** This transverse view through the fetal maxilla shows a gap (*arrow*) in the alveolar ridge (*arrowheads*). This indicates that a previously visualized cleft lip extends posteriorly to involve the palate as well.

**e-FIG 9-16** Dandy-Walker malformation. Note that the cerebellar hemispheres are small and widely separated (*arrowheads*). The vermis is absent, and a posterior fossa cyst (PFC) is present. Compare this view to the normal posterior fossa shown in [e-Figure 9-9](#).

**e-FIG 9-17** Large choroid plexus cysts (arrowheads), which in this case nearly fill the choroid plexus, leaving a small rim of cerebral tissue. This fetus has trisomy 18.

**e-FIG 9-18** Moderate hydrocephalus from aqueductal stenosis. The choroid plexus (CP) is quite thin, and the lateral ventricles are markedly dilated, as is the third (3rd) ventricle. Anterior and posterior horns (AH, PH) are also depicted.

**e-FIG 9-19** Normal lateral ventricles (LAT VENT). The width at the atrium (calipers) measures less than 10 mm. The choroid plexus (CP) fills the atrium of the ventricle from side to side.

**e-FIG 9-20** Mild ventriculomegaly. The lateral ventricle measures 12 mm at the atrium (calipers) and the choroid plexus appears compressed. This finding improved and was associated with a normal outcome. Vp, ventricle posterior.

**e-FIG 9-21** Isolated posterior horn dilation (arrow), termed *colpocephaly*. This is a sign of agenesis of the corpus callosum.

**e-FIG 9-22** Axial view of the brain showing an arachnoid cyst (AC). The midline is laterally displaced, and the ventricles (arrows) are small, especially on the side of the cyst. 3rd, third ventricle; Th, thalamus.

**e-FIG 9-23** Axial view of the fetal head shows a porencephalic cyst. The liquefied space involves much of the lateral aspect of the cerebral hemisphere. The anterior (Ant) and posterior (Post) aspects of the head are designated.

**e-FIG 9-24** Transvaginal coronal view showing alobar holoprosencephaly. Note the undivided cerebral cortex (C) and anterior ventricle (V) and the bulbous, undivided thalamus (T).

**e-FIG 9-25** Semilobar holoprosencephaly. This is a transvaginal coronal view of the fetal head. Note the partial division of the cortex (*single arrow*) and that the falx is not completely formed. Also, the lateral ventricles communicate across the midline (*double arrow*). The choroid plexus (CP) droops across the midline.

sequestration. The presence of these conditions can be life threatening because vital chest structures are compressed or displaced. Space-occupying chest lesions can severely impair lung growth. Compression of the esophagus by a lung mass may cause symptomatic polyhydramnios. Similar pressure on the central veins and lymphatics may cause fetal death from generalized hydrops.

**With diaphragmatic hernia, the heart is displaced to the side opposite the location of the defect, which is on the left in 75% of cases. The condition can be distinguished from other chest masses by the appearance of bowel, stomach, and other abdominal organs in the chest at the level of the four-chamber view of the heart (e-Fig. 9-26).** In the midabdominal view, the stomach is typically not seen with left-sided hernias and is shifted toward the right in right-sided lesions. The intrahepatic umbilical vein is usually shifted toward the side of the defect, and variable amounts of liver will sometimes be seen prolapsed into the chest. Ultrasound does not usually demonstrate significant lung tissue on the affected side. The contralateral lung can be very small. Displacement of the GI tract often results in swallowing abnormalities, and half of such cases develop polyhydramnios.

**CPAM appears as a solid or multicystic lung mass (e-Figs. 9-27 and 9-28)** that is almost always unilateral and confined to one lobe. Frequently, a shift in the mediastinum is apparent with compression of the contralateral lung. Nonimmune hydrops can develop, and this finding is associated with a poor prognosis. **Because an apparently very large CPAM can seem to regress as a pregnancy advances, the clinician should be cautious about predicting a poor outcome.**<sup>80</sup> Most affected children require nonemergent surgical resection.

**Pulmonary sequestration** is a congenital anomaly in which a mass of lung tissue arises from the foregut independently of the normal lung. It does not communicate with the tracheobronchial tree, and it receives its blood supply directly from the aorta (e-Fig. 9-29). Ultrasound shows an echogenic intrathoracic or intraabdominal mass, usually just above or just below the diaphragm. **Color Doppler ultrasound can sometimes show the aberrant blood supply, thus distinguishing a pulmonary sequestration from CPAM.** A pulmonary sequestration usually must be removed in childhood but rarely causes prenatal complications.<sup>81</sup>

#### FOUR-CHAMBER VIEW OF THE HEART

In addition to the position of the heart within the chest, the axis should be carefully noted. The sonographer must identify the fetal right and left side based on the position of the fetus, not the position of the organs. Otherwise, abnormalities of sidedness—such as situs inversus—would be missed.

The starting place for diagnosing congenital heart defects is the four-chamber view (e-Fig. 9-30). Examples of defects that present with an abnormal four-chamber view include many septal defects and hypoplastic left heart syndrome. Ventricular septal defects account for 20% to 30% of congenital heart defects. Whereas large defects can often be seen in the four-chamber view (e-Fig. 9-31), small defects are commonly missed even by experienced examiners. Some significant defects are in the anterior, membranous portion and are not visible with the four-chamber view. **The most obvious septal defect visible with prenatal ultrasound is an atrioventricular canal defect. With this, a large defect is evident in the atrial and ventricular septum, and a common atrioventricular valve is present (e-Fig. 9-32). This particular lesion has a strong association**

**with Down syndrome, which is present in about half of the cases.** In about half of the cases of ventricular septal defects, other more complex malformations are present. It is difficult to distinguish an atrial septal defect from a normal patent foramen ovale.

**Hypoplastic left heart syndrome** is suspected when the left ventricle, which should be similar in size to the right ventricle, appears very small with a four-chamber view (e-Fig. 9-33). To better characterize such defects, visualizing the outflow tracts is critical (see Figs. 9-37 and 9-38). In hypoplastic left heart syndrome, the ascending aorta and aortic arch are very narrow in comparison with the pulmonary artery and ductus arteriosus.

#### OUTFLOW TRACTS

Many relatively common serious congenital heart defects may be missed entirely unless the outflow tracts are assessed. One example of such a condition is the tetralogy of Fallot, which consists of a ventricular septal defect (VSD), pulmonary stenosis, and an aorta that overrides the VSD (e-Figs. 9-34 and 9-35). The fourth part of the tetralogy, hypertrophy of the right ventricle, develops postnatally. Transposition of the great arteries may also present with a completely normal four-chamber view. This disorder is recognized with the outflow tract views when the aorta and pulmonary artery run parallel to each other instead of crossing (e-Fig. 9-36). The aorta, which can be recognized from the shape of the arch, arises from the right ventricle and runs anterior to the main pulmonary artery, which arises posteriorly from the left ventricle. A VSD is found in 40% of cases.

#### Abdomen

**The fetal stomach should always be visualized after the first trimester.** If the stomach is small or absent and does fill after 30 to 60 minutes of observation, esophageal atresia should be suspected. In most cases, ultrasound also shows polyhydramnios that results from an inability of the fetus to swallow amniotic fluid normally (e-Fig. 9-37 and Video 9-2). An empty stomach in a fetus with anhydramnios is not suggestive of GI pathology but simply reflects the absence of fluid available for the fetus to swallow.

**Duodenal atresia** is usually easily diagnosed by third-trimester fetal ultrasound. The diagnosis is based on the demonstration of the “double bubble” sign in which adjacent cysts are seen that represent the fluid-filled dilated stomach and proximal duodenum (e-Fig. 9-38). Polyhydramnios is almost always seen in these cases, and trisomy 21 is present in 30%. **Small bowel obstruction further along the intestinal tract is less common than duodenal atresia. Ultrasound in these cases shows multiple actively peristalsing loops of distended small bowel (e-Fig. 9-39 and Video 9-3). The degree of polyhydramnios depends on the proximity of the obstruction to the stomach.**

#### Urinary Tract

##### KIDNEYS

**Bilateral renal agenesis** is usually first suspected with ultrasound when amniotic fluid is absent and the fetal bladder cannot be visualized (e-Fig. 9-40). The diagnosis is confirmed by the absence of kidneys in the renal fossae (e-Fig. 9-41). The diagnosis is sometimes difficult because the absent amniotic fluid makes adequate visualization of the fetal anatomy challenging and because the discoid-shaped adrenals can be confused with fetal kidneys. Transvaginal scanning can be very helpful because with no amniotic fluid, the fetus is often close to the upper vagina. Bilateral agenesis is invariably associated with pulmonary hypo-

**e-FIG 9-26** Transverse view through the fetal chest showing a left-sided diaphragmatic hernia. The heart (Ht) is displaced to the right side of the chest, and the stomach (St) is posterior and to the left of the heart. The left chest is filled with fetal bowel (Bo). The right lung (RL) is relatively well preserved.

**e-FIG 9-27** This is a type III congenital pulmonary adenomatoid malformation (CPAM), which appears as a solid tumor that displaces the heart (Ht) to the right. The relatively small right lung (RL) and spine (Sp) are also indicated.

**e-FIG 9-28** A type II congenital pulmonary adenomatoid malformation (CPAM) appears as an echogenic mass (*arrowheads*) that involves the right lung (RL). Note the presence of medium-sized cysts within the mass.

**e-FIG 9-29** Coronal view of a pulmonary sequestration (*outlined by arrowheads*) located at the base of the lung just above the diaphragm. The fetal chest (Ch) is to the right and the abdomen (Abd) is to the left. The blood supply to the mass arises directly from the aorta (Ao).

**e-FIG 9-30** Normal four-chamber view of the heart. Note that the heart's position is central in the chest and the axis is about 45 degrees to the left of the midline. The ventricles are approximately equal in size, but the left ventricle (LV) extends further into the apex. The moderator band is seen in the right ventricle (*arrow*). The intraventricular septum is intact, and the foramen ovale (*arrowhead*) is seen.

**e-FIG 9-31** Large ventricular septal defect (*arrowhead*). LV, left ventricle; RV, right ventricle.

**e-FIG 9-32** Large atrioventricular septal defect (AVSD). The left ventricle (LV) and right ventricle (RV) are indicated.

**e-FIG 9-33** Hypoplastic left heart syndrome. Note the very small left ventricular (LV) lumen compared with the right ventricle (RV). The apex of the heart (Ap) and the spine (Sp) are also labeled.

**e-FIG 9-34** Tetralogy of Fallot. The aorta (Ao) overrides the ventricular septal defect and receives flow from both right and left ventricles (RV and LV).

**e-FIG 9-35** Hypoplastic pulmonary artery (PA) in a fetus with tetralogy of Fallot. Note the discrepancy in size between the ascending aorta (Ao) and the pulmonary artery.

**e-FIG 9-36** Transposition of the great vessels. The aorta (Ao) arises from the anterior (right) ventricle, and the pulmonary artery (PA) arises from the more posterior left ventricle (LV). The vessels do not cross but run parallel to one another. RT, right thorax; LT, left thorax.

**e-FIG 9-37** Transverse view through the abdomen of a fetus with esophageal atresia. Note the absence of a visible stomach on the left (L) side of the abdomen at the level of the umbilical vein (UV). Note also the presence of polyhydramnios, a result of abnormal fetal swallowing.

**e-FIG 9-38** Transverse view through the abdomen of a fetus with duodenal atresia. Note the “double bubble” sign, a result of the adjacent dilated stomach (St) and proximal duodenum (Du). Note also the presence of increased amniotic fluid.

**e-FIG 9-39** Transverse view through the abdomen of a fetus with jejunal atresia. Multiple loops of dilated small bowel (SB) are apparent. With real-time ultrasound, these loops were seen to be actively peristalsing.

**e-FIG 9-40** Coronal view of the head and chest of a fetus with bilateral renal agenesis. Note the complete absence of amniotic fluid.

**e-FIG 9-41** Transverse view of the lower abdomen in a fetus with bilateral renal agenesis. The spine (Sp) and renal fossae (RF) are identified. In this fetus, no bladder filling was seen and color Doppler showed no renal arteries.

plasia, which is the cause of death in liveborn infants. In this setting, ultrasound shows a small, bell-shaped chest (e-Fig. 9-42).

**Infantile polycystic kidney disease** is an autosomal-recessive disorder characterized by bilateral symmetric enlargement of the kidneys. In this condition, normal parenchyma is replaced by dilated collecting tubules that measure less than 2 mm in diameter. These cysts are not seen macroscopically with ultrasound but rather give the kidneys a markedly echogenic appearance (e-Fig. 9-43). In most cases, the kidneys are nonfunctioning in the fetus, and no bladder filling or amniotic fluid production occurs; these neonates die of pulmonary hypoplasia.

**Multicystic dysplasia** is a disorder with sporadic occurrence characterized by noncommunicating cysts of various sizes scattered randomly through the kidneys. The renal parenchyma between the cyst has an echogenic appearance (e-Fig. 9-44). The disorder can be bilateral, unilateral, or segmental. Affected kidneys may become quite large. **This condition should be differentiated from hydronephrosis, in which the parenchyma is normal and a dilated renal pelvis communicates with dilated calyces.** In bilateral multicystic dysplasia, urine is not produced, so the bladder is not visualized and no amniotic fluid is present. As with renal agenesis, unilateral disease is associated with normal bladder filling and amniotic fluid volume and has an excellent prognosis.

Varying degrees of dilation of the renal pelvis and calyces are seen with **hydronephrosis** (e-Fig. 9-45). The degree of dilation is recorded as the anterior-posterior (A-P) diameter of the renal pelvis (see e-Fig. 9-2). Mild dilation of the renal pelvis, termed *pyelectasis* or *pelviectasis*, is often a benign physiologic finding. **However, if the A-P diameter is greater than 4 mm, referral for a targeted ultrasound and a follow-up ultrasound at 32 weeks are recommended. If the pelvis measures 7 mm or more beyond 32 weeks, postnatal evaluation is indicated.**<sup>82</sup>

These cutoffs were set in order to ensure a sensitivity of nearly 100% for detecting any postnatal compromise or the need for surgery. Using these cutoffs, 20% to 50% of cases have normal kidneys at postnatal evaluation. Persistent hydronephrosis is most often caused by ureteropelvic junction obstruction or vesicoureteral reflux. Dilated ureters signify the presence of severe vesicoureteral reflux (e-Fig. 9-46), bladder outlet obstruction, or ureterovesical junction obstruction. The latter condition is often associated with a duplicated collecting system. A ureterocele may form at the point of ureteral implantation into the bladder.

## BLADDER

Bladder outlet obstruction is most commonly seen in male fetuses and is usually caused by posterior urethral valves. These are membranous structures in the posterior urethra that cause varying grades of urethral obstruction. More complex malformations that involve the urogenital tract may also cause bladder outlet obstruction and are more common when the affected fetus is a female. Sonographically, bladder outlet obstruction is diagnosed when the bladder is abnormally enlarged and normal emptying is not seen (e-Fig. 9-47). When the obstruction is severe, other findings include oligohydramnios, dilated ureters, hydronephrosis, and cystic dysplasia of the kidneys (e-Figs. 9-48 and 9-49). **When complete urethral obstruction has been present from early in pregnancy, anhydramnios causes lethal pulmonary hypoplasia and ureteral reflux results in irreversible damage to the kidneys.** *Prune belly syndrome* occurs in male fetuses and has the same sonographic appearance as

bladder outlet obstruction. With this condition, however, the impairment of bladder emptying is thought to result from a neuromuscular defect in the bladder and not physical obstruction of the urethra.

## Placenta and Umbilical Cord

### UMBILICAL CORD INSERTION INTO THE ABDOMEN

**Omphalocele** is a ventral wall defect characterized by a membrane-covered herniation of the intraabdominal contents into the base of the umbilical cord. Bowel loops, stomach, and liver are the most frequently herniated organs (e-Fig. 9-50). **With omphalocele comes a 75% rate of associated birth defects, and the karyotype is abnormal in 20% of cases.**<sup>83</sup> These other problems account for most of the mortality associated with this condition.

**Gastroschisis** is a right paraumbilical defect of the anterior abdominal wall associated with evisceration of the abdominal organs. Gastroschisis is distinguished from omphalocele by the fact that the umbilical cord inserts normally into the abdominal wall, and no membrane covers the herniated viscera (e-Fig. 9-51). Most commonly, only bowel loops are involved, but liver, stomach, and bladder may be outside the abdomen. Because of associated atresias or obstruction at the small abdominal wall ring, bowel loops and the stomach may be dilated inside or outside the abdomen. **Gastroschisis is rarely associated with chromosome abnormalities and usually does not involve abnormalities outside of the GI tract.**<sup>84</sup>

### NUMBER OF UMBILICAL CORD VESSELS

An attempt should be made to confirm that two arteries and a vein are present in the umbilical cord. In late pregnancy, this can be easily ascertained by looking at a transverse cut of the cord in a free loop (see Fig. 9-26). In the second trimester, two umbilical arteries are most easily confirmed by identifying the vessels as they course around the fetal bladder. These can be seen with gray-scale ultrasound but are made much more obvious with color Doppler ultrasound. **A single umbilical artery is present in 1% of all newborns. Because of the 20% incidence of associated malformations, this finding should prompt a detailed fetal survey. Several studies have suggested an increased risk of growth restriction and stillbirth, so follow-up growth ultrasounds and testing for fetal well-being should be considered.**

## Spine

Normal transverse views of the spine show intact skin with the echocenters in an equilateral triangle (e-Fig. 9-52). Coronal views show these same lateral echocenters running parallel to each other (e-Fig. 9-53). With spina bifida, transverse views of the spine show widening of the lateral echocenters. A meningo-myelocele sac is usually present (e-Fig. 9-54). In coronal images, the ossification centers, which usually run a parallel course down the back, are widened in the area of the defect (e-Fig. 9-55). The meningo-myelocele sac is also seen in a sagittal view (e-Fig. 9-56). **The presence of clubfoot and absence of movement of the lower extremities signify a poor prognosis for motor function of the lower extremities.**

## Extremities

In most cases of confirmed skeletal dysplasia, the long bones are obviously abnormal, with measurements that fall far below the normal range. Concern sometimes arises when routine

**e-FIG 9-42** Bell-shaped chest (to left of the image) indicating hypoplastic lungs caused by anhydramnios.

**e-FIG 9-43** Infantile polycystic kidney disease. This coronal view shows the enlarged, echogenic kidneys (*outlined with arrowheads*) characteristic of this condition.

**e-FIG 9-44** Transverse view of the fetal abdomen showing bilateral multicystic dysplastic kidneys (*outlined with arrowheads*). Note the cysts do not communicate with one another and do not resemble a dilated renal pelvis or calyces. Because neither kidney is functioning, no amniotic fluid is present, and the condition is lethal. The spine (Sp) is labeled.

**e-FIG 9-45** Unilateral hydronephrosis. The cystic areas in the kidney all communicate and consist of dilated calyces (*arrows*) that drain to a dilated renal pelvis (P).

**e-FIG 9-46** Vesicoureteral reflux. The ureter (Ur) and renal calyces (Ca) are dilated. The bladder (Bl) is also indicated.

**e-FIG 9-47** Bladder outlet obstruction. The bladder (Bl) is markedly dilated and extends almost all the way to the diaphragm. The bladder has a "keyhole" shape. The narrow portion in the fetal pelvis is the dilated proximal urethra. The fetal rump (Ru) is labeled.

**e-FIG 9-48** With complete bladder outlet obstruction, vesicoureteral reflux is usually manifested by the dilated ureter (Ur) and hydronephrosis (arrow). Sp, spine.

**e-FIG 9-49** When the obstruction is complete, the lack of egress of urine from the upper tract causes hydronephrosis (Hy) and cystic dysplasia of the renal parenchyma (arrow). The complete absence of amniotic fluid indicates a high-grade obstruction. Sp, spine.

**e-FIG 9-50** Transverse view through the abdomen of a fetus with omphalocele. The abdominal wall defect is demarcated by the arrowheads. The umbilical cord enters the omphalocele sac anteriorly (arrow). The sac contains much of the fetal liver (Li). Sp, spine.

**e-FIG 9-51** Transverse view through the abdomen of a fetus with gastroschisis. The extruded bowel loops (arrows) are shown. Note that no membrane covers the bowel, as would be the case with omphalocele. Sp, spine.

**e-FIG 9-52** Normal transverse abdominal view of a 20-week-old fetus. Note how the lateral echocenters of the spine run in parallel rows (arrowheads).

**e-FIG 9-53** Normal coronal view of the spine in a 20-week fetus. Note how the lateral echocenters run in parallel rows (arrowheads).

**e-FIG 9-54** Transverse view of the lumbar spine in a fetus with a neural tube defect. Note the divergence of the posterior echocenters (*arrowheads*) of the spine and the meningocele sac (*arrow*).

**e-FIG 9-55** Coronal view of the spine of a fetus with a lumbar neural tube defect. Note how the lateral echocenters diverge in the area of the defect (*arrows*).

**e-FIG 9-56** Sagittal view of the lumbosacral spine in a fetus with spina bifida showing the meningocele sac.

measurement of the femur gives a result several weeks less than expected for the gestational age. **For most long bone nomograms, the lower confidence limit corresponds to “2 weeks behind” up to 28 weeks, and “3 weeks behind” beyond 28 weeks.** For this reason, when the femur is more than 2 or 3 weeks less than expected, a detailed survey of fetal anatomy—especially of the long bones—is advisable. **A femur/foot ratio close to 1 usually implies that the fetus is normal or merely constitutionally small.**

**Achondroplasia is the most common form of skeletal dysplasia and is associated with a normal life span.** Ultrasound shows severe shortening of the long bones, a relatively large head with a protruding forehead, and polyhydramnios. Although this condition has autosomal-dominant inheritance, 80% of cases result from new mutations.

**Thanatophoric dysplasia is the most common lethal skeletal dysplasia.** In this condition, extreme shortening of the long bones occurs (e-Figs. 9-57 and 9-58). The femur is often bowed, resembling an old-fashioned telephone receiver (e-Fig. 9-59). The fetus has a small, narrow chest that results in lethal pulmonary hypoplasia (e-Figs. 9-60 and 9-61), and the abdomen and head appear relatively enlarged. In about one in six cases, the head has a “cloverleaf” shape. Hydrocephalus, frontal bossing (e-Fig. 9-62), and polyhydramnios are common.

Over a dozen discrete forms of osteogenesis imperfecta exist, all characterized by abnormalities of the biochemical composition of the bone matrix. The more severe forms are lethal, with hypoplastic lungs (e-Fig. 9-63), very short limbs with multiple fractures (e-Fig. 9-64), and demineralized bones (e-Fig. 9-65). More mild forms may show few or no fractures, bowing of the femurs, and limb lengths close to the normal range.

Clubfoot is best diagnosed with a coronal view of the lower leg, with the tibia and fibula both seen in a lengthwise section. **A normal foot is perpendicular to this plane, but a clubfoot is turned down and in and is seen falling within the coronal plane** (e-Fig. 9-66). It may be very difficult to diagnose clubfoot in the third trimester or in the presence of oligohydramnios.

## Hydrops

The term *hydrops* refers to generalized edema in the neonate manifested by skin edema and accumulations of fluid in body cavities, including the pleural spaces, pericardium, and peritoneal cavity (e-Fig. 9-67). Prior to the introduction of Rh immune prophylaxis, most hydrops resulted from erythroblastosis fetalis (see Chapter 34). Currently, the great majority of cases of hydrops are from nonimmune causes. With improvement in diagnostic methods, the etiology of most cases of nonimmune hydrops can be determined. Box 9-3 lists the more common causes of nonimmune hydrops. In recent years it has become apparent that parvovirus infection is responsible for many of the cases of hydrops that were previously classified as “idiopathic” (see Chapter 53).

## CLINICAL VALUE OF BIRTH DEFECT SCREENING

**It is surprisingly difficult to prove that prenatal ultrasound reduces morbidity or mortality in newborns with birth defects.** The RADIUS study demonstrated similar outcomes in the control group and in the group with routine screening.<sup>67</sup> A randomized trial of routine ultrasound conducted in Finland demonstrated a decrease in perinatal mortality when routine

### BOX 9-3 CAUSES OF HYDROPS FETALIS

- Twin-to-twin transfusion
- Chromosome abnormalities
- Structural heart defects
- Cardiac arrhythmia, especially tachyarrhythmia
- Cardiac tumor
- High-output failure from vascular malformation or tumor
  - Sacrococcygeal teratoma
  - Vein of Galen malformation
  - Placenta chorangioma
  - Twin reverse arterial perfusion sequence
- Fetal anemia
  - Parvovirus infection
  - Alpha-thalassemia
  - Fetomaternal hemorrhage
- Other infection
  - TORCH infections
  - Syphilis
- Chest mass
  - Congenital cystic adenomatoid malformation
  - Pulmonary sequestration

*TORCH*, toxoplasmosis, other infections, rubella, cytomegalovirus, and herpes simplex.

ultrasound was used, but this was because most pregnancies with serious malformations were terminated, not because offspring from continued pregnancies did better.<sup>85</sup> However, studies have shown an improved outcome when congenital heart defects were diagnosed with prenatal ultrasound.<sup>86,87</sup> Although less critical, the prenatal diagnosis of urinary tract malformations can also lead to proper postnatal evaluation and treatment, presumably leading to improved long-term prognosis.<sup>88</sup> **Although definitive proof is scarce for most conditions, it seems self-evident that prenatal diagnosis has its advantages.** For one, it gives parents the option of pregnancy termination when serious malformations are diagnosed. Another advantage is that it allows families and caregivers time to gather complete information about the fetal problem so that practical and emotional preparations can be made. Plans can be made for delivery at the proper time at a high-risk perinatal center where the newborn can receive optimal care. **When the mother delivers at the tertiary care center, there is no need to transport a potentially unstable newborn, and the mother and baby are not separated.**

Routine ultrasound to screen for birth defects involves significant costs, but the cost per defect diagnosed is not out of line with other accepted screening tests. The cost/benefit ratio is much more favorable when exams are performed by sonographers with good detection rates.<sup>89</sup> Ideally, in offering a screening ultrasound, the obstetrician should inform the patients in general terms of the sensitivity of this test in the setting in which it is to be performed.

## “ENTERTAINMENT” ULTRASOUND EXAMINATIONS

As previously noted, when birth defects are suspected, 3-D ultrasound can provide helpful images. In recent years, 3-D ultrasound has been increasingly offered to patients in a non-medical setting for entertainment or to provide keepsake images of the fetus. **The use of ultrasound for nondiagnostic**

**e-FIG 9-57** Ultrasound measurements of a fetus with thanatophoric dysplasia. The gestational age is 21 weeks (yellow line), and all of the long bones are 6 to 7 weeks behind (red lines).

**e-FIG 9-58** Short, stubby forearm and lower leg in a fetus with thanatophoric dysplasia. RAD, radius; FIB, fibula; TIB, tibia.

**e-FIG 9-59** Very short “telephone receiver” femur in a fetus with thanatophoric dysplasia. FL, femur length.

**e-FIG 9-60** Sagittal view showing a bell-shaped chest in a fetus with thanatophoric dysplasia. These fetuses have lethal pulmonary hypoplasia.

**e-FIG 9-61** Three-dimensional image of the chest and trunk in a fetus with thanatophoric dysplasia, showing very short ribs.

**e-FIG 9-62** Sagittal view of the face showing frontal bossing.

**e-FIG 9-63** Bell-shaped chest in a fetus with a lethal form of osteogenesis imperfecta.

**e-FIG 9-64** Very short, fractured femur (*arrow*) in a fetus with a lethal form of osteogenesis imperfecta.

**e-FIG 9-65** Demineralized, compressible skull in a fetus with a lethal form of osteogenesis imperfecta.

**e-FIG 9-66** Fetal clubfoot. The foot is everted 90 degrees, placing the flat aspect of the foot in the same plane as the lower leg.

**e-FIG 9-67** Transverse view through the chest of the fetus with generalized hydrops. Severe skin edema (SE) is present along with bilateral pleural effusions. The heart (Ht) and lungs (L) are labeled.

purposes has been condemned by the AIUM and the ACOG.<sup>65,90</sup> Concerns raised in their policy statements include possible adverse bioeffects of ultrasound energy, the possibility that an examination could give false reassurance to women, and the fact that abnormalities may be detected in settings where personnel are not prepared to discuss and provide follow-up for concerning findings. The 2007 statement by the AIUM regarding the prudent use of ultrasound in obstetrics states, “**The AIUM advocates the responsible use of diagnostic ultrasound and strongly discourages the nonmedical use of ultrasound for entertainment purposes. The use of ultrasound without a medical indication to view the fetus, obtain a picture of the fetus, or determine the fetal gender is inappropriate and contrary to responsible medical practice. Ultrasound should be used by qualified health professionals to provide medical benefit to the patient.**”<sup>65</sup>

### KEY POINTS

- ◆ Sonographers should become familiar with the basic physics of ultrasound, equipment controls, and scanning techniques to optimize ultrasound images.
- ◆ All of the elements of the standard obstetric ultrasound exam are important for clinical management and should not be neglected.
- ◆ Because most birth defects occur in fetuses of low-risk women, all standard exams should include a full anatomic survey.
- ◆ Physicians who perform and interpret obstetric ultrasound examinations should have appropriate training and experience.
- ◆ Appropriate documentation of ultrasound studies is important for good medical care.
- ◆ Pregnancy dating by ultrasound measurements is most accurate early in pregnancy. Guidelines have been established for when ultrasound dates should be used in preference to menstrual dates.
- ◆ Ultrasound for fetal weight estimation is of limited usefulness for the prevention of shoulder dystocia and other complications associated with fetal macrosomia.
- ◆ The AIUM and ACOG strongly discourage nonmedical use of ultrasound for entertainment purposes.
- ◆ It is not expected that all birth defects will be diagnosed by prenatal ultrasound.
- ◆ The sensitivity of ultrasound for the detection of birth defects depends on the level of training of examiners and the maintenance of a structured approach to the fetal examination.
- ◆ Performance of the first trimester ultrasound component of the aneuploidy screen requires formal training and certification.
- ◆ Individuals who perform prenatal sonography should be aware of conditions that can be detected with a standard examination.

**The goal of genetic screening is to identify individuals or couples at risk for having a child with an inherited condition, chromosome abnormality, or birth defect.** Ideally, screening should take place before conception to ensure that couples are fully informed of their reproductive options, including preimplantation genetic screening and diagnosis, or screening should be done as early as possible in pregnancy to allow couples the opportunity to consider aneuploidy screening and prenatal diagnostic testing. Genetic screening begins with a thorough personal and family history, followed by genetic counseling if indicated. **Approximately 3% of liveborn infants will have a major congenital anomaly; about one half of these anomalies are detected at birth and are due to a genetic cause—a chromosome abnormality, single-gene mutation, or polygenic/multifactorial inheritance.** Less frequently, malformations may be due to nongenetic causes or teratogens (see [Chapter 8](#)). The detection of many congenital malformations is possible using ultrasonography and fetal echocardiography (see [Chapter 9](#)). Screening for aneuploidy, inherited disorders, and structural malformations is an integral part of routine obstetric care. When indicated and desired, amniotic fluid, placental tissue, and cord blood can be readily obtained and analyzed for chromosome abnormalities and genetic disorders. In this chapter, we review genetic history and counseling, common chromosome abnormalities, aneuploidy screening and cytogenetic testing, mendelian disorders, molecular carrier and diagnostic testing, and techniques for prenatal and preimplantation genetic diagnostic testing.

## GENETIC HISTORY

**Obstetricians/gynecologists should attempt to take a thorough personal and family history to determine whether a woman, her partner, or a relative has a heritable disorder, birth defect, mental retardation, or psychiatric disorder that may increase their risk of having an affected offspring.** To address this question, some will find it helpful to elicit genetic information through the use of questionnaires or checklists.

The clinician should inquire into the health status of first-degree relatives (siblings, parents, offspring), second-degree relatives (nephews, nieces, aunts, uncles, grandparents), and third-degree relatives (first cousins, especially maternal). **A positive family history of a genetic disorder may warrant referral to a clinical geneticist or genetic counselor who can accurately assess the risk of having an affected offspring and review genetic screening and testing options.** In some cases, it may be straightforward enough for the well-informed obstetrician to manage. For example, if a birth defect such as a cleft lip and palate or neural tube defect (NTD) exists in a second- or third-degree relative, the risk for that anomaly will usually not prove substantially increased over that of the general population. In contrast, identification of a second-degree relative with an

autosomal-recessive disorder such as cystic fibrosis (CF) increases the risk for an affected offspring; therefore more extensive genetic counseling should be considered. Adverse reproductive outcomes such as repetitive spontaneous abortions, stillbirths, and anomalous liveborn infants should be noted. Couples who have such histories should undergo chromosome studies to exclude balanced translocations, which could impact a subsequent pregnancy (see [Chapter 27](#)).

Parental ages should be recorded. Advanced maternal age confers an increased risk for aneuploidy.<sup>1,2</sup> A few studies indicate an increased frequency of aneuploidy in sperm in the sixth and seventh decades. However, risks are only marginally increased above background, **and data do not indicate that the risks of having aneuploid liveborns is increased based on paternal age.** A paternal-age effect is associated with a small aggregate increased risk (0.3% to 0.5% or less in men over 40 years of age) for sporadic gene mutations for certain autosomal-dominant conditions such as achondroplasia and craniosynostosis. No specific screening tests exist for anomalies associated with advanced paternal age, although some of these conditions may be detected by ultrasonography (see [Chapter 9](#)).

Ethnic origin should also be recorded because certain genetic diseases are increased in selected ethnic groups; this will be discussed in this chapter. Such queries also apply to gamete donors.

## GENETIC COUNSELING

Although situations exist in which referral to a clinical geneticist or genetic counselor is indicated, it is impractical for obstetricians to refer all patients with genetic inquiries. **Obstetricians should be able to counsel patients before performing screening tests for aneuploidy and NTDs, carrier screening, and diagnostic procedures such as amniocentesis.** Therefore salient principles of the genetic counseling process are described in this section.

### Communication

Pivotal to counseling is communication in terms readily understood by patients. It is useful to preface remarks with a few sentences that recount the major causes of genetic abnormalities, such as cytogenetic, single-gene, polygenic/multifactorial (“complex”), and environmental causes (i.e., teratogens). Writing out unfamiliar words and using tables or diagrams to reinforce important concepts is helpful, and repetition is essential. Allow the couple not only to ask questions but also to talk with one another to formulate their concerns.

Preprinted information, videos, and select Web sites that cover common genetic conditions are useful and have the additional advantage of emphasizing that the couple’s problem is not unique. For unique situations, the provision of detailed letters serves as a couple’s permanent record, and these help to allay misunderstanding and assist in dealing with relatives.

Irrespective of how obvious a diagnosis may seem, confirmation is always obligatory. Accepting a patient's verbal recollection does not suffice, nor would accepting a diagnosis made by a physician not highly knowledgeable about the condition. Medical records should be requested and reviewed. It may be necessary for an appropriate specialist to examine the affected individual and order confirmatory diagnostic tests; examining first-degree relatives may also be required to detect subtle findings. This is particularly applicable for autosomal-dominant disorders such as neurofibromatosis or Marfan syndrome, for which variable expressivity is expected. **Accurate counseling requires a definitive diagnosis. However, the physician should not hesitate to acknowledge whether a definitive diagnosis cannot be established.**

### Nondirective Counseling

In genetic counseling, the clinician should provide accurate genetic information and outline the options for screening and testing without being prescriptive. Of course, completely nondirective counseling is probably unrealistic. Despite the difficulties of remaining truly objective, the clinician should attempt to provide information in a nondirective manner and then support the couple's decision.

### Psychological Defenses

**If not appreciated, psychological defenses can impede the entire counseling process.** Anxiety is low in couples counseled for advanced maternal age or for an abnormality in a distant relative. So long as anxiety remains low, comprehension of information is usually not impeded. However, couples who have experienced a stillborn infant, an anomalous child, or multiple repetitive abortions are inherently more anxious; thus their ability to retain information may be hindered.

**Couples who experience abnormal pregnancy outcomes manifest the same five stages of grief that occur after the death of a loved one: (1) denial, (2) anger, (3) bargaining, (4) grief/depression, and (5) acceptance.** Deference should be paid to this sequence by not attempting definitive counseling immediately after the birth of an abnormal neonate. The obstetrician should avoid discussing specific recurrence risks for fear

of adding to the immediate burden. By 4 to 6 weeks, the couple has begun to cope and is often more receptive to counseling.

An additional psychological consideration is that of parental guilt. A person naturally searches for exogenous factors that might have caused an abnormal outcome. In the process of such a search, guilt may arise. Conversely, a tendency to blame the spouse may be seen. Usually, guilt or blame is not justified, but occasionally the "blame" has a basis in reality (e.g., in autosomal-dominant traits). Fortunately, most couples can be assured that nothing could have prevented a given abnormality in their offspring. Appreciating psychological defenses helps in understanding the failure of ostensibly intelligent and well-counseled couples to comprehend genetic information.

### CHROMOSOME ABNORMALITIES

A basic fund of knowledge about common chromosome disorders is essential for the obstetrician who offers genetic screening for aneuploidy or who may encounter an abnormal fetus or infant during pregnancy or at delivery. With increasing utilization of chromosome microarrays for prenatal diagnosis, it is important for obstetricians to be familiar with the clinical significance of both numeric and structural chromosome abnormalities.

**The incidence of chromosome aberrations is 1 in 160 newborns. In addition, more than 50% of first-trimester spontaneous abortions and at least 5% of stillborn infants exhibit chromosome abnormalities** (see [Chapter 27](#)). The chromosome abnormalities that generate the greatest attention are the autosomal trisomies ([Table 10-1](#)). Autosomal trisomy usually arises as a result of nondisjunction that produces a gamete with 24 chromosomes, rather than the expected 23 chromosomes; this results in a zygote having 47 chromosomes. **This error most commonly occurs during maternal meiosis and is associated with the well-known maternal-age effect.** [Table 10-2](#) shows the year-to-year (maternal age) increase in frequency of Down syndrome and other aneuploidies.<sup>1</sup> The frequency is about 30% higher in midpregnancy than at term, which reflects lethality throughout pregnancy.<sup>2</sup> Some trisomies—for example, trisomy 16—arise almost exclusively in maternal meiosis, usually

**TABLE 10-1** INCIDENCE AND CLINICAL FEATURES OF MAJOR AUTOSOMAL TRISOMIES

| AUTOSOMAL TRISOMY | INCIDENCE LIVE BIRTHS | CLINICAL FEATURES   |
|-------------------|-----------------------|---|
| Trisomy 21        | 1 in 800              | <p><i>Facial features:</i> brachycephaly; oblique palpebral fissures; epicanthal folds; broad nasal bridge; protruding tongue; small, low-set ears with an overlapping helix and a prominent antihelix; iridal Brushfield spots</p> <p><i>Skeletal features:</i> broad, short fingers (brachymesophalangia); clinodactyly (incurving fifth finger resulting from an abnormality of the middle phalanx); a single flexion crease on the fifth digit; wide space between the first two toes</p> <p>Cardiac defects, duodenal atresia, neonatal hypotonia</p> <p>Increased susceptibility to respiratory infections and leukemia</p> <p>Mean survival extends into the fifth decade</p> <p>Mean IQ is 25 to 70</p> |
| Trisomy 13        | 1 in 20,000           | <p>Holoprosencephaly, eye anomalies (microphthalmia, anophthalmia, or coloboma), cleft lip and palate, polydactyly, cardiac defects, cutaneous scalp defects, hemangiomas on the face or neck, low-set ears with an abnormal helix, and rocker-bottom feet (convex soles and protruding heels)</p> <p>Intrauterine and postnatal growth restriction</p> <p>Severe developmental retardation</p>   |
| Trisomy 18        | 1 in 8000             | <p><i>Facial features:</i> microcephaly, prominent occiput, low-set and pointed "fawnlike" ears, micrognathia</p> <p><i>Skeletal anomalies:</i> overlapping fingers (V over IV, II over III), short sternum, shield chest, narrow pelvis, limited thigh abduction or congenital hip dislocation, rocker-bottom feet with protrusion of the calcaneum, and a short dorsiflexed hallux ("hammer toe")</p> <p>Cardiac defects, renal anomalies</p> <p>Intrauterine growth restriction, developmental retardation</p>   |

Data from Hook EB. Rates of chromosome abnormalities at different maternal ages. *Obstet Gynecol.* 1981;58:282; and Hook EB, Cross PK, Schreinemachers DM. Chromosomal abnormality rates at amniocentesis and in live-born infants. *JAMA.* 1983;249:2034.

\*Because sample size for some intervals is relatively small, confidence limits are sometimes relatively large. Nonetheless, these figures are suitable for genetic counseling.

<sup>†</sup>47,XXX excluded for ages 20 to 32 years (data not available).

maternal meiosis I. For a few chromosomes, the frequency of errors is relatively higher in meiosis II (e.g., trisomy 18), and in yet others, errors in paternal meiosis are not uncommon (e.g., trisomy 2). **Autosomal trisomy can recur and has a recurrence risk of approximately 1% following either trisomy 18 or 21.** This suggests that genetic factors perturb meiosis, a phenomenon that serves as justification for offering prenatal genetic screening or testing after one aneuploid conception.

In addition to numeric abnormalities, structural chromosome abnormalities such as translocations, deletions, and duplications can occur. Individuals with a balanced translocation caused by an interchange between two or more chromosomes are usually phenotypically normal. However, such individuals are at increased risk for offspring with unbalanced gametes, which may result in recurrent pregnancy loss, fetal demise, congenital anomalies, and mental retardation. Small, often submicroscopic deletions and duplications of chromosome material can result in recognizable syndromes, such as the 22q11 deletion syndrome, and may cause structural malformations as well as cognitive, behavioral, and neuropsychological problems.

This section reviews the common autosomal trisomies and sex chromosome abnormalities an obstetrician is likely to encounter, and we discuss the clinical significance of deletions and duplications.

**FIG 10-1** An infant with trisomy 21. (From Simpson JL, Elias S. *Genetics in Obstetrics and Gynecology*, ed 3. Philadelphia: WB Saunders; 2003:24.)

## Autosomal Trisomy

### Trisomy 21

**Trisomy 21, or Down syndrome, is the most frequent autosomal chromosome syndrome** with characteristic craniofacial features and congenital anomalies (Fig. 10-1; see also Table 10-1). The relationship of Down syndrome to advanced maternal age is well known (see Table 10-2). Approximately 95% of cases arise in maternal meiosis, usually meiosis I, and have 47 chromosomes (47,XX,+21 or 47,XY,+21). Mosaicism for chromosome 21 occurs in 2% to 4% of cases of Down syndrome and usually results in a higher IQ (70 to 80). Women with Down syndrome are usually fertile, and although relatively few trisomic mothers have reproduced, about 30% of their offspring are also trisomic. Men are invariably infertile.

**Translocations (sporadic or familial) most commonly associated with Down syndrome involve chromosomes 14 and 21.** One parent may have the same translocation, 45t(14q;21q), referred to as a *robertsonian translocation*. **Empiric risks for having an offspring with Down syndrome are approximately 10% for female robertsonian translocation carriers and 2% for male translocation carriers.** A potential concern is that offspring who are diploid (46,XX or 46,XY) actually have uniparental disomy (UPD), a condition in which both chromosomes originate from the same parent. In a study of 65 robertsonian translocation carriers (44t[13q;14q], 11t[14q;21q], 4t[14q;22q], and six others), only one UPD case was observed (0.6%).<sup>3</sup> The authors also surveyed 357 inherited and 102 de novo published cases and concluded that overall risk for UPD 14 or 15 was 3%.

Other structural rearrangements that result in Down syndrome include t(21q;21q) and translocations that involve chromosome 21 and other acrocentric chromosomes (13,15 or 22). In t(21q;21q) carriers, normal gametes do not ordinarily form. Thus only trisomic or monosomic zygotes are produced, and the

latter presumably appear as preclinical embryonic losses. Parents who have other translocations have a low empiric risk of having offspring with Down syndrome.

### Trisomy 13

**Trisomy 13 occurs in about 1/20,000 live births.** The clinical features of trisomy 13 are summarized in Table 10-1. Most cases are caused by nondisjunction (47,XX,+13 or 47,XY,+13) and are maternal in origin. Robertsonian translocations are responsible for fewer than 20% of cases and are invariably associated with two group D (13 to 15) chromosomes joining at their centromeric regions. If neither parent has a rearrangement, the risk for subsequent affected progeny is not increased. If either parent has a balanced 13q;14q translocation, the recurrence risk for an affected offspring is increased but only to 1% to 2%. The exception is a 13q;13q parental translocation in which no normal gametes are formed; this has the same dire prognosis as a 21q;21q translocation. For live births with trisomy 13, survival beyond 3 years is rare.

### Trisomy 18

Trisomy 18 occurs in 1 per 8000 live births (see Table 10-1). Stillbirth is not uncommon. Fetal movement is feeble, and approximately 50% develop nonreassuring fetal status during labor. For live births, mean survival is measured in months, and pronounced developmental and growth retardation is apparent. Approximately 80% of trisomy 18 cases are caused by primary nondisjunction (47,+18). Errors usually arise in maternal meiosis, frequently meiosis II. Recurrence risk is about 1%.

### Other Autosomal Trisomies

All autosomes show trisomies, but usually the trisomies other than those described above end in abortuses. In addition to trisomies 13, 18, and 21, only a few other trisomies are detected in liveborns (8, 9, 14, 16, and 22), often as mosaics in conjunction with a normal cell line (46 chromosomes). All exhibit some degree of mental retardation, various structural anomalies, and intrauterine growth restriction (IUGR).

### Autosomal Deletions and Duplications

**Well-described genetic disorders have been associated with deletions or duplications of a number of chromosomes (Table 10-3).** Although some of these may be diagnosed on a routine karyotype, most will only be detected by microarray analysis

**(MA) capable of detecting deletions and duplications smaller than 5 Mb (5,000,000 base pairs).** Over 210 microdeletions and almost 80 microduplications have been reported as a result of the increased utilization of MA.<sup>4</sup> Specific clinical features vary but may include learning difficulties, mental retardation, neurologic and behavioral disorders, psychiatric disorders, and various congenital anomalies. De novo, large (1 Mb or greater) deletions or duplications, also referred to as *copy number variants* (CNVs), may contain dosage-sensitive genes and are more likely to be of clinical significance; however, even small CNVs can be significant. A growing body of literature and registries have compiled data on the outcomes of postnatal and prenatally ascertained CNVs. MA has been recommended as a first-tier test for the postnatal evaluation of individuals with undiagnosed developmental delay, intellectual disabilities, autism spectrum disorder, and/or multiple congenital anomalies based on a review of 33 studies showing that pathogenic CNVs were found in 12.2% of the 21,698 individuals studied (10% higher than with routine karyotype).<sup>5</sup> It is also important to recognize that many CNVs are of no ostensible clinical significance. In some cases, the clinical significance remains unknown; these CNVs are referred to as *variants of uncertain significance* (VOUS).

**Most deletions and duplications occur sporadically because of nonallelic homologous recombination mediated by low-copy repetitive sequences of DNA during meiosis or mitosis and are not related to parental age. Hence, although the recurrence risk is low (<1%), it still may be elevated above baseline as a result of germline mosaicism.** Thus a couple may be prompted to consider prenatal testing in a future pregnancy. However, CNVs can be familial; therefore parental studies are recommended. If a parent has the same CNV as one child, the risk to subsequent offspring is 50%. **It is important to note that the phenotype of many deletion and duplication syndromes is highly variable, and even within the same family, this can range from mild to severe.** In some cases, a parent may appear phenotypically normal. The inability to accurately predict the outcome can lead to uncertainty and heightened anxiety; thus it is critically important that patients receive the most up-to-date information from an experienced counselor or geneticist.

### Sex Chromosome Abnormalities

#### Monosomy X (45,X)

The incidence of 45,X in liveborn girls is about 1 in 10,000. **Monosomy X, or Turner syndrome, accounts for 10% of all**

**TABLE 10-3** COMMON DELETION SYNDROMES

| CHROMOSOME REGION | SYNDROME                       | CLINICAL FEATURES  |

GU, genitourinary; IUGR, intrauterine growth restriction; SGA, small for gestational age.

first-trimester abortions; therefore it can be calculated that more than 99% of 45,X conceptuses are lost early in pregnancy. The error usually (80%) involves loss of a paternal sex chromosome. Mosaicism is frequent and usually involves a coexisting 45,X cell line.

Common features include primary ovarian failure, absent pubertal development due to gonadal dysgenesis (streak gonads), and short stature (<150 cm). Structural abnormalities of the X chromosome may also result in premature ovarian failure. Both the long arm and the short arm of the X chromosome contain determinants necessary for ovarian differentiation and for normal stature. Various somatic anomalies include renal and cardiac defects, skeletal abnormalities (cubitus valgus and clinodactyly), vertebral anomalies, pigmented nevi, nail hypoplasia, and a low posterior hairline. Performance IQ is lower than verbal IQ, but overall IQ is considered normal. Adult-onset diseases include hypertension, coronary artery disease, hypothyroidism, and type 2 diabetes mellitus.

Low-dose estrogen therapy is needed to induce puberty, and long-term hormone replacement is needed in adulthood. Pregnancy may be achieved with the use of donor eggs but requires careful monitoring of cardiovascular status before and throughout pregnancy and in the postpartum period. Growth hormone treatment increases the final adult height 6 to 8 cm. Comprehensive guidelines for evaluation and clinical management of Turner syndrome are available.<sup>6</sup>

### Klinefelter Syndrome

About 1 in 1000 males are born with Klinefelter syndrome, the result of two or more X chromosomes (47,XXY; 48,XXXY; and 49,XXXXY). Characteristic features include small testes, azoospermia, elevated follicle-stimulating hormone (FSH) and luteinizing hormone levels, and decreased testosterone. The most common chromosome complement associated with this phenotype is 47,XXY.

Mental retardation is uncommon in 47,XXY males, but behavioral problems and receptive language difficulties are common. Mental retardation is almost invariably associated with 48,XXXY and 49,XXXXY. Skeletal, trunk, and craniofacial anomalies occur infrequently in 47,XXY but are commonly observed in 48,XXXY and 49,XXXXY. Regardless of the specific chromosome complement, patients with Klinefelter syndrome all have male phenotypes. The penis may be hypoplastic, but hypospadias is uncommon. With intracytoplasmic sperm injection and other assisted reproductive technology (ART), siring a pregnancy is now possible. Simpson and colleagues<sup>7</sup> and Graham and colleagues<sup>8</sup> have provided guidelines on evaluation and clinical management.

### Polysomy X in Girls (47,XXX; 48,XXXX; 49,XXXX)

About 1 in 800 liveborn girls has a 47, complement. The IQ of such individuals is 10 to 15 points lower than that of their siblings. The absolute risk for mental retardation does not exceed 5% to 10%, and even then, IQ is usually 60 to 80. Most of these individuals have a normal reproductive system. The theoretic risk of women with the 47, complement delivering an infant who also has an abnormal chromosome complement is 50%, given half of the maternal gametes carry 24 chromosomes (24,XX). Empiric risks are much less. Somatic anomalies are uncommon in those with the 47, complement, but anomalies may occur and have been observed in some prenatally detected cases.<sup>9</sup> However, 48,XXXX and 49,XXXXX individuals are

invariably retarded and are more likely to have somatic malformations than individuals with the 47, complement.

### Polysomy Y in Boys (47,XYY and 48,XXYY)

Presence of more than one Y chromosome is another frequent chromosome abnormality in liveborn boys (1 in 1000). Those born 47,XYY are more likely than 46,XY boys to be tall and are at increased risk for learning disabilities, speech and language delay, and behavioral and emotional difficulties. These individuals have normal male phenotype and sexual development.

### Screening for Aneuploidy

Noninvasive screening for chromosome disorders such as trisomies 21 and 18 is routinely offered to women during pregnancy regardless of maternal age. Several noninvasive approaches to screening are available that utilize maternal serum analytes and/or ultrasonography in the first and second trimesters (Table 10-4). More recently, noninvasive prenatal testing (NIPT) using cell-free DNA (cfDNA) has been introduced into clinical practice and can be performed as early as 10 weeks' gestation. However, screening has limitations that must be taken into consideration when deciding which testing strategy best meets the patient's needs and preferences. **That is, screening is not equivalent to testing, which implies a definitive answer.** Pretest counseling should thus remind parents of the possibilities of false-negative or false-positive test results. Women with a positive screening test for aneuploidy should be referred for genetic counseling and offered an invasive diagnostic test.

### First-Trimester Screening

First-trimester screening can be performed between 11 and 14 weeks using a combination of biochemical markers, pregnancy-associated plasma protein A (PAPP-A) and free  $\beta$ -human chorionic gonadotropin ( $\beta$ -hCG), and ultrasound measurement of the nuchal translucency (NT), a sonolucent space present in all fetuses behind the fetal neck. The detection rate for trisomy 21 is greater than 80% with a false-positive rate of 5% compared with a 70% detection rate based on NT measurement alone.<sup>10</sup> In trisomy 21, PAPP-A levels are typically reduced, whereas hCG and the NT measurement are increased. **First-trimester screening is comparable or**

From Wapner R, Thom E, Simpson JL, et al. First trimester screening for trisomies 21 and 18. *N Engl J Med*. 2003;349:1405.

\*The National Institute of Child Health and Human Development first-trimester only screening (nuchal translucency, pregnancy-associated plasma protein A, free  $\beta$ -human chorionic gonadotropin) cohort of Wapner and colleagues. The sample of 8515 pregnancies prospectively applied a cutoff of 1/270. Detection rate increases with prevalence (increased maternal age) albeit at the cost of more procedures. Because the mean maternal age was 34.5 years, data were then modeled to apply to the U.S. population (whose mean maternal age is 27 years) at a 5% to 1% false-positive rate.

superior to second-trimester screening alone and, most importantly, it provides parents with the option of earlier diagnostic testing in the event the screen indicates that the fetus is at high risk for aneuploidy. However, mandatory training and quality assurance for the NT measurement is a critical necessity.

Several large, multicenter, prospective studies have validated the clinical application of first-trimester screening. When comparing studies, it is important to keep in mind that detection rates vary according to sample characteristics. In particular, sensitivity for noninvasive screening is age dependent, and software is constructed such that the proportion of cases detected at a given age is greater for older women than for younger women. Hence the false-positive rate and the related procedure rate also increase with maternal age. Detection rates also depend not just on the trimester but on the week of gestation and on the arbitrarily set false-positive rate. If more procedures are accepted (i.e., the false-positive rate is higher), detection rates increase. The converse is also true.

In the first U.S. large-scale, prospective study of over 5800 women using both ultrasound (NT) and serum analytes (PAPP-A, free  $\beta$ -hCG), the detection rate for trisomy 21 was 87.5% (7 of 8 cases) in women younger than 35 years of age. In women older than 35 years, the detection rate was 92% (23 of 25), albeit with higher false-positive and invasive procedure rates. For trisomy 18, detection rates were 100% in both age groups.<sup>11</sup> In 2003, an National Institute of Child Health and Human Development (NICHD) multicenter cohort study, the Biochemistry Ultrasound Nuchal Translucency (BUN) Study, reported results in 8514 women screened between 74 and 97 days' gestation (Table 10-5).<sup>12</sup> Applying the traditional midtrimester screen positive cutoff of 1 in 270, 85.2% of trisomy 21 pregnancies were identified with a false-positive rate of 9.4%. The high false-positive rate was predictable, given the higher mean maternal age of the sample. Stratifying by age, the detection rate for trisomy 21 was 66.7% for patients younger than age 35 years with a 3.7% false-positive rate, and it was 89.8% in patients older than age 35 years with a 15.2% false-positive rate. The detection rate for trisomy 18 was 90.9%. Modeling for the general population (with a lower mean age) and setting a

From Malone FD, Canick JA, Ball RH, et al. First-trimester or second-trimester screening or both for Down's syndrome. *N Engl J Med*. 2005;353:2001.

\*If first-trimester ultrasound revealed septated cystic hygromas, intervention was taken (chorionic villus sampling was offered). Otherwise results were not disclosed until after second-trimester screening. Compiled data were then used to compare detection rates that would have occurred given various approaches, all at 5% false-positive (procedure) rates for each.

AFP, alpha-fetoprotein; hCG, human chorionic gonadotropin; NT, nuchal translucency; PAPP-A, pregnancy-associated plasma protein A; uE<sub>3</sub>, unconjugated estriol.

false-positive procedure rate of 5%, sensitivity for trisomy 21 was estimated to be 78.7%; at a false-positive rate of 1%, the sensitivity was estimated to be 63.9%. These findings were consistent with other studies.

**Two other large, collaborative studies also have provided results comparable to the NICHD BUN study.** The Serum, Urine, and Ultrasound Screening Study (SURUSS) was a 25-center European trial<sup>13</sup> in which 47,000 patients were evaluated in both the first and second trimesters. Using a similar design, Malone and colleagues<sup>14</sup> studied 38,167 women in 15 U.S. centers in the NICHD First- and Second-Trimester Evaluation of Risk (FASTER) trial. Detection rates for Down syndrome were 87% at 11 weeks and 85% at 12 weeks (Table 10-6). In this study, 134 women who had fetuses with a septated cystic hygroma were removed from the cohort; 51% had a chromosome abnormality and 34% had other major abnormalities.<sup>15</sup> The group later stratified their data and found that **NT greater than 4 mm was never associated with a normal noninvasive screen; therefore women with an NT that exceeded this threshold should be offered diagnostic testing without needing to undergo further analyte analysis.**<sup>16</sup> In fact, only 8% of pregnancies with NT greater than 3 mm had a screen-negative value.

Nicolaidis<sup>10</sup> tabulated that NT, PAPP-A, and hCG detected 87% of 215 trisomy fetuses at a false-positive rate of 5%. Later results of Avgidou and colleagues<sup>17</sup> reported superior results from the same U.K. group. This group screened 30,564 women with NT, PAPP-A, and hCG, providing results the same day and detecting 93% of trisomy 21 cases. The incorporation of the other sonographic markers such as the presence of a nasal bone, reverse ductus venosus flow, and tricuspid regurgitation has been proposed to increase the detection rates further. In general these markers are not utilized except in specialized centers.

When an increased NT measurement is associated with a normal karyotype, fetal loss rates are increased and other fetal

anomalies and genetic syndromes are observed, in particular, congenital heart defects.<sup>18</sup> **A targeted ultrasound examination during the second trimester and fetal echocardiography are recommended when the NT measurement is 3.5 mm or greater and the fetal karyotype is normal.**

### Second-Trimester Serum Screening

**The most widely used second-trimester aneuploidy screening test is the so-called quad screen, which utilizes four biochemical analytes—alpha-fetoprotein (AFP), hCG, unconjugated estriol (uE<sub>3</sub>), and dimeric inhibin A (INHA). Performed between 15 and 22 weeks' gestation, the detection rate for trisomy 21 is about 75% in women who are less than 35 years of age and over 80% in women 35 years or older, with a false-positive rate of 5%. For trisomy 18, using only the first three markers provides a detection rate of about 70%. Serum screening does not detect other age-related forms of aneuploidy such as Klinefelter syndrome (47,XXY).**

**Serum hCG and INHA levels are increased in women carrying fetuses with Down syndrome.<sup>19</sup> Levels of AFP and uE<sub>3</sub> in maternal serum are lower in pregnancies affected with Down syndrome compared with unaffected pregnancies.<sup>20</sup>** Typically, levels of AFP, uE<sub>3</sub>, and hCG are reduced in trisomy 18. A simple approach to detect trisomy 18 is to offer invasive prenatal diagnostic testing whenever serum screening for each of these three markers falls below certain thresholds (maternal serum  $\alpha$ -fetoprotein [MSAFP], 0.6 multiples of the median [MoM]; hCG, 0.55 MoM; uE<sub>3</sub>, 0.5 MoM).<sup>21</sup> Using these thresholds would detect 60% to 80% of trisomy 18 fetuses with a 0.4% amniocentesis rate. Calculating individual risk estimation on the basis of three markers and maternal age, Palomaki and colleagues<sup>22</sup> reported that 60% of trisomy 18 pregnancies can be detected with a low false-positive rate of 0.2%. The value of individual risk estimates is that one in nine pregnancies identified as being at increased risk for trisomy 18 by serum screening would actually be affected.

Confounding factors influence serum screening, and adjustments for gestational age, maternal weight, ethnicity, diabetes, and number of fetuses are necessary. Weight adjustment is needed because without adjustment, dilutional effects would result in heavier women having a spuriously low value, whereas thinner women would have a spuriously elevated value. In women with type 1 diabetes mellitus, a population at increased risk for NTDs, the median levels of MSAFP, uE<sub>3</sub> and hCG are lower than in nondiabetic women. In black women, who have a lower risk for a fetal NTD, the median MSAFP is higher than in other ethnic groups. Maternal smoking increases MSAFP by 3% but decreases maternal serum uE<sub>3</sub> and hCG levels by 3% and 23%, respectively.<sup>23</sup> Maternal serum hCG is higher and MSAFP is lower in pregnancies conceived in vitro compared with pregnancies conceived spontaneously.<sup>23</sup> A claim has been made that adjustments should be made for prior aneuploidy;  $\beta$ -hCG is reported to be 10% higher in a pregnancy after aneuploidy, whereas PAPP-A is increased 15% in the first trimester.<sup>24</sup>

### First- and Second-Trimester Screening

**Several approaches have been proposed using the combination of both first- and second-trimester screening to increase the detection rate over that achieved by screening in either trimester alone, with detection rates of 88% to 96% with false-positive rates of 5% reported.** A caveat is that

independent screening (i.e., using both first- and second-trimester screening tests to assess the risk separately and independently) is not recommended because of the unacceptably high false-positive rates.

Sequential screening begins with first-trimester screening. A woman is informed of the adjusted risk for aneuploidy based on the first-trimester results. If her risk is high (greater than 1 in 50), she is offered genetic counseling and diagnostic testing. If the risk is low or moderate, a second-trimester screening test is performed with results of both the first- and second-trimester screening tests used to generate a final adjusted risk for trisomies 21 and 18. **This is called the *stepwise approach*. With contingency screening, not all women will proceed to second-trimester screening because this occurs only with an intermediate risk; if the risk is low after the first-trimester screening, no further testing is indicated.** The detection rates of the contingency approach are about 90% with low positive screening rates (2% to 3%). Malone and colleagues<sup>25</sup> compared several different first- plus second-trimester contingent sequential approaches (see Table 10-5). They concluded that the optimal method was contingency screening, in which patients were divided into three groups: (1) women whose calculated (NT, PAPP-A, hCG) first-trimester risk was greater than 1/30 would undergo chorionic villus sampling (CVS); (2) women whose risk was less than 1/1500 would undergo no further testing; and (3) all other women would undergo second-trimester serum testing. Using this approach, only 21.8% of the cohort would need second-trimester testing in order to detect 93% of trisomy 21 cases with a 4.3% false-positive rate; 65% would be detected in the first trimester with only 1.5% of patients having CVS procedures.

**Integrated screening has the highest theoretic detection rate (93% to 96%), but with this approach, the first-trimester screening results are withheld until the second-trimester screen is completed.** The individual receives only a single adjusted risk for trisomy 21 and trisomy 18 based on the results of both the first- and second-trimester screen. The obvious disadvantage with this approach is that the individual does not have an option of early diagnostic testing in the event that the first-trimester screen would have indicated a high risk for trisomy 21 or 18. Another is that patients may not return for their second-trimester screening. Fortunately, Cuckle and colleagues<sup>26,27</sup> showed that disclosure of first-trimester results could be made with very little loss in sensitivity of integrated screening.

When an NT measurement cannot be obtained, and in communities where NT measurement is not available, serum integrated screening is acceptable. In the FASTER trial, the sensitivity was 88%.<sup>14</sup> With this approach, the first-trimester PAPP-A and the second-trimester serum analytes are used to adjust the risk for trisomy 21, and the individual receives one adjusted risk after the second-trimester screen is completed.

### Cell-Free DNA Analysis

**The newest screening test for aneuploidy uses maternal cell-free DNA (cfDNA).** Maternal plasma contains small fragments of cfDNA (50 to 200 base pairs) derived from the breakdown of both maternal and fetal cells, primarily derived from the placenta. The concept of using cfDNA for prenatal diagnosis is not new; cfDNA has been used successfully to determine fetal sex in pregnancies at risk for X-linked disorders by identifying the Y-chromosome signal. In Europe, noninvasive testing is

commonly used to determine fetal Rhesus factor (Rh) status in RhD-negative women using real-time polymerase chain reaction (PCR) amplification. A similar approach can be adapted for the detection of some single-gene disorders. However, to screen for aneuploidy requires a different approach—the use of massively parallel DNA shotgun sequencing (MPSS).

The detection of aneuploidy is more difficult than for single-gene disorders because detecting fetal trisomy must reflect quantitative differences between affected and unaffected pregnancies. With MPSS technology, millions of fragments of maternal and fetal DNA are sequenced simultaneously in a single sample of maternal plasma, which is assigned to a chromosome region and counted. A woman carrying a trisomy 21 fetus will have relatively more chromosome 21 counts than a woman carrying a normal fetus. Alternatively, some laboratories use a targeted approach that sequences specific chromosomes of interest, such as 18 and 21, and adjusts for the proportion of fetal DNA (fetal fraction) to provide a patient-specific risk assessment that takes into account maternal age. An alternative approach is to use single nucleotide polymorphism (SNP)-based sequencing, which allows for the detection of triploidy and some of the common deletion syndromes.

**Several studies have demonstrated the ability to detect fetal trisomy 21 using MPSS.** A blinded, nested, case-control study of 4664 pregnancies at increased risk for trisomy 21 from 27 prenatal diagnostic centers worldwide validated the use of cfDNA analysis as a screening test for trisomy 21. In this study, 209 of 221 cases of trisomy 21 were detected; sensitivity was 98.6% with a false-positive rate of 0.2%.<sup>28</sup> Subsequently, Palomaki and colleagues<sup>29</sup> reported that all cases of trisomy 18 in this cohort were detected with a false-positive rate of 0.28%, but only 91.7% of the cases of trisomy 13 were detected with a false-positive rate of 0.97%.

Norton and colleagues<sup>30</sup> conducted a multicenter, prospective cohort study—the Noninvasive Chromosomal Evaluation (NICE) study—of over 3200 primarily high-risk women undergoing invasive diagnostic testing. For trisomy 21, the sensitivity was 100% with a false-positive rate of 0.03%, whereas the sensitivity for trisomy 18 was 97.4% and the false-positive rate was 0.07%. Two patients were classified as high risk for trisomy 18 and had a normal karyotype; this highlights the need for confirmatory diagnostic testing when an NIPT is positive or shows high risk for aneuploidy. Further, 29% of the chromosome abnormalities in this cohort were abnormalities other than trisomy 18 and 21 or were sex chromosome abnormalities such as unbalanced translocations, deletions, and duplications.

In a series of 1982 consecutive pregnancies at 12 weeks' gestation or greater referred for NIPT at a center in Hong Kong, 11 pregnancies screened positive for sex chromosome abnormalities, and 85.7% were confirmed to be fetal in origin.<sup>31</sup> Fetal mosaicism was detected in two cases, emphasizing that it is important to counsel patients about this possibility. Maternal mosaicism for 45,X/XX and confined placental mosaicism also lead to false-positive NIPT results, underscoring the importance of confirmatory invasive diagnostic testing.

Another limitation of cfDNA screening is the reported assay failure rate of up to 5%. One of the reasons is a low fetal fraction; a minimum fetal fraction of 4% is required. The ability to detect the small differences between euploid and triploid fetuses depends on the relative proportion of fetal to maternal cfDNA. The average fetal fraction at 10 to 22 weeks' gestation is 10% independent of gestational age, maternal age, race/ethnicity, or

fetal karyotype.<sup>30</sup> Fetal fraction decreases with maternal weight, and if NIPT fails in an obese patient, it may be necessary to repeat the test on a second sample or to offer serum and/or ultrasound screening as an alternative. Further consideration should be given to offering invasive testing because recent studies have reported a higher frequency of aneuploidy when cfDNA testing fails.

**The American College of Obstetricians and Gynecologists (ACOG) and the American College of Medical Genetics (ACMG) recommend that women be offered aneuploidy screening, and both acknowledge that NIPT is one of the screening options for women at increased risk for aneuploidy.**<sup>32,33</sup> This includes women 35 years or older and those with fetal ultrasound markers and structural anomalies associated with aneuploidy, prior pregnancy with trisomy, positive serum screening test, or a parental robertsonian translocation with risk for trisomy 21 or 13. However, as studies of low-risk women are conducted, we can expect that NIPT will become more widely available. In a cohort study of over 2000 women who presented for routine first-trimester screening (11 to 14 weeks) with a mean maternal age of 31.8 years, Nicolaides and colleagues<sup>34</sup> demonstrated that cfDNA analysis using targeted MPSS is feasible in a lower-risk population. The detection rate for trisomy 21 was 100% with a false-positive rate of 0.1%. Norton and colleagues<sup>35</sup> reported similar results in the international, blinded, prospective multicenter Noninvasive Examination of Trisomy (NEXT) study, which compared cfDNA to first-trimester screening at 10 to 14 weeks' gestation in 15,841 women (mean age 30.7) with a singleton gestation. The positive predictive value was 80.9% (95% confidence interval [CI], 66.7 to 90.9). Although all cases of trisomy 21 and 13 were detected, it is important to note that cfDNA testing did *not* detect one in 10 cases of trisomy 18, nor would it have detected the other forms of aneuploidy found in this study population. Furthermore, the rate of aneuploidy among patients with no cfDNA results was 2.7%, a prevalence of 1 in 38.<sup>35</sup> Hence, careful consideration should be given to offering diagnostic testing to this group of patients.

In the United States, Bianchi and colleagues<sup>36</sup> conducted a multicenter study to compare the false-positive rates of cfDNA analysis to routine first- and second-trimester screening. In 1914 women (mean age 29.6 years), the false-positive rate for trisomy 21 with cfDNA testing was significantly lower, 0.3% compared with 3.6%. All cases of aneuploidy were detected, but this finding should be interpreted cautiously because of the small sample size. **Patients will need to be counseled that a negative cfDNA test does *not* ensure an unaffected pregnancy and cannot provide the diagnostic accuracy of an invasive prenatal diagnostic test, especially if fetal structural anomalies exist or with a family history of a genetic disorder.**

### Aneuploidy Screening in Multiple Gestation

In dizygotic pregnancies, each twin has an individual risk for trisomy 21; analysis of the European National Down Syndrome Cytogenetic Registry found that dizygotic pregnancies were one third more likely to have at least one fetus with trisomy 21 than age-adjusted singleton pregnancies.<sup>37</sup> The pregnancy-specific and fetus-specific risks should be the same for monozygotic twins as for singleton pregnancies, although the study found the actual risk to be about a third that of a singleton pregnancy. Unfortunately, **Down syndrome screening using multiple**

**serum markers is less sensitive in twin pregnancies than in singleton pregnancies.** Using singleton cutoffs, one study showed that 73% of monozygotic twin pregnancies but only 43% of dizygotic twin pregnancies with Down syndrome were detected, given a 5% false-positive rate.<sup>38</sup> Decreased sensitivity in detecting trisomy 21 in dizygotic twins reflects the blunting effect of the concomitant presence of one normal and one aneuploid fetus. Thus patients with twins should be informed that the detection rate by serum screening is less than that in singleton pregnancies. First-trimester screening identifies about 70% of Down syndrome pregnancies; NT measurement alone has been shown to be as effective a screening test for higher-order multiple gestation as it is for twin gestations. The addition of the nasal bone (NB) assessment to the NT measurement increased the detection rate to 87% at a screen-positive rate of 5% and to 89% when serum analytes were included in a retrospective study of 2094 twin pregnancies.<sup>39</sup> First-trimester screening further provides the option of early diagnostic testing if the risk is increased and if selective reduction is undertaken.

Experience using cfDNA analysis in multiple gestations is limited, but a few studies suggest that cfDNA has similar sensitivity and specificity rates as in singleton pregnancies.<sup>40,41</sup> For dizygotic twins, a higher fetal fraction (minimum of 8%) may be necessary to detect a quantitative difference. NIPT should be interpreted cautiously in pregnancies with a vanishing twin; the results may be discordant because the vanishing twin may continue to release cfDNA into the maternal circulation. SNP-based NIPT may be helpful in identifying this phenomenon.

### Ultrasound Screening for Aneuploidy

Second-trimester ultrasonography may detect anomalies associated with aneuploidy, such as cardiac defects or duodenal atresia (see Chapter 9). In 1985, Benacerraf and colleagues<sup>42</sup> showed a **significant association between the thickness of the fetal nuchal skin fold and the presence of trisomy 21.** For the first time, a “marker,” as opposed to an actual birth defect, could be used to assess the likelihood that Down syndrome was present. **Other markers now commonly used in the genetic sonogram include the NB length, short femur or humerus, echogenic intracardiac focus, echogenic bowel, and pyelectasis.** The use of these markers has gradually become common clinical practice. As markers were studied in larger numbers of women, it became possible to assign likelihood ratios to each marker and to do a formal risk adjustment from the a priori risk to an ultrasound-adjusted risk. However, **most of the markers perform poorly as individual predictors of Down syndrome and have a very low sensitivity and a high rate of false-positive results.**<sup>43</sup> Further, the test performance depends on the skill of the examiner and the subjective assessment required for several markers, particularly echogenic intracardiac focus and echogenic bowel. Most women who undergo a genetic sonogram have no markers, but **women should be informed that the absence of markers does not rule out the possibility of Down syndrome or other chromosome abnormalities.**

The incidental finding of “soft markers,” minor markers such as echogenic intracardiac focus or pyelectasis, in otherwise low-risk pregnancies can cause a great deal of anxiety in the expectant parents. Opinions vary as to what to do when these soft markers are noted in a low-risk patient. A reasonable approach is to refer such a patient for consultation with an expert to evaluate the presence of other markers in the context of other screening tests (i.e., multiple marker screening or cfDNA).

## Prenatal Diagnostic Testing for Chromosome Abnormalities

Every chromosome disorder is potentially detectable in utero with the availability of chromosome microarrays. Thus any pregnant woman could undergo an invasive procedure, if she so desired, to assess the chromosome status of the fetus. However, for most couples, the risks of an invasive procedure outweigh the diagnostic benefits. Many will elect noninvasive screening with the understanding that the sensitivity is less than 100% and that the screen is only intended to identify pregnancies at increased risk for the common trisomies. In the setting of a “positive” screening test, a true test—which requires an invasive diagnostic procedure—is then necessary. In this section, we review the indications for prenatal diagnostic testing for chromosome abnormalities and also discuss the types of tests currently available.

### Indications for Prenatal Cytogenetic Testing

**In January 2007, ACOG published a new recommendation that all women, regardless of age, should have the option of invasive testing without first having been screened.**<sup>44</sup> Prenatal cytogenetic testing can be as basic as a routine G-banded karyotype, or it might include a whole genome microarray. In some cases, a more targeted approach may be desirable and could include either fluorescence in situ hybridization (FISH) for a specific chromosome region of interest or a targeted chromosome microarray.

### PREVIOUS CHILD WITH A CHROMOSOME ABNORMALITY

After the birth of one child, stillborn fetus, or abortus with a chromosome abnormality, couples may elect to have prenatal diagnostic testing in subsequent pregnancies. **With autosomal trisomy, the likelihood that subsequent progeny will have an autosomal trisomy is about 1%, even if parental chromosome complements are normal.** The recurrence risk for other de novo chromosome abnormalities is low (1% or less because of the possibility of germline mosaicism), and diagnostic testing can provide reassurance.

### PARENTAL CHROMOSOME REARRANGEMENTS

An uncommon but important indication for prenatal cytogenetic studies is presence of a parental chromosome abnormality such as a balanced translocation, inversion, deletion, or duplication. A mother or father with a balanced translocation is at risk for offspring with an unbalanced translocation and, hence, an abnormal phenotype. Fortunately, **empiric data show that theoretic risks for abnormal (unbalanced) offspring are greater than empiric risks, but miscarriages are common.** It is for this reason that preimplantation genetic diagnosis (PGD) can be especially helpful. The risk for having a liveborn infant with an unbalanced chromosome complement varies by rearrangement, sex of the parental carrier, and method of ascertainment.<sup>45</sup> Pooled empiric risks tabulated at CVS or amniocentesis approximate 12% risk for clinically abnormal offspring of either male or female translocation carriers with reciprocal translocations.<sup>46</sup> For robertsonian (centric fusion) translocations, risks vary according to the chromosomes involved as discussed above.

A parent with a deletion or duplication has a 1 in 2 chance of transmitting the abnormal chromosome and having an affected child. Due to the wide phenotypic variability of many of the deletion/duplication syndromes, it can be difficult to predict the phenotype of an affected offspring prenatally.

### ASSISTED REPRODUCTION THROUGH INTRACYTOPLASMIC SPERM INJECTION

Intracytoplasmic sperm injection (ICSI) is used in ART when the man is subfertile. Empiric data demonstrate an increased frequency of aneuploidies, mainly sex chromosome anomalies (1% to 2%).<sup>47</sup> The excess risk appears unrelated to the ICSI technique, rather it relates to the underlying male infertility that necessitated ICSI.

### CYTOGENETIC TESTING

**The gold standard for prenatal cytogenetic testing has been the G-banded karyotype**, first introduced in the late 1970s. Karyotyping can detect numeric abnormalities, balanced translocations, and structural abnormalities greater than 5 to 10 Mb (5 to 10 million base pairs). The routine karyotype remains a valid test for those interested in knowing whether the fetus has a major trisomy or for the cytogenetic evaluation of a couple with a history of recurrent pregnancy loss (see Chapter 27). However, with the availability of tests with a higher resolution for detecting chromosome rearrangements of less than 5 Mb, such as chromosome MAs, **ACOG recommends that women who desire an invasive prenatal diagnostic test be offered MAs as an option.**<sup>48</sup> Recent studies also support the use of MAs for the evaluation of the fetus with a structural malformation.<sup>46,49-51</sup> When a specific chromosome region is of interest, a more targeted approach using FISH may be utilized.

### CHROMOSOME MICROARRAYS

**Chromosome MAs allow comprehensive analysis of the entire genome at a finer resolution than a routine karyotype and are capable of detecting trisomies and submicroscopic deletions and duplications of the genome (CNVs).** CNVs can be detected using either comparative genomic hybridization (CGH) or SNP arrays (Fig. 10-2). For both, the principle is based on single-stranded DNA annealing (hybridizing) with a complementary single-stranded DNA. To look for CNVs, a sample of test DNA is labeled with a fluorochrome (e.g., red), denatured to single-stranded DNA, and then hybridized to single-stranded copies of DNA of known sequence differentially labeled (e.g., green) and embedded on a platform (array) in an ordered fashion. If equal amounts of control and test DNA are present, the color of the hybridized mixture could be expected to be yellow. If the test DNA were in excess (e.g., trisomy or duplication), the mixture for the relevant chromosome region would be relatively more of the color used to connote test (patient) DNA. This would be red in the previous example. SNP arrays can also detect homozygosity or heterozygosity for regions of DNA and can detect triploidy, UPD, and consanguinity.

Several different commercial platforms are available, but all interrogate sequences of DNA along every chromosome. “Coverage” varies slightly based on sensitivity sought, and all have redundancy—that is, a given region that is interrogated more than once to ensure replicability before making a diagnosis. Targeted arrays contain sequences from the pericentromeric and telomeric regions of the chromosome as well as clinically significant deletion and duplication syndromes. Although less sensitive than a whole-genome array, a targeted MA reduces the likelihood of finding CNVs of uncertain significance.

Several studies have demonstrated that prenatal microarrays are reliable and have several advantages over conventional cytogenetic testing, especially in the fetus with a structural malformation. The NICHD prospective prenatal cytogenetic array

**FIG 10-2** Schematic diagram illustrating principles of array comparative genome hybridization (CGH). Patient DNA is labeled in red (CY5), whereas references (normal control) are labeled in green (CY3). When denatured into single-stranded DNA, patient DNA and control DNA hybridize with DNA of the same type embedded on a platform (circles). The diagram shows only 33 “spots” of similar sequence, whereas in actual practice, a diagnostic platform would consist of thousands of embedded sequences. If the region being interrogated shows equal amounts of patient DNA and control DNA, the signal is yellow. A green signal indicates deficiency of test DNA (deletion or mosaicism), whereas a red signal indicates excess of test DNA (duplication or trisomy). Array CGH detects trisomies just like a karyotype; smaller deletions or duplications (<5 million base pairs) are detected only by array CGH. (Courtesy Ron J. Wapner, Columbia University, New York.)

study of 4401 women with varying indications for prenatal genetic diagnosis detected all of the trisomies, sex chromosome abnormalities, and unbalanced translocations identified by routine karyotype.<sup>49</sup> **In addition, clinically significant CNVs were detected in 6% of the 755 fetuses with a normal karyotype and suspected structural anomalies or growth abnormalities (Table 10-7).** Clinically significant CNVs were also detected in 1.7% of those with advanced maternal age or a positive serum screen result. These chromosome abnormalities were not detected on a routine karyotype. A smaller study that used high-resolution SNP arrays yielded comparable findings (1.6% in cases of advanced maternal age and 6.9% for ultrasound anomalies).<sup>49</sup> Similar results were found in a retrospective analysis of 2858 prenatal samples referred with abnormal sonographic findings, and 6.2% with a known normal karyotype had a clinically significant CNV.<sup>46</sup> The majority of samples in this study were tested using a whole-genome array. The odds of finding a clinically significant CNV increased when anomalies were present in two or more organ systems (9.5%) but were less common in samples referred for isolated growth abnormalities

**TABLE 10-7** FREQUENCY OF COMMON BENIGN, PATHOGENIC, AND POTENTIALLY CLINICALLY SIGNIFICANT MICRODELETIONS AND DUPLICATIONS ON CHROMOSOME MICROARRAY ANALYSIS OF PRENATAL SAMPLES WITH A NORMAL KARYOTYPE

| INDICATION FOR PRENATAL DIAGNOSIS | NORMAL KARYOTYPE NUMBER | COMMON BENIGN NUMBER (%) | KNOWN PATHOGENIC AND POTENTIAL FOR CLINICAL SIGNIFICANCE NUMBER (%) [CI]* |
|-----------------------------------|-------------------------|--------------------------|---|
| Any                               | 3822                    | 1234 (32.3)              | 96 (2.5) [2.1-3.1]  |
| Advanced maternal age             | 1966                    | 628 (31.9)               | 34 (1.7) [1.2-2.4]  |
| Positive Down syndrome screening  | 729                     | 247 (33.9)               | 12 (1.6) [0.9-2.9]  |

<sup>†</sup>Other indications include family history, previous pregnancy with chromosomal abnormalities, and elective decision.

(2.6%) or so-called soft markers on ultrasound examination (2.6%). Lee and colleagues<sup>51</sup> reported a 10.5% detection rate with a single anomaly and 15.4% with two or more anomalies. A number of factors may explain the differences among studies, including a bias toward a higher percentage of trisomies, types of malformations, lack of standardized definition of anomalies from referring practices, incomplete information on the number and type of anomalies, lack of postnatal confirmation of ultrasound anomalies, sample size, and types of arrays utilized. Based on the current evidence, ACOG and the Society for Maternal-Fetal Medicine recommend that MA replace conventional cytogenetic analysis in patients undergoing invasive diagnostic testing for the evaluation of a fetus with one or more structural abnormalities.<sup>48</sup>

**One of the major concerns with this technology is the identification of VOUS. The NICHD study detected VOUS in 3.4% of cases with a normal karyotype,** but it is equally important to note that one third were reclassified several years later as pathogenic.<sup>49</sup> As cases are ascertained and followed longitudinally, additional information will provide more accurate information for genetic counseling. The percentage of VOUS reported in the literature will vary with the microarray platform utilized. Shaffer and colleagues<sup>50</sup> reported on their experience with MAs of over 5000 prenatal samples over 7 years. The rate of VOUS was 4.2%; however, if only de novo variants were considered, the rate dropped to 0.39%, the same rate reported using a whole-genome SNP array.<sup>50</sup> Such a low rate may be acceptable in light of the diagnostic yield obtained with MAs.

In addition to identifying clinically significant CNVs in the fetus, prenatal MAs have the potential to identify variants in the parents that may connote increased susceptibility to cancer or adult-onset disorders. MAs may also reveal consanguinity or nonpaternity; therefore it is critical that patients are informed of the limitation and potential test results prior to testing to minimize the anxiety and distress associated with uncertain or unexpected findings.<sup>52</sup>

**One disadvantage of array CGH compared with the traditional karyotype is that chromosome MAs cannot distinguish between balanced translocations and normal karyotype; unbalanced (duplication, deficiency) rearrangements are readily detected.** Another difficulty is the inability to detect low-level mosaicism in which one of the two cell lines is infrequent. In some platforms, triploidy cannot be excluded. On the other hand, MAs can be performed on uncultured DNA, and this has been shown to be useful in the evaluation of stillbirths in which cell cultures for chromosome abnormalities are not often successful. The NICHD Stillbirth Collaborative Research

**FIG 10-3** Fluorescence in situ hybridization (FISH) performed on interphase nuclei obtained from peripheral blood lymphocytes. Dual-color FISH has been performed using Vysis (Abbot Molecular) locus-specific probes for chromosome 13 (green) and chromosome 21 (red). Chromosomal DNA is stained with DAPI (blue). Two signals for each indicates disomy (normal numbers) for these two chromosomes. (Courtesy Helen Tempest, Florida International University, Miami.)

Network demonstrated a higher success rate with MAs compared with conventional karyotyping (87.4% vs. 70.5%) in the evaluation of 532 stillbirths.<sup>53</sup> The detection rate of chromosome abnormalities was also higher (8.3% vs. 5.8%).

#### FLUORESCENCE IN SITU HYBRIDIZATION

Prior to the availability of MAs, FISH was a useful adjunct to a karyotype to examine a specific chromosome region or rapidly screen for aneuploidy. FISH is still useful when a parent with a known deletion or a couple with a previous affected child requests prenatal diagnosis for just that specific region.

**DNA sequences unique to the chromosome in question are labeled with a fluorochrome and are hybridized to a metaphase chromosome or interphase nuclei (Fig. 10-3).** Cells with two copies should show two separate signals; trisomic cells show three signals. One signal is present in the setting of a deletion. Because of geometric vicissitudes (e.g., one chromosome overlying another may not be appreciated in a two-dimensional scan), not every trisomic cell shows three signals; however, the modal count is readily determined. A single cell can be interrogated for up to five chromosomes. **FISH uses**

**interphase cells and thus permits rapid or same-day diagnosis of aneuploidy. This becomes particularly important when a rapid diagnosis is needed to aid in the management of a fetus at high risk, such as one with multiple anomalies detected by ultrasound.** FISH can also be used on preserved tissue (e.g., paraffin blocks) when culture for metaphase analysis is obviously not possible.

#### QUANTITATIVE FLUORESCENT POLYMERASE CHAIN REACTION

Polymerase chain reaction (PCR) is a widely used test that permits a small amount of DNA (e.g., from one cell) to be amplified to generate an amount sufficient for a diagnostic test. In quantitative PCR (QPCR), the rapidity with which the exponential increase in DNA occurs allows rapid and accurate detection of major numeric chromosome disorders in CVS.<sup>54</sup> This technique can be a powerful adjunct to conventional cytogenetics and in some venues, such as in Europe, it has replaced the traditional karyotype in prenatal diagnosis.

#### Accuracy of Prenatal Cytogenetic Diagnosis

Although invasive diagnostic testing for routine cytogenetic testing has markedly declined with the availability of noninvasive screening for aneuploidy and higher resolution MA, it is important for the obstetrician/gynecologist to be aware of the common pitfalls associated with analysis of chorionic villi or amniotic fluid cells. One problem is that cells may not grow, or growth may be insufficient for proper analysis (although with MAs, this is not a problem). Uncommonly, there may be maternal cell contamination, which can be minimized by discarding the first 1 to 2 mL of aspirated amniotic fluid during amniocentesis. In CVS, examination under a dissecting microscope allows the clinician to distinguish villi from maternal decidua.

**A more vexing concern is that chromosome abnormalities detected in villi or amniotic fluid may not reflect fetal status.**

Chromosome aberrations may arise in culture (in vitro) or may be confined to placental tissue. This possibility should be suspected when mosaicism (more than one cell line) is restricted to only one of the several culture flasks or to clones initiated from a single amniotic fluid or CVS specimen, or when an abnormal karyotype with a known severely anomalous phenotype does not correlate with a normal ultrasound. Although the reference laboratory and clinical geneticists are naturally expected to have requisite expertise, the obstetrician should be prepared to discuss certain common dilemmas with the patient.

#### MOSAICISM

Cells that contain at least one additional structurally normal chromosome are not uncommon (1% to 2%) in amniotic fluid or CVS specimens. If these abnormal cells are found in a single culture or clone, the phenomenon is termed *pseudomosaicism* and is usually of no clinical significance. **True mosaicism is more likely when the same abnormality is present in more than one clone or culture flask,** and it is confirmed by studies of the abortus or liveborn infant in 70% to 80% of cases<sup>55</sup> and actually can never truly be excluded because the abnormality could be restricted to tissue not readily accessible.

Numeric problems are more frequent in short-term cultures, which can be performed on chorionic villi but not on amniotic fluid cells. Metaphases from the trophoblasts or villi can accumulate within hours of sampling, allowing rapid results. In CVS, discrepancies may arise between short-term trophoblast cultures

and long-term cultures, which are initiated from the mesenchymal core of villi.<sup>5</sup> Discrepancies may further exist between CVS preparations and the embryo. If CVS results seem at odds with clinical findings, it is reasonable to track interval growth and, if abnormal, to perform a follow-up amniocentesis. Several rare trisomies in particular (+16, +22, +7) may not be confirmed. **Sometimes mosaicism is present in the placenta but not in the embryo; this is called *confined placental mosaicism* (CPM).** In this circumstance, the likelihood of anomalies is considered low.<sup>56</sup> However, the U.S. NICHD Collaborative CVS trial observed increased late loss rates (8.6%) in pregnancies showing CPM compared with pregnancies without mosaicism (3.4%). **Although CPM usually does not have clinical significance,<sup>57</sup> two potential adverse effects associated with CPM should be considered: IUGR and UPD.** UPD, the inheritance of both homologous chromosomes from a single parent, may result from a reduction to disomy from a trisomic embryo rescue.<sup>58</sup> The phenotypic effect of UPD depends on the chromosome involved.<sup>59</sup> Imprinted genes that have phenotypic effects with regard to UPD include chromosomes 7 (Russell-Silver syndrome), 11 (Beckwith-Wiedemann syndrome), 14 (mental retardation and multiple anomalies), and 15 (Prader-Willi and Angelman syndromes).

Potential technical problems notwithstanding, **amniotic fluid analysis and chorionic villi analysis are highly accurate for the detection of numeric chromosome abnormalities.** The U.S. NICHD Collaborative CVS trial<sup>57</sup> evaluated 11,473 chorionic villus samples by direct methods, long-term culture, or both. There were no incorrect sex predictions. No diagnostic errors occurred among 148 common autosomal trisomies (+13, +18, +21), 16 sex chromosome aneuploidies, and 13 structural aberrations; no normal cytogenetic diagnosis with CVS has ever been followed by birth of a trisomic infant. Overall, accuracy of CVS by karyotype is comparable to that of amniocentesis. However, with MAs, the ability to detect submicroscopic chromosome abnormalities has further increased the accuracy of prenatal diagnosis.

#### IMPLICATIONS OF DE NOVO STRUCTURAL ABNORMALITIES

If an ostensibly balanced inversion or translocation is detected in the fetus but is not found in either parent, the rearrangement arose de novo. The inversion or translocation may not actually be balanced; genes around breakpoints may be deleted but unappreciated by routine cytogenetic analysis. **The risk for the fetus being abnormal has been tabulated at 6% for a de novo reciprocal inversion and 10% to 15% for a de novo translocation.**<sup>60</sup> Risks are not chromosome specific but represent pooled data that involve many chromosomes. These risks also apply only to anatomic or developmental abnormalities evident at birth, not taking into account abnormalities that become evident only later in life. **Thus when a de novo structural abnormality is present, an MA should be performed to determine whether a gain or loss has occurred at the breakpoint as a result of the abnormality.** This will allow for more precise counseling; if array CGH shows no abnormality, the likelihood of an abnormality is markedly reduced.

Marker chromosomes, also called *supernumerary chromosomes*, by definition cannot be fully characterized on the basis of standard cytogenetic analyses. These small chromosomes usually contain a centromere, a high proportion are derived from the short arms of acrocentric chromosomes (13, 14, 15, 21, and 22), and their significance depends on whether the marker is de novo

or familial. In reviewing 15,522 prenatal diagnostic procedures, Hume and colleagues<sup>61</sup> ascertained 19 marker chromosomes, 5 from CVS specimens and 14 from amniotic fluid samples. Monitoring these pregnancies with high-resolution ultrasonography revealed an association between de novo marker chromosomes and anomalies. When ultrasound examination was normal, the likelihood of a phenotypically normal offspring was high. With MA, the origin of the marker chromosomes can usually be established.

## SINGLE-GENE OR MENDELIAN DISORDERS

**Approximately 1% of liveborn infants are phenotypically abnormal as result of gene mutations,** and yet most inherited disorders are rare except in some ethnic groups in which common mutations have been identified. With the sequencing of the human genome and the development of molecular diagnostic testing, it is now possible to identify carriers for some single-gene mutations and to more accurately assess their risk for having an affected offspring. **The risk is 50% for autosomal-dominant disorders like Marfan syndrome or for X-linked disorders such as fragile X syndrome or Duchenne muscular dystrophy. For autosomal recessive disorders like CF or Tay-Sachs disease, if both parents have a mutation, there is a 1 in 4 chance of an affected offspring in each pregnancy.** Individuals and couples at risk with known mutations may elect to have either prenatal or preimplantation genetic testing. Further, with the identification of the common gene mutations for many disorders, especially in some ethnic groups, it is now possible to offer population-based carrier screening. Also, some carriers are ascertained through the birth of an affected child or as a result of state newborn screening programs, which screen for over 30 inherited conditions at birth. In this section, we review carrier screening, newborn screening, and DNA-based molecular diagnosis—the platform for preimplantation and prenatal genetic testing.

### Carrier Screening for Heritable Disorders

**Carrier screening is performed to determine whether an individual has a mutation in one of two copies (heterozygous carrier) of the gene of interest.** Screening is voluntary, and informed consent is recommended. Ideally, individuals should be provided with information about the condition, its prevalence and severity, and treatment options in addition to information about the test, including detection rates and the limitations. When the detection rate is less than 100%, it is important to explain that a negative screening test reduces the likelihood that an individual is a carrier and is at risk for having an affected offspring, but it does not eliminate the possibility. Individuals should also be assured that their test results are confidential. For some individuals, genetic counseling may assist with the decision-making process; therefore it may be helpful to provide individuals with disease-specific educational material. Further, it is prudent to document in the medical record that screening tests were offered and the individual's decision.

**ACOG recommends population carrier screening for selected disorders in families amenable to prenatal diagnosis in which no previously affected individual has been born (Table 10-8).**<sup>62-66</sup> DNA-based tests also exist for fragile X mental retardation and spinal muscular atrophy (SMA). ACOG does not currently recommend universal screening for fragile X, but testing is recommended with a family history of unexplained

**TABLE 10-8** GENETIC SCREENING IN VARIOUS ETHNIC GROUPS

| ETHNIC GROUP  | DISORDER              | SCREENING TEST   |
|---|-----------------------|--|
| All   | Cystic fibrosis       | DNA analysis of a selected panel of 23 CFTR mutations (alleles present in 0.1% of the general U.S. population) |
| Blacks  | Sickle cell anemia    | MCV <80%, followed by hemoglobin electrophoresis   |
| Ashkenazi Jews  | Tay-Sachs disease     | Decreased serum Hexosaminidase-A or DNA analysis for selected alleles  |
|   | Canavan disease       | DNA analysis for selected alleles  |
|   | Familial dysautonomia | DNA analysis for selected alleles  |
| Cajuns  | Tay-Sachs disease     | DNA analysis for selected alleles  |
| French-Canadians  | Tay-Sachs disease     | DNA analysis for selected alleles  |
| Mediterranean (Italians, Greeks)  | $\beta$ -Thalassemia  | MCV <80%, followed by hemoglobin electrophoresis if iron deficiency has been excluded                          |
| Southeast Asians (Filipino, Chinese, Vietnamese, Laotian, Cambodian) and Africans | $\alpha$ -Thalassemia | MCV <80%, followed by hemoglobin electrophoresis if iron deficiency has been excluded                          |

CFTR, cystic fibrosis transmembrane conductance regulator; MCV, mean corpuscular volume.

mental retardation, autism, a motor movement disorder, premature ovarian failure, and, of course, fragile X syndrome itself as well as at the request of the patient.<sup>65</sup> ACOG also does not recommend population screening for SMA, formerly called *Werdnig-Hoffman disease*.<sup>66</sup> On the other hand, the ACMG recommends SMA screening, reasoning that 95% of carriers can be detected for a disorder in which the panethnic population incidence is comparable to that of CF.<sup>67</sup> Individualized testing to assess carrier status is recommended for individuals with a family history of an inherited condition if the gene and the mutation have been identified.

**A cost-effective approach to carrier screening begins with testing the partner at risk (e.g., family history of the disease of interest) or the mother. However, it is also acceptable to test both concurrently. If one member of the couple has a mutation for an autosomal recessive disorder, the next step is to test the partner. When both parents are carriers for an autosomal recessive disorder, the risk of having an affected offspring is 25%.** Genetic counseling is recommended, and the couple is informed of the availability of prenatal diagnostic testing, PGD, donor gametes (eggs or sperm), and adoption to avoid the risk of having an affected child. In addition, the parents should be informed that their relatives are at risk and should also be informed of the availability of carrier screening. Infrequently, a screening test may identify an individual with two mutations who is so mildly affected that the mutations escaped medical attention. In this situation, the individual may benefit from a referral to a specialist for further evaluation.

### Ashkenazi Jewish Genetic Diseases

A number of genetic conditions are very prevalent among individuals of Ashkenazi Jewish ancestry (Table 10-9). Heterozygote or carrier detection rates for each condition are 95% to 99%, the sensitivity reflecting that only a few mutations are responsible for each disorder in this specific population. In aggregate, the likelihood of an Ashkenazi Jewish individual being heterozygous for one of the autosomal-recessive disorders listed in this section is 1 in 4.<sup>62</sup> In the United States, Jewish individuals may be uncertain whether they are of Ashkenazic or Sephardic descent (90% are Ashkenazi); thus obstetricians should offer screening to *all* Jewish couples. ACOG recommends carrier screening for Ashkenazi couples for Tay-Sachs, CF, Canavan disease, and familial dysautonomia and also recommends that couples be made aware of the availability of carrier screening for other less prevalent and less severe diseases.<sup>61</sup> These disorders include mucopolipidosis IV, Niemann-Pick disease type A, Fanconi anemia type C, Bloom syndrome, and Gaucher disease. Many laboratories and programs offer expanded carrier screening to Ashkenazi Jews.

Screening usually involves molecular testing for common selected mutations. In all the disorders listed in Table 10-8, screening only a few mutations (alleles for the mutant gene) will detect a very high percentage of heterozygotes. In Tay-Sachs disease, for example, molecular testing in Ashkenazi Jews detects 94% of heterozygotes; screening by the more laborious biochemical methods (based on ratio of hexosaminidase A to total hexosaminidase—A plus B) detects 98%.<sup>62</sup> If only one partner is Ashkenazi, ACOG<sup>61</sup> suggests screening that individual first. In low-risk populations (e.g., non-Ashkenazi Europeans), the carrier frequency for Tay-Sachs is only 1 in 300. Given that molecular heterogeneity is so prevalent, biochemical testing is often necessary in testing individuals who are not Ashkenazi Jews.

With the exception of Tay-Sachs disease and CF, the carrier rate and the detection rate applicable for the non-Jewish partner has not been established and, hence, screening is of limited value. It may thus not be possible to provide the couple with an accurate assessment of their risk to have an affected child.

### Hemoglobinopathies

Sickle cell disease occurs most commonly among individuals of African origin but is also found in high frequency in Greeks, Italians (Sicilians), Turks, Arabs, Southern Iranians, and Asian Indians. Classic sickle cell disease is caused by homozygosity for a single base-pair mutation in the  $\beta$ -globin gene (hemoglobin S; see Chapter 44). **Approximately 1 in 12 blacks are carriers of a single copy (heterozygous) of the mutation and have sickle cell trait. Hemoglobin electrophoresis is the recommended screening test because it can detect other abnormal forms of hemoglobin and thalassemia.**<sup>63</sup>

Thalassemia is caused by the reduced synthesis of either  $\alpha$ - or  $\beta$ -globin (see Chapter 44) and is more common among individuals of Southeast Asian, African, West Indian, Mediterranean (Greek, Italian), Asian, and Middle Eastern origin. ACOG recommends a complete blood count (mean corpuscular volume [MCV]) and hemoglobin electrophoresis to detect thalassemia.<sup>63</sup> MCV values of less than 80% are indicative of either iron deficiency anemia or thalassemia heterozygosity; therefore it is necessary to test for iron deficiency. If a deficiency is not found, an elevated hemoglobin A<sub>2</sub> and hemoglobin F will confirm  $\beta$ -thalassemia. DNA-based testing is necessary to detect  $\alpha$ -globin deletions, which cause  $\alpha$ -thalassemia.<sup>63</sup>

### Cystic Fibrosis

Carrier screening for CF was initially recommended by ACOG and ACMG in 2001.<sup>64,68</sup> CF is more common in whites of Northern European and Ashkenazi Jewish ancestry and primarily affects pulmonary and pancreatic function. The disorder usually is manifested early in childhood; 10% to 20% are detected at birth because of meconium ileus. Increasing accumulation of viscous secretions progressively leads to chronic respiratory obstruction. Malnutrition and poor postnatal growth arise secondary to blockage of pancreatic ducts that produce insufficient pancreatic enzymes, which interferes with intestinal absorption. The majority of men with CF have azoospermia, the result of congenital bilateral absence of the vas deferens (CBAVD). Sometimes CBAVD is the only manifestation of CF. In these cases, the mutant alleles are less deleterious than those that cause severe CF. Individuals without pancreatic involvement have a milder course and longer survival (median survival 56 years compared with 30 years).<sup>25</sup> **CF may be diagnosed by the chloride sweat test or suspected on a newborn screening test, but mutation testing or DNA sequencing is used to confirm the diagnosis.** Once a mutation is identified in a given family, genetic studies are indicated to detect other carriers (heterozygotes) and affected relatives.

Since the initial report that localized the gene for CF, over 1500 disease-causing mutations have been identified, but one mutation— $\Delta F508$ , a deletion of phenylalanine (F) at codon 508—accounts for about 75% of CF mutations in whites who are not Ashkenazi Jews.<sup>69</sup> ACOG and ACMG recommend using a panethnic panel of 23 mutations as a screening test to identify CF carriers.<sup>64</sup> Many commercial laboratories offer gene sequencing and/or expanded carrier screening panels that include mutations that are less prevalent in the general population that minimally increase the sensitivity. Neither is recommended for routine carrier screening, although an expanded panel or sequencing may be considered if a family member is affected and routine panels have failed to reveal a mutation. Even if the entire gene is sequenced, not all CF mutations will be identified. Those not identified

\*The current panel encompasses 23 mutations.

**TABLE 10-11** LIKELIHOOD OF AFFECTED FETUS AFTER CYSTIC FIBROSIS CARRIER SCREENING

|                                      | NON-HISPANIC EUROPEAN WHITE | ASHKENAZI JEW |
|--------------------------------------|-----------------------------|---------------|
| No screening                         | 1/2500                      | 1/2304        |
| Both partners negative               | 1/173,056                   | 1/640,000     |
| One partner negative, one untested   | 1/20,800                    | 1/38,400      |
| One partner positive, one negative   | 1/832                       | 1/1600        |
| One partner positive, other untested | 1/100                       | 1/96          |
| Both partners positive               | 1/4                         | 1/4           |

These calculations are based on the frequencies shown in Table 10-6.

presumably act in promoter regions or perturb posttranslational modification.

The carrier frequency and detection rates in various ethnic groups is shown in Table 10-10. The likelihood of having an affected offspring when one or both partners are tested and screen positive or negative is shown in Table 10-11. The detection rate varies depending on ethnic origin. Individuals without a family history of CF, an affected partner, or a partner with CBAVD may benefit from genetic counseling, expanded screening, and, possibly, gene sequencing.

### Newborn Screening

Screening the neonate is mandated by each state, although parents may decline testing and in some states need to consent. These screening tests may also identify couples who are carriers and who may benefit from genetic counseling to learn about their options in subsequent pregnancies.

The ACMG and the March of Dimes have recommended screening for a core panel of 31 conditions, including inborn errors of metabolism amenable to treatment such as phenylketonuria, galactosemia, and homocystinuria; endocrine conditions such as hypothyroidism and 21-hydroxylase deficiency; sickle cell anemia; and congenital hearing loss. Information by state is available at [www.marchofdimes.com/professionals/580.asp](http://www.marchofdimes.com/professionals/580.asp) or at the National Newborn Screening and Genetics Resource Center's Web site at [genes-r-us.uthscsa.edu](http://genes-r-us.uthscsa.edu).

### Molecular Approach to Prenatal Diagnosis of Single-Gene Disorders

Sequencing the human genome has revealed approximately 22,000 genes (based on certain established sequencing criteria that define a gene). The function of many genes is still unknown, but increasingly, mendelian disorders of potential prenatal genetic diagnostic interest are being identified, and

their molecular perturbations are known. The molecular basis of recognized single-gene disorders varies and includes point mutations that lead to a single nucleotide and hence to a single amino acid change (e.g., sickle cell anemia), premature stop codons that truncate the protein gene products, deletions of three nucleotides that lead to loss of entire amino acids, and deletions of one or two nucleotides that lead to frame shifts that result in an altered reading frame with all subsequent amino acids being coded erroneously.

**In a given disorder, it is exceptional for a single molecular perturbation to be responsible for all cases, as is the case in sickle cell anemia and achondroplasia.** One or more perturbations may account for a significant proportion within a given ethnic group; however, the molecular basis in the broader population is typically more heterogeneous. An array of mutations may be used for diagnostic or carrier testing as described above, or targeted sequencing of such genes may be performed. Still, the molecular basis may not always be evident for every affected individual, even in well-studied disorders like CF. **If sequencing all coding regions of the gene in question does not reveal a perturbation, the assumption is that the pathogenesis involves the promoter region or posttranscriptional processes (e.g., translation).**

The general approach for detecting single-gene disorders involves the determination of a known molecular perturbation. Alternatively, if the actual mutation is not known, linkage analysis can still be used to identify affected cases if the chromosome location has been determined. Suppose a couple is at risk for a known disorder, but the molecular basis in their family is unknown. In linkage analysis, the clinician relies on polymorphic markers upstream and downstream from the mutation site. These polymorphisms are without clinical significance but can serve as markers (short tandem repeats of nucleotides; SNPs). At every locus, polymorphic or mutant, one marker allele is of paternal origin and one is maternal. A panel of markers can be identified that coexist (in phase) with the chromosome having the mutation, said to be *cis* and in contrast to those markers on the chromosome having the normal allele (*trans*). That is, given two chromosomes, one set of markers will be on the chromosome containing the mutant allele for the disorder in question (dominant or recessive), whereas the other will lie on the "normal" chromosome. Studying affected and unaffected family members will allow the clinician to determine the "phase" of markers unique to that family. If there are no surviving affected family members, the clinician may still be able to deduce phase (*cis* versus *trans*) by analyzing individual sperm, should the disorder have arisen de novo in a male. Regardless, the principle is that a diagnosis can be deduced without knowledge of the precise nucleotide perturbations.

A molecularly based diagnosis can thus be readily achieved for patients at risk for hundreds of disorders. Any nucleated fetal cell—chorionic villus, amniotic fluid cell, or blastomere from an embryo—will suffice. Technical details are beyond the purview of this text, save appreciation that **molecular diagnosis is highly accurate in good laboratories but perfect in none.**

### Mendelian Disorders Without Known Molecular Basis

Some disorders remain whose genetic basis is not yet elucidated. If the causative gene is not known and thus cannot be localized, linkage analysis is not applicable. Whether the concern originates in a previously affected child or in the current pregnancy, the clinician may have to resort to imaging (see Chapter 9), assuming cytogenetic findings (including MAs) are normal in the previously affected child, and structural anomalies are present.

### MULTIFACTORIAL AND POLYGENIC DISORDERS

It is postulated that some congenital malformations, especially those that involve a single organ system, are the result of the cumulative effects of more than one gene (polygenic) and gene-environment interactions (multifactorial). These include hydrocephaly, anencephaly, and spina bifida (NTDs); facial clefts (cleft lip and palate); cardiac defects; pyloric stenosis; omphalocele; hip dislocation; uterine fusion defects; and club foot (Box 10-1). **After the birth of one child with a defect involving only one organ system, the recurrence risk in subsequent offspring is 1% to 5%.** The frequency is less than would be expected if only a single gene were responsible, but it is still greater than that for the general population. The recurrence risks are similar for offspring of an affected parent.

Many of these congenital anomalies can be diagnosed in utero using ultrasonography or fetal echocardiography (see Chapter 9). A few are associated with elevated AFP levels in the maternal serum and amniotic fluid. In this section, we review the use of serum markers and ultrasound to screen and diagnose NTDs.

#### BOX 10-1 MULTIFACTORIAL/POLYGENIC TRAITS

Hydrocephaly (except some forms of aqueductal stenosis and Dandy-Walker syndrome)  
 Neural tube defects (anencephaly, spina bifida, encephalocele)  
 Cleft lip with or without cleft palate  
 Cleft lip (alone)  
 Cardiac anomalies (most types)  
 Diaphragmatic hernia  
 Pyloric stenosis  
 Omphalocele  
 Renal agenesis (unilateral or bilateral)  
 Ureteral anomalies  
 Posterior urethral valves  
 Hypospadias  
 Müllerian fusion effects  
 Müllerian aplasia  
 Limb reduction defects  
 Talipes equinovarus (clubfoot)

These are relatively common traits considered to be inherited in polygenic/multifactorial fashion. For each, normal parents have recurrence risks of 1% to 5% after one affected child. After two affected offspring, the risk is higher.

### Screening for Neural Tube Defects

**Maternal serum AFP (MSAFP) is a useful screening test for open NTDs.**<sup>70</sup> MSAFP screening for NTD detection should be performed at 15 to 20 weeks' gestation. As with aneuploidy screening, corrections must be made for gestational age, multiple gestations, and presence of diabetes mellitus. Maternal serum values above 2.0 or 2.5 MoM are considered elevated with respect to NTDs. Values above 2.0 MoM are considered elevated in women with type 1 diabetes, whereas in twin gestations, MSAFP is considered abnormal only at 4.5 to 5.0 MoM or greater.

**Approximately 3% to 5% of women have an elevated MSAFP depending on the threshold set and accuracy of pregnancy dating; most are false-positive results.** If gestational age assessment is determined accurately (e.g., by first-trimester sonogram), the number of women who have an abnormal serum value is relatively lower. If MSAFP is elevated, an ultrasound examination should be performed to look for evidence of an NTD or other anomalies, such as gastroschisis or omphalocele, as well as to confirm gestational age and the number of fetuses. **MSAFP is greater than 2.5 MoM in 90% of pregnancies with anencephaly and in 80% with open spina bifida.**<sup>69</sup> **With ultrasound alone, it is possible to achieve very high detection rates for NTDs (90% or higher in experienced centers), and this has led some centers to utilize ultrasonography as the primary screening test, acknowledging limitations that exist for the detection of small spinal defects.** Some NTDs may be evident on sonogram as early as 11 to 14 weeks' gestation. In some cases, amniocentesis to measure the amniotic fluid AFP and acetylcholinesterase levels may be necessary.

An elevation of MSAFP may not reflect an NTD because of other circumstances, such as (1) underestimated gestational age, inasmuch as MSAFP increases as gestation progresses; (2) unrecognized multiple gestation (60% of twins and almost all triplets with MSAFP values that would be elevated if judged on the basis of singleton values); (3) fetal demise, presumably reflecting fetal blood extravasating into the maternal circulation; (4) Rh isoimmunization, cystic hygroma, and other conditions associated with fetal edema; and (5) other anomalies, mainly abdominal wall defects such as gastroschisis and omphalocele.

The sensitivity for detection of an NTD in twin gestations is predictably lower than in singleton gestations; it is only about 30% for spina bifida given a threshold of 4.5 MoM. The lower sensitivity exists because twins are usually discordant for an NTD. **Ultrasound is recommended in twin gestations for assessment of NTD.**

If aneuploidy screening is performed in the second trimester, an MSAFP value will already be available as part of serum analyte screening for aneuploidy. First-trimester MSAFP is, however, not a sensitive method for detecting NTDs. **If first-trimester aneuploidy screening is done alone, or if cell-free fetal DNA or CVS is performed, second-trimester MSAFP screening or ultrasound is recommended to detect NTDs.**

### Obstetric Significance of Unexplained Elevated Maternal Serum Alpha-Fetoprotein

Often, no evident cause is detected after a comprehensive assessment of a patient with an elevated MSAFP. This group of patients has been consistently described to be at higher risk of adverse perinatal outcomes that include spontaneous abortion, preterm birth, small size for gestational age, low birthweight, and infant death. On the other hand, extremely low MSAFP

values ( $<0.25$  MoM) have also been associated with increased morbidity that includes spontaneous abortion, preterm birth, stillbirth, and infant death.<sup>71-73</sup>

## INDICATIONS FOR PRENATAL GENETIC TESTING

Indications for prenatal genetic studies arise from those clinical situations associated with an increased risk for a diagnosable prenatal genetic condition. These include **maternal age, parental chromosome rearrangements, prior pregnancy with a chromosome abnormality, and carriers for an inheritable condition.** Other risk factors become evident only during the pregnancy. These include positive results for aneuploidy screening, ultrasound detection of fetal structural anomalies, and IUGR.

## PROCEDURES FOR PRENATAL GENETIC DIAGNOSIS

Prenatal detection of chromosome abnormalities and many genetic conditions requires an invasive procedure such as amniocentesis or CVS to obtain fetal cells or placental tissue for chromosome and genetic testing. Less frequently, cordocentesis is performed to obtain fetal blood. In this section, we review these techniques and their safety.

As a common feature of any prenatal invasive procedure, the patient should receive genetic counseling and should be fully informed about the nature of the procedure, and the patient and her spouse must provide informed consent. Information about the nature, accuracy, and possible results of the test; how, when, and by whom it is performed; safety of the procedure; culture failure rates; reporting time; and postprocedure recommendations should be communicated to the patient.

### Amniocentesis

Genetic amniocentesis was first performed in the 1950s. Analytes such as AFP can be measured in the amniotic fluid, and amniocytes can be cultured for cytogenetic and molecular analyses. **Genetic amniocentesis is usually performed after 15 weeks' gestation. Early amniocentesis (EA) before 14 weeks' gestation, especially before 13 weeks' gestation, should be avoided because of higher rates of pregnancy loss, amniotic fluid leakage, and talipes equinovarus.**<sup>74</sup>

A 20- or 22-gauge spinal needle with a stylet is introduced percutaneously into the amniotic cavity under continuous ultrasound guidance, taking care to avoid the fetus and umbilical cord. A local anesthetic may be given at the puncture site. Approximately 20 to 30 mL of amniotic fluid is aspirated, and the first 1 or 2 mL is usually discarded to avoid maternal-cell contamination. Rh immune globulin should be administered to the Rh-negative, Du-negative, unsensitized patient who has an Rh-positive fetus or a fetus whose Rh status is unknown.

Continuous visualization of the needle by ultrasound significantly reduces the incidence of bloody amniotic fluid, dry taps, and the need for multiple insertions. Bloody amniotic fluid is occasionally aspirated; however, the blood is almost always maternal in origin and does not adversely affect amniotic cell growth. Brown, dark red, or wine-colored amniotic fluid indicates that intraamniotic bleeding has occurred earlier in the pregnancy, and hemoglobin breakdown products are persistent in the fluid; pregnancy loss eventually occurs in about one third

of such cases. If the abnormally colored fluid is associated with an elevated amniotic AFP level, the outcome is almost always unfavorable (fetal demise or fetal abnormality). Greenish amniotic fluid is the result of meconium staining and apparently is not associated with poor pregnancy outcome.

After amniocentesis, the patient may resume all normal activities. Common sense dictates that strenuous exercise such as jogging or aerobic exercise is deferred for a day or so. Deferring sexual activity for 24 to 48 hours also seems prudent. The patient should report persistent uterine cramping, vaginal bleeding, leakage of amniotic fluid, or fever; however, physician intervention is almost never required, unless, of course, overt abortion occurs.

### Amniocentesis in Twin Pregnancies

**In multiple gestations, amniocentesis can usually be performed on all fetuses. It is important to assess and record chorionicity, placental location, fetal viability, anatomy, and gender and to carefully identify each sac, should selective termination be desired at a later date. A simple and reliable technique to ensure that the same sac is not sampled twice is to inject 2 to 3 mL of indigo carmine following aspiration of amniotic fluid from the first sac, before the needle is withdrawn.** A second amniocentesis is then performed at a site determined after visualizing the membranes that separate the two sacs. Aspiration of clear fluid confirms that the second (new) sac was entered. Gestations greater than two can be managed similarly, sequentially injecting dye into successive sacs. Cross-contamination of fetal cells in multiple gestations appears rare, but confusion may sometimes arise in interpreting amniotic fluid acetylcholinesterase (AChE) or AFP results. Some obstetricians aspirate the second sac without dye injection, use a single-puncture technique, or perform simultaneous visualization of the two inserted needles in each sac.

If only one fetus in a multiple gestation is abnormal, parents should be prepared to choose between aborting all fetuses or continuing the pregnancy with one or more normal fetuses and one abnormal fetus. Selective termination in the second trimester is possible but is associated with a higher rate of complications (fetal loss and prematurity) than if it is done in the first trimester; therefore **CVS should be considered the preferred test for multiple gestations.**

### Safety of Amniocentesis

**The risk of amniocentesis is very low in experienced hands: approximately 1 in 300 to 500 procedure-related losses or less.**<sup>74</sup> The risk for pregnancy loss has decreased since the large collaborative studies to assess safety were first done in the 1970s. In none of these early collaborative studies was quality ultrasonography, as defined by today's standards, available, nor was concurrent ultrasonography universally applied. By contrast, studies conducted within the past decade universally use quality ultrasound and have shown no statistical difference in outcomes for women who did and did not undergo amniocentesis. The risk does not appear to increase when amniocentesis is performed in twins.

Maternal risks are low, and symptomatic amnionitis occurs only rarely (0.1%). Minor maternal complications such as transient vaginal spotting or minimal amniotic fluid leakage occur in 1% or less of cases, but these complications are almost always self-limited in nature. Other complications include intraabdominal viscus injury or hemorrhage. The most serious is fulminant

FIG 10-4 Transcervical chorionic villus sampling.

sepsis (such as with *Escherichia coli* or clostridial species) that results in maternal mortality, but this is extraordinarily rare.

### Chorionic Villus Sampling

**Chorionic villus sampling (CVS) allows genetic diagnosis in the first trimester of pregnancy.** If desired, pregnancy termination can be performed earlier, when it is safer for the mother. For example, the maternal death rate is 1 per 100,000 early in pregnancy compared with 7 to 10 per 100,000 in mid pregnancy.<sup>75</sup> Early diagnosis also makes it feasible to perform selective fetal reduction in multiple gestations, when the risks are less than in the second trimester. Early termination also protects patient privacy. Both chorionic villi analysis and amniotic fluid cell analysis offer the same information concerning chromosome status, enzyme levels, and gene mutations. CVS is not useful for the few assays that require amniotic fluid liquor, such as AFP for the detection of NTDs.

**CVS is performed between 10 and 13 weeks' gestation by either a transcervical (TC-CVS) or transabdominal (TA-CVS) approach (Figs. 10-4 and 10-5).** TC-CVS is usually performed with a flexible polyethylene catheter with a metal obturator, which is introduced through the cervical canal toward the placenta under direct ultrasonographic visualization. After withdrawal of the obturator, 10 to 25 mg of villi is aspirated by negative pressure into a 20- or 30-mL syringe that contains tissue culture media. TA-CVS is performed by introducing an 18- or 20-gauge spinal needle percutaneously into the long axis of the placenta under ultrasound guidance. After removal of the stylet, villi are aspirated into a 20-mL syringe that contains about 5 mL of tissue culture media, keeping negative pressure and performing a gentle, longitudinal, back-and-forth movement of the needle. TA-CVS can be performed later in gestation for rapid fetal karyotyping or when there is oligohydramnios and a fluid pocket is not accessible. After the first trimester, this procedure is better known as *late CVS* or *placental biopsy*. Placental biopsy has now replaced cordocentesis for rapid fetal karyotyping during the second and third trimesters in many centers,

FIG 10-5 Transabdominal chorionic villus sampling.

given that it carries a lower risk, is technically easier, and can yield cytogenetic results within 24 to 48 hours.

In many cases, either TA-CVS or TC-CVS is acceptable. However, one approach may be preferable in certain situations. For example, cervical myomas or sharply angulated uteri may preclude transcervical passage of the catheter, whereas TA-CVS would permit sampling. The transabdominal approach is preferable in the presence of genital herpes, cervicitis, or bicornuate uteri. With either approach, Rh immune globulin should be administered to the Rh-negative, Du-negative, unsensitized patient unless the fetus is known to be Rh negative. Sampling women sensitized to red blood cell antigens should be deferred until later in gestation when amniocentesis can be performed.

### Safety of Chorionic Villus Sampling

**CVS is a relatively safe procedure. Several studies, including randomized studies in the United States and Italy, reported that the risk for pregnancy loss is similar to that of second-trimester amniocentesis.**<sup>76,77</sup> However, a systematic review to assess comparative safety between TA-CVS and TC-CVS and EA and second-trimester amniocentesis concluded that second-trimester amniocentesis and TA-CVS are safer than TC-CVS and EA.<sup>78</sup> A simple comparison to amniocentesis may not be valid when CVS is performed because of an increased NT measurement, a cystic hygroma, or any other anomaly in which the risk for miscarriage is increased.

**The prevalence of IUGR, placental abruption, and premature delivery is no higher in women who undergo CVS than in the general population.** In the early 1990s, controversy about the safety of CVS focused on the risk for limb reduction defects (LRDs). **The consensus of most studies was that LRD is not a major concern when CVS is performed by experienced individuals at 10 to 13 weeks of gestation.**<sup>74</sup> A possible

association between late first-trimester CVS (13 to 14 weeks) and a higher risk for hypertension and preeclampsia was reported,<sup>24</sup> but other reports have not confirmed this. It could be hypothesized that focal placental disruption is the involved mechanism, which supports the theory that disturbances of early placentation lead to maternal hypertension.

**In summary, patients should be informed that in experienced hands, the fetal loss rates are comparable in CVS and second-trimester amniocentesis; and when the CVS procedure is performed after 9 completed weeks, the risk for limb reduction problems is low and is no higher than the general population risk of 6 per 10,000.<sup>74</sup>**

### Chorionic Villus Sampling in Twin Pregnancies

In experienced hands, CVS is safe in multiple gestations. In a U.S. study,<sup>79</sup> the total loss rate of chromosomally normal fetuses (spontaneous abortions, stillbirths, neonatal deaths) was 5%, only slightly higher than the 4% absolute rate observed in singleton pregnancies.<sup>16</sup> **A critical issue in counseling twin pregnancies for prenatal diagnosis is to establish chorionicity** (see Chapter 32). Monochorionic twins are monozygotic; therefore they carry the same genetic constitution with a few exceptions. Thus if no significant sonographic differences are seen in either fetus, only one sample need be obtained. For dichorionic twin pregnancies, both placentas must be sampled. When the placentas appear to be fused, it can be helpful to identify the cord insertion sites to avoid the cross-contamination of chorionic tissue, leading to either false-positive or false-negative results. Alternatively, amniocentesis may be the preferred test.

CVS is widely used before selective reduction in multiple gestations. Here, it is especially desirable to sample the inferiorly lying fetus (usually retained to minimize risk for ascending infection) as well as at least two or three of the other fetuses potentially slated to be retained.

### Invasive Diagnostic Testing in Women With Hepatitis B, Hepatitis C, and Human Immunodeficiency Virus

Bloodborne viruses constitute a risk factor for maternal-fetal transmission. Available evidence is limited, but the risk for transmission for hepatitis B seems to be very low.<sup>80</sup> Knowledge of the maternal hepatitis B “e” antigen status is valuable in the counseling of risks associated with amniocentesis. Less information is available about hepatitis C, but to date there is no evidence that transmission is increased following amniocentesis.<sup>80</sup> **Invasive prenatal testing can be carried out in women who carry hepatitis B or C; however, the patient should be informed of the limited data on transmission.**

**In HIV-positive women, noninvasive testing is preferable, and invasive testing should be avoided, particularly in the third trimester when the relative risk for transmission is fourfold when an invasive procedure is performed.<sup>80,81</sup>** Some authors have suggested that procedures early in pregnancy would carry a very low risk, provided that antiretroviral therapy is administered and the maternal viral load is low. For those who insist on an invasive test, amniocentesis is the preferred test, and every effort should be made to avoid traversing the placenta.

### Fetal Blood Sampling

Ultrasound-directed percutaneous umbilical blood sampling (PUBS), also termed *cordocentesis* or *funipuncture*, can be used to obtain fetal blood for cytogenetic or molecular analyses.

**One of the most common indications for PUBS is a fetal malformation detected during the second and third trimesters. However, as previously described, placental biopsy is a safer, easier, and faster alternative that has replaced fetal blood sampling in many centers.** Further, improvements in cytogenetic and molecular diagnostic testing have decreased the need for fetal blood sampling. For instance, fetal blood sampling was once frequently performed for diagnostic reasons in regions with a high prevalence of hemoglobinopathies. Now, most of those diagnoses are made by DNA-based analysis of chorionic villi.

Fetal blood samples may still be used to help clarify chromosome mosaicism detected in cultured amniotic fluid cells or chorionic villi or for the prenatal evaluation of fetal hematologic abnormalities. The fetal hematocrit can be measured to assess anemia resulting from Rh or other blood antigen isoimmunization states. Fetal blood has been used for the diagnosis of blood factor abnormalities (gene products) such as hemophilia A, hemophilia B, and von Willebrand disease. PUBS is also a valuable diagnostic approach in cases of nonimmune hydrops fetalis because a single procedure provides the opportunity to assess different hematologic, genetic, and infectious etiologies.

### Technique

Cordocentesis is usually performed from 18 weeks onward, although successful procedures have been reported as early as 12 weeks. Ultrasonographic examination before the procedure is necessary to assess fetal viability, placental and umbilical cord location, fetal position, and presence or absence of fetal or placental anomalies. Color-flow Doppler imaging is an important tool in evaluating the cord and placenta. Maternal sedation is not usually required, but oral benzodiazepine before the procedure may be of benefit. Although there is no good evidence, many centers use prophylactic antibiotics.

Under continuous ultrasound guidance, a 21- or 22-gauge spinal needle with a stylet is inserted percutaneously and is directed into the umbilical vein. The needle may be inserted using a freehand technique or with a needle-guiding device fixed to the transducer. Most experienced maternal-fetal medicine specialists use the freehand technique. **The umbilical vein is preferred over the artery because the vein is larger and is less likely to be associated with fetal bradycardia and significant hemorrhage when punctured.** Puncture of the umbilical cord at the placental insertion site is technically easier but is associated with a higher rate of maternal blood contamination. Free loops of cord and the intrahepatic vein are alternatives.

Once the needle is positioned in the umbilical vein, the stylet is removed, and a small amount of blood is aspirated into a heparin-coated syringe. It is crucial to confirm that the sample is fetal in origin, thus a small amount is used for a complete blood count to assess the MCV. **Fetal blood cells (140 fL) are larger than maternal cells (80 fL). The MCV of a sample of fetal blood should be higher than 100.** A useful alternative when a complete blood analysis cannot be performed at once is the Apt test, or hemoglobin alkaline denaturation test, especially before 28 weeks of gestation. Based on the ability of fetal hemoglobin to resist denaturation in alkaline conditions, the Apt test is a rapid, inexpensive, and simple bedside alternative.

Fetal movements can interfere with the procedure and can sometimes dislodge the needle, which increases the risk of complications (bleeding, cord hematoma) and the necessity of further cord punctures. In some situations, it may be helpful to

perform a fetal neuromuscular blockade as is done in therapeutic cordocentesis. An intravascular injection as part of the cordocentesis or intramuscular administration of pancuronium bromide (0.1 to 0.3 mg/kg of estimated fetal weight) can achieve fetal paralysis.<sup>82</sup>

In at least 1% of pregnancies, a single umbilical artery is present, which is usually larger in diameter than normal umbilical cord arteries. The fetal loss risk associated with puncture of a single umbilical artery (two-vessel cord) appears to be no different from that with a normal three-vessel cord. Nevertheless, the use of Doppler color-flow mapping to guide the procedure and an experienced operator is recommended.

### Safety of Fetal Blood Sampling

Loss rates for patients undergoing PUBS vary greatly by indication and by operator experience, more so than with amniocentesis or CVS. No randomized clinical trial has been reported.

**Collaborative data from 14 North American centers sampling 1600 patients at varying gestational ages for a variety of indications found an uncorrected fetal loss rate of 1.6%.<sup>83</sup>**

Tongsong and associates<sup>83</sup> compared a cohort of 1281 women with a singleton gestation without a fetal anomaly and undergoing cordocentesis between 16 and 24 weeks of gestational age with a control group matched for maternal and gestational age; the fetal loss rate was 3.2% in the study group compared with 1.8% in the controls. In another series of 2010 cordocentesis procedures in singleton pregnancies, the procedure-related fetal loss rates within 2 weeks were 1% when performed before 24 weeks and 0.8% after 24 weeks.<sup>84</sup> Cordocentesis can be successfully performed in multifetal gestation; limited data suggest higher overall fetal loss rates (10.5%) with no increase in the procedure-related loss rates.<sup>85</sup>

Bleeding from the cord puncture is the most common complication and may be seen in 30% to 41% of cases.<sup>86</sup> Duration of bleeding is significantly longer after arterial than after umbilical vein puncture. However, usually the blood loss is not clinically significant in either case. Van Kamp and coworkers<sup>87</sup> also describe bleeding from the puncture site significantly more often and of longer duration after transamniotic cord puncture than after transplacental puncture. Transient fetal bradycardia occurs in approximately 10% of procedures. Both umbilical artery puncture and severe, early-onset growth restriction were associated with increased rates of bradycardia. Finally, the extent of fetomaternal hemorrhage or transfusion depends on the duration of the procedure, bleeding time, puncture site, and use of a transplacental approach.

Maternal complications are rare but include amnionitis and transplacental hemorrhage.<sup>87</sup> In general, these complications do not significantly compromise maternal health status. However, there are case reports of severe sepsis.<sup>39</sup>

## PREIMPLANTATION GENETIC DIAGNOSIS

Preimplantation genetic diagnosis (PGD) is not simply “earlier” prenatal genetic diagnosis but an additional approach with novel applications. **PGD allows diagnosis within 6 days of conception, when implantation occurs.**

### Obtaining Embryonic and Gamete DNA

There are three potential approaches for obtaining embryonic DNA for PGD as a part of ART: (1) polar body biopsy, prior to or at the time of fertilization; (2) blastomere biopsy

(aspiration) from the 3-day six- to eight-cell cleaving embryo; and (3) trophoctoderm biopsy from the 5- to 6-day blastocyst.

Initial work in most centers involved blastomere biopsy, the zona pellucida being traversed by mechanical or laser means to remove a blastomere. A pitfall is that removal of a blastomere reduces embryo survival by 10%; removal of two cells reduces the pregnancy rate further and is generally not performed.<sup>88</sup>

Polar bodies are extruded at both the first and second meiotic divisions, as the number of chromosomes is first reduced (46 to 23) in meiosis I, and then each chromosome is divided into single chromatids in meiosis II. Diagnosis is by deduction given that the oocyte per se is not tested. As an example, if the first polar body shows *no* chromosome 21, the oocyte can safely be presumed to have *two* 21 chromosomes and, hence, once fertilized, the embryo would be trisomic. The same deductive reasoning can be applied in single-gene disorders. If a polar body from a heterozygous female shows a mutant allele, the nondisturbed oocyte can be deduced to be genetically normal.

The obvious disadvantage of polar body biopsy is the inability to assess paternal genotype, which precludes application if the father has an autosomal-dominant disorder and makes analysis less efficient in managing couples at risk for autosomal-recessive traits. However, 95% of chromosome abnormalities arise from maternal meiotic errors, thus polar body approaches are almost always applicable. The reader can refer to the work of Simpson<sup>89</sup> or Kuliev and colleagues<sup>90</sup> for additional details, in particular concerning how to handle recombination observed in the first polar body.

**At present, the preferred approach for PGD involves biopsy of the trophoctoderm in the 5- to 6-day blastocyst.**

Given 120 or more total cells, more cells can be safely removed at biopsy, which facilitates diagnosis. Another advantage is that the trophoctoderm forms the placenta, thus cells removed were not destined to be in the embryo (inner cell mass). The additional 2 to 3 days in culture for blastocysts beyond that required for an eight-cell embryo further allows self-selection against nonthriving embryos. Approximately one third of embryos with chromosome abnormalities are selected against (lost) between days 3 and 5; however, PGD is still necessary to exclude the remaining aneuploidies. The value of trophoctoderm biopsy has been enhanced by the ability to cryopreserve a biopsied embryo. This allows transfer at a later time, when the endometrium should be more receptive after the effects of ovulation stimulation have dissipated.

### Novel Indications Addressed Only by Preimplantation Genetic Diagnosis

#### To Avoid Pregnancy Termination

**PGD is the only prenatal genetic diagnostic approach available for couples who wish to avoid an abnormal fetus yet are opposed to pregnancy termination for religious or other reasons.** In fact, PGD using only the first polar body allows preconceptional diagnosis—that is, before fertilization has even occurred and an embryo has been formed. The second polar body is, however, not extruded until the mature oocyte is fertilized, thus its analysis would not truly be preconceptional.

#### Nondisclosure of Parental Genotype

Suppose a person at risk for an adult-onset disorder wishes to remain unaware of his or her genotype yet not transmit any mutation present to his or her offspring. Prototypic indications involve Huntington disease and autosomal-dominant

early-onset Alzheimer disease. PGD is the only practical prenatal diagnostic approach because multiple embryos can be screened and only unaffected embryos transferred; the patient volitionally remains oblivious to diagnostic results and whether he or she is or is not destined to develop the conditions. A caveat is that the scenario must be repeated in subsequent cycles, even if the (undisclosed) patient proves unaffected. Otherwise, any at-risk patients would readily deduce their genotype.

### Human Leukocyte Antigen–Compatible Embryos for Umbilical Cord Blood Stem Cell Transplantation

Given a couple at risk for certain single-gene disorders that affect bone marrow (e.g.,  $\beta$ -thalassemia), it may be desirable to avoid having another genetically abnormal child. Having the transferred embryo be a human leukocyte antigen (HLA)–compatible sibling would be invaluable if an older, moribund sibling has a lethal disease that could be treated by stem cell transplantation to repopulate his or her bone marrow. Stem cell transplantation using cord blood is very successful (95%) if the cord blood is HLA compatible but much less so (65%) if not HLA compatible. PGD allows selection of the one in four embryos that are HLA compatible with a liveborn sibling.

This strategy is practical only with PGD because if the pregnancy is at risk for an autosomal-recessive disorder, the likelihood of a genetically normal, HLA-compatible embryo is only 3 in 16—that is, the odds are 1 in 4 for the desired HLA-compatible embryo, multiplied by the 3 in 4 likelihood of also being unaffected, or 3 in 16. Experience using the above approach has paralleled predictions.

**In the United States and Turkey, testing for HLA-compatible embryos *without* risk for genetic disease is also well accepted. The prime indication is an older sibling with leukemia. In the United States, approximately one third of HLA PGD cases are performed for this purpose;** this indication is uncommon in the United Kingdom.

### Preimplantation Genetic Diagnosis for Chromosomal Indications

#### METHODOLOGY

Because it is not possible to reliably obtain a karyotype on a single cell, preimplantation cytogenetic analysis (numeric or structural) must rely on other methods. Initially, this involved FISH using chromosome-specific probes.<sup>91</sup>

Array CGH now allows interrogation of all chromosomes and some microdeletions and microduplications, whereas FISH can only evaluate 9 to 12 chromosomes. Of note, the type of array CGH used in PGD is different from that used in chorionic villi or amniotic fluid cells; it has lower resolution and was principally designed only for aneuploidy detection. Thus the dilemma of disclosing or not disclosing CNVs of uncertain clinical significance arises only rarely in PGD. An alternative approach that allows interrogation of all 24 chromosomes uses SNP “karyomapping” or “comprehensive screening.”

#### NUMERIC CHROMOSOME ABNORMALITIES

Excluding aneuploidy in couples at increased risk who also wish to avoid clinical pregnancy termination uniquely requires PGD. Ordinarily, excluding aneuploidy definitively would not be accomplished by PGD but rather by CVS or amniocentesis. However, PGD would be more logical if a couple must undergo ART for infertility, and PGD offers the added benefit of transferring only euploid embryos. Indeed, an inverse relationship exists

between the ART pregnancy rate and frequency of miscarriages. That ART success declines precipitously beginning late in the fourth decade is not due to endometrial factors, as witnessed by successful pregnancies following use of donor oocytes for women in their sixth decade and beyond. However, miscarriage of aneuploid embryos increases with age. Thus an obvious strategy would be to perform PGD, transfer euploid embryos, and increase the proportion of potentially viable pregnancies.

By 2000, larger PGD and ART centers in the United States and Europe were thus offering PGD to improve pregnancy rates in older women, using FISH with a limited number of (5 to 9) chromosome-specific probes. Despite these experienced centers not being able to conduct a randomized controlled trial (RCT), impressive results were observed.<sup>89,91</sup> However, RCTs in smaller centers later failed to show salutary benefits. Although these RCTs had methodologic flaws, lack of an RCT showing benefit understandably impeded acceptance. By 2012, however, new approaches were being applied. First, trophoctoderm biopsy became the principal method, rather than cleavage-stage embryo biopsy, which is subject to mosaicism and can sometimes be technically demanding. Second, most importantly array- or SNP-based 24-chromosome aneuploidy testing became possible, as noted. In 2012, RCTs from several U.S. labs showed a 20% improvement in blastocyst-transfer pregnancy rates when comparing transfer of a single PGD euploid pregnancy to a single nonbiopsied embryo.<sup>92,93</sup> **Although encouraging, the use of PGD has not yet clearly demonstrated the ability to improve the frequency of liveborn neonates in RCTs.**

PGD aneuploidy testing also has the potential to reduce multiple gestations in ART, given that multiple embryos are often transferred on the assumption that not all embryos will generate viable pregnancies. But if they do, multiple gestations can arise. Forman and colleagues<sup>94</sup> performed an RCT of women at a mean age of approximately 35 years who were undergoing ART. There were two arms: transfer of two blastocysts without PGD versus transfer of one blastocyst known to be euploid by PGD. Pregnancy rates were not statistically different (65% vs. 61%), but the rate of twins was impressively different (55% vs. 0%).

#### STRUCTURAL CHROMOSOME ABNORMALITIES

PGD is applicable for detecting unbalanced translocations. In [Chapter 27](#) we describe how translocations predispose to unbalanced gametes that often yield miscarriages. This unavoidably delays the time needed to achieve a normal pregnancy. In couples with a translocation, the mean time to achieve a natural liveborn pregnancy is 5 years, much greater than in couples without a translocation.<sup>95</sup> Therefore PGD can shorten the amount of time it takes to achieve a liveborn delivery for those with a translocation. One caveat when using array CGH in PGD is that genetically normal embryos cannot be distinguished from those that are translocation carriers because in both, the same (normal) amount of DNA is present.

### Preimplantation Genetic Diagnosis for Single-Gene Disorders

**Approximately one fourth of PGD cases are performed for couples at risk for one or more single-gene disorders.** Like other forms of single-gene prenatal genetic diagnosis, PGD can be performed when the chromosomal location of the gene with the disorder is known, even if the causative mutation is not. Over 300 different conditions have been tested by PGD

worldwide, the most frequent being hemoglobinopathies, CF, fragile X syndrome, and Duchenne muscular dystrophy. Kuliev and colleagues<sup>90</sup> enumerated experience with PGD for single-gene disorders at their center in 2982 cycles that involved 1685 patients. This yielded 1095 pregnancies and 1118 live births; 47 pregnancies were still ongoing at the time of publication.

The major technical pitfall in single-gene PGD is the small amount of DNA that must be amplified to provide a sufficient amount for diagnostic tests. The technology for whole-genome amplification (WGA) is imperfect, such that 5% to 10% of alleles are not amplified sufficiently even in the most experienced hands.<sup>90</sup> This results in the phenomenon of allele dropout (ADO), which probably reflects stochastic phenomena (i.e., failure of probes to locate and anneal with patient DNA) and likely is exacerbated if embryo damage occurs during biopsy. Linkage data are thus obligatory in single-gene PGD analysis to limit the chance of erroneous or noninformative results that could arise if only the mutant allele were interrogated.

**Another indication for PGD involves adult-onset mendelian conditions.** PGD is most frequently performed for pregnancies at risk for adult-onset cancers, such as with the presence of *BRCA1*, Li-Fraumeni syndrome, multiple endocrine neoplasia (MEN), familial adenomatous polyposis (FAP), retinoblastoma, and von Hippel-Lindau syndrome.<sup>96</sup> In the United States, relatively little controversy now exists for testing for these conditions, but reticence remains in Europe.

### Safety of Preimplantation Genetic Diagnosis

Removal of an embryonic cell logically might decrease survival or prevent implantation, and hence it would reduce pregnancy rates. This appears true at least with respect to removal of blastomeres<sup>88</sup>; **viability is reduced by 10% when a single blastomere is removed.** Viability aside, the totipotential nature of embryonic cells means, at least theoretically, that biopsy will not cause anomalies in liveborn infants. The reason is that loss of one or more cells prior to irrevocable differentiation into a specific embryologic developmental pathway should not confer organ-specific damage if another cell has the capacity to accomplish the same purpose.

**Indeed, available data indicate no increased rate of birth defects in liveborn infants who had been subjected as embryos to PGD.<sup>97</sup> In addition, no differences are apparent between offspring that result from single-gene PGD testing for single-gene mutations versus PGD testing for aneuploidy.**

### INTACT FETAL CELLS

**Intact fetal cells exist in maternal blood at an estimated ratio of one intact fetal cell per million to 10 million maternal cells.** Noninvasive diagnosis based on intact fetal cells is very attractive because genetic information derived from a single nucleated fetal cell would be considerably greater than that currently attainable by cell-free fetal DNA methods. If feasible and not overly expensive, the recovery of intact fetal cells noninvasively would likely be the optimal method of prenatal genetic diagnosis.

Enriching for nucleated fetal red blood cells and interrogating FISH with chromosome-specific probes, Price and colleagues<sup>98</sup> were the first to detect fetal aneuploidy (trisomy 18) in maternal blood. This advance soon was followed by noninvasive detection of trisomy 21 by others.<sup>99</sup> The major problem became that the expected number of fetal cells was not recovered, presumably

having been lost in processing. An NICHD collaborative study assessed the accuracy of intact fetal cell recovery in four centers that used two different methods. Overall, 74% of aneuploidies were detected (32 of 43 cases).<sup>100</sup> However, this method was laborious and was hindered by lack of consistent cell recovery. Noninvasive prenatal testing thereafter began to focus on cell-free fetal DNA, as discussed above. However, several biotech groups have continued to pursue recovery of intact fetal cells, including nucleated red blood cells. None currently offers clinical testing.

**At present the most promising approach appears to involve recovery of fetal trophoblasts in maternal blood.** Paterlini-Brechot and colleagues initially demonstrated proof of principle for recovering individual trophoblasts on a filter. Fetal origin was confirmed based on paternal polymorphisms, and fetal genotype was determined. A 2012 study<sup>101</sup> of 63 consecutive cases of CF and SMA showed clinically useful sensitivity and specificity.

**In summary, ability to recover, transport, and analyze intact fetal cells in maternal blood would be transformative and would likely replace all other approaches used to obtain fetal DNA. However, additional development is still necessary before clinical utility will exist.**

### KEY POINTS

- ◆ About 3% of liveborn infants have a major congenital anomaly due to a chromosome abnormality, single-gene mutation or multifactorial/polygenic inheritance, or exogenous factors (teratogens).
- ◆ Noninvasive screening tests for the common autosomal trisomies should be offered at any age, providing patient-specific aneuploidy risks. First-trimester screening using serum analytes (free hCG and PAPP-A) and an NT measurement has a detection rate of 85% to 87% with a false-positive rate of 5%. For women at high risk for trisomy 21, cfDNA analysis is available as early as 10 weeks' gestation, with a detection rate of greater than 99%; however, confirmatory invasive diagnostic testing is recommended.
- ◆ Second-trimester noninvasive screening with four analytes—hCG, AFP, uE<sub>3</sub>, and inhibin A—has an 80% detection rate and can be performed in conjunction with first-trimester screening to yield a higher detection rate of 95%.
- ◆ Invasive prenatal diagnosis with chromosome microarrays allows comprehensive analysis of the entire genome at a finer resolution than a routine karyotype and is capable of detecting trisomies and unbalanced translocations as well as submicroscopic deletions and duplications of the genome (CNVs). It has several advantages over conventional cytogenetic testing, especially in the fetus with a structural malformation. Clinically significant CNVs were detected in 6% of the fetuses with a normal karyotype and suspected structural anomalies or growth abnormalities.
- ◆ Screening for carriers for  $\beta$ -thalassemia and  $\alpha$ -thalassemia can be inexpensively performed on the basis of an MCV less than 80% followed by hemoglobin electrophoresis, once iron deficiency has been excluded.

- ◆ CF is found in all ethnic groups, but the heterozygote frequency is higher in non-Hispanic whites of northern European (1 in 25) or Ashkenazi Jewish origin (1 in 24) than in other ethnic groups (black 1/61, Hispanic 1/58, Asian 1/94). More than 1500 mutations have been identified in the gene for CF, but carrier screening is obligatory only for a specified panel of 23 mutations. In northern European white and Ashkenazi Jewish individuals, the heterozygote detection rate using the specified panel is 88% and 94%, respectively. In other ethnic groups, detection rates are lower (64% in blacks, 72% in Hispanics, and 49% in Asian Americans).
- ◆ Most single-gene disorders can now be detected by molecular methods if fetal tissue is available, given that the location of the causative mutant gene is known for most disorders. Linkage analysis can be applied if the gene has been localized but not yet sequenced or if the mutation responsible for the disorder in a given family remains unknown despite sequencing. This option represents a transformational improvement over previous methods, which relied on a number of different indirect approaches.
- ◆ Amniocentesis (15 weeks or later) and CVS (10 to 13 weeks) are equivalent in safety (1 in 300 to 500 loss rate) and diagnostic accuracy. Amniocentesis before 13 weeks is not recommended because of an unacceptable risk for pregnancy loss and clubfoot (talipes equinovarus).
- ◆ Congenital malformations that involve a single organ system (e.g., spina bifida, facial clefts, cardiac defects) are considered multifactorial or polygenic. After the birth of one child with a birth defect that involves only one organ system, the recurrence risk in subsequent offspring is 1% to 5%. Many of these congenital anomalies can be diagnosed in utero using ultrasonography or fetal echocardiography.
- ◆ Neural tube defects may be detected by either ultrasonography or MSAFP screening in the second trimester.
- ◆ PGD requires removal of one or more cells (polar body blastomere, trophectoderm) from the embryo. Diagnosis uses molecular techniques to detect single-gene disorders and either FISH or chromosome array CGH to detect chromosome abnormalities (e.g., trisomy). PGD also allows for avoidance of clinical pregnancy termination, fetal (embryonic) diagnosis without disclosure of parental genotype (e.g., Huntington disease), and selection of HLA-compatible embryos.

Antepartum fetal evaluation is an ever growing and changing science. **The goal of evidence-based antepartum fetal evaluation is to decrease perinatal mortality and permanent neurologic injury through judicious use of reliable and valid methods of fetal assessment without acting prematurely to modify an otherwise-healthy pregnancy or providing a false sense of well-being in cases of impending morbidity.** The opportunity for obstetric care providers to participate in this delicate balance has been made possible by continued advances in our ability to assess the physiologic well-being of the fetus, concurrent with great improvement in neonatal care and survival.<sup>1</sup> However, despite these advances in antepartum fetal surveillance and the widespread use of antepartum testing programs, the ability of these techniques to prevent intrauterine injury or death remains unproved in many cases.<sup>2</sup> The focus of this chapter is on antepartum evaluation in the United States and similarly technologically advanced and resource-rich countries, noting that the worldwide problem of stillbirth is a vast and compelling area of international interest.<sup>3</sup>

## DEFINING THE PROBLEM OF PERINATAL MORTALITY

Identification of fetuses at risk for perinatal mortality has historically been the goal of antepartum fetal assessment. Our emerging understanding that long-term neurologic disability is an integrally related and often competing entity to perinatal mortality makes this goal more complex.<sup>2</sup>

**The National Center for Health Statistics (NCHS) provides two different definitions for perinatal mortality,** acknowledging that variation in definitions and reporting rates both among states in the United States and throughout different

countries worldwide makes comparisons difficult; an agenda to develop a classification consensus has been the focus of a number of international committees, including the National Institute for Child Health and Human Development (NICHD).<sup>3</sup> The NCHS National Vital Statistics Report (NVSr) on fetal and perinatal mortality describes two different definitions for *perinatal mortality rate* (PMR). *Definition I* includes deaths of infants of less than 7 days of age and fetal deaths of 28 weeks of gestation or more per 1000 live births plus fetal deaths, whereas *definition II* is more comprehensive and includes infant deaths of less than 28 days of age and fetal deaths of 20 weeks or more per the same denominator.<sup>4,5</sup> The definitions of PMR provided by the World Health Organization (WHO) and the American College of Obstetricians and Gynecologists (ACOG) differ slightly and include the number of fetuses and live births weighing at least 500 g rather than using a gestational age cutoff.<sup>6,7</sup> According to the NCHS, “Fetal death means death prior to the complete expulsion or extraction from its mother of a product of human conception, irrespective of the duration of pregnancy and which is not an induced termination of pregnancy. The death is indicated by the fact that after such expulsion or extraction, the fetus does not breathe or show any other evidence of life such as beating of the heart, pulsation of the umbilical cord, or definite movement of voluntary muscles.”<sup>4</sup> The term *fetal death* is used in these definitions and hereafter in this chapter rather than *stillbirth*, *spontaneous abortion*, or *miscarriage*.

In 2006, about 26,000 fetal deaths occurred in the United States. **Although the PMR has fallen steadily in the United States since 1965, the number of fetal deaths has not changed substantially in the past decade** (Fig. 11-1).<sup>4,5,8</sup> Using NCHS definition I, the PMR reported in 2006 was 6.5 per 1000, and fetal deaths accounted for about 50% of all perinatal mortality in the United States.<sup>4</sup> The PMR varies greatly by maternal race and ethnicity (Fig. 11-2). In 2006, rates (per 1000) were lowest for Asian/Pacific Islander women (4.83), followed by non-Hispanic white (5.34), Hispanic (5.76), and Native American/Alaskan Native women (6.72). The rate for non-Hispanic black women (11.76) was the highest among the racial and ethnic

groups and was more than twice the rate for non-Hispanic white women. The significantly greater PMR in blacks results from higher rates of *both* neonatal and fetal deaths.<sup>4</sup>

### Characteristics of Fetal Death

Another way to consider the contribution of fetal events on PMR is to look at the infant mortality rate (Fig. 11-3).<sup>4</sup> Although the infant mortality rate includes all deaths of infants younger than 1 year of age, 50% of all infant deaths occur in the first week of life, and 50% of these losses result during the first day of life.<sup>7</sup> The infant mortality rate has fallen progressively and even more steeply over time than the fetal death rate, from 47 per 1000 in 1940 to 6.14 per 1000 in 2010.<sup>6,9-11</sup> In 2010 about 24,500 infant deaths (6.14 per 1000 live births) were reported, which included 16,200 neonatal deaths (4.05 per 1000 live births), and 12,900 of these were in the first week of life.<sup>6,9-11</sup> In

**FIG 11-1** U.S. trends in fetal mortality rates over time by period of gestation, 1990 through 2006. (Data from the Centers for Disease Control and Prevention/National Center for Health Statistics, National Vital Statistics System, August 2012.)

**FIG 11-2** U.S. fetal mortality rates by maternal race and ethnicity, 2006. (Data from the Centers for Disease Control and Prevention/National Center for Health Statistics, National Vital Statistics System, August 2012.)

**FIG 11-3** Relative magnitude of components of fetal and infant mortality, United States 2006. (Data from the Centers for Disease Control and Prevention/National Center for Health Statistics, National Vital Statistics System, August 2012.)

2010, the leading causes of infant mortality were congenital malformations, deformations, and chromosome abnormalities (21%); disorders related to short gestation and low birthweight, not elsewhere classified (17%); sudden infant death syndrome (8%); and maternal complications of pregnancy (6%). Together, these leading causes accounted for over 50% of all infant deaths in the United States in 2010.<sup>10</sup> Clearly, **perinatal events play an important role in infant mortality.**

### Causes of Fetal Death

**In addition to declining frequency in PMR over time, the overall pattern of perinatal deaths in the United States has changed considerably during the past 40 years.** Manning and associates<sup>12</sup> suggest that antepartum deaths may be divided into four broad categories: (1) chronic asphyxia of diverse origin; (2) congenital malformations; (3) superimposed complications of pregnancy, such as Rh isoimmunization, placental abruption, and fetal infection; and (4) deaths of unexplained cause. Fretts and colleagues<sup>13,14</sup> analyzed the causes of deaths, confirmed by autopsy, in fetuses weighing more than 500 g in 94,346 births at the Royal Victoria Hospital in Montreal from 1961 to 1993. The population studied was predominantly white, participated in prenatal care, and included patients from all socioeconomic groups. Overall, the fetal death rate in this group declined by 70%, from 11.5 per 1000 in the 1960s to 3.2 per 1000 during 1990 to 1993.<sup>14</sup> The decline in the fetal death rate in this cohort was attributed to the prevention of Rh sensitization, antepartum and intrapartum fetal surveillance, improved detection of intrauterine growth restriction (IUGR) and fetal anomalies with ultrasound, and improved care of maternal diabetes mellitus and preeclampsia. The role of antenatal diagnosis and management of congenital malformations and aneuploidy is obviously critical to a goal of reducing perinatal morbidity and mortality and will be discussed separately (see [Chapters 9, 10, and 27](#)).

Fretts and colleagues<sup>13,14</sup> noted that most of the deaths in the Canadian cohort occurred between 28 and 36 weeks' gestation and that the diagnosis of IUGR was rarely identified before death. In addition to IUGR, leading causes of fetal death after 28 weeks' gestation included abruptio placentae and unexplained antepartum losses. Despite a marked fall in unexplained fetal deaths, from 38.1 to 13.6 per 1000, this category was used for more than 25% of all stillbirths. Fetal to maternal hemorrhage

may occur in 10% to 15% of cases of unexplained fetal deaths. Fetal deaths caused by infection, most often associated with premature rupture of the membranes (PROM) before 28 weeks' gestation, did not decline over the 30 years of the study and accounted for about 19% of fetal deaths. Further population-based analyses of the causes of fetal death have confirmed these findings, including a 2011 evaluation by the Stillbirth Collaborative Research Network, which utilized rigorous methods to classify as many "unexplained" fetal deaths as possible.<sup>15</sup>

**In summary, based on available data, about 30% of antepartum fetal deaths may be attributed to asphyxia (IUGR, prolonged gestation), 30% to maternal complications (placental abruption, hypertension, preeclampsia, and diabetes mellitus), 15% to congenital malformations and chromosome abnormalities, and 5% to infection. At least 20% of fetal deaths have no obvious fetal, placental, maternal, or obstetric etiology, and this percentage increases with advancing gestational age.** Late-gestation stillbirths are more likely to have no identifiable etiology.<sup>6</sup> The ability of our current methods of surveillance to make an impact on the perinatal mortality will depend on the ability of available tests to predict and predate injury and on use of obstetric interventions to prevent adverse outcomes. In one British series,<sup>16</sup> obstetric and pediatric assessors reviewed the circumstances surrounding each case of perinatal death to identify any *avoidable* factors that may have contributed to the death. Of the 309 perinatal deaths in this population (half fetal and half in the first week of life), 59% were considered to have had avoidable factors, including 74% of normal-birthweight infants with no fetal abnormalities and no maternal complications. Most avoidable factors were found to be obstetric rather than pediatric or maternal and social. The failure to respond appropriately to abnormalities during pregnancy and labor—including results from the monitoring of fetal growth or intrapartum fetal well-being, significant maternal weight loss, or reported reductions in fetal movement—constituted the largest groups of avoidable factors. This characterization of avoidable factors that contribute to perinatal death has been confirmed in additional studies.

### Timing of Fetal Death

Another way to classify fetal deaths may be to differentiate those that occur during the antepartum period and those that occur during labor, or *intrapartum deaths*. **Antepartum fetal death is much more common than intrapartum fetal death, and unexplained fetal death occurs far more commonly than unexplained infant death.**<sup>4,11,17</sup> In a population-based study in the United States in 2007, the antepartum fetal death rate was 3.7 per 1000, compared with 0.6 per 1000 intrapartum fetal deaths.<sup>17</sup> Although most fetal deaths occur before 32 weeks' gestation, in planning a strategy for antepartum fetal monitoring, the risk for fetal death must be examined in the population of women who are still pregnant at that point in pregnancy.<sup>18</sup> When this approach is taken, the data would suggest that fetuses at 40 to 41 weeks are at a threefold greater risk and those at 42 or more weeks are at a twelvefold greater risk for intrauterine death than fetuses at 28 to 31 weeks. The risks are even higher in multiple gestations as pregnancy progresses. For twin gestations, the optimal time for delivery to prevent late-gestation perinatal deaths is by 39 weeks, and for triplets, 36 weeks.<sup>19</sup> The issue of timing is also illustrated by a recent cohort study of over 75,000 singleton pregnancies with fetal growth restriction, the focus of which was to find the point at which the competing

Stillbirth Classification of Cause of Death. *Obstet Gynecol.* 2009;114:901-914.)

risks of fetal death and neonatal death were in balance, in order to inform delivery decisions. In this cohort, the balance point was 32 to 34 weeks.<sup>20</sup>

### Identifying Those at Risk

Some risk factors have a clear etiologic relationship to fetal compromise and death, such as exposures to teratogens or maternal conditions that alter the fetal environment or blood supply or content. Other risk factors—such as epidemiologic factors that include maternal age, race, and body habitus—have a perhaps more complex and less well-understood link to fetal death risk (Fig. 11-4).<sup>3</sup> Common risk factors for fetal death in the United States are listed in Table 11-1.<sup>2,21</sup> Many of these conditions can coexist in individual patients, which makes assessment of the contribution of each factor to perinatal mortality a challenge. A recent concept of looking at individual risk factors as part of a “triple risk model” may prove useful in making sense of this challenge, similar to that used to understand contributors to sudden infant death syndrome (SIDS). In this model, proposed by Warland and Mitchell,<sup>22</sup> an interplay exists among maternal, fetal, and placental factors and a stressor. They posit that whereas these factors in isolation may be insufficient to cause fetal death, they may prove lethal in combination (Fig. 11-5). Also necessary to consider is the contribution of these conditions to fetal injury that results in liveborn children with permanent neurologic compromise; this has yet to be determined but is an important alternative outcome to perinatal mortality that deserves further study.<sup>2</sup>

## DETAILS ON SELECT ANTENATAL CONDITIONS

### Maternal Characteristics

#### Maternal Age

Multiple investigators<sup>2,14,23</sup> have found that after controlling for risk factors such as multiple gestation, hypertension, diabetes mellitus, placenta previa and placental abruption, previous abortion, and prior fetal death, women 35 years of age or older have a greater risk for fetal death than women younger than 30 years, and women 40 years or older have an even further increased risk.

**A J-shaped curve relationship exists between maternal age and fetal deaths, with the highest rates in teenagers and women older than 35 years (Fig. 11-6).** The interplay of fetal death, maternal age, and gestational age was demonstrated in a population-based 2006 study in the United States of almost 5.5 million births.<sup>24</sup> In this cohort, compared with their counterparts aged 30 to 34 years at 41 weeks of gestation, women older than 35 to 39 years had the same risk for fetal death at 40 weeks, and women older than 40 years had the same risk at 39 weeks. Only 10% of the women older than 35 years had medical comorbidities, and the results of this study did *not* change when those women were excluded; this highlights the point that the increase in fetal death risk exists in otherwise healthy older gravidas compared with younger women.

#### Maternal Race

The variation in fetal death risk in the United States by maternal race is complex, which makes ascertainment of biologic risk factors related to race difficult.<sup>21</sup> Factors that contribute to increased rates of fetal death among black women compared with white women include disparities in socioeconomic status, access to health care, and preexisting medical conditions.<sup>25</sup> A 2009 population-based study of more than 5 million U.S. births demonstrated that the greatest black-and-white disparity is in preterm perinatal death, with a hazard ratio at 20 to 23 weeks of 2.75, which decreases to 1.57 at 39 to 40 weeks. Lower education levels and higher rates of medical, pregnancy, and labor complications contributed more to the adverse outcomes in blacks than in whites, with congenital anomalies more contributory in whites.<sup>26</sup>

### Socioeconomic Factors, Prenatal Care, and Substance Abuse

Poor access to prenatal care and poor underlying health and nutrition have been linked to increased risk for fetal death both in developing and developed nations. As with other sociodemographic risk factors, these potential influences on fetal death risk are difficult to quantify and may be additive to other high-risk conditions.<sup>27</sup> Smoking and abuse of alcohol or illicit drugs, along with obesity, represent potentially modifiable risk factors for

**TABLE 11-1** COMMON RISK FACTORS FOR FETAL DEATH IN THE UNITED STATES

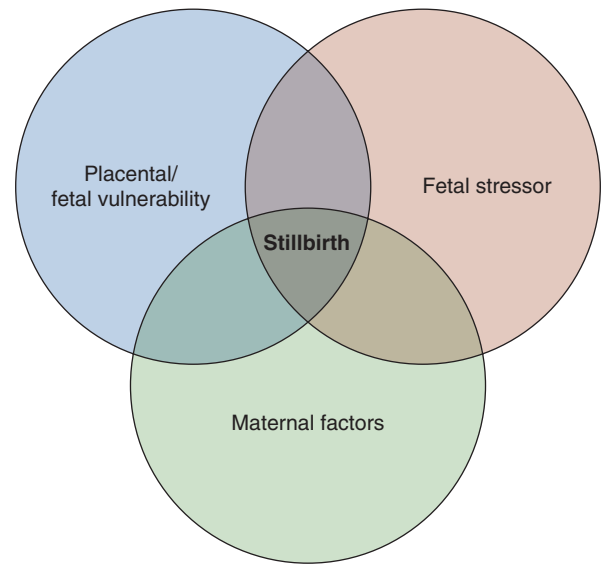

| RISK FACTOR                                       | PREVALENCE (%) | ODDS RATIO |
|---|----------------|------------|
| All pregnancies                                   | —              | 1.0        |
| Low-risk pregnancies                              | 80             | 0.86       |
| Obesity:  |                |            |
| BMI 25-29.9                                       | 21-24          | 1.4-2.7    |
| BMI ≥30   | 20-34          | 2.1-2.8    |
| Nulliparity compared with second pregnancy        | 40             | 1.2-1.6    |
| Fourth child or greater compared with second      | 11             | 2.2-2.3    |
| Maternal age (reference: <35 yr):                 |                |            |
| 35-39 yr  | 15-18          | 1.8-2.2    |
| ≥40 yr  | 2              | 1.8-3.3    |
| Multiple gestation:                               |                |            |
| Twins   | 2.7            | 1.0-2.2    |
| Triplets or greater                               | 0.14           | 2.8-3.7    |

fetal death. Although these behaviors are attractive candidates for fetal death prevention through counseling and modification of intake, prospective trials of behavior modification strategies have generally been underpowered to detect a difference in fetal death with these interventions.<sup>21</sup>

**FIG 11-5** Triple risk model in which an interplay of maternal factors, fetal/placental factors, and a stressor contribute to fetal death. Whereas these factors in isolation may be insufficient to cause fetal death, they may prove lethal in combination. (From Warland J, Mitchell EA. A triple risk model for unexplained late stillbirth. *BMC Pregnancy Childbirth.* 2014;14:142.)

## Maternal Comorbidities

### Obesity

Prepregnancy obesity is associated with increased perinatal mortality, especially in late gestation. This has been demonstrated in several large series, including a meta-analysis of 38 studies that included more than 3 million women.<sup>28</sup> The connection between obesity and fetal death is still under investigation and is made more complex by the frequent comorbidities encountered in patients with prepregnancy obesity. Theoretic contributors to adverse perinatal outcomes in this group include placental dysfunction, sleep apnea, metabolic abnormalities, and difficulty in clinical assessment of fetal growth.<sup>21</sup> The strength of the association increases with advancing body mass index (BMI) and with advancing gestational age.

### Diabetes Mellitus

**Although historically, insulin-dependent diabetes has been a major risk factor for fetal death, the fetal death rate in women with optimal glycemic control now approaches that of women without diabetes.**<sup>2,29</sup> However, the relationship between glycemic control and fetal death remains uncertain. Poor glycemic control is associated with increased perinatal mortality, in large part as a result of congenital anomalies; indicated preterm deliveries; and sudden, unexplained fetal death. A recent population-based study of over 1 million births in Ontario, Canada, revealed an odds ratio (OR) of 2.3 for fetal death among women with pregestational diabetes compared with those without diabetes.<sup>29</sup> No evidence suggests that gestational diabetes controlled by diet alone is associated with increased rates of intrauterine fetal death.<sup>2,30</sup>

### Hypertensive Disorders

Studies have shown conflicting evidence regarding whether fetal death rates with well-controlled preexisting hypertension are comparable to those in the general population or increased. The increased risk for perinatal mortality associated with

**FIG 11-6** Relationship of fetal death and maternal age across gestation. (From Reddy UM, Ko CW, Willinger M. Maternal age and the risk of stillbirth throughout pregnancy in the United States. *Am J Obstet Gynecol.* 2006;195:764-770.)

hypertension is most often related to complicated hypertension, with sequelae of placental insufficiency that include IUGR and oligohydramnios. Proteinuric hypertension, especially pre-eclampsia with severe features or eclampsia, may be associated with fetal death through placental and coagulation-related pathways, including placental abruption.<sup>3,31</sup>

### Thrombophilia

In general, no demonstrable link has been found between inherited thrombophilia and risk for fetal death.<sup>3,32</sup> Although initial reports seemed to support an association between fetal death and thrombophilia, such as factor V Leiden mutation and prothrombin gene mutation, large prospective trials have failed to substantiate this association. The presence of circulating maternal antiphospholipid antibodies—in particular lupus anticoagulant, anticardiolipin antibodies, and anti- $\beta_2$ -glycoprotein I antibodies—in the antiphospholipid antibody syndrome (APLAS) have been associated with a variety of adverse pregnancy outcomes, including fetal loss.<sup>33</sup> The mechanism of these adverse outcomes remains unclear but likely includes inflammation, thrombosis, and placental infarction.<sup>3</sup> However, the link between fetal death and these antibodies or the presence of APLAS is still under investigation, but evidence is insufficient to conclude that an increased risk exists for fetal death.<sup>34</sup>

### Intrahepatic Cholestasis

**The cause of fetal death in women with gestational cholestasis remains unknown, and timing and predictive features of impending fetal death remain unpredictable.** Fetal deaths in these pregnancies are not preceded by signs of placental insufficiency such as growth restriction or abnormal placental pathology, and normal fetal heart rate tracings proximal to fetal death (i.e., within 24 hours) have often been reported. It has also not been established whether maternal serum levels of bile acids, liver enzymes, or pharmacologic therapy modify or predict the risk of fetal death.<sup>35</sup>

### Renal Disease and Systemic Lupus Erythematosus

With chronic maternal renal disease, perinatal outcome is largely associated with the degree of renal dysfunction and the presence of coexisting hypertension or diabetes. Although data are limited

by lack of prospective studies with appropriate control groups, the greatest risk for fetal death appears to be in mothers with severe renal impairment (i.e., serum creatinine levels  $>2.4$ – $2.8$  mg/dL).<sup>36</sup> As with maternal renal disease, the prognosis for fetal outcome in women with systemic lupus erythematosus (SLE) is dependent on disease state and comorbid conditions, including hypertension, circulating autoantibodies, and renal involvement.<sup>37</sup> Prognosis for fetal survival in pregnancies complicated by both maternal renal disease and maternal SLE has improved over time with advances in therapies that promote disease quiescence for both of these conditions.

## Obstetric Factors

### Fertility History and Assisted Reproductive Technology

Multiple aspects of a woman's obstetric and fertility history may contribute to risk for fetal death in a current pregnancy, including parity, use of assisted reproductive technology (ART), and history of prior adverse obstetric outcomes. Both nulliparity and high parity are associated with an increased risk for fetal death compared with low multiparity (one, two, or three prior births).<sup>38</sup> This association is likely mediated through a variety of sociodemographic risk factors related to overall health and interconception health status, although studies have confirmed the association between parity and fetal death after controlling for several social and medical comorbidities. History of prior adverse pregnancy outcomes—including fetal growth restriction, preterm birth, and fetal death—marks a current pregnancy at risk for fetal death. However, the association with preventable recurrent fetal death is complex and is modified by coexistence of other high-risk conditions. Recurrence risk for fetal death in particular has received recent scrutiny because rates vary dramatically by study population and presence of other risk factors. Given that many fetal deaths occur in pregnancies with no identifiable risk factors and that well-designed studies with appropriate comparison groups (i.e., low-risk women without identifiable risk factors) are lacking, clinician and patient perception of increased risk in a pregnancy subsequent to a fetal death will likely continue to drive management of these patients.<sup>39</sup> Regarding use of ART and risk for fetal death, several systematic reviews have confirmed an independent association between the use of in vitro fertilization in particular and fetal death.

However, whether the association is mediated through the technologies themselves or the underlying infertility or through other undetermined mechanisms remains unclear.<sup>40</sup>

### PARITY

Nulliparity and high parity have both been associated with fetal death in contrast to women having their second child. This association has not been fully explored and may be subject to significant confounding influences, including advanced maternal age, related conditions in nulliparous women with delayed childbearing in developed nations, and other medical and socioeconomic comorbidities in women with high parity.<sup>8,21</sup>

### MULTIPLE GESTATIONS

The higher rate of perinatal mortality in multiple gestations compared with singletons is related both to complications unique to multiple gestations, such as twin-to-twin transfusion syndrome, and to more general complications, such as fetal abnormalities and growth restriction.<sup>21,41</sup> Additionally, many women who carry more than one fetus have maternal risk factors for increased perinatal mortality, including advanced maternal age and use of ART, and are subject to development of complications such as preeclampsia and preterm delivery.<sup>2,42</sup> Optimal timing of delivery between 37 and 38 weeks has been considered for twins, compared with 39 to 40 weeks among singletons, because of increased rate of late fetal death in this group.<sup>43</sup> Chorionicity is of paramount importance in determining fetal risk, and rates of adverse outcomes are higher among monochorionic twins.<sup>2,42</sup>

### Early Pregnancy Markers

**First- and second-trimester serum markers for aneuploidy, when abnormally low or elevated, have been associated to varying degrees with adverse perinatal outcomes even in the absence of aneuploidy.** Biophysical uterine factors have also been studied in this light. Regarding fetal death after 24 weeks, markers of interest include first-trimester levels of pregnancy-associated plasma protein A (PAPP-A) of less than the fifth percentile (0.415 multiples of the median [MoM]); second-trimester free  $\beta$ -human chorionic gonadotropin (free  $\beta$ -hCG),  $\alpha$ -fetoprotein (AFP), and inhibin A of more than 2 MoM; and uterine artery pulsatility index above the 90th percentile. The sensitivity and positive predictive value of these markers for fetal death are still under investigation. The pathophysiologic link between these markers and adverse outcomes is unclear and likely variable but most plausibly involves abnormal placental attachment or function.<sup>44</sup>

### Amniotic Fluid Abnormalities

The predictive value of either oligohydramnios or polyhydramnios for adverse pregnancy outcomes, in particular fetal death, typically lies in their association with other abnormal conditions, such as maternal diabetes mellitus, hypertensive disorders, rupture of membranes, fetal growth restriction, or fetal anomalies. Isolated oligohydramnios and polyhydramnios have not been conclusively linked to increased risk for fetal death; nevertheless, evaluation of amniotic fluid volume as a marker of long-term fetal health status is a mainstay of antepartum fetal evaluation.<sup>2,45</sup>

### Fetal Growth Restriction

IUGR is a well-known risk factor for perinatal death that has historically been underrecognized before fetal death. Placental

dysfunction is commonly implicated in nonmalformed and chromosomally normal IUGR fetuses. This topic is reviewed in further detail in [Chapter 33](#).

### Postterm Pregnancy

The definition of *postterm pregnancy* has been reevaluated in the past decade based on reappraisal of the peak time of fetal risk in relation to the 40-week mark (see [Chapter 36](#)). The pathophysiology of increased fetal death risk in the postterm pregnancy is thought to be mediated by impaired placental oxygen exchange and is often associated with oligohydramnios. Traditionally oligohydramnios has been used as a marker for increased risk in the postterm pregnancy for which intervention in the form of delivery is thought to be necessary, although as described previously, whether oligohydramnios is independently associated with fetal death in pregnancies after 40 weeks' gestation is unproven.<sup>46</sup>

### Fetal Malformations

Pregnancies complicated by major fetal anomalies are at increased risk of stillbirth, independent of coexisting fetal growth restriction, as demonstrated recently in a large retrospective cohort study.<sup>47</sup> The overall stillbirth rate among fetuses with a major anomaly was 55 per 1000 compared with 4 per 1000 in non-anomalous fetuses with an adjusted odds ratio of 15. The rate of stillbirth was highest in fetuses with congenital cardiac defects. The authors caution that in this group of at-risk fetuses in particular, "health care practitioners caring for these patients should weigh the competing risks of postnatal mortality with antenatal death."

### Conclusions

The best use of available antenatal testing modalities may vary according to the risk profile of each individual pregnancy. Discussion of condition to specific testing will be undertaken after review of the individual testing modalities described later.

## POTENTIAL UTILITY OF ANTEPARTUM FETAL TESTING

Can antepartum fetal deaths and injury be prevented? Before using antepartum fetal testing, the obstetrician must ask several important questions:

1. Does the test provide information not already known by the patient's clinical status?
2. Can the information be helpful in managing the patient?
3. If an abnormality is detected, is a treatment available for the problem?
4. Could an abnormal test result lead to increased risk for the mother or fetus?
5. Will the test ultimately decrease perinatal morbidity and mortality?

A large body of clinical and research experience suggests that antepartum fetal assessment can have a significant impact on the frequency and causes of antenatal fetal deaths.<sup>1</sup> However, according to several reviews of the benefits and costs of antenatal testing, "strong evidence for the efficacy of antepartum testing is lacking."<sup>48</sup> **Unfortunately, few of the antepartum tests commonly used in clinical practice today have been subjected to large-scale prospective and randomized evaluations that can speak to the true efficacy of testing.**<sup>32,49</sup> In most cases, the test has been applied and good perinatal outcomes have been

observed; therefore the test has gained further acceptance and has been used more widely. In such cases, it is uncertain whether the information provided by the test has accurately led to the improved outcomes or the total program of care has made the difference. When prospective randomized investigations are conducted, large numbers of patients must be studied because many adverse outcomes, such as intrauterine death, are uncommon even in high-risk populations. For example, although several controlled trials have failed to demonstrate improved outcomes with nonstress testing, the study populations ranged from only 300 to 530 subjects.

To determine the clinical application of antepartum diagnostic testing, the predictive value of the tests must be considered. The *sensitivity* of the test is the probability that the test will be positive or abnormal when the disease is present; the *specificity* of the test is the probability that the test result will be negative when the disease is *not* present. Note that the sensitivity and specificity refer not to the actual numbers of patients with a positive or abnormal result but to the proportion or probability of these test results. The predictive value of an abnormal test would be that fraction of patients with an abnormal test result who have the abnormal condition, and the predictive value of a normal test would be the fraction of patients with a normal test result who are normal.

Antepartum fetal tests may be used to screen a large obstetric population to detect fetal disease. In this setting, a test of high sensitivity is preferable to minimize the risk of missing a patient whose fetus might be compromised. It would be prudent to be willing to overdiagnose the problem—that is, to accept some false-positive diagnoses. In further evaluating the patient whose fetus may be at risk, and when attempting to confirm the presence of disease, a test of high specificity is preferable. It is best not to intervene unnecessarily and deliver a fetus that was doing well. In this setting, multiple tests may be helpful. When multiple test results are normal, they tend to exclude disease; however, when all are abnormal, they tend to support the diagnosis of fetal disease.

**The prevalence of the abnormal condition has great impact on the predictive value of antenatal fetal tests** and the number needed to evaluate with testing and to treat with interventions (delivery) to presumably prevent fetal death. The impact of these parameters on the utility of testing was illustrated in a decision analysis of the risks and benefits of antepartum testing late in pregnancy for women 35 years or older using the McGill Obstetric/Neonatal Database (MOND) to obtain risk estimates.<sup>50</sup> In this model, as in practice, the relative benefit of antenatal testing lies in the balance of the number of fetal deaths prevented with the number and type of interventions required to prevent them. At an estimated risk for unexplained fetal death of 5.2 per 1000 pregnancies (nulliparas  $\geq 35$  years of age in the McGill cohort), 863 additional antenatal tests, 71 additional inductions of labor, and 14 additional cesarean deliveries would be required to prevent one additional fetal death using this model. Comparatively, using the same model at an estimated risk of 1 to 2 per 1000 pregnancies, 2862 additional antenatal tests, 233 additional inductions, and 44 additional cesarean deliveries would be required to prevent one additional fetal death. Thus **the number needed to evaluate and treat to prevent one fetal death decreases as risk for fetal death increases in the population being tested.**

**In interpreting the results of studies of antepartum testing, the obstetrician must consider the application of that test to**

**FIG 11-7** Hypothetical distribution of test results in a normal and diseased population demonstrating the differences in test sensitivity and specificity with a change in test threshold. Making it more difficult for the fetus to pass the test by raising the test threshold (A) will increase the sensitivity but decrease the specificity of the test. On the other hand, making the test easier to pass by decreasing the test threshold (C) will increase the specificity of the test but decrease the sensitivity. (Modified from Carpenter M, Coustan D. Criteria for screening tests for gestational diabetes. *Am J Obstet Gynecol.* 1982;144:768.)

**his or her own population.** If the study has been done in a population of patients at great risk, it is more likely that an abnormal test will be associated with an abnormal fetus. If the obstetrician is practicing in a community with patients who are, in general, at low risk, an abnormal test result will more likely be associated with a false-positive diagnosis.

For most antepartum diagnostic tests, a cutoff point used to define an abnormal result must be arbitrarily established. The cutoff point is selected to maximize the separation between the normal and diseased populations (Fig. 11-7). Changing the cutoff will have a great impact on the predictive value of the test. For example, suppose that 10 accelerations in 10 minutes were required for a fetus to have a reactive nonstress test (NST; threshold A). The fetus that fulfilled this rigid definition would almost certainly be in good condition. However, many fetuses that failed to achieve 10 accelerations in 10 minutes would also be in good condition but would be judged to be abnormal using this cutoff. In this instance, the test would have many abnormal results; it would be highly sensitive and capture all of the abnormal fetuses, but it would have a low specificity. If the number of accelerations required to pass an NST were lowered to one in 10 min, it would decrease the sensitivity of the test (threshold C). That is, the clinician might miss a truly sick fetus. At the same time, however, the specificity of the test or its ability to predict that percentage of patients who are normal would improve. Using the criterion of two accelerations of the fetal heart rate in 20 min for a reactive NST (threshold B), it is hoped that the test will have both high sensitivity and high specificity.

## WHAT DO THESE TESTS TELL US ABOUT THE FETUS?

### Fetal State

To be able to diagnose suspected fetal compromise using tests of fetal biophysical state, blood flow, and heart rate, we must be able to appreciate how these parameters appear under normal conditions and in response to suboptimal conditions.

**Regarding fetal biophysical characteristics, it must be appreciated that during the third trimester, the normal fetus can exhibit marked changes in its neurologic state.**<sup>51</sup> Four fetal states have been identified. The near-term fetus spends about 25% of its time in a *quiet sleep state* (state 1F) and 60% to 70% in an *active sleep state* (state 2F). Active sleep is associated with rapid eye movement (REM). In fetal lambs, electrocortical activity during REM sleep is characterized by low-voltage, high-frequency waves. The fetus exhibits regular breathing movements and intermittent abrupt movements of its head, limbs, and trunk. The fetal heart rate in active sleep (state 2F) exhibits increased variability and frequent accelerations with movement. During quiet, or non-REM, sleep, the fetal heart rate slows, and heart rate variability is reduced. The fetus may make infrequent breathing and startled movements. Electrocortical activity recordings at this time reveal high-voltage, low-frequency waves. Near term, periods of quiet sleep may last 20 minutes, and those of active sleep, about 40 minutes.<sup>51</sup> The mechanisms that control these periods of rest and activity in the fetus are not well established. External factors such as the mother's activity, her ingestion of drugs, and her nutrition may play a role. Specific factors that may decrease fetal movement in the third trimester include fetal anomalies, particularly central nervous system (CNS) anomalies; maternal exposures, including corticosteroids, sedatives, smoking, and anxiety; low amniotic fluid volume; and decreased placental blood flow due to placental insufficiency.<sup>52</sup>

When evaluating fetal condition using the NST or the biophysical profile (BPP), the clinician must consider whether a fetus who is not making breathing movements or showing accelerations of its baseline heart rate is in a quiet sleep state or is neurologically compromised. In such circumstances, prolonging the period of evaluation usually allows a change in fetal state, and more normal parameters of fetal well-being will appear.

Regarding regulation of fetal heart rate and blood flow, **fetal adaptation to hypoxemia is mediated through changes in heart rate and redistribution of cardiac output.** However, changes in fetal cardiac output are generally observed during hypoxemia only with coexisting acidemia. In response to sudden hypoxemia, fetal heart rate slowing and increased variability can be observed initially through vagally mediated chemoreceptor responses. With prolonged hypoxemia (30-60 min), increasing levels of circulating adrenergic agonists and modulation of vagal activity by endogenous opiates lead to a fetal heart rate return to or rise from the previous baseline.<sup>53</sup> Development of acidemia on top of hypoxemia can accelerate the rate of fetal deterioration and amplify the hypoxemia by a shift of the oxyhemoglobin dissociation curve to the right, which further reduces the oxygen-carrying capacity of fetal blood and eventually leads to a redistribution of cardiac output that can be appreciated as a "brain-sparing" effect in the evaluation of fetal blood flow. Redistribution of blood flow in the compromised fetus preferentially preserves perfusion not only to the brain but also to the heart and adrenal glands.<sup>53</sup>

**Fetal movement is a more indirect indicator of fetal oxygen status and CNS function, and decreased fetal movement is noted in response to hypoxemia.**<sup>2</sup> However, gestational development of fetal movement must be considered when evaluating fetal well-being as marked by fetal activity. Periods of absent fetal movement become more prolonged as gestation advances, and normal fetuses progressively exhibit longer periods of quiescence as the late second and third trimesters advance. Up to and perhaps longer than 40 minutes of fetal inactivity at 40 weeks

may be a normal finding, compared with less than 10 minutes at 20 weeks and less than 20 minutes at 32 weeks.<sup>53</sup> Keeping these trends in mind, an abnormal degree or absence of fetal movement can be an appropriate marker for fetal hypoxemia. However, fetal activity levels have been seen in animal studies to adapt to inducement of hypoxemia with a resumption of fetal breathing and body movements after a prolonged period of hypoxemia, especially if induced gradually. Therefore observation of these fetal states during antenatal testing does not guarantee a normoxic fetus.

## BIOPHYSICAL TECHNIQUES OF FETAL EVALUATION

Descriptions of the predictive value of several commonly performed antenatal tests of fetal well-being are presented in [Table 11-2](#), and details on each methodology are given in the sections that follow.

### Maternal Assessment of Fetal Activity

Studies performed using real-time ultrasonography have demonstrated that during the third trimester, the human fetus spends 10% of its time making gross fetal body movements and that 30 such movements are made each hour.<sup>54</sup> Periods of active fetal body movement last about 40 minutes, whereas quiet periods last about 20 minutes. Patrick and colleagues<sup>54</sup> noted that the longest period without fetal movements in a normal fetus was about 75 minutes. The mother is able to perceive about 70% to 80% of gross fetal movements. The fetus does make fine body movements such as limb flexion and extension, hand grasping, and sucking; these probably reflect more coordinated CNS function, although the mother is generally unable to perceive these fine movements. Fetal movement appears to peak between 9:00 PM and 1:00 AM, a time when maternal glucose levels are falling.<sup>51,54</sup> In a study in which maternal glucose levels were carefully controlled with an artificial pancreas, Holden and coworkers found that hypoglycemia was associated with increased fetal movement. Fetal activity does not increase after meals or after maternal glucose administration,<sup>55</sup> but it may increase during exposure to music, as was demonstrated in one novel randomized trial.<sup>56</sup>

**The decrease in fetal movement with hypoxemia makes maternal assessment of fetal activity a potentially simple and widely applicable method of monitoring fetal well-being. However, prospective trials of this method for prevention of perinatal mortality have failed to conclusively show benefit.**<sup>2</sup> Neldam demonstrated a 73% reduction in avoidable fetal deaths in a prospective trial of more than 1500 women instructed to count fetal movements. In contrast, a subsequent international

**TABLE 11-2** COMPARISON OF SELECTED ANTENATAL TESTS

| TEST                         | FALSE-NEGATIVE RATE (%) | FALSE-POSITIVE RATE (%) |
|------------------------------|-------------------------|-------------------------|
| Contraction stress test      | 0.04                    | 35-65                   |
| Nonstress test               | 0.2-0.8                 | 55-90                   |
| Biophysical profile          | 0.07-0.08               | 40-50                   |
| Modified biophysical profile | 0.08                    | 60                      |

Modified from Signore C, Freeman RK, Spong CY. Antenatal testing: a reevaluation. Executive Summary of a Eunice Kennedy Shriver National Institute of Child Health and Human Development Workshop. *Obstet Gynecol.* 2009;113:687-701.

trial<sup>57</sup> of more than 68,000 women randomized to routine fetal movement assessment versus no formal assessment of fetal activity failed to show a significant reduction in fetal deaths in the group randomized to routine movement counting. Significant differences were noted in the method of fetal movement counting (FMC), the definition of “abnormal” fetal movements, patient compliance with the intervention, and provider response to patients who presented to care as a result of an abnormal fetal movement count in the latter, compared with the former, trial and throughout the literature on this topic. This illustrates the difficulties in validating and reproducing the results of these trials and the uncertain clinical benefit that may be derived from introducing maternal assessment of fetal movement into routine clinical practice. A 2007 Cochrane review<sup>58</sup> of four trials that involved more than 71,000 women concluded that evidence is insufficient to recommend routine FMC to prevent fetal death.

Despite these results, this type of fetal assessment may offer some advantages. Although the range in fetal activity will be wide but normal, with FMC, each mother and her fetus serve as his or her own control.<sup>18</sup> Factors that affect maternal perception of fetal movement are not well understood. Fetal and placental factors that may contribute include placental location, the length and type of fetal movements, and amniotic fluid volume (AFV), although whether AFV affects maternal perception or actual fetal movement is unclear.<sup>52</sup> Maternal factors that may influence the evaluation of fetal movement include maternal activity, parity, obesity, medications, and psychological factors, including anxiety. Studies of these associations have demonstrated conflicting results.<sup>52</sup> **About 80% of all mothers are able to comply with a program of counting fetal activity.**<sup>18</sup>

Several methods have been used to monitor fetal activity in research and clinical practice. These methods include FMC over a prescribed time period, such as 30 to 60 minutes one to three times daily, or conversely a target number of fetal movements to be counted over a variable time range. A variety of “normal” and “abnormal” FMC results or thresholds have been proposed, to which the patient should be instructed to respond by presenting for further evaluation of the condition of the fetus (Fig. 11-8). These potential triggers for further evaluation include fewer than three movements in 1 hour or no movements for 12 hours, Sadovsky’s “movement alarm signal”; fewer than three movements an hour for 2 consecutive days; or inability to count 10 movements in a 12-hour period, the Cardiff “count-to-10” method advocated by Pearson and Weaver. The count-to-10 method has received wide scrutiny and is used perhaps most frequently in clinical practice. The use of this technique as a screening tool has most recently been reexamined by Froen and associates.<sup>59</sup> In a cohort of 1200 women instructed to start their fetal movement count at the first convenient time of the day,

they found that the mean time to count to 10 was less than 10 minutes, compared with significantly longer and more variable average times reported in previous investigations. Noting the variation in defining normal and abnormal patterns and maternal perception of fetal movement as mentioned previously, Froen and associates concluded that significant research is needed to better define the changes in fetal activity patterns and perception associated with good and adverse perinatal outcomes.

Potential negative impacts of maternal assessment of fetal activity include maternal anxiety and a potential increase in utility of other testing modalities and antepartum admissions.<sup>60</sup> However, given the likely low impact of false-positive FMC results, and the fact that this has been the only form of antenatal testing to be compared with no testing and found to have a favorable impact on fetal death, it seems reasonable to continue to prescribe some form of maternal assessment of fetal movement to patients until more conclusive evidence can be generated. As stated by Froen and associates<sup>59</sup> in a 2008 review, “The fact that FMC versus no counting seems to be beneficial irrespective of the chosen definition of decreased fetal movement (DFM) would support the hypothesis that benefit was derived from increased maternal vigilance regarding FM. When awareness, vigilance, and fetal movement counting is to be promoted, we have suggested that a maternal perception of significant and sustained reduction in fetal activity should remain the main definition of DFM. Any alarm limits, as ‘10 FM in 2 hours,’ should only be for guidance as a ‘rule of thumb.’”

### Contraction Stress Test

**The contraction stress test (CST), also known as the oxytocin challenge test (OCT), was the first biophysical technique widely applied for antepartum fetal surveillance.** It was well known that uterine contractions produced a reduction in blood flow to the intervillous space. Analyses of intrapartum fetal heart rate monitoring had shown that a fetus with inadequate placental respiratory reserve would demonstrate recurrent late decelerations in response to hypoxia, in particular a fetal arterial oxygen pressure below 20 mm Hg (see Chapter 15). As noted earlier, this drop in fetal heart rate in response to transient hypoxia is mediated by a vagal response to transient systemic fetal vascular reactivity provoked by hypoxia. The CST extended these observations to the antepartum period. The response of the fetus at risk for uteroplacental insufficiency to uterine contractions formed the basis for this test.

To perform the CST, the patient is placed in the semi-Fowler position at a 30- to 45-degree angle with a slight left tilt to avoid the supine hypotensive syndrome. Continuous external fetal heart rate and uterine contraction monitoring is recorded, and a baseline is obtained before stimulating uterine activity. Maternal blood pressure is determined every 5 to 10 minutes to detect maternal hypotension. In some cases, adequate uterine activity occurs spontaneously, and additional uterine stimulation is unnecessary. An adequate CST requires uterine contractions of moderate intensity that last about 40 to 60 seconds with a frequency of three in 10 minutes. These criteria were selected to approximate the stress experienced by the fetus during the first stage of labor. If uterine activity is absent or inadequate, intravenous oxytocin is begun to initiate contractions, and it is increased until adequate uterine contractions have been achieved.<sup>32</sup> Several methods of nipple stimulation have been used to induce adequate uterine activity, and the success rate at achieving adequate contractions and test results is comparable

**FIG 11-8** Maternal assessment of fetal activity is a valuable screening test for fetal condition. Should the mother report decreased fetal activity, a nonstress test is performed. In this situation, most nonstress tests are reactive.

to that of oxytocin infusion.<sup>32,42</sup> After the CST has been completed, the patient should be observed until uterine activity has returned to its baseline level. Contraindications to the test include a high risk for premature labor, such as in patients with PROM, multiple gestations, and cervical incompetence, although the CST has not been associated with an increased incidence of premature labor.<sup>61</sup> The CST should also be avoided in conditions in which uterine contractions may be dangerous, such as placenta previa and a previous classic cesarean delivery or uterine surgery.

Most clinicians use the definitions proposed by Braly and Freeman and colleagues<sup>61,62</sup> to interpret the CST (detail in Table 11-3):

*Negative:* No late or significant variable decelerations

*Positive:* Late decelerations with at least 50% of contractions

*Suspicious:* Intermittent late or variable decelerations

*Hyperstimulation:* Decelerations with contractions longer than 90 seconds' duration or a greater than 2-minute frequency

*Unsatisfactory:* Fewer than three contractions per 10 minutes or an uninterpretable tracing

### Predictive Value of the Contraction Stress Test

A negative CST has been consistently associated with good fetal outcome. Studies have shown the incidence of perinatal death within 1 week of a negative CST (i.e., the false-negative rate) to be less than 1 per 1000.<sup>2,42,63,64</sup> Many of these deaths, however, can be attributed to cord accidents, malformations, placental abruption, and acute deterioration of glucose control in patients with diabetes. Thus **the CST, like most methods of antepartum fetal surveillance, cannot predict acute fetal compromise.** If the CST is negative and reactive, a repeat study is usually scheduled in 1 week (Fig. 11-9). A negative but nonreactive CST is not suggestive of acute fetal compromise but cannot be seen as constituting the same low false-negative rate over the course of 1 week as a negative reactive CST. A negative nonreactive CST is usually repeated in 24 hours (Fig. 11-10). Changes in the patient's clinical condition may warrant more frequent studies. A positive CST has been associated with an increased incidence of intrauterine death, late decelerations in labor, low 5-minute Apgar scores, IUGR, and meconium-stained amniotic fluid (Fig. 11-11)<sup>63</sup> with an overall likelihood of perinatal death after a positive CST ranging from 7% to 15%.

**TABLE 11-3** INTERPRETATION OF CONTRACTION STRESS TEST

| FINDING          | DESCRIPTION   | INCIDENCE (%) |
|------------------|---|---------------|
| Negative         | No late decelerations appear anywhere on the tracing with adequate uterine contractions (three in 10 min).  | 80            |
| Positive         | Late decelerations that are consistent and persistent present with the majority (>50%) of contractions without excessive uterine activity; if persistent late decelerations are seen before the frequency of contractions is adequate, the test is interpreted as positive. | 3-5           |
| Suspicious       | Decelerations are late and inconsistent.  | 5             |
| Hyperstimulation | Uterine contractions closer than every 2 min or lasting more than 90 sec or five uterine contractions in 10 min; if no late decelerations are seen, the test is interpreted as negative.  | 5             |
| Unsatisfactory   | The quality of the tracing is inadequate for interpretation or adequate uterine activity cannot be achieved.  | 5             |

**FIG 11-9** A reactive and negative contraction stress test. With this result, the test would ordinarily be repeated in 1 week.

**FIG 11-10** A nonreactive and negative contraction stress test. After this result, the test would ordinarily be repeated in 24 hours.

**FIG 11-11** A nonreactive and positive contraction stress test with fetal tachycardia. At 34 weeks, a poorly compliant patient with type 1 diabetes mellitus reported decreased fetal activity. The nonstress test revealed a fetal tachycardia of 170 beats/min and was nonreactive. The CST was positive, and a biophysical profile score was 2. The patient's cervix was unfavorable for induction. The patient underwent a low transverse cesarean delivery of a 2200-g male infant with Apgar scores of 1 and 3. The umbilical arterial pH was 7.21.

On the other hand, the incidence of false-positive CSTs has been significant; depending on the end point used, it can be between 35% and 65%.<sup>2,64</sup> The positive CST is more likely to be associated with fetal compromise if the baseline heart rate lacks accelerations and the latency period between the onset of the uterine contractions and the onset of the late deceleration is less than 45 seconds.

**The high incidence of false-positive CSTs is one of the greatest limitations of this test because such results could lead to unnecessary premature intervention.** False-positive CSTs may be attributable to misinterpretation of the tracing; supine hypotension, which decreases uterine perfusion; uterine hyperstimulation, which is not appreciated using the tocodynamometer; or an improvement in fetal condition after the CST has been performed. The high false-positive rate also indicates that a patient with a positive CST need not necessarily require an elective cesarean delivery. If a trial of labor is to be undertaken after a positive CST, the cervix should be favorable for induction so that direct fetal heart rate monitoring and careful assessment of uterine contractility with an intrauterine pressure catheter can be performed. A suspicious or equivocal CST or one that is unsatisfactory or shows hyperstimulation should be repeated in 24 hours. In one series, 7.5% of patients with an initially suspicious CST exhibited positive tests on further evaluation, 53.7% became negative, and 38.8% remained suspicious.<sup>65</sup> In follow-up studies of children who demonstrated a positive CST, few have exhibited abnormalities in neurologic and psychological development.<sup>66</sup> A potential determinant in the long-term outcome for these children may have been the early recognition of non-reassuring fetal heart rate patterns that enabled the prevention of intrapartum compromise.

### Nonstress Test

Observations made in the mid twentieth century that **accelerations of the fetal heart rate in response to fetal activity, uterine contractions, or stimulation reflect fetal well-being formed the basis for the nonstress test (NST).** The NST is the most widely applied technique for antepartum fetal evaluation despite the uncertainty regarding its reliability and reproducibility as a test of fetal assessment. The basic technology that underlies its performance and application has changed little

since its introduction and wide acceptance into antenatal practice.<sup>67</sup>

In late gestation, the healthy fetus exhibits an average of 34 accelerations above the baseline fetal heart rate each hour.<sup>68</sup> These accelerations, which average 20 to 25 beats/min in amplitude and about 40 seconds in duration, require intact neurologic coupling between the fetal CNS and the fetal heart.<sup>68</sup> Fetal hypoxia disrupts this pathway. At term, fetal accelerations are associated with fetal movement more than 85% of the time, and more than 90% of gross movements are accompanied by accelerations. Fetal heart rate accelerations may be absent during periods of quiet fetal sleep. Studies by Patrick and associates<sup>68</sup> demonstrated that the longest time between successive accelerations in the healthy term fetus is about 40 minutes. However, the fetus may fail to exhibit heart rate accelerations for up to 80 minutes and still be normal.

Although an absence of fetal heart rate accelerations is most often attributable to a quiet fetal sleep state, CNS depressants such as narcotics and phenobarbital, as well as the  $\beta$ -blocker propranolol, can reduce heart rate reactivity. Chronic smoking is known to decrease fetal oxygenation through an increase in fetal carboxyhemoglobin and a decrease in uterine blood flow. Fetal heart rate accelerations are also decreased in smokers.

The NST is usually performed in an outpatient setting. In most cases, only 10 to 15 minutes are required to complete the test. It has virtually no contraindications, and few equivocal test results are observed. The patient may be seated in a reclining chair, with care taken to ensure that she is tilted to the left to avoid the supine hypotensive syndrome.<sup>32</sup> The patient's blood pressure should be recorded before the test is begun and then repeated at 5- to 10-minute intervals. The fetal heart rate is monitored using the Doppler ultrasound transducer, and the tocodynamometer is applied to detect uterine contractions or fetal movement. Fetal activity may be recorded by the patient using an event marker, or it may be noted by the staff performing the test.

### Fetal Heart Rate Patterns Observable on the Nonstress Test

#### REACTIVE

The most widely applied definition of a reactive test requires that at least two accelerations of the fetal heart rate, each with a peak

**FIG 11-12** A reactive nonstress test. Accelerations of the fetal heart greater than 15 beats/min and that last longer than 15 sec can be identified. When the patient appreciates a fetal movement, she presses an event marker on the monitor, which creates arrows on the lower portion of the tracing.

**FIG 11-13** A nonreactive nonstress test. No accelerations of the fetal heart rate are observed. The patient has perceived fetal activity as indicated by the arrows in the lower portion of the tracing.

amplitude of 15 beats/min and total duration of 15 seconds, be observed in 20 minutes of monitoring (Fig. 11-12).<sup>69</sup> Gestational age affects reactivity criteria because sympathetic and parasympathetic influences on fetal heart rate change with advancing gestational age. Compared with the early third trimester, increased frequency and amplitude of fetal heart rate accelerations are seen after 30 weeks of gestation; although half of normal fetuses demonstrate accelerations with fetal movements at 24 weeks, nearly all fetuses will do so after 30 weeks. Similarly, before 30 to 32 weeks' gestation, acceptable criteria for a reactive fetal heart rate tracing include accelerations with a peak of only 10 beats/min amplitude and 10 seconds' duration rather than the widely applied 15-and-15 definition for reactivity described above.<sup>69</sup>

### NONREACTIVE

If the criteria for reactivity are not met, the test is considered nonreactive (Fig. 11-13). The most common cause for a nonreactive test is a period of fetal inactivity or quiet sleep. Therefore the test may be extended for an additional 20 minutes with the expectation that the fetal state will change and reactivity will appear. Keegan and colleagues<sup>70</sup> noted that about 80% of tests that were nonreactive in the morning became reactive when repeated later the same day. In an effort to change the fetal state, some clinicians have manually stimulated the fetus or attempted

to increase fetal glucose levels by giving the mother orange juice. No evidence suggests that such efforts will increase fetal activity.<sup>71,72</sup> If the test has been extended for 40 minutes, and reactivity has not been seen, a BPP or CST should be performed. Of those fetuses that exhibit a nonreactive NST, about 25% will have a positive CST on further evaluation.<sup>73-75</sup> Reactivity that occurs during preparations for the CST has proved to be a reliable index of fetal well-being.

Overall, on initial testing, 85% of NSTs are reactive and 15% are nonreactive (Fig. 11-14).<sup>73</sup> Fewer than 1% of NSTs prove unsatisfactory because of inadequately recorded fetal heart rate data.

The likelihood of a nonreactive test is substantially increased early in the third trimester. Between 24 and 28 weeks' gestation, about 50% of NSTs are nonreactive, and 15% of NSTs remain nonreactive between 28 and 32 weeks.<sup>76</sup> After 32 weeks, the incidences of reactive and nonreactive tests is comparable to that seen at term. **In summary, when accelerations of the baseline heart rate are seen during monitoring in the late second and early third trimesters, the NST has been associated with fetal well-being.**

When nonreactive, the NST is extended in an attempt to distinguish the fetus in a period of prolonged quiet sleep from those who are hypoxemic or asphyxiated. **Most fetuses that exhibit a nonreactive NST are not compromised but simply**

fail to exhibit heart rate reactivity during the 40-minute period of testing. Malformed fetuses also exhibit a significantly higher incidence of nonreactive NSTs.<sup>77</sup> Vibroacoustic stimulation (VAS) may be used to change the fetal state from quiet to active sleep (Fig. 11-15). Auditory brainstem response appears to be functional in the fetus at 26 to 28 weeks' gestation. Thus VAS may significantly increase the incidence of reactive NSTs after 26 weeks' gestation and may reduce the testing time, making this a potentially useful adjunct to antepartum fetal testing.<sup>76,78</sup> Most studies of VAS have used an electronic artificial larynx that generates sound pressure levels measured at 1 meter in air of 82 dB with a frequency of 80 Hz and a harmonic of 20 to 9000 Hz. Whether it is the acoustic or vibratory component of this stimulus that alters fetal state is unclear. VAS may produce a significant increase in the mean duration and amplitude of heart rate accelerations, fetal heart rate variability, and

gross fetal body movements within 3 minutes of stimulation.<sup>79</sup> Several studies using VAS have shown a decreased incidence of nonreactive NSTs from 13% to 14% down to 6% to 9%. A reactive NST after VAS stimulation appears to be as reliable an index of fetal well-being as spontaneous reactivity.<sup>79</sup> However, those fetuses that remain nonreactive even after VAS may be at increased risk for poor perinatal outcome, with increased rates of intrapartum fetal distress and growth restriction and low Apgar scores.

In most centers that use VAS, the baseline fetal heart rate is first observed for 5 minutes. If the pattern is nonreactive, a stimulus of 3 seconds or less is applied near the fetal head. If the NST remains nonreactive, the stimulus is repeated at 1-minute intervals up to three times. If the fetus still does not respond, further evaluation should be carried out with a BPP or CST. Studies have confirmed the safety of VAS use during pregnancy, and no long-term evidence of hearing loss has been found in children followed in the neonatal period and up to 4 years of age.<sup>80</sup> Other interventions to safely shorten NST time have been investigated, most with equivocal results.<sup>81</sup> **In summary, VAS may be helpful in shortening the time required to perform an NST and may be especially useful in centers where large numbers of NSTs are done.**

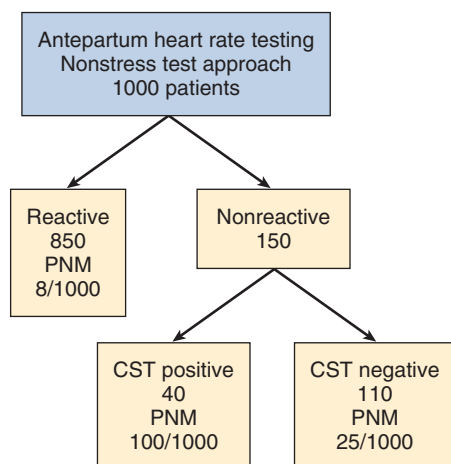

## Other Nonstress Test Patterns or Findings

### SINUSOIDAL PATTERN

On rare occasions, a sinusoidal heart rate pattern may be observed, as described in Chapter 15. This undulating heart rate pattern with virtually absent variability has been associated with fetal anemia and asphyxia, congenital malformations, and medications such as narcotics. In one of the earliest reports on the use of the NST, Rochard and coworkers<sup>82</sup> described a sinusoidal pattern in 20 of 50 pregnancies complicated by Rh isoimmunization. One half of these pregnancies ended in a perinatal death, and 40% of the surviving infants required prolonged hospitalization. Only 10% of the babies with a sinusoidal pattern had an uncomplicated course.

### BRADYCARDIA

Before 27 weeks' gestation, the normal fetal heart rate response to fetal movement may in fact be a bradycardia. However, in settings with a high a priori risk of fetal compromise, such as

**FIG 11-14** Results of nonstress testing in 1000 high-risk patients. In general, 85% of tests are reactive, and 15% are nonreactive. Of those patients with a nonreactive nonstress test (NST), about 25% have a positive contraction stress test (CST) on further evaluation. The highest perinatal mortality (PNM) is observed in patients with a nonreactive NST and a positive CST. Patients with a nonreactive NST and a negative CST have a PNM rate higher than that found in patients whose NST is initially reactive. (PNM rates are based on data from Evertson L, Gauthier R, Schiffrin B, et al. Antepartum fetal heart rate testing. I. Evolution of the nonstress test. *Am J Obstet Gynecol.* 1979;133:29.)

**FIG 11-15** Reactive nonstress test after vibroacoustic stimulation. The stimulus was applied at the point marked by the musical notes, and a sustained fetal heart rate acceleration was produced.

**FIG 11-16** A nonstress test in this primigravid patient of 43 weeks' gestation reveals a spontaneous bradycardia. The fetal heart rate has fallen from a baseline of 150-100 beats/min. Upon induction of labor, the patient required cesarean delivery for fetal distress associated with severe variable decelerations. The amniotic fluid was decreased in amount and was meconium stained.

IUGR associated with antiphospholipid syndrome, bradycardia at a gestational age of 26 to 28 weeks may be a predictor of impending fetal death. In these challenging cases, the entire clinical situation needs to be evaluated and discussed in full with the parents; this should include a neonatology consultation, initiated before intervention and delivery of a very preterm fetus exhibiting fetal heart rate decelerations.

*Significant* fetal heart rate bradycardias have been observed in 1% to 2% of all NSTs, defined as a fetal heart rate of 90 beats/min or a fall in the fetal heart rate of 40 beats/min below the baseline for 2 minutes or longer (Fig. 11-16). In a review of 121 cases, bradycardia was associated with increased perinatal morbidity and mortality, particularly antepartum fetal death, cord compression, IUGR, and fetal malformations.<sup>83</sup> Although about one half of the NSTs associated with bradycardia were reactive, the incidence of a nonreassuring fetal heart rate pattern in labor that led to emergency delivery in this group was identical to that of patients who exhibited nonreactive NSTs. Clinical management decisions should be based on the finding of bradycardia *not* on the presence or absence of reactivity. Bradycardia has a higher positive predictive value for fetal compromise (fetal death or fetal intolerance of labor) than does the nonreactive NST. In this setting, antepartum fetal death is most likely due to a cord accident.

**If a bradycardia is observed, an ultrasound examination should be performed to assess amniotic fluid volume and to detect the presence of anomalies.** Expectant management in the setting of a bradycardia has been associated with a PMR of 25%. Therefore several reports have recommended that delivery be undertaken if the fetus is mature. When the fetus is premature, the physician might elect to administer corticosteroids to accelerate fetal lung maturation before delivery. Continuous fetal heart rate monitoring is necessary if expectant management is followed.

### TACHYCARDIA

The fetal heart rate baseline evaluation must also take gestational age into account, as with fetal heart rate reactivity. Vagal activity has a greater influence on fetal heart rate at baseline as gestation advances; thus baseline fetal heart rate will decrease from an average of 155 beats/min at 20 weeks to 145 beats/min at 30 weeks. **The most common etiology of fetal tachycardia is maternal-fetal fever secondary to maternal-fetal infection**

**such as chorioamnionitis.** Other causes include chronic hypoxemia, maternal hyperthyroidism, and fetal tachyarrhythmia. Fetal heart rates above 200 beats/min, and certainly above 220 beats/min, should increase the index of suspicion of fetal tachyarrhythmia and lead to further fetal cardiac evaluation with a targeted fetal echocardiogram. For fetal heart rates between 160 and 180 beats/min, the presence or absence of baseline variability is an important indicator of fetal acid-base status. Fetal acidosis is more likely if baseline variability is absent.<sup>69</sup>

### ARRHYTHMIA

Among fetal arrhythmias, most (approximately 90%) are tachyarrhythmias. Fetal tachyarrhythmia is most often diagnosed when the fetal ventricular heart rate is faster than 180 beats/min. Common causes of fetal tachyarrhythmias are paroxysmal supraventricular tachycardia and atrial flutter. The administration of antiarrhythmic therapy to the pregnant mothers of fetuses with sustained supraventricular tachycardia represented the first examples of successful prenatal cardiac therapy. Multiple publications describe treatment protocols for this arrhythmia. Characteristics of fetuses who may need treatment include hydrops fetalis in the face of a sustained arrhythmia and a gestational age too early to preclude safe delivery and postnatal treatment. In such cases, therapy is best initiated with medications that have a relatively broad therapeutic margin and a low risk for proarrhythmia (unwanted precipitation or exacerbation of the arrhythmia) for the fetus and the mother. Digoxin is the most commonly used first-line agent but is rarely effective in the presence of fetal hydrops, for which sotalol or flecainide are typical first-line choices.<sup>84</sup>

Fetal bradyarrhythmia is diagnosed when the fetal ventricular heart rate is slower than 100 beats/min, mainly because of atrioventricular block. About half of all cases are caused by fetal cardiac anomalies, and of the remaining cases with normal cardiac structure, many are related to maternal antibodies. These antibodies, which include SS-A and SS-B, may directly target the fetal atrioventricular node or the myocardium, resulting in heart block and myocarditis. Fetuses with bradyarrhythmia may develop hydrops fetalis, particularly with sustained bradycardia at a rate less than 55 beats/min. In utero heart failure with congenital heart block, with or without congenital heart disease, represents an indication for electrical pacemaker therapy in surviving neonates. This condition is less often successfully treated

antenatally than fetal tachyarrhythmia. Available therapies include maternal administration of  $\beta$ -agonists, which have been shown to increase fetal ventricular rate by 10% to 20%, and steroid or immunoglobulin administration, which may be effective in cases of fetal heart block caused by maternal antibodies. Potential improved fetal outcome includes reversal of hydrops in several reports.<sup>84</sup>

## DECELERATION

**In most cases, mild variable decelerations are not associated with poor perinatal outcome.** Meis and associates<sup>85</sup> reported that variable decelerations of 20 beats/min or more below the baseline heart rate but lasting less than 10 seconds were noted in 50.7% of patients undergoing an NST. Whereas these decelerations were more often associated with a nuchal cord, they were not predictive of IUGR, a nonreassuring fetal heart rate pattern, or more severe variable decelerations during labor. When mild variable decelerations are observed, even if the NST is reactive, an ultrasound examination should be performed to rule out oligohydramnios. A low amniotic fluid index (AFI) and mild variable decelerations increase the likelihood of a cord accident. If late decelerations in response to contractions are observed in the performance of an NST, criteria for interpretation of a CST should then be used.

## Predictive Value of the Nonstress Test

**The NST is most predictive when it is normal or reactive.** The reported false-negative rate over multiple studies ranges from 0.2% to 0.8%, which corresponds to a fetal death rate of 3 to 8 per 1000 within 1 week of a reactive NST. The false-positive rate is considerably higher and ranges from 50% to more than 90% in various studies.<sup>2,42</sup>

A 2012 Cochrane review<sup>67</sup> integrated the results of six randomized controlled trials that included 2105 women; four studies with 1636 women compared nonstress testing (or NST with results revealed) to no NST (or NST with results concealed), and two studies with 469 women compared NST with computerized analysis to traditional (visually analyzed) NST. The six included studies only recruited high-risk women, and none provided information about singleton and multiple pregnancies. Of note, all four of the studies that compared NST with no NST were performed in the 1980s. In the studies that compared NST with no NST, no significant differences were identified in the risk for perinatal mortality (risk ratio [RR], 2.05; 95% confidence interval [CI], 0.95-4.42; 2.3% vs. 1.1%). In addition, no differences were identified in rates of cesarean delivery, “potentially preventable perinatal mortality,” Apgar scores, neonatal intensive care unit (NICU) admissions, gestational age at birth, or neonatal seizures. However, in the two studies that compared computerized analysis to visual analysis, a significant reduction was seen in perinatal mortality with computerized analysis (RR, 0.20; 95% CI, 0.04-0.88; 0.9% vs. 4.2%).<sup>67</sup> The authors concluded that the analysis was underpowered to detect possible important differences in perinatal mortality and pointed out that many aspects of antenatal and postnatal care may have changed since the included trials were performed. They called for new studies to assess the effects of the traditional and computer-analyzed NST in order to assess the true impact on perinatal mortality and other outcomes.

**In selected high-risk pregnancies, the false-negative rate associated with a weekly NST may be unacceptably high, especially in those pregnancies complicated by pregestational**

diabetes mellitus, IUGR, and prolonged gestation. In these cases, increasing the frequency of the NST to twice weekly may be advisable.<sup>86,87</sup>

## Fetal Biophysical Profile

**The use of real-time ultrasonography to assess antepartum fetal condition has enabled the obstetrician to perform an in utero physical examination and evaluate dynamic functions that reflect the integrity of the fetal CNS.**<sup>88</sup> As emphasized by Manning and colleagues,<sup>89</sup> “fetal biophysical scoring rests on the principle that the more complete the examination of the fetus, its activities, and its environment, the more accurate may be the differentiation of fetal health from disease states.”

Fetal breathing movements (FBMs) were the first biophysical parameter to be assessed using real-time ultrasonography. It is thought that the fetus exercises its breathing muscles in utero in preparation for postdelivery respiratory function. With real-time ultrasonography, FBM is evidenced by downward movement of the diaphragm and abdominal contents and by an inward collapsing of the chest. FBMs become regular at 20 to 21 weeks and are controlled by centers on the ventral surface of the fourth ventricle of the fetus.<sup>90</sup> They are observed about 30% of the time, are seen more often during REM sleep, and demonstrate intact neurologic control when present. Although the absence of FBMs may reflect fetal asphyxia, this finding may also indicate that the fetus is in a period of quiet sleep.<sup>51</sup> Several factors other than fetal state and hypoxia can influence the presence of FBM. As maternal glucose levels rise, FBM becomes more frequent, and during periods of maternal hypoglycemia, FBM decreases. Maternal smoking reduces FBM, probably as a result of fetal hypoxemia. Narcotics that depress the fetal CNS also decrease FBM.

Regarding other observable fetal states as markers of fetal oxygen status and well-being, Vintzileos and coworkers<sup>90</sup> stressed that **fetal biophysical activities that are present earliest in fetal development are the last to disappear with fetal hypoxia.** The fetal tone center in the cortex begins to function at 7.5 to 8.5 weeks, therefore fetal tone would be the last fetal parameter to be lost with worsening fetal condition. The fetal movement center in the cortex nuclei is functional at 9 weeks and would be more sensitive than fetal tone. As noted earlier, FBM becomes regular at 20 to 21 weeks. Finally, fetal heart rate control, which resides within the posterior hypothalamus and medulla, becomes functional at the end of the second trimester and early in the third trimester. An alteration in fetal heart rate would theoretically be the earliest sign of fetal compromise.

Using these principles, Manning and colleagues<sup>91</sup> developed the concept of the fetal BPP score. These researchers elected to combine the NST with four parameters that could be assessed using real-time ultrasonography: FBM, fetal movement, fetal tone, and amniotic fluid volume (AFV). FBM, fetal movement, and fetal tone are mediated by complex neurologic pathways and should reflect the function of the fetal CNS at the time of the examination. On the other hand, AFV should provide information about the presence of chronic fetal asphyxia. Finally, the ultrasound examination performed for the BPP has the added advantage of detecting previously unrecognized major fetal anomalies. A BPP score was developed that is similar to the Apgar score used to assess the condition of the newborn.<sup>91</sup> The presence of a normal parameter, such as a reactive NST, was awarded 2 points, whereas the absence of that parameter was scored as 0. The highest score a fetus can receive is 10, and the

**TABLE 11-4** CRITERIA OF BIOPHYSICAL PROFILE SCORING

| BIOPHYSICAL VARIABLE (SCORE = 0) | NORMAL (SCORE = 2)  | ABNORMAL  |
|----------------------------------|---|---|
| Fetal breathing movements        | At least one episode of $\geq 30$ sec duration in 30-min observation  | Absent or no episode of $\geq 30$ sec duration in 30 min  |
| Gross body/limb movement         | At least three discrete body/limb movements in 30 min (episodes of active continuous movement considered a single movement)                                 | Up to two episodes of movements in 30 min   |
| Fetal tone                       | At least one episode of active extension with return-flexion of fetal limb or trunk, with opening and closing of the hand considered to reflect normal tone | Either slow extension with return-partial flexion, movement of limb in full extension, or absent fetal movement |
| Reactive fetal heart rate        | At least two episodes of acceleration of $\geq 15$ beats/min and 15 sec duration associated with fetal movement in 20 min*                                  | Fewer than two accelerations or acceleration $< 15$ beats/min in 20 min   |
| Amniotic fluid volume            | At least one pocket of amniotic fluid measuring $\geq 2$ cm in two perpendicular planes   | Either no amniotic fluid pockets or a pocket $< 2$ cm in two perpendicular planes                               |

\*For gestational age  $> 30$  weeks.

**TABLE 11-5** MANAGEMENT BASED ON BIOPHYSICAL PROFILE

| SCORE | INTERPRETATION                        | MANAGEMENT   |
|-------|---------------------------------------|--|
| 10    | Normal; low risk for chronic asphyxia | Repeat testing at weekly to twice-weekly intervals.  |
| 8     | Normal; low risk for chronic asphyxia | Repeat testing at weekly to twice-weekly intervals.  |
| 6     | Suspect chronic asphyxia              | If $\geq 36$ -37 wk gestation or $< 36$ wk with positive testing for fetal pulmonary maturity, consider delivery; if $< 36$ wk and/or fetal pulmonary maturity testing is negative, repeat biophysical profile in 4-6 hr; deliver if oligohydramnios is present. |
| 4     | Suspect chronic asphyxia              | If $\geq 36$ wk gestation, deliver; if $< 32$ wk gestation, repeat score.  |
| 0-2   | Strongly suspect chronic asphyxia     | Extend testing time-120 min; if persistent score is 4 or less, deliver regardless of gestational age.  |

Modified from Manning FA, Harman CR, Morrison I, et al. Fetal assessment based on fetal biophysical profile scoring. *Am J Obstet Gynecol*. 1990;162:703; and Manning FA. Biophysical profile scoring. In Nijhuis J, ed: *Fetal behaviour*. New York, Oxford University Press; 1992:241.

lowest score is 0. The BPP may be used as early as 26 to 28 weeks' gestation. The time required for the fetus to achieve a satisfactory BPP score is closely related to fetal state, with an average of only 5 minutes if the fetus is in a 2F state but over 25 minutes if it is in a 1F state.<sup>92</sup>

The criteria proposed by Manning and colleagues<sup>91</sup> are shown in Table 11-4, and the clinical actions recommended in response to these scores are presented in Table 11-5. A low score on the BPP does not prohibit attempted vaginal delivery if other obstetric factors are favorable.

In a prospective blinded study of 216 high-risk patients, no perinatal deaths were observed when all five variables described earlier were normal, but a PMR of 60% was seen in fetuses with a score of zero.<sup>91</sup> Fetal deaths were increased fourteenfold with the absence of fetal movement, and the PMR was increased eighteenfold if FBM was absent. Any single test was associated with a significant false-positive rate that ranged from 50% to 79%. However, combining abnormal variables significantly decreased the false-positive rate to as low as 20%. The false-negative rate—that is, the incidence of babies who were compromised but who had normal testing—was low and ranged from a PMR of 6.9 per 1000 for infants with normal amniotic fluid volume to 12.8 per 1000 for fetuses with a reactive NST. These investigators found that in most cases, the ultrasound-derived BPP parameters and NST could be completed within a relatively short time; each requires about 10 minutes.

Manning and colleagues<sup>93</sup> presented their experience with 26,780 high-risk pregnancies followed with the BPP. In their protocol, a routine NST is not performed if all of the ultrasound parameters are found to be normal for a score of 8. An NST is performed when one ultrasound finding is abnormal. The corrected PMR in this series was 1.9 per 1000 with fewer than 1 fetal death per 1000 patients within 1 week of a normal profile. Of all patients tested, almost 97% had a score of 8, which means

that only 3% required further evaluation for scores of 6 or less. In a study of 525 patients with scores of 6 or less, poor perinatal outcome was most often associated with either a nonreactive NST and absent fetal tone or a nonreactive NST and absent FBM.<sup>94</sup> A significant inverse linear relationship was observed between the last BPP score and both perinatal morbidity and mortality (Figs. 11-17 and 11-18).<sup>95</sup> Depending on the end point used, the false-positive rate ranged from 75% for a score of 6 to less than 20% for a score of 0. Manning has summarized the data reported in eight investigations using the BPP for fetal evaluation. Overall, 23,780 patients and 54,337 tests were reviewed. The corrected PMR, excluding lethal anomalies, was 0.77 per 1000.

**The BPP correlates well with fetal acid-base status.** Vintzileos and associates<sup>90</sup> studied 124 patients undergoing cesarean birth *before* the onset of labor. Deliveries were undertaken for severe preeclampsia, elective repeat cesarean delivery, growth restriction, breech presentation, placenta previa, and fetal macrosomia. *Acidosis* was defined as an umbilical cord arterial pH less than 7.20. The earliest manifestations of fetal acidosis were a nonreactive NST and loss of FBM. With scores of 8 or more, the mean arterial pH was 7.28, and only 2 of 102 fetuses were acidotic. Nine fetuses with scores of 4 or less had a mean pH of 6.99, and all were acidotic.

Some studies have demonstrated that antenatal corticosteroid administration may have an effect on the BPP, decreasing the profile score. Because corticosteroids are used in cases of anticipated premature delivery (24-34 weeks), any false-positive results on biophysical testing may lead to inappropriate intervention and delivery. Kelly and coworkers reported that BPP scores were decreased in more than one third of the fetuses tested at 28 to 34 weeks' gestation. This effect was seen within 48 hours of corticosteroid administration. Neonatal outcome was not affected. Repeat BPPs within 24 to 48 hours were normal in

**FIG 11-17** The relationship between five indexes of perinatal morbidity and last biophysical profile (BPP) score before delivery. A significant inverse linear correlation is observed for each variable. *IUGR*, intrauterine growth restriction; *NICU*, neonatal intensive care unit. (From Manning FA, Harman CR, Morrison I, et al. Fetal assessment based on fetal biophysical profile scoring. *Am J Obstet Gynecol.* 1990;162:703.)

cases in which the BPP score had decreased by 4 points. The most commonly affected variables were FBM and the NST. Other investigators have reported transient suppression of FBM and heart rate reactivity after corticosteroid administration at less than 34 weeks' gestation, with return of these parameters to normal by 48 to 96 hours after corticosteroid treatment. This effect must be considered at institutions where daily BPPs are used to evaluate the fetus in cases of preterm labor or preterm premature rupture of the membranes (PPROM).

Some controversy concerns the utility of the BPP in predicting chorioamnionitis in pregnancies complicated by preterm labor or PPRM. Sherer and colleagues reported that the absence of FBM is associated with histologic evidence of fetal inflammation and intrauterine infection in patients with preterm labor and intact membranes before 32 weeks' gestation. However, they recommend that this finding not be used to guide clinical management because of the low positive predictive value of absent FBM. Lewis and associates performed a randomized trial of daily NSTs versus BPP in the management of PPRM. They concluded that neither daily NSTs nor BPPs had high sensitivity in predicting infectious complications in these patients. Daily BPPs increased cost without apparent benefit.

**FIG 11-18** The relationship between perinatal mortality (PNM), both total and corrected for major anomalies, and the last biophysical profile (BPP) score before delivery. A highly significant inverse and exponential relationship is observed. (From Manning FA, Harman CR, Morrison I, et al. Fetal assessment based on fetal biophysical profile scoring. *Am J Obstet Gynecol.* 1990;162:703.)

Manning and colleagues have described the correlation between biophysical scoring and the incidence of cerebral palsy in Manitoba. In patients referred for a BPP, an inverse, exponential, and highly significant relationship was found between last BPP score and the incidence of cerebral palsy. Scores of 6 or less had a sensitivity of 49%. The more abnormal the last BPP, the greater the risk for cerebral palsy. Gestational age, birthweight, and assumed timing of the injury were not related to the incidence of cerebral palsy, which ranged from 0.7 per 1000 live births for a normal BPP score to 13.1 per 1000 live births for a score of 6 to 333 per 1000 live births for a score of 0.

Several drawbacks of the BPP should be considered. Unlike the NST and CST, an ultrasound machine is required, and unless the BPP is videotaped, it cannot be reviewed. If the fetus is in a quiet sleep state, the BPP can require a long period of observation. The present scoring system does not consider the impact of hydramnios. For example, in a pregnancy complicated by diabetes mellitus, the presence of excessive amniotic fluid may be an indicator of fetal risk.

### Predictive Value of the Biophysical Profile

To summarize the results of multiple studies, the false-negative rate of a normal BPP is less than 0.1%, or less than

**1 fetal death per 1000 within 1 week of a normal BPP.**<sup>2</sup> The false-positive rate of a particular test has always been of concern because of the possibility of unnecessary intervention (usually delivery) and subsequent iatrogenic complications. The BPP was developed in part to address the issue of the high false-positive rate of the CST and the NST. Little attention has been paid to the possible false-positive rate of the abnormal or equivocal BPP. This is particularly relevant because the BPP is most commonly used as the final back-up test in the NST and CST sequence of testing and is critically important when dealing with the premature fetus. As noted earlier, the false-positive rate of a score of 0 is less than 20%, but for a score of 6, it is up to 75%. Inglis and coworkers used VAS to define fetal condition with BPP scores of 6 or less in 81 patients at 28 to 42 weeks. Obstetric and neonatal outcomes of 41 patients whose score improved to normal after VAS were compared with those of 238 patients who had normal scores without VAS. The obstetric and neonatal outcomes were not significantly different between the two groups. VAS improved the BPP in about 80% of cases. Use of VAS for an equivocal BPP did not increase the false-negative rate and may reduce the likelihood of unnecessary obstetric intervention.

A 2008 Cochrane review<sup>96</sup> included evaluation of 2829 women randomized to BPP versus NST. The majority were term pregnancies. No differences were found in perinatal mortality, cesarean delivery rate, Apgar scores, or admission to the NICU. As with the 2012 Cochrane review<sup>67</sup> of the NST mentioned earlier, this analysis was underpowered to detect a significant difference in perinatal mortality among BPP and other modalities. The authors also note that “it is regrettable that since the introduction of the BPP in the 1980s, and following reports of observational studies of tens of thousands of pregnancies, less than 3000 women have been enrolled into randomized trials.”

### Modified Biophysical Profile

In an attempt to simplify and reduce the time necessary to complete testing, a variety of modifications of the full BPP have been evaluated by focusing on the components of the BPP that are most predictive of perinatal outcome. The NST, an indicator of present fetal condition, may be combined with assessment of AFV (see Chapter 35), a marker of long-term status, in a modified BPP (mBPP). In this setting, a deepest vertical pocket (DVP) of amniotic fluid greater than 2 by 1 cm is usually considered normal, although different criteria have been applied. **Multiple investigations**, including a trial by Miller and colleagues of 56,617 antepartum tests in 15,482 women, **have demonstrated comparable results of the mBPP to the full BPP, namely a false-negative rate (or rate of fetal death within 1 week of a normal mBPP) of 0.8 per 1000.** Nageotte and associates<sup>97</sup> demonstrated that the mBPP was as good a predictor of adverse fetal outcome as a negative CST. Additional evaluation for an abnormal mBPP is required in about 10% of patients. If the NST is nonreactive despite VAS or extended monitoring, or if the AFV is abnormal, either a full BPP or CST is performed. The CST as a back-up test is associated with a higher rate of intervention for an abnormal test than the use of a complete BPP as a back-up test. Overall, the mBPP has a false-positive rate comparable to that of the NST but higher than that of the CST and full BPP. The low false-negative rate and ease of performance of the mBPP make it an excellent approach for the evaluation of large numbers of high-risk patients. As such,

although potentially still a useful test, the CST has become less frequently used in current practice.

Whether to use a full AFI for AFV assessment or an abbreviated measure, the DVP, has undergone investigation. Chauhan and colleagues performed a randomized trial of more than 1000 women and found that the AFI led to more diagnoses of oligohydramnios, a higher rate of intervention, and more iatrogenic prematurity but offered no advantage in detecting or preventing adverse outcomes. Similarly, a 2009 Cochrane review<sup>98</sup> of five trials that included more than 3200 women concluded that no differences were apparent in perinatal outcomes. However, the use of AFI did result in an increased rate of diagnosis of oligohydramnios and an increased rate of induction of labor compared with DVP. This review could not comment on the relative ability of AFI, compared with DVP, for prevention of perinatal death because no deaths were reported in the included trials. Based on these data, more recent endorsement of DVP as the primary fluid to assessment strategy has been proposed.<sup>32</sup>

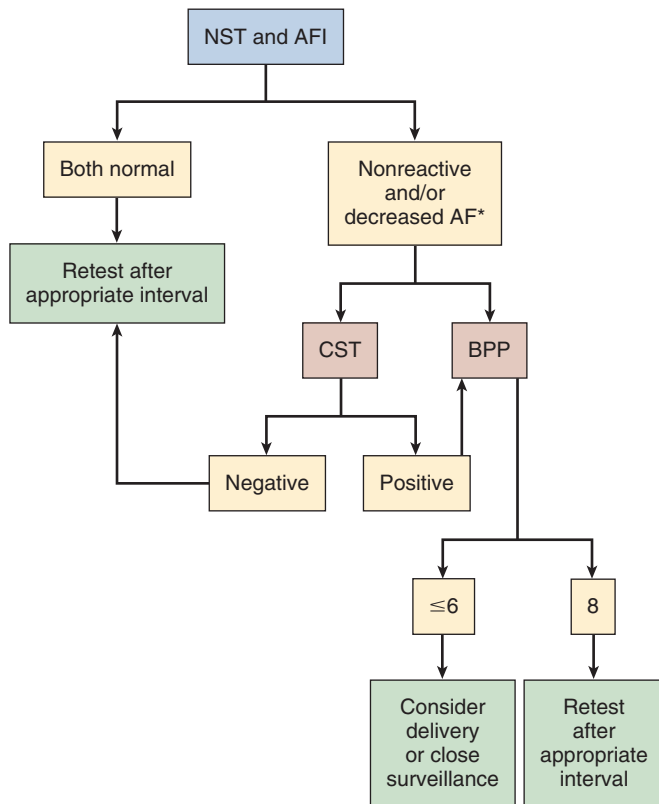

### Doppler Ultrasound

The advent of Doppler ultrasound has permitted noninvasive assessment of the fetal, maternal, and placental circulations. With Doppler ultrasound, we can obtain information about uteroplacental blood flow and resistance, which may be markers of fetal adaptation and reserve. **This method of fetal assessment has only been demonstrated to be of value in reducing perinatal mortality and unnecessary obstetric interventions in fetuses with suspected IUGR and possibly other disorders of uteroplacental blood flow.**<sup>2</sup> A detailed description of the underlying principles and use of Doppler ultrasound for fetal assessment of IUGR is available in Chapter 33. For the purposes of this chapter on antenatal fetal assessment, Doppler interrogation of fetal vascular flow and resistance can be conceptualized as a follow-up test to determine fetal reserve in cases of suspected IUGR and not as a primary method of antenatal fetal surveillance for either high- or low-risk pregnancies.

Perhaps ironically, however, Doppler ultrasound has been more stringently evaluated in randomized trials than other antenatal testing methods, as has been summarized in an editorial by Divon and Ferber. The most recent summary of the available evidence comes from a 2013 Cochrane review of 18 randomized trials that included more than 10,000 high-risk women, in which the use of Doppler ultrasound was associated with decreased perinatal deaths (RR, 0.71; 95% CI, 0.52-0.98) and significantly fewer inductions of labor and cesarean deliveries. Studies of low-risk pregnancies have not shown a benefit from the use of Doppler ultrasound, as has been most recently described in a 2010 systematic review of five studies that included more than 14,000 women.

## CLINICAL APPLICATION OF TESTS OF FETAL WELL-BEING

**Our ability to detect and prevent impending fetal death or injury depends not only on the predictive value of the tests used and the population selected for testing but also on our ability to respond to abnormal test results.** To have an impact on testing outcomes and the overall fetal death rate, we must consider available strategies to deal with abnormal test results. These strategies would ideally include a series of antenatal evaluations and interventions short of premature delivery, with premature delivery ultimately reserved for cases when it is ascertained

**FIG 11-19** Flow chart for antepartum fetal surveillance in which the nonstress test (NST) and amniotic fluid index (AFI) are used as the primary methods for fetal evaluation. A nonreactive NST and decreased AFI are further evaluated using either the contraction stress test (CST) or the biophysical profile (BPP). Further details regarding the use of the BPP are provided in Table 11-6. \*If the fetus is mature and amniotic fluid volume is reduced, delivery should be considered before further testing is undertaken. (Modified from Finberg HJ, Kurtz AB, Johnson RL, et al. The biophysical profile: a literature review and reassessment of its usefulness in the evaluation of fetal well-being. *J Ultrasound Med.* 1990;9:583.)

that intrauterine injury or death can no longer be delayed or prevented. Figure 11-19 presents a practical testing scheme that has been used successfully by several centers.<sup>88</sup> This strategy would include using combinations of antepartum tests in an organized sequence to evaluate the fetus further; administration of antenatal steroids; potentially modified maternal activity level; and correction of maternal metabolic, cardiopulmonary, or other medical disorders. In some cases, fetal therapy may be indicated, such as intrauterine transfusion for anemia, removal of fluid from body cavities, diagnostic procedures, and direct administration of medication to the fetus.

Testing can be initiated at early gestational ages in high-risk pregnancies (25-26 weeks) to identify the fetus at risk. Maternal and fetal interventions can then be considered. Obviously, safe prolongation of intrauterine life is the primary goal, and better understanding of the pathophysiology of the premature fetus and the use of combinations of tests will allow this to be accomplished.

The question of routine antepartum fetal surveillance must be carefully examined. Antepartum fetal testing can more accurately predict fetal outcome than antenatal risk assessment using an established scoring system. Patients judged to be at high risk based on known medical factors but whose fetuses demonstrate

normal antepartum fetal evaluation have a lower PMR than patients considered at low risk whose fetuses have abnormal antepartum testing results. Routine antepartum fetal evaluation would be necessary to detect the considerable proportion of fetuses destined for fetal death or injury with no identifiable risk factors. It would therefore seem reasonable to consider extending some form of antepartum fetal surveillance to all obstetric patients, such as maternal assessment of fetal activity as described previously.

The question is how best to combine antenatal tests in clinical practice and in which patients. **The approach to prescribing testing modalities must take into account gestational age, medical comorbidities, and sociodemographic risk factors** described in this chapter in order to prevent fetal injury or death without causing iatrogenic prematurity or an excess of testing and worry. According to a summary by Fretts and Duru<sup>23</sup> in 2008, “The best opportunity for stillbirth reduction is to identify patients who have an increased risk of stillbirth late in pregnancy, where the downside of antepartum testing and early delivery, if warranted, can be minimized.”

The condition to specific use of antenatal testing may be illustrated by the following examples. In a prolonged pregnancy, a **parallel testing scheme** would be used. In this situation, the obstetrician is not concerned with fetal maturity but rather with fetal well-being. Several tests are performed at the same time, such as antepartum fetal heart rate testing and the BPP. It is acceptable in this high-risk situation to intervene when a single test is abnormal. It seems prudent to accept a false-positive test result to avoid the intrauterine death of a mature and otherwise healthy fetus. In most other high-risk pregnancies, such as those complicated by diabetes mellitus or hypertension, it is preferable to allow the fetus to remain in utero as long as possible. In these situations, a **branched testing scheme** is used to decrease the likelihood of unnecessary premature intervention, the obstetrician uses a series of tests and, under most circumstances, would only deliver a premature infant when all parameters suggest fetal compromise. In this situation, the physician must consider the likelihood of neonatal respiratory distress syndrome (RDS) and review these risks with colleagues in neonatology.

The comparable performance of the various available antenatal tests, along with their utility in series, has been illustrated by numerous investigators (see Table 11-2). Maternal assessment of fetal activity would appear to be a reasonable first-line screening test for both high- and low-risk patients. The use of this approach may decrease the number of unexpected intrauterine deaths in so-called normal pregnancies. The NST and mBPP remain the primary methods used for antepartum fetal evaluation in high-risk patients at most centers, with full BPP and CST to assess fetal condition in patients who exhibit a persistently nonreactive NST or abnormal mBPP. This sequential approach may be particularly valuable in avoiding unnecessary premature intervention. The NST and mBPP can be quickly performed in an outpatient setting and are easily interpreted. In contrast, the CST is usually performed near the labor and delivery suite, it may require an intravenous infusion of oxytocin and may be more difficult to interpret. However, the ability of the CST to stress the fetus and evaluate its response to intermittent interruptions in intervillous blood flow may provide an earlier warning of fetal compromise than the NST or mBPP.

**The frequency with which to use specific tests will depend on a number of features, including the predictive value of the test and the underlying condition prompting the test.** Most

tests described previously have relatively reliable risk profiles over the course of a week when normal, with decreased intervals between tests recommended for abnormal results. Regarding the underlying condition contributing to risk for adverse outcomes, consideration must be given to whether that condition is stable, worsening, or improving. The gestational age at which to initiate testing has not been clearly defined for most high-risk conditions. **Initiating testing at 32 to 34 weeks of gestation has historically been prescribed for most high-risk pregnancies, with earlier testing recommended for cases with multiple comorbidities or particularly worrisome features.**

In considering the pros and cons of testing in the preterm period, it is worthwhile to return to the question of potential harms of testing, from increases in preterm birth and cesarean delivery rates to maternal anxiety and financial costs. Although no evidence exists of improved outcomes from any one testing strategy, as a counterpoint some authors have begun to study whether the implementation of testing increases the chances of induction of labor or cesarean delivery rates. In addition, it is reasonable to question whether a program of antenatal testing contributes to maternal anxiety or other indirect costs that are difficult to quantify. Kafali and colleagues<sup>36</sup> demonstrated increased maternal anxiety scores after an NST session and a decrease in anxiety scores in women randomized to administration of music during the NST. Taking patient-specific risk factors, and perhaps maternal preferences, into account when considering an individualized testing plan is most likely to contribute to optimal outcomes.

On behalf of the Eunice Kennedy Shriver National Institute of Child Health and Human Development Workshop, Signore and coworkers<sup>2</sup> have proposed a series of guidelines for condition-specific antenatal testing based on the available evidence (Table 11-6). In their 2009 publication, they stress that **“the basis for antepartum testing relies on the premise that the fetus whose**

**oxygenation in utero is challenged will respond with a series of detectable physiologic adaptive or decompensatory signs as hypoxemia or frank metabolic acidemia develop,”** hence the recommendation for the use of antenatal tests in series to follow the changes in observable measures of fetal response to a suboptimal intrauterine environment. Although this proposed strategy is certainly not comprehensive, it is hoped that future research into specific testing strategies stratified by risk category will enhance our ability to prescribe these tests effectively and safely.

### Evidence for Condition-Specific Testing

For most of the conditions identified as constituting an increased risk for fetal death, insufficient studies exist to permit an evidence-based recommendation for a particular testing scheme. In addition to this limitation, condition-specific testing is problematic as a general strategy for prevention of fetal death, given the many fetal deaths that occur in pregnancies otherwise categorized as low risk or without identifiable risk factors.<sup>2</sup> However, it is incumbent on care providers to consider all conditions associated with an increased risk for fetal death or other adverse outcomes as a potential indication for some form of antenatal surveillance<sup>2,32</sup> and to individualize antenatal testing plans based on specific underlying conditions. This strategy is outlined in an excellent summary by Kontopoulos and Vintzileos,<sup>99</sup> in which they explore several pathophysiologic mechanisms as potentially distinct etiologies for risk of fetal death in different populations. **The authors acknowledge that no ideal single test or testing strategy exists for all high-risk pregnancies but that clinician judgment and logic, as well as evidence from observational trials, should guide testing strategies for each patient.**

Difficulty in generating evidence-based recommendations for condition-specific testing schemes in cases of identified risk factors can be illustrated by considering the example of

**TABLE 11-6** PROPOSED INITIAL TESTING STRATEGY BY SELECTED ANTENATAL CONDITION

| RISK FACTOR                                 | TEST                        | FREQUENCY            | START  |
|---|-----------------------------|----------------------|--|
| All pregnancies                             | FMC                         | Daily                | 24-28 wk                                     |
| Low-risk pregnancies                        | FMC                         | Daily                | 24-28 wk                                     |
| Insulin-treated diabetes:                   |                             |                      |  |
| Uncomplicated pregestational or gestational | mBPP                        | Twice weekly         | 32 wk  |
| With hypertension, renal disease, or IUGR   | As above, plus consider CST | Weekly               | 26-28 wk                                     |
| Hypertensive disorders:                     |                             |                      |  |
| Uncomplicated                               | mBPP                        | Twice weekly         | 32 wk  |
| With comorbidities                          | mBPP                        | Twice weekly         | 26-28 wk                                     |
| IUGR  | mBPP/Doppler                | Once or twice weekly | At diagnosis                                 |
| Multiple gestation:                         |                             |                      |  |
| Twins                                       |                             |                      |  |
| Concordant growth                           | mBPP                        | Weekly               | 32 wk  |
| Discordant growth or AFV                    | mBPP                        | Twice weekly         | At diagnosis                                 |
| Triplets or greater                         | mBPP                        | Twice weekly         | 28 wk  |
| Oligohydramnios                             | mBPP                        | Twice weekly         | At diagnosis                                 |
| Intrahepatic cholestasis                    | mBPP                        | Weekly               | 34 wk  |
| Renal disease                               | mBPP                        | Weekly               | 30-32 wk                                     |
| Decreased fetal movement                    | mBPP                        | PRN                  | At diagnosis                                 |
| Previous fetal death                        | mBPP                        | Once or twice weekly | 32-34 wk or 1 wk before previous fetal death |
|   | Alternative: BPP or CST     | Weekly               |  |
| Postterm pregnancy                          | mBPP                        | Once or twice weekly | ≥41 wk                                       |
| SLE   | mBPP                        | Weekly               | 26 wk  |
| Renal disease                               | mBPP                        | Once or twice weekly | 30-32 wk                                     |
| Intrahepatic cholestasis                    | mBPP                        | Weekly               | 34 wk  |

hypertensive disorders. Well-designed prospective trials that provide evidence for any specific testing strategy are not available despite the very frequent use of a variety of antenatal testing schemes used in clinical practice for hypertensive disorders. The heterogeneity of pathophysiologic mechanisms at play in the general category of hypertensive disorders contributes to the difficulty in generating specific recommendations. Freeman<sup>37</sup> summarized the situation in a 2008 review and noted that despite previous testing guidelines that recommended a wider application of antenatal testing in women with varying degrees of hypertension, the most recent expert recommendations do not support antepartum fetal testing for mild to moderate blood pressure abnormalities, nor do they support it in the absence of preeclampsia or IUGR. However, for many practitioners, the evidence that all forms of chronic hypertension constitute an increased risk for fetal death and adverse outcomes prompts broad use of testing modalities for these patients.

Another challenge in the implementation of condition-specific testing may lie in the appreciation and acknowledgment of individual patient characteristics as risk factors for fetal death, in particular certain demographic risk factors without clear pathophysiologic links. For example, the condition of advanced maternal age has garnered a great deal of investigation into associations with fetal death and other adverse pregnancy outcomes and related management strategies. However, the same cannot be said for other demographic risk factors such as obesity and black race, which have equal or greater relative risks of fetal death yet are arguably less accepted in the community as being risks for adverse outcomes.

## ASSESSMENT OF FETAL PULMONARY MATURATION

This section reviews those techniques that enable the obstetrician to predict the risks of RDS for the infant who requires premature delivery. The risk of iatrogenic prematurity for the neonate balanced against the risk of continued antepartum assessment of the potentially compromised fetus determines ultimate management strategies. As one marker of fetal maturity that can be assessed antenatally, incorporation of the discussion of fetal pulmonary maturity assessment with that of antepartum assessment is critical.

RDS is caused by a deficiency of pulmonary surfactant, an antiatelectasis factor that is able to maintain a low stable surface tension at the air-water interface within alveoli. Surfactant decreases the pressure needed to distend the lung and prevents alveolar collapse (see [Chapter 22](#)). The type 2 alveolar cell is the major site of surfactant synthesis. Surfactant is packaged in lamellar bodies, discharged into the alveoli, and carried into the amniotic cavity with pulmonary fluid.

Phospholipids account for more than 80% of the surface to active material within the lung, and more than 50% of this phospholipid is dipalmitoyl lecithin. The latter is a derivative of glycerol phosphate and contains two fatty acids and the nitrogenous base choline. Other phospholipids contained in the surfactant complex include phosphatidylglycerol (PG), phosphatidylinositol, phosphatidylserine, phosphatidylethanolamine, sphingomyelin, and lysolecithin. PG is the second most abundant lipid in surfactant and significantly improves its properties.

Important differences in neonatal adaptation, including development of RDS, have been demonstrated not only between

preterm and term neonates but also with each advancing gestational week from 37 to 39 weeks. This places even more responsibility on the physician to judiciously assess indications for and timing of delivery before 39 weeks. In weighing the risks and benefits of effecting delivery as a result of antenatal testing results before 39 weeks, assessment of fetal pulmonary maturity may in some cases be indicated. At the same time, it is important to recognize that many perinatal processes contribute to the prognosis for neonatal respiratory function, including surfactant deficiency, immaturity, and intrapartum complications—all prime factors in determining the pathogenesis of RDS that may not be predicted by fetal pulmonary maturity testing.

## Tests of Fetal Pulmonary Maturity

Available methods for evaluating fetal pulmonary maturity rely generally on either presence or quantitation of components of pulmonary surfactant or measurement of surfactant function. The former category has become the most common and reliable in current practice, although no data show that one method is preferable to the others with regard to prediction of pulmonary maturity. **In general, a test that is positive for fetal pulmonary maturity will much more accurately predict the absence of RDS than a negative test will predict the presence of RDS.**

With the exception of amniotic fluid specimens obtained from the vaginal pool, the evaluation of fetal pulmonary maturation requires that a sample of amniotic fluid be obtained by amniocentesis. This is generally a low-risk procedure with few potential adverse outcomes, including unsuccessful amniocentesis (1.6%-4.4%) and complications that require same-day delivery (0.7%-3.3%).

## Quantitation of Pulmonary Surfactant

Methods of quantifying pulmonary surfactant include the lecithin/sphingomyelin (L/S) ratio, presence of PG, visual inspection of fluid, and surfactant/albumin ratio.

The L/S ratio was the first reliable assay for the assessment of fetal pulmonary maturity. The amniotic fluid concentration of lecithin increases markedly at about 35 weeks' gestation, whereas sphingomyelin levels remain stable or decrease. Amniotic fluid sphingomyelin exceeds lecithin until 31 to 32 weeks, when the L/S ratio reaches 1. Lecithin then rises rapidly, and an L/S ratio of 2 is observed at about 35 weeks. Wide variation in the L/S ratio at each gestational age has been noted. Nevertheless, a ratio of 2 or greater has repeatedly been associated with pulmonary maturity. Note that the presence of blood or meconium in the amniotic fluid sample can cause erroneous results.

PG, which does not appear until 35 weeks' gestation and increases rapidly between 37 and 40 weeks, is a marker of completed pulmonary maturation. A rapid immunologic semiquantitative agglutination test (AmnioStat-FLM; Irvine Scientific, Santa Ana, CA) can be used to determine the presence of PG within 30 min and requires only 1.5 mL of amniotic fluid. Presence of blood and meconium do not interfere with PG assessment.

Visual inspection of amniotic fluid can give some information about the presence of pulmonary surfactant components. During the first and second trimesters, amniotic fluid is yellow and clear. It becomes colorless in the third trimester. By 33 to 34 weeks' gestation, cloudiness and flocculation are noted, and as term approaches, vernix appears. Amniotic fluid with obvious vernix or fluid so turbid it does not permit the reading of newsprint through it will usually have a mature L/S ratio.

The ratio of the surfactant-albumin in amniotic fluid was previously a popular test run on an automated fluorescence polarimeter that was easy to use, low in cost, and had high reproducibility. Currently the device is not commercially available for use, although newer platforms may be in development.

### Measurements of Surfactant Function

Lamellar bodies are the storage form of surfactant released by fetal type 2 pneumocytes into the amniotic fluid. A lamellar body count requires less than 1 mL of amniotic fluid and takes only 15 minutes to perform using a commercial cell counter. A count greater than 30,000 to 55,000/ $\mu$ L is highly predictive of pulmonary maturity, whereas a count below 10,000/ $\mu$ L suggests a significant risk for RDS. Neither meconium nor blood has a significant effect on the lamellar body count. The ease and relatively low cost of this test have contributed to its popularity, although poor concordance among various instruments for the assay of lamellar body counts has been noted.

### Determination of Fetal Pulmonary Maturation in Clinical Practice

As data have been assimilated in recent years related to lung maturity assessment and its role in high-risk pregnancy management, new important paradigms are emerging. Traditionally, lung maturity tests have been interpreted in categorical fashion, usually as either “positive,” indicating lung maturity and a low risk for RDS, or “negative,” indicating the absence of maturity and a higher risk for RDS. However, the presence of RDS in neonates is associated with both gestational age and lung maturity assessments. As further information has been gathered, it is now possible to stratify risk for RDS based on both gestational age and lung maturity assessment. This represents a more appropriate use of the lung maturity tests. **In assessing the risk for RDS complicating subsequent delivery, results from fetal lung maturity testing are most appropriately correlated with the gestational age at the time of fluid retrieval.**

An even more recent paradigm shift that has taken place over the last several years has seen a decrease in the frequency with which fetal lung maturity testing is recommended and used. Both ACOG and the NICHD<sup>32,100</sup> have endorsed increased stringency of indications for late preterm and early term births, which if followed stand to decrease the opportunities for clinical uncertainty around need for delivery and thus decrease the need for fetal lung maturity testing. As noted in the 2011 NICHD publication on this topic, “If significant maternal or fetal risk exists, delivery should occur regardless of biochemical maturity, and if delivery could be deferred owing to the absence of pulmonary maturity, there is not a stringent indication for prompt delivery. Additionally, it is recognized that a mature fetal lung profile denoting the presence of pulmonary surfactant does not necessarily translate to maturity of other organ systems.”<sup>100</sup>

### SUMMARY

We must be aware of our limited understanding of the pathophysiology of fetal death and injury in many situations, and we must attempt judicious use of antenatal testing measures with the hope of preventing some adverse outcomes and with the goal of doing no harm. Although

we assume that by testing and intervening with delivery for abnormal test results we are contributing to a good outcome, as Scifres and Macones<sup>48</sup> stated in their 2008 review of costs and benefits of antenatal testing, “In the absence of data we cannot be assured that our interventions, even if they prevent stillbirth, may not involve a tradeoff between long-term neurologic dysfunction and fetal death.” Additionally, aside from potential unknown medical sequelae of antenatal testing and interventions, monetary, time, and psychological costs must also be considered, but these are difficult to quantify in both research settings and in practice.

As clinicians aim to implement evidence-based strategies to screen for and prevent fetal injury and death, the limitations of existing research must be considered. Because it is in many ways impractical and perhaps unethical to carry out placebo-controlled trials of antenatal testing methodologies in high-risk pregnancies, we must acknowledge that this type of rigorous evidence is not likely to be imminently forthcoming.<sup>2</sup> Nevertheless, we propose that biologic plausibility and clinician judgment prevail over therapeutic nihilism in clinical practice and that future research efforts embrace a creative approach to both condition-specific and apparently unpredictable fetal death and injury.

### KEY POINTS

- ◆ Although the PMR has fallen steadily in the United States since 1965, the number of fetal deaths has not changed substantially in the past decade.
- ◆ Perinatal events play an important role in infant mortality and long-term disability of survivors in addition to their contribution to fetal death.
- ◆ At least 20% of fetal deaths have no obvious fetal, placental, maternal, or obstetric etiology, and this percentage increases with advancing gestational age.
- ◆ The prevalence of an abnormal condition (i.e., fetal death) has great impact on the predictive value of antepartum fetal tests.
- ◆ Few of the antepartum tests commonly used in clinical practice today have been subjected to large-scale prospective and randomized evaluations that can speak to the true efficacy of testing.
- ◆ Fetal adaptation to hypoxemia is mediated by changes in heart rate and redistribution of cardiac output.
- ◆ The decrease in fetal movement with hypoxemia makes maternal assessment of fetal activity a potentially simple and widely applicable method of monitoring fetal well-being. However, prospective trials of this method for prevention of perinatal mortality have failed to conclusively show benefit.
- ◆ The CST has a low false-negative rate but a high false-positive rate and is cumbersome to perform and thus is used less frequently in common practice than other testing modalities.
- ◆ The observation that accelerations of the fetal heart rate in response to fetal activity, uterine contractions, or stimulation reflect fetal well-being is the basis for the NST.

- ◆ Use of VAS for a nonreactive NST or equivocal BPP does not increase the false-negative rate and may reduce the likelihood of unnecessary obstetric intervention.
- ◆ The NST has a low false-negative rate, although higher than that of CST, and a high false-positive rate.
- ◆ Fetal biophysical activities can be evaluated with real-time ultrasonography by BPP, and those fetal biophysical activities that are present earliest in fetal development are the last to disappear with fetal hypoxia.
- ◆ The mBPP performs comparably to the full BPP. Both modalities have a false-negative rate, or rate of fetal death within 1 week of a normal test, of 0.8 per 1000.
- ◆ Most amniotic fluid tests of fetal pulmonary maturation accurately predict pulmonary maturity, but results should be taken in context with anticipated total neonatal maturity as indicated by gestational age.
- ◆ Condition-specific testing involves modifying the frequency, type, and initiation of antenatal tests according to maternal high-risk conditions.
- ◆ Both costs and benefits should be considered when using a particular testing strategy, taking into account competing risks of fetal death and postnatal morbidity.

## OVERVIEW

The initiation of normal labor at term requires endocrine, paracrine, and autocrine signaling between the fetus, uterus, placenta, and the mother. Although the exact trigger for human labor at term remains unknown, it is believed to involve conversion of fetal dehydroepiandrosterone sulfate (DHEAS) to estriol

and estradiol by the placenta. These hormones upregulate transcription of progesterone, progesterone receptors, oxytocin receptors, and gap junction proteins within the uterus, which helps to facilitate regular uterine contractions. The *latent phase* of labor is characterized by a slower rate of cervical dilation, whereas the *active phase* of labor is characterized by a faster rate of cervical dilation and does not begin for most women until the cervix is dilated 6 cm. The duration of the second stage of labor can be affected by a number of factors including epidural use, fetal position, fetal weight, ethnicity, and parity. This chapter will review the characteristics and physiology of normal labor at term. Factors that affect the average duration of the first and second stage of labor progress will be reviewed, and an evidence-based evaluation of strategies to support the mother during labor and facilitate safe delivery of the fetus will be presented.

## LABOR: DEFINITION AND PHYSIOLOGY

**Labor is defined as the process by which the fetus is expelled from the uterus. More specifically, labor requires regular, effective contractions that lead to dilation and effacement of the cervix.** This chapter describes the physiology and normal characteristics of term labor and delivery.

The physiology of labor initiation has not been completely elucidated, but the putative mechanisms have been well reviewed by Liao and colleagues.<sup>1</sup> Labor initiation is species specific, and the mechanisms of human labor are unique. **The four phases of labor from quiescence to involution are outlined in Figure 12-1.**<sup>2</sup> The first phase is **quiescence**, which represents that time in utero before labor begins, when uterine activity is suppressed by the action of progesterone, prostacyclin, relaxin, nitric oxide, parathyroid hormone–related peptide, and possibly other hormones. During the **activation phase**, estrogen begins to facilitate expression of myometrial receptors for prostaglandins (PGs) and oxytocin, which results in ion channel activation and increased gap junctions. This increase in the gap junctions between myometrial cells facilitates effective contractions.<sup>3</sup> In

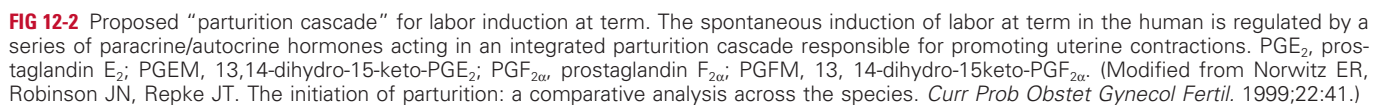

**FIG 12-1** Regulation of uterine activity during pregnancy and labor. (Modified from Challis JRG, Gibb W. Control of parturition. *Prenat Neonat Med.* 1996;1:283.)

essence, the activation phase readies the uterus for the subsequent **stimulation phase**, when uterotonics—particularly PGs and oxytocin—stimulate regular contractions. In the human, this process at term may be protracted, occurring over days to weeks. The final phase, **uterine involution**, occurs after delivery and is mediated primarily by oxytocin. The first three phases of labor require endocrine, paracrine, and autocrine interaction between the fetus, membranes, placenta, and mother.

**The fetus has a central role in the initiation of term labor in nonhuman mammals; in humans, the fetal role is not completely understood (Fig. 12-2).**<sup>2-5</sup> In sheep, term labor is initiated through activation of the fetal hypothalamic-pituitary-adrenal (HPA) axis, with a resultant increase in fetal adrenocorticotrophic hormone (ACTH) and cortisol.<sup>4,5</sup> Fetal cortisol increases production of estradiol and decreases production of progesterone by a shift in placental metabolism of cortisol dependent on placental 17 $\alpha$ -hydroxylase. The change in the circulating progesterone/estradiol concentration stimulates placental production of oxytocin and PG, particularly PGF<sub>2 $\alpha$</sub> , which in turn promotes myometrial contractility.<sup>4</sup> If this increase in fetal ACTH and cortisol is blocked, progesterone levels remain unchanged, and parturition is delayed.<sup>5</sup> In contrast, humans lack placental 17 $\alpha$ -hydroxylase, maternal and fetal levels of progesterone remain elevated, and no trigger exists for parturition because of an increase in fetal cortisol near term. Rather, in humans, evidence suggests that **placental production of corticotropin-releasing hormone (CRH) near term activates the fetal hypothalamic-pituitary axis and results in increased production of dehydroepiandrosterone by the fetal adrenal gland.**<sup>6</sup> Fetal dehydroepiandrosterone is converted in the placenta to estradiol and estriol. Placenta-derived estriol potentiates uterine activity by enhancing the transcription of maternal (likely decidual) PGF<sub>2 $\alpha$</sub> , PG receptors, oxytocin receptors, and gap-junction proteins.<sup>6-8</sup> In

**humans, no documented decrease in progesterone has been observed near term, and a fall in progesterone is not necessary for labor initiation.** However, some research suggests the possibility of a **functional progesterone withdrawal** in humans. Labor is accompanied by a decrease in the concentration of progesterone receptors and a change in the ratio of progesterone receptor isoforms A and B in both the myometrium<sup>9-11</sup> and the membranes.<sup>12</sup> During labor, increased expression of nuclear and membrane progesterone receptor isoforms serve to enhance genomic expression of contraction-associated proteins, increase intracellular calcium, and decrease cyclic adenosine monophosphate (cAMP).<sup>13</sup> More research is needed to elucidate the precise mechanism through which the human parturition cascade is activated. Fetal maturation might play an important role as might maternal cues that affect circadian cycling. Most species have distinct diurnal patterns of contractions and delivery, and in humans, the majority of contractions occur at night.<sup>2,14</sup>

Oxytocin is commonly used for labor induction and augmentation, and a full understanding of the mechanism of oxytocin action is important. **Oxytocin is a peptide hormone synthesized in the hypothalamus and released from the posterior pituitary in a pulsatile fashion. At term, oxytocin serves as a potent uterotonic agent capable of stimulating uterine contractions at intravenous (IV) infusion rates of 1 to 2 mIU/min.**<sup>15</sup> Oxytocin is inactivated largely in the liver and kidney, and during pregnancy, it is degraded primarily by placental oxytocinase. Its biologic half-life is approximately 3 to 4 minutes, but it appears to be shorter when higher doses are infused. Concentrations of oxytocin in the maternal circulation do not change significantly during pregnancy or before the onset of labor, but they do rise late in the second stage of labor.<sup>15,16</sup> Studies of fetal pituitary oxytocin production and the umbilical arteriovenous differences in plasma oxytocin strongly suggest that the fetus secretes oxytocin that reaches the maternal side of

the placenta.<sup>15,17</sup> **The calculated rate of active oxytocin secretion from the fetus increases from a baseline of 1 mIU/min before labor to around 3 mIU/min after spontaneous labor.**

Significant differences in myometrial oxytocin receptor distribution have been reported, with large numbers of fundal receptors and fewer receptors in the lower uterine segment and cervix.<sup>18</sup> Myometrial oxytocin receptors increase on average by 100- to 200-fold during pregnancy and reach a maximum during early labor.<sup>15,16,19,20</sup> This rise in receptor concentration is paralleled by an increase in uterine sensitivity to circulating oxytocin. Specific high-affinity oxytocin receptors have also been isolated from human amnion and decidua parietalis but not decidua vera.<sup>15,18</sup> **It has been suggested that oxytocin plays a dual role in parturition. First, through its receptor, oxytocin directly stimulates uterine contractions. Second, oxytocin may act indirectly by stimulating the amnion and decidua to produce PG.**<sup>18,21-23</sup> **Indeed, even when uterine contractions are adequate, induction of labor at term is successful only when oxytocin infusion is associated with an increase in PGF production.**<sup>18</sup>

Oxytocin binding to its receptor activates phospholipase C.<sup>24</sup> In turn, phospholipase C increases intracellular calcium both by stimulating the release of intracellular calcium and by promoting the influx of extracellular calcium. Oxytocin stimulation of phospholipase C can be inhibited by increased levels of cAMP.<sup>24</sup> Increased calcium levels stimulate the calmodulin-mediated activation of myosin light-chain kinase. Oxytocin may also stimulate uterine contractions via a calcium-independent pathway by inhibiting myosin phosphatase, which in turn increases myosin phosphorylation. **These pathways (of PGF<sub>2α</sub> and intracellular calcium) have been the target of multiple tocolytic agents: indomethacin, calcium channel blockers, β-mimetics (through stimulation of cAMP), and magnesium.**

## MECHANICS OF LABOR

Labor and delivery are not passive processes in which uterine contractions push a rigid object through a fixed aperture. The ability of the fetus to successfully negotiate the pelvis during labor and delivery depends on the complex interactions of three variables: uterine activity, the fetus, and the maternal pelvis. This complex relationship has been simplified in the mnemonic *powers, passenger, passage*.

### Uterine Activity (Powers)

The *powers* refer to the forces generated by the uterine musculature. Uterine activity is characterized by the frequency, amplitude (intensity), and duration of contractions. Assessment of uterine activity may include simple observation, manual palpation, external objective assessment techniques (such as external tocodynamometry), and direct measurement via an intrauterine pressure catheter (IUPC). **External tocodynamometry** measures the change in shape of the abdominal wall as a function of uterine contractions and, as such, is qualitative rather than quantitative. Although it permits graphic display of uterine activity and allows for accurate correlation of fetal heart rate (FHR) patterns with uterine activity, external tocodynamometry does not allow measurement of contraction intensity or basal intrauterine tone. **The most precise method for determination of uterine activity is the direct measurement of intrauterine pressure with an IUPC.** However, this procedure should not be performed unless indicated given the small but

finite associated risks of uterine perforation, placental disruption, and intrauterine infection.

Despite technologic improvements, the definition of “adequate” uterine activity during labor remains unclear. **Classically, three to five contractions in 10 minutes has been used to define adequate labor; this pattern has been observed in approximately 95% of women in spontaneous labor.** In labor, patients usually contract every 2 to 5 minutes, with contractions becoming as frequent as every 2 to 3 minutes in late active labor and during the second stage. Abnormal uterine activity can also be observed either spontaneously or as a result of iatrogenic interventions. **Tachysystole is defined as more than five contractions in 10 minutes averaged over 30 minutes. If tachysystole occurs, documentation should note the presence or absence of FHR decelerations. The term hyperstimulation should no longer be used.**<sup>25</sup>

Various units of measure have been devised to objectively quantify uterine activity, the most common of which is the *Montevideo unit* (MVU), a measure of average frequency and amplitude above basal tone (the average strength of contractions in millimeters of mercury multiplied by the number of contractions per 10 min). Although 150 to 350 MVU has been described for adequate labor, 200 to 250 MVU is commonly accepted to define adequate labor in the active phase.<sup>26,27</sup> No data identify adequate forces during latent labor. Although it is generally believed that optimal uterine contractions are associated with an increased likelihood of vaginal delivery, data are limited to support this assumption. **If uterine contractions are “adequate” to effect vaginal delivery, one of two things will happen: either the cervix will efface and dilate, and the fetal head will descend, or caput succedaneum (scalp edema) and molding of the fetal head (overlapping of the skull bones) will worsen without cervical effacement and dilation. The latter situation suggests the presence of cephalopelvic disproportion (CPD), which can be either *absolute*, in which the fetus is simply too large to negotiate the pelvis, or *relative*, in which delivery of the fetus through the pelvis would be possible under optimal conditions but is precluded by malposition or abnormal attitude of the fetal head.**

### Fetus (Passenger)

The passenger, of course, is the fetus. Several fetal variables influence the course of labor and delivery. **Fetal size** can be estimated clinically by abdominal palpation or ultrasound or by asking a multiparous patient about her best estimate, but all of these methods are subject to a large degree of error. **Fetal macrosomia** is defined by the American College of Obstetricians and Gynecologists (ACOG) as birthweight greater than or equal to the 90th percentile for a given gestational age or greater than 4500 g for any gestational age,<sup>28</sup> and it is associated with an increased likelihood of planned cesarean delivery, labor dystocia, cesarean delivery after a failed trial of labor, shoulder dystocia, and birth trauma.<sup>29</sup> **Fetal lie** refers to the longitudinal axis of the fetus relative to the longitudinal axis of the uterus. Fetal lie can be longitudinal, transverse, or oblique (Fig. 12-3). In a singleton pregnancy, only fetuses in a longitudinal lie can be safely delivered vaginally.

**Presentation** refers to the fetal part that directly overlies the pelvic inlet. In a fetus presenting in the longitudinal lie, the presentation can be cephalic (vertex) or breech. *Compound presentation* refers to the presence of more than one fetal part overlying the pelvic inlet, such as a fetal hand and the vertex. *Funic*

*presentation* refers to presentation of the umbilical cord and is rare at term. In a cephalic fetus, the presentation is classified according to the leading bony landmark of the skull, which can be either the occiput (vertex), the chin (mentum), or the brow (Fig. 12-4). **Malpresentation**, a term that refers to any presentation other than vertex, is seen in approximately 5% of all term labors (see Chapter 17).

FIG 12-3 Examples of fetal lie.

**Attitude** refers to the position of the head with regard to the fetal spine (the degree of flexion and/or extension of the fetal head). Flexion of the head is important to facilitate **engagement** of the head in the maternal pelvis. When the fetal chin is optimally flexed onto the chest, the **suboccipitobregmatic diameter** (9.5 cm) presents at the pelvic inlet (Fig. 12-5). This is the smallest possible presenting diameter in the cephalic presentation. As the head deflexes (extends), the diameter presenting to the pelvic inlet progressively increases even before the malpresentations of brow and face are encountered (see Fig. 12-5) and may contribute to failure to progress in labor. The

FIG 12-5 Presenting diameters of the average term fetal skull.

**FIG 12-6** Fetal presentations and positions in labor. LOA, left occiput anterior; LOP, left occiput posterior; LOT, left occiput transverse; ROA, right occiput anterior; ROT, right occiput transverse; ROP, right occiput posterior. (Modified from Norwitz ER, Robinson J, Repke JT. The initiation and management of labor. In Seifer DB, Samuels P, Kniss DA, eds. *The Physiologic Basis of Gynecology and Obstetrics*. Philadelphia: Lippincott, Williams & Wilkins; 2001.)

architecture of the pelvic floor along with increased uterine activity may correct deflexion in the early stages of labor.

**Position of the fetus refers to the relationship of the fetal presenting part to the maternal pelvis, and it can be assessed most accurately on vaginal examination.** For *cephalic presentations*, the fetal occiput is the reference: if the occiput is directly anterior, the position is occiput anterior (OA); if the occiput is turned toward the mother's right side, the position is right occiput anterior (ROA). In the *breech presentation*, the sacrum is the reference (right sacrum anterior). The various positions of a cephalic presentation are illustrated in Figure 12-6. In a *vertex presentation*, position can be determined by palpation of the fetal sutures: the sagittal suture is the easiest to palpate, but palpation of the distinctive lambdoid sutures should identify the position of the fetal occiput; the frontal suture can also be used to determine the position of the front of the vertex.

Most commonly, the fetal head enters the pelvis in a transverse position and then, as a normal part of labor, it rotates to an OA position. Most fetuses deliver in the OA, left occiput anterior (LOA), or ROA position. **Malposition** refers to any position in labor that is not in the above three categories. In the past, fewer than 10% of presentations were occiput posterior (OP) at delivery.<sup>30</sup> However, epidural analgesia may be an independent risk factor for persistent OP presentation in labor. In an observational cohort study, OP presentation was observed in 12.9% of women with epidurals compared with 3.3% of controls ( $P = .002$ ).<sup>31</sup> In a Cochrane meta-analysis of four randomized controlled trials (RCTs), malposition was 40% more likely for women with an epidural compared with controls; however, this difference was not statistically significant, and more RCTs are needed (odds ratio [OR] 1.40; 95% confidence interval [CI],

0.98 to 1.99).<sup>32</sup> **Asynclitism** occurs when the sagittal suture is not directly central relative to the maternal pelvis. If the fetal head is turned such that more parietal bone is present posteriorly, the sagittal suture is more anterior; this is referred to as *posterior asynclitism*. In contrast, *anterior asynclitism* occurs more parietal bone presents anteriorly. The occiput transverse (OT) and OP positions are less common at delivery and are more difficult to deliver.

**Station is a measure of descent of the bony presenting part of the fetus through the birth canal (Fig. 12-7).** The current standard classification (−5 to +5) is based on a quantitative measure in centimeters of the distance of the leading bony edge from the ischial spines. The *midpoint* (0 station) is defined as the plane of the maternal ischial spines. The ischial spines can be palpated on vaginal examination at approximately 8 o'clock and 4 o'clock. For the right-handed person, they are most easily felt on the maternal right.

An abnormality in any of these fetal variables may affect both the course of labor and the route of delivery. For example, OP presentation is well known to be associated with longer labor, operative vaginal delivery, and an increased risk of cesarean delivery.<sup>31,33</sup>

### Maternal Pelvis (Passage)

**The passage consists of the bony pelvis—composed of the sacrum, ilium, ischium, and pubis—and the resistance provided by the soft tissues.** The bony pelvis is divided into the *false* (greater) and *true* (lesser) pelvis by the pelvic brim, which is demarcated by the sacral promontory, the anterior ala of the sacrum, the arcuate line of the ilium, the pectineal line of the pubis, and the pubic crest culminating in the symphysis

**FIG 12-7** The relationship of the leading edge of the presenting part of the fetus to the plane of the maternal ischial spines determines the station. Station +1/+3 (old classification), or +2/+5 (new classification), is illustrated.

(Fig. 12-8). Measurements of the various parameters of the bony female pelvis have been made with great precision, directly in cadavers and using radiographic imaging in living women. Such measurements have divided the true pelvis into a series of planes that must be negotiated by the fetus during passage through the birth canal, which can be broadly termed the *pelvic inlet*, *mid-pelvis*, and *pelvic outlet*. Pelvimetry performed with radiographic computed tomography (CT) or magnetic resonance imaging (MRI) has been used to determine average and **critical limit values** for the various parameters of the bony pelvis (Table 12-1).<sup>34,35</sup> Critical limit values are measurements that may be

\*The critical limit values cited imply a high likelihood of cephalopelvic disproportion.

**FIG 12-8** Superior (A) and anterior (B) view of the female pelvis. (From Repke JT. *Intrapartum Obstetrics*. New York: Churchill Livingstone; 1996:68.)

associated with a significant probability of CPD depending upon fetal size and gestational age.<sup>34</sup> However, subsequent studies were unable to demonstrate threshold pelvic or fetal cutoff values with sufficient sensitivity or specificity to predict CPD and the subsequent need for cesarean delivery prior to the onset of labor.<sup>36,37</sup> **In current obstetric practice, radiographic CT and MRI pelvimetry are rarely used given the lack of evidence of benefit and some data that show possible harm (increased incidence of cesarean delivery); instead, a clinical trial of the pelvis (labor) is used.** The remaining indications for radiography, CT pelvimetry, or MRI are evaluation for vaginal breech delivery or evaluation of a woman who has suffered a significant pelvic fracture.<sup>38</sup>

**Clinical pelvimetry is currently the only method of assessing the shape and dimensions of the bony pelvis in labor.**<sup>36</sup> A useful protocol for clinical pelvimetry is detailed in Figure 12-9 and involves assessment of the pelvic inlet, midpelvis, and pelvic outlet. Reported average and critical-limit pelvic diameters may be used as a historical reference during the clinical examination to determine pelvic shape and assess risk for CPD. The inlet of the true pelvis is largest in its transverse diameter and averages 13.5 cm.<sup>36</sup> The *diagonal conjugate*, the distance from the sacral promontory to the inferior margin of the symphysis pubis as assessed on vaginal examination, is a clinical representation of the anteroposterior (AP) diameter of the pelvic inlet. The *true conjugate, or obstetric conjugate*, of the pelvic inlet is the distance from the sacral promontory to the superior aspect of the symphysis pubis. The obstetric conjugate has an average value of 11 cm and is the smallest diameter of the inlet. It is considered to be contracted if it measures less than 10 cm.<sup>36</sup> The obstetric conjugate cannot be measured clinically but can be estimated by subtracting 1.5 to 2.0 cm from the *diagonal conjugate*, which has an average distance of 12.5 cm.

**The limiting factor in the midpelvis is the transverse interspinous diameter** (the measurement between the ischial spines), which is usually the smallest diameter of the pelvis but should be greater than 10 cm. The pelvic outlet is rarely of clinical significance, however. The average pubic angle is greater than 90 degrees and will typically accommodate two fingerbreadths.<sup>36</sup> The AP diameter from the coccyx to the symphysis pubis is approximately 13 cm in most cases, and the transverse diameter between the ischial tuberosities is approximately 8 cm and will typically accommodate four knuckles (see Fig. 12-9).

**The shape of the female bony pelvis can be classified into four broad categories: gynecoid, anthropoid, android, and platypelloid (Fig. 12-10).** This classification is based on the radiographic studies of Caldwell and Moloy<sup>39</sup> and separates those with more favorable characteristics (gynecoid, anthropoid) from those less favorable for vaginal delivery (android, platypelloid). In reality, however, many women fall into intermediate classes, and the distinctions become arbitrary. **The gynecoid pelvis is the classic female shape. The anthropoid pelvis—with its exaggerated oval shape of the inlet, largest AP diameter, and limited anterior capacity—is more often associated with delivery in the OP position. The android pelvis is male in pattern and theoretically has an increased risk of CPD, and the broad and flat platypelloid pelvis theoretically predisposes to a transverse arrest.** Although the assessment of fetal size, along with pelvic shape and capacity, is still of clinical utility, it is a very inexact science. **An adequate trial of labor is**

**the only definitive method to determine whether a fetus will be able to safely negotiate through the pelvis.**

Pelvic soft tissues may provide resistance in both the first and second stages of labor. In the first stage, resistance is offered primarily by the cervix, whereas in the second stage, it is offered by the muscles of the pelvic floor. In the second stage of labor, the resistance of the pelvic musculature is believed to play an important role in the rotation and movement of the presenting part through the pelvis.

## CARDINAL MOVEMENTS IN LABOR

The *cardinal movements* refer to changes in the position of the fetal head during its passage through the birth canal. Because of the asymmetry of the shape of both the fetal head and the maternal bony pelvis, such rotations are required for the fetus to successfully negotiate the birth canal. **Although labor and birth comprise a continuous process, seven discrete cardinal movements are described: (1) engagement, (2) descent, (3) flexion, (4) internal rotation, (5) extension, (6) external rotation or restitution, and (7) expulsion (Fig. 12-11).**

### Engagement

**Engagement refers to passage of the widest diameter of the presenting part to a level below the plane of the pelvic inlet (Fig. 12-12).** In the cephalic presentation with a well-flexed head, the largest transverse diameter of the fetal head is the biparietal diameter (9.5 cm). In the breech, the widest diameter is the bitrochanteric diameter. Clinically, engagement can be confirmed by palpation of the presenting part both abdominally and vaginally. **With a cephalic presentation, engagement is achieved when the presenting part is at zero station on vaginal examination.** Engagement is considered an important clinical prognostic sign because it demonstrates that, at least at the level of the pelvic inlet, the maternal bony pelvis is sufficiently large to allow descent of the fetal head. In nulliparas, engagement of the fetal head usually occurs by 36 weeks' gestation; however, in multiparas engagement can occur later in gestation or even during the course of labor.

### Descent

**Descent refers to the downward passage of the presenting part through the pelvis. Descent of the fetus is not continuous; the greatest rates of descent occur in the late active phase and during the second stage of labor.**

### Flexion

**Flexion of the fetal head occurs passively as the head descends owing to the shape of the bony pelvis and the resistance offered by the soft tissues of the pelvic floor.** Although flexion of the fetal head onto the chest is present to some degree in most fetuses before labor, complete flexion usually occurs only during the course of labor. **The result of complete flexion is to present the smallest diameter of the fetal head (the suboccipitobregmatic diameter) for optimal passage through the pelvis.**

### Internal Rotation

**Internal rotation refers to rotation of the presenting part from its original position as it enters the pelvic inlet (usually OT) to the AP position as it passes through the pelvis.** As with flexion, internal rotation is a passive movement that results from the shape of the pelvis and the pelvic floor musculature.

**FIG 12-10** Characteristics of the four types of female bony pelvis. (Modified from Callahan TL, Caughey AB, Heffner LJ, eds. *Blueprints in Obstetrics and Gynecology*. Malden, MA: Blackwell Science; 1998;45.)

The pelvic floor musculature, including the coccygeus and ileo-coccygeus muscles, forms a V-shaped “hammock” that diverges anteriorly. As the head descends, the occiput of the fetus rotates toward the symphysis pubis—or, less commonly, toward the hollow of the sacrum—thereby allowing the widest portion of the fetus to negotiate the pelvis at its widest dimension. Owing to the angle of inclination between the maternal lumbar spine and pelvic inlet, the fetal head engages in an asynclitic fashion (i.e., with one parietal eminence lower than the other). With uterine contractions, the leading parietal eminence descends and is first to engage the pelvic floor. As the uterus relaxes, the pelvic floor musculature causes the fetal head to rotate until it is no longer asynclitic.

## Extension

**Extension occurs once the fetus has descended to the level of the introitus.** This descent brings the base of the occiput into contact with the inferior margin at the symphysis pubis. At this point, the birth canal curves upward. The fetal head is delivered by extension and rotates around the symphysis pubis. The forces responsible for this motion are the downward force exerted on the fetus by the uterine contractions along with the upward forces exerted by the muscles of the pelvic floor.

## External Rotation

External rotation, also known as *restitution*, refers to the return of the fetal head to the correct anatomic position in relation to the fetal torso. This can occur to either side

depending on the orientation of the fetus; this is again a passive movement that results from a release of the forces exerted on the fetal head by the maternal bony pelvis and its musculature and mediated by the basal tone of the fetal musculature.

## Expulsion

**Expulsion refers to delivery of the rest of the fetus.** After delivery of the head and external rotation, further descent brings the anterior shoulder to the level of the symphysis pubis. **The anterior shoulder is delivered in much the same manner as the head, with rotation of the shoulder under the symphysis pubis.** After the shoulder, the rest of the body is usually delivered without difficulty.

## NORMAL PROGRESS OF LABOR

Progress of labor is measured with multiple variables. With the onset of regular contractions, the fetus descends in the pelvis as the cervix both effaces and dilates. With each vaginal examination to judge labor progress, the clinician must assess not only cervical effacement and dilation but fetal station and position. This assessment depends on skilled digital palpation of the maternal cervix and the presenting part. As the cervix dilates in labor, it thins and shortens—or becomes more *effaced*—over time. Cervical *effacement* refers to the length of the remaining cervix and can be reported in length or as a percentage. If percentage is used, 0% effacement at term refers to at least a 2 cm long or a very thick

**FIG 12-11** Cardinal movements of labor.

FIG 12-12 Engagement of the fetal head.

cervix, and 100% effacement refers to no length remaining or a very thin cervix. Most clinicians use percentages to follow cervical effacement during labor. Generally, 80% or greater effacement is observed in women who are in active labor. Dilation, perhaps the easiest assessment to master, ranges from closed (no dilation) to complete (10 cm dilated). For most women, a cervical dilation that accommodates a single index finger is equal to 1 cm, and two index fingers' dilation is equal to 3 cm. If no cervix can be palpated around the presenting part, the cervix is 10 cm or completely dilated. The assessment of station, discussed earlier, is important for documentation of progress, but it is also critical when determining if an operative vaginal delivery is feasible. Fetal head position should be regularly determined once the woman is in active labor; ideally, this should occur before significant caput has developed, which obscures the sutures. Like station, knowledge of the fetal position is critical before performing an operative vaginal delivery (see Chapter 14).

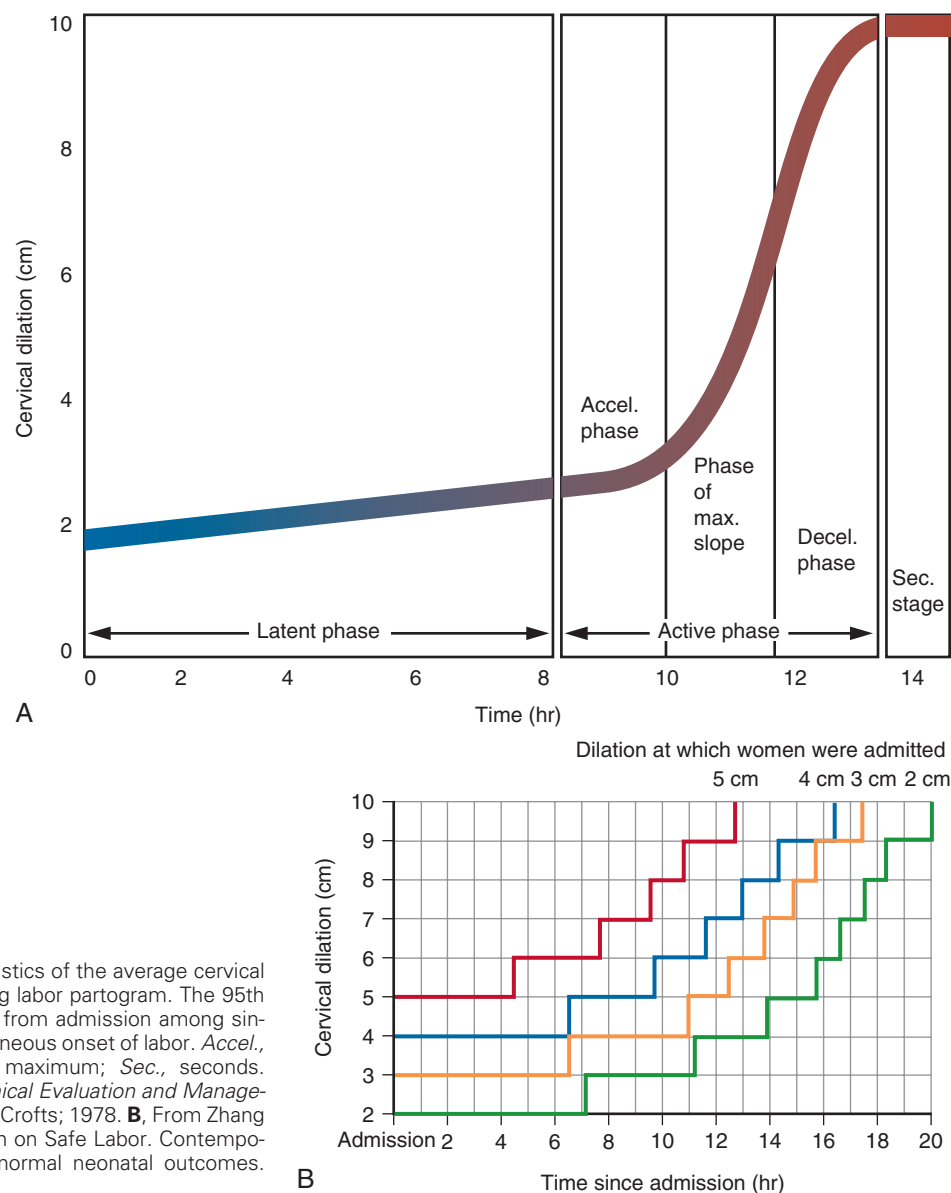

**Labor occurs in three stages: the first stage is from labor onset until full dilation of the cervix; the second stage is from full cervical dilation until delivery of the baby; and the third stage begins with delivery of the baby and ends with delivery of the placenta.** The first stage of labor is divided into two phases: the first is the *latent phase*, and the second is the *active phase*. The *latent phase* begins with the onset of labor and is characterized by regular, painful uterine contractions and a slow rate of cervical change. When the rate of cervical dilation is accelerated, latent labor ends and active labor begins. Labor onset is a retrospective diagnosis that is difficult to identify objectively. It is defined by the initiation of regular painful contractions of sufficient duration and intensity to result in cervical dilation or effacement. Women are frequently at home during this time; therefore the identification of labor onset depends on patient memory and the timing of contractions in relation to the cervical examination. **The active phase of labor is defined as the period in which the greatest rate of cervical dilation occurs.** Identification of the point at which labor transitions from the latent to the active phase will depend upon the frequency of cervical examinations and retrospective

examination of labor progress. **Historically, based upon Friedman's<sup>40</sup> seminal data on cervical dilation and labor progress from the 1950s and 1960s, active labor required 80% or more effacement and 4 cm or greater dilation of the cervix.** He analyzed labor progress in 500 nulliparous and multiparous women and reported normative data that have been used for more than half a century to define our expectations of normal and abnormal labor.<sup>40,41</sup>

Friedman revolutionized our understanding of labor because he was able to plot static observations of cervical dilation against time and successfully translate the dynamic process of labor into a sigmoid-shaped curve (Fig. 12-13). Friedman's data popularized the use of the labor graph, which first depicted only cervical dilation and was then later modified to include fetal descent.<sup>42</sup> Four-centimeter cervical dilation marks the transition from the latent to the active phase because it corresponds to the flexion point on the averaged labor curve generated from a review of 500 individual labor curves in the original Friedman dataset.<sup>40</sup> **Rates of 1.5 and 1.2 cm dilation per hour in the active phase for multiparous and nulliparous women, respectively, represent the 5th percentile of normal.<sup>41</sup> These data have led to the general concept that in active labor, a rate of dilation of at least 1 cm per hour should occur.**

More recent analysis of contemporary labor from several studies challenges our understanding of the cervical dilation at which active labor occurs and suggests that the transition from the latent phase to the active phase of labor is a more gradual process.<sup>43</sup> An analysis of labor curves for 1699 multiparous and nulliparous women who presented in spontaneous labor at term and underwent a vaginal delivery determined that only half of the women with a cervical dilation of 4 cm were in the active phase.<sup>44</sup> By 5 cm of cervical dilation, 75% of the women were in the active phase, and by 6 cm cervical dilation, 89% of the women were in the active phase.<sup>44</sup> Zhang and colleagues<sup>45</sup> reviewed data from the National Collaborative Perinatal Project, a historic cohort of 26,838 term parturients in spontaneous labor from 1959 through 1966. This study used a repeated measures analysis to construct labor curves for parturients whose intrapartum management was similar to those studied by Friedman in the 1950s. The cesarean delivery rate was 5.6%, and only 20% of nulliparas and 12% of multiparas received oxytocin for labor augmentation. **This study determined that labor progress in nulliparous women who ultimately had a vaginal delivery is in fact slower than previously reported until 6 cm of cervical dilation.<sup>45</sup>** Specifically, most nulliparous women were not in active labor until approximately 5 to 6 cm of cervical dilation, and the slope of labor progress did not increase until after 6 cm. These findings were confirmed in an analysis<sup>46</sup> of contemporary data collected prospectively by the Consortium on Safe Labor, which enrolled and followed 62,415 singleton term parturients who presented in spontaneous labor at 19 institutions from 2002 through 2007. This dataset included a greater percentage of women with oxytocin augmentation (45% to 47%) and epidural analgesia (71% to 84%) compared with those studied by Friedman in the 1950s. Zhang and colleagues<sup>45</sup> reported the median and 95th percentile of time to progress from one centimeter to the next and confirmed that labor may take more than 6 hours to progress from 4 to 5 cm and more than 3 hours to progress from 5 to 6 cm regardless of parity (Table 12-2). Multiparas had a faster rate of cervical dilation compared with nulliparas only after 6 cm of cervical dilation had been reached. **These data suggest that it**

\*Median elapsed time in hours (95th percentile). An interval-censored regression model was used to estimate the distribution of time for progression from one centimeter to the next with the assumption of log normal distribution of the labor data.

would be more appropriate to utilize a threshold of 6 cm cervical dilation to define active phase labor onset and that the rate of cervical dilation for nulliparas at the 95th percentile of normal may be greater than the 1 cm per hour previously expected. These are important findings that suggest clinicians using the Friedman dataset to determine the threshold for active labor may be diagnosing active phase arrest prematurely, which could result in unnecessary cesarean deliveries (see Chapter 13).<sup>3,42,45,46</sup>

The labor partogram commonly in use today was based upon the graph introduced in 1964 by Schulman and Ledger,<sup>47</sup> in which labor progression focused on latent and active phase only. Another and perhaps better approach, based upon contemporary data from the Consortium on Safe Labor,<sup>46</sup> is shown in Figure 12-13, along with the modified Friedman curve. The Zhang partogram (see Fig. 12-13, B) graphically depicts the 95th percentile of the duration of labor in hours stratified by cervical dilation on admission. Cervical dilation is not recorded as a continuous measure, and as a result, interval

**TABLE 12-3** SUMMARY OF MEANS AND 95TH PERCENTILES FOR DURATION OF FIRST- AND SECOND-STAGE LABOR

| PARAMETER              | MEAN       | 95TH PERCENTILE |
|------------------------|------------|-----------------|
| <b>Nulliparas</b>      |            |                 |
| Latent labor           | 7.3-8.6 hr | 17-21 hr        |
| First stage            | 6-13.3 hr  | 16.6-30 hr      |
| Second stage           | 36-57 min  | 122-197 min     |
| Second stage, epidural | 79 min     | 336 min         |
| <b>Multiparas</b>      |            |                 |
| Latent labor           | 4.1-5.3 hr | 12-14 hr        |
| First stage            | 5.7-7.5 hr | 12.5-13.7 hr    |
| Second stage           | 17-19 min  | 57-81 min       |
| Second stage, epidural | 45 min     | 255 min         |

Data from references 40-41, 46, and 52-55.

cervical change over time is depicted in a stair-step pattern. The Zhang partogram may be more appropriate for the identification of those parturients with a duration of labor that exceeds the 95th percentile of normal. Its clinical utility, however, has yet to be confirmed and validated.

Factors that affect the duration of labor include parity, maternal body mass index (BMI), fetal position, maternal age, and fetal size. Longer labors are associated with increased maternal BMI,<sup>48</sup> fetal position other than OA,<sup>49</sup> and older maternal age.<sup>5,50,51</sup> Data conflict in regard to the effect of epidural use on the duration of the first stage of labor. Retrospective cohort studies have suggested that epidural use may significantly increase the duration of the first stage of labor.<sup>47,52,53</sup> However, a Cochrane meta-analysis of 11 RCTs did not identify a statistically significant difference in the mean length of the first stage of labor in women randomized to epidural analgesia compared with those who went without (average mean difference [MD] 18.51 min; 95% CI, -12.91 to 49.92).<sup>32</sup> Additional studies are needed to confirm the effect of epidural use on the 95th percentile duration for the first stage of normal labor. Table 12-3 summarizes the means and 95th percentile duration of first- and second-stage labor that have been reported.<sup>40,41,46,47,52-55</sup>

Factors significantly associated with a prolonged second stage included induced labor, chorioamnionitis, older maternal age, OP position, delayed pushing, nonblack ethnicity, epidural analgesia, and parity of five or more.<sup>50,56</sup> Of note, Friedman's second-stage lengths are somewhat artificial because most nulliparous women in that era had a forceps delivery once the duration of the second stage reached 2 hours. More recent labor duration data that evaluated women in spontaneous labor without augmentation or operative delivery from multiple countries report similar mean labor durations, which suggests that these normative data are reliable and useful (see Table 12-3). A Cochrane meta-analysis<sup>32</sup> of 13 RCTs confirmed that epidural use significantly increased the mean duration of the second stage compared with no epidural (average MD in second stage length with an epidural, 13.66 min; 95% CI, 6.67 to 20.66 min). According to the ACOG/Society for Maternal-Fetal Medicine (SMFM) obstetric care consensus,<sup>57</sup> it is important to consider not just the mean or median duration of the second stage with epidural analgesia but also the 95th percentile duration. In a recent large retrospective cohort study of 33,239 women with term spontaneous vaginal deliveries, an epidural was associated with an increase in the 95th percentile duration of the second stage in nulliparous women by 94 minutes ( $P < .001$ ).<sup>54</sup> For multiparous women with a spontaneous vaginal delivery, an

epidural increased the 95th percentile duration of the second stage by 102 minutes ( $P < .001$ ; see Chapter 16).<sup>54</sup> Determination of the upper limits of time for normal second-stage labor that incorporates epidural use and other more contemporary labor interventions are helpful in identifying normative values for labor duration that are associated with the lowest risk of maternal and neonatal morbidity.<sup>52,53,58</sup>

The third stage of labor is generally short. In a case series of nearly 13,000 singleton vaginal deliveries at greater than 20 weeks' gestation, the median third-stage duration was 6 minutes and exceeded 30 minutes in only 3% of women.<sup>59</sup> However, third stages lasting greater than 30 minutes were associated with significant maternal morbidity that included an increased risk of blood loss greater than 500 mL, a decrease in postpartum hematocrit by greater than or equal to 10%, need for dilation and curettage, and a sixfold increased risk of postpartum hemorrhage.<sup>59,60</sup> These data suggest that if spontaneous separation does not occur, manual removal and/or extraction of the placenta should be considered after 30 minutes to reduce the risk of maternal hemorrhage. The factors associated with a prolonged third stage of labor include preterm delivery, preeclampsia, labor augmentation, nulliparity, maternal age over 35 years, and a second-stage labor duration greater than 2 hours.<sup>61,62</sup> Several strategies to minimize the risk of postpartum hemorrhage for women in the third stage of labor have been recommended and include early administration of a uterotonic agent after delivery of the anterior fetal shoulder, early cord clamping, controlled traction on the umbilical cord, and fundal massage to facilitate early placental separation.<sup>63,64</sup> A Cochrane meta-analysis<sup>63</sup> of seven randomized to quasi-randomized controlled studies found that for a heterogeneous population of women at mixed risk of bleeding, active management of the third stage of labor was associated with a significant reduction in blood loss over 1000 mL (relative risk [RR], 0.34; 95% CI, 0.14 to 0.87) and a lower risk of anemia (hemoglobin [Hgb], <9 g/dL; average RR, 0.50; 95% CI, 0.30 to 0.83). However, a significant reduction in neonatal birthweight was reported, likely due to early cord clamping and reduced time for placental transfusion. In women at low risk for postpartum hemorrhage, active management of labor was not associated with a significant reduction in the risk of maternal hemorrhage (blood loss >500 mL) or maternal anemia (Hgb <9 g/dL) compared with women who were expectantly managed.<sup>65</sup>

## Interventions That Affect Normal Labor Outcomes

Various interventions have been suggested to promote normal labor progress, including maternal ambulation and upright maternal positioning during active labor.<sup>65,66</sup> A well-designed randomized trial<sup>65</sup> of over 1000 low-risk women in early labor at 3- to 5-cm cervical dilation compared ambulation with usual care and found no differences in the duration of the first stage, need for oxytocin, use of analgesia, neonatal outcomes, or route of delivery. These results suggest that given appropriate staffing resources and fetal surveillance protocols, walking in the first stage of labor is an option that may be considered for low-risk women. A Cochrane review of 25 randomized to quasi RCTs of considerable heterogeneity found that in low-risk nulliparous women, upright rather than recumbent positioning during labor was associated with a significantly shorter first stage of labor by 1 hour and 22 minutes (average MD, -1.36; 95% CI, -2.22 to -0.51), less epidural use, and

**a reduction in the risk of cesarean delivery by 30% (RR, 0.71; 95% CI, 0.54 to 0.94).**<sup>66</sup> Women should be encouraged to consider upright positioning in labor, and the potential benefits should be discussed to facilitate informed decision making. In a Cochrane review<sup>67</sup> of 22 trials that involved 15,288 low-risk women randomized to continuous labor support (doula) compared with routine care, **the presence of a labor doula was associated with a significant reduction in the use of analgesia, oxytocin, and operative vaginal delivery (RR, 0.90; 95% CI, 0.85 to 0.96) or cesarean delivery (RR, 0.78; 95% CI, 0.67 to 0.91) and an increase in personal satisfaction.** These data were compelling enough for doula support to receive an A rating, meaning that it should be recommended for use during labor.<sup>68</sup> Other models of **continuous labor support with a friend or family member should be encouraged** if a doula is unavailable.

The benefits of IV hydration in labor have been less well studied. The use of IV fluids is a routine practice in many labor and delivery units, although its benefit compared with oral hydration has not been well elucidated, and the volume and type of IV fluid that may promote optimal progress in labor is unclear. A Cochrane review<sup>69</sup> of nine randomized trials included studies of considerable heterogeneity. Two trials compared women randomized to receive up to 250 mL/hr of Ringer's lactate solution and oral intake versus oral intake alone. No difference was found in the cesarean delivery rate. However, a reduced duration of labor was reported for women with a vaginal delivery who received Ringer's lactate (MD, -28.86 min; 95% CI, -47.41 to -10.30). Four trials compared rates of IV fluids (125 mL/hr vs. 250 mL/hr) in women whose oral intake was restricted, and a significant reduction in the duration of labor was reported in women who received IV fluid at 250 mL/hr.<sup>69</sup> With regard to the type of IV fluid, in a randomized trial of nulliparas in active labor, IV administration at 125 mL/min of dextrose in normal saline (NS) was associated with a significant reduction in labor length and in second-stage length compared with normal saline.<sup>70</sup> Although **the available data suggest that IV fluid is beneficial in labor**, additional studies are needed to determine the risks and benefits of appropriate oral hydration. Furthermore, the optimal volume of fluid replacement in labor from all sources, oral and IV, is unclear.

### Active Management of Labor

**Dystocia refers to a lack of progress of labor for any reason, and it is the most common indication for cesarean delivery (CD) in nulliparous women and the second most common indication for CD in multiparous women.** In the late 1980s, in an effort to reduce the rapidly rising rate of CD, active management of labor was popularized in the United States based on findings in Ireland, where the routine use of active management was associated with very low rates of CD.<sup>71</sup> **Protocols for active management included (1) admission only when labor was established, evidenced by painful contractions and spontaneous rupture of membranes, 100% effacement, or passage of blood-stained mucus; (2) artificial rupture of membranes on diagnosis of labor; (3) aggressive oxytocin augmentation for labor progress of less than 1 cm/hr with high-dose oxytocin (6 mIU/min initial dose, increased by 6 mIU/min every 15 min to a maximum of 40 mIU/min); and (4) patient education.**<sup>71</sup> Observational data suggested that this management protocol was associated with rates of CD of 5.5% and delivery within 12 hours in 98% of women.<sup>71</sup> Only 41% of the nulliparas

actually required oxytocin augmentation. Multiple nonrandomized studies were subsequently published that attempted to duplicate these results in the United States and Canada.<sup>72-75</sup> Two of these reported a significant reduction in cesarean delivery when compared with historical controls.<sup>72,74</sup> However, in two of three RCTs, no significant decrease in the rate of cesarean delivery was observed with active compared with routine management of labor.<sup>76-77</sup> In the third RCT, the overall CD rate was not significantly different. However, when confounding variables were controlled, CD was significantly lower in the actively managed group.<sup>75</sup> In all randomized trials, labor duration was significantly decreased by a range of 1.7 to 2.7 hours, and neonatal morbidity was not different between groups. **In a recent Cochrane review,<sup>78</sup> a meta-analysis of 11 trials (7753 women) concluded that early oxytocin augmentation in women with spontaneous labor was associated with a significant decrease in CD (RR, 0.87; 95% CI, 0.77 to 0.99).** A meta-analysis of eight trials (4816 women) determined that early amniotomy and oxytocin augmentation was associated with a significantly shortened duration of labor (average MD, 1.28 hr; 95% CI, -1.97 to -0.59).<sup>78</sup> Of note, amniotomy alone did not affect labor length or the rate of CD. This reduction in labor duration has significant cost and bed-management implications, especially for busy labor and delivery units. **Perhaps the most important factor in active management is delaying admission until active labor has been established.**

### Second Stage of Labor

**Abnormal progress in fetal descent is the dystocia of the second stage.** A wide range of mean and 95th percentile second-stage labor durations have been reported for vaginal deliveries and are influenced by parity, presence or absence of epidural analgesia, and local or regional practice patterns (see Table 12-3). According to the summary of a National Institutes of Health (NIH)-sponsored workshop on prevention of the first cesarean, **no specific threshold maximum second-stage duration exists beyond which all women should undergo operative vaginal delivery.**<sup>79</sup> However, a direct correlation has been found between second-stage duration, adverse maternal outcomes (hemorrhage, infection, perineal lacerations), and the likelihood of a successful vaginal delivery.<sup>80</sup> A secondary analysis<sup>42</sup> of a multicenter study on fetal pulse oximetry compared second-stage duration with maternal and perinatal outcomes in 4126 nulliparous women. Chorioamnionitis (overall rate, 3.9%), third- and fourth-degree lacerations (overall rate, 8.7%), and uterine atony (overall rate, 3.9%; combined OR, 1.31 to 1.60; 95% CI, 1.14 to 1.86) were significantly increased with longer second-stage duration. Adverse maternal outcomes with longer labor duration in multiparous women have also been reported.<sup>81,82</sup> In regard to the correlation between adverse neonatal outcomes and longer second-stage lengths, the reports are mixed; one study reported a lack of association between neonatal outcomes and the duration of the second stage of labor in nulliparous women.<sup>80,83-85</sup> However, in a study of 43,810 nulliparas in the second stage of labor, **second-stage lengths of greater than 3 hours were associated with increased maternal and neonatal morbidity.**<sup>86</sup> In nulliparous women with an epidural who had a nonoperative vaginal delivery, a prolonged second stage greater than 3 hours was associated with an increased risk of a shoulder dystocia (adjusted OR, 1.62; 95% CI, 1.17 to 1.65), 5-minute Apgar score less than 4 (adjusted OR, 2.58; 95% CI, 1.07 to 6.17), increased risk of neonatal intensive care unit (NICU)

**TABLE 12-4** RECOMMENDATIONS FOR 95TH PERCENTILE DURATION FOR THE SECOND STAGE OF LABOR

| 95TH PERCENTILE                  |         |
|----------------------------------|---------|
| <b>Multiparas</b>                |         |
| Second stage without an epidural | 2 hours |
| Second stage with an epidural    | 3 hours |
| <b>Nulliparas</b>                |         |
| Second stage without an epidural | 3 hours |
| Second stage with an epidural    | 4 hours |

Modified from Spong C, Berghella V, Wenstrom K, et al. Preventing the first cesarean delivery: Summary of a joint Eunice Kennedy Shriver National Institute of Child Health and Human Development, Society for Maternal-Fetal Medicine, and American College of Obstetricians and Gynecologists Workshop. *Obstet Gynecol*. 2012;120(5):1181.

admission (adjusted OR, 1.25; 95% CI, 1.02 to 1.53), and neonatal sepsis (adjusted OR, 2.01; 95% CI, 1.39 to 2.91).<sup>86</sup> It should be noted that although these results are significant, the absolute incidence of each event is extremely low. **These findings suggest that the benefits of vaginal delivery with second-stage prolongation must be weighed against possible small but significant increases in neonatal risk.**<sup>80</sup> Although less frequent, adverse neonatal outcomes for multiparous women with a prolonged second-stage duration have also been reported.<sup>80-82</sup>

Based upon the available evidence, a workshop convened by the Eunice Kennedy Shriver National Institute of Health Child Health and Human Development (NICHD), ACOG, and SMFM recommend at least a 3- to 4-hour second-stage duration for nulliparous women and at least a 2- to 3-hour second-stage duration for multiparas, if maternal and fetal conditions permit.<sup>79</sup> Documentation of patient progress and individualization of care is paramount because longer durations of pushing may also be appropriate. Epidural use or fetal malposition, for example, may prolong the duration of the second stage. Recommended guidelines to identify those with abnormal prolongation of the second stage stratified by parity and epidural use are detailed in Table 12-4. These limits should not be used arbitrarily to justify ending the second stage. They can, however, be used to identify a subset of women who require further evaluation.<sup>83</sup>

As with active labor, poor progress in the second stage may be related to inadequate contractions; therefore initiating oxytocin in the second stage may be effective to facilitate descent if contraction frequency is diminished. If malposition is diagnosed, rotation to OA—either manually or by forceps—may also be indicated in the second stage to facilitate descent. For women with a prolonged second-stage duration, arbitrary time cutoffs are unnecessary if steady progress is observed and fetal status is reassuring.<sup>87-91</sup> Whereas evidence suggests maternal morbidity is significantly higher in women with a prolonged second stage,<sup>83,92</sup> it is important to note that the decision to proceed with an operative vaginal delivery or cesarean delivery simply to shorten the second stage must be based upon weighing the risks of operative delivery against the risks associated with a prolonged second stage and the likelihood of a successful vaginal delivery (see Chapters 13 and 14).

Multiple factors influence the duration of the second stage; these include epidural analgesia, nulliparity, older maternal age, maternal BMI, longer active phase, greater birthweight, and excess maternal weight gain.<sup>83,92</sup> Modifiable factors that have been evaluated in management of the second

stage include maternal position, decreasing or discontinuation of epidural analgesia (see Chapter 16), and delayed pushing. A Cochrane review of five RCTs that studied the risks and benefits of discontinuation of second-stage epidural analgesia found no difference in route of delivery, operative vaginal delivery rate, or second-stage duration.<sup>93-96</sup> However, a Cochrane review of 38 RCTs to evaluate epidural versus no epidural in labor found that epidural analgesia was clearly associated with an increased duration of the second stage of labor (MD, 13.66 min; 95% CI, 6.67 to 20.66) and rate of operative delivery (OR, 1.42; 95% CI, 1.28 to 1.57).<sup>32,95,97</sup> A recent retrospective review<sup>98</sup> of second-stage durations for 4605 women reported a 60-minute increase in the median duration of second-stage labor for nulliparas with an epidural compared with those without. In women who had a vaginal delivery, the 95th percentile duration of the second stage was 95 minutes longer for nulliparas with an epidural and 101 minutes longer for multiparas with an epidural compared with those who went without an epidural ( $P < .001$ ). Delayed pushing was compared with immediate pushing in the second stage in nulliparas with epidural analgesia to determine whether this strategy would reduce the need for operative delivery.<sup>97,99-101</sup> It has been suggested that delaying pushing until the woman feels the urge to push would maximize maternal pushing efforts, reduce maternal exhaustion, and decrease the risk of operative vaginal delivery.

**A meta-analysis of 12 RCTs found that delayed pushing was associated with an increased rate of vaginal delivery. However, this benefit was not statistically significant among the quality studies reviewed.**<sup>97,99-102</sup> Delayed pushing prolonged the duration of the second stage (weighted MD, 56.92 min; 95% CI, 42.19 to 71.64) and shortened the duration of active pushing (weighted MD, 21.98 min; 95% CI, -31.29 to -12.68).<sup>102</sup> However, no significant difference was found in the operative vaginal delivery rate.<sup>102</sup> Only one trial reported a significant decrease in midpelvic operative deliveries.<sup>99</sup> Risks associated with delayed pushing have also been reported. In a retrospective evaluation of 5290 term multiparous and nulliparous women, delayed pushing was associated with a statistically significant increase in cesarean and operative delivery rates, increased maternal fever, and a significant decrease in arterial cord pH.<sup>103,104</sup> **Data suggest that delayed pushing is not associated with fewer cesarean or operative deliveries and may have maternal risks. Additional studies are needed to determine whether delayed pushing is associated with increased neonatal risk.**

Finally, the effect of maternal position in the second stage has been evaluated.<sup>105,106</sup> A Cochrane review<sup>107</sup> of five RCTs evaluated the effect of any upright position compared with recumbent positioning in the second stage of labor on route of delivery and duration of labor. No statistically significant difference between groups was observed for operative delivery, duration of second stage, or neonatal outcome.<sup>107</sup> A significant increase in the percent of women with an intact perineum in the upright group was identified<sup>106</sup>; therefore **nonrecumbent positioning in the second stage should be considered.**

## SPONTANEOUS VAGINAL DELIVERY

Preparation for delivery should take into account the patient's parity, the progression of labor, fetal presentation, and any labor complications. Among women for whom delivery complications are anticipated (risk factors for shoulder dystocia or

multiple gestation), transfer to a larger and better equipped delivery room, removal of the foot of the bed, and delivery in the lithotomy position may be appropriate. If no complications are anticipated, delivery can be accomplished with the mother in her preferred position. Common positions include the lateral (Sims) position or the partial sitting position.

**The goals of clinical assistance at spontaneous delivery are the reduction of maternal trauma, prevention of fetal injury, and initial support of the newborn. When the fetal head crowns and delivery is imminent, gentle pressure should be used to maintain flexion of the fetal head and to control delivery, potentially protecting against perineal injury. Once the fetal head is delivered, external rotation (restitution) is allowed. If a shoulder dystocia is anticipated, it is appropriate to proceed directly with gentle downward traction of the fetal head before restitution occurs. During restitution, nuchal umbilical cord loops should be identified and reduced; in rare cases in which simple reduction is not possible, the cord can be doubly clamped and transected. The anterior shoulder should then be delivered by gentle downward traction in concert with maternal expulsive efforts; the posterior shoulder is delivered by upward traction. These movements should be performed with the minimal force possible to avoid perineal injury and traction injuries to the brachial plexus.**

**No evidence shows that DeLee suction reduces the risk of meconium aspiration syndrome in the presence of meconium; thus this should not be performed.**<sup>108</sup> For a vigorous infant, the ACOG Committee on Obstetric Practice and the American Academy of Pediatrics (AAP) no longer recommend routine suctioning in the presence of meconium. If the infant is depressed, and meconium staining is evident, intubation and visualization of meconium or other foreign material below the vocal cords is recommended and should be performed by appropriately trained providers per AAP guidelines.<sup>109</sup>

**The timing of cord clamping is usually dictated by convenience and is commonly performed immediately after delivery. However, an ongoing debate exists about the benefits and risks to the newborn of late cord clamping.** A Cochrane review of 15 RCTs that compared late (>2 minutes) and immediate cord clamping in term infants showed a significant increase in infant hematocrit, ferritin, and stored iron at 2 to 6 months with no significant increase in the risk of maternal hemorrhage.<sup>110,111</sup> However, a significant increase was also seen in neonatal polycythemia and treatment for neonatal jaundice in the delayed group. A Cochrane review<sup>112</sup> of 15 RCTs to compare late (>30 seconds) to immediate cord clamping in preterm infants (<37 weeks' gestation) showed significant decreases in anemia that required transfusion, intraventricular hemorrhage (IVH), and necrotizing enterocolitis in infants with delayed clamping. Those infants who had their cords clamped later were also noted to have a higher bilirubin levels. No significant difference was reported in the risk of grade 3 or 4 IVH or intraventricular leukomalacia, primarily due to considerable heterogeneity among the studies.<sup>112</sup> **In 2012, ACOG issued a committee opinion affirming the practice of delayed cord clamping for preterm infants in light of the up to 50% reduction in the risk of IVH reported for these infants when delayed cord clamping is performed.**<sup>113</sup> **However, for term infants, ACOG determined that evidence was insufficient to either confirm or refute the benefits of delayed cord clamping.** Additional studies are needed to determine barriers to

implementation of delayed cord clamping in preterm infants and to further determine the benefits and risks of this practice for term infants in resource-rich locations.<sup>114</sup>

If possible, the steps described here are best done with the infant on the mother's abdomen. Initially, the infant should be wiped dry and kept warm while any mucus remaining in the airway is suctioned. **Keeping the infant warm is particularly important, and because heat is lost quickly from the head, placing a hat on the infant is appropriate.** After clamping of the cord, the vigorous term infant should be placed on the mother's bare skin if at all possible. Early *skin-to-skin contact* (SSC) refers to the placement of the naked infant in a prone position onto the mother's bare chest and abdomen near the breast with the infant's side and back covered by blankets or towels.<sup>115</sup> Early SSC is recommended for the healthy term newborn immediately after vaginal delivery and as soon as possible after cesarean delivery by ACOG, the AAP, and the Baby-Friendly Health Initiative developed by the World Health Organization.<sup>116,117</sup> Meta-analysis of data from RCTs (13 trials, 702 participants) suggests that **immediate or early SSC increases the likelihood of breastfeeding initiation at 1 to 4 months (RR 1.27; 95% CI, 1.06 to 1.53) and results in higher blood glucose at 75 to 90 min of life compared with standard care (MD, 10.56 mg/dL; 95% CI, 8.40 to 12.72).**<sup>118</sup> Positive effects of SSC on maternal-infant bonding, breastfeeding duration, cardiorespiratory stability, and body temperature have also been demonstrated.<sup>118-120</sup> The term *Kangaroo care* refers to a model of postdelivery care that includes continuous SSC contact and exclusive breastfeeding for low birthweight (LBW) infants, and it was originally promoted as an alternative to incubators in resource-poor settings. A meta-analysis of the RCTs **identified a significant reduction in neonatal mortality, nosocomial infection and sepsis, and hypothermia as well as improvements in measures of infant growth, breastfeeding, and mother-infant attachment with kangaroo care compared with conventional methods for LBW infants.**<sup>121</sup> Additional prospective RCTs are needed to further characterize the benefits and limitations, if any, of SSC and kangaroo care in term and stable LBW infants; in resource-rich, compared with resource-poor, settings; and after cesarean delivery.

## DELIVERY OF THE PLACENTA AND FETAL MEMBRANES

**The third stage of labor can be managed either passively or actively. Passive management** is characterized by clamping of the cord once spontaneous pulsations have ceased and delivery of the placenta by gravity or spontaneously, without manipulation of the uterus or traction on the cord. **Placental separation is heralded by lengthening of the umbilical cord and a gush of blood from the vagina, signifying separation of the placenta from the uterine wall.** With passive management, uterotonic medications are not given until after delivery of the placenta. With *active management* of the third stage, uterotonic medication is administered shortly after delivery of the baby but prior to delivery of the placenta. Controlled umbilical cord traction and countertraction are used to support the uterus until the placenta separates and is delivered, followed by uterine massage after delivery of the placenta. Two techniques of controlled cord traction are commonly used to facilitate separation and delivery of the placenta: in the *Brandt-Andrews maneuver*, a

hand pressed against the abdomen secures the uterine fundus to prevent uterine inversion, while the other hand exerts sustained downward traction on the umbilical cord; with the *Créde maneuver*, the cord is fixed with the lower hand, and while the uterine fundus is secured and sustained, upward traction is applied by a hand pressed against the abdomen. Care should be taken to avoid evulsion of the cord.

**Implementation of active management strategies in the third stage of labor can significantly decrease the risk of postpartum hemorrhage.** In a meta-analysis of three RCTs to compare active to expectant management, subjects randomized to active management were 66% less likely to have postpartum hemorrhage (estimated blood loss [EBL]  $\geq 1000$  mL; RR, 0.34; 95% CI, 0.14 to 0.87).<sup>122,123</sup> Active management of the third stage of labor is recommended by ACOG District II and the California Maternal Quality Care Collaborative (CMQCC) as an integral component of multifaceted perinatal quality initiatives to reduce the severe maternal morbidity and mortality that results from obstetric hemorrhage. Active management of the third stage of labor specifically includes administration of dilute IV oxytocin or 10 units of intramuscular oxytocin after delivery of the fetus and prior to delivery of the placenta (ACOG District II). In the CMQCC obstetric hemorrhage protocol, additional components of the active management strategy include umbilical cord clamping at or prior to 2 minutes after delivery, controlled cord traction to facilitate delivery of the placenta, followed by fundal massage to facilitate uterine involution (CMQCC).

**After delivery, the placenta, umbilical cord, and fetal membranes should be examined. Placental weight (excluding membranes and cord) varies with fetal weight, with a ratio of approximately 1:6.** Abnormally large placentae are associated with such conditions as hydrops fetalis and congenital syphilis. **Inspection and palpation of the placenta should include the fetal and maternal surfaces and may reveal areas of fibrosis, infarction, or calcification.** Although each of these conditions may be seen in the normal term placenta, extensive lesions should prompt histologic examination. Adherent clots on the maternal placental surface may indicate recent placental abruption; however, their absence does not exclude the diagnosis. A missing placental cotyledon or a membrane defect suggestive of a missing succenturiate lobe also suggests retention of a portion of placenta and should prompt further clinical evaluation. **Routine manual exploration of the uterus after delivery is unnecessary unless retained products of conception or a postpartum hemorrhage is suspected.**

**The site of insertion of the umbilical cord into the placenta should be noted.** Abnormal insertions include *marginal insertion*, in which the cord inserts into the edge of the placenta, and *membranous insertion*, in which the vessels of the umbilical cord course through the membranes before attachment to the placental disc. The cord should be inspected for length; the correct number of umbilical vessels, normally two arteries and one vein; true knots; hematomas; and strictures. The average cord length is about 50 to 60 cm. A single umbilical artery discovered on pathologic examination is associated with an increased risk of fetal growth restriction and up to a 6.77-fold higher risk of one or more major congenital anomalies (OR, 6.77; 95% CI, 5.7 to 8.06).<sup>124-127</sup> Therefore this finding should be relayed to the attending neonatologist or pediatrician, and any abnormalities of the placenta or cord should be noted in the mother's chart.

## EPISIOTOMY AND PERINEAL INJURY AND REPAIR

**Following delivery of the placenta, the vagina and perineum should be carefully examined for evidence of injury.** If a laceration is seen, its length and position should be noted and repair should be initiated. Adequate analgesia, either regional or local, is essential for repair. Special attention should be paid to repair of the perineal body, the external anal sphincter, and the rectal mucosa (see Chapter 18). Failure to recognize and repair rectal injury can lead to serious long-term morbidity, most notably fecal incontinence. The cervix should be inspected for lacerations if an operative delivery was performed or when bleeding is significant with or after delivery.

Perineal injuries, either spontaneous or with the episiotomy, are the most common complications of spontaneous or operative vaginal deliveries. **A first-degree tear is defined as a superficial tear confined to the epithelial layer; it may or may not need to be repaired depending on size, location, and amount of bleeding. A second-degree tear extends into the perineal body but not into the external anal sphincter. A third-degree tear involves superficial or deep injury to the external anal sphincter, whereas a fourth-degree tear extends completely through the sphincter and the rectal mucosa. All second-, third-, and fourth-degree tears should be repaired (see Chapter 18).** Significant morbidity is associated with third- and fourth-degree tears, including risk of flatus and stool incontinence, rectovaginal fistula, infection, and pain (see Chapter 14). Primary approximation of perineal lacerations affords the best opportunity for functional repair, especially if rectal sphincter injury is evident. The external anal sphincter should be repaired by direct apposition or overlapping the cut ends and securing them using interrupted sutures.

**Episiotomy is an incision into the perineal body made during the second stage of labor to facilitate delivery.** It is by definition at least a second-degree tear. Episiotomy can be classified into two broad categories, midline and mediolateral. **With a midline episiotomy, a vertical midline incision is made from the posterior fourchette toward the rectum (Fig. 12-14).** After adequate analgesia has been achieved, either local or regional, straight Mayo scissors are generally used to perform the episiotomy. Care should be taken to displace the perineum from the fetal head. The size of the incision depends on the length of the perineum but is generally approximately half of the length of the perineum and should be extended vertically up the vaginal mucosa for a distance of 2 to 3 cm. Every effort should be made to avoid direct injury to the anal sphincter. **Complications of midline episiotomy include increased blood loss, especially if the incision is made too early; fetal injury; and localized pain. With a mediolateral episiotomy, an incision is made at a 45-degree angle from the inferior portion of the hymeneal ring (Fig. 12-15).** The length of the incision is less critical than with midline episiotomy, but longer incisions require lengthier repair. The side to which the episiotomy is performed is usually dictated by the dominant hand of the practitioner. **Because such incisions appear to be moderately protective against severe perineal trauma, if an episiotomy is needed, the mediolateral episiotomy is the procedure of choice for women with inflammatory bowel disease (see Chapter 48) because of the critical need to prevent rectal injury.** Historically, it was believed that episiotomy improved outcome by reducing pressure on the fetal head, protecting the maternal perineum from

FIG 12-14 Cutting a midline episiotomy.

extensive tearing and preventing subsequent pelvic relaxation. However, consistent data since the late 1980s confirm that *midline episiotomy* does not protect the perineum from further tearing, and data do not show that episiotomy improves neonatal outcome.<sup>128,129</sup> Midline episiotomy was associated with a significant increase in third- and fourth-degree lacerations in spontaneous vaginal delivery in nulliparous women with both spontaneous and operative vaginal delivery.<sup>128-135</sup> Episiotomy had the highest odds ratio (OR, 3.2; CI, 2.73 to 3.80) for anal sphincter laceration in a large study of nulliparous women when compared with other risk factors, including forceps delivery.<sup>136</sup> Few papers reported that midline episiotomy was associated with no difference in fourth-degree tears compared with no episiotomy.<sup>137</sup> Randomized trials that compared routine to indicated use of episiotomy report a 23% reduction in perineal lacerations that required repair in the indicated group (11% to 35%).<sup>138</sup> Finally, a recent Cochrane review of eight RCTs that compared restrictive to routine use of episiotomy showed a significant reduction of severe perineal tears, suturing, and healing complications in the restrictive group.<sup>139</sup> Although the restrictive episiotomy group had a significantly higher incidence of anterior tears, no difference was found in pain measures between the groups. All of these findings were similar whether midline or mediolateral episiotomy was used. Based on the lack of consistent evidence that

episiotomy is of benefit, routine episiotomy has no role in modern obstetrics.<sup>128,129,139-141</sup> In fact, a recent evidence-based review recommended that episiotomy should be avoided if possible, based on U.S. Preventive Task Force quality of evidence.<sup>68</sup> Based on these data and the ACOG recommendations,<sup>141</sup> rates of midline episiotomy have decreased, although episiotomies are performed in 10% to 17% of deliveries, which suggests that elective episiotomy continues to be performed.<sup>131-138</sup> In one study, decreasing episiotomy rates from 87% in 1976 to 10% in 1994 were associated with a parallel decrease in the rates of third- or fourth-degree lacerations (9% to 4%) and an increase in the incidence of an intact perineum (10% to 26%).<sup>131</sup>

**The relationship of episiotomy to subsequent pelvic relaxation and incontinence has been evaluated, and no studies suggest that episiotomy reduces risk of incontinence.** Fourth-degree tears are clearly associated with future incontinence,<sup>142</sup> and neither midline nor mediolateral episiotomy is associated with a reduction in incontinence.<sup>143</sup> No data suggest that episiotomy protects the woman from later incontinence; therefore avoidance of fourth-degree tearing should be a priority.

If an episiotomy is deemed indicated, the decision of which type to perform rests on their individual risks. It does appear that mediolateral episiotomy is associated with fewer

**FIG 12-15** Cutting a mediolateral episiotomy.

fourth-degree tears compared with midline episiotomy.<sup>144-146</sup> However, other studies do not show benefit of mediolateral over midline episiotomy for future prolapse.<sup>143</sup> Chronic complications such as unsatisfactory cosmetic results and inclusions within the scar may be more common with mediolateral episiotomies, and blood loss is greater. Finally, it must be remembered that neither episiotomy type has been shown to reduce severe perineal tears compared with no episiotomy.

Although there is no role for *routine* episiotomy, *indicated* episiotomy should be performed in select situations, and providers should receive training in the skill.<sup>137</sup> Potential indications for episiotomy include the need to expedite delivery in the setting of FHR abnormalities or for relief of shoulder dystocia.

## ULTRASOUND IN LABOR AND DELIVERY

**Ultrasound is a useful adjunct to the clinical examination in the peripartum period.** Sonographic findings may be used to confirm the clinical impression of fetal lie and presentation and gestational age when needed. In women with vaginal bleeding, ultrasound can identify placental location and rule out placenta

previa prior to a digital examination of the cervix. In women with twins, ultrasound estimation of fetal lie and weight are an integral component of patient counseling regarding mode of delivery for the first and second twin. In women with a breech-presenting fetus at term, ultrasound can be used to confirm presentation, placental location, and amniotic fluid volume prior to patient counseling and performance of a breech version. In the third stage of labor, ultrasound may be used to assist with removal of the placenta for those with a prolonged third stage and/or to better facilitate uterine evacuation during a postpartum hemorrhage.

**The association between sonographic cervical length (CL) at term and labor outcome has also been studied.** An evaluation of weekly CL measurements between 37 and 40 weeks in term nulliparous women found that cervical shortening could only be documented in 50% of the participants prior to onset of spontaneous labor and that 25% of the participants had a CL of more than 30 mm within the last 48 hours prior to delivery.<sup>147</sup> CL measurements obtained between 37 and 38 weeks' gestation were found to have a low sensitivity and negative predictive value for spontaneous labor prior to 41 weeks' gestation. In an

evaluation of a more ethnically heterogeneous population, however, a significant correlation was identified between a single CL measurement obtained between 37 and 40 weeks, delivery within 7 days, and delivery prior to 41 weeks' gestation.<sup>148</sup> A term cervical length of 25 mm had a sensitivity of 77.5% and a negative predictive value 84.7% for spontaneous labor within 7 days. A CL of 30 mm had a sensitivity of 73.1%, specificity of 40.7%, and a positive predictive value of 81% for delivery prior to 41 weeks' gestation in the cohort studied.<sup>148</sup> Although these data are interesting and encouraging, additional studies are needed to determine whether term CL evaluation can be used as an adjunct to the clinical examination to better distinguish those who are most likely to have spontaneous labor between 37 and 40 weeks' gestation from those who would benefit from reassurance and continued expectant management.

**An association has been found between cervical parameters at term and successful labor induction.**<sup>149-151</sup> The likelihood of a vaginal delivery following labor induction at term depends in part upon maternal parity and the dilation, effacement, consistency, and position of the cervix.<sup>149</sup> The **Bishop score** is the most commonly used tool for preinduction cervical assessment. Although it was initially designed to predict the likelihood of vaginal delivery success in multiparous women, the Bishop score has been demonstrated to be applicable to nulliparous women as well,<sup>149-150</sup> although it is limited in that it is subjective and has been demonstrated to have significant interobserver and intraobserver variability.<sup>151-153</sup> For women undergoing labor induction, however, a Bishop score of less than 6 has been reported to be a poor predictor of vaginal delivery and labor induction success.<sup>151</sup> The length of the cervix, an open or closed internal cervical os, and the presence of membranes within the endocervical canal (*funneling*, or *wedging*) are ultrasound parameters that provide a more detailed description of the cervix, particularly when the external os is closed on digital examination. However, data conflict in regard to the association between sonographic cervical parameters and the risk of cesarean delivery with labor induction.<sup>151,154</sup> A meta-analysis<sup>155</sup> of 20 prospective trials that evaluated the association between preinduction CL and successful labor induction found that a shorter CL was associated with successful induction (likelihood ratio of a positive test, 1.66; 95% CI, 1.20 to 2.31), and a longer CL was associated with a failed induction (likelihood ratio of a negative test, 0.51; 95% CI, 0.39 to 0.67). However, subgroup analysis of seven studies found that a specific preinduction CL of less than 30 mm was not predictive of vaginal delivery. A subgroup analysis of 10 studies found that CL was equivalent to Bishop score with regard to prediction of labor induction success, route of delivery, vaginal delivery within 24 hours, and achievement of the active stage of labor. A more recent meta-analysis<sup>156</sup> of 31 studies, including 12 studies published after 2006, found that in nulliparous women undergoing induction of labor, a CL of more than 30 mm best identified those at high risk for cesarean delivery, with a sensitivity of 0.70, specificity of 0.74, positive likelihood ratio of 2.7, and a negative likelihood ratio of 0.40. CL of more than 30 mm performed as well as a Bishop score less than 6 with regard to its sensitivity and specificity in nulliparous women.<sup>150</sup> A long cervix (>30 mm) and the absence of funneling were found to approximately double the odds of failed induction, whereas a short cervix and funneling decreased the odds of failed induction by up to 50%. CL and the assessment of wedging (funneling) can be easily performed and can provide a more objective description of the cervix;

however, these are of limited value. Currently, we do not have sufficient evidence that ultrasound parameters should replace the clinical examination or that such parameters should be used to supplant the indication for induction.

**Fetal head position and station during labor are best determined by careful digital pelvic examination.** However, evidence suggests that depending upon the degree of cervical dilation and the presence or absence of caput, an assignment of fetal head position may not be possible in up to 61% of patients in the first stage and in up to 31% of patients in the second stage of labor.<sup>157</sup> An OP fetal head presentation and the presence of caput can also make determination of fetal position and station difficult.<sup>158</sup> Several studies reported that during digital vaginal examinations in which a fetal head position is clinically assigned, the position was only accurate 50% to 60% of the time during the first stage and 30% to 40% of the time during the second stage compared with ultrasound.<sup>158-161</sup> In the second stage of labor, determination of the station of the fetal head within the pelvis is a similarly challenging clinical parameter to assess despite our reliance upon bony pelvic landmarks. In a study using a fetal mannequin and a pelvic trainer, it was found that mid, low, high, and outlet pelvic classifications were incorrectly assigned 30% of the time by resident physicians and 34% of the time by attending physicians.<sup>162</sup>

Ultrasound may be considered as an adjunct to the clinical examination in the second stage, when head position is difficult to assess by palpation because of caput. Sonographic visualization of the orbits will help to determine the general position of the face and occiput within the maternal pelvis. In a study of 514 term nulliparous women who required second-stage operative vaginal delivery, subjects were randomized to predelivery assessment of head position by ultrasound and clinical examination or by clinical examination alone.<sup>163</sup> Head position at delivery was incorrectly predicted by clinical examination 20% of the time compared with a 1.6% error rate when head position was determined by clinical examination and ultrasound ( $P < .001$ ). No statistically significant difference was found between groups in the maternal or neonatal outcomes studied. Additional trials are needed to determine whether ultrasound-based evaluations of fetal position and station have sufficient sensitivity to influence clinical decision making regarding second-stage labor and route of delivery.<sup>156,158,163,164</sup>

### KEY POINTS

- ◆ Labor is a clinical diagnosis that includes regular painful uterine contractions and progressive cervical effacement and dilation.
- ◆ The fetus likely plays a key role in determining the onset of labor, although the precise mechanism by which this occurs is not clear.
- ◆ Labor has three stages: the first stage is from labor onset until full dilation of the cervix, the second stage is from full cervical dilation until delivery of the baby, and the third stage begins with delivery of the baby and ends with delivery of the placenta. The first stage of labor is divided into two phases: the first is the *latent phase* and the second is the *active phase*.
- ◆ Active labor is diagnosed as the time when the slope of cervical change increases, which is more difficult to

identify in nulliparas and may not occur until at least 6 cm dilation.

- ◆ The ability of the fetus to successfully negotiate the pelvis during labor and delivery is dependent on the complex interaction of three variables: uterine force, the fetus, and the maternal pelvis.
- ◆ Labor length is affected by many variables that include parity, epidural use, fetal position, fetal size, and maternal BMI.
- ◆ Upright, rather than recumbent, positioning during labor was associated with a significantly shorter first stage of labor, less epidural use, and a reduction in the risk of cesarean delivery by 30%.
- ◆ The presence of a labor doula was associated with a significant reduction in the use of analgesia, oxytocin, and operative vaginal delivery or cesarean delivery and an increase in patient satisfaction.
- ◆ Routine midline episiotomy is associated with a significant increase in the incidence of severe perineal trauma and should be avoided.
- ◆ Active management of the third stage of labor was associated with a significant reduction in blood loss greater than 1000 mL and therefore a lower risk of maternal anemia.
- ◆ Ultrasound may be a useful adjunct to the clinical examination in the peripartum period.

## OVERVIEW

*Labor* is the physiologic process by which a fetus is expelled from the uterus to the outside world. A switch from *contractures* (long-lasting, low-frequency activity) to *contractions* (frequent, high-intensity, high-frequency activity) occurs before progressive cervical effacement and dilation of the cervix and regular uterine contractions.<sup>1</sup> The timing of the switch varies from patient

to patient. The exact trigger for the onset of labor is unknown, but considerable evidence suggests that the fetus provides the stimulus through complex neuronal-hormonal signaling (see Chapter 12).

The mean duration of a human singleton pregnancy is 280 days or 40 weeks from the first day of the last menstrual period assuming a normal 28-day menstrual cycle. In 2012, an **American College of Obstetricians and Gynecologists (ACOG) and Society for Maternal-Fetal Medicine (SMFM) working group<sup>2</sup>** convened and recommended that the conventional “term” be replaced by the designations *early term* (37 0/7 to 38 6/7 weeks of gestation), *full term* (39 0/7 weeks of gestation to 40 6/7 weeks of gestation), *late term* (41 0/7 weeks to 41 6/7 weeks of gestation), and *postterm* (42 0/7 weeks of gestation and beyond). These new gestational age designations are intended to improve data reporting, delivery of health care, and research.

## DIAGNOSIS

*Labor* is a clinical diagnosis defined as uterine contractions that result in progressive cervical effacement and dilation, often accompanied by a bloody discharge referred to as *bloody show*, followed by birth of the baby. The diagnosis of bona fide labor is often elusive, and wide variations exist in the clinical spectrum of normal labor in addition to many opinions of the definitions for normal and abnormal labor progress. To gain an understanding of abnormal labor progress and induction of labor, a fundamental understanding of normal spontaneous labor is needed.

## ABNORMAL LABOR AT TERM

The original guidelines for normal human labor progress are derived from Friedman’s<sup>1</sup> clinical observations of women in labor in the 1950s. Friedman characterized a sigmoid pattern for labor when graphing cervical dilation against time (Fig. 13-1). He divided labor into three functional divisions: preparatory,

**FIG 13-1** Characteristics of the average cervical dilation curve for nulliparous labor. (Modified from Friedman EA. *Labor: clinical evaluation and management*, 2nd ed. Norwalk, CT, Appleton-Century-Crofts; 1978.)

dilational, and pelvic. The *preparatory division* is better known as the *latent phase*, during which little cervical dilation occurs but considerable changes are taking place in the connective tissue components of the cervix, and the *dilational division*—or *active phase*—is when dilation proceeds at its most rapid rate to complete cervical dilation; these two phases together make up the *first stage of labor*. The *pelvic division*, or *second stage of labor* refers to the time of full cervical dilation to the delivery of the infant. The *third stage of labor* refers to the time from the delivery of the infant to expulsion of the placenta.

Subsequent observations challenge Friedman's original labor curves. Between 1959 and 1966, the National Collaborative Perinatal Project (NCPP) prospectively observed labor progression along with several other factors possibly associated with cerebral palsy. This large multicenter project gathered data at a time when natural labor progress could be evaluated more easily than current obstetric practices allow. Using these data, Zhang and colleagues<sup>3</sup> derived a labor curve from this cohort of women and compared it to labor curves from the more recent Consortium on Safe Labor (CSL). Differences between these two labor curves are apparent, most notably that the nulliparous women in the NCPP had a more gradual transition to the active phase and that the active phase in the multiparous women began around 5 cm dilation (Figs. 13-2 and 13-3). Further, the rate of cervical dilation was slower in both nulliparous and multiparous women compared with that described by Friedman,<sup>1</sup> especially from 4 to 6 cm, with an acceleration point that suggests an active phase that occurs around 6 cm. Beyond 6 cm, cervical dilation was more rapid in multiparous than in nulliparous women.<sup>4</sup>

Since the 1960s, maternal characteristics and obstetric practices have changed significantly. Women have an older mean age and a higher mean body mass index (BMI), and oxytocin and epidural anesthesia are more frequently used,<sup>5</sup> all of which can affect the length of labor. Yet even after adjusting for maternal

**FIG 13-2** Average labor curves for nulliparas. NCPP, National Collaborative Perinatal Project; CSL, Consortium on Safe Labor. (Modified from Laughon KS, Branch DW, Beaver J, et al. Changes in labor patterns over 50 years. *Am J Obstet Gynecol*. 2012;206:419.e1-e9.)

and obstetric characteristics, the longer overall median differences in the first stage of labor persisted in the more recent data. This is likely because of changes in contemporary obstetric practice. Regardless of the differing results of these two investigations, a **graduated approach for diagnosis of labor protraction and arrest should be considered based on the level of cervical dilation** (Table 13-1).

### Disorders of the Latent Phase

Historically, the first stage of labor has been divided into the *latent phase* and the *active phase* based on the work by Friedman in the 1950s. The onset of latent labor is considered to be the point at which regular uterine contractions are perceived. Friedman found that the mean duration of latent labor was 6.4 hours for nulliparas and 4.8 for multiparas, and the 95th percentile

**TABLE 13-1** LABOR AT TERM (ZHANG)

| CERVICAL DILATION (CM) | PARITY 0   | PARITY 1   | PARITY 2+  |
|------------------------|------------|------------|------------|
| From 3 to 4            | 1.2 (6.6)  |            |            |
| From 4 to 5            | 0.9 (4.5)  | 0.7 (3.3)  | 0.7 (3.5)  |
| From 5 to 6            | 0.6 (2.6)  | 0.4 (1.6)  | 0.4 (1.6)  |
| From 6 to 7            | 0.5 (1.8)  | 0.4 (1.2)  | 0.3 (1.2)  |
| From 7 to 8            | 0.4 (1.4)  | 0.3 (0.8)  | 0.3 (0.7)  |
| From 8 to 9            | 0.4 (1.3)  | 0.3 (0.7)  | 0.2 (0.6)  |
| From 9 to 10           | 0.4 (1.2)  | 0.2 (0.5)  | 0.2 (0.5)  |
| From 4 to 10           | 3.7 (16.7) | 2.4 (13.8) | 2.2 (14.2) |

Data presented in hours as median (95th percentile).

**FIG 13-3** Average labor curves for multiparas. NCPP, National Collaborative Perinatal Project; CSL, Consortium on Safe Labor. (Modified from Laughon KS, Branch DW, Beaver J, et al. Changes in labor patterns over 50 years. *Am J Obstet Gynecol.* 2012;206:419.e1-e9.)

for maximum length in latent labor was 20 hours for nulliparous women and 14 hours for multiparous women (Table 13-2). The definitions of prolonged latent phase are still based on the data from Friedman, and modern investigators have not focused on the latent phase of labor.

**Because the duration of latent labor is highly variable, even in the setting of a prolonged latent phase, expectant management is appropriate because most women will ultimately enter the active phase.** Some women can spend days in latent labor; provided no indication exists for delivery, awaiting active labor is appropriate. With few exceptions, women who do not enter the active phase will either stop contracting or they will achieve the active phase following amniotomy, oxytocin administration, or both.

Another option is to administer “therapeutic rest,” especially if contractions are painful or the patient is exhausted, with an analgesic agent such as morphine to abate or alleviate painful contractions and allow the patient to rest comfortably until active labor begins.

### Disorders of the Active Phase

Active labor demarcates a rapid change in cervical dilation. Active-phase abnormalities can be divided into either *protraction disorders* (slower progress than normal) or *arrest disorders* (complete cessation of progress). **Based on Friedman’s work, the active phase begins once cervical dilation progresses at a minimum rate of 1.2 cm/hr for nulliparous women and**

**TABLE 13-2** PROGRESSION OF SPONTANEOUS LABOR AT TERM (FRIEDMAN)

| PARAMETER               | MEDIAN    | 95TH PERCENTILE |
|-------------------------|-----------|-----------------|
| <b>Nulliparas</b>       |           |                 |
| Total duration          | 10.1 hr   | 25.8 hr         |
| Stages:                 |           |                 |
| First                   | 9.7 hr    | 24.7 hr         |
| Second                  | 33.0 min  | 117.5 min       |
| Third                   | 5.0 min   | 30 min          |
| Latent phase (duration) | 6.4 hr    | 20.6 hr         |
| Maximal dilation (rate) | 3.0 cm/hr | 1.2 cm/hr       |
| Descent (rate)          | 3.3 cm/hr | 1.0 cm/hr       |

| Total duration          | 6.2 hr    | 19.5 hr         |
| Stages:                 |           |                 |
| First                   | 8.0 hr    | 18.8 hr         |
| Second                  | 8.5 min   | 46.5 min        |
| Third                   | 5.0 min   | 30 min          |
| Latent phase (duration) | 4.8 hr    | 13.6 hr         |
| Maximal dilation (rate) | 5.7 cm/hr | 1.5 cm/hr       |
| Descent (rate)          | 6.6 cm/hr | 2.1 cm/hr       |

Data from Friedman EA. Primigravid labor: a graphicostatistical analysis. *Obstet Gynecol.* 1955; 6:567; Friedman EA. Labor in multiparas: a graphicostatistical analysis. *Obstet Gynecol.* 1956;8:691; and Cohen W, Friedman EA (eds). *Management of Labor.* Baltimore, University Park Press; 1983.

**1.5 cm/hr for multiparous women.** Labor is considered protracted if less than these minimum rates of change are seen. Rates of cervical dilation varied greatly in Friedman’s report<sup>1</sup> and ranged from 1.2 to 6.8 cm/hr.

*Active-phase arrest* traditionally has been defined as the absence of cervical change for 2 hours or more in the presence of adequate uterine contractions and cervical dilation of at least 4 cm. However, revisions in the definitions of *labor progress* have been made using data from the CSL. **The threshold for the active phase of labor is now cervical dilation of 6 cm.** Before this dilation is achieved, standards of active-phase progress should not be applied. Thus neither a protracted active phase nor arrest of dilation should be diagnosed in a nullipara before 6 cm cervical dilation, and the lower limit of normal active-phase dilation is about 0.5 cm/hr rather than the 1.0 or 1.2 cm/hr reported by Friedman and others.

Several studies have evaluated the optimal duration of oxytocin augmentation in labor protraction or arrest of labor. In a study of more than 500 women, Rouse and colleagues<sup>6</sup> found that extending the minimum period of oxytocin augmentation for active-phase labor arrest from 2 to at least 4 hours allowed the majority of women who had not progressed at the 2-hour mark to deliver vaginally without an adverse effect on neonatal outcome. Thus as long as fetal and maternal status are reassuring, **the diagnosis of arrest (i.e., no cervical change) in the first stage of labor should be reserved for women at or beyond 6 cm cervical dilation with membrane rupture and one of the following: 4 hours or more of adequate contractions (e.g., more than 200 Montevideo units) or 6 hours or more of inadequate contractions.**<sup>7</sup>

**The most common cause of a protraction disorder is inadequate uterine activity.** External tocodynamometry is used to evaluate the duration of and time interval between contractions but cannot be used to evaluate the strength of uterine contractions. The external monitor is held against the abdominal wall and records a relative measurement of uterine contraction intensity, which reflects the monitor’s movement as the uterine shape changes. More precise measurements of uterine activity must be

obtained with an *intrauterine pressure catheter* (IUPC). After amniotomy, an IUPC can be placed into the uterus to measure the pressure generated during a uterine contraction. **An IUPC is frequently used when inadequate uterine activity is suspected owing to a protraction or arrest disorder. It can also be used to titrate oxytocin augmentation of labor to the desired effect, particularly when an external monitor cannot effectively record contractions.** The lower limit of contraction pressure required to dilate the cervix has been observed to be 15 mm Hg over baseline. Normal spontaneous contractions often exert pressures up to 60 mm Hg.

Once inadequate uterine activity is diagnosed with an IUPC in the setting of a protraction or arrest disorder, oxytocin is usually administered. Typically, the dose is increased until labor progresses normally with adequate contractions that occur at 2- to 3-minute intervals and last 60 to 90 seconds, with a peak intrauterine pressure of 50 to 60 mm Hg and a resting tone of 10 to 15 mm Hg (i.e., uterine activity equal to 150 to 350 Montevideo units).

Another common cause of protraction disorders is abnormal positioning of the fetal presenting part. Some examples of malpresentation are an extended, rather than flexed, fetal head; brow or face presentation; and occiput posterior (OP) position. When persistent OP position is present, labor is reported to be prolonged an average of 1 hour in multiparous women and 2 hours in nulliparous women. In one series, sonography showed OP position in 35% of women in early active labor, indicating that this may contribute to prolongation of labor in many women. In another investigation,<sup>8</sup> the prevalence of persistent OP position at the time of vaginal delivery regardless of parity was 5.5% (7.2% in nulliparas and 4.0% in multiparas). The OP position was found to be associated with longer first and second stages and a lower rate of vaginal delivery (26% for nulliparas and 57% for multiparas) when compared with the occiput anterior (OA) position (74% for nulliparas and 92.3% for multiparas).<sup>8</sup> Most fetuses in the OP position undergo spontaneous anterior rotation during the course of labor, and expectant management is generally indicated.

*Cephalopelvic disproportion* (CPD) refers to the size disproportion of the fetus relative to the mother, and it can be the cause of a protraction or arrest disorder. This is a diagnosis of exclusion that is often made when a protracted labor course is observed. Most frequently, malposition of the fetal presenting part is the culprit rather than true CPD. Unfortunately, despite past efforts, there is no way to accurately predict CPD. In a decision analysis,<sup>9</sup> it has been estimated that thousands of unnecessary cesarean deliveries would need to be performed in low-risk pregnancies to prevent one diagnosis of true CPD.

Evaluation of arrest of the first stage of labor includes an assessment of uterine activity with an IUPC; performance of clinical pelvimetry; and evaluation of fetal presentation, position, station, and estimated fetal weight. Amniotomy and oxytocin therapy can be initiated if uterine activity is found to be inadequate. The majority of gravidas respond to this intervention, resume progression of cervical dilation, and achieve vaginal delivery.

### Electromechanical Classification

An alternative classification system for disorders of the active phase of labor is based on the electromechanical state of the uterus and regard uterine tone. This classification reflects an understanding of the propagation of electrical signals through

the myometrium. In normal labor, a gradient of myometrial activity sweeps from the fundus and propagates toward the cervix through the excitation of cellular gap junctions. *Hypotonic dysfunction* reflects an inefficient generation and propagation of these action potentials through the myometrium or a lack of contractile response of myometrial cells to the initial stimulus. Hypotonic uterine contractions are infrequent, of low amplitude, and are accompanied by low or normal baseline intrauterine pressures. Maternal discomfort is minimal.

*Hypertonic dysfunction* is primarily a condition of primiparas and usually occurs in early labor. It is characterized by the presence of regular uterine contractions that fail to effect cervical effacement and dilation. Frequent contractions of low amplitude are often associated with an elevated basal intrauterine pressure. Maternal discomfort is usually significant. Therapeutic rest or expectant management can be initiated in this clinical situation if the patient is in latent labor. When diagnosed, the most likely scenario is that the patient will soon enter active labor. If the patient is in active labor and is found to have hypertonic dysfunction, amniotomy can be performed with or without concomitant oxytocin administration.

### Disorders of the Second Stage

The second stage of labor begins once the cervix becomes fully dilated and ends with the delivery of the neonate. Although fetal descent begins before the cervix becomes fully dilated, the majority of fetal descent occurs once full cervical dilation is achieved. At this time, maternal expulsion efforts may begin. Parity, delayed pushing, use of epidural analgesia, maternal BMI, birthweight, OP position, and fetal station at completed dilation all have been shown to affect the length of the second stage of labor.<sup>10</sup>

In an effort to define a normal second stage of labor, multiple investigators have studied the relationship between the duration of the second stage of labor and adverse maternal and neonatal outcomes. In one secondary analysis of a multicenter randomized study of fetal pulse oximetry in which 4126 nulliparous women were examined, none of the following outcomes were related to the duration of the second stage: 5-minute Apgar score of less than 4, umbilical artery pH less than 7, intubation in the delivery room, need for admission to the neonatal intensive care unit (NICU), or neonatal sepsis.<sup>11</sup> Fewer investigators have examined the duration of the second stage of labor and the relationship to neonatal outcomes in multiparous women. In one study of 5158 multiparous women, when second stage exceeded 3 hours, the risk of 5-minute Apgar scores of less than 7, admissions to the NICU, and composite neonatal morbidity were all increased.<sup>12</sup>

With appropriate monitoring, however, the absolute risks for adverse fetal or neonatal consequences of increasing second-stage duration appear to be, at worst, low and incremental. Although the risk of a 5-minute Apgar score below 7 and neonatal depression at birth were statistically increased when the second stage was longer than 2 hours, in a study of 58,113 multiparous women, the absolute risk of these outcomes was low (<1.5%) with a second-stage labor duration less than 2 hours, and it did not double even with durations greater than 5 hours.<sup>13</sup> Given the findings in these studies, the absolute permissible maximum length of time spent in the second stage of labor has not been identified.

*Protraction of descent* is defined as descent of the presenting part during the second stage of labor that occurs at less than

1 cm/hr in nulliparous women and less than 2 cm/hr in multiparous women. *Arrest (failure) of descent* refers to no progress in descent. Both diagnoses require evaluation of five factors: (1) uterine activity, (2) maternal expulsive efforts, (3) fetal heart rate status, (4) fetal position, and (5) clinical pelvimetry. Decisions then may be made regarding interventions, such as increasing or initiating oxytocin infusion to improve maternal expulsive efforts or proceeding with operative vaginal or cesarean delivery. **Management of the second stage of labor can be difficult, and decisions regarding intervention must be individualized.**

The median duration of the second stage is 50 to 60 minutes for nulliparas and 20 to 30 minutes for multiparas, but the range of second-stage duration is highly variable.<sup>13,14</sup> Janakiraman and colleagues compared the second stage in 3139 induced women to that of 11,588 women in spontaneous labor. No differences in the length of the second stage or in the risk of a prolonged second stage were noted between the groups, although the induced nulliparas appeared to be at increased risk for postpartum hemorrhage and cesarean delivery (4.2% vs. 2.0%, odds ratio [OR] 1.62; 95% confidence interval [CI], 1.02 to 2.58; and 10.9% vs. 7.2%, OR 1.32; 95% CI, 1.01 to 1.71, respectively).

In classic obstetric teaching, the upper limit for the duration of the second stage of labor was considered to be 2 hours. In the available literature, before diagnosing arrest of labor in the second stage—and if maternal and fetal conditions permit—it suggests at least 2 hours of pushing should be allowed with multiparous women, and at least 3 hours should be allowed with nulliparous women. Longer durations may be appropriate on an individualized basis (e.g., with epidural analgesia or with fetal malposition) as long as progress is documented.<sup>15</sup> The labor guidelines from the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD)<sup>16</sup> suggest allowing at least 1 additional hour if an epidural is present (i.e., at least 3 hours in multiparous and at least 4 hours in nulliparous women) before diagnosing second-stage arrest. **A specific absolute maximum length of time spent in the second stage of labor beyond which all women should undergo operative delivery has not been identified.**

Many authors have studied the perinatal and maternal effects of a prolonged second stage. Several studies found no increase in infant morbidity or mortality with a second stage lasting longer than 2 hours,<sup>17</sup> although the rate of vaginal delivery decreased after 3 hours in the second stage. However, a recent population-based cohort study by Allen and colleagues<sup>13</sup> examined 63,404 nulliparous women and found increased risks of low 5-minute Apgar score, birth depression, and admission to the NICU with increasing duration of the second stage greater than 3 hours. This study is the largest thus far to evaluate neonatal and maternal outcomes with a prolonged second stage. **In this study, as well as others, evidence shows that maternal morbidities—including perineal trauma, chorioamnionitis, instrumental delivery, and postpartum hemorrhage—increase with prolonged second stages that last greater than 2 hours.**

### Disorders of the Third Stage

The third stage of labor is the period from delivery of the infant to the expulsion of the placenta. Separation of the placenta is the consequence of continued uterine contractions. Signs of placental separation include a gush of blood, lengthening of the umbilical cord, and change in shape of the uterine fundus from discoid to globular with elevation of the fundal height. **The**

**interval between delivery of the infant and delivery of the placenta and fetal membranes is usually less than 10 minutes and is complete within 15 minutes in 95% of deliveries.**<sup>18</sup>

The most important risk associated with a prolonged third stage is hemorrhage; this risk increases proportionally with increased duration.<sup>19</sup> **Because of the associated increased incidence of hemorrhage after 30 minutes, most practitioners diagnose retained placenta after this time interval has elapsed.** Interventions to expedite placental delivery are usually undertaken at this point.

Management of the third stage of labor may be expectant or active. *Expectant management* refers to the delivery of the placenta without cord clamping, cord traction, or the administration of uterotonic agents such as oxytocin. *Active management* consists of some combination of early cord clamping, controlled cord traction, and administration of a uterotonic agent. Oxytocin is the usual uterotonic agent given, but others have been used, such as misoprostol or other prostaglandin compounds. **Compared with expectant management of the third stage, active management has been associated with a reduced risk of postpartum hemorrhage.**<sup>20</sup> Cochrane reviewers evaluated five trials that comprised 6486 women and compared active and expectant management. They confirmed that active management reduced the risk of maternal hemorrhage (relative risk [RR], 0.34; 95% CI, 0.14 to 0.87) but that significant increases in maternal diastolic blood pressure, afterpains, and analgesia use occurred as well. These adverse events may reflect the side effects of the various uterotonic medications used in different countries.

Some debate exists regarding the timing of oxytocin administration when active management of the third stage is practiced—that is, whether it should be after the placenta has delivered or after the anterior shoulder of the fetus has delivered. A randomized controlled trial (RCT) that included 1486 women compared the effects of oxytocin administration upon delivery of the anterior shoulder to administration after delivery of the placenta and showed no significant differences in blood loss or retained placenta between the groups.<sup>21</sup>

Retained placenta can usually be treated with measures such as manual removal or sharp curettage. Attempting manual removal can be performed under regional anesthesia or conscious sedation. If this is not successful, a sharp curettage can be performed under sonographic guidance. Prophylactic broad-spectrum antimicrobial agents are often administered when manual removal of the placenta is performed, although little evidence supports or refutes their use.<sup>22</sup>

### Anesthesia Effects on Labor Progress

Conduction epidural anesthesia's effect on the rate of cervical change remains controversial, (see Chapter 16). Unfortunately, RCTs have several limitations, mainly that there cannot be a placebo group. Thus multiple randomized trials have investigated cesarean delivery rates between women who received epidural anesthesia versus those who received systemic analgesia in labor. A 2005 Cochrane review<sup>23</sup> that involved 20 studies reported no increase in cesarean delivery rates between women who received epidural anesthesia versus those who received systemic analgesia for labor (RR, 1.07; 95% CI, 0.93 to 1.23). A more recent meta-analysis<sup>24</sup> that involved 15 RCTs and included 4619 patients also compared the effects of epidural anesthesia to parenteral opioids. The incidence of cesarean delivery was the same between the groups, although the incidence of operative

vaginal delivery was increased in the conduction anesthesia group [OR, 1.92; 95% CI, 1.52 to 1.22). It has been difficult to establish whether this increase in operative vaginal delivery was due to a direct effect of the epidural analgesia on the progress of labor or an indirect effect, such as greater opportunities for resident training. No difference in the duration of the first stage was noted; however, the second stage was prolonged by approximately 16 minutes (95% CI, 10 to 23 minutes). This statistically significant finding lacks clinical relevance.<sup>24</sup>

It has also been suggested that receiving epidural anesthesia during latent labor, as opposed to during the active phase, results in prolongation of the labor. Accordingly, many practitioners refrain from administering epidural analgesia until the patient reaches 4 cm or more dilation. In one investigation, 12,693 nulliparas were randomized to receive early epidural analgesia (at first request if cervical dilation was at least 1 cm) or late epidural analgesia (parenteral meperidine until cervical dilation of 4 cm was achieved). The median cervical dilation at the time of epidural placement was 1.6 cm for the early group and 5.1 for the late group. These researchers found no difference in the incidence of cesarean birth, operative vaginal delivery, or length of the first or second stages of labor.

## MANAGEMENT OF ABNORMAL LABOR AND DELIVERY

### Pharmacologic Augmentation

When the first stage of labor is protracted or an arrest disorder is diagnosed, an evaluation of uterine activity; clinical pelvimetry; and fetal position, station, and estimated weight should be performed. If uterine activity is found to be suboptimal, the most common remedy is oxytocin augmentation. Various oxytocin dosing regimens have been described in the obstetric literature. Local protocols for oxytocin administration should include the dose of oxytocin being delivered (mU/min) as opposed to the volume of fluid being infused (mL/min) and should specify initial dose, incremental increases with time, and maximum permissible dose. Although oxytocin currently is used in a majority of labors in the United States, it is important for clinicians to recognize that it is also the medication implicated in approximately half of all paid obstetric litigation claims, and it is the medication most commonly associated with preventable adverse events during childbirth.<sup>25</sup>

Misoprostol solution given orally has been proposed as an alternative augmentation agent. Ho and colleagues<sup>26</sup> randomized 231 women to a solution of 20 µg misoprostol, prepared by dissolving one 200-µg tablet of misoprostol in 200 mL tap water, or to intravenous (IV) oxytocin. The results of this admittedly small study revealed similar rates of vaginal delivery between the two groups, and no difference was noted in side effects or neonatal outcomes.

### Side Effects

One of the advantages of oxytocin administration is that if uterine overactivity is encountered, the infusion can quickly be stopped, and **the half-life of oxytocin is approximately 3 minutes**. The most frequently encountered complication of oxytocin or prostaglandin administration is uterine overactivity. However, until an NICHD workshop attempted to provide standardized nomenclature for uterine activity and electronic fetal heart monitoring,<sup>27</sup> no uniform definitions existed for terms like *hyperstimulation* and *tachysystole*. These guidelines

define *tachysystole* as more than five contractions in 10 minutes averaged over a 30-minute window, and they recommend abandoning the terms *hyperstimulation* and *hypercontractility*.<sup>27</sup>

Because oxytocin is structurally and functionally related to vasopressin, one of its side effects is, in rare instances, water intoxication and hyponatremia. Historically, bolus injections of oxytocin were thought to cause hypotension, and the current practice for labor management is administration by infusion pump or slow drip. Some investigators<sup>28</sup> have suggested that a 10-IU bolus of oxytocin given in the third stage of labor is not associated with adverse hemodynamic responses compared with oxytocin given as an infusion. However, Jonsson and colleagues found that an IV bolus was associated with ST depressions seen on the electrocardiogram. **Given that no advantage has been found with the use of IV boluses of oxytocin, and given the potential hemodynamic adverse consequences, this form of administration is not recommended.** Finally, uterine rupture is rare and in most instances occurs in women who have had a prior uterine surgery, such as a cesarean delivery or myomectomy.

Recent investigations have shed light on the question of labor augmentation and induction for women attempting a trial of labor after cesarean delivery (TOLAC; see Chapter 20). Whereas no randomized trials have been done, a large prospective investigation<sup>29</sup> evaluated more than 17,000 women attempting TOLAC. The incidence of uterine rupture was 0.4% for those subjects who spontaneously labored versus 0.9% for those who received augmentation and 1.0% for subjects who underwent induction. Other complications of attempting TOLAC are illustrated in Table 13-3. **ACOG currently recommends the use of oxytocin in augmentation and induction of women undergoing a TOLAC.**<sup>30</sup>

## INDUCTION OF LABOR

*Induction of labor* refers to the iatrogenic stimulation of uterine contractions before the onset of spontaneous labor to accomplish vaginal delivery, and it is one of the most commonly performed obstetric procedures in the United States.<sup>31</sup> *Augmentation of labor* refers to increasing the frequency and intensity of existing uterine contractions to accomplish vaginal delivery in a patient who is in labor but is not progressing adequately.

### Indications and Contraindications

Induction of labor should be undertaken when the benefits of delivery to either mother or fetus outweigh the risks of pregnancy continuation.<sup>31</sup> Many accepted medical and obstetric indications for labor induction exist (Table 13-4). Contraindications include those that preclude vaginal delivery (Table 13-5).

With regard to induction of labor versus expectant management for gestational hypertension or preeclampsia without severe features, investigators in the Netherlands performed a trial in which 756 patients were randomized to receive induction ( $n = 377$ ) or expectant monitoring ( $n = 379$ ). Of women who were randomized to induction of labor, 117 (31%) experienced poor maternal outcome compared with the 166 (44%) allocated to expectant management (RR, 0.71; 95% CI, 0.59 to 0.86;  $P = .0001$ ). No cases of maternal or neonatal death or eclampsia were recorded.<sup>32</sup> Thus in women with gestational hypertension or preeclampsia without severe features, induction of labor is associated with improved maternal outcome, and it should be advised at 37 weeks' gestation.

**TABLE 13-3** MATERNAL COMPLICATIONS ASSOCIATED WITH TRIAL OF LABOR AFTER PREVIOUS CESAREAN

| COMPLICATION                     | TRIAL OF LABOR<br>(N = 17,898) | ELECTIVE REPEATED CESAREAN<br>DELIVERY (N = 15,801) | ODDS RATIO<br>(95% CI) | P VALUE |

**TABLE 13-4** ACCEPTED INDICATIONS FOR LABOR INDUCTION

|  |
|--|
| Hypertensive disorders                   |
| • Preeclampsia/eclampsia                 |
| • Gestational hypertension               |
| Maternal medical conditions              |
| • Diabetes mellitus                      |
| • Renal disease                          |
| • Chronic pulmonary disease              |
| • Cholestasis of pregnancy               |
| Premature rupture of membranes           |
| Chorioamnionitis                         |
| Abruptio placentae                       |
| Fetal compromise                         |
| • Fetal growth restriction               |
| • Isoimmunization                        |
| • Nonreassuring antepartum fetal testing |
| • Oligohydramnios                        |
| • Multiple gestations                    |
| Fetal demise (≥41 wk)                    |

**TABLE 13-5** ACCEPTED ABSOLUTE CONTRAINDICATIONS TO LABOR INDUCTION

|   |
|---|
| Prior classic uterine incision or transfundal uterine surgery (other high-risk cesarean incision) |
| Prior uterine rupture   |
| Active genital herpes infection   |
| Placenta or vasa previa   |
| Umbilical cord prolapse   |
| Transverse or oblique fetal lie   |
| Absolute cephalopelvic disproportion (as in women with pelvic deformities)                        |
| Category III fetal heart rate tracing   |

“Impending” macrosomia, a favorable cervix, patients considered to be at increased risk for preeclampsia (such as having a prior history of preeclampsia), or concerns about intrauterine growth restriction (e.g., a fetus with an estimated weight at the 19th percentile) are *not* accepted medical indications for induction. Additionally, preterm or early-term induction is not medically indicated for maternal anxiety or discomfort related to normal pregnancy, previous pregnancy with labor abnormalities such as rapid labor or shoulder dystocia, or simply because the mother lives far from the hospital. Currently, experts concur that elective induction should not be performed before 39 weeks of gestation; however, insufficient data are available to recommend for or against induction of labor at 39 or more weeks of gestation.<sup>33</sup>

**TABLE 13-6** EVALUATION BEFORE INDUCTION OF LABOR

| PARAMETER      | CRITERIA  |
|----------------|---|
| Maternal       | Confirm the indication for induction.<br>Review contraindications to labor and/or vaginal delivery.<br>Perform clinical pelvimetry to assess the shape and adequacy of the bony pelvis.<br>Assess the cervical condition (assign Bishop score).<br>Review risks, benefits, and alternatives of induction of labor with the patient. |
| Fetal/neonatal | Confirm gestational age.<br>Assess the need to document fetal lung maturity status.<br>Estimate fetal weight, either by clinical or ultrasound examination.<br>Determine fetal presentation and lie.<br>Confirm fetal well-being.   |

Examination of the maternal and fetal condition is required before undertaking labor induction (Table 13-6). Indications and contraindications for induction should be reviewed along with the alternatives. Risks and benefits of labor induction should be discussed with the patient, including the risks of cesarean delivery (discussed later). Confirmation of gestational age is critical, and evaluation of fetal lung maturity status should be performed if indicated (Table 13-7).<sup>31</sup> Fetal weight should be estimated, clinical pelvimetry should be performed, and fetal presentation should be confirmed; in addition, a cervical examination should be performed and documented, and labor induction should be performed at a location where personnel are available who are familiar with the process and its potential complications. Uterine activity and electronic fetal monitoring (EFM) are recommended for any gravida receiving uterotonic medications.

### Prolonged Pregnancy

In a joint Committee Opinion,<sup>2</sup> the ACOG and SMFM discourage the use of the label *term pregnancy* and instead have replaced it with the labels *early term*, *full term*, *late term*, and *postterm*. **Postterm pregnancy (≥42 weeks of gestation) is associated with increased risks for the fetus and mother** (see Chapter 36). According to a large epidemiologic study by Hilder and colleagues,<sup>34</sup> the perinatal mortality rate—which combines stillbirths (fetal death after 20 weeks’ gestation) and early neonatal deaths (death of a liveborn infant within the first 28 days of life)—at greater than 42 weeks of gestation is approximately twice that at term (4 to 7 deaths vs. 2 to 3 deaths per 1000

**TABLE 13-7** CRITERIA FOR CONFIRMATION OF GESTATIONAL AGE AND/OR FETAL PULMONARY MATURITY

|                                 | PARAMETERS  |
|---------------------------------|---|
| Confirmation of gestational age | Fetal heart tones have been documented as present for $\geq 30$ weeks by Doppler ultrasound.<br><i>At least 36 weeks have elapsed since a positive serum or urine human chorionic gonadotropin pregnancy test.</i><br>Ultrasound measurement at less than 20 weeks' gestation supports gestational age of 39 weeks or more.   |
| Fetal pulmonary maturity        | If term gestation cannot be confirmed by two or more of the above obstetric clinical or laboratory criteria, amniotic fluid analysis can be used to provide evidence of fetal lung maturity. A variety of tests are available. The parameters for evidence of fetal pulmonary maturity include: <ol style="list-style-type: none"> <li>1. Lecithin/sphingomyelin (L/S) ratio greater than 2.1</li> <li>2. Presence of phosphatidylglycerol</li> <li>3. TDx-FLM assay shows <math>\geq 70</math> mg surfactant per gram of albumin</li> <li>4. Presence of saturated phosphatidylcholine (SPC) 500 ng/mL or more in nondiabetic patients (<math>\geq 1000</math> ng/mL for pregestational diabetic patients)</li> <li>5. Lamellar body count exceeds 30,000/<math>\mu</math>L</li> </ol> |

deliveries) and increases more than sixfold at 43 weeks of gestation and beyond.

Two more recent studies<sup>35,36</sup> consisted of prospective cohort evaluations of singleton pregnancies based on ultrasound dating. Nakling and Backe<sup>35</sup> found the incidence of postterm pregnancies to be 7.6% in the cohort, with 0.3% of pregnancies progressing to 301 days (43 weeks' gestation) if inductions were not permitted prior to 43 weeks. This investigation found a significantly increased rate of perinatal mortality after 41 weeks' gestation. In contrast, Heimstad and colleagues<sup>36</sup> found an increased trend toward intrauterine fetal demise at 42 weeks' gestation compared with that at 38 weeks, but this study allowed inductions prior to 43 weeks and did not calculate the perinatal mortality rates. Factors that may contribute to the increased rate of perinatal deaths are uteroplacental insufficiency, meconium aspiration, intrauterine growth restriction (IUGR), and intrauterine infection.<sup>37</sup> For these reasons, common practice has been to deliver patients by 42 0/7 weeks.

Postterm pregnancy is also associated with increased risks for the pregnant woman, including an increase in labor dystocia (9% to 12% vs. 2% to 7% at term) and an increase in severe perineal injury (3.3% vs. 2.6% at term).<sup>36,38-40</sup>

Overall, comparisons of induction of labor to expectant management in observational studies have found no difference in, or a decreased risk of, cesarean delivery among women who are induced.<sup>41-44</sup> This is also true for women with an unfavorable cervix.<sup>45</sup> For example, a meta-analysis revealed that women at less than 42 0/7 weeks' gestation who underwent induction of labor had a lower cesarean section delivery rate than those who received expectant management.<sup>46</sup> In this meta-analysis, 11 RCTs and 25 observational studies were included and overall, expectant management of pregnancy was associated with a higher odds of cesarean delivery than was induction of labor (OR, 1.22; 95% CI, 1.07 to 1.39). Also, in a 2012 Cochrane meta-analysis of three smaller studies of induction of labor at 41 0/7 weeks, a reduction in the rate of cesarean delivery was demonstrated.<sup>47</sup> Thus the evidence base suggests that labor inductions at 41 0/7 weeks should be performed to reduce the risk of cesarean delivery and the risk of perinatal morbidity and mortality.

### Elective Induction of Labor

The rate of induction of labor more than doubled from 1990 through 2010, from 9.6% to 23.8%. Induction rates were at least twice as high in 2010 compared with 1990 for women at

all gestational ages except for those in the post term, whose rate of induction rose 90%.<sup>48</sup> Reasons for the general increase over time in inductions include the availability of better cervical ripening agents, patient and provider desire for a more convenient time of delivery, and more acceptance of a variety of indications for induction. Nevertheless, the overall induction rate declined slightly in 2011, to 23.7% (from 23.8% in 2010), and then it declined again in 2012, to 23.3%.<sup>48</sup> Induction rates were lower for all gestational age categories.

**Elective induction of labor refers to the initiation of labor for convenience in an individual with a term pregnancy who is free of medical or obstetric indications.** Although elective induction at or after 39 weeks of gestation is not recommended or encouraged, it may be appropriate in specific instances, such as for women with a history of very short labors or those who live a great distance from the hospital.<sup>31</sup> Also, a patient who has experienced a prior stillbirth at or near term may request labor induction to ease anxiety and fears about the loss of a subsequent pregnancy. In addition, certain maternal medical conditions require multispecialty participation, in which the benefit of a planned delivery in order to have experienced personnel readily available is most appropriate, such as when a fetal anomaly is present.

Some concerns have been raised that induction of labor increases the rate of cesarean delivery and increases health care costs. Seyb and colleagues noted in their investigation that the mean time spent on labor and delivery was almost twice as long, and postpartum stays were prolonged for those induced. The total cost associated with hospitalization for elective induction was also 17.4% higher than for those in spontaneous labor. These findings were confirmed in investigations by Maslow and Sweeney and Cammu and colleagues.<sup>49</sup>

However, these results are based on the faulty comparison of women who are induced with those in spontaneous labor.<sup>40</sup> In fact, most observational studies that compare induction of labor to expectant management—which is the actual clinical alternative to labor induction—have found either no difference or a decreased risk of cesarean delivery among women who are induced.<sup>41</sup> Because these studies are retrospective in nature, they should be interpreted with caution.

In addition, several RCTs have been recently undertaken. In a meta-analysis by Caughey and colleagues,<sup>46</sup> nine RCTs were evaluated. These trials utilized patients undergoing expectant management, rather than spontaneous labor, as the comparison group for the patients being electively induced, and the

meta-analysis revealed a decreased risk of cesarean delivery in the induction group compared with the group managed expectantly (RR, 1.17; 95% CI, 1.05 to 1.29). Similarly, Cochrane reviewers<sup>50</sup> examined 19 trials that included 7984 women and found that women induced at 37 to 40 completed weeks were less likely to have a cesarean delivery than those in the expectant management group (RR, 0.58; 95% CI, 0.34 to 0.99). Caughey and colleagues<sup>51</sup> also examined the risk of cesarean delivery for each week of gestational age ranging from 38 to 41 weeks. In their retrospective study, which again compared induction to expectant management, cesarean delivery was decreased in the induction groups.

With regard to perinatal outcomes, it appears that compared with infants who undergo spontaneous labor, fewer electively induced infants have meconium passage and therefore likely have a reduced incidence of meconium aspiration syndrome.<sup>46</sup> Macrosomia also may be reduced, as noted in an ecological study performed by Zhang and colleagues.<sup>52</sup> This study revealed that the increased induction rate between 1992 and 2003 (14% to 27%) was significantly associated with reduced mean fetal birth weight ( $r = -0.54$ ; 95% CI,  $-0.71$  to  $-0.29$ ) and rate of macrosomia ( $r = -0.55$ ; 95% CI,  $-0.74$  to  $-0.32$ ).

The risk of respiratory morbidity associated with labor induction was illustrated in a retrospective review of infants admitted to the NICU following elective delivery at term.<sup>53</sup> These results support delaying elective delivery until 39 weeks' gestation (Table 13-8). In further support of these findings, Clark and colleagues<sup>54</sup> performed a prospective observational study of 27 hospitals that included 17,794 deliveries. Of these, 14,955 (84%) occurred at 37 weeks or greater; 6562 (44%) of them were planned deliveries, rather than spontaneous. Among the planned deliveries, 4645 (71%) were elective. The percentage of the electively delivered infants admitted to the NICU was 17.8% ( $n = 43$ ) at 37 to 38 weeks, 8% ( $n = 118$ ) at 38 to 39 weeks, and 4.6% ( $n = 135$ ) at 39 weeks. These studies reiterate the importance of considering neonatal morbidity with elective induction prior to 39 weeks' gestation. After 39 weeks, however, one study<sup>55</sup> has suggested that infants of electively induced mothers were less likely to receive ventilatory support, become septic, or be admitted to the NICU.

One other concern regarding elective induction is the cost. Kaufman and colleagues<sup>56</sup> studied the economic consequences of elective induction of labor at term. Using decision analysis, these researchers examined a hypothetical cohort of 100,000 pregnant patients for whom an initial decision was made to either

induce labor at 39 weeks or follow the patient expectantly through the remainder of the pregnancy. All patients in this model underwent induction at 42 weeks' gestation if they were not yet delivered. Using baseline estimates, the investigators concluded that elective induction would result in more than 12,000 excess cesarean deliveries and would impose an annual cost to the medical system of nearly \$100 million. A policy of induction at any gestational age, regardless of parity or cervical ripeness, requires economic expenditures by the medical system. Although they never were cost saving, inductions in this study were less expensive at later gestational ages, for multiparous patients, and for those women with a favorable cervix. The inductions most costly to the health care system were those performed in nulliparas with unfavorable cervixes at 39 weeks. That said, this model incorporated the assumption that labor induction increased the risk of cesarean delivery. When all outpatient and inpatient costs are considered, it remains uncertain whether labor induction is more costly than expectant management.

### Prediction of Labor Induction Success

In observational studies, characteristics associated with successful induction include multiparity, tall stature (over 5 feet 5 inches), nonobese maternal weight or BMI, and infant birth-weight less than 3.5 kg.<sup>53,57</sup> However, these characteristics are predictive of success even in spontaneous labors. Success can vary widely depending on the characteristics of the population being induced (e.g., intact or ruptured membranes, parity, baseline cervical exam), induction methods, and choice of end points (delivery within 24 or 48 hr, dose/duration of oxytocin infusion, route of delivery, and maternal and neonatal morbidity).

Some researchers<sup>58</sup> have tried to identify, with varying success, biochemical and biophysical assays to predict the probability of vaginal delivery following labor induction. These measures include digital evaluation of the cervix, ultrasonographic cervical length measurements, and use of fetal fibronectin before labor induction.

**Cervical status is one of the most important factors for predicting the likelihood of success in induction of labor.** The modified Bishop score is the system most commonly used in clinical practice in the United States to evaluate the cervix prior to induction. This system tabulates a score based upon the station of the presenting part and four characteristics of the cervix: (1) dilation, (2) effacement, (3) consistency, and (4) position (Table 13-9).<sup>59</sup> If the Bishop score is *high*, variously defined but often considered to be a score of 8 or higher, the likelihood of vaginal delivery is similar whether labor is spontaneous or induced.<sup>60</sup> In contrast, a low Bishop score, variously defined but

**TABLE 13-8 NEONATAL RESPIRATORY MORBIDITY**

| GESTATIONAL AGE (WEEKS)        | FREQUENCY OF NICU ADMISSION PER 1000 DELIVERIES | ODDS RATIO (95% CI) |

often considered to be 6 or lower, increases the likelihood that induction will fail to result in vaginal delivery.<sup>31</sup> These relationships are stronger in nulliparous women.<sup>61,62</sup> As an example, a study<sup>61</sup> of 4635 spontaneous and 2647 induced labors in nulliparous women at term reported that the cesarean delivery rates were almost doubled for women with induced labors with Bishop scores below 5 compared with those with Bishop scores of 5 or higher (32% vs. 18%). Of note, the relationship between a low Bishop score and failed induction, prolonged labor, and a high cesarean birth rate was first described prior to widespread use of cervical ripening agents.<sup>63</sup> However, this relationship has persisted even after introduction of these agents.

Sonographic assessment of cervical length for predicting the outcome of labor induction has been evaluated in numerous studies. A systematic review<sup>64</sup> of 20 prospective studies found that short cervical length was associated with successful induction (likelihood ratio of a positive test, 1.66; 95% CI, 1.20 to 2.31) and failed induction (likelihood ratio of a negative test, 0.51; 95% CI, 0.39 to 0.67). The results of the study are limited by the fact that the trials that were included used different cervical length cutoff values (16.5 to 35 mm). Additionally, subgroup analysis on the seven trials that used a cervical length cutoff of 30 mm demonstrated that cervical length did not accurately predict any single specific outcome. Sonographic cervical length performed poorly for predicting vaginal delivery within 24 hours (sensitivity 59%, specificity 65%), vaginal delivery (sensitivity 67%, specificity 58%), or achievement of active labor (sensitivity 57%, specificity 60%), and it did not perform significantly better than the Bishop score for predicting a successful induction. In another systematic review<sup>65</sup> of 31 prospective studies that comprised 5029 women, cervical length did not perform better than Bishop score for predicting a successful induction. Thus **the role of ultrasound examination as a tool for selecting women likely to have a successful induction is uncertain, and more data are needed before this test can be recommended in choosing candidates for induction.**

The presence of an elevated fetal fibronectin (fFN) concentration in cervicovaginal secretions also has been used to try to predict success of induction, and fFN is thought to represent a disruption or inflammation of the chorionic-decidual interface. In some studies,<sup>66</sup> women with a positive fFN result had a significantly shorter interval before delivery than those with a negative fFN result, and a reduction was seen in the frequency of cesarean delivery. However, other investigations<sup>67</sup> have not confirmed these findings.

Bailit and colleagues<sup>68</sup> used a decision analysis to determine whether the vaginal delivery rate is increased in nulliparous women who undergo elective labor induction following fFN testing. In this model, three management strategies were evaluated: (1) no elective induction of labor for any candidate until 41 weeks' gestation (expectant management), (2) induction only of those patients with a positive fFN result at 39 weeks, and (3) elective induction for every woman at 39 weeks' gestation without performance of an fFN test. These investigators found that the expectant management strategy had the highest rate of vaginal delivery, and they concluded that the best approach to improve vaginal delivery rates was to avoid elective induction in nulliparous women.

Thus the role of fFN testing as a tool for selecting women likely to have a successful induction is uncertain. More data are needed before this test can be recommended for choosing candidates for induction.

## Cervical Ripening

As discussed earlier, the condition of the cervix greatly influences the success of inducing labor. Cervical ripening is a complex process that results in physical softening and distensibility of the cervix and ultimately leads to partial cervical effacement and dilation.<sup>69</sup> Remodeling of the cervix involves enzymatic dissolution of collagen fibrils, increase in water content, and chemical changes. These changes are induced by hormones (estrogen, progesterone, relaxin), cytokines, prostaglandin, and nitric oxide synthesis enzymes.<sup>69</sup> Cervical ripening methods fall into two main categories: *pharmacologic* and *mechanical* (Table 13-10). **Because the state of the cervix plays such a crucial role in labor induction, a cervical examination is essential before determining which, if any, method to use for labor induction.**

## Failed Induction

Vaginal delivery is the goal of the induction process; however, this occurs less often than when women labor spontaneously. It is important for the clinician to recall that cervical ripening itself can take some time, and that the development of an active labor pattern should be achieved prior to the determination that the induction has failed. **No universal standard exists for what constitutes a failed induction.** The key principle is to allow adequate time for cervical ripening and development of active labor before diagnosing a failed induction. The importance of allowing enough time to progress from the latent phase of labor to the active phase is illustrated by a number of reports.

In one large prospective study,<sup>60</sup> the mean duration of the *latent phase* of labor—defined as the interval from initiation of induction with either prostaglandins or oxytocin to a cervical dilation of 4 cm—in women with a Bishop score of 0 to 3 was 12 hours in multiparas and 16 hours in nulliparas. In another study,<sup>70</sup> requiring a minimum of 12 hours of oxytocin administration after membrane rupture before diagnosing failed labor induction led to vaginal deliveries in 75% of nulliparas and eliminated failed labor induction as an indication for cesarean delivery in parous women. A third series<sup>71</sup> found that 73% of women who ultimately delivered vaginally had a latent phase of up to 18 hours. *Latent phase* was defined as the interval from initiation of oxytocin or amniotomy to the beginning of the active phase (i.e., cervical dilation of 4 cm with 80% effacement or 5 cm dilation).

In a retrospective cohort study,<sup>72</sup> the duration of the *first stage*—defined as cervical dilation from 4 to 10 cm—was significantly longer in induced labor than in spontaneous labor: the median (95th percentile) for induced versus spontaneous labor in nulliparas was 5.5 hours (16.8 hr) versus 3.8 hours

(11.8 hours); and for multiparas, it was 4.4 hours (16.2 hours) versus 2.4 hours (8.8 hours). Although the short ( $\leq 1$  hour) *active phase*, defined as cervical dilation from 6 to 10 cm, was similar for induced and spontaneous labors, each centimeter of dilation between 3 and 5 cm could take 8 to 10 hours (95th percentile) in induced labor, and dilating from 5 to 6 cm could take 4 to 6 hours (95th percentile).

The workshop convened by the NICHD, SMFM, and ACOG<sup>16</sup> proposed that *failed induction* be defined as failure to generate regular contractions approximately every 3 minutes and failure of the cervix to change after at least 24 hours of oxytocin administration. If safe and feasible, membranes should also be artificially ruptured. Of note, the time for cervical ripening is not included in calculating the length of induction or diagnosing a failed induction.

Lin and Rouse<sup>73</sup> proposed that *failed induction* be defined as the inability to achieve cervical dilation of 4 cm and 80% effacement or 5 cm (regardless of effacement) after a minimum of 12 to 18 hours of both oxytocin administration and membrane rupture. They also specified that uterine contractile activity should reach five contractions in 10 minutes or 250 Montevideo units, which is the minimum level achieved by most women whose labor is progressing normally.

Beckman<sup>74</sup> evaluated a group of 978 nulliparous women after either artificial or spontaneous rupture of membranes to determine factors that could predict failed induction. After membrane rupture and 10 hours of oxytocin administration, the 8% of women not in the active phase of labor had an approximately 75% chance of being delivered by cesarean section for failed induction; after 12 hours of oxytocin administration, the chance of cesarean delivery was almost 90%. Multivariate analysis showed that short maternal stature and use of pharmacologic or mechanical methods of cervical ripening contributed to an increased probability of cesarean delivery. Similarly, a linear relationship was found between lack of cervical dilation and cesarean delivery. The authors concluded that the continuation of oxytocin after amniotomy for women who had not yet reached at least 4 cm dilation was not unreasonable, but that beyond 12 hours, the benefit was unclear.

**Membrane rupture and oxytocin administration should in most cases be a prerequisite before diagnosis of failed induction of labor. Additionally, experts have proposed waiting at least 24 hours in the setting of both oxytocin and ruptured membranes before diagnosing failed induction of labor.**<sup>16</sup>

## TECHNIQUES FOR CERVICAL RIPENING AND LABOR INDUCTION

### Oxytocin

Oxytocin is a polypeptide hormone produced in the hypothalamus and secreted from the posterior lobe of the pituitary gland in a pulsatile fashion. It is identical to its synthetic analogue, which is among the most potent uterotonic agents known. Synthetic oxytocin is an effective means of labor induction.<sup>75</sup> Exogenous oxytocin administration produces periodic uterine contractions first demonstrable at approximately 20 weeks' gestation, with increasing responsiveness with advancing gestational age primarily due to an increase in myometrial oxytocin binding sites. Little change occurs in myometrial sensitivity to oxytocin from 34 weeks to term; however, **once spontaneous labor begins, the uterine sensitivity to oxytocin increases rapidly.**

**This physiologic mechanism makes oxytocin more effective in augmenting labor than in inducing it, and it is even less successful as a cervical ripening agent.**

Oxytocin is most often given intravenously. It cannot be given orally because the polypeptide is degraded to small, inactive forms by gastrointestinal enzymes. **The plasma half-life is short, estimated at 3 to 6 minutes, and steady-state concentrations are reached within 30 to 40 minutes of initiation or dose change. Synthetic oxytocin is generally diluted by placing 10 units in 1000 mL of an isotonic solution, such as normal saline, yielding an oxytocin concentration of 10 mU/mL. It is given by infusion pump to allow continuous, precise control of the dose administered.**

Although oxytocin is an effective means of labor induction in women with a favorable cervix, as noted earlier, it is less effective as a cervical ripening agent. Many RCTs that have compared oxytocin with various prostaglandin (PG) formulations and other methods of cervical ripening confirm this observation. Lyndrup and colleagues compared the efficacy of labor induction with vaginal PGE<sub>2</sub> with continuous oxytocin infusion in 91 women with an unfavorable cervix (Bishop score  $< 6$ ). They found PGE<sub>2</sub> more efficacious for labor induction with fewer women undelivered at 24 hours. However, they also found no difference in vaginal delivery rates after 48 hours between the two groups. In a larger study that involved 200 women with an unfavorable cervix undergoing labor induction, vaginally applied PGE<sub>2</sub> was compared with continuous oxytocin infusion. These investigators found a shorter time interval to active labor, a significantly greater change in Bishop score, fewer failed inductions, and fewer multiple-day inductions with PGE<sub>2</sub> compared with oxytocin. No difference in the rate of cesarean delivery was found between the groups overall. In a Cochrane review<sup>75</sup> of 110 trials that included more than 11,000 women and compared oxytocin with any vaginal PG formulation for labor induction, oxytocin alone was associated with an increase in unsuccessful vaginal delivery within 24 hours (52% vs. 28%; RR, 1.85; 95% CI, 1.41 to 2.43). No difference was found in the rate of cesarean delivery between the groups. When intracervical PGs were compared with oxytocin alone for labor induction, oxytocin alone was associated with an increase in unsuccessful vaginal delivery within 24 hours (51% vs. 35%; RR, 1.49; 95% CI, 1.12 to 1.99) and an increase in cesarean delivery (19% vs. 13%; RR, 1.42; 95% CI, 1.11 to 1.82).

In the setting of *premature rupture of membranes* (PROM) at term, defined as rupture of membranes before the onset of labor, labor induction is recommended if spontaneous labor does not ensue within a certain amount of time because as the time between rupture of membranes and the onset of labor increases, so may the risk of maternal and fetal infection.<sup>76</sup> A series of systematic reviews examined the outcomes of pregnancies with PROM at or near term.<sup>76</sup> One trial accounts for most of the patients included in the analysis. Hannah and colleagues studied 5041 women with PROM at term. Subjects were randomly assigned to receive IV oxytocin, vaginal PGE<sub>2</sub> gel, or expectant management for up to 4 days. Those randomized to the expectant management group were induced if complications such as chorioamnionitis developed. The rates of neonatal infection and cesarean delivery were not statistically different between the groups. Rates of clinical chorioamnionitis were lower in the group that received IV oxytocin. When Cochrane reviewers<sup>75</sup> compared oxytocin alone with vaginal PGs in 14 trials for labor induction after PROM, both medications

**TABLE 13-11** LABOR STIMULATION WITH OXYTOCIN: EXAMPLES OF LOW- AND HIGH-DOSE OXYTOCIN DOSING REGIMENS

| REGIMEN               | STARTING DOSE (mU/MIN) | INCREMENTAL INCREASE (mU/MIN) | DOSAGE INTERVAL (MIN) |
|-----------------------|------------------------|-------------------------------|-----------------------|
| Low dose              | 0.5-1.0                | 1                             | 30-40                 |
| Alternative low dose  | 1-2                    | 2                             | 15-30                 |
| High dose             | 6                      | 6*                            | 15-40                 |
| Alternative high dose | 4                      | 4                             | 15                    |

From Induction of Labor. ACOG Practice Bulletin No 107. American College of Obstetricians and Gynecologists. *Obstet Gynecol.* 2009;114:386.

\*The incremental increase should be reduced to 3 mU/min if tachysystole is present and should be reduced to 1 mU/min for recurrent tachysystole.

were found to be equally efficacious. Thus both can be used in this clinical setting.

The optimal regimen for oxytocin administration is debatable, although success rates for varying protocols are similar. Protocols differ as to the initial dose, incremental time period, and steady-state dose (Table 13-11).<sup>31</sup> A maximum oxytocin dose has not been established, but most protocols do not exceed 42 mU/min.

**Low-dose protocols mimic endogenous maternal physiology and are associated with lower rates of uterine tachysystole.** Low-dose oxytocin is initiated at 0.5 to 1 mU and is increased by 1 mU/min at 30- to 40-minute intervals. An alternative low dose begins at 1 to 2 mU/min increased by 2 mU/min with shorter incremental time intervals of 15 to 30 minutes.

High-dose oxytocin regimens are often used in active management of labor protocols. These regimens are largely used for labor augmentation, rather than for labor induction, and often start with an initial oxytocin dose of 6 mU/min<sup>77</sup> that is increased by 6 mU/min at 15- to 40-minute intervals or start at 4 mU/min with 4 mU/min incremental increases every 15 minutes. A prospective study<sup>78</sup> that involved nearly 5000 women at Parkland Hospital compared low- and high-dose oxytocin regimens for labor induction, and augmentation was undertaken. The high-dose protocol provided for reduction of the dosage to 3 mU/min in the presence of uterine tachysystole. The results indicated that subjects given the high-dose regimen had a significantly shorter mean admission to delivery time, fewer failed inductions, fewer forceps deliveries, fewer cesarean deliveries for failure to progress, less chorioamnionitis, and less neonatal sepsis than subjects given the low-dose regimen. Notably, these subjects had a higher rate of cesarean delivery performed for "fetal distress," but no differences in neonatal outcomes were noted. Merrill and Zlatnik<sup>79</sup> conducted a randomized, double-blind trial that included 1307 patients and compared high-dose oxytocin (4.5 mU/min initially increased by 4.5 mU/min every 30 minutes) with a low-dose regimen (1.5 mU/min initially, increased by 1.5 mU/min every 30 minutes) for augmentation and induction of labor. Oxytocin solutions were prepared by a central pharmacy, and infusion volumes were identical to ensure double masking. In the group that received high-dose oxytocin, labor was significantly shortened whether the drug was used for induction (8.5 vs. 10.5 hours,  $P < .001$ ) or for augmentation (4.4 vs. 5.1 hours,  $P = .3$ ). No significant difference was reported in the rates of cesarean delivery between the two regimens (15% vs. 11.3%,  $P = .17$ ). However, more decreases or discontinuations of oxytocin were seen in the high-dose group both for

**TABLE 13-12** STANDARDIZED OXYTOCIN REGIMEN

1. Dilution: 10 U oxytocin in 1000 mL normal saline for a resultant concentration of 10 mU oxytocin/mL
2. Infusion rate: initial dose 2 mU/min (infusion rate 12 mL/hr)
3. Incremental increase: 2 mU/min or 12 mL/hr every 45 min until contraction frequency is adequate
4. Maximum dose: 16 mU/min or 96 mL/hr

From Hayes EJ, Weinstein L. Improving patient safety and uniformity of care by a standardized regimen for the use of oxytocin. *Am J Obstet Gynecol.* 2008;198(6):622.e1-7. Epub 2008 Mar 20.

uterine tachysystole and fetal heart rate abnormalities, yet neonatal outcomes were observed to be similar in both groups.

Satin and colleagues<sup>78</sup> studied the differences in outcomes when oxytocin was used to *augment*, as opposed to *induce*, labor. The low-dose regimen consisted of a starting dose of 1 mU/min with incremental increases of 1 mU/min at 20-min intervals until 8 mU/min then 2 mU/min increases up to a maximum of 20 mU/min. The high-dose regimen consisted of a starting dose of 6 mU/min with increases of 6 mU/min at 20-minute intervals up to a maximum dose of 42 mU/min. Labor augmentation was more than 3 hours shorter in the high-dose group, and high-dose augmentation resulted in fewer cesarean deliveries for labor dystocia and fewer failed inductions when compared with the low-dose regimen. A literature review of randomized clinical trials of high- versus low-dose oxytocin regimens published from 1966 to 2003 revealed that high-dose oxytocin decreased the time from admission to vaginal delivery but did not decrease the incidence of cesarean delivery compared with low-dose therapy. The only double-blinded randomized trial that has been published had similar findings.<sup>79</sup> In a 2014 Cochrane review of nine trials, high-dose oxytocin reduced the induction to delivery interval in high-quality trials but did not decrease the frequency of cesarean delivery compared with a low-dose regimen. In this review, high-dose regimens were associated with a higher rate of tachysystole, with similar maternal and neonatal complications in both regimens.

### Oxytocin Dosing Intervals and Protocols

Several experts have suggested that implementation of a standardized protocol is desirable to minimize errors in oxytocin administration.<sup>80-82</sup> Clark and colleagues<sup>82</sup> implemented an oxytocin checklist-based protocol at a tertiary facility and evaluated outcomes in 100 women prior to utilization of the protocol versus another 100 women after the protocol was put into practice. In the checklist-managed group, the maximum dose of oxytocin used to achieve delivery was significantly lower. No differences were noted before or after the protocol in the length of labor, total time of oxytocin administration, or rate of operative vaginal or abdominal delivery. When the protocol was then implemented throughout the Hospital Corporation of America system (125 obstetric facilities in 20 states), the rate of cesarean delivery decreased from 23.6% to 21.0%, and Apgar scores below 8 and newborn complications requiring NICU admission also decreased. Hayes and Weinstein<sup>80</sup> defined a standardized protocol for oxytocin administration based on a literature review and also described the specific pharmacokinetics of oxytocin (Table 13-12). **However, at this time, no protocol has demonstrated its superiority in both efficacy and safety over another.**

Limited data are available to guide how long the oxytocin infusion should be maintained once an adequate contraction pattern has been achieved. One noninferiority study<sup>83</sup> involved

138 subjects and compared the strategy of continuing oxytocin until delivery versus discontinuing oxytocin at onset of active labor, and it suggested discontinuation of prolonged labor. The authors of a meta-analysis<sup>84</sup> assessed the effect of discontinuation of oxytocin after onset of the active phase of labor. Eight studies were included and involved 1232 subjects, and these researchers observed decreased cesarean delivery in subjects who had oxytocin discontinued (OR, 0.51; 95% CI, 0.35 to 0.74). Similarly, cases of nonreassuring fetal heart patterns were less likely among women who did not receive oxytocin after the establishment of the active phase of labor (OR, 0.63; 95% CI, 0.41 to 0.97).

### Prostaglandins

Administration of PG results in dissolution of collagen bundles and an increase in submucosal water content of the cervix. These changes in cervical connective tissue at term are similar to those observed in early labor. PGs are endogenous compounds found in the myometrium, decidua, and fetal membranes during pregnancy. The chemical precursor is arachidonic acid. PG formulations have been used since they were first synthesized in the laboratory in 1968, and PG analogues were originally given intravenously and by oral routes. Later, local administration of PGs in the vagina or the endocervix became the route of choice because of fewer side effects and acceptable clinical response. Side effects of all PG formulations and routes may include fever, chills, vomiting, and diarrhea.

The efficacy of locally applied PG (vaginal or intracervical) for cervical ripening and labor induction has been demonstrated in a Cochrane review that involved more than 10,000 women. For example, vaginal PGE<sub>2</sub> reduced the likelihood of vaginal delivery not being achieved within 24 hours, the risk of the cervix remaining unfavorable or unchanged, and the need for oxytocin. In addition, no difference was found between cesarean delivery rates, although there was a trade-off with PGE<sub>2</sub> use because the risk of uterine tachysystole with fetal heart rate changes was increased.

The various administration vehicles for PG (tablet, gel, and timed-release pessary) appear to be equally efficacious. The optimal route, frequency, and dose of PGs of all types and formulations for cervical ripening and labor induction have not been determined. Also, PG formulations of any kind should be avoided in women with a prior uterine scar, such as a prior cesarean delivery or myomectomy, because their use has been associated with an increased risk of uterine rupture.<sup>85</sup> Uterine activity and fetal heart rate monitoring are indicated for 0.5 to 2 hours after administration of prostaglandins for cervical ripening and should be maintained as long as regular uterine activity is present.<sup>31</sup>

### Prostaglandin E<sub>2</sub>

One of the first RCTs to use intravaginal PG was conducted in 1979 by Liggins. Eighty-four term women with singleton pregnancies were randomly assigned to three groups that received either placebo or a 0.2 mg or 0.4 mg PGE<sub>2</sub> compound. Labor was established in 48 hours in 9.3% of women who received a placebo, 65.4% of women who received 0.2 mg PGE<sub>2</sub>, and 85.7% of women who received 0.4 mg PGE<sub>2</sub>. Rayburn summarized the experience with more than 3313 pregnancies representing 59 prospective clinical trials in which either intracervical or intravaginal PGE<sub>2</sub> was used for cervical ripening before the induction of labor. He concluded that **local administration of PGE<sub>2</sub> is effective in enhancing cervical effacement and**

**dilation thus reducing the failed induction rate, shortening the induction-to-delivery interval, and reducing oxytocin use and cesarean delivery for failure to progress.** These findings were confirmed in a meta-analysis of 44 trials performed worldwide using various PG compounds and dosing regimens. Because no difference in clinical outcomes are apparent when comparing intravaginal or intracervical PGE<sub>2</sub> preparations, and for ease of administration and patient satisfaction, vaginal administration is recommended.<sup>86</sup> A sustained-release vaginal pessary for PGE<sub>2</sub> has been developed whose use eliminates the need for repeated dosing. Although data are limited, when comparing the efficacy of the intravaginally applied PGE<sub>2</sub> to the sustained-release suppository, no difference is apparent in rates of vaginal delivery, fetal heart rate abnormalities, or uterine tachysystole.

Currently, two PGE<sub>2</sub> preparations have been approved by the United States Food and Drug Administration (FDA) for cervical ripening. Although not approved by the FDA for cervical ripening, a variety of other PGE<sub>2</sub> compounds are available—such as suppositories in the United States and tablets in Europe and other parts of the world. PGE<sub>2</sub> was originally manufactured as a 20-mg vaginal suppository. However, to prepare the medication in smaller doses for induction of labor at term, pharmacists resuspend the suppository into small amounts of methylcellulose gel. The preparation is then frozen in plastic syringes in various doses.

Prepidil contains dinoprostone, 0.5 mg per 3-g syringe (2.5 mL gel) for intracervical administration. The dose can be repeated in 6 to 12 hours if cervical change is inadequate and uterine activity is minimal following the first dose. The manufacturer recommends that the maximum cumulative dose of dinoprostone not exceed 1.5 mg (three doses) within a 24-hour period. Oxytocin should not be initiated until 6 to 12 hours after the last dose because of the potential for uterine tachysystole with concurrent oxytocin and prostaglandin administration.

Cervidil is a vaginal insert that contains 10 mg of dinoprostone in a timed-release formulation. The vaginal insert administers the medication at 0.3 mg/hr and may be left in place for up to 12 hours. An advantage of the vaginal insert over the gel formulation is that the insert may be removed with the onset of active labor, rupture of membranes, or with the development of uterine tachysystole. This abnormality of uterine contractions is more often defined as six or more contractions in 10 minutes for a total of 20 minutes and may be associated with concurrent fetal heart rate tracing abnormalities. Per the manufacturer's recommendations, oxytocin may be initiated 30 to 60 minutes after removal of the insert.

These two preparations are relatively expensive, require refrigerated storage, and become unstable at room temperature.

### Prostaglandin E<sub>1</sub>

Misoprostol is a synthetic PGE<sub>1</sub> analogue available as 100-μg and 200-μg tablets. The current FDA approved use for misoprostol is for the treatment and prevention of peptic ulcer disease related to chronic nonsteroidal antiinflammatory drug (NSAID) use. **Administration of misoprostol for preinduction cervical ripening is considered a safe and effective off-label use by ACOG.**<sup>87</sup> Misoprostol is inexpensive and is also stable at room temperature, and it can be administered orally or placed vaginally with few systemic side effects. Although not scored, the tablets may be divided to provide 25- or 50-μg doses.

Multiple studies suggest that misoprostol tablets placed vaginally are either superior to or equivalent in efficacy compared with intracervical PGE<sub>2</sub> gel.<sup>88</sup> More recently, a meta-analysis of

70 trials revealed the following points regarding the use of misoprostol compared with other methods of cervical ripening and labor induction. Misoprostol improved cervical ripening compared with placebo and was associated with a reduced failure to achieve vaginal delivery within 24 hours (RR, 0.36; 95% CI, 0.19 to 0.68). Compared with other vaginal prostaglandins for labor induction, vaginal misoprostol was more effective in achieving vaginal delivery within 24 hours (RR, 0.80; 95% CI, 0.73 to 0.87). Compared with vaginal or intracervical PGE<sub>2</sub>, oxytocin augmentation also was less common with misoprostol (RR, 0.65; 95% CI, 0.57 to 0.73). However, uterine tachysystole with fetal heart rate changes (RR, 2.04; 95% CI, 1.49 to 2.80) and meconium-stained amniotic fluid (RR, 1.42; 95% CI, 1.11 to 1.81) were more common with misoprostol. Most studies suggested that restricting the dose of misoprostol to 25 µg every 4 hours significantly reduced the risk of uterine tachysystole with and without fetal heart rate changes and meconium passage. Most important, regardless of misoprostol dose, no significant differences were reported in immediate neonatal outcomes.

Although based on its review of the existing evidence, ACOG recommends 25 µg dosing every 3 to 6 hours with vaginally applied misoprostol, the optimal dose and timing interval is not known.<sup>31</sup> If necessary, oxytocin may be initiated 4 hours after the final misoprostol dose. A meta-analysis that compared 25-µg with 50-µg dosing reported that 50-µg dosing resulted in a higher rate of vaginal delivery within 24 hours with higher rates of uterine tachysystole and meconium passage but without compromising neonatal outcomes. A higher frequency of *fetal acidosis*, defined as an umbilical arterial pH of less than 7.16, was found in infants born to mothers given 50 µg of intravaginally applied misoprostol every 3 hours compared with those born to mothers given 25 µg every 3 hours. In their Committee Opinions on the use of misoprostol for labor induction, ACOG concludes that safety using the higher 50-µg (every 6 hours) dosing could not be adequately evaluated, may be associated with uterine tachysystole with fetal heart rate decelerations, and suggests the higher doses should only be used in select circumstances.

A misoprostol vaginal insert (MVI) that contains a controlled-release retrievable polymer chip for gradual delivery of 200 µg over 24 hours has been developed and is available in some countries in Western Europe, but it is currently not available in the United States.<sup>89,90</sup> The 200 µg dose is released at a mean rate of approximately 7 µg/hr while the insert remains in place, allowing a constant dosing to occur over a 24-hour period with the benefit of rapid and easy removal if needed.

Oral misoprostol for cervical ripening has also been studied. This route of administration has promise for offering more patient comfort, satisfaction, and convenience. Most trials compared oral misoprostol dosages of 20 to 50 µg with similar vaginal misoprostol dosing regimens, such as 25 to 50 µg. This oral dosing regimen appears to be no more effective than vaginal administration for achieving vaginal delivery, but it may be associated with less uterine tachysystole. A clear, positive dose-response relationship exists between the dosage of oral misoprostol and the frequency of tachysystole.<sup>91</sup>

Some investigators have described titrating oral misoprostol to its desired effect.<sup>92</sup> This method appears to achieve vaginal delivery rates similar to vaginally administered misoprostol with less uterine tachysystole. Low doses of oral misoprostol were achieved by making a solution (e.g., dissolving a 200 µg tablet

in 200 mL tap water) because this was believed to provide more accurate dosing than simply cutting the tablet into pieces. Because oral dosing has a short (2 hr) duration of action, administration was repeated at 2-hour intervals.

In a Cochrane review of 76 RCTs that included 14,412 women, oral misoprostol appeared to be at least as effective as current methods of induction. In 12 trials (3859 women) that compared oral misoprostol with vaginal dinoprostone, women given misoprostol were less likely to need cesarean delivery (21% compared with 26% of women), although the time in labor was longer. The 37 trials (6417 women) that compared oral and vaginal misoprostol reported similar effectiveness, but those taking oral misoprostol had better neonatal outcomes at birth and less postpartum hemorrhage. Nine trials<sup>93</sup> that comprised 1282 women showed that oral misoprostol was equivalent to IV oxytocin but resulted in significantly fewer cesarean deliveries. The authors of this Cochrane review recommend that if clinicians choose to use oral misoprostol, a dose of 20 to 25 µg in solution is preferred for both the safety considerations and the imprecision of dividing misoprostol tablets for recommended dosages. However, concerns have been raised that the pharmacy and nursing administration needed for dose titration adds a layer of complexity, and more data are needed to shed light on the optimal dosing, safety, and cost-effectiveness of oral misoprostol for cervical ripening and labor induction.

Other novel methods of administration for misoprostol that have been assessed include buccal and sublingual routes. The theory is that avoiding first-pass hepatic circulation from oral administration will lead to bioavailability similar to that achieved with vaginal administration. In an RCT that included 250 women admitted for labor induction, 50 µg of sublingual misoprostol was compared with 100 µg of orally administered misoprostol given every 4 hours to a maximum of five doses. Sublingual misoprostol appeared to have the same efficacy as orally administered misoprostol to achieve vaginal delivery within 24 hours with no increase in uterine tachysystole. In another RCT, 152 women received either buccal misoprostol (200 µg for first two doses, then 300 µg to total 1600 µg) or vaginal (50 µg for first two doses, then 100 µg to total 500 µg). No statistically significant difference was noted in time to vaginal delivery, the rate of vaginal delivery, or the rate of uterine tachysystole. Based on only three small trials included in the Cochrane meta-analysis, sublingual misoprostol appears to be at least as effective as the same dose administered orally, although data are inadequate to comment on the relative complications and side effects. Therefore more data are needed to clarify not only the safety but the efficacy of buccal and sublingual misoprostol.

Alternative Methods

Researchers have evaluated several other methods and compounds as mechanical and pharmacologic alternatives for cervical ripening and labor induction in term pregnancies (Table 13-13). Some of the advantages of the mechanical techniques include low cost, low risk of tachysystole, and few systemic side

TABLE 13-13      ALTERNATIVE METHODS FOR INDUCTION

| PHARMACOLOGIC   | MECHANICAL                               |
|-----------------|--|
| Mifepristone    | Stripping (sweeping) fetal membranes     |
| Estrogen        | Amniotomy                                |
| Relaxin         | Hygroscopic dilators                     |
| Hyaluronic acid | Foley balloon catheter above internal os |

effects. The disadvantages of mechanical methods include a small increase in risk of infection from introduction of a foreign body, the potential for disruption of a low-lying placenta, and some maternal discomfort upon manipulation of the cervix. **All of these methods likely work, at least in part, by causing the release of prostaglandin F2-alpha from the decidua and adjacent membranes or PGE<sub>2</sub> from the cervix.** Also, the dilators (e.g., laminaria) and balloon catheter physically cause gradual cervical dilation with minimal discomfort to the patient.

**Stripping or sweeping of the fetal membranes** refers to digital separation of the chorioamniotic membrane from the wall of the cervix and lower uterine segment by inserting the examiner's finger beyond the internal cervical os and then rotating the finger circumferentially along the lower uterine segment. Investigations<sup>94</sup> have studied routine membrane stripping at 38 or 39 weeks to either prevent prolonged pregnancies or decrease the frequency of more formal inductions after 41 weeks. Two randomized trials compared outcomes of women who underwent membrane stripping or no membrane stripping at initiation of labor induction with oxytocin. The results of these trials suggested that membrane stripping increased the rate of spontaneous vaginal delivery and shortened the induction to delivery interval. However, differences in study design and heterogeneous management of induction preclude definitive conclusions. None of these trials reported harmful side effects that could be attributed to the procedure.

Although the existing meta-analysis on the use of membrane stripping<sup>95</sup> did not reveal an increase in either maternal or neonatal infection associated with the procedure, it is unclear whether these studies included carriers of Group B *Streptococcus* (GBS). Only one small study evaluated GBS colonization associated with sweeping membranes, and whereas no additional risk was found in women with sweeping, the study was too small to exclude an effect. GBS colonization is not a contraindication to membrane stripping because no direct evidence of harm exists, but given the limited data for the procedure in known GBS carriers, the potential benefits and risks should be carefully weighed before performing the procedure in known carriers.<sup>96</sup>

Another commonly used method for cervical ripening is the **transcervical balloon catheter**, which appears to be as effective for preinduction cervical ripening as PGE<sub>2</sub> gel and intravaginal misoprostol. The combination of a balloon catheter plus administration of a prostaglandin does not appear to be more effective than prostaglandins alone.

## MIDTRIMESTER INDUCTION

In particular circumstances, such as when a fetus has died in utero or in cases of termination of pregnancy, a woman may choose to have an induction of labor to effect delivery of the fetus. Although in the case of an intrauterine demise, some women would prefer expectant management in order to avoid an induction of labor, this approach raises concerns regarding the development of a consumptive coagulopathy and/or intrauterine infection. Some studies<sup>97</sup> report that 80% to 90% of women will spontaneously labor within 2 weeks of a fetal demise, but the latency period may be longer.

Options for delivery in the case of intrauterine demise or pregnancy termination in the mid second trimester include induction of labor and dilation and evacuation (D&E; Table 13-14). The decision for which mode of delivery to choose must

**TABLE 13-14** SECOND-TRIMESTER TERMINATION METHODS

| SURGICAL                | MEDICAL  |
|-------------------------|--|
| Dilation and evacuation | Intravenous oxytocin                           |
| Laparotomy              | Intraamniotic hyperosmotic fluid               |
| Hysterotomy             | 20% saline                                     |
| Hysterectomy            | 30% urea                                       |
|                         | Prostaglandins E2, F2-alpha, E1, and analogues |
|                         | Mifepristone                                   |
|                         | Various combinations of above                  |

be individualized by practitioner experience, gestational age, and a patient's desires. The emotional and psychological factors vary with each patient, with one advantage of induction being the delivery of an intact fetus, whereas an advantage of D&E may be avoiding a prolonged induction.

Most of the research available regarding modes of midtrimester delivery is extrapolated from the investigations performed on second trimester abortions. One study compared patients undergoing surgical termination between 14 and 24 weeks of gestation with women undergoing labor induction and revealed an overall lower rate of complications in those undergoing D&E (4% vs. 29%). Cochrane reviewers<sup>98</sup> recently concluded that D&E is superior to intraamniotic instillation of prostaglandin F2-alpha and may be favored over mifepristone and misoprostol, but larger randomized studies are necessary to confirm the latter finding. At this time, both methods of delivery are considered reasonably safe.

Several methods of labor induction have been utilized, but no single protocol is currently accepted as best practice. More recent protocols have implemented regimens with gemeprost or misoprostol, both PGE<sub>1</sub> analogues; however, a meta-analysis of randomized trials to compare the two medications reported that misoprostol suppositories were associated with a reduced need for narcotic analgesia and surgical evacuation of the uterus. The application of gemeprost is limited secondary to its expense and instability at room temperature. It is also not currently available in the United States. At this time, the World Health Organization (WHO) also recommends the use of mifepristone prior to PGE<sub>1</sub> analogues for expeditious and safe second trimester abortions. As an antiprogesterin, mifepristone increases uterine sensitivity to prostaglandins, which permits lower doses and minimizes side effects. However, current studies<sup>99</sup> do not reveal any advantage of pretreatment with mifepristone for induction in second-trimester fetal demise.

**When planning an induction of labor, gestational age plays a significant role regarding the methods of induction.** When the gestational age is less than 28 weeks, the uterus is less sensitive to oxytocin and therefore prostaglandins or mechanical devices may be required to commence labor. Current induction protocols vary by dose, route, and gestational age (Table 13-15). It is important to keep in mind that although side effects (uterine tachysystole, nausea, vomiting, diarrhea) and safety remain important considerations for the patient in these circumstances, fetal well-being is no longer an issue.

Women with a prior cesarean delivery are candidates for induction of labor with PG in these circumstances as well. A recent review by Berghella and colleagues reported an incidence of uterine rupture of 0.4%, hysterectomy 0%, and transfusion 0.2% for women undergoing second-trimester misoprostol terminations.

### SUMMARY

Induction of labor is one of the most commonly performed procedures in obstetrics and can be undertaken for a variety of medical and obstetric indications. The likelihood for success in the induction of labor has been studied with focus on a number of clinical, biochemical, and radiographic approaches. Cervical dilation at the time of induction is the factor most associated with success, but no single factor has been shown to be a good predictor. A variety of pharmacologic and mechanical methods for cervical ripening are available. The most commonly used approaches include prostaglandins, such as dinoprostone and misoprostol, and transcervical Foley balloon catheter placement. Augmentation of labor is usually accomplished with IV oxytocin, which can be administered using either low- or high-dose infusion protocols. In the case of a midtrimester induction, either induction of labor or dilation and evacuation is considered a safe approach.

### KEY POINTS

- ◆ *Labor* is a clinical diagnosis defined as uterine contractions that result in progressive cervical effacement and dilation, often accompanied by a bloody discharge referred to as *bloody show*, that results in birth of the baby.

- ◆ The diagnosis of labor protraction and arrest should account for the level of cervical dilation.
- ◆ Because the duration of latent labor is highly variable, expectant management is most appropriate.
- ◆ The most common causes of protraction or arrest disorders are inadequate uterine activity and abnormal positioning of the fetal presenting part.
- ◆ Under new guidelines, neither a protracted active phase nor arrest of dilation should be diagnosed in a nullipara before 6 cm cervical dilation.
- ◆ Before a diagnosis of arrest of active-phase arrest is made, rupture of membranes should have occurred and the cervix must be dilated at least 6 cm, with either 4 hours or more of adequate contractions (e.g., more than 200 Montevideo units) or 6 hours or more of inadequate contractions and no cervical change.
- ◆ Induction of labor should be undertaken when the benefits of delivery to either mother or fetus outweigh the risks of pregnancy continuation.
- ◆ Studies have demonstrated that routine induction of labor at 41 weeks' gestation is not associated with an increased risk of cesarean delivery regardless of parity, state of the cervix, or method of induction.
- ◆ If elective induction is undertaken for nonmedical reasons, women should have pregnancies of 39 weeks' gestation or more.
- ◆ It is important for the clinician to recall that cervical ripening itself can take some time and that the

development of an active labor pattern should be achieved prior to the determination that the induction has failed.

- ◆ Induction of labor with IV oxytocin, intravaginal prostaglandin compounds, and expectant management (with defined time limits) are all reasonable options for women and their infants in the face of PROM at term because they result in similar rates of neonatal infection and cesarean delivery.
- ◆ Options of delivery for midtrimester stillbirth or induction for pregnancy termination include induction of labor and dilation and evacuation. The decision for which mode of delivery to choose must be individualized by practitioner experience, gestational age, and a patient's desires.

**Obstetric forceps are the one instrument that makes the practice of obstetric care unique to obstetricians. The proper use of these instruments has afforded safe and timely vaginal delivery to those whose abnormal labor course and/or urgent need for delivery required their use.**

Following the introduction of forceps by Chamberlin during the 1600s, much discussion about the proper use and timing of forceps application ensued. After Smellie's retirement from practice in 1760, forceps began to be used more frequently,

resulting in an increase in both maternal and neonatal injury owing to the application techniques common at the time. In his 1788 text entitled "An Introduction to the Practice of Midwifery," Thomas Denman<sup>1</sup> stated that "the head of the child shall have rested for 6 hours as low as the perineum before the forceps are applied though the pains should have ceased during that time." Denman's law then became widely accepted as the standard of this time. However, after the news of Princess Charlotte's death following the birth of a stillborn Prince on November 6, 1817, a review of Denman's law ensued with much public discussion regarding the timely use of forceps. Princess Charlotte's labor had been managed by one of Denman's students and son-in-law, Sir Richard Croft, whose second-stage labor management during this delivery came into question. Croft had permitted the second stage to last 24 hours, including 6 hours on the perineum, as Denman's law had advised. However, the Princess delivered a 9 lb stillborn male heir, and within 24 hours of delivery, the Princess herself died of a massive postpartum hemorrhage. Disturbed with depression and despair at the blame for the death of both the Princess and the heir to the British throne, Croft shot himself 3 months later. During a lecture delivered at the Royal College of Obstetricians and Gynaecologists (RCOG) on September 28, 1951, Sir Eardley Holland<sup>2</sup> named his lecture on these events "A Triple Obstetric Tragedy" in which he described a mother, baby, and accoucheur all dead, victims of a mistaken system. In a subsequent text in 1817, Denman<sup>3</sup> wrote: "Care is also to be taken that we do not, through an aversion to the use of instruments, too long delay that assistance we have the power of affording them." The debate regarding the use of these instruments continued into the twentieth century with prophylactic forceps delivery advocated by DeLee<sup>4</sup> in 1920. This clinical management strategy resulted in forceps delivery rates in excess of 65% by 1950.

With these lessons in mind, a review of operative vaginal delivery in modern obstetric practice is extremely important and

timely. Rates of cesarean delivery have risen in both the United States and the United Kingdom,<sup>5,6</sup> increasing 60% between 1996 and 2009 in the United States, when the rate reached 32.9%—the highest rate ever reported—and increasing 100% between 1990 and 2008 (12% to 24%) in the United Kingdom. Between 2009 and 2013, the rate of cesarean delivery in the United States has declined only slightly to 32.7%. In contrast, rates of forceps and vacuum extraction to assist delivery have decreased dramatically from 9% in 1990 to 3.4% in 2012.<sup>7</sup> Forceps have been used for fewer than 1% of all births in the United States since 2005 (0.59% in 2013).<sup>7</sup> However, most residency training programs in the United States still expect proficiency in outlet and low forceps delivery (less than or greater than a 45-degree rotation), whereas less than 40% expect proficiency in midforceps delivery.<sup>8</sup> However, to make education and teaching of these procedures even more challenging, new resident work hour restrictions have resulted in a decline in resident experience with both primary cesarean delivery and vacuum-assisted vaginal delivery despite increased institutional volumes of these procedures. In a study by Blanchard and colleagues,<sup>9</sup> the decrease in experience was shown to be dramatic: they noted a 54% decline in experience with primary cesarean delivery and a 56% decline in vacuum-assisted vaginal delivery. Because both forceps and vacuum extractors are acceptable and safe instruments for operative vaginal delivery, operator experience is the determining factor in deciding which instrument should be used in a specific clinical situation.<sup>10</sup> Declining use and resident experience may make it difficult to provide the level of operator skills required for proficiency of this obstetric art. However, because most women prefer a vaginal delivery, focused experience with the use of these instruments during residency training is crucial to ensure safe, timely, and effective vaginal delivery. Furthermore, women are more likely to achieve a spontaneous vaginal delivery in a subsequent pregnancy after forceps delivery than after cesarean delivery (78% vs. 31%).<sup>11-14</sup> The challenge, therefore, is to ensure that women who experience second-stage labor abnormalities are afforded all options for a safe and timely delivery.

## OPERATIVE VAGINAL DELIVERY

### Classification, Prerequisites, and Indications

The use of a well-defined and consistent classification system for operative vaginal deliveries facilitates the comparison of maternal and neonatal outcomes among spontaneous delivery, cesarean delivery, and operative vaginal delivery as well as instruction in these techniques. It is intuitive that not all operative vaginal deliveries are the same with respect to degree of difficulty or maternal and fetal risk; therefore classification systems have been developed and modified over time. In 1949, Titus created a classification system that permitted general practitioners to perform operative vaginal delivery without consultation from a specialist. This system divided the pelvis into thirds from the ischial spines to the inlet and, in the opposite direction, in thirds to the outlet. Dennen<sup>15</sup> proposed an alternative classification system in 1952 that was based on the four major obstetric planes of the pelvis with the following definitions: *high forceps* is the biparietal diameter (BPD) in the plane of the inlet but above the ischial spines; *midforceps* is the BPD just at or below the ischial spines and the sacral hollow not filled; *low midforceps* is the BPD below the ischial spines, the leading bony part within

a fingerbreadth of the perineum between contractions, and the hollow of the sacrum filled; and *outlet forceps* is the BPD below the level of the ischial spines, the sagittal suture in the anteroposterior diameter, and the head visible at the perineum during a contraction.

In 1965, the American College of Obstetricians and Gynecologists (ACOG) created a classification system<sup>16</sup> that defined *midforceps* extremely broadly, from the ischial spines to the pelvic floor and any rotation. This category clearly included many forceps operations that ranged from delivery of a straightforward anteroposterior position of the fetal vertex to complex rotations. The broad category for these operations led many practicing clinicians to question whether the classification should be narrowed to reflect the clinically significant differences between deliveries such as these.

In 1988, ACOG revised the classification<sup>17</sup> of forceps operations to address two significant shortcomings of the previous system: that *midforceps* was too widely defined and *outlet forceps* was too narrowly defined. This system was validated in 1991 by Hagadorn-Freathy and colleagues,<sup>18</sup> who demonstrated that 25% of deliveries in this study that would have been previously classified as midforceps but were reclassified into the low forceps (greater than 45-degree rotation) and midforceps categories were associated with 41% of episiotomy extensions and 50% of the lacerations in the cohort. Clearly, the outcomes of these operations confounded the relatively low-risk group of low-forceps operations with up to 45-degree rotation, which would also have been classified as midforceps by the previous system. In short, these investigators validated the 1988 ACOG classification scheme by demonstrating that the higher station and more complex deliveries carried a greater risk of maternal and fetal injury compared with those that were more straightforward. This differentiation was lost in the 1965 classification scheme owing to the broad definition of *low forceps*. It is extremely important to appropriately classify operative vaginal delivery based on this system, including accurate determination of fetal station and position. The 1988 classification scheme for operative vaginal delivery is shown in Box 14-1.

With respect to operative vaginal delivery of the vertex, *station* is defined as the relationship of the estimated distance in centimeters between the leading bony portion of the fetal head and the level of the maternal ischial spines, and *position* refers to the relationship of the occiput to a denominating location on the maternal pelvis. Operative vaginal delivery with a fetus in the left occiput anterior (LOA) position with the leading bony portion of the vertex 3 cm below the ischial spines (+3 station) would be classified as low forceps, less than 45-degree rotation delivery. It is also important to note that this classification system applies to both forceps and vacuum extraction instruments and that the precise position and station must be known before the placement of either instrument.

In addition to precise evaluation of the position and station, several other extremely important data are necessary before performing an operative vaginal delivery. The prerequisites for application of either forceps or vacuum extractor are listed in Table 14-1. When these prerequisites have been met, the following two indications are appropriate for consideration of either forceps delivery or vacuum extraction: (1) **prolonged second stage** (for nulliparous women, lack of continuing progress for 3 hours with regional analgesia or 2 hours without regional analgesia; for multiparous women, lack of continuing progress for 2 hours with regional analgesia or 1 hour

**BOX 14-1 1988 OPERATIVE VAGINAL DELIVERY CLASSIFICATION****Outlet**

- Scalp is visible at the introitus without separating the labia.
- Fetal skull has reached the pelvic floor.
- Sagittal suture is in the AP diameter or LOA/ROA or LOP/ROP positions.
- Fetal head is at or on the perineum.
- Rotation does not exceed 45 degrees.

**Low Forceps**

- Leading point of fetal skull is at +2 cm or greater and not on the pelvic floor.
- Rotation 45 degrees or less to LOA/ROA to OA or LOP/ROP to OP, or rotation is 45 degrees or more.

**Midforceps**

- Station is above +2 cm but head is engaged.

**High**

- High forceps delivery is not included in this classification.

Modified from the American College of Obstetricians and Gynecologists (ACOG). Committee on Obstetrics, Maternal and Fetal Medicine: Obstetric Forceps. Technical Bulletin No. 59, February 1988.  
 AP, anteroposterior; LOA, left occiput anterior; LOP, occiput posterior; OA, occiput anterior; OP, occiput posterior; ROA, right occiput anterior; ROP, occiput posterior.

**TABLE 14-1 PREREQUISITES FOR FORCEPS OR VACUUM EXTRACTOR APPLICATION**

- Fetal vertex is engaged.
- Membranes have ruptured.
- Cervix is fully dilated.
- Position is precisely known.
- Assessment of maternal pelvis reveals adequacy for the estimated fetal weight.
- Adequate maternal analgesia is available.
- Bladder is drained.
- Operator is knowledgeable.
- Operator is willing to abandon the procedure if necessary.
- Informed consent has been obtained.
- Necessary support personnel and equipment are present.

without regional analgesia) and (2) **suspicion of immediate or potential fetal compromise** (nonreassuring fetal heart rate tracing or shortening of the second stage of labor for maternal benefit [i.e., maternal exhaustion, maternal cardiopulmonary or cerebrovascular disease]).

**OPERATIVE VAGINAL DELIVERY INSTRUMENTS****Forceps Instruments**

Invention and modification have led to a description and use of more than 700 varieties of forceps instruments. Most of them are of historic interest only, but many common features remain among those still in use. **Except when used at cesarean delivery, forceps are paired instruments and are broadly categorized according to their intended use as classic forceps, rotational forceps, and specialized forceps designed to assist vaginal breech deliveries.** Each forceps type consists of two

**FIG 14-1** Anatomy of the forceps.

halves joined by a lock, which may be sliding or fixed. The key structures of forceps include the blade, shank, lock, finger guards, and handle (Fig. 14-1). The *toe* refers to the tip of the blade, and the *heel* is the end of the blade that is attached to the shank at the posterior lip of the fenestration (if present). The *cephalic curve* is defined by the radius of the two blades when in opposition, and the *pelvic curve* is defined by the upward—or reverse, as in the case of Kielland and Piper forceps—curve of the blades from the shank. The handles transmit the applied force, the screw or lock represents the fulcrum, and the blades transmit the load (Fig. 14-2).<sup>19</sup>

The pelvic curve permits ease of application along the maternal pelvic axis (Fig. 14-3). **Forceps have two functions, traction and rotation, both of which can only be accomplished by some degree of compression on the fetal head. The cephalic curvature of the blade is designed to aid in the even distribution of force about the fetal parietal bone and malar eminence.** Blades may be solid (Tucker-McLane), fenestrated (Simpson), or pseudofenestrated (Luikart-Simpson). The pseudofenestration modification can be applied to the design of any type of forceps and is known as the *Luikart modification*. In general, use of solid or pseudofenestrated blades results in less risk of maternal soft tissue injury, especially during rotation, but fenestrated blades provide improved traction in comparison to solid blades.

**Classic Forceps**

**Classic forceps instruments are typically used when rotation of the vertex is not required for delivery.** However, they may be used for rotations such as the Scanzoni-Smellie maneuver. All classic forceps have a cephalic curve, a pelvic curve, and an English lock, in which the articulation is fixed in a slot into which the shank of the opposite blade fits. The type of classic forceps instrument is determined by its shank, whether overlapping or parallel. Examples of classic forceps with parallel shanks include Simpson, DeLee, Irving, and Hawks-Dennen forceps. Classic forceps with overlapping shanks include Elliott and Tucker-McLane. **Because these instruments have a more rounded cephalic curve than the Simpson forceps, they are often used for assisting delivery of the unmolded head, such as that commonly encountered in the multiparous patient.** In addition, because the Tucker-McLane forceps have a shorter, solid blade and overlapping shanks, they are more often used for rotations than other classic instruments.

## TYPES OF FORCEPS

## Classical forceps

## Rotational forceps

## Forceps for delivery of aftercoming head of the breech

*JWKOI/M. Carley*

**FIG 14-2** Classification of forceps.

FIG 14-3 Stepwise approach to application of obstetric forceps.

### Rotational Forceps

Forceps instruments used for rotation are characterized as having a cephalic curve amenable to application to the molded vertex and either only a slight pelvic curve or none at all. The absence of a pelvic curve in these instruments facilitates rotation of the vertex without moving the handles of the instrument through a wide arc, as is necessary when using one of the classic instruments to accomplish rotation. Forceps that may be used for rotation include some of the classic instruments (e.g., Tucker-McLane) and those with minimal pelvic curvature (e.g., Kielland and Leff). In 1916, Christian Kielland of Norway described the rationale for the introduction of his new forceps<sup>20</sup>:

When the head is high, it has to be pulled through a greater length of the birth canal, which is incompletely prepared. The child's head is in such a position that it cannot be grasped by the blades of the forceps in the way that is possible when the head is low and completely rotated. The forceps do not hold the head in the biparietal diameter but over the occipital and frontal areas, which cannot withstand much pressure. These factors are responsible for the difficulties that occur in such a delivery, but they do not

entirely explain the amount of force required nor the resistance encountered. In the search for an explanation of the chief cause for the remarkable amount of force that had to be used, it was thought that traction might be in the wrong direction, because the blade of the ordinary forceps is curved to correspond with the birth canal. This type of forceps cannot be depressed sufficiently low against the perineum without the risk of damaging it or losing the good position on the fetal head when an attempt is made to exert traction in the pelvic axis.

After their introduction, **Kielland forceps** have become a frequently used instrument for rotation of the vertex (see Fig. 14-1). These forceps have a slightly backward pelvic curve with overlapping shanks and a sliding lock. The advantages of the Kielland forceps, compared with the classic instruments for rotation, include the following:

- The straight design places the handle and shanks in the same plane as the long axis of the fetal head, permitting the toe to travel through a very small arc during rotation.
- The distance between the heel and the intersecting point of the shanks is long, which accommodates heads of various shapes and sizes, associated with unusual molding.

- A slight degree of axis traction is produced by the reverse pelvic curve.
- The sliding lock permits placement of the handles at any level on the shank to accommodate the asynclitic head and subsequent correction of asynclitism.

In 1955, another forceps used for rotation of the vertex was introduced by Leff.<sup>21</sup> These forceps have a locking shank with short, straight, and narrow blades and a smaller cephalic curve than the Kielland forceps. In a series of 104 consecutive rotational forceps deliveries (>90 degrees) using Leff forceps, compared with 163 nonrotational forceps deliveries with traditional instruments, Feldman and colleagues<sup>22</sup> demonstrated a lower episiotomy rate (66% vs. 82%) and a lower perineal laceration rate (16% vs. 23%) with the Leff forceps compared with the nonrotational forceps group, attributed to a 40% spontaneous vaginal delivery rate after Leff forceps rotation. In addition, no difference was reported in the low incidence of fetal bruising between the groups (3% in each). They concluded that Leff forceps were also a safe option for rotation of the persistent occiput posterior (OP) fetal position.

### Other Specialized Instruments

**Forceps to assist with delivery of the aftercoming head during vaginal breech delivery (Piper forceps) have a cephalic curve, a reverse pelvic curve, long parallel shanks, and an English lock** (see Fig. 14-2). This design provides easy application to the aftercoming head, stabilizing and protecting the fetal head and neck during delivery. The long shanks permit the body of the breech to rest against it during delivery of the head (see Chapter 17).

### Vacuum Extraction Devices

Swedish obstetrician Tage Malmström is credited with the introduction of the first successful vacuum cup into the field of modern obstetrics in 1953. It consisted of a metal cup, suction tubing, and a traction chain.<sup>23</sup> Vacuum devices are classified by the material used to make the cup, either stainless steel or plastic (silicone). So-called soft (plastic) cups are used much more commonly in the United States than the stainless steel cups owing to the lower rates of scalp trauma associated with these devices,<sup>24</sup> which consist of **a cup connected to a handle grip with tubing that connects them both to a vacuum source (Fig. 14-4). The vacuum generated through this tubing attaches the fetal scalp to the cup and allows traction on the vertex. The vacuum force can be generated either from wall suction or by a handheld device with a pumping mechanism.**

### Stainless Steel Devices

The Malmström device is the most commonly used instrument for vacuum extraction in the world.<sup>25</sup> This device consists of a mushroom-shaped stainless steel cup, two vacuum hoses, a traction chain and attached metallic disk, a traction handle, and a vacuum source. The cup is available in 40, 50, and 60 mm diameter sizes and is designed such that the diameter of the opening is smaller than the internal diameter of the cup. Therefore when vacuum is established, the fetal scalp fills the internal dimension of the cup, and an artificial caput succedaneum is formed (the “chignon”). This allows for the appropriate traction force to be applied to the vertex without a “pop-off” or detachment.

**FIG 14-4** “M”-style mushroom vacuum extractor cup with a centrally located stem and handle.

### Soft-Cup Devices

These devices may be classified into three groups by the shape of the cup: funnel shaped, bell shaped, and mushroom shaped (Figs. 14-5 and 14-6). The Kobayashi style funnel-shaped Silastic cup is the prototype and the largest cup available (65 mm). It was designed to fit over the fetal occiput without requiring formation of a chignon. This feature results in a lower rate of scalp trauma and more rapid time to effect delivery compared with the stainless steel devices but with a slightly higher failure rate owing to pop-off.<sup>24</sup> Bell-shaped cups are available from a number of vendors and include the MityVac (Prism Enterprises), Kiwi (Clinical Innovations), and CMI (Utah Medical). **The mushroom-shaped cups are a hybrid of the stainless steel and plastic devices.** Examples of these devices include the M-cup (MityVac), OmniCup (Kiwi), and Flex Cup (CMI). The maneuverability of these devices is superior to either the funnel-shaped or bell-shaped devices owing to their smaller size and increased flexibility of the traction stem relative to the cup. However, like other vacuum devices, they are still limited in their use for either OP or occiput transverse (OT) positions owing to an inability to achieve the proper median flexing application. Advances to the Kiwi product have resulted in a style of cup in which the stem is completely collapsible against the cup (see Fig. 14-5), thus allowing placement of the vacuum on the point of flexion of the head that is asynclitic or in the OP position.

## OPERATIVE VAGINAL DELIVERY TECHNIQUES

### Classic Forceps: Application for Occiput Anterior and Occiput Posterior Positions

**Forceps blades are labeled *left* and *right* based on the maternal side into which they are placed. For example, the *left blade* refers to the maternal left side, and its handle is held in the operator's left hand for placement** (see Fig. 14-3).<sup>26</sup> The posterior blade is conventionally placed first because it provides a splint for the fetal head to prevent rotation from the occiput

**FIG 14-5** Two Kiwi vacuum devices demonstrating the handheld pump and pressure gauge device. Unlike the cup in **B**, the stem on the cup in **A**, the OmniCup, is flexible and can be laid flat against the cup. (From Vacca A. *Handbook of Vacuum Delivery in Obstetric Practice*. Albion, Australia: Vacca Research Pty. Ltd.; 2003.)

**FIG 14-6** Placement of the OmniCup with flexible stem at the point of flexion of a fetus in the occiput posterior position; this is difficult to accomplish with traditional vacuum devices. (From Vacca A. *Handbook of Vacuum Delivery in Obstetric Practice*. Albion, Australia: Vacca Research Pty, Ltd.; 2003.)

anterior (OA) position to a more OP position when the second blade is applied. Therefore when the fetus is OA to LOA, the left blade is placed first. The operator holds the handle of the left blade in his or her left hand with the toe of the blade directed toward the floor. With the plane of the shank perpendicular to the floor, the cephalic curve of the blade is to be applied to the curve of the fetal head. To protect the vaginal sidewalls, the fingers of the right hand are placed within the left vagina with the palm of the hand facing the fetal skull. The cephalic curve of the blade should lie evenly against the fetal skull as the toe of the blade is placed at approximately 6 o'clock. The operator's right thumb guides the heel of the blade and the right index finger guides the toe of the blade gently over the left parietal bone. The handle of the blade should be held lightly with the left thumb and index finger. As the blade is inserted into the pelvis, its shank and handle are to be rotated counterclockwise toward the right maternal thigh and then inward toward the maternal midline. This movement will guide the toe of the blade over the left parietal bone and onto the left malar eminence. The force applied by the left thumb and index finger on the handle should be minimal as the blade enters the maternal pelvis. If there is anything more than very light or slight resistance to blade entry into the maternal pelvis, the blade should be removed and the application technique reevaluated. Once the blade has been applied, an assistant may hold it in place. To place the right blade, this process is repeated with opposite hands doing the maneuvers described earlier.

When the fetus is in a right occiput anterior (ROA) position, the right fetal parietal bone is located in the posterior maternal pelvis so the posterior blade will be the right blade, and this is placed first. Once both blades are in place, if the handles do not lock easily, the application is incorrect. The blades should have a bimalar, biparietal placement when applied properly (Fig. 14-7). Once the handles are locked, proper blade location must be confirmed. Identification of the posterior fontanel, sagittal suture, lambdoid sutures, and blade fenestrations enable the operator to confirm proper forceps blade placement before their use. **The three criteria needed to confirm proper forceps application are (1) the posterior fontanel should be one fingerbreath above the plane of the shanks and midway between**

**the blades, or the lambdoid sutures (or anterior fontanel for the OP fetus) should be equidistant from the upper edge of each blade; (2) the sagittal suture should be perpendicular to the plane of the shanks; and (3) if using fenestrated blades, the fenestrations should be barely palpable.<sup>26</sup> The operator should not be able to place more than one fingertip between the fenestration and the fetal head.**

The direction of traction on the fetal head is determined by the station of the BPD (see Fig. 14-3). For example, higher fetal stations require a steeper angle of traction below the horizontal. The shape of the maternal pelvis may be visualized as the terminal end of the letter "J." As the fetal head descends within the pelvis, the axis of traction follows a curved line upward from the floor. The axis of traction rises above the horizontal as the fetal head crowns and extends just as the head does in a spontaneous vaginal delivery. With the axis traction principle, force is directed in two vectors—downward and outward. One hand holds the shanks and exerts downward traction while the operator's other hand holds the handles and exerts traction outward. As the vertex descends and exits, there will be a natural extension of the fetal head, and the forceps should guide the vertex through this pathway in such a fashion that the forceps handle will curve anteriorly relative to the patient, with the forceps handle nearly anterior to the pubic symphysis. An alternative method is to use it as an axis traction instrument; this attachment may be joined to the handle to facilitate traction below the handles in the line of the pelvic axis (see Fig. 14-3) and allows the forceps to follow the natural extension of the fetal head. **Forceps traction should begin with the uterine contraction and should coincide with maternal pushing efforts until the contraction ends. Fetal heart tones should be monitored. Descent should occur with each pull, and if no descent occurs after two to three pulls, the operative delivery should be halted and measures should be taken to proceed with cesarean delivery.** (See Video 14-1 for an example of the technique of forceps application and delivery.) Switching to a vacuum should be done very cautiously (see "Sequential Use of Vacuum and Forceps" later in this chapter).

Forceps may also be appropriate for OP, left occiput posterior (LOP), or right occiput posterior (ROP) positions if the station

**FIG 14-7** Proper application of obstetric forceps. (From O'Brien WF, Cefalo RC. Labor and delivery. In Gabbe SG, Niebly JR, Simpson JL, eds. *Obstetrics: Normal and Problem Pregnancies*, ed 3. New York: Churchill Livingstone; 1996:377.)

of the bony part of the head is truly at least +2 station. **Infants in persistent OP position represent a unique challenge.** With a deflexed or extended head, a wider diameter presents through the pelvic outlet, which requires more force for descent of the fetal head. Proper assessment of fetal station can be made complex by extension and molding of the head.<sup>26</sup> With fetal molding, the widest diameter of the fetal head may be at a much higher station than the leading bony part, thus making traction within the proper pelvic axis difficult to ascertain. The tendency is to overestimate station in OP positions, so the operator must be confident in their station assessment.

### Rotational Forceps: Application for Occiput Transverse Positions

Rotation must be accomplished from the OT position before delivery of the fetal head. This may happen spontaneously, with manual assistance, or with use of forceps when appropriate. The reader is referred to *Dennen's Forceps Deliveries* for a more extensive review of forceps rotation techniques.<sup>26</sup> **Forceps rotations should be attempted only with an experienced operator.**

#### Classic Forceps

For left occiput transverse (LOT) positions, the posterior left blade should be applied first. The toe of the blade is placed at 6 o'clock, and the cephalic curve is applied to the fetal head. The handle is lowered to facilitate blade entry into the posterior pelvis and rests below the horizontal, the degree of which will be determined by fetal station. **The anterior right blade is known as the wandering blade,** and it is inserted with the right hand posteriorly at approximately 7 o'clock. Upward pressure on the blade is exerted with the fingers of the left hand as the right hand moves the handle in a clockwise arc across the left thigh toward the floor. The toe of the blade "wanders" from posterior to anterior, around the frontal bone, to rest anterior to the right ear. Elevation of the handle of the right blade permits movement of the blade further into the pelvis beyond the symphysis and articulation at the handles. The proper attitude of flexion is created by moving the handles toward the pelvic midline. Rotation of the fetal head is accomplished by counter-clockwise rotation of the handles in a wide arc across the left thigh toward 12 o'clock. With classic forceps, a wide rotational arc at the handles produces the desired smaller arc of rotation at the toe of the blades. Once the OA position is reached, the blades may be readjusted before the generation of traction. This same procedure may be used for the right occiput transverse (ROT) position with classic forceps. In this instance, however, the right blade is posterior and should be applied first.

#### Kielland Forceps

**Kielland forceps were originally designed for delivery of the fetal head in deep transverse arrest.**<sup>20</sup> They are now also used for rotation of the fetal head from OP or OT positions. The advantage of Kielland forceps lies in the reverse pelvic curve, which permits placement of the blades in the direct OT position without elevation of the fetal head and loss of station. Unlike classic forceps, with Kielland forceps the anterior blade is applied first. **Three methods of Kielland forceps application have been described: (1) the inversion method, or classic application, (2) the wandering method, and (3) the direct method.**<sup>26</sup>

The *inversion method* may be used in OT and LOP or ROP positions. In an LOT position, the right anterior blade is gently

guided below the symphysis with assistance from the operator's left hand. With this application, the cephalic curve is facing up and beyond the symphysis, the handle is dropped below the horizontal, and the blade is rotated 180 degrees toward the midline until the cephalic curve rests on the parietal bone and malar eminence. If resistance is met with the inversion technique, the wandering technique may be used.

The *wandering method* for Kielland forceps is similar to that used for classic forceps. It requires initial placement of the anterior blade onto the posterior parietal bone with the cephalic curve directly applied to the fetus. The blade is then gently advanced around the face and frontal bone until it rests above the anterior fetal ear.

The *direct method* of application is preferred when the head is at low fetal station near the pelvic outlet. If the anterior ear is palpable beyond the symphysis, the forceps may be directly applied, often with less difficulty than with the other two methods. With the cephalic curve facing the fetus, the blade is applied by lowering the handle toward the floor. The toe is then gently advanced with guidance from the operator's opposite hand, and the posterior blade is inserted at 6 o'clock with the cephalic curve facing the fetal skull; the operator's free hand is inserted into the posterior pelvis palm side up, and the blade is gently guided into position over the posterior ear. The sliding lock will permit closure of the blades and correction of asynclitism, when the axis of the fetal head is oriented obliquely to the axial planes of the pelvis (see Chapter 12). Unlike rotation with classic forceps, the reverse pelvic curve of Kielland forceps permits rotation directly on the axis of the shanks.<sup>26</sup> The shanks and handles are rotated around the midline point of application and should be held during rotation in a plane perpendicular to the plane of the fetal BPD. In some instances, the fetal head may need to be elevated and even disengaged to accomplish the rotation. This is performed by keeping the handles of the Kielland forceps well below the horizontal plane, pushing the forceps in an anterior-cephalad direction with respect to the maternal pelvis (e.g., toward the maternal umbilicus). Failure to angle in such a direction will result in the forceps making contact with the sacral promontory and an inability to achieve the room needed for rotation. During the rotation, one finger should follow the sutures to ensure that the forceps and fetal head move as a single unit. Generally speaking, use of one hand should provide sufficient force to complete the rotation and is a good guide for avoiding excess force. After successful rotation, proper forceps placement should be confirmed before downward traction is applied. Alternatively, the Kielland forceps could be removed, and classic forceps can be placed before traction. (See Video 14-2 for a demonstration of Kielland forceps application and delivery.)

### Forceps Rotation: Application for the Occiput Posterior Position

The fetal head may be rotated from OP to OA by use of the Scanzoni-Smellie technique using classic forceps.<sup>27</sup> The posterior blade should be applied first and then appropriate placement of forceps should be confirmed. Minimal elevation of the fetal head upward within the pelvis will facilitate rotation. Movement of the handles in a wide arc toward the fetal back will enable rotation from the LOP position to OA. After rotation of the handles in a wide arc, the toe of the blades will be upside down with respect to the fetal malar eminence. They must then be removed and replaced properly before traction on the fetal head. Rotation

from OP may also be accomplished with Kielland forceps. After successful rotation, traction can be applied for delivery of the fetal head.

### Vacuum Extraction

As with forceps, successful use of the vacuum extractor is determined by proper application on the fetal head and traction within the pelvic axis.<sup>28</sup> The leading point of the fetal head is the ideal position for vacuum cup placement. It is labeled the *flexion point*, or *pivot point*, and is located on the sagittal suture 2 to 3 cm below the posterior fontanel for the OA position and 2 to 3 cm above the posterior fontanel for the OP position.<sup>28</sup> Placement of the vacuum cup over the pivot point maintains the attitude of flexion for a well-flexed head and creates flexion in a deflexed head if traction is applied correctly. Incorrect placement on an asynclitic head results in unequal distribution of force and increases the risk of neonatal intracranial injury and scalp lacerations.<sup>28,29</sup> Therefore knowledge of exact fetal position is important for efficacious vacuum placement. The force generated by vacuum suction is substantial, with recommended pressures ranging from 550 to 600 mm Hg (11.6 psi).<sup>30</sup> After initial placement of the cup, correct application must be confirmed, which includes determining that no vaginal tissue is caught beneath the vacuum cup before the vacuum pressure is raised to the desired level. **Just as with forceps, traction should begin with each contraction and should coincide with maternal pushing efforts. Routine traction between contractions should be avoided.** In the absence of maternal pushing, traction alone increases the force required for fetal descent and increases the risk of cup detachment.<sup>28</sup> Twisting or rocking of the vacuum cup to facilitate descent of the fetal head is not recommended because of an increased risk of scalp laceration and intracranial hemorrhage (ICH).<sup>28,31</sup> With correct application, traction in the pelvic axis often results in flexion and autorotation, depending on fetal station and the vacuum cup selected.<sup>29</sup>

**Detachment of the vacuum cup during traction should be viewed as an indication for reevaluation of the site of application, direction of axis traction, and fetal maternal pelvic dimensions.** The rapid decompression that results from cup detachment for the soft and rigid vacuum cups has been associated with scalp injury, and it should not be viewed as a safety mechanism that is without potential for fetal risk.<sup>29,32</sup> **Data are limited to provide evidence-based support for the maximum duration of safe vacuum application, the maximum number of pulls required before delivery of the fetal head, and the maximum number of pop-offs or cup detachments before abandonment of the procedure.**<sup>28,29,33,34</sup> There is a general consensus, however, that descent of the fetal bony vertex should occur with each pull, and if no descent occurs after three pulls, the operative attempt should be stopped. Most authorities have recommended that the maximum number of cup detachments (pop-offs) be limited to two or three and that the duration of vacuum application before abandonment of the procedure be limited to a maximum of 20 to 30 minutes.<sup>34,35</sup> A randomized controlled trial (RCT) compared maintenance of suction of 600 mm Hg throughout the operative delivery to reduction of suction to 100 mm Hg between contractions and found no differences in duration of operative delivery or in neonatal outcome.<sup>36</sup> Finally, vacuum cup selection may play a role in the likelihood of successful vaginal delivery. The soft cup instruments used in modern practice are associated

with less scalp trauma but have a higher failure rate than rigid metal vacuum cups.<sup>35</sup> A meta-analysis of nine RCTs of soft versus rigid vacuum extractor cups determined that the average failure rates were 16% and 9% for the soft and metal cups, respectively, and the detachment rates were 22% and 10% for the soft and metal cups, respectively. Higher failure rates with the soft cup may be secondary to difficulties associated with proper placement and traction, particularly if the fetus is deflexed, malpositioned, or at higher station.<sup>27,35</sup>

## RISKS AND BENEFITS OF OPERATIVE VAGINAL DELIVERY

### Benefits of Operative Vaginal Delivery

**Most women desire a vaginal delivery.**<sup>14</sup> Therefore the safe and effective application of instrumental delivery during the second stage of labor is crucial. **In addition, acknowledging the benefits of operative vaginal delivery and the maternal views following these interventions is an important component to enhance counseling.** In a cohort study of 393 women who had either a “difficult” operative vaginal delivery performed in the operating suite or a cesarean delivery for an arrest disorder in the second stage of labor, an equal proportion of patients in both groups desired future pregnancy (51% vs. 54%) when asked before hospital discharge. However, women who had an operative vaginal delivery were much more likely to desire a subsequent vaginal delivery compared with women delivered by cesarean section when asked immediately postpartum (79% vs. 39%)<sup>11</sup> and when asked again 3 years later (87% vs. 33%).<sup>12</sup> In addition, of those patients who achieved pregnancy within 3 years of the index delivery in this cohort, substantially more women who had an operative vaginal delivery achieved subsequent vaginal delivery compared with those who had a prior cesarean delivery (78% vs. 31%).<sup>12</sup> Johanson and colleagues<sup>37</sup> followed patients 5 years after a randomized trial that compared forceps delivery with vacuum extraction and demonstrated that more than 75% achieved a spontaneous vaginal delivery with a larger fetus in their second pregnancy.

Because women report fear of childbirth as a common reason for avoiding future pregnancies,<sup>12</sup> patients who had an operative delivery were asked about their views on this procedure, including preparation for this type of delivery. Most women felt that their birth plan or antenatal classes had not properly prepared them for the possibility of an operative delivery in the second stage of labor.<sup>13</sup> In addition, most had difficulty understanding the need for the intervention despite a review of the indications by the medical staff before discharge. These patients desired more focused antenatal information on operative delivery and a postdelivery debriefing by their delivering physician or midwife focused on the reasons for the intervention and their future pregnancy and delivery implications.<sup>13</sup>

### Maternal Risks

The focus of recent attention regarding operative vaginal delivery has been the risk of perineal trauma and subsequent pelvic floor dysfunction. The principle risks appear to be those of urinary and fecal incontinence. However, the difficulty in establishing the precise risks of this dysfunction in patients who have had an operative vaginal delivery compared with those who have not is confounded by many factors, including the indication for the operative delivery, number of deliveries, maternal weight, neonatal birthweight

**and head circumference, perineal body length, episiotomy, and the effects of maternal aging.**<sup>38</sup> We will examine three aspects of maternal risk associated with operative vaginal delivery: significant perineal trauma (third- and fourth-degree lacerations), urinary incontinence, and fecal incontinence.

### Perineal Trauma

*Significant perineal trauma* is generally defined as a third-degree laceration that involves the anal sphincter or a fourth-degree laceration that involves the rectal mucosa (see [Chapter 18](#)). Estimated frequencies of these injuries vary based on multiple maternal factors that include parity, birthweight, type of delivery, and use of episiotomy. **In a large, population-based retrospective study of more than 2 million vaginal deliveries, the frequency of severe perineal injury was noted to be 11.5% in nulliparous patients, 13.8% in patients with a successful vaginal birth after cesarean delivery, and 1.8% in multiparous patients.**<sup>39</sup> Increased risks of anal sphincter injuries were found to be associated with primiparity, macrosomia, shoulder dystocia, maternal diabetes mellitus, prolonged pregnancy, non-reassuring fetal heart rate patterns, and operative vaginal delivery. In contrast to other studies that demonstrated a much larger risk of severe perineal injury as a result of forceps and vacuum delivery (sevenfold to eightfold), the study by Handa and colleagues<sup>39</sup> observed an odds ratio (OR) of only 1.4 for forceps delivery and 2.3 for vacuum delivery, suggesting that operative vaginal delivery may be associated with a much lower risk of third- and fourth-degree lacerations than was previously thought. In addition, these researchers found that episiotomy was associated with a 10% decrease in anal sphincter laceration. Other studies have also observed that episiotomy associated with forceps use either did not increase the risk of third- or fourth-degree lacerations<sup>40</sup> or it reduced their risk.<sup>41</sup> Reduction in episiotomy use has also been associated with fewer severe perineal lacerations in two different studies that evaluated a total of more than 7000 consecutive deliveries.<sup>42,43</sup> Whether more liberal use of episiotomy affects the rate of severe perineal lacerations remains to be evaluated in a prospective randomized trial.

### Urinary Incontinence

*Stress urinary incontinence* is defined as the involuntary leakage of urine during effort or exertion and occurs at least once weekly in one third of adult women.<sup>44</sup> **Both pregnancy and the interval following pregnancy predispose women to urinary incontinence.** Viktrup and Lose<sup>45</sup> observed that **32% of nulliparous women developed urinary incontinence during pregnancy and 7% developed it after delivery. One year following delivery, only 3% reported incontinence; however, 5 years later, 19% of women asymptomatic following delivery had incontinence.** The Norwegian Epidemiology of Incontinence in the County of Nord-Trøndelag (EPINCONT) study, with an 80% response rate to a survey of more than 11,000 nulliparous patients, observed a 24% prevalence of urinary incontinence and increased urinary incontinence symptoms with increasing age, body mass index (BMI), and number of years since delivery.<sup>46</sup> In addition, incontinence was significantly associated with birthweight greater than 4000 g and fetal head circumference greater than 38 cm. Having at least one vacuum or forceps delivery in this cohort did not affect the risk of developing urinary incontinence. In a prospective study of the short- and long-term effects of forceps delivery compared with spontaneous vaginal delivery, which included both patient survey and clinical

examination data, Meyer and colleagues<sup>47</sup> observed a similar incidence of urinary incontinence at both 9 weeks (32% vs. 21%) and 10 months (20% vs. 15%). In addition, bladder neck and urethral sphincter function and intravaginal pressures were similar between the groups. The only difference noted was an increased incidence of a weak pelvic floor in the forceps group (20% vs. 6%) at the 10-month examination. In a 5-year follow-up study of patients randomized to either forceps or vacuum delivery, Johanson and colleagues<sup>48</sup> observed no difference in the incidence of urinary dysfunction between these groups. However, in a prospective observational study that used patient survey data, Arya and colleagues<sup>49</sup> reported that urinary incontinence after forceps delivery was more likely to persist at 1 year compared with spontaneous vaginal delivery or vacuum delivery (11% vs. 3%). In a nulliparous cohort of more than 1100 women who were continent prior to pregnancy, only those who had a cesarean delivery had significantly reduced odds of reporting persistent incontinence at 18 months postpartum, whereas those whose vaginal births were assisted with either forceps or vacuum reported no difference in persistent incontinence compared with those who had a spontaneous vaginal delivery.<sup>50</sup> In addition, a study by Macleod and colleagues<sup>51</sup> reported that performance of an episiotomy was found to be protective against stress incontinence in those patients who were randomized to routine episiotomy versus restrictive episiotomy.

**The only prospective randomized trial to assess urinary incontinence symptoms after planned elective cesarean delivery compared with planned vaginal delivery is the Term Breech Trial.**<sup>52</sup> At 3 months postpartum, women randomized to cesarean delivery reported less urinary incontinence compared with those in the planned vaginal delivery group (4.5% vs. 7.3%; relative risk [RR], 0.62; 95% confidence interval [CI], 0.41 to 0.93). Finally, in a long-term (34-year) follow-up study of patients following either forceps, spontaneous vaginal delivery, or an elective cesarean delivery without labor, urinary incontinence was found more frequently in those women who had a spontaneous vaginal delivery compared with those who had a forceps delivery (19% vs. 7%). In addition, the total number of vaginal deliveries was the only risk factor attributed to urinary incontinence in this cohort (OR, 19.5; 95% CI, 4.01 to 34.8;  $P = .001$ ).<sup>53</sup> **The precise association between mode of vaginal delivery (spontaneous, forceps, or vacuum) and urinary incontinence remains unclear at this time in light of the many other factors that appear to contribute to this condition.** However, forceps delivery appears to have little if any effect on the subsequent development of urinary incontinence; therefore it is reasonable to counsel patients that the use of forceps or vacuum for an appropriate obstetric indication likely has no increased long-term effect on urinary incontinence compared with spontaneous vaginal delivery.

### Fecal Incontinence

**Overall rates of anal sphincter injury noted at the time of vaginal delivery in nulliparous patients are reported to be between 7% and 11.5%.**<sup>39,54,55</sup> **Operative vaginal delivery has been associated with an increased risk of perineal injury, specifically third- and fourth-degree lacerations.**<sup>39,40</sup> However, what is not clear is the precise incidence of occult anal sphincter injury in patients who deliver vaginally and the resulting effect on fecal incontinence. In the largest prospective study to evaluate the prevalence of anal sphincter injury after forceps delivery

EAS, external anal sphincter; IAS, internal anal sphincter; MD, missing data.

in nulliparous women using endoanal ultrasound, de Parades and colleagues<sup>56</sup> examined 93 patients 6 weeks after delivery and found a 13% prevalence of anal sphincter injury. These findings are in contrast to other studies that have evaluated fewer patients each but found a higher prevalence of anal sphincter injury shortly following forceps delivery (Table 14-2).<sup>56-61</sup>

The difficulty with many of the studies noted in Table 14-2 is the extremely low number of patients who return for the endoanal ultrasound following delivery. For example, even though Sultan and colleagues<sup>60</sup> recruited patients from a previous RCT of forceps and vacuum delivery, only 44 of the original 313 patients (14%) were assessed. Because not all patients were evaluated, it is possible that significant selection bias occurred and that the actual prevalence of anal sphincter injury was lower because those patients most symptomatic would be likeliest to return for endoanal ultrasound. Indeed, in the largest randomized trial to date to evaluate anal sphincter function following forceps or vacuum extraction, Fitzpatrick and colleagues<sup>61</sup> were able to follow up on all 61 patients randomized to forceps delivery and demonstrated a much lower rate of anal sphincter injury than previously reported (56%). Even though in this study, more patients who delivered by forceps described altered fecal continence compared with those who had vacuum delivery (59% vs. 33%), no differences were seen in endoanal ultrasound defects or in anal manometry results. In addition, no differences were reported in symptom scores between the groups, and the degree of disturbance to continence was low in both groups; the most common symptom was occasional flatal incontinence.

However, de Parades and colleagues<sup>56</sup> found lower rates of anal sphincter injury (13%) and complaints of altered fecal continence (30%) following forceps delivery. Most symptomatic patients complained of persistence of incontinence of flatus (17 of 28), as noted in the study by Fitzpatrick.<sup>61</sup> In addition, a significant increase in the daily number of stools was associated with anal sphincter defects visible on endoanal ultrasound, but the development of altered fecal continence symptoms was not.<sup>56</sup>

Even though it appears that immediate complaints of altered fecal continence and evidence of anal sphincter injury may be as high as 60% immediately following operative vaginal delivery, data from long-term follow-up does not bear this figure out. For example, Johanson and colleagues<sup>48</sup> followed patients 5 years after randomization to either forceps or vacuum delivery and found no significant difference in complaints of altered fecal continence between the groups (15% vs. 26%). In addition, most patients in the forceps and vacuum groups who noted altered fecal continence had occasional incontinence of flatus or diarrhea as their only symptom (70% and 68%, respectively). In addition, 34-year follow-up data on 42 patients delivered by forceps, compared with 41 patients

delivered by spontaneous vaginal delivery, demonstrated a higher rate of anal sphincter injury on ultrasonography in the forceps group (44% vs. 22%), but no difference was apparent in the rate of altered fecal continence (14% vs. 10%).<sup>53</sup> **These data suggest that forceps delivery is a risk for sphincter injury but not for long-term fecal incontinence.** In fact, logistic regression revealed that greater neonatal birthweight, and not forceps delivery, was the contributing risk for significant fecal incontinence in this study.<sup>53</sup> However, in a large longitudinal study that surveyed 3763 women up to 12 years after delivery, 6% self-reported persistent fecal incontinence from either their 3-month or 6-year follow-up survey. Logistic regression analysis demonstrated that any forceps delivery, maternal age between 30 and 34 years, and obesity as defined by BMI were all independently associated with persistent fecal incontinence.<sup>62</sup> Therefore, based on these studies, anal sphincter injury rates in women who deliver by forceps may be higher, and outcome data regarding the effect of forceps delivery on long-term rates of fecal incontinence are in conflict; thus further study of these outcomes is required to adequately assess this risk. These observations could reflect the body's ability to heal and compensate for anal sphincter injury over time and may also be the basis for questioning the importance and validity of early outcome assessments of anal incontinence.

### Fetal Risks

The focus of possible fetal injury associated with operative vaginal delivery includes craniofacial/intracranial injury and neurologic/cognitive effects. The risks of fetal injury are generally instrument specific, and vacuum deliveries account for significantly higher rates of cephalohematoma and subgaleal and retinal hemorrhages, and forceps deliveries account for a nonsignificantly higher rate of scalp and facial injuries.<sup>63</sup> In addition, the sequential use of vacuum and forceps requires particular attention because use in this manner is associated with a maternal and neonatal risk that is greater than the sum of the individual risks of these instruments.<sup>55</sup>

### Craniofacial and Intracranial Injury

#### CEPHALOHEMATOMA AND SUBGALEAL HEMORRHAGE

Rates of subperiosteal cephalohematoma in vacuum-assisted vaginal deliveries are higher than rates for either forceps or spontaneous vaginal delivery (112/1000, 63/1000, and 17/1000, respectively).<sup>64,65</sup> However, the most clinically significant and potentially life-threatening injury in this category is a subgaleal hemorrhage (see Chapter 22). This "false cephalohematoma" was first described by Nägele in 1819 to differentiate it from a true subperiosteal cephalohematoma.<sup>66</sup> **Subgaleal hemorrhage occurs when blood collects in the loose areolar tissue in the**

space between the galea aponeurotica and the periosteum. If the veins that connect the dural sinus and the scalp rupture in this layer due to shear forces, the potential space within this loosely applied connective tissue in the subgaleal space may expand with blood well beyond the limits of the suture lines (unlike a subperiosteal cephalohematoma, which is limited to blood and fluid collections within the margins of the suture lines). This space has the potential volume of several hundred milliliters of blood, which can produce profound neonatal hypovolemia, leading to hypoxia, disseminated intravascular coagulation (DIC), end-organ injury, and death.<sup>67</sup> Older literature cites several causes of subgaleal hemorrhage, along with the source: for vacuum extraction, it was 48%; spontaneous vaginal delivery, 28%; forceps, 14%; and cesarean delivery, 9%.<sup>66</sup> Although this is older literature reported in an era when a “low forceps” delivery was broadly defined by the 1965 ACOG classification scheme, it is most important to note that these potentially life-threatening bleeds can also occur with spontaneous vaginal deliveries.

**More recent data suggest that subgaleal hemorrhage occurs nearly exclusively with the vacuum device<sup>68-70</sup>** with an incidence of subgaleal bleeding of 26 to 45 per 1000.<sup>71</sup> Benaron<sup>72</sup> reported an incidence of 1 per 200 with soft silicone vacuum cups. Subgaleal hemorrhage has an estimated incidence of approximately 4 per 10,000 spontaneous vaginal deliveries.<sup>66</sup> In a 30-month prospective study, Boo<sup>73</sup> evaluated more than 64,000 neonates and found that the incidence per live birth was much higher for vacuum extraction than for other modes of delivery (41/1000 vs. 1/1000). Both the type of cup and the duration of its use are predictors of scalp injury. Soft cups are more likely to be associated with a decreased incidence of scalp injuries but may not be less likely to result in a subgaleal hemorrhage.<sup>4</sup> In one study, vacuum application duration of more than 10 minutes was the best predictor of scalp injury.<sup>74</sup>

**In May 1998, the Food and Drug Administration (FDA) issued a public health advisory<sup>31</sup> regarding the use of vacuum-assisted delivery devices. The advisory cited a fivefold increase in the rate of deaths and serious morbidity during the previous 4 years, compared with the past 11 years, and recommended use of these devices only when a specific obstetric indication is present.** Other recommendations included the following:

- Persons who use vacuum devices for assisted delivery should be versed in their use and aware of the indications, contraindications, and precautions supported in the accepted literature and current device labeling.
- The recommended use for all these products is to apply steady traction in the line of the birth canal. Rocking movements or applying torque to the device may be dangerous. Because the instructions may be different for each device type or style, it is important to use the instructions provided by the manufacturer of the particular product being used.
- Alert those who will be responsible for the infant's care that a vacuum-assisted delivery device has been used so that they can monitor the infant for signs of complications.
- Educate the neonatal care staff about the complications of vacuum-assisted delivery devices that have been reported to the FDA and in the literature. They should watch for the signs of these complications in any infant in whom a vacuum-assisted delivery device was used.
- Report reactions associated with the use of vacuum-assisted delivery devices to the FDA.

Despite the fact that many recommend allowing no more than three pop-offs before successful delivery, no clear evidence suggests that three applications are safe; if the cup slips during traction without descent of the vertex, neonatal scalp injury may still occur.<sup>74</sup> For example, Benaron<sup>72</sup> demonstrated that the risk of injury and bleeding is increased in nulliparous patients and in those with severe dystocia, malposition, and forceful, prolonged vacuum extractor use. Therefore caution must be taken with the use of vacuum extractor devices to avoid prolonged (>30 minutes) or forceful use.

### INTRACRANIAL HEMORRHAGE

**Rates of clinically significant intracranial hemorrhage for vacuum, forceps, and cesarean delivery during labor are similar (1/860, 1/664, and 1/907, respectively) but are higher than those for cesarean delivery without labor (1/2750) and for spontaneous vaginal delivery (1/1900).**<sup>75</sup> Because cesarean delivery following abnormal labor was associated with the same rate of ICH as forceps and vacuum in this study, it is likely that the common risk factor for any increased risk of ICH is abnormal labor, not the type of operative vaginal delivery performed. In fact, because the prevalence of clinically silent subdural hemorrhage is approximately 6% following uncomplicated spontaneous vaginal delivery, the presence of this hemorrhage in an otherwise asymptomatic neonate does not necessarily indicate excessive birth trauma and again reflects the natural history of labor and delivery.<sup>76</sup> In these neonates, the silent subdural hemorrhages all resolved within 4 weeks of delivery.

### NEUROLOGIC AND COGNITIVE EFFECTS

**Vacuum-assisted vaginal deliveries increase the risk of neonatal retinal hemorrhages by approximately twofold compared with forceps deliveries.**<sup>63</sup> Despite this finding, data on the long-term consequences of these hemorrhages do not demonstrate any significant effect. Johanson and colleagues<sup>48</sup> followed a cohort of children 5 years following an RCT of forceps versus vacuum extraction and found a 13% rate of visual problems in the group. However, no difference was found between those delivered by forceps compared with those delivered by vacuum extraction (12.8% vs. 12.5%). Seidman and colleagues<sup>77</sup> were also unable to detect any increased risk of vision abnormalities in a cohort of 1747 individuals delivered by vacuum extraction compared with more than 47,000 individuals delivered by spontaneous vaginal delivery and examined at age 17 years by the Israeli Defense Forces draft board.

**In addition, no long-term effect of operative vaginal delivery on cognitive development is apparent.** Seidman and colleagues<sup>77</sup> demonstrated that mean intelligence scores at age 17 years were no different between those delivered by forceps or vacuum extraction compared with those delivered by spontaneous vaginal delivery. However, the mean intelligence scores for those delivered by cesarean delivery were significantly lower than those of the spontaneous delivery group. Similarly, in a 1993 report from patients within the Kaiser system in Oakland, CA, Wesley and colleagues<sup>78</sup> were unable to detect a difference in cognitive development by measuring IQ in 1192 children delivered by forceps, compared with 1499 who delivered spontaneously, who were examined at age 5 years. Furthermore, of the 1192 forceps deliveries, 114 were midforceps deliveries, and no differences in IQ were seen at age 5 compared with 1500 controls. **Finally, no association between forceps delivery and epilepsy in adulthood is apparent.** Murphy and colleagues<sup>79</sup>

evaluated a cohort of more than 21,000 individuals and found forceps delivery was not associated with an increased risk of epilepsy or anticonvulsant therapy when compared with other methods of delivery.

Regarding long-term neurologic outcomes, in a 5-year follow-up of a prospective cohort of 264 women with term, singleton, cephalic pregnancies that required a second-stage operative delivery from 1999 to 2000, neonates delivered by forceps were found to have no significant differences in neurodevelopmental outcome compared with those delivered by cesarean section.<sup>80</sup>

**Evidence also suggests that forceps-assisted vaginal births may be protective against outcomes associated with poor long-term neurologic consequences.** A retrospective review<sup>81</sup> of neonatal outcomes from more than 1 million singleton births between 1995 and 2003 revealed that when compared with vacuum-assisted vaginal delivery or cesarean delivery, forceps-assisted vaginal deliveries were associated with a reduced risk of adverse neurologic outcomes, including seizures and 5-minute Apgar scores less than 7.

### Complex Operative Vaginal Delivery Procedures

#### Rotations Greater Than 45 Degrees

The correct application and delivery technique using forceps is critical to the safe performance of this procedure. The outcomes of forceps delivery are often directly compared and contrasted with those of spontaneous vaginal delivery. When these comparisons are made, forceps deliveries are associated with a higher rate of maternal injury than spontaneous vaginal deliveries. However, the comparison of these two modes of delivery is not appropriate because forceps applications require an indication for use that confounds the clinical outcome when compared with spontaneous vaginal delivery. A more appropriate comparison to forceps delivery, or to operative vaginal delivery in general, is cesarean delivery for second-stage arrest disorder. Unfortunately, no prospective randomized trials directly compare these two modes of delivery. However, **numerous retrospective studies that have compared midcavity and rotational forceps delivery with cesarean delivery demonstrate no increased risk of fetal/neonatal adverse outcomes including Apgar score, umbilical cord blood gas values, birth trauma, and neonatal intensive care unit (NICU) admission.**<sup>82-85</sup> Specifically, the rates of neonatal morbidity associated with Kielland forceps rotation are similar to cesarean delivery, including rates of cephalohematoma (9% to 17%), facial bruising (13% to 18%), facial nerve injury (1% to 5%), neonatal encephalopathy (<1%), and brachial plexus injury (<1%).<sup>85-87</sup> Interestingly, rates of maternal morbidity (intraoperative and postoperative complications, blood loss, and length of stay) have been found to be higher in patients delivered by cesarean delivery compared with those delivered by midcavity forceps delivery.<sup>82,83</sup>

**The outcomes of rotational forceps deliveries have also been evaluated and compared with nonrotational forceps delivery.** Healy and colleagues<sup>88</sup> evaluated 552 Kielland forceps rotations, 95 Scanzoni-Smellie maneuvers with classic instruments, and 160 manual rotations followed by delivery with a classic instrument and found no difference in neonatal outcomes between the groups. Krivac and colleagues<sup>89</sup> compared 55 Kielland forceps rotations with 213 nonrotational forceps deliveries and found that 15 of the rotations were greater than 90 degrees, and 40 were less than 90 degrees but greater than 45 degrees.

They found that the Kielland forceps-rotation group had both a longer labor and longer second stage than the nonrotational group and a higher rate of 1-minute Apgar scores less than 6 and meconium at delivery. However, the nonrotational forceps group had a greater incidence of postpartum hemorrhage (14% vs. 7%) and a higher rate of third- and fourth-degree lacerations (24% vs. 14%). No other differences in maternal or neonatal morbidity were noted, which included no difference in rates of nerve compromise (<1%), facial bruising (7%), shoulder dystocia (1%), or NICU admissions. Hankins and colleagues<sup>90</sup> performed a retrospective case-controlled study that compared 113 forceps deliveries greater than 90 degrees compared with 167 forceps deliveries less than 45 degrees. **No differences in major fetal injury were demonstrated between these two groups. Major fetal injury was defined as skull fracture, subdural hematoma and brachial plexus or facial nerve injury, and fetal acidemia (pH less than 7.0).** Finally, Feldman and colleagues<sup>91</sup> compared 104 rotational forceps deliveries using Leff forceps for persistent OP position with 163 nonrotational forceps deliveries and found lower rates of episiotomy (66% vs. 82%) and perineal lacerations (16% vs. 23%) in the forceps-rotation group and no differences in the rates of neonatal morbidity between the groups. **These data suggest that when properly applied and used, forceps deliveries that require more than a 45-degree rotation may be safely accomplished without increased risk of maternal or neonatal morbidity, therefore it should remain a management option for women with second-stage labor abnormalities.**

#### Midpelvic Cavity Delivery

Like rotational forceps deliveries, delivery of the fetus from a 0 or +1 station (midpelvic or midforceps) requires a specific set of skills and precautions. **In 1988, ACOG reported on required conditions for a midforceps delivery that included (1) an experienced person performing or supervising the procedure, (2) adequate anesthesia, (3) assessment of maternal-fetal size, and (4) willingness to abandon the attempt at delivery.** This information should be taken together with the prerequisites set forth by Richardson and colleagues<sup>92</sup>: **the midforceps procedure (1) must rationally be needed as an alternative method of delivery to cesarean delivery, (2) must be associated with demonstrably less maternal morbidity than cesarean delivery, and (3) should not result in fetal harm.** Several studies that have compared cesarean delivery with midforceps procedures show that midforceps delivery is not associated with more adverse neonatal outcomes including cord blood gases, Apgar scores, NICU admissions, and birth trauma.<sup>82,83,93</sup> In 1997, Revah and colleagues<sup>93</sup> reported their findings of a retrospective chart review of 401 cesarean deliveries over a 7-year period in which a trial of operative delivery (forceps or vacuum) was conducted in 75 cases. No differences were reported for any maternal or fetal outcome between cesarean delivery with a trial of operative delivery versus no operative delivery attempt. **Although the outcomes of these studies are reassuring, because of the technical skills required, it is most reasonable to abide by the guidance set forth in the ACOG practice bulletin<sup>71</sup> published in 2000, which states, "Unless the preoperative assessment is highly suggestive of successful outcome, trial of operative vaginal delivery is best avoided."** In short, following the ACOG statement and the previously stated prerequisites provides the skilled practitioner with guidelines and support for attempting a safe midpelvic cavity delivery.

### Sequential Use of Vacuum and Forceps

The sequential use of these instruments appears to increase the likelihood of adverse maternal and neonatal outcomes more than the sum of the relative risks of each instrument.<sup>55,65</sup>

Compared with spontaneous vaginal delivery, deliveries by sequential use of vacuum and forceps are associated with significantly higher rates of ICH (RR, 3.9; 95% CI, 1.5 to 10.1), brachial plexus injury (RR, 3.2; 95% CI, 1.6 to 6.4), facial nerve injury (RR, 3.0; 95% CI, 4.7 to 37.7), neonatal seizures (RR, 13.7; 95% CI, 2.1 to 88.0), requirement for mechanical ventilation of the neonate (RR, 4.8; 95% CI, 2.1 to 11.0), severe perineal lacerations (RR, 6.2; 95% CI, 6.4 to 20.1), and postpartum hemorrhage (RR, 1.6; 95% CI, 1.3 to 2.0).<sup>55</sup> Therefore **care should be taken to avoid the sequential use of these instruments to reduce maternal and neonatal morbidity.** Such switching of instruments should be limited to situations in which application of one type of instrument fails, and it should be performed by individuals skilled and experienced with operative vaginal delivery procedures.

### Trial of Operative Vaginal Delivery

Historically, an unsuccessful operative vaginal delivery has been associated with a high maternal and neonatal morbidity and up to a 38% fetal mortality rate and 2% maternal mortality rate.<sup>94</sup> Reports of increased morbidity and mortality in these cases led to the development of the concept of a trial of forceps in which immediate cesarean delivery was performed if, following correction of malposition and gentle traction, further descent of the fetal vertex was not noted.<sup>95</sup> These attempts were often performed in the operating room instead of the delivery room, permitting rapid transition to cesarean delivery. **Following implementation of this concept, rates of morbidity and mortality have fallen, documenting no difference in neonatal or maternal outcomes associated with a failed forceps or vacuum attempts in the absence of a nonreassuring fetal heart rate tracing.**<sup>96</sup>
