Goel, S. K., Singh, M., & Xu, D. (2002). Efficient peer-to-peer data dissemination in mobile ad-hoc networks. *Proceedings of the International Conference on Parallel Processing*.

CONCLUSION

In this article, we studied the peer-to-peer systems over mobile ad hoc networks with a comparison of different settings for the peer-to-peer overlay and underlying mobile ad hoc network. We show that the cross-layer approach performs better than separating the overlay from the access networks in Table 1. Our results would potentially provide useful guidelines for mobile operators, value-added service

Table 1. How efficient does a user try to find a specific piece of data?

| | Efficiency | Scalability | Implementation |
|--------------------------|---------------|-------------|----------------|
| Broadcast over Broadcast | $O(n^2)$ | n/a | Easy |
| DHT over Broadcast | $O(n \log n)$ | Bad | Medium |
| Cross-Layer Broadcast | $O(n)$ | Medium | Difficult |
| Cross-Layer DHT | $O(\log n)$ | Good | n/a |

P2P: Peer-to-peer.

Mobile Gaming

Krassie Petrova

Auckland University of Technology, New Zealand

INTRODUCTION

A number of multifunctional handheld devices with Internet and multimedia capabilities are currently available on the market. The mobile network technologies implemented make it possible for a range of value-added mobile services known as “mobile entertainment” to be offered to paying subscribers (Carlsson, Hyvonen, Repo, & Walden, 2005). Examples include watching streamed news, downloading music and images, or playing a game on one’s mobile phone (alone, or in an interaction with other players).

Mobile game development depends on the choice of a middleware platform, as the application needs to be portable across a wide spectrum of handheld devices and technologies (Yuan, 2004; Hagleitner & Mueck, 2002). A business model for offering mobile gaming as a service has been successfully trialled in Japan where playing games is one of the main components of the popular Japanese entertainment platform iMode (Natsuno, 2003, pp.88-90).

Research in the area of mobile gaming adoption has focused on the investigation of the value generation process and on identifying the critical factors for mobile gaming acceptance. A number of critical success factors have been identified (e.g., Shcheglick, Barnes, Scornavacca, & Tate, 2004; Moore & Rutter, 2004; Yoon, Ha, & Choi, 2005), adapting and extending existing mobile business frameworks and models (e.g., Siau, Lim, & Shen, 2001; Varshney & Vetter, 2002; Lee, Hu, & Yeh, 2003; Barnes, 2003). This short article investigates the relationship between mobile gaming customers and the mobile gaming value chain, and discusses the implications from mobile gaming supply and demand perspectives.

BACKGROUND

Playing mobile games (“mobile gaming”) is classified as a “mobile entertainment” application (Barnes & Huff, 2003; Van de Kar, Maitland, de Montalvo, & Bouwman, 2003). Mobile entertainment includes personal leisure activities undertaken via a network technology. Entertainment services might feature data transfer including voice and video over significant geographic distance while the user of the service is either on the move or has the potential to move without interrupting the activity (Ollila, Kronzell, Bakos, & Weisner, 2003).

Mobile gaming is also an example of a mobile commerce (m-commerce) application, provided through a specially designed m-commerce service. Typically, an m-commerce service involves payment: a monetary transaction which the customer conducts using the mobile payment mechanism provided with the service (Paavilainen, 2002). In the case of mobile gaming, the player’s subscriber account with the mobile network operating the service is used to collect the revenue. Subsequently the network operator makes payments to other service providers who might be involved: content developers and publishers, portal aggregators, and retailers (Wiener, 2003).

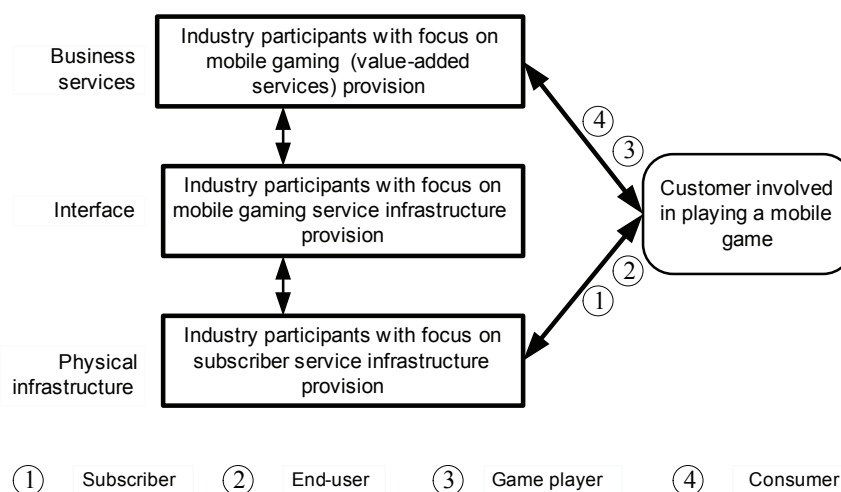

Some mobile games are simply downloaded and played off-line, paying once or with every update. Such games might be suitable for “low-end” handheld devices and might use text messaging. Other mobile games need to be played on smartphones, as interactivity among multiple players needs to be supported. These real-time mobile games require a persistent network connection to a dedicated game server. Advancements in mobile game development include the inclusion of location-based features into the game (Moore & Rutter, 2004; Maitland, van de Kar, de Montalvo, & Bouwman, 2005). In all cases, the mobile game player does not need to be stationary – he or she is “released” from the need to use a stationary networked device (Finn, 2005). The assumed mobility of the mobile game player is one of the defining features of mobile gaming.

A leader in mass mobile entertainment, the Japanese company NTT DoCoMo developed a comprehensive mobile service and platform: iMode. Entertainment applications and specifically mobile gaming are seen as the catalyst for the increased use of the range of other iMode services (Baldi & Thaug, 2002; Natsuno, 2003, p.92; Barnes & Huff, 2003; Funk, 2003, p. 28). In the global market, mobile gaming is seen as a viable business opportunity (Kleijnen, de Ruyter, & Wetzels, 2003, p. 205; Anckar & D’Incau, 2002; Paavilainen, 2002). According to some predictions, by 2010 the revenue from downloading mobile games might reach US\$8.4 billion (Graft, 2006).

THE MOBILE GAMING VALUE CHAIN

A number of value chain models (e.g., Buellingen & Woerter, 2004; Siau et al., 2001, Barnes, 2003) and mobile frameworks (e.g., Varshney & Vetter, 2002; Stanoevska-Slabeva, 2003)

Figure 1. Customer relationships in mobile gaming (Derived from Petrova, 2005)

for m-commerce have been suggested in the literature and used to map industry players, roles and functions. A multiple value-chain model representing the relationships between a customer and the mobile gaming industry is shown in Figure 1. It applies the m-commerce reference model proposed by Petrova (2005) to the mobile entertainment value Web (Ollila et al., 2003) to identify the relationships between the customer (a mobile game player) and the mobile industry participants.

The network developers and providers, along with device developers, create the physical foundation needed for mobile gaming, and together with the mobile network providers, form a physical infrastructure layer. The interface layer includes developers of middleware platforms, which serve as game developing and servicing environments and enable the use of the networks and technologies for game service provision. The top layer represents the category of value-added services where mobile games are offered to customers directly or as a part of a mobile entertainment package. The main industry participants are mobile game developers, publishers and aggregators.

A company involved in mobile gaming can be categorised under more than one category: *Vodafone*, for example, provides a subscriber network and subscriber service, as well as mobile game downloading through its portal *Vodafone Live!* (Harmer, 2003). The revenue model of the company depends on its position in the value chain (Ollila et al., 2003).

MOBILE VALUE CHAIN RELATIONSHIPS

Mobile network operators are part of the physical infrastructure by building and maintaining the network. In most

cases they also provide subscriber services and access to the network (e.g., *Vodafone*, *Orange*). The 2G-2.5G technologies currently implemented include CDMA, GSM, and GPRS, and are capable of maintaining real-time, persistent network connection (Mobile Games, 2001). Customers interact with mobile network operators as subscribers to the network service (Relationship 1 in Figure 1).

Mobile device supply manufacturers (e.g., *Nokia*, *Siemens*, *Motorola*) provide customers with the devices needed to connect to a network and to access the services provided. In the case of mobile gaming, devices might need extended functionality such as a very fast processor (Leavitt, 2003). Customers interact with devices as information technology (IT) end-users (Relationship 2 in Figure 1).

A feature of the mobile gaming industry sector is the coupling between device and network technology: a handheld device might be designed to be used only with a particular technology and for access to networks based on that technology. The IT end-user experience will depend on the characteristics of the device and the underlying wireless network technology.

In the interface category, some widely used middleware products for game development are WAP and iMode (Baldi & Thaug, 2002; Lee et al., 2003). New software platforms (J2ME and BREW) and operating systems (Symbian) allow for the development of portable mobile games. The industry participants in this category provide the service infrastructure needed by game developers and other related content providers, but typically do not interact directly with customers (although *Nokia* have developed a mobile phone microbrowser). Rather they serve as a link between the physical infrastructure and the business services that bring mobile gaming to the customer.

Table 1. Critical success factors, customer roles and industry players (extended from Petrova & Qu, 2006)

| Critical Success Factor | | Customer Role | Industry Participants |
|-------------------------|--|---------------|---|
| Facilitating conditions | Providing payment and billing mechanisms | Consumer | Aggregators/publishers/mobile service infrastructure providers |
| Trialability | Providing opportunities for a free trial of a service | | Aggregators/publishers |
| Compatibility | Meeting the gaming needs of specific customer segments | Game player | Game developers/publishers |
| Observability | Emphasizing the social importance of playing a mobile game | | Aggregators/publishers |
| Image | Emphasising the status of the game player | | Aggregators/publishers |
| Normative beliefs | Building a critical mass to create social pressure | | Aggregators/publishers |
| Complexity | Ensuring easy to use gaming applications | IT End-User | Device manufacturers/game developers |
| Trust | Alleviating security and privacy concerns | | Mobile network operators/application service infrastructure providers |
| Relative advantage | Providing a ubiquitous and accessible mobile gaming service | | Mobile network operators/application service infrastructure providers |
| Self-efficacy | Technical services matching different customer segment needs | Subscriber | Device manufacturers/game developers |

In the business services category, mobile game developers (for example *In-Fusio*) and mobile game aggregators and publishers (for example *MFORMA*, *Digital Bridges*) provide games to customers. Customers act as game players (Relationship 3 in Figure 1) and as consumers who pay for the valued added service (Relationship 4 in Figure 1).

CUSTOMER ROLES AND CRITICAL SUCCESS FACTORS

Understanding the priorities of a customer would lead to a better understanding of the criticality of the success factors of mobile gaming adoption and to more informed decision-making when offering a mobile gaming service to a targeted audience. From the discussion above, the question that arises is: What is the significance of customer roles in mobile gaming adoption?

Well known models and theories have been used to investigate customer adoption of different mobile applications

(Barnes & Huff, 2003; Kleijnen et al., 2003; 2004; Pagani & Schipani, 2003; Carlsson et al., 2005; Pedersen, 2005; Yoon, Ha, & Choi, 2005). Key contributing factors based on customer attitudes and perspectives (Moore & Rutter, 2004; Pedersen, Methlie, & Thorbjornsen, 2002) and potential adoption drivers (Baldi & Thaug, 2002) have been identified. Petrova and Qu (2006) extracted a set of critical success factors for mobile gaming adoption based on findings from the literature, and proposed a framework for studying the adoption process (Table 1, first two columns). Extending this work further, in Table 1 (the last two columns) each factor is matched to a specific customer role based on the relationships discussed in the previous section.

Most of the critical success factors (seven) relate to two customer roles: “game player” and “IT end-user.” They represent a relationship with the physical infrastructure layer and the business services layer of the mobile gaming industry, respectively, and constitute a “first priority” group of factors. The remaining three factors (matching the roles of “consumer” and of “subscriber”) form the “second priority” group—also related to both infrastructure and business

Table 2. Future trends in mobile game development

| Game Development Trends | Example |
|--|---|
| Games for 3G mobile networks | “Virtual Girlfriend” (<i>Artificial Life Inc.</i> , Hong Kong) |
| Multi-player, networked, interactive games | “MLSN Sports Picks” (<i>Digital Chocolate Inc.</i> , Finland) |
| Location-based games | “The Shroud” (<i>Your World Games</i> , U.S.) |
| Games for casual game players | Puzzle games (<i>Future Platforms</i> , UK). Backgammon (<i>Nokia</i> and <i>Octopi</i> , U.S.) |
| Highly personalised mobile gaming services. | “Vomitron” (<i>Ninemsn</i> , Australia). “PrizePlay” (<i>Sennari</i> , U.S.A). iMode in Japan, Europe and Australia. |
| 3D games. | “V-Rally 3D” (<i>Fishlabs</i> , Germany) |
| Games which can be used for learning, or for awareness development | “FreedomHIV/AIDS” (<i>ZMQ</i> , India) |

services provision. The significance of these results and their implications are discussed next.

Customer Priorities

Four factors are related to the role of the customer as a “game player.” The implications are that mobile gaming will be successfully adopted by customers who are likely to enjoy mobile gaming as a social activity. Therefore mobile game content needs to be tailored to match the needs of particular social groups; developers will need to provide content of greater diversity—for example, multi-player games, building a virtual world (Raghu, Ramesh, & Whinston, 2002) and location-based gaming (Finn, 2005). The importance of the social context is confirmed by the success of mobile gaming in Japan (Barnes & Huff, 2003) and in other Asian countries (Kymalainen, 2004, p. 131). Game developers, aggregators and publishers should continue to focus on market segments that display a strong, pre-existing disposition towards mobile gaming as innovation. According to Baldi and Thaug (2002) and Kleijnen et al. (2004), Internet usage is such a predictor. Non-core gamer markets might also be penetrated with a range of casual games.

Three success factors relate to the role of the customer as an IT end-user. The implication for industry participants involved in the provision of physical infrastructure is that the usability of handheld devices will continue to be important as it brings “compelling” value to the customer (Venkatesh, Ramesh, & Massey, 2003). Network operators might need to consider “opening up their networks” to facilitate the development and provisioning of interactive games, operable across provider networks (Smorodinsky, 2002), while

game developers will need to develop more portable applications (Yuan, 2004). All industry participants will need to address users’ concerns for privacy and security, possibly by adapting solutions developed for e-commerce (Yiliantila, 2004, p. 71).

In summary, the adoption factors related to the consumer roles of “game player” and “IT end-user” are the ones that will ultimately determine the success of mobile gaming application and services.

Customer Support

Two factors relate to the customer role of “consumer” and one to the role of “subscriber.” The implication is that that mobile game customers will expect a transaction and trading environment similar to other commercial environments, where customer and technical support are readily available (Kleijnen, de Ruyter, & Wetzels, 2003, p. 213). Industry participants from both the infrastructure layer and the business services layer will need to explore different cooperation strategies to be able to meet these requirements and so gain sustainable competitive advantage (Feldmann, 2002).

In summary, while adoption factors related to the customer roles of “consumer” and “subscriber” are not crucial, they will have a strong influence on customer choice and loyalty.

FUTURE TRENDS

The game development effort is focused on providing games targeting different customer segments, games exploring new technologies and games enhancing personalization. A

summary of the future trends in mobile game development is provided in Table 2 along with some examples from the industry to illustrate them.

An important global industry trend is the move to define mobile game interoperability standards, so that game development can focus on producing games deployable across multiple game servers, wireless networks, and handheld devices. An example is the work of the Open Mobile Alliance (OMA) Games Services working group.

Academic work will continue to focus on multi-platform development and middleware architecture, on factors influencing adoption and on the development of innovative business models, studying customers from diverse cultural backgrounds and their needs and priorities.

CONCLUSION

The article reviews the literature on mobile games provision and adoption and outlines the different roles played by customers involved in mobile gaming. A mobile gaming framework is introduced, including critical success factors, customer roles and industry participants. Two priority groups of success factors are identified. The factors related to customers acting as “game players” and “IT end-users” are crucial for selecting and penetrating a market segment that is ready to adopt mobile gaming as a social activity; the factors related to customers acting as “consumers” and “subscribers” play an important but secondary role and might confer competitive advantage in the selected market. The future trends in mobile gaming will be towards the development of multi-player real-time games, and providing interoperability across platforms and networks, which will facilitate new market segment penetration.

KEY TERMS

Aggregator: A content provider who maintains relationships with several mobile network operators and delivers mobile game content to their users in a transparent way (i.e., using the same mobile number). Example: *MFORMA* (U.S.).

Binary Runtime Environment for Wireless (BREW): An application development platform for client applications designed for mobile networks using CDMA, based on the “C++” programming language.

Code Division Multiple Access (CDMA): A wireless technology used in 2G mobile networks, which is also developed for 3G services (e.g., W-CDMA, CDMA2002)

Developer: Typically a team of designers, artists, and engineers designing and creating game content (including graphics and sound). Example: *Future Platforms* (UK).

General Packet Radio Services (GPRS): An advanced technology for mobile data transmission based on GSM.

Supports mobile multimedia applications and Web interaction, and enables pay-per-data models.

Global System for Mobile Communication (GSM): A standard for digital mobile telephony especially popular in Europe, but used worldwide. Provides across-border compatibility and maintains services at the 2G level.

Java 2 Platform Micro Edition (J2ME): An application development platform used primarily for client applications designed for mobile networks using GSM, based on the “Java” programming language.

Publisher: A company involved in controlling and marketing a mobile game, often funding its development. Example: *Your World Games* (U.S.).

Second Generation (2G) Mobile Telephony: Includes a range of technologies for wireless communication such as GSM and CDMA. Provides digitised voice communication, short messaging service (SMS) and some special features.

Symbian: An operating system for mobile devices with data processing capabilities (an open industry standard).

Third Generation (3G): “third generation.” A range of advanced wireless communication technologies capable of supporting multimedia, video streaming, and video-conferencing.

Wireless Application Protocol (WAP): A set of open standards to enable Web and e-mail access and data display on handheld devices.

Mobile Healthcare Communication Infrastructure Networks

Phillip Olla

Madonna University, USA

INTRODUCTION

M-health is defined as “mobile computing, medical sensor, and communications technologies for healthcare” (Istepanian & Zhang, 2004). The use of the m-health terminology relates to applications and systems such as telemedicine and biomedical sensing systems (Budinger, 2003). The rapid advances in information and communication technology (ICT) (Godoe, 2000), nanotechnology, bio-monitoring (Budinger, 2003), mobile networks (Olla, 2005a), pervasive computing (Akyildiz & Rudin, 2001), wearable systems, and drug delivery approaches (Amy & Richards, 2004) are transforming the healthcare sector. The insurgence of innovative technology into healthcare practice is not only blurring the boundaries of the various technologies and fields, but is also causing a paradigm shift that is blurring the boundaries between public health, acute care, and preventative health (Hatcher & Heetebry, 2004). These developments have not only had a significant impact on current e-health and telemedical systems (Istepanian & Zhang, 2004), but they are also leading to the creation of a new generation of m-health systems with convergence of devices, technologies, and networks at the forefront of the innovation.

The phenomenon to provide care remotely using ICT can be placed into a number of areas such as m-health, telemedicine, and e-health. Over the evolution of telemedicine, new terminologies have been created, as new health applications and delivery options became available and the application areas extended to most healthcare domains. This resulted in confusion, and identification of what falls under telemedicine and what falls under telehealth or e-health became more complicated as the field advanced. New concepts such as pervasive health and m-health are also adding to this confusion. The first section of this article provides the background of telemedicine and the advancements of mobile networks, which are collectively the foundation of m-health. The evolution and growth of telemedicine is highly correlated with ICT advancements and software development. Telemedicine advancements can be categorized into three eras (Bashshur, Reardon, & Shannon, 2000; Tulu & Chatterjee, 2005) discussed in the next section.

There are numerous wireless infrastructures available for healthcare providers to choose from. Mobile networks that provide connectivity within buildings use different

protocols from the standard digital mobile technologies such as global mobile systems (GSMs), which provide wide area connectivity. The second section of this article provides a summary of these mobile technologies that are having a profound impact on the healthcare sector. This section is then followed by the conclusion.

ERAS OF TELEMEDICINE

The *first era* of telemedicine solely focused on the medical care as the only function of telemedicine. This era can be named the telecommunications era of the 1970s. The applications in this era were dependent on broadcast and television technologies in which telemedicine applications were not integrated with any other clinical data. The *second era* of telemedicine was a result of digitalization in telecommunications, and it grew during 1990s. The transmission of data was supported by various communication mediums ranging from telephone lines to integrated service digital network (ISDN) lines. During this period there was a high costs attached to the communication mediums that provided higher bandwidth. The bandwidth issue became a significant bottleneck for telemedicine in this era. Resolving the bandwidth constraints has been a critical research challenge for the past decade, with new approaches and opportunities created by the Internet revolution; now more complex and ubiquitous networks are supporting the telemedicine. The *third era* of telemedicine was supported by the networking technology that was cheaper and accessible to an increasing user population. The improved speed and quality offered by Internet2 is providing new opportunities in telemedicine. In this new era of telemedicine, the focus shifted from an technology assessment to a deeper appreciation of the functional relationships between telemedicine technology and the outcomes of cost, quality, and access.

This article proposes a *fourth era*, which is characterized by the use of Internet protocol (IP) technologies, ubiquitous networks, and mobile/wireless networking capabilities, and can be observed by the proliferation of m-health applications that perform both clinical and non-clinical functions. Since the proliferation of mobile networks, telemedicine has attracted a lot more interest from both academic researchers and industry (Tachakra, Wang, Istepanian, & Song, 2003). This has resulted

in many mobile/wireless telemedicine applications being developed and implemented. Critical healthcare information regularly travels with patients and clinicians, and therefore the need for information to become securely and accurately available over mobile telecommunication networks is key to reliable patient care and reliable medical systems.

The telecommunication industry has progressed significantly over the last decade. There has been significant innovation in digital mobile technologies. The mobile telecommunication industry has advanced through three generations of systems and is currently on the verge of designing the fourth generation of systems (Olla, 2005b). The recent developments in digital mobile technologies are reflected in the fast-growing commercial domain of mobile telemedical services. Specific examples include mobile ECG transmissions, video images and tele-radiology, wireless ambulance services to predict emergency and stroke morbidity, and other integrated mobile telemedical monitoring systems (Istepanian & Zhang, 2004; New Scientist, 2005; Istepanian & Lacal, 2003; Warren, 2003). There is no doubt that mobile networks can introduce additional security concerns to the healthcare sector.

As security is a major concern, it is important to implement a mobile trust model that will ensure that a mobile transaction safely navigates multiple technologies and devices without compromising the data or the healthcare systems. M-health transactions can be made secure by adopting practices that extend beyond the security of the wireless network used and implementing a trusted model for secure end-to-end mobile transactions. The mobile trust model proposed by Wickramasinghe and Misra (2005) utilizes both technology and adequate operational practices to achieve a secure end-to-end mobile transaction. The first level highlights the application of technologies to secure elements of a mobile transaction. The next level of the model shows the operational policies and procedures needed to complement technologies used. No additional activity is proposed for the mobile network infrastructure since this element is not within the control of the provider or the hospital.

The next section will discuss the mobile network technologies and infrastructure which are key components of any m-health system; the network infrastructure acts as a channel for data transmission and is subject to the same vulnerabilities, such as sniffing, as in the case of fixed network transaction. The mobile networks discussed in the next section are creating the growth and increased adoption of m-health applications in the healthcare sector.

MOBILE HEALTHCARE COMMUNICATION INFRASTRUCTURE

The implementation of an m-health application in the healthcare environment leads to the creation of a mobile

healthcare delivery system (MHDS). An MHDS can be defined as the carrying out of healthcare-related activities using mobile devices such as a wireless tablet computer, personal digital assistant (PDA), or a wireless-enabled computer. An activity occurs when authorized healthcare personnel access the clinical or administrative systems of a healthcare institution using mobile devices (Wickramasinghe & Misra, 2005). The transaction is said to be complete when medical personnel decide to access medical records (patient or administrative) via a mobile network to either browse or update the record.

Over the past decade there has been an increase in the use of new mobile technologies in healthcare such as Bluetooth and wireless local area networks (WLANs) that use different protocols from the standard digital mobile technologies such as 2G, 2.5, and 3G technologies. A summary of these technologies are presented below, and an overview of the speeds and range is presented in Table 1.

These mobile networks are being deployed to allow physicians and nurses easy access to patient records while on rounds, to add observations to the central databases, and to check on medications, among a growing number of other functions. The ease of access that wireless networks offer is matched by the security and privacy challenges presented by the networks. This serious issue requires further investigation and research to identify the real threats for the various types of networks in the healthcare domain.

Second-Generation (2G/2.5G) Systems

The second-generation cellular systems were the first to apply digital transmission technologies such as time division multiple access (TDMA) for voice and data communication. The data transfer rate was on the order of tens of kbit/s. Other examples of technologies in 2G systems include frequency division multiple access (FDMA) and code division multiple access (CDMA).

The 2G networks deliver high-quality and secure mobile voice and basic data services such as fax and text messaging, along with full roaming capabilities around the world. 2G technology is in use by more than 10% of the world's population, and it is estimated that 1.3 billion customers across more than 200 countries and territories around the world use this technology (GSM, 2005). The later advanced technological applications are called 2.5G technologies and include networks such as general packet radio service (GPRS) and EDGE. GPRS-enabled networks provide functionality such as: 'always-on', higher capacity, Internet-based content and packet-based data services enabling services such as color Internet browsing, e-mail on the move, visual communications, multimedia messages, and location-based services. Another complimentary 2.5G service is enhanced data rates for GSM evolution (EDGE), which offers similar capabilities to the GPRS network.

Table 1. Mobile networks

| Networks | Speed | Range and Coverage | Main Issues for M-Health |
|--|---|---|--|
| 2nd-Generation GSM | 9.6 kilobits per second (KBPS) | World wide coverage, dependent on network operators' roaming agreements | Bandwidth limitation, interference |
| High-Speed Circuit-Switched Data (HSCSD) | Between 28.8 KBPS and 57.6 KBPS | Not global, only supported by service providers network. | Not widely available, scarcity of devices |
| General Packet Radio Service (GPRS) | 171.2 KBPS | Not global, only supported by service providers network | Not widely available |
| EDGE | 384 KBPS | Not global, only supported by service providers network | Not widely available, scarcity of devices |
| UMTS | 144 KBPS—2 MBPS depending on mobility | When fully implemented, should offer interoperability between networks, global coverage | Device battery life, operational costs |
| Wireless Local Area | 54 MBPS | 30-50 m indoors and 100-500 m outdoors; must be in the vicinity of hot spot | Privacy, security |
| Personal Area Networks—Bluetooth | 400 KBPS symmetrically, 150-700 KBPS asymmetrically | 10-100m | Privacy, security, low bandwidth |
| Personal Area Networks—ZigBee | 20 kb/s-250 KBPS depending on band | 30m | Security, privacy, low bandwidth |
| WiMAX | Up to 70MBPS | Approx. 40m from base station | Currently no devices and networks cards |
| RFID | 100 KBPS | 1 m; non-line-of-sight and contactless transfer of data between a tag and reader | Security, privacy |
| Satellite Networks | 400 to 512 KBPS new satellites have potential of 155 MBPS | Global coverage | Data costs, shortage of devices with roaming capabilities; bandwidth limitations |

Third-Generation (3G) Systems

The most promising period is the advent of 3G networks, which are also referred to as the Universal Mobile Telecommunications System (UMTS). A significant feature of 3G technology is its ability to unify existing cellular standards, such as code-division multiple-access (CDMA), global system for mobile communications (GSM, 2005), and time-division multiple-access (TDMA), under one umbrella. Over 85% of the world's network operators have chosen 3G as the underlying technology platform to deliver their third-generation services (GSM, 2004). Efforts are underway to integrate the many diverse mobile environments in addition to blurring the distinction between the fixed and mobile networks. The continual roll out of advanced wireless communication and mobile network technologies will be the major driving force for future developments in m-health systems (Istepanian & Zhang, 2004). Currently the GSM version of 3G alone saw the addition of more than 13.5 million users, representing an annual growth rate of more than 500% in 2004. As of December 2004, 60 operators in 30 countries were offering 3GSM services. The global 3GSM customer base is approaching

20 million and has already been commercially launched in Africa, the Americas, Asia Pacific, Europe, and the Middle East (GSM, 2005), thus making this technology ideal for developing affordable global m-health systems.

Fourth Generation (4G)

The benefits of fourth-generation network technology include (Istepanian, Laxminarayan, & Pattichis, 2005; Olla, 2005a; Qiu, Zhu, & Zhang, 2002): voice-data integration, support for mobile and fixed networking, and enhanced services through the use of simple networks with intelligent terminal devices. 4G also incorporates a flexible method of payment for network connectivity that will support a large number of network operators in a highly competitive environment. Over the last decade, the Internet has been dominated by non-real-time, person-to machine communications (UMTS, 2002). The current developments in progress will incorporate real-time person-to-person communications, including high-quality voice and video telecommunications, along with extensive use of machine-to-machine interactions to simplify and enhance the user experience.

Currently the Internet is used solely to interconnect computer networks. IP compatibility is being added to many types of devices such as set-top boxes to automotive and home electronics. The large-scale deployment of IP-based networks will reduce the acquisition costs of the associated devices. The future vision is to integrate mobile voice communications and Internet technologies, bringing the control and multiplicity of Internet application services to mobile users (Olla, 2005b). 4G advances will provide both mobile patients and citizens the choices that will fit their lifestyle and make it easier for them to interactively get the medical attention and advice they need, when and where it is required, and how they want it, regardless of any geographical barriers or mobility constraints.

Worldwide Interoperability for Microwave Access (WiMAX)

WiMAX is considered to be the next generation of wireless fidelity (WiFi), wireless networking technology that will connect you to the Internet at faster speeds and from much longer ranges than current wireless technology allows (<http://wimaxed.com/>). WiMax has been undergoing testing and is expected to launch commercially by 2007. The research firm Allied Business Research predicts that by 2009, sales of WiMax accessories will top US\$1 billion (Taylor & Kendall, 2005), and Strategy Analytics predicts a market of more than 20 million WiMAX subscriber terminals and base stations per year in 2009 (ABI, 2005).

The technology holds a lot of potential for m-health applications, with the capabilities of providing data rates of up to 70 mbps over distances of up to 50 km. The benefits to both developing and developed nations are immense. There has been a gradual increase in popularity of this technology. Intel recently announced plans to mass produce and release processors aimed to power WiMax-enabled devices (WiMax, 2005). Other technology organizations investing to further the advancement of this technology include Qwest, British Telecom, Siemens, and Texas Instruments. They aim to get the prices of the devices powered by WiMax to affordable levels so that the public can adopt them in large numbers, making it the next global wireless standard. There are already Internet service providers in metropolitan areas offering pre-WiMAX service to enterprises in a number of cities including New York, Boston, and Los Angeles (WiMax, 2005).

Wireless Local Area Networks

Wireless local area networks (WLANs) use radio or infrared waves and spread spectrum technology to enable communication between devices in a limited area. WLAN allows users to access a data network at high speeds of up to 54 Mb/s as long as users are located within a relatively short

range (typically 30-50 meters indoors and 100-500 meters outdoors) of a WLAN base station (or antenna). Devices may roam freely within the coverage areas created by wireless “access points,” the receivers and transmitters connected to the enterprise network. WLANs are a good solution for healthcare today, plus they are significantly less expensive to operate than wireless WAN solutions such as 3G (Daou-Systems, 2001).

Personal Area Networks

A wireless personal area network (WPAN) (IBM Research, 2006; Istepanian & Zhang, 2004) is the interconnection of information technology devices within the range of an individual person, typically within a range of 10 meters. For example, a person traveling with a laptop, a PDA, and a portable printer could wirelessly interconnect all the devices, using some form of wireless technology. WPANs are defined by IEEE Standard 802.15 (IEEE Working Group, 2006). The most relevant enabling technologies for m-health systems are Bluetooth (<http://www.bluetooth.org/>) and ZigBee (<http://www.zigbee.org/>). ZigBee is a set of high-level communication protocols designed to use small, low-power digital radios based on the IEEE 802.15.4 standard for wireless personal area networks. ZigBee is aimed at applications with low data rates and low power consumption. ZigBee’s current focus is to define a general-purpose, inexpensive, self-organizing network that can be shared by industrial controls, medical devices, smoke and intruder alarms, building automation, and home automation. The network is designed to use very small amounts of power, so that individual devices might run for a year or two with a single alkaline battery, which is ideal for use in small medical devices and sensors. The Bluetooth specification was first developed by Ericsson and later formalized by the Bluetooth Special Interest Group established by Sony Ericsson, IBM, Intel, Toshiba, and Nokia, and later joined by many other companies. A Bluetooth WPAN is also called a *piconet* and is composed of up to eight active devices in a master-slave relationship. A piconet typically has a range of 10 meters, although ranges of up to 100 meters can be reached under ideal circumstances. Implementations with Bluetooth versions 1.1 and 1.2 reach speeds of 723.1 kbit/s. Version 2.0 implementations feature Bluetooth Enhanced Data Rate (EDR) and thus reach 2.1 Mbit/s (<http://www.bluetooth.org/>; <http://en.wikipedia.org/wiki/>).

Radio Frequency Identification (RFID)

RFID systems consist of two key elements: a tag and a reader/writer unit capable of transferring data to and from the tag. An antennae linked to each element allows power to be transferred between the reader/writer and remotely sited tag through inductive coupling. Since this is a bi-directional

process, modulation of the tag antenna will be reflected back to the reader's/writer's antenna, allowing data to be transferred in both directions. Some of the advantages of RFID that makes this technology appealing to the healthcare sector are:

- no line-of-sight required between tag and reader;
- non-contact transfer of data between a tag and reader;
- tags are passive, which means no power source is required for the tag component;
- data transfer range of up to 1 meter is possible; and
- rapid data transfer rates of up to 100 Kbits/sec.

The use of RFID in the healthcare environment is set to rise and is currently being used for drug tracking. RFID technology is expected to decrease counterfeit medicines and make obtaining drugs all the more difficult for addicts (Weil, 2005). There are also applications that allow tagging of patients, beds, and expensive hospital equipment.

Satellite Technologies

Satellite broadband uses a satellite to connect customers to the Internet. Two-way satellite broadband uses a satellite link to both send and receive data. Typical download speeds are 400 to 512 kbps, while upload speeds on two-way services are typically 64 to 128 kbps. Various organizations (Inmarsat Swift64, 2000) have been investigating the development of an ultra-high-data-rate Internet test satellite for use for making a high-speed Internet society a reality (JAXA, 2005). Satellite-based telemedicine service will allow a real-time transmission of electronic medical records and medical information anywhere on earth. This will make it possible for doctors to diagnose emergency patients even from remote areas, and also will increase the chances of saving lives by receiving early information as ambulance data rates of 155mbps are expected. One considerable drawback associated with using this technology is cost (Olla, 2004).

CONCLUSION

The first section of this article provides the background of telemedicine and the advancements of mobile networks, which is fuelling the increase of m-health applications in the healthcare domain. The evolution and growth of telemedicine is highly correlated with ICT advancements and software development. This article has also summarized the various mobile network technologies that are being used in the healthcare sector. The mobile technologies described above have a significant impact on the ability to deploy mobile healthcare applications and systems.

KEY TERMS

Bluetooth: Worldwide industrial specification for wireless personal area networks (PANs). Bluetooth provides a way to connect and exchange information between devices like personal digital assistants (PDAs), mobile phones, laptops, PCs, printers, and digital cameras via a secure, low-cost, globally available short range radio frequency.

Global System for Mobile Communications (GSM): A digital worldwide mobile phone and data standard. GSM service is used by over 1.5 billion people across more than 210 countries and territories. The ubiquity of the GSM standard makes international roaming very common between mobile phone operators, enabling subscribers to use their phones in many parts of the world.

M-Health: Mobile computing, medical sensor, and communications technologies for healthcare.

Personal Area Network (PAN): A computer network with a reach of a meters used for communication among computer devices such as telephones and personal digital assistants or medical sensors close to the human body.

Radio Frequency Identification (RFID): An automatic identification system that transmits, stores, and remotely retrieves data using mobile devices called RFID tags or transponders. The purpose of an RFID system is to enable data to be transmitted by a mobile device, called a tag, which is read by an RFID reader and processed according to the needs of a particular application.

Mobile Hunters

Jörg Lonthoff

Technische Universität Darmstadt, Germany

INTRODUCTION

Growing Internet mobility due to various transmission methods such as broadband data transmission get mobile service providers interested in providing services that offer more than voice telephony. Modern cellular phones support general packet radio service (GPRS) have a color display and are usually Java-compliant. This meets the device's requirements for context-based services. As global system for mobile communications (GSM)-based cellular phones are widely used and, at least in Europe, the GSM-network is available almost everywhere, the context variable "location" seems useful for extending the relevant value-added services (Rao & Minakakis, 2003, p. 61). For example, there are services for finding friends in the vicinity (Buddy Alert by Mobiloco, www.mobiloco.de) and mobile navigation systems for cellular phones (NaviGate by T-Mobile, www.t-mobile.de/navigate). But there has not yet been a real breakthrough for location-based services (LBSs) (Lonthoff & Ortner, 2006).

Supported by T-Systems International, we developed the adventure game "Mobile Hunters." The game demonstrates what is possible with LBS and uses the currently available infrastructure mobile network providers offer for creating a virtual playing field. This playing field will be adapted to the real world. The object of the game is a hunt. Players can either be a hunter who must find a fugitive or a fugitive who has to make sure he is not getting caught. Of course, this hunt will become eventful as there are a variety of obstacles. Playing a so-called mobile location-based game (MLBG) could increase the acceptance of further LBSs.

This article will first summarize the current state of research in this field and then present *mobile location-based gaming*. Then the reader will get to know the game "Mobile Hunters." After that, we will discuss the lessons learned from the game, and possible further developments will be considered. At the end of this, we draw a short conclusion.

BACKGROUND

MLBGs are a special category of location-based games, as follows:

A MLBG is a location-based game running on a mobile device. By using a communication channel the game exchanges

Figure 1. Taxonomy for location-based services

information with a game server or other players. (Lonthoff & Ortner, 2006)

Applying this definition, the fields *location-aware games* and *spatially aware games* become relevant. Figure 1 shows all terms relevant in MLBG.

Location-Based Services

The added value of mobile services opens up opportunities for service providers to address a new dimension of the user: the user's spatiotemporal position. Such services are called location-based services. LBSs are based on a variety of localization methods for determining a user's position. In the field of so-called *context-aware computing* (Schilit, Adams, & Want, 1994, p. 85), LBSs provide location information as context references (Dey, 2001). There are many possibilities of using the location reference in an application system (Unni & Harmon, 2003, p. 417; Schiller & Voisard, 2004). All of these services are based on mobile positioning. Mobile positioning comprises all technologies for determining the location of mobile devices. A position can be determined in two different ways: using network-based technology (the network provides the position) or using terminal-based technology (the device provides the position).

Network-Based Positioning Technologies

GSM-networks offer basically six different methods of network-based localization (Röttger-Gerigk, 2002). Cell of

origin (COO) is the simplest mobile positioning technique. It identifies the cell (cell ID) in which a cellular phone is logged on. The cell ID is connected with the radiation range of a mobile base station. The cellular coverage area has a certain range around the position of the mobile base station. One mobile base station can have several radiation areas (cell IDs), whereby these cells always refer to the same geographic position of the mobile base station's location (Hansmann, Merk, Nicklous, & Stober, 2001, p. 243). The positioning accuracy that can be achieved depends on the size of the cellular coverage area; it may range between 25 m and 35 km in diameter. In addition, there are more complex techniques such as angle of arrival (AOA), time of arrival (TOA), time difference of arrival (TDOA), signal attenuation (SA), and the radiocamera system.

Terminal-Based Positioning Technologies

Cell of origin can also be considered a terminal-based technique, as the desired cell ID can be read out directly from the device (terminal). To do this, however, a reference database is needed that contains the geographic coordinates stored for each cell ID. The following further terminal-based techniques are available: enhanced observed time difference (E-OTD), as well as the satellite-based systems such as the global positioning system (GPS), or assisted-GPS (A-GPS), which works without modifications to the cellular phone network infrastructure, except that the mobile device must possess a GPS receiver.

Gaming

Mobile games for cellular phones are currently experiencing a growing demand. There is a trend towards more complicated 3D games. This trend is supported by the current hardware development that is the availability of high-performance cellular phones or smart phones, respectively. Games that allow direct communication with remote participants are of great interest (multi-player games). Multi-player games on offer can be played using a wireless application protocol (WAP) portal or locally by two people (infrared) or by several players (Bluetooth).

Games for personal digital assistants (PDAs) are also very interesting. Such games are usually intended for one player. But games for several players become possible, if infrared, Bluetooth, or wireless local area network (WLAN) are used.

In location-based games the movements of a player (in the sense of a geographical change of location) influence the game. Nicklas, Pfisterer, and Mitschang (2001, pp. 61-62) suggest a classification of location-based games into mobile games, location-aware games, and spatially aware games.

Mobile games require as a location reference only one more player who is in the vicinity. The location information itself is not considered in the game. A typical example of this kind of game is Snake, a game of dexterity for two delivered with the older Nokia cellular phone models that can be played using infrared or Bluetooth. Location-aware games include information about the location of a player in the game. A typical example would be a treasure quest whereby a player must reach a particular location. Spatially aware games adapt a real-world environment to the game. This creates a connection between the real world and the virtual world. The MLBG "Mobile Hunters" presented in the following belongs to this category of games.

CHARACTERISTICS AND CHALLENGES OF MLBG

Important for MLBG are the type of device used, the communication and network infrastructure it is based on, the way positions are determined, and the kind of game.

Devices such as cellular phones, smart phones, and PDAs can be used, possibly laptop also. In addition to this rough classification, the device properties can serve for further distinction: the operating system, client programming (Java virtual machine, Web-client/WAP-client), the types of available user interfaces, as well as battery life and processor power.

The relevant communication media are wide area networks such as WLAN, GSM, and universal mobile telecommunication system (UMTS). These technologies vary in range and bandwidth. The accuracy of a determined position depends on the technique used and on the network structure.

When looking at the type of game, two dimensions are of interest: the number of players and the type of game. There are single-player games and multi-player games. You can also play multi-player games alone, if players are simulated. Massive-multi-player games are a special type of game in which the end of the game is not defined. Players can actively participate in the game for some time and improve their ranking in the community associated with the game. Relevant genres of game would be role-playing games, scouting games, real-time strategy games, and first-person-shooter games.

Users can find a variety of game collections on the Internet that include MLBGs. For example:

- www.smartmobs.com/archive/2004/12/28/location-based_.html
- www.we-make-money-not-art.com/archives/001653.php
- www.in-duce.net/archives/locationbased_mobile_phone_games.php

Newer publications offer studies (Jegers & Wiberg, 2006) and overviews (Magerkurth, Cheok, Nilsen, & Mandryk, 2005; Rashid, Mullins, Coulton, & Edwards, 2006) of pervasive games, including MLBGs.

What is fascinating about MLBG is: “This ability for you to actually use your real-world movements to play the game means that you are no more playing a game... You are in the Game!” (Mikoishi, 2004).

If you want to turn a “classic” game into an MLBG, there are four central problem areas, identified by Nicklas et al. (2001, p. 62): adaptation of the playing field, adaptation of the pawn in a game, representation of cards or objects, and adaptation of the moves in the game.

Another challenge results from the characteristics of mobile networks. In MLBG it may happen that some of the players interrupt the connection for short periods of time. These interruptions must be covered.

MOBILE HUNTERS

The Game

The idea of the adventure game “Mobile Hunters” was inspired by the well-known board game “Scotland Yard” (Ravensburger, 1983). The creation of a players’ community reflects partly the notion of massive multi-player games. To be able to start a game session, at least two players must participate. There are two possible roles in the game: one or more hunters and one fugitive. The hunters want to catch the fugitive before the specified playing time is over. The fugitive must try to escape the hunters or, to prove that he is innocent, collect a number of items as proof of his innocence.

After logging onto the “Mobile Hunters” server with user name and password as authentication, a player can initiate a game. Once a game has been initiated, several more play-

ers can enter into the game. If a new player enters into the game, the game server checks whether the potential player’s location is within an appropriate distance to the center of the playing field. This ensures that the spatial distance between the players does not become too large. The person who initiated the game decides when the number of players is sufficient and then starts the game. The maximum number of players can be specified.

When the game is started, the game server randomly assigns the roles and informs the players about whether they are a hunter or a fugitive. When the game has been started, the game server distributes all the items for hunters and fugitives randomly on the playing field. After this initialization phase the game begins synchronously on all participating clients and the countdown for the playing time starts. In previously specified intervals (default 1.5 minutes), the current position of the fugitive appears on a map in the hunters’ display. In the playing field there are a number of locked (virtual) boxes that players can open if their position is the same as the position of the box (geo-coordinate with specified radius = playing field). Some of the boxes are visible only for hunters. These boxes contain offensive weapons. The fugitive can only see the boxes that contain items for him. These are items for defense or proof of innocence. Table 1 gives an overview of the various items.

A player can attack, if one player is located in the same position and the attacker has a weapon. If a hunter attacks another hunter, the person attacked will become incapable of action for some time (default 30 seconds)-his client’s menu will be hidden. In this attack the attacker loses his weapon. If a hunter attacks a fugitive, the fugitive can defend himself using a matching item for defense. If this happens, the attacker will become incapable of action for some time (default 30 seconds). If the fugitive cannot defend himself, the hunter wins.

The fugitive wins if he is able to find a certain number (default 3) of items that prove his innocence or if no attack

Table 1. Overview of the items available for the players

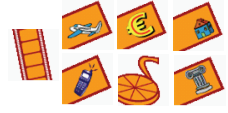

| Recipient | Type | Instance | Purpose |
|-----------|---------|---|--|
| Hunter | Attack |  | In the boxes the hunter will find offensive weapons he can use to attack the fugitive or for attacking another hunter to make him incapable of action (e.g., handcuffs). |
| Fugitive | Proof |  | In the boxes the fugitive will find items that can prove his innocence (e.g., a theater ticket). |
| Fugitive | Defense |  | In the boxes the fugitive will find items he can use to defend himself against attacks by a hunter (e.g., paper clip for defense against handcuffs) |

Figure 2. Overall architecture

on him was successful during the duration (default 30 minutes) of the game.

Architecture

In the development of “Mobile Hunters,” we only used technologies that have already been accepted in the market and are, or will most certainly be, widely spread, to facilitate acceptance of the game. We chose the GSM network, which is currently the most widely used (Nicklas et al., 2001, p. 61), to ensure a wide range of application. We chose a Java-compliant cellular phone (Nokia 6680) as the playing device.

It was essential that the positioning technique would only use the available cellular phone network infrastructure and that it would not be necessary to make modifications to it. This is why COO seemed best suited.

The implementation is based on a client/server architecture. Communication between the components is realized using the German T-Mobile GSM network. For data transfer we chose GPRS; communication takes place on an application level via secure hypertext transfer protocol (HTTPS). The “Mobile Hunters” server is a Java-based game server, which provides the user management and the game management. For determining the current position of each player, T-Systems’ research platform “Permission and Privacy Gateway” (PPGW) is used. PPGW also provides the “Mobile Hunters” server with maps of the areas in question. Figure 2 shows the overall architecture schematically.

Client

The “Mobile Hunters” client (see Figure 3) is the game’s user interface. It displays the current map segments; here, interaction with the other players takes place. Players also use the “Mobile Hunters” client to register and log on.

Current prerequisites are a cellular phone with Symbian operating system version 7.0 and a Java 2 Micro Edition (J2ME) framework. A class implemented in Symbian C++ is needed for reading out the cell ID the cellular phone uses. The cell ID is transmitted to the “Mobile Hunters” server. The server requests the current status in specified intervals (default every 10 seconds). The necessary unique identification of each player is the user’s name he or she entered at the beginning of the game.

Server

The “Mobile Hunters” server’s task is to centrally control the game. On the server, identification and authentication of the users takes place, as well as the game logic and the communication between PPGW and the clients. Every initialization as well as the specification of the playing field happens dynamically on the game server. The server was implemented in Java as an Apache Tomcat application on a Microsoft Windows 2003 Server platform and connected

Figure 3. “Mobile Hunters” client on Nokia 6680 at Luisenplatz, Darmstadt, Germany

to a Microsoft SQL Server via Java database connectivity (JDBC)/open database connectivity (ODBC). This ensures a clear separation of application level and data level. The server establishes the connection to the PPGW for requesting the geographic data of each cell ID used in the game at any time. The PPGW has a reference database where the relevant geo-reference-data for each cell ID are stored. The geographic data that correspond to the cell IDs are returned by the PPGW via an eXtensible Markup Language (XML)-based interface. The server keeps a high-score list to challenge the gaming community. Using a configuration file, the parameters that can be controlled are passed to the server.

LESSONS LEARNED

The adaptation of the game's concept to the virtual world turned out to be difficult because of the inaccuracy of positioning. Cell switches occur even if a player does not move. This may happen, for example, if several participants are logged on to a cell and, due to the limits of bandwidth or for reasons of optimization, a neighboring cell is allocated to the cellular phone.

Cellular coverage areas have different sizes: in an urban area approximately 25 m, in rural areas up to 35 km. Therefore "Mobile Hunters" is suited for playing in high-density urban areas. The cellular coverage areas of single cells overlap with those of other cells. Large cells cover smaller cells almost completely. It is still under discussion whether to exclude cells from the game if they are too large and from which size on they should be banned. To increase the accuracy of positioning, GPS or A-GPS offers interesting opportunities for mobile network providers and for the MLBG.

When a "classic" game is adapted to an MLBG, it is important to make sure the point of the game is kept and that the duration of the game is adequate. The hype phases we observe are much shorter with games than with any other service offers. Once a game is considered boring or error prone, acceptance drops. For the game "Mobile Hunters" to be funny and exciting, a game duration of 30 minutes is recommended. The interval in which a fugitive's current position is displayed should be 1.5 minutes, the time a player is incapable of action should be 30 seconds, and the interval in which the cell ID is read ought to be less than one second. A powerful processor such as the Nokia 6680 (220 MHz) is necessary for playing this game. It is very important to develop the client's code in a way best suited for cellular phones (Lonthoff, Ortner, & Wolf, 2006). Session handling is essential for playing an MLBG. The user interface must be designed quite simply, so that no explanations will be necessary.

Our mobile-specific modeling resulted in a very economic consumption of resources and of handling communication

data. In a 30-minute game, only an average of 300 kB data is transferred. Half of that data volume is used for loading the graphics (maps and icons) at the beginning of the game.

CONCLUSION

The conclusion we draw is that we have partly succeeded in adapting the real world to a game's virtual world. It is possible to read out the cell ID from a variety of mobile devices using different techniques. However, no standard application programming interface (API) is currently available to offer this functionality. This means that anyone who wants to create a game needs to develop a suitable API for every single cellular phone, if the game is to be widely used. This problem may be solved by deploying a middleware such as BREW from Qualcomm Inc. (www.qualcomm.com/brew; Tarumi, Matsubara, & Yano, 2004, p. 546).

Addressing the human play instinct, MLBGs increase the acceptance of LBSs. Playing, the use of LBSs will become effortless and people will get interested in such systems. Location-based games are becoming a mass market. If this mass market can be served, prices for location requests will go down.

The experience gained in the field of gaming also applies to situations in private and business life. Advertising and interactive marketing (Han, Cho, & Choi, 2005, p. 103) are potential application domains. Possibly, brand-new application systems useful in everyday life can be developed and implemented. In this context "application system" is understood in a comprehensive way for all tasks in user and computer-based information processing (Ortner, 2005, p. 34).

KEY TERMS

General Packet Radio Service (GPRS): An IP-based data communication service for cellular phones using GSM networks.

Global System for Mobile Communications (GSM): The most popular standard in the world for second-generation (2G) cellular phone systems.

Java 2 Micro Edition (J2ME): A special Java environment for small but smart devices, using a minimum of resources.

Location-Based Service (LBS): A context-based service using the context variable "location." In the area of m-commerce and m-business, LBSs enable new value-added services by using the customers' location.

Mobile Location-Based Game (MLBG): A MLBG is a location-based game running on a mobile device. By using a communication channel, the game exchanges information with a game server or other players.

Mobile Hunter: A pretty nice MLBG developed by the Department of Commercial Information Technology I at Technische Universität Darmstadt, Germany, in cooperation with T-Systems International.

Mobile Positioning: Summarizes technologies for providing the location of a mobile device.

Permission and Privacy Gateway (PPGW): A T-Systems research and development platform that provides a location interface. The PPGW was developed as a location brokerage platform that aggregates location sources (cell ID, WLAN, A-GPS, RFID) and offers this information to service providers using a unified interface.

Mobile ICT

Dermott McMeel

University of Edinburgh, Scotland

INTRODUCTION

Within building construction, the appropriation of a specific technology can vary across different job functions and participants (designer, foreman, stone mason, etc.). Embraced by some yet ignored by others, we can illicit insights into certain technologies and devices by reflecting not only on where they are successful but where they are problematic (Wiszniewski, Coyne, & Christopher, 1999) causing breakdowns and dysfunction in systems.

The rugged nature of the site condition quite often prohibits the proliferation of very delicate or expensive mobile equipment. Laser levels, point cloud generators, proprietary information and communication technology (ICT) devices, and so forth are limited to specific instances on the site where the usage is supervised and controlled, and all too often, “construction organisations have found that the ICT investment has failed to meet their expectations” (Peansupap & Walker, 2005). Robust, less expensive equipment is not subject to such extensive regulation (tape measures, bubble levels, nail guns), and their usage is often more prolific and creative. Various groups are charged with—and attempt to—fit ICTs into the current construction process; these ICTs are shown to create a much ‘smoother’ flowchart (COMIT, 2004). It is an established fact that the way in which a problem is presented generates a particular type of solution (Ortony, 1979; Schön, 1979); we would then suggest that contrary to popular representation and documentation of the construction process (Cox & Hamilton, 1995), there are perhaps more revealing models for presenting and understanding the communicative processes of the construction site than the established flowchart. Focusing on the ICT technology of mobile phones, we reflect on three different roles within a construction project: a director of a large construction organization, a site manager within that organization, and ‘micro-contractors’ of construction—that is, specialist subcontractors or small building contractors. We explore the usage and effects of the mobile phone in these different roles within a construction project.

OFFICIAL/UNOFFICIAL: THE FALSE DICOTOMY

There has always been unregulated communication within regulated work, and mobile phone usage has contributed to

powerful unregulated and ‘unofficial’ (in the litigious sense) means for communication within construction. Theorists readily draw on concepts of space and containment to define communications. At the very least, language is an exercise in categorization, assuming similar meanings under a particular word or sign. Reddy (1979) suggests that these assumptions contribute to miscommunication, particularly when communicating across differing cultural categories. In formal communications there is an understanding that certain communiqués are meant for particular recipients, within certain categories of communications. This bureaucratization of communications has its place, but communication also requires the transgression of boundaries (Deleuze, 1988; Shannon & Weaver, 1963).

It has been suggested in a previous paper that parallels exist between construction and Carnival (McMeel, Coyne, & Lee, 2005). These unofficial means breakdown boundaries and thresholds (a distinctive feature of Carnival) and enables unexpected interaction, not unlike the ‘crossroads’ extensively employed when discussing native American Trickster figures (Hyde, 1998). These unexpected interactions cause discomfort and empowerment, both of which are symptoms of the Carnival condition.

CONSTRUCTION AS CARNIVAL

All the symbols of the Carnival idiom are filled with this pathos of change and renewal...of prevailing truths and authorities. We find here a characteristic logic, the peculiar logic of the ‘inside out’ (a l’ envers), of the ‘turnabout,’ of a continual shifting from the top to bottom, from front to rear, of numerous parodies and travesties. (Bakhtin, 1984)

The construction process too has “prevailing truths and authorities”; we suggest that mobile phones have contributed to further breakdown or “suspension, both ideal and real, of hierarchical rank” (Bakhtin, 1984) within construction. Other features of Carnival introduce notions of re-interpretation and redundancy (Attali, 1985). Here we provide theoretical grounding to such assertions, and draw upon our findings from interviews and observation on the construction site and discuss the pros and cons of mobile ICT in construction under the emergent themes of contiguity, abstractedness, porosity, and instantaneity.

Contiguity (Contact)

This temporary suspension, both ideal and real, of hierarchical rank created during Carnival time a special type of communication impossible in everyday life...permitting no distance between those who came in contact with each other and liberating from norms of etiquette and decency imposed at other times. (Bakhtin, 1984)

According to Bakhtin, the renewal and revitalization are the hallmarks of the Carnival, and are brought about when hierarchical barriers are momentarily dropped and populations cross-pollinate. This created an intriguing relationship between high and low society, and the interstices between. Ritual has played—and arguable continues to play—a part in construction (Jones, 2000). We have previously suggested (McMeel et al., 2005) that traditional ritualistic ceremonies (groundbreaking, topping of) served as a melting pot for laborers, architects, clients, and engineers—groups who would not otherwise meet—to mix. Pedreschi (2000) reflects on the architect/engineer Eladio Dieste and attributes his success, in part, to his skill in choosing excellent interlocutors to work for him, thus his team encouraged discussion rather than dictation.

Our findings suggest that mobile phones encourage this crossing of boundaries and reveal the predominant tendency by users to contact the ‘top of the pile’, as in the case of the director of a small specialist stair manufacturer subcontractor. If the director (SF) as the ‘top of the pile’ is contacted, it will indeed garner results, by virtue of the fact that his company is relatively small and SF oversees every set of stairs manufactured. Within a large construction company, contacting the director (EMC) who is ‘out of the loop’ of the day-to-day running of most projects would still allow him to re-direct the query to achieve resolution. Either way contiguity was expected and, when not achieved, often generated feelings of offense, as discussed with SF who deposits his mobile phone with the administration staff when he is attending a meeting or is on the workshop floor. The administrative staff regularly encounters hostility from callers who take exception to calling SF’s personal number and speaking to someone else.

Distraction (Abstractedness)

Shock from the Carnival-esque can be caused by distraction from it; when surrounded by and embraced, it can be both surreal, exciting, and invigorating; if however it is thrust upon you, it is distracting and perhaps frightening. The construction site differs here in that distraction when in a dangerous environment can be fatal. In the words of EMC: “If you can’t use a mobile phone when you’re driving, you shouldn’t be allowed to use one if your operating heavy machinery should you?”

Perhaps the process of ‘making’ things (either stairs or buildings) has its own unique environment, one of noise and dirt in this particular case. The ‘making’ process perhaps suffers from distraction, not from traditional notions of distraction (i.e., noise and dirt), but from the distraction of outside interventions: “If I’m on the workshop floor it’s not to wander round and have a break...I’m probably attending to something a dam side more important than a phone call” (SF). Several other examples were discussed where site workers received calls (while guiding cranes, for example), and while no accidents ensued, their concentration on the task at hand was compromised. Whether it was the skill of the workshop environment or individuals in high-risk areas, distractions were problematic and repeatedly caused by incoming messages or calls.

Porosity (Screening)

This comes from the Greek ‘pore’, literally meaning ‘passage’ or ‘gateway’ (OED). When finding the gateway closed, we find callers either lose interest, as in the case of the estate agents who would call CR (site manager of a large construction company) on a daily basis. The information they require can be obtained elsewhere; CR as the site manager is simply most up to date on matters such as completion time, floor areas, and so forth—he is the ‘top of the (sub-)pile’, so to speak. Or callers focus their attention on times when the ‘gateway’ is open, in the case of site manager CR at designated break times, when he would be in his site hut close to his phone.

When receiving calls we have seen smaller ‘micro-contractors’ (7-10 employees) prioritize their calls. By looking at the name and number, they can decide whether the call requires immediate attention or could wait or was unimportant and could be ignored. Depending on the decision, the call is answered, noted for a call back, or ignored.

Within the realm of Web portals, permeability and porosity has been explored (Coyne, Lee, & Parker, 2004) in terms of commerce, discourse, and interaction. At an organizational site level, the porosity of the mobile phone allowed for incoming calls to be prioritized by knowing who was calling and what their role on a specific job was. It could then be determined by the recipient if the call required an immediate quick answer, in which case it was answered with only a small pause to the task at hand, or if it was urgent and required a substantial break until the matter was resolved. What seemed to be problematic was “this automatic reaction to answer the phone” (director of a large construction company).

Instantaneity (Immediacy)

The quality of being instantaneous; instantaneousness. (OED online)

The Carnival—like the construction of a building—is a momentary occurrence, and it is always in flux, changing and evolving; as a result, the ability to make an instant connection is perhaps highly beneficial. An immediate discussion or the ability to make an instant order is strongly valued, particularly by the micro-contractor who may have three or four projects running concurrently: “I can get a call from one of the other jobs about something that has come up and I can give them an answer straight away ... then the job can keep moving ... do you know what I mean?” SF gives this example: “Yesterday ... someone told me we were running low on nails, I forgot until I was in the car and phoned admin to order them and here (holds up an invoice) is the docket confirming the order.”

The mobile phone affordance of going directly to ‘the top of the pile’ would seem to be complemented—in terms of problem solving at least—by the ability to immediately resolve or pass the query from the top of the pile to whom-ever is appropriate—like the ‘game of catch’ (Attali, 1985), where the ‘ball’ is constantly moving and changing hands, only when it stops is it forgotten about.

This immediacy however also has the tendency to act as a displacement activity and a distraction, which can of course be ameliorated by the porosity of the mobile. Opinion is divided however in its effects on forward planning. EMC, the director of a large construction company, feels there is a tendency to use the phone as a substitute for planning, leaving things to the last minute and dealing with them on the phone. As a result EMC is quite proactive in methods of training new management staff. The micro-contractor however feels they enhance his planning, he can keep update, make orders, and change his strategy during the course of the day as he gets updates from other sites.

CONCLUSION

While the contact afforded by mobile ICTs would certainly seem to enhance communication within the construction industry, it is undoubtedly in certain environs dangerous to allow devices that cause distraction. With caller id, they also present the opportunity to avoid or displace people or subjects that are particularly problematic to the receiver; unlike formal means of communication, no formal record exists of the process of attempted communication.

Apart from the health and safety issues of distraction, the next major concern with the use of mobile phones was for organization and planning. While the micro-contractor and small subcontractor felt it perhaps enhanced the particular nature of their business, the director of a large construction company felt it was in danger of being used as a substitute for forward planning; while this is discouraged, there is perhaps the anxiety that such behavior undermines the procedural

aspects of day-to-day working and—more importantly—the management skill of individuals.

There is no prescription here for successful implementation of mobile ICTs, just the realization that the dispersal of the mobile phone across many groups and participants within the construction industry has affected the dynamics of communication within construction and thus affected construction itself. We suggest alternative models might give insights into understanding communication on the construction site and different technologies’ effects on it. Even usage of the common phone is both diverse and complex, yet the features of the mobile phone are undoubtedly still underutilized. Our work continues to look into how we might use these devices as portals for site workers to access relevant information.

ACKNOWLEDGMENT

The themes in this article have been inspired and nurtured by discussions with Richard Coyne and John Lee. Thanks must also be extended to E. Mc Kenna, Sean Farrell, and Cyril Ronaghan for their insights into their business and practice, and for their time and patience.

KEY TERMS

Anthropology: Much of the theoretical underpinning for this article comes from anthropological sources, writers who have studied social and cultural phenomenon. We suggest that this pool of information has much to contribute to the discussion of mobile ICTs in construction.

Bakhtin: Writer who has extensively studied and written on Carnival in its most primitive form.

Carnival: This is taken in the Bakhtinian sense, a primal event in which everyone participates, there is no differentiation—in true Carnival—between spectator and performer, both are one in the same, as such new forms of communication would emerge.

Construction: The process of building a building, and more generally, making something.

Dirt: Anthropologically, 'dirt' is a potent metaphor which we invoke here as a representation of things which do not have allotted place. It represents material which is non-placed and problematic for systems to handle.

Information and Communication Technology (ICT): Term usually associated with e-mail, phones, skype, and so on; a technology used for communication. Not however exclusive to digital means, for example a pen could be an ICT.

Micro-Contractor: A term used here to identify a specific sort of building contractor. This type is a contractor/entrepreneurial company of 7-10 people. The size seems important to the adoption and seeming benefits of using ICT.

Mobile Knowledge Management

Zuopeng (Justin) Zhang

Sajjad M. Jasimuddin

University of Wales – Aberystwyth, UK

INTRODUCTION

Mobility appears to be the most important organizational and technological trend in the foreseeable future. According to IDC, two-thirds of U.S. workers will be mobile by 2006. The increasing mobility of workforces and knowledge seems to pose new challenges for organizations to effectively manage knowledge assets (cited in *Mobile & Wireless Advisor*, 2002). Recent advances in mobile computing make it possible for workers to use information and knowledge resources for business virtually from everywhere, which creates opportunities for organizations to engage in mobile knowledge management (mKM).

This article attempts to propose mKM strategies by studying how mobile knowledge assets can be leveraged and mKM processes can be incorporated into the main KM processes by looking at two aspects of knowledge mobility organizations. The knowledge retention processes will also be the focus to further analyze how to merge the knowledge retention processes into the main KM processes. Finally, the integration of mKM strategy into the main knowledge management processes within organizations will be explored.

The rest of the article proceeds as follows. The next section discusses the background followed by the main focus of the article, presenting strategies of mobile knowledge management and implementations. The article concludes by outlining future directions.

BACKGROUND

mKM has become an emerging business practice for knowledge management within organizations. Several studies have also touched upon the notion of mKM recently. For instance, Mummy (n.d.), an EU-based information technology company, proposes a detailed mKM model discussing related key concepts. Loutchko and Birnkraut (2005) suggest the application of mobile knowledge portals in managing mobile knowledge assets. Grimm, Tazari, and Balfanz (2002) propose a technical framework for mobile knowledge management by identifying the abstract use cases of mKM systems and by outlining a reference model that can be used to validate mKM concepts in their system architectures.

Derballa and Pousttchi (2004) examine how mobile technologies can be used to support KM and particularly to support the knowledge distribution process. With the general introduction of relevant mobile technologies, they apply the theory of mobile-added values to analyze how mobile technologies contribute to the support of KM processes. Fagrell (2000) looks at various issues related to mKM from an Informatics perspective, which includes empirical studies of mobile work, technologies for mKM systems, and the design and validation of prototype systems, observing mobile service electricians and mobile news journalists. He develops and refines mobile technologies to be used in knowledge systems, and also makes a contribution in outlining a generalized technological architecture that can be applied to mobile work settings. However, managing mobile knowledge assets are not explicitly investigated. The article will partially fill that gap by studying how mobile knowledge assets can be leveraged and how the mKM process can be incorporated into the main KM processes.

STRATEGIES OF MOBILE KNOWLEDGE MANAGEMENT

In this section, the mKM strategies will be discussed focusing on how mobile knowledge assets can be leveraged and mKM processes can be incorporated into main KM processes. To discuss mKM strategies, two special characteristics of mobile knowledge management need to be considered: the mobility of organizational knowledge and that of corporate environment. The mobility of organizational knowledge may result from the innate nature of knowledge as well as high turnarounds of workforces within organizations. As a result, an additional knowledge retention process is required to fully leverage the mobile knowledge assets, as shown in Figure 1. Environmental mobility within organizations determines the special features of mKM processes from the main KM processes. mKM processes are shown to have the similar components and flows as those of main KM processes. However, each sub-process within the mKM processes may have distinctive features. Therefore, mKM should be incorporated into the main knowledge management processes of organizations considering its special features.

Figure 1. mKM: Leverage and integration

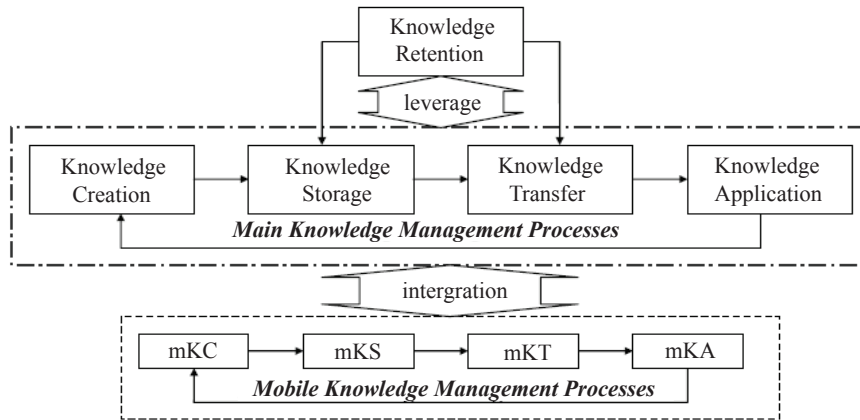

Figure 2. The relationship of m[KM], [mK]M, and KM

KM, [mK]M, m[KM], and [mKM]

KM is used to denote the entire knowledge management processes within organizations. To investigate mKM strategies, the implications of mobile knowledge management will be discussed from the following three subsets:

1. **m[KM]:** mobile “Knowledge Management”
2. **[mK]M:** “mobile Knowledge” Management
3. **[mKM]:** intersection of m[KM] and [mK]M.

The first subset m[KM] focuses on the mobility of knowledge management processes due to the mobile KM environment of organizations. In particular, this subset deals with the management and integration of mobile processes of knowledge in mobile environments. The second subset [mK]M emphasizes knowledge management from the perspective of the knowledge mobility in organizations. Specifically, the second subset manages and leverages knowledge assets by taking into account the innate mobile nature of knowledge. The third subset is the intersection of m[KM] and [mK]M, which considers the mobility issues of both organizational knowledge and corporate environment.

As shown in Figure 2, some KM processes belong to m[KM] processes, some to [mK]M, and others to [mKM]—the intersection of m[KM] and [mK]M. The degree of knowl-

Figure 3. The relationship between [mK]M and m[KM]

| | | Dimensions of environmental mobility | |
|----------------------------------|---------------|--------------------------------------|--------------|
| | | Time | Location |
| Dimensions of knowledge mobility | Detachability | Upgradability | Generality |
| | Volatility | Longevity | Immutability |

edge mobility refers to the innate property of knowledge. The second refers to the increasing mobile environment of knowledge management.

UGLI: Relationship between [mK]M and m[KM]

Based on the prior discussion on [mK]M and m[KM], the relationship between m[KM] and [mK]M is investigated in this section. The mobility of knowledge is considered from the following two aspects: detachability and volatility. Detachability denotes the degree of knowledge to be detachable and applicable in the mobile environment. Volatility means that knowledge may not be captured and retained in a timely manner and in its completeness due to the innate nature of knowledge, the turnaround of organizational members, and the mobility of environments. Although these two aspects describe different characteristics of mobile knowledge, they are essentially related—knowledge with high volatility is difficult to be detached, and knowledge with high detachability must be relatively stable.

The environmental mobility is also measurable from two dimensions, time and location, which are then related with the two dimensions of knowledge mobility as shown in Figure 3. The relationship between knowledge mobility and

Figure 4. mKM strategies

| | | | |
|-------------------------|------|-----------------------|-------------|
| | | Mobility of knowledge | |
| | | Low | High |
| Mobility of environment | Low | KM | [mK]M |
| | | Conservation | Leverage |
| | High | m[KM] | [mKM] |
| | | Integration | Combination |

environmental mobility can be denoted by UGLI—that is, upgradeability, generality, longevity, and immutability:

- **Upgradability:** Measures knowledge detachability against the time dimension under a mobile environment. Knowledge with low upgradability can be applied to solve problems with few upgrades over certain periods of time.
- **Generality:** Implies the connectivity of modularized knowledge with various situations. In other words, how well detached knowledge may be applied under different contexts or conditions. Knowledge with high generality can be applicable with few modifications for various contexts.
- **Longevity:** Denotes the stability of knowledge over certain periods of time as well as knowledge sensitivity of being captured against time.
- **Immutability:** Describes the volatility of knowledge against the location dimension of the mobile environment. Knowledge with higher immutability will be easier to be captured from various locations, codifiable and stored, and then transferred to other locations for applications.

Mobile knowledge with high detachability normally has low upgradability and high generality, and mobile knowledge with high volatility normally has low longevity and immutability.

CLIC: mKM Strategies and Implementation

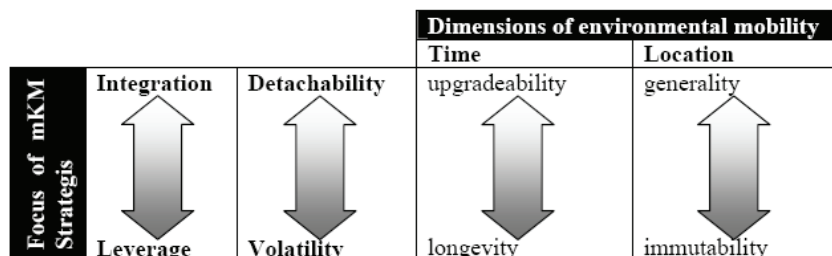

Having discussed the relationship between [mK]M and m[KM], the focus will be on the strategy of mobile knowledge management and its implementation. Based on the degrees of knowledge mobility and environmental mobility, four situations of knowledge management can be summarized with different focuses: KM, [mK]M, m[KM], and [mKM]. For each of these four cases, the knowledge management strategies are proposed as shown in Figure 4.

The strategies of mobile knowledge management can be categorized as CLIC—that is, conservation, leverage, integration, and combination:

- **Conservation:** When both the mobility of knowledge and that of environment are low, the firm should focus on its traditional knowledge management strategy.
- **Leverage:** When the mobility of knowledge is high and that of environment is low, the firm should modify its original strategy to leverage its mobile knowledge assets.
- **Integration:** When the mobility of knowledge is low and that of environment is high, the firm needs to adjust its original strategy to integrate its mobile knowledge management processes into its main processes.
- **Combination:** When both the mobility of knowledge and that of environment are high, the firm should combine both the leverage and integration strategies into its original knowledge management strategies.

Among these four strategies, integration and leverage are the bases of managing mobile knowledge assets. Although they have different focuses, both integration and leverage strategies have to deal with the knowledge mobility issue while taking into account the environmental mobility. However, the integration strategy focuses more on the detachability dimension, whereas the leverage strategy focuses on the volatility dimension. As demonstrated in Figure 5, companies implementing integration strategies should draw more attention to the issues of upgradeability and generality

Figure 5. The focus of mKM strategies

of knowledge mobility, whereas those implementing leverage strategies should concentrate on the issues of longevity and immutability.

Mobile technologies and devices enable the fulfillment of integration and leverage strategies. As described by Derballa and Pousttchi (2004), there are four major attributes of mobile technologies that add value to its original networks: ubiquity, context-sensitivity, identifying functions, and command and control functions. These special attributes of mobile technologies support mKM strategies to increase knowledge detachability and lower knowledge volatility. The interfacing processes of mKM strategies between mobile KM and main KM processes may include uploading, downloading, and synchronization, which connects mobile users with the main knowledge base so that mobile knowledge management processes can be integrated and mobile knowledge can be leveraged.

Considering a firm that implements mKM strategies through mobile technologies, it will have to make the following decisions:

1. how much to invest on mobile technologies to implement mKM strategies, and
2. how to balance the tradeoffs between integration and leverage strategies.

The first decision may be made by analyzing the total impact of mKM strategies on the firm's business goal and its original KM plans. The second decision can be made based on both the degree of knowledge mobility and environment mobility, and the actual effects that may be achieved from integration and leverage strategies. As noted earlier, companies emphasizing knowledge mobility should focus on leverage strategy, whereas those emphasizing environmental mobility should focus on integration strategy. In addition, the effects of technology investments on both strategies have to be considered. For instance, it is relatively more difficult to reduce knowledge volatility by investing in mobile technologies because the innate nature of knowledge mobility is immutable. Finally, the transition between two strategies should also be taken into account. Knowledge with low volatility may be easy to be detached. Hence, the implementation of leverage strategy may help fulfill integration strategy by increasing knowledge detachability.

FUTURE TRENDS

The proposed mKM strategies for organizational knowledge management are by no means the best strategies available to manage mobile knowledge assets with the help of mobile technologies. However, such mKM strategies provide great insights for better understanding of the relationship between

mKM and knowledge management, which also lays the solid foundation for related future research.

First, more discussion can be made on the relationship between the detachability and volatility dimensions for the issue of knowledge mobility. The transition between these two dimensions is also worthwhile for further investigation, which may clarify the effects achieved through the enablement of mobile technologies.

Second, the dimensions used to measure the mobility of organizational knowledge may be compared with other dimensions of knowledge in organizations, such as tacitness (tacit or explicit) and location (exogenous and endogenous), as espoused by Jasimuddin (2005), which will provide a better understanding of the nature of mobile knowledge assets.

Third, related analytical models can be formulated along with the mKM strategies and decisions discussed in this article. Taking into account the relationships and effects of m[KM] and [mK]M, an analytical model may provide insights for better understanding of the intricacies of various factors influencing the management of mobile knowledge assets.

Finally, the strategic model of mKM may be empirically tested to further reveal the critical factors of the implementations of mKM strategies. Empirical tests may not only corroborate the usefulness of the strategies outlined here, but also help us better comprehend other related factors during the implementation of the strategies.

CONCLUSION

Knowledge management has been regarded as an important business practice for organizations to gain competitive edge. With corporate environments becoming increasingly mobile, organizations are seeking innovative ways to manage mobile knowledge assets. Four different situations of knowledge management—KM, m[KM], [mK]M, and [mKM]—within organizations are categorized by taking into account both the mobility of organizational knowledge and that of the corporate environment, which lays the foundation for our further discussion on the strategies of mobile knowledge management. Most specifically, the UGLI relationship between m[KM] and [mK]M is proposed based on two dimensions of knowledge mobility and environmental mobility. The UGLI (upgradeability, generality, longevity, and immutability) relationship suggests how mobile knowledge assets are perceived and interpreted under mobile corporate environments. Moreover, the CLIC strategies are outlined for mobile knowledge management according to the four situations of knowledge management. The CLIC (conservation, leverage, integration, and combination) strategies are based on how to manage mobile knowledge under mobile environments. Such a discussion of strategies for mobile knowledge management seems to provide valuable insights

and guidelines for managers to adopt and implement appropriate organizational strategies by focusing on various aspects of mobile knowledge assets.

KEY TERMS

Detachability: Denotes the degree of knowledge to be detachable and applicable in the mobile environment.

Knowledge Management: The process of capturing organizational members' knowledge and then interpreting, transmitting, preserving, and refining it for organizational use.

Knowledge Mobility: The movement of organizational knowledge that may result from the innate nature of knowledge as well as high turnarounds of workforces within organizations.

Knowledge Retention: Referred to as the preservation of knowledge by an organization either in its people's heads, in databases, or on paper.

Mobile Knowledge Management: The process of managing mobile knowledge assets in mobile environments due to increasing mobility of the workforce.

Organizational Knowledge: Information interpreted by organizational members that helps to make effective action for the organization.

Volatility: Means that knowledge may not be captured and retained in a timely manner and in its completeness due to the innate nature of knowledge, the turnaround of employees in organizations, and the mobility of environments.

Mobile Learning

David Parsons

Massey University, New Zealand

INTRODUCTION

Mobile learning (variously shortened to M-Learning, M-learning, m-learning, mlearning, M Learning, or mLearning!) describes any form of education or training that is delivered using some kind of mobile device. As the power and sophistication of mobile devices increases, and wireless networks become faster and more ubiquitous, learning with a mobile device will become an integral part of the general spectrum of technology-supported learning. Furthermore, the special characteristics of mobile learning, including ubiquity, convenience, localization, and personalization, give it unique qualities that help it stand out from other forms of learning.

For some, mobile learning is simply an extension of electronic learning (e-learning), indeed it is sometimes referred to as mobile e-learning, and both can be seen, conceptually at least, as subsets of distance learning (Georgiev, Georgieva, & Smrikarov, 2004). However, such an approach fails to take into account either the restrictions of the mobile device, the special circumstances of the mobile learner, or the value-added aspects of mobility such as on-demand learning, ad-hoc networking, and location and context awareness.

Unlike desktop electronic learning environments, mobile learning can take place in changing contexts and via a range of mobile devices with many variations in form factor. Mobile learning systems must be adaptive both to the learner (in terms of his or her developing learning model and profile) and to the device (in terms of its functionality and its current environment). Therefore the hardware and software architectures for a mobile learning system provide a major technical challenge. Overcoming these difficulties can, however, enhance the learning experience, since mobile learning has the benefits of mobility and its supporting platform, which can be summarized as being ubiquity, convenience, localization, and personalization. Ubiquity means that the learning content can be accessed anywhere, regardless of location. With ever-increasing coverage by mobile network providers, mobile learning services can have an increasingly ubiquitous presence. This is particularly useful where mobile learning provides support for learners in the field, where information is urgently needed on site, perhaps to help diagnose medical conditions, analyze field data, or repair equipment. As mobile devices become more pervasive in our everyday lives, using these devices for learning becomes more convenient. High-speed 'always-on' data connections mean that the learner

can access material when it is convenient to them, enabling learning to take place on an ad hoc basis.

Localization is a specific strength of mobile devices, since they can use location awareness to provide services that are targeted to the user's current locality. Location awareness has been used in a number of mobile learning solutions to enhance the user's experience, for example in the Ambient Wood project, where children explored a woodland environment using mobile technology (Rogers et al., 2004). Finally, personalization is a key component of mobile learning for two reasons. First, the difficulty of navigation and small screen size of mobile devices means that it is important to target learning material to the user as much as possible. Second, such targeting is easier for enrollment-based services like education, where the provider is likely to be able to gather considerable information about learners and construct accurate profiles of their activities and requirements.

In defining mobile learning we should also be aware that mobile learning does not necessarily mean wireless learning. A number of mobile learning solutions, typically those deployed on personal digital assistants (PDAs), enable the user to install a complete learning module that runs as a standalone application on the device. This type of approach is used in mobile applications that act as simple electronic training manuals, as well as tourist and museum guides, where the requirement for the software is short term and context driven, though location awareness may not be supported in non-wireless systems. While these types of mobile learning applications can be valuable, systems that include wireless connectivity can provide more interactivity, context awareness, and learner choice.

USING THE MOBILE ENVIRONMENT FOR LEARNING

As well as solving technical problems, developing a successful mobile learning solution depends on imaginative use of the mobile environment. There are examples in the literature of systems that leverage mobility to mimic film narrative, integrate mobile devices into multi-technology environments, encompass group game play, and store material in virtual spaces. In many cases these systems take advantage of location awareness and the ability of wireless devices to support communication between group members. Thus mobility enables individuals to participate in distributed simulations

and role plays across both space and time. Examples include the use of mobile devices to model the spread of disease and enable multi-role simulations. Learning scenarios with multiple branches can be used to indicate the usefulness of different outcomes, depending upon the decisions made by the learner, for example in medical diagnosis (Setaro, 2001). Lundin and Nulden (2003) describe multimedia scenarios used in a professional context based on the PIER approach, which has four main building blocks: problem-based learning, interactive multimedia, experiential learning, and role playing.

A number of examples of mobile learning are driven very much by the context of the learner, where the mobile device can be taken into an environment and be used as learning support in that environment. Examples of this type of system include those that provide location-aware information that is relevant to the context, those that allow the sharing of information about related contexts, and those that provide information about a context, regardless of actual location. *Location-aware* systems that provide information include tourist systems, and museum and archaeological systems. An interesting example is Urban Tapestries, which links urban stories to specific London locations (Walker, 2004). An early but interesting example of sharing information about related contexts is Wireless Coyote, where mobile learners working in different areas assisted each other's analyses of the environment (Grant, 1993). Sharples (2002) refers to this type of mobile learning system as conversational learning, stressing the value of interactivity between mobile learners. Systems that provide context-related information regardless of actual location include a mobile bird-watching learning system (Chen, Kao, Sheu, & Chiang, 2002) and ELDIT, a language translation system (Trifonova, Knapp, Ronchetti, & Gamper, 2004).

TYPES OF MOBILE LEARNING DELIVERY

Mobile learning can support many types of learners who will require different types of content and modes of delivery, and a mobile system may integrate with a wider academic or professional program or it may be stand alone. To support the flexibility of the learner, the content of a mobile curriculum needs to be broken down into short and focused nuggets of learning, the type of content that can be accessed in the 'downtime' of the learner, particularly in mobile learning systems that target the professional in the field. In situations where learning is used in a professional context, there is a concept of *just-in-time learning* (Koschembahr, 2005), where the mobile learning content has an on-the-job training focus. In this vein, workers in industries such as retail and fast food can get what might be called *fast learning* (McGee, 2003), focusing on low-level training modules and product

information. A characteristic of this approach is the blurring of boundaries between acquiring information and learning. This encourages the view that, before long, an employee will not even be able to differentiate learning from other everyday job functions. However, we might question whether such a system is actually delivering learning, since the information being conveyed is often transient and trivial.

MOBILE LEARNING AS A DISRUPTIVE TECHNOLOGY

One of the key characteristics of a disruptive technology is that its adopters are prepared to accept a reduction in some qualities in order to benefit from innovation (Funk, 2004). There are some positive indications that mobile learning can be successful even in limited technical environments, suggesting that it has the characteristics of a disruptive technology. Research has shown that learners are prepared to accept technological limitations for the benefits of mobility. A study by Ericsson in 2002 showed that even with a simple wireless access protocol (WAP) browser interface, users felt that mobile learning could be a quality experience (Ericsson, 2002). In the study, 77% of participants felt that mobility actually increased the quality of electronic learning, and all felt that one of its key benefits was its ability to increase access to education and training. Another study using the short message service (SMS) as an interactivity mechanism also suggested that the lack of sophistication of the platform need not be a major stumbling block to the quality of the learning experience. This study indicated that mobile learning applications can have depth and complexity, and encourage wider scale participation, even where it might be expected that technical limitations would discourage the learner (Stone, Briggs, & Smith, 2002). It seems therefore that technological sophistication is not necessarily a measure of usefulness, since even simple technologies like classroom response systems have proved effective, engendering rich social practice around basic systems (Roschelle, 2003).

CONCLUSION

In summary, mobile learning is a specialized field from both a technical and educational perspective, and one that will become increasingly important as wireless communication networks and mobile devices become more pervasive and sophisticated. In many ways, electronic and mobile learning will move closer together as the power and sophistication of mobile devices increase. However there will always be certain aspects of mobility, in particular ubiquity and location awareness, that will make mobile learning a unique and special approach to education.

KEY TERMS

Conversational Learning: Using mobile devices as an aid to learning by interacting with other learners.

Localization: The delivery of services to the user that are aware of the user's current location and therefore tailored to that context.

Mobile Learning: Learning that takes place using some kind of mobile device.

Personalization: Providing content to the user that is based on his or her user profile.

Short Message Service (SMS): A service that allows short text messages to be passed between mobile phones via unused time on the control channel, using a store and forward mechanism.

Ubiquity: The availability of a service in most, if not all locations.

Wireless Access Protocol (WAP): A communications protocol developed specifically for mobile phones which supports page markup using the Wireless Markup Language (WML).

Mobile Learning Environments

Sheffield Hallam University, UK

Martin Beer

Sheffield Hallam University, UK

INTRODUCTION

Mobile learning requires a methodology for creating mobile learning scenarios and producing learning objects to implement them. It also requires a technology to deliver the learning objects to users via mobile computing devices such as personal digital assistants, smart phones, and tablet computers. This article will describe both the pedagogic methodology and the technology using the European research project *MOBIlearn* as an example.

A key part of the *MOBIlearn* project is the integration of new technologies in education. It aims at improving access to knowledge for selected target users, giving them ubiquitous access to appropriate learning objects (Taylor, 2003). "The *MOBIlearn* project intends to develop software that supports the use of mobile devices (smart phones, PDAs, Tablet PCs and laptops with wireless network connection) for various learning scenarios, including non-institutional learning" (*MOBIlearn*, 2005). The aim of *MOBIlearn* is therefore "... the creation of a virtual network for the diffusion of knowledge and learning via a mobile environment ... to ... demonstrate the convergence and merging of learning supported by new technology, knowledge management, and new forms of mobile communication" (*MOBIlearn*, 2002, Annex 1, p. 7).

The pedagogic aim of the system is to provide users with the ability to engage in formal, non-formal, and informal learning in a personal collaborative virtual learning environment. To this end, three scenarios were used as the basis of developing the requirements for the system. These were a formal university course and a related orientation activity, a non-formal health care scenario, and an informal scenario based around museums and galleries. The requirements of the system were captured from three user-developed scenarios. A use case model was produced for each of these scenarios plus a fourth model describing generic or common requirements. These requirements were further documented for the technical developers in a database based on a Volere template (Robertson & Robertson, 2001).

The philosophy behind the *MOBIlearn* system is that it provides a set of interoperable services. Services should be able to communicate asynchronously using unstable communication channels (*MOBIlearn*, 2005). At the center of

the system is the component providing the portal services including the main portal. This represents the single access point for the user to all the services provided by the *MOBIlearn* system.

One of the challenges of creating a mobile learning environment that spanned more than one domain was extracting generic requirements applicable to all domains. A corollary to this was identifying requirements that were specific to a domain.

Scenarios

Initially the *MOBIlearn* requirements were provided by three scenarios:

1. A visit to an art gallery.
2. Access to training and basic medical knowledge in a hospital.
3. Master's in business administration.

Development of these scenarios was essential for deriving both user and technical requirements.

In the *MOBIlearn* project a series of distributed development teams were established with specific roles or workpackages. One of these workpackages involved the development of requirement specifications to be used by the technical workpackage teams.

Initially these requirements were derived from the user scenarios listed above using the use cases alone, one set for each scenario. The next stage was to amalgamate these into a single specification which could then be handed on to the software developers for the final system. The technical teams then developed a series of services which were required to implement the use cases.

MOBIlearn Pedagogic Design

The pedagogic basis of the system is the learner who interacts with the mobile learning portal to access learning objects and participate in online activities. *MOBIlearn* provides a tool to facilitate collaboration and teamwork. It expands on systems such as OTIS (Occupational Therapy Internet School) (Beer, Slack, & Armitt, 2005) to provide a framework that can be

Figure 1. Types of learning and their relationship to the scenarios

used in variety of learning situations. It also allows a variety of learning styles.

Learners today want to learn when and where they want, in formal, non-formal, and informal ways (Brand, Petrak, & Zitterbart, 2002; Cook & Smith, 2004).

The types of learning are characterized by the following attributes:

- **Formal**
 - Mandatory participation
 - Objectives and means controlled by educator
- **Non-Formal**
 - Voluntary participation
 - Objectives controlled by learners
 - Means controlled by educator
- **Informal**
 - Grows out of spontaneous situations
 - Objectives and means controlled by learners
 - There may be a facilitator who may provide some content

The second feature of the environment is that it facilitates communities of learners. In the case of the museum scenarios, the learners are operating in an informal environment motivated by their own interests (Cook & Smith, 2004). The methodology gives them the ability to join a virtual community with interests like their own. The learner is under no obligation to formally join (or leave) the community and can participate as much or as little as he or she wishes. This particular scenario has many features in common with the Virtual Museum of Canada (Soren, 2005), but is also designed to be used in a real museum (the Uffizi Gallery in Florence, Italy, being a test site) to give a richer experience than the traditional audio guides.

The health care scenario on the other hand is a non-formal learning environment where a *community of practice*

(CoP) is being established. The system is designed to deliver training case studies where a learner assesses a situation and suggests a course of action. This can then be discussed with other learners who will have different levels of experience. Learning has no start or end point, and new members can join (and leave) at any time; however, it may be a condition of employment that staff engage with this continuing development. New case studies can be added, including ones suggested by the learners. This does contradict some of Ellis, Oldridge, and Vasconcelos's (2003) criteria for a community of practice, specifically a voluntary and emergent group. However, if staff engages with the learning environment, a virtual community of practice could develop, meeting other criteria including a mutual source of gain.

Finally there is the MBA scenario, which is based in formal learning where students use the system to access resources, undertake tasks, and discuss topics with fellow students and academics. There is immersion and presence in the online learning environment. This encourages students to build trust and teamwork (Beer et al., 2005). The environment is more constrained and there is a specific enrolment and end point. Although it is theoretically possible to start and end a course at any time, this does not yet happen.

There are features that are common to all three scenarios, for example, there will be some base content. In the case of the museums, this will be information about exhibitions and within that, information about specific exhibits. In the case of health care, there are a series of reference *obletes* (learning objects) relating to various diseases and situations. For the MBA, there are formal course materials. All scenarios have discussion areas or forums allowing collaborative learning and providing for the foundations for a community of learning and practice to be built.

Development

The development methodology for MOBIlearn was a combination of the *service-oriented approach* (SOA) and prototyping loosely based on Boehm et al.'s (1998) spiral model. Modeling was done using the use-case modeling tool of UML (Rumbaugh, Jacobson, & Booch, 1999). Initially a use case model was produced for each of the scenarios. These were examined for commonality, and a common or generic use case diagram was produced mapping user requirements used in all scenarios (see Figure 2). For each of the use cases, a detailed description was produced based on the template suggested by Cockburn (1998) (see Figure 3).

The use case diagrams were then cross-referenced in the requirements database, which was based on Volere shells (Robertson & Robertson, 2001) (see Figure 4). The database was then passed on to the development teams who grouped requirements according to their functional similarity. This became the basis of the service-oriented architecture described as follows.

MOBIlearn Architecture

MOBIlearn is an example of a personal virtual environment (PVLE) (Xu, Wang, & Wang, 2005) consisting of domain-level knowledge from the content provider (e.g., a museum or university) and a meta-level model to allow a learner's

profile to be matched to the environment and the mobile device he or she is using.

Each of the development scenarios has its own objects, but what they all have in common is that they need to be delivered in a flexible way to a variety of devices. For example the interface characteristics of a tablet computer are far different from those of a PDA. One challenge is therefore to deliver the correct interface to a learning object or oblette to the mobile device.

Figure 5. High-level component diagram in the MOBIlearn architecture (MOBIlearn documentation V 2.47, p. 32)

There are a variety of ways of delivering learning materials to devices with differing characteristics including re-authoring, transcoding, and the functional-based object model (Kinshuk & Goh, 2003). Ideally, an open standard should be used to allow different content providers to make their material available on mobile devices. The approach taken in MOBIlearn is to use re-authoring where page descriptions are held as XML which is compatible with the standard suggested by Loidl (2005).

Figure 5 shows the overall architecture of the MOBIlearn system. Users are users of the system who interact with it using a variety of mobile devices. In other words these two system components are not part of what was developed. Using their mobile devices, a user's main interaction is with the main portal service that controls access. The main portal service then calls other services depending on the user's selection. When a user logs on, the services in the adaptive human interface component are used to deliver the appropriate interface to the user's device. After logging on, a user may wish to download a learning object which will require a call to the content management component. Based on what that component sees, it may wish to engage in a collaborative activity requiring a call to the services of the communication and collaboration component.

CONCLUSION AND FUTURE DIRECTIONS

MOBIlearn provides an architecture and methodology to support users using a variety of learning styles and requirements. It can be used in a variety of learning situations ranging from

formal university courses to informal communities with a common interest. Learners have an online presence and can engage in collaboration and teamwork. The services a learner needs to do this are delivered via a portal and adapted to the physical device he or she is using.

The implications of this are enormous. In the informal learning environment of a museum, a learner will no longer be dependent on audio guides and labels. The system can deliver a much richer experience, plus the learner will be able to collaborate with other learners with similar interests. Health care and other professionals will be able to use the system as a support and training tool while on the job. In the formal learning environment, the system will add more flexibility for both distance and face-to-face learners.

KEY TERMS

Community of Practice (CoP): A flexible group informally bound by common interests.

Formal Learning: Learning in a structured and controlled environment with fixed, specified learning objectives.

Informal Learning: Learning motivated by personal interest with no specific learning objective and structured by the individual or by an independent informal group.

MOBIlearn: A system that provides both a methodology and a technology to deliver flexible learning in a mobile environment.

Non-Formal Learning: Learning in a formal environment, but with no formal learning objectives.

Oblette: A learning object or self-contained piece of material designed to meet a learning objective.

Pedagogy: The set of activities of educating or instructing or teaching; activities that impart knowledge or skill.

Service Oriented: A set of interoperable services, developed independently, which interact to provide the learning environment.

Mobile Medical Image Viewing Using 3G Wireless Network

Carrison K. S. Tong

Pamela Youde Nethersole Eastern Hospital, Hong Kong

Eric T. T. Wong

Hong Kong Polytechnic University, Hong Kong

INTRODUCTION

Teleradiology is a routine practice for radiologists to make urgent diagnosis by remote viewing radiological images such as computed tomographic (CT), magnetic resonance (MR), computed radiographic (CR), and digital radiographic (DR) images outside their hospitals. Traditionally, due to limited network bandwidth and huge image file sizes, this technique was limited to fixed-point communication using an integrated services digital network (ISDN) and broadband network. Without any prior information, most radiologists would invariably require high-quality display units and lossless compressed images for their clinical diagnosis. Besides the technical issues involved in the uninterrupted provision of a 24-hour teleradiology service, most hospital administrators have to consider a series of management issues on the quality of this service such as data confidentiality, integrity, and accessibility.

This article presents the implementation process of a high-quality teleradiology service using the third-generation (3G) wireless network. In the provision of this service, several high-quality notebook computers with a 15-inch liquid crystal display (LCD) screen of resolution 1,024 x 768 pixels and 32-bit color have been configured to view medical images in the digital imaging and communications in medicine (DICOM) format using a Web browser. These notebook computers are connected with 3G mobile phones so that users could access the Internet using Web browsers through the 3G network at a speed of at least 384 kbps. The users could also use the Web browser for logging into the hospital network through an application tunneling technique in a virtual private network (VPN). When logging into the VPN, for security purposes the network authentication is enhanced by a one-time and two-factor authentication (OTTFA) mechanism. In OTTFA, the user password contains two parts: a personal password and a randomly generated password. After successfully logging into the hospital network, the user has to log into the image server using another account name and password. The above are all important to ensure the high standard of confidentiality of the system.

The data volume of the image server is about 1 TB, stored in a level-5 configured redundant array of inexpensive

disks (RAID). For management of this huge amount of data, the location of each image in the storage unit is stored in a Structural Query Language (SQL)-based database. Each image also has DICOM tags for storage of the patient name, identity (ID) number, study date, and time. After the success of each login, the user can query the image server for related images using the patient's demographic data such as the study date. These are used to enhance the integrity of the system.

There are three image servers configured in a high available (HA) cluster using a load-balancing switch. The user could access any one of the servers for diagnostic purpose using the teleradiology technique. This setting is used to ensure the availability of the service 24 hours a day/7 days a week. The above system has operated for six months, and zero downtime was recorded. This leads to the belief that it is feasible to operate a quality teleradiology system using 3G networking technology with the important concerns of data confidentiality, integrity, and accessibility being dealt with in an effective manner.

BACKGROUND

Teleradiology is the process of sending radiologic images from one point to another through digital, computer-assisted transmission, typically over standard telephone lines, a wide-area network (WAN), or over a local area network (LAN). Through teleradiology, images can be sent to another part of the hospital or around the world.

In a hospital environment, it is not unusual that sometimes certain senior or experienced clinical staff would not be available onsite. These senior clinical staff may standby at home, on business trip, or just on their way to work. For urgent medical cases, remote consultation is required. It is important to have multimedia communication, including voice, text, and picture, between the senior clinicians and the hospital. A reliable, secure, easy-access, manageable, high-speed, standardized, multimedia medical consultation system is required.

PROBLEM

Today, teleradiology is still facing many limitations such as low network bandwidth, limited locations, and implementation issues associated with security, standards, and data management.

Limited Locations and Low Network Bandwidth

Depending on data-transfer rate requirements and economic considerations, images can be transmitted by means of common telephone lines using twisted pairs of copper wire, digital phone lines such as ISDN, coaxial cable, fiber-optic cable, microwave, satellite, and frame relay or T1 telecommunication links.

Today most teleradiology systems run over standard telephone lines. Over the next couple of years, we should see a substantial migration to switched-56 and ISDN lines, which offer higher speed and better line quality than standard dial-up phone lines. Other high-speed lines, including T1 and SMDS (shared multimegabit data services), will also become more popular as prices continue to drop.

However, remote consultation on fixed lines can only be performed in pre-installed locations such as a radiologist's home. A wide-area wireless network can provide a more flexible teleradiology service for the users (Oguchi, Murase, Kaneko, Takizawa, & Kadoya, 2001; Reponen et al., 2000; Tong, Chan, & Wong, 2003).

Security in a 3G Network

The fragile security of 2.5G and 3G wireless applications was abundantly evident in Japan recently when malicious e-mails to wireless handsets unleashed a malevolent piece of code which took control of the communications device and, in some cases, repeatedly called Japan's national emergency number. Other cell phones merely placed several long-distance calls without the user's knowledge, while others froze up, making it impossible for subscribers to use any of the carrier's services. Incidents like this and others involving spamming, denial of service (DoS), virus attacks, content piracy, and malevolent hacking are becoming rampant. The security breaches that have posed a constant threat to desktop computers over the last decade are migrating to the world of wireless communications where they will pose a similar threat to mobile phones, smart phones, personal digital assistants (PDAs), laptop computers, and other yet-to-be-invented devices that capitalize on the convenience of wireless communications

SOLUTIONS

Standard

In 2003, the American College of Radiology (ACR) published a technical standard of teleradiology in which the DICOM standard (Bidgood & Horii, 1992) was used as a framework for medical-imaging communication. The DICOM standard was developed by the ACR and the National Electrical Manufacturers Association (NEMA) with input from various vendors, academia, and industry groups. Based upon the open system interconnect (OSI) reference model, which defines a seven-layer protocol, DICOM is an application-level standard, which means it exists inside layer 7. DICOM provides standardized formats for images, a common information model, application service definitions, and protocols for communication.

3G Network

3G stands for third generation (Collins & Smith, 2001) and is a wireless industry term for a collection of international standards and technologies aimed at increasing efficiency and improving the performance of mobile wireless networks (data speed, increased capacity for voice and data, and the advent of packet data networks vs. today's switched networks). As second-generation (2G) wireless networks evolve into third-generation systems around the globe, operators are working hard to enable 2G and 3G compatibility and worldwide roaming, including WCDMA, CDMA2000, UMTS, and EDGE technologies. In this project 3G technology was applied in teleradiology service for improving the speed of communication.

Types of 3G

Wideband Code Division Multiple Access (WCDMA)

This is a technology for wideband digital radio communications of Internet, multimedia, video, and other capacity-demanding applications. WCDMA has been selected for the third generation of mobile telephone systems in Europe, Japan, and the United States. Voice, images, data, and video are first converted to a narrowband digital radio signal. The signal is assigned a marker (spreading code) to distinguish it from the signal of other users. WCDMA uses variable rate techniques in digital processing and can achieve multi-rate transmissions. WCDMA has been adopted as a standard by the ITU under the name IMT-2000 direct spread.

Code Division Multiple Access 2000 (CDMA 2000)

Commercially introduced in 1995, CDMA quickly became one of the world's fastest-growing wireless technologies. In 1999, the International Telecommunications Union selected CDMA as the industry standard for new "third-generation" wireless systems. Many leading wireless carriers are now building or upgrading to 3G CDMA networks in order to provide more capacity for voice traffic, along with high-speed data capabilities. Today, over 100 million consumers worldwide rely on CDMA for clear, reliable voice communications and leading-edge data services.

Universal Mobile Telecommunication (UMTS)

This is the name for the third-generation mobile telephone standard in Europe, standardized by the European Telecommunications Standards Institute (ETSI). It uses WCDMA as the underlying standard. To differentiate UMTS from competing network technologies, UMTS is sometimes marketed as 3GSM, emphasizing the combination of the 3G nature of the technology and the GSM standard which it was designed to succeed. At the air interface level, UMTS itself is incompatible with GSM. UMTS phones sold in Europe (as of 2004) are UMTS/GSM dual-mode phones, hence they can also make and receive calls on regular GSM networks. If a UMTS customer travels to an area without UMTS coverage, a UMTS phone will automatically switch to GSM (roaming charges may apply). If the customer travels outside of UMTS coverage during a call, the call will be transparently handed off to available GSM coverage. However, regular GSM phones cannot be used on the UMTS networks.

Enhanced Data for Global Evolution (EDGE)

EDGE is a technology that gives GSM the capacity to handle services for the third generation of mobile telephony. EDGE was developed to enable the transmission of large amounts of data at a high speed, 384 kilobits per second. EDGE uses the same TDMA (time division multiple access) frame structure, logic channel, and 200 kHz carrier bandwidth as today's GSM networks which allows existing cell plans to remain intact.

Image Resolution

Digital images, whether viewed on a computer monitor, transmitted over a phone line, or stored on a hard disk or archival medium, are pictures that have a certain spatial resolution. The spatial resolution, or size, of a digital im-

age is defined as a matrix with a certain number of pixels (information dots) across the width of the image and down the length of the image. The more pixels, the better the resolution. This matrix also has depth. This depth is usually measured in bits and is commonly known as shades of gray: a 6-bit image contains 64 shades of gray; 7-bit, 128 shades; 8-bit, 256 shades; and 12-bit, 4096 shades.

The size of a particular image is referenced by the number of horizontal pixels "by" (or "times") the number of vertical pixels, and then by indicating the number of bits in the shades of gray as the depth. For example, an image might have a resolution of 640×480 and 256 shades of gray, or 8 bits deep. The number of bits in the data set can be calculated by multiplying $640 \times 480 \times 8$ equals 2,457,600 bits. Since there are 8 bits in a byte, the 640×480 image with 256 shades of gray is 307,200 bytes or .3072 megabytes of information.

Data Compression

Although images should be permanently archived as raw data or with only lossless data compression (no data is destroyed), hardware and software technologies exist that allow teleradiology systems to compress digital images into smaller file sizes so that the images can be transmitted faster. Compression is usually expressed as a ratio: 3:1, 10:1, or 15:1. The compression ratio refers to the ratio of the size of a compressed file to the original uncompressed file.

Certain images can withstand a substantial amount of compression without a visual difference: computed tomography and magnetic resonance images have large areas of black background surrounding the actual patient image information in virtually every slice. The loss of some of those pixels has no impact on the perceived quality of the image nor does it significantly change reader-interpretive performance.

Image Transmission

Image-transmission time is directly proportional to the file size of the digital image. The greater the amount of digital information in an image which involves the image matrix size and the number of bits per pixel, the longer the time required to transmit the image from one location to another. A radiological image contains a large amount of digital information. For example, an image with a relatively low resolution of $512 \times 512 \times 8$ bits contains 2,097,152 bits of data, and a $1,024 \times 1,024 \times 8$ -bit image has 8,388,608 bits of data. Transmission time has to follow the laws of size. The only way to decrease the transmission time is either to increase the speed of the modem or reduce the number of bits (compress the image) being sent. The following formula is used to calculate the time to transmit an image:

Table 1. Shades of gray and matrix depth

| Shades of Gray | Matrix Depth | Shades of Gray | Matrix Depth |
|----------------|--------------|----------------|--------------|
| 256 | 8 bits | 16 | 4 bits |
| 128 | 7 bits | 8 | 3 bits |
| 64 | 6 bits | 4 | 2 bits |
| 32 | 5 bits | 2 | 1 bit |

$$\frac{(\text{Matrix Size}) \times (\text{Matrix Depth} + 2 \text{ bits}) \times (\text{Percentage of Compression})}{(\text{Modem Speed})} = \text{Seconds to Transmit}$$

Matrix Depth is the shades of gray as shown in Table 1.

For modem or router control, most devices add 2 bits when transmitting as overhead.

Data Management

According to the ACR Technical Standard for Teleradiology, each examination data file must have an accurate corresponding patient and examination database record that includes patient name, identification number, examination date, type of examination, and facility at which the examination was performed. A Structural Query Language (SQL) database has been installed for the registration of each incoming and query of studies.

Web Technology

Web technology offers a significant advantage to physicians who need to receive images quickly, and who require real-time image navigation and manipulation to perform diagnostic tasks effectively. It facilitates the use of graphical-user interfaces, making teleradiology and picture archiving and communication system (PACS) applications easier to use and more responsive. Additionally, clients and servers can be run on different platforms, allowing end users to free themselves from particular proprietary architectures. Software applications designed for client-server computing can interface seamlessly with most hospital information systems (HISs) (RCR, 1999) or radiology information systems (RISs), while providing rapid soft-copy image distribution.

Storage

RAID (Marcus & Stern, 2003) stands for redundant array of inexpensive (or identical) disks. RAID employs a group of hard disks and a system that sorts and stores data in various forms to improve data-acquisition speed and provide improved data protection. To accomplish this, a system of levels (from 1 to 5) “mirrors,” “stripes,” and “duplexes” data onto a group of hard disks. All images were stored in the RAID of the server for high availability of the service.

Display

Today, most of the gray shades were produced by a mixing of primary colors in the video boards. Three types of video boards are commonly available, including 16-bit, 24-bit, and 32-bit color video cards. The video board with higher bits can be configured in a lower bit mode. The 16-bit color mode is called “High Color” mode with almost “good enough” quality to show photo images, at least for most purposes; 16-bit color is 5 bits each of red, green, and blue packed into one 16-bit word (2 bytes per pixel). Five bits can show 32 shades of each primary RGB channel, and $32 \times 32 \times 32$ is 32K colors. Green used the extra one bit for 6 bits to achieve 64K colors overall, but half of them are green. The human eye is most sensitive to green-yellow, and more shades are a bigger advantage there. Green has twice the luminance of red and six times more than blue, so this is very reasonable. Video boards do vary, but 24 bits is normally not so much better in most cases, except in wide smooth gradients.

Video boards for the last few years are 24-bit color or “true color”; 24-bit color is 8 bits each of RGB, allowing 256 shades of each primary color, and $256 \times 256 \times 256 = 16.7$ million color combinations. Studies show that the human eye can detect about 100 intensity steps (at any one current brightness adaptation of the iris), so 256 tones of each primary is more than enough. We would not see any difference between RGB (90,200,90) and (90,201,90), but we can detect 1% steps (90,202,90) (on a cathode ray tube (CRT) tube, but 18-bit LCD panels show 1.5% steps). So our video systems and printers simply do not need more than 24 bits.

Theoretically, there is no true 32-bit color display mode. The confusion is that 24-bit color mode normally uses 32-bit video mode today, referring to the efficient 32-bit accelerator chips (word size). The 24-bit color mode and so-called 32-bit video mode show the same 24-bit colors, the same 3 bytes RGB per pixel; 32-bit mode simply discards one of the four bytes (wasting 25% of video memory), because having 3 bytes per pixel severely limits video acceleration functions. Processor chips can only copy data in byte multiples (8, 16, 32, or 64 bits). A 24-bit copy done with a hardware video accelerator would require three 8-bit transfers per pixel instead of one 32-bit transfer; 32-bit video mode is for speed, and it shows 24-bit color.

Liquid Crystal Display (LCD)

In teleradiology, it is more convenient to use LCD for image display than CRT. In LCD, there are no CRTs. Instead, thin “sandwiches” of glass contain liquid-crystal filled cells (red, green, and blue cells) that make up a pixel. Arrays of thin film transistors (TFTs) provide the voltage power, causing the crystals to untwist and realign so that varying amounts of light can shine through each, creating images. This par-

Figure 1. Schematic diagram of 3G wireless medical image viewing system

ticular sensitivity to light makes LCD technology very useful in projection such as LCD front projectors, where light is focused through LCD chips.

Specifically, there are five layers to the LCD display: a backlight, polarized glass sheet, colored pixel layering, coating of liquid crystal solution that responds to signals off a wired grid of x and y coordinates, followed by a second glass sheet. To create an image, electrical charges, precision coordinated in various degrees and volts, effect the orientation of the liquid crystals, opening and closing them and changing the amount of light that passes through specific colors of pixels. LCD technology has increased its accuracy that can produce sharp and more accurate color images than earlier passive-matrix technologies.

One-Time and Two-Factor Authentication

OTTFa is an authentication protocol that requires two independent ways to establish identity and privileges in which at least one is continuously and non-repetitively changing. This contrasts with traditional password authentication, which requires only one factor such as the knowledge of a password in order to gain access to a system. OTTFa technique provides a secure authentication protocol for the teleradiology service.

Application Tunneling (Port Forwarding)

Application tunneling (or port forwarding) is a combination technique of routing by port combined with packet rewriting. A convention router examines the packet header and dispatches the packet on one of its other interfaces, depending on the packet destination address. Port forwarding examines the packet header and forwards it on to another host with the header rewriting depending on the destination

port. The application of application tunneling is its inability of the destination machine to see the actual originator of the forwarded packets and instead seeing them as originating from the router. One of the applications of application tunneling is in a virtual private network gateway, as shown in Figure 1. Using the application tunneling technique, the security of the teleradiology system can be strengthened considerably.

High Available Server Cluster

The purpose of high available (HA) clustering is to maintain a non-stop teleradiology service for the users. In the current design, there are three image servers configured to form an HA cluster using a load-balancing switch. The user could access any one of the servers for making of diagnosis using the teleradiology technique. Other clustering techniques being used include operating system clustering, Internet protocol (IP) failover, and fault tolerance (FT) techniques.

Implementation Result

The overall design of the 3G wireless medical image viewing system is shown in Figure 1. The medical images received from the PACS or imaging modalities were stored in the DICOM Web server.

The operation of the system is shown in Figures 2 through 10. The users can use a laptop computer as a remote client for the connection to the Internet through a 3G network gateway provided by their service provider (see Figure 2). From the Internet, the users can make a connection to the VPN gateway and be authenticated by the OTTFa server. After login, the VPN gateway will redirect the user to the DICOM Web server using the application tunneling technique. After another login of the DICOM Web server, users can query the server for related studies. Finally, once the related studies are found and selected, all related images can be retrieved and displayed as shown in Figures 9 and 10.

FUTURE TRENDS

4G Wireless Network

4G is the next generation of wireless networks that will replace 3G networks sometimes in future. In another context, 4G is simply an initiative by academic R&D laboratories to move beyond the limitations and problems of 3G to meet its promised performance and throughput. In reality, as of the first half of 2002, 4G is a conceptual framework for or a discussion point to address future needs of a universal high-speed wireless network that will interface with the wireline backbone network seamlessly. 4G also represents the hope and ideas of a group of researchers at Motorola, Qualcomm, Nokia, Ericsson, Sun, HP, NTT DoCoMo, and other infrastructure vendors who must respond to the needs of MMS, multimedia, and video applications if 3G never materializes in its full glory.

A comparison of key parameters of 4G with 3G is as shown in Table 2.

CONCLUSION

The above-mentioned 3G wireless medical image viewing system is providing a transfer speed of 384 kbps, which is comparable to a T1 fixed line of a speed of 1.4 mbps, but with greater accessibility and confidentiality. This system has been used successfully to ensure the availability of the teleradiology service 24 hours a day and 7 days a week. Throughout its construction and operation, it is found that the

ACR and DICOM standards have provided useful guidelines on achieving the quality assurance and integrity expectations of this kind of service.

KEY TERMS

Application Tunneling: A combination technique of routing by port combined with packet rewriting.

Digital Imaging and Communication in Medicine (DICOM): A standard developed by the American College of Radiology (ACR) and the National Electrical Manufacturers Association (NEMA) to provide standardized formats for images, a common information model, application service definitions, and protocols for communication.

One-Time Two-Factor Authentication: An authentication protocol that requires two independent ways to establish identity and privileges in which at least one is continuously and non-repetitively changing.

Port Forwarding: Another name for application tunneling.

Redundant Array of Inexpensive (or Identical) Disks (RAID): Employs a group of hard disks and a system that sorts and stores data in various forms to improve data-acquisition speed and provide improved data protection.

Teleradiology: The process of sending radiologic images from one point to another through digital, computer-assisted transmission, typically over standard telephone lines, a wide-area network (WAN), or over a local area network (LAN).

Mobile Multicast

Thomas C. Schmidt

HAW Hamburg, Germany

Matthias Wählisch

FHTW Berlin, Germany

INTRODUCTION

The submission of datagrams from a node to a group of receivers must be seen as a powerful extension of the Internet routing layer (Deering, 1989). Multicast group communication forms an integral building block of a wide variety of applications, ranging from public content distribution and streaming over voice and videoconferencing, collaborative environments, and gaming up to the self-organization of distributed systems. Its support by network layer multicast will be needed, whenever globally distributed, scalable, serverless, or instantaneous communication is required. As broadband media delivery more and more emerges to be a typical mass scenario, scalability and bandwidth efficiency of multicast routing continuously gains relevance. Internet multicasting will be of particular importance to mobile environments, where users commonly share frequency bands of limited capacity. The rapidly increasing mobile reception of ‘infotainment’ streams may soon require a wide deployment of mobile multicast services.

The fundamental approach to deal with mobility in the next-generation Internet is stated in the Mobile IPv6 RFC (Johnson, Perkins, & Arkko, 2004). Multicast has only roughly been treated therein, but raises quite distinctive aspects within a mobility-aware Internet infrastructure. On the one hand multicast routing itself supports dynamic route configuration, as members may join and leave ongoing group communication over time. On the other hand multicast group membership management and routing procedures are intricate and too slow to function smoothly for mobile users. In addition multicast imposes a special focus on source addresses. Applications commonly identify contributing streams through source addresses, which must not change during sessions, and routing paths in most protocols are chosen from destination to source.

Mobile multicast has been a concern for about ten years (Xylomenos & Polyzos, 1997) and led to innumerable proposals for solutions. Intricate multicast routing procedures, though, are not easily extensible to comply with mobility requirements. Any client subscribed to a group while in motion requires delivery branches to pursue its new location; any mobile source requests the entire delivery tree to adapt to its changing positions. Significant effort has been already

invested in protocol designs for mobile multicast receivers. Only limited work has been dedicated to multicast source mobility, which poses the more delicate problem (Romdhani, Kellil, Lach, Bouabdallah, & Bettahar, 2004a). In multimedia conference scenarios each member commonly operates as receiver and as sender for multicast-based group communication. In addition, real-time communication such as voice or video over IP places a severe temporal requirement on mobility protocols: seamless handover scenarios need to limit disruptions or delay to less than 100 milliseconds. Jitter disturbances are not to exceed 50 milliseconds. Note that 100 milliseconds is about the duration of a spoken syllable in real-time audio.

While multicast routing itself has been proposed to support mobility on the Internet (Helmy, 2000), consensus on an efficient, robust, and widely deployable scheme of multicast for mobile hosts is still lacking (Schmidt & Wählisch, 2005a). In this review we will summarize the state of the art in current work to multicast to Mobile IPv6 networks. The principle conceptual problems are discussed and analyzed. Propositions for improvement and possible directions to further proceed towards a mobile multicast are presented.

BACKGROUND

Multicast mobility must be considered a generic term that subsumes a collection of quite distinct functions. First, multicast communication divides into any source multicast (ASM) (Deering, 1989) and source-specific multicast (SSM) (Bhattacharyya, 2003; Holbrook & Cain, 2005). Second, the roles of senders and receivers are asymmetric and need distinction. Both individually may be mobile. Their interaction is facilitated by a multicast routing function—such as DVMRP (Waitzman, Partridge, & Deering, 1988), PIM-SM/SSM (Estrin et al., 1998) or CBT (Ballardie, 1997)—and the IPv6 multicast listener discovery protocol (Deering, Fenner, & Haberman, 1999).

Any multicast mobility solution must account for all of these functional blocks. It should enable seamless continuity of multicast sessions when moving from one IPv6 subnet to another. It should preserve the multicast nature of packet distribution and approximate optimal routing. It should sup-

port per-flow handover for multicast traffic, as properties and designations of flows may be of individual kind.

Multicast routing dynamically adapts to session topologies, which then may change under mobility. However, routing convergence arrives at a time scale of seconds, even minutes and is far too slow to support seamless handovers for interactive or real-time media sessions. The actual temporal behavior strongly depends on the routing protocol in use and on the geometry of the current distribution tree. A mobility scheme that arranges for adjustments—that is, partial changes or full reconstruction—of multicast trees is forced to make provision for time buffers sufficient for protocol convergence. Special attention is needed with a possible rapid movement of the mobile node, as this may occur at much higher rates than compatible with protocol convergence.

IP layer multicast packet distribution is an unreliable service, which is bound to connectionless transport protocols. Packet loss thus will not be handled in a predetermined fashion. Mobile multicast handovers should not cause significant packet drops. Due to statelessness the bi-casting of multicast flows does not cause foreseeable degradations of the transport layer.

Group addresses in general are location transparent, even though there are proposals to embed unicast prefixes or rendezvous point addresses (Savola & Haberman, 2004). Source addresses contributing to a multicast session are interpreted by the routing infrastructure and by receiver applications, which frequently are source address aware. Multicast therefore inherits the mobility address duality problem for source addresses, being a logical node identifier (HoA) on the one hand and a topological locator (CoA) on the other.

Multicast sources in general operate decoupled from their receivers in the following sense: a multicast source submits data to a group of unknown receivers, thus operating without any feedback channel. It neither has means to inquire on properties of its delivery trees, nor will it be able to learn about the state of its receivers. In the event of an inter-tree handover, a mobile multicast source therefore is vulnerable to losing receivers without taking notice.

MULTICAST LISTENER MOBILITY

A mobile multicast listener entering a new IP subnet may simply re-subscribe to its previously received groups. It thereby will encounter one of the following conditions. In the new network the requested multicast service may be supported, but the multicast groups under subscription may not be forwarded to it. The current distribution trees for the desired groups may reside at large routing distance. It may as well occur that some or all groups under subscription of the mobile node are received by one or several local group members at the instance of arrival and that multicast streams natively flow.

The temporal behavior of the multicast handover will largely depend on the conditions met. The mobile node may employ predictive or reactive accelerating schemes to reduce performance degradation. For a detailed analysis, see Schmidt and Wählisch (2005b).

ASM SOURCE MOBILITY

A node submitting data to an Any Source Multicast group defines the root of either a shared or a source-specific delivery tree. Beside root location forwarding along, this delivery tree will be bound to a topological network address due to reverse path forwarding (RPF) checks. A mobile multicast source moving away is *solely* enabled to either inject data into a previously established delivery tree by using its previous topologically correct source address, or to (re-)define a multicast distribution tree compliant to its new location. In pursuing the latter the mobile sender will have to proceed without control of the new tree construction due to decoupling of sender and receivers.

Conforming to address transparency and temporal handover constraints will be the key problems for any route optimizing mobility solution. Additional issues arrive from possible packet loss and from multicast scoping. A mobile source away from home must attend scoping restrictions which arise from its home and its visited location (Johnson et al., 2004).

SSM SOURCE MOBILITY

Fundamentally Source Specific Multicast has been designed for changeless addresses of multicast senders. Source addresses in client subscription to SSM groups are directly used for route identification. Any SSM subscriber is thus forced to know the topological address of its group contributors. SSM source identification invalidates when source addresses change under mobility.

Consequently, source mobility for SSM packet distribution introduces a significant conceptual complexity in addition to the problems of mobile ASM. As a listener is subscribed to an (S,G) channel membership and as routers have established an (S,G)-state shortest path tree rooted at source S, any change of source addresses under mobility requests for state updates at all routers and all receivers. A moving source would have to update its change of CoA with all listeners, which subsequently had to newly subscribe and initiate corresponding source-specific trees. As the principle multicast decoupling of a sender from its receivers likewise holds for SSM, the need for client update turns into a severe problem.

Figure 1. Relative router coincidence between subsequent multicast distribution trees rooted at 5 hops distance

PROPERTIES OF MULTICAST DISTRIBUTION TREES

The efficiency of multicast distribution trees has been studied well and was empirically derived to follow a Chuang and Sirbu (1998) scaling law—that is, the number of links employed in a multicast tree with m receivers is well approximated by $\langle L_u \rangle m^{0.8}$, where $\langle L_u \rangle$ represents the average number of unicast hops for the corresponding network. Van Mieghem, Hooghiemstra, and van der Hofstad (2001) semi-analytically derived that the number of routers in the Internet, which can be reached from a root, grows exponentially in the number of hops with an effective router degree of 3.2. From the perspective of mobile sources, the geometric evolution of multicast trees according to a moving root is of increased importance. The number of hops between subsequent root routers, the mobility “step-size,” should serve as an appropriate measure of variation.

Source-specific shortest path trees subsequently generated from mobility steps are highly correlated. They most likely branch towards identical receivers and are rooted at a distance, which corresponds to the “step size” undertaken by the moving source. Figure 1 visualizes the relative change of distribution trees as a function of receiver multiplicity for a medium step size of 5. It is interesting to note that even in larger networks, a range from 80 to above 90% of multicast tree routers remains fixed under a mobility step. Simulations have been performed based on real-world Internet topology data, representing the ATT core network (Heckmann, Piringer, Schmitt, & Steinmetz, 2003) and subsamples from the SCAN Project (2005).

SOLUTIONS

Two principal approaches to mobile multicast have been foreseen in (Johnson et al., 2004):

Remote subscription forces the mobile node to re-initiate multicast distribution subsequent to handover, using its current Care-of-Address. This approach of tree discontinuation relies on the dynamics of multicast routing to adapt to network changes. Aside from service disruption on handover, remote subscription allows for a transparent mobility management for mobile listeners. Mobile ASM senders will experience a mobility-driven change of source addresses, and thus need to transmit a home address destination option to maintain session persistence at the application layer. Mobile SSM sources cannot follow a pure remote subscription approach, as receivers are subscribed to a static source address and thus will lose communication on handovers.

Bi-directional tunneling guides the mobile node to tunnel all multicast data via its home agent. This solution hides all movement and results in static multicast trees. It transparently may be employed by mobile multicast listeners and sources, on the price of triangular routing and possibly significant performance degradations due to widely spanned data tunnels. The additional delay due to packet forwarding through the home agent strongly depends on network topology and has been evaluated in Schmidt and Wählisch (2006). For densely meshed single provider networks, an average delay excess of about 50% was found, whereas in large samples of 15,000 inter-provider core nodes, the bi-directional tunneling more than doubled network transmission times.

Both schemes carry the distinct advantage of immediate employability, as they do not require changes to existing

protocols. Accordingly the combination of operating remote subscription at mobile receivers and bi-directional tunneling at mobile sources (i.e., hybrid approaches) can be frequently found in the literature (Romdhani et al., 2004a).

Agent-based inter-tree handovers have been established as the common approach to compensate for performance deficits in remote subscription or bi-directional tunneling. They attempt to balance between the anchorless remote subscription and the purely static bi-directional tunneling. Static agents typically act as local tunneling proxies, allowing for some inter-agent handover while the mobile node moves away. A decelerated inter-tree handover will be the outcome of agent-based multicast mobility, where extra effort is needed to sustain session persistence through address transparency of mobile sources.

Aside from many conceptual papers (Romdhani et al., 2004a), there are proposals of agent-based approaches compliant to the unicast real-time mobility infrastructure of Fast MIPv6, the M-FMIPv6 (Suh, Kwon, Suh, & Park, 2004), and of Hierarchical MIPv6, the M-HMIPv6 (Schmidt & Wählisch, 2005c), and to context transfer (Jonas & Miloucheva, 2005).

“Fast Multicast Protocol for Mobile IPv6 in the Fast Handover Environments” adds support for mobile multicast receivers to Fast MIPv6. On predicting a handover to a next access router, the mobile node submits its multicast group addresses under subscription with its fast binding update to the previous access router. Routers thereafter exchange those groups. In the ideal case, the new access router will be enabled to subscribe to all requested groups, even before the MN has disconnected from its previous network.

“Seamless Multicast Handovers in a Hierarchical Mobile IPv6 Environment (M-HMIPv6)” extends the hierarchical MIPv6 architecture to support mobile multicast receivers and sources. Mobility anchor points act as proxy home agents, controlling group membership for multicast listeners and issuing traffic to the network in place of mobile senders. Handovers within a domain of one mobility anchor point remain invisible in this micro mobility approach. At the event of an inter-anchor handover, the previous anchor point will be triggered by a reactive binding update and act as a proxy forwarder. Subsequent to MIPv6 handover, continuous data reception is thus assured, while a remote subscription continues within the new domain. A home address destination option has been added to streams from a mobile sender. Consequently transparent source addressing is provided to the socket layer.

It should be noted that none of the above approaches addresses SSM source mobility, except the bi-directional tunneling. Jelger and Noel (2002) suggest mobile SSM handover improvements by employing anchor points within the source network, causing a continuous data reception during client-initiated handovers. Their approach can be understood

as a fairly direct transformation of traditional agent-based solutions in ASM mobility: in the event of a handover, the mobile source reconnects with the previous anchor point and distributes a new “SSM-Source Handover Notification” binding update option. On reception of this binding update, listeners re-subscribe to the new source address channel, while multicast streams continuously are bi-casted down the previous distribution tree. In applying an ASM-type agent-based approach, the authors disregard consequences of the decoupling principle for SSM. Bi-casting to the previous SSM tree cannot be terminated until all receivers have established membership of the new distribution tree, which is of unforeseeable progress.

Tree modification schemes have deserved very little attention as procedures that modify existing distribution trees to continuously serve for data transmission of mobile sources. In the case of DVMRP routing, Chang and Yen (2004) propose an algorithm to extend the root of a given delivery tree to incorporate a new source location in ASM. To fix DVMRP forwarding states and heal RPF-check failures, the authors rely on a complex additional signaling protocol.

Focusing on inter-domain mobile multicast routing in PIM-SM, Romdhani et al. (2004b) propose a tunnel-based backbone distribution of packets between newly introduced “mobility-aware rendezvous points” (MRPs). These MRPs operate on extended multicast routing tables, which simultaneously hold HoA and CoA. This solution accounts for the ASM inter-domain source activation problem (Romdhani et al., 2004a).

O’Neill (2002) suggests a scheme to overcome reverse path forwarding (RPF) check failures originating from multicast source address changes, by introducing extended routing information, which accompanies data in a hop-by-hop option header.

Finally Schmidt and Wählisch (2006) introduce a scheme for mobile SSM sources of continuously morphing the previous distribution tree into the new tree. A mobile multicast source (MS) away from home will transmit unencapsulated data to a group using its HoA on the application layer and its current CoA on the Internet layer, just as unicast packets are transmitted by MIPv6. In extension to unicast routing, though, the entire Internet layer (i.e., routers included) will be aware of the permanent HoA. Subsequent to handover the mobile source will immediately continue to deliver data along an extension of its previous source tree. Delivery is done by elongating the root of the previous tree from the previous designated router to the next designated router. All routers along the path, located at root elongation or previous delivery tree, thereby will learn MS’s new CoA and implement appropriate forwarding states. Routers on this extended tree will use RPF checks to discover potential shortcuts. Registering a new CoA as source address, those routers that receive the state update via the topologically

incorrect interface will submit a join in the direction of a new shortest path tree and prune the old tree membership as soon as data arrives. All other routers will re-use those parts of the previous delivery tree that which coincide with the new shortest path tree.

Tree modification schemes introduce the potential of unencapsulated data transmission to multicast groups continuous under mobility. They are well suited for ASM and SSM source mobility, and minimize packet loss and delay. However, their disadvantage lies in the requirement to change existing multicast routing protocols.

FUTURE TRENDS

During the past decade multicast routing has encountered hesitance in deployment, which is mainly due to its complexity and potential threads as the outcome of unrestricted packet duplication in ASM. It is widely believed that simpler mechanisms for group distribution in Source Specific Multicast will lead to a pervasive dissemination of multicast infrastructure and services throughout the Internet. Facing mobility, a significant extra burden is added onto multicast deployment, which is even enhanced for SSM. The dispute on multicast network efficiency vs. deployment complexity thus arouses anew (Garyfalos, Almeroth, & Sanzgiri, 2004).

However, multicast services in a mobile environment may soon become inescapable, when multimedia distribution services will develop as a strong business case for IP portables. At first, the deployment of simple bi-directional tunneling or micromobile proxy services can be foreseen. As mobility will unfold dominance and as efficiency will show a larger impact in costly radio environments, the evolution of multicast protocols will naturally follow mobility constraints. This future-generation Internet routing will have to provide seamless mobile multicasting and presumably will operate directly on the shapes of distribution trees.

CONCLUSION

Mobile multimedia group services are one of the major driving forces, but also a severe challenge for the Internet infrastructure today. In this overview we discussed the principle conceptual difficulties of mobile multicast and derived the current state of the art for solutions. A special focus has been donated to source mobility from the perspective of Source Specific Multicast. Initial ideas for new mobile SSM communication and routing schemes were presented, as they may serve as a starting point for revitalizing the research on practically feasible solutions to this intricate field of development.

KEY TERMS

Any Source Multicast (ASM): The distribution of packets from an arbitrary source to a group of receivers. Receivers are addressed by a delocalized group address and remain unidentified by the source.

Bi-Casting: A technique of duplicating packets on the network to reduce packet loss. Forwarding, for example, may be done via new and previous access routers.

Care-of Address (CoA): The mobile node's temporary IP address in its visited network.

Home Address (HoA): The mobile node's permanent IP address in its home network.

Home Agent (HA): A router representing the absent mobile node in its home network. It intercepts packets destined to the mobile node's home address and tunnels these to the Care-of Address of the mobile node.

Inter-Tree Handover: Change of packet distribution from one to another multicast delivery tree.

Rendezvous Point: The root of a per-group *shared tree*.

Reverse Path Forwarding (RPF) Check: A routing algorithm verifying whether a multicast packet was received on the closest interface to the root of the distribution tree. RPF checks prevent multicast packet distribution from exhibiting loops.

Shared Tree: A multicast distribution tree rooted at a source-independent *rendezvous point* and serves for packet distribution of different of multiple sources.

Source-Specific Multicast (SSM): The distribution of packets from an initially specified source to a group of receivers. Listeners must actively subscribe by address to each source they want to receive traffic from.

Source-Specific Tree: A multicast distribution tree rooted at the multicast sender.

Mobile Payment and the Charging of Mobile Services

INTRODUCTION

According to the sweeping enthusiasm that characterized much of the news reporting in the years 1999 and 2000, mobile phones should by now have been firmly established as payment terminals in the most diverse fields. However, reality today is a different matter. Mobile payment as an established payment system seems to be a distant prospect in the case of most countries.

Since the mid-1990s there have been serious efforts to use mobile phones for payment processes. The starting point for these considerations was the fact that mobile phones are particularly suitable for conducting payment processes due to their specific characteristics, high diffusion in population, and users' positive attitude towards them (e.g., Henkel, 2002). In recent years several studies showed that customers in principle take an interest in mobile payment (e.g., Khodawandi, Pousttchi, & Wiedemann, 2003; Eisenmann, Linck, & Pousttchi, 2004). A further study bridged the gap of these and other studies' explanatory power, and confirmed a high interest also in the total population. During a representative study in September 2004, 49.6% of the German participants indicated that they are interested in and willing to use mobile payment (MobilMedia, 2004).

The commercial history of mobile payment procedures is short, but simultaneously characterized by rapid development. One of the first commercial mobile payment procedures was launched by the Finnish *mobile network operator* (MNO) Sonera in 1997. Customers were able to pay for goods at vending machines (Dahlberg, Mallat, & Öörni, 2003). New technological innovations used in mobile payment procedures and new use case scenarios for mobile payment have been developed at an increasingly fast pace ever since. Among the leading countries in mobile payment are Austria, South Korea, Singapore, Norway, Spain, Japan, Finland, and Italy, in which end-to-end solutions and clear business models have proved to be sustainable after four to five years of field trials and pilot projects (Taga & Karlsson, 2004).

However, in other countries the situation is disillusioning. For instance on the German market (which is not only the most important European market, but also a good sample for developments in many western markets), banks (e.g.,

Payitmobile), MNOs (e.g., Genion M-Payment), as well as quite a number of specialized intermediaries (e.g., Paybox, Geldhandy, or Street Cash) tried one's luck in recent years. Also the vertical alliance of the four large-scale and internationally active MNOs—Orange, Telefonica Moviles, T-Mobile, and Vodafone—was not able to start its integrated mobile payment system Simpay. When it was initiated in 2002, the primary objective was to introduce a pan-European mobile payment system for all payment scenarios. However, after six months a smaller compromise was made: providing a solution for their most urgent problem, charging mobile services, and additionally enabling payments for digital goods on the Internet. Also this did not come off. After numerous delays and intestine strife between the founders, Simpay finally stopped its activities in the middle of 2005 (Pousttchi & Wiedemann, 2006).

Thus, it can be concluded for the majority of countries that most mobile payment procedures were quit after the test stage, and procedures that came into the market had some diffusion, but outside of Asia, not many of these can be categorized as economically successful, although the preconditions for acceptance of mobile payment by customers are very good.

BACKGROUND

The diffusion of mobile phones during the nineties and the success of mobile services such as ring tones and logos have raised high expectations toward mobile commerce. We define *mobile commerce* as any kind of business transaction, on the condition that at least one side uses mobile communication techniques (Turowski & Pousttchi, 2004).

Mobile payments are expected to become one of the most important applications in mobile commerce (Varshney & Vetter, 2002). On closer examination of mobile payment, we have to differentiate two basic functions: payments inside and outside mobile commerce. Inside mobile commerce mobile payment is used for payments of mobile offers and is ideally system inherent. In the area of charging mobile services, we distinguish two basic terms: mobile billing and mobile payment. We refer to *mobile billing* as billing of

telecommunication services by an MNO within an existing billing relationship (Turowski & Pousttchi, 2004). The MNO could also be a mobile virtual network operator (MVNO) to which our following models and concepts would apply analogously. We define *mobile payment* as that type of payment transaction processing in the course of which—within an electronic procedure—at least the payer employs mobile communication techniques in conjunction with mobile devices for initiation, authorization, or realization of payment (Pousttchi, 2003). If a mobile payment procedure is provided by an MNO, we will have the intersection of mobile billing and mobile payment.

Analyzing different mobile payment procedures on joint characteristics, Kreyer, Pousttchi, and Turowski (2002) derive five standard types. The standard type with the most practical relevance today is the standard type phone bill, which is characterized by an MNO as the mobile payment service provider and the mobile phone bill as the settlement method. These procedures are normally either limited to the mobile commerce scenario or especially developed for this scenario. An example for the first case is the system inherent payment procedure of i-mode; examples for the second case are the different applications of premium rate SMS and the procedure m-pay of Vodafone.

As later discussed, mobile payment is crucial for mobile commerce, but not limited to this scenario. Outside mobile commerce, a mobile payment procedure can be understood as a mobile commerce application to complete payments in different situations. For this purpose four general settings, defined as payment scenarios, are to be considered (Kreyer et al., 2002; Khodawandi et al., 2003): transaction on the stationary Internet (electronic commerce scenario), at any kind of vending machine (stationary merchant automat scenario), in traditional retail (stationary merchant person scenario), and between end-customers (customer-to-customer scenario). The emphasis of this article is on mobile payment inside mobile commerce (mobile commerce scenario).

Analyzing the business model of a mobile service, we can distinguish—similar to electronic commerce—between direct and indirect revenue sources and transaction-dependent and transaction-independent revenue types (Turowski & Pousttchi, 2004, according to Wirtz, 2001). Concepts based exclusively on indirect revenues, for example, financed by advertisement, already failed on the stationary Internet, except for very few exceptions. The realization of transaction-independent revenues in mobile commerce (e.g., by sale of a subscription) is appropriate for certain kinds of services. However, subscription will have a rather inhibiting effect on the diffusion of many typical mobile services, in particular if customers want to use the service spontaneously or only occasionally. If direct transaction-dependent revenues are to be realized, then an adequate charging form between providers and customers will be necessary. Whereas in electronic commerce we still see an important

role of traditional payment systems (e.g., Krueger, Leibold, & Smasal, 2006), a payment system for mobile commerce will typically not be adequate until it shares fundamental characteristics of the mobile offer it is to bill for, in particular its ubiquity (Pousttchi, Selk, & Turowski, 2002). This is in line with Coursaris and Hassanein (2002) and Mallat (2004). Their arguments are based on the fact that mobile commerce provides an opportunity for customers to reach services anytime and anywhere, and this implicates that also the payment procedure needs to follow these properties. Likewise, already Kieser (2001) Zobel (2001) derived the necessity of available mobile payment procedures from the necessity of charging of goods and services in the mobile commerce scenario, and additionally from the fact that traditional payment procedures are inapplicable in mobile commerce. Since companies are not going to invest in the development of innovative mobile applications or services unless they can be charged for appropriately, the existence of adequate possibilities for charging of the goods and services is crucial (Pousttchi et al., 2002). This is in line with Dahlberg et al. (2003) who stated that problems with payments profoundly hinder the development of mobile commerce.

As a result mobile payment is crucial for, but not limited to the mobile scenario. On the contrary, the universal applicableness of a mobile procedure in scenarios outside mobile commerce is relevant for its acceptance (Kreyer et al., 2002).

MOBILE PAYMENT INSIDE MOBILE COMMERCE

Offer Models

The most important subset of mobile commerce is the area of mobile value-added services. Due to the fact that the transmission of data is a substantial component, it is classified as a telecommunication service in the broader sense. Hence, the charging by the MNO is legally allowed in most countries, whereas payment outside of mobile commerce often requires a banking license. Typical examples for mobile added-value services are news, financial information services, or entertainment services. In principle, we distinguish two offer models: the offer by the MNO and the direct offer by a mobile content provider (Turowski & Pousttchi, 2004). The offer by the MNO is an MNO-centered solution. The MNO produces mobile services or buys them from a mobile content provider (just as he or she buys into network infrastructure or mobile devices) and thus offers a single face to the customer for network and services. An explicit payment process is not necessary, because typically only transmission is charged and consequently, mobile billing is applied similar to mobile voice services. This model was (and still is) usual on many markets and documents the market power of the

MNO inhibiting the direct relationship between customers and mobile content providers.

However, this poses a couple of problems to the MNO. Procurement and offer of content are not counted among MNO core competencies, whereupon these are very complex issues, especially if successful offers are to be made for different target groups. But the effort's result is mostly only an increased data transmission and consequently improved network capacity utilization. Thus, the offer of high-quality content pays off only conditionally through volume-dependent pricing. To come up against this, it is also possible to demand additional remuneration for high-quality content. However, the MNO relatively hopelessly competes with other actors counting content among their core competence—that is, branded content providers with an existing customer base like media companies or major sports clubs—and often already possesses an existing customer relationship outside of mobile commerce.

This is the reason why in times of 2.5G and 3G mobile networks, the model direct offer by the mobile content provider following the i-mode paradigm from Japan will prevail to an increasing degree (Natsuno, 2003). In this model, the mobile content provider has a direct customer relationship and generates direct revenues by the service offer. By means of service's content and quality, the mobile content provider provides customers with added value that is paid by them in addition to the transmission. The mobile content provider and MNO compensate added value and transmission costs. In this model the mobile content provider is added to the relationship between the MNO and the customer as a so-called third party whose services must be charged in any manner. Typically, B2C value-added services are charged by the MNO that has an existing billing relationship with customers. We refer to this as third-party billing. The MNO performs data transmission and also acts as a payment service provider for the content provider. Therefore he charges a higher fee to the customer which includes the value of the content as well as its transmission.

Charging Concepts for Third-Party Billing

Basically, there are three basic *charging concepts* for third-party billing: sponsoring, charging by premium fee, and charging by fixed price (Turowski & Pousttchi, 2004). In this context the *sponsoring* concept plays a special role. Services are free of charge for customers, because they are provided at the mobile content provider's expense. The mobile content provider may even pay the MNO for data transmission, offering not only the content, but even the access to it completely for free to the customer. Sponsoring models are not common up to now. A typical example for a completely free service would be a car manufacturer who offers a video download with a commercial for its new car model. Sponsoring models

will also become relevant if business models financed by advertisement are applied or if the free service aims at the usage of further service offer with costs.

For the two other charging concepts, customers will pay the MNO by the mobile phone bill. Both are based on the principle of revenue sharing between MNO and mobile content provider. From the perspective of most MNOs, the preferred solution is *premium fee charging*, meaning that customers pay a data volume fee for transmission and additionally a so-called premium fee for the value of the content or service. The MNO as payee gets the data volume fee and transfers the premium rate to the mobile content provider after deducting a compensation for his charging costs. The simplest example for charging by premium fee is charging services by premium SMS or premium MMS. Customers pay for sending (or, as common in some markets, also for receiving) the SMS a higher fee consisting of the SMS basic price and a premium rate. The latter underlies a revenue sharing. In case of singly ordered SMS/MMS services, charging by premium fee is simple and broadly accepted, although other services demand a more complex application.

However, apart from SMS, the existence of a data volume fee causes acceptance problems on the customers' side. On the one hand customers do not benefit from the size of transmitted volume; on the other hand customers with low affinity to technology are not able to imagine how much for example one kilobyte of data is. Figure 1 explains the premium fee charging concept; the delineation follows the e³-value method of Gordijn, Akkermans, and van Vliet (2000) and shows the benefits as value flows between the parties of the stakeholder network which are therefore represented by arrows.

From the perspective of most consumers, the preferred solution is *fixed price charging*. Customers pay a fixed price for the usage of the service. This revenue is shared between MNO and mobile content provider according to an agreed ratio. The problem with this solution lies in the fact that "real" revenue sharing is necessary (whereas beforehand, transmission and content have been paid separately). Hence, the ratio must include the transmission costs of the service. This concept is called "airtime revenue sharing" and seen as extremely unpleasant by the vast majority of MNOs, as they hope to compensate declining voice revenues with this and thus defend their margins strongly. Figure 2 illustrates the fixed price charging concept.

FUTURE TRENDS

Mobile payment is highly attractive to consumers. Outside mobile commerce we have to distinguish two different goals: in markets with an established banking infrastructure such as Europe, the United States, or Australia, this concerns a new channel to existing payment methods and is primarily a

Figure 1. Premium fee charging

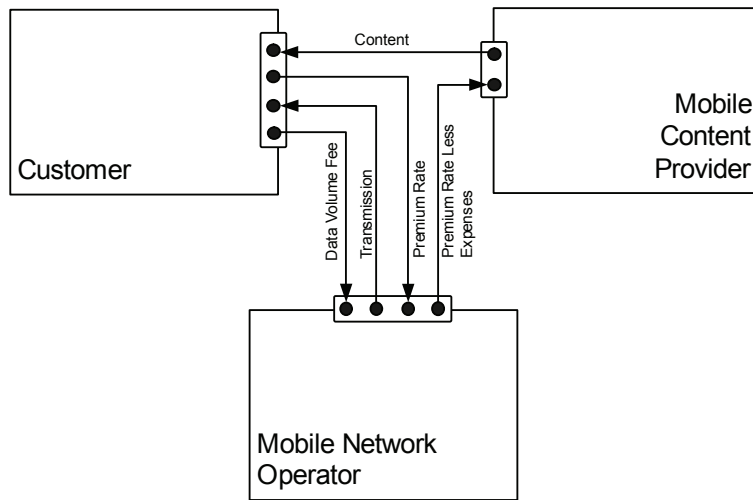

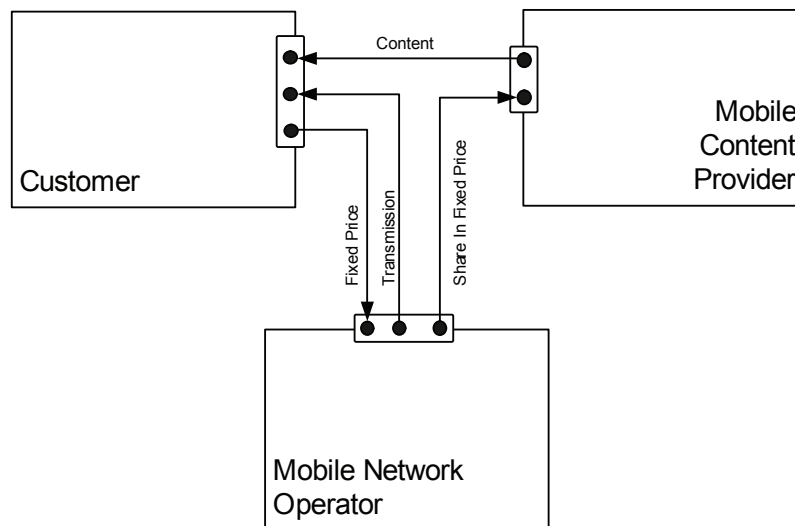

Figure 2. Fixed price charging

question of convenience. In emerging markets such as many countries in Africa or South America, mobile payment is more likely to become a new payment method. The aim for the latter, under the keyword “banking the unbanked,” is to enable millions of people who do not own a bank account but a mobile phone to replace cash transactions. Payment service providers with a focus outside of mobile commerce are often bank-driven.

Mobile payment inside mobile commerce is closely related to the core business of the MNOs who, in most markets, control the access to and charging for mobile content. Often

they do so without caring about customer preferences, or they even result in obstructing the market for mobile content. On the other hand they come more and more under pressure by market fragmentation through MVNO models and declining voice margins. Current trends show a de-globalization of the MNO business, for instance in the failure of i-mode outside of Japan, in the failure of Vodafone in the Japanese market, and in the failure of a European MNO to play a major role in the U.S. market. The consequences of this de-globalization for payment and charging strategies of the MNO promise to be interesting.

CONCLUSION

Mobile payment is seen as an important issue since the mid-1990s, first as an m-commerce application to complete payments in the “real world” and secondly in order to charge for third-party mobile services. Both of these are still promising, but not yet successful in most markets.

In order to enable uptake of mobile services, MNOs have to offer payment methods that follow customer preferences, especially fixed-price charging, and that provide incentives to the owners of valuable content, especially airtime revenue sharing.

De-globalization of MNO business and increased pressure on MNOs may lead to easier and more open approaches to mobile payment on national markets, including banks, merchants, and content providers in these markets.

KEY TERMS

Direct Offer by the Mobile Content Provider: Offer model for mobile services in which mobile content providers have a direct customer relationship and generate direct added value by the service offer.

Fixed Price Charging: Charging concept in which customers pay a fixed price for the mobile services which is shared between the MNO and the mobile content provider.

Mobile Billing: Billing of telecommunication services by an MNO within the scope of an existing billing relationship.

Mobile Commerce: Any kind of business transaction, on the condition that at least one side uses mobile communication techniques.

Mobile Payment: Type of payment transaction processing in the course of which—within an electronic procedure—at least) the payer employs mobile communication

techniques in conjunction with mobile devices for initiation, authorization, or realization of payment.

Offer by the MNO: Offer model for mobile services in which MNOs produce mobile services or buy them from a mobile content provider, and the offer appears as MNO and mobile content provider simultaneously.

Premium Fee Charging: Charging concept in which customers pay a data volume fee for the transmitted data volume and additionally a premium rate for the value-added service.

Sponsoring: Charging concept in which services are free for customers, because they are provided at the mobile content provider's expense.

Standard Type Phone Bill: The mobile payment standard type is characterized by an MNO as mobile payment service provider and a mobile phone bill as settlement method.

Mobile Phone Gambling

Mark Griffiths

Nottingham Trent University, UK

INTRODUCTION

It is often claimed by marketeers that online gambling (i.e., the combining of gambling and the Internet into one convenient package) makes commercial sense. Gambling looks like it might make another step towards convenience with the advent of mobile phone gambling. This is gambling on the move, whenever, wherever, with the wireless world of mobile gambling. Since it is somewhat unnatural to always be near a computer, it could be argued that wireless mobile phones are the ideal medium for gambling. Whenever gamblers have a few minutes to spare (at the airport, commuting to work, waiting in a queue, etc.), they can occupy themselves by gambling (Griffiths, 2005a).

BACKGROUND AND BRIEF OVERVIEW

The mobile phone industry has grown rapidly over the last few years. It is predicted that by the end of 2005, the number of international mobile phone users will pass the two billion mark. The latest research by Mintel (2005a) highlights that mobile phone revenues from mobile gambling and gaming is increasingly rapidly. In 2004, mobile gaming revenue reached \$200 million. According to the Mintel report, by 2009, mobile gambling is set to generate \$3 billion in the United States alone. Despite the huge figure, mobile gambling will only likely account for around 1.5% of mobile industry revenues. It will also be a small part of the overall market as Mintel predicts that the U.S. casino gambling market will generate revenues of almost \$71 billion by 2009 (compared to the \$48.3 billion generated in 2004).

In the UK, mobile phone gambling has also increased dramatically. Mintel (2005b) reported that the number of betting pages downloaded by the end of 2005 was expected to approach three million, up 367% on 2004. Mobile phone users in the UK are set to spend £740m on phone downloads by the end of 2005. This is 18 times the £40m spent in 2002. Ring tones for phones account for approximately one-third of all mobile downloads. Arcade-style games (26%), screensavers and wallpaper (13%), and music (8%) are all popular. However, the biggest growth area has been in gambling, which now accounts for 9% of all mobile phone downloads in the UK.

These predictions also seemed to be backed up by Juniper Research (2005) who predicted mobile gambling revenues will

total about \$19.3 billion worldwide by 2009, with lotteries accounting for about \$7.9 billion, sports betting bringing in \$6.9 billion, and casino-style gambling contributing \$4.5 billion. Juniper predicts that lotteries will make most money for mobile gambling operators because governments are generally less censorious about lotteries than other forms of gambling. They are also easy to play and relatively low cost compared to other types of gambling (Griffiths & Wood, 2001). This means that mobile lotteries are likely to become established fairly quickly in a greater number of markets. Given the ubiquity of lotteries worldwide, it only requires a very small percentage of players to buy their tickets via their mobile phone for the resulting global dollar revenues to run into the billions. Juniper also claims that the growth in the UK National Lottery is almost wholly attributable to mobile betting.

Conventional wisdom says that two things have the power to drive any new consumer technology—pornography and gambling (Griffiths, 2001, 2004a). These activities helped satellite and cable television, video, and the Internet. It has been claimed in the media that Internet gambling and adult (pornography) sites are about the only e-businesses easily succeeding, as they provide adult entertainment in a convenient and guilt-free environment. The wireless world of the mobile phone may not be too different. So will gambling compete with pornography for dominance of mobile commerce? Along with pornography, gambling sites are one enterprise that should have little trouble reaching profitability—especially if this is combined with sports events. Sports are huge on the Internet. There are thousands of communities on the Internet built around sports teams or leagues, and even more “unofficial” team sites set up by fans. The most successful of those communities will look to “mobilize” and then “monetize.”

To some extent, the majority of gamblers are risk-takers to begin with (Griffiths, 2004b). Therefore, they may be less cautious with new forms of technology. Third-generation (3G) mobile phones are ideal for bet placing, and gamblers will be able to check on their bets and place new ones. Furthermore, it is anonymous and can provide immediate gratification, anytime, anywhere. Anonymity and secrecy may be potential benefits of mobile gambling, as for a lot of people there is still stigma attached to gambling in places like betting shops and casinos (Griffiths & Parke, 2002). Mobile gambling is also well suited to personal (i.e., one-to-one) gambling, where users bet against each other rather than bookies. Online betting exchanges (e.g., betfair.com)

are prime examples of where people bet on anything and everything with each other (Griffiths, 2005b).

So what types of gambling will work best on mobile phones? Internet gambling lends itself most naturally to “casino-style” games like slot machines, blackjack, roulette, poker, and so forth. These games require more in the form of graphics, sound, and interactivity. These types of gambling are not ideal for mobile devices but have now been introduced on 3G devices. It is unlikely that mobile phone graphics and technology can compete with Internet Web browsers (although the technology is improving all the time). Intuitively, mobile phone gambling is best suited for sports and event betting. With mobile phone betting, all that is required is real-time access to data about the event to be bet on (e.g., a horse race, a football match), and the ability to make a bet in a timely fashion.

These basic requirements are easily provided by the current generation of mobile phones and the appropriate software. At present, it looks as though mobile phones’ biggest influence will be on sports betting. The placing of the bet is not the driving motivation in event wagering. Since being the spectator is what sports fans are really interested in, the sports gambler does not need fulfillment from the process of gambling. People betting on sports will use mobile phones because they are easy, convenient, and take no time to boot up. Once they have their sports book registered as a bookmark on their phone, they can access it and place a bet within minutes.

FUTURE TRENDS

However, the situation will change over time. The new generation of mobile phones already has the capability to play typical “casino-style” games like blackjack, poker, and slots. The limiting aspects of the technological and protocol demands of mobile gambling (graphics, sound, and displays on mobile and personal digital assistant devices) are largely being resolved through technological advance.

These advances will allow punters to watch sporting events live on their phones while wagering in real time. Consider the following scenario. A betting service that knows where you are and/or what you are doing has the capacity to suggest something context related to the mobile user to bet on. For instance, if the mobile phone user bought a ticket for a soccer match using an electronic service, this service may share this information with a betting company. If in that match the referee gives a penalty for one team, a person’s mobile phone could ring and give the user an opportunity (on screen) to bet whether or not the penalty will be scored. On this type of service, the mobile phone user will only have to decide if he or she wants to bet, and if so, the amount of money. Two clicks and the bet will be placed. Context, timeliness, simplicity, and above all user

involvement look like enough also to convince people who never entered a bet shop.

The scenario described is not as far-fetched as it would seem. Manchester United soccer club has transformed itself into a powerful media company. It has launched its own digital TV channel, signed up a host of big-name technology partners (including Vodaphone, Sun, Lotus, and Informix), and started an ISP service. Its partnership with Vodaphone is perhaps a sign of the shape of things to come. In addition to sponsoring the club’s kit, Vodafone will also get the chance to develop co-branded mobile services with the club. This will offer users access to content similar to the company’s Web site (receiving real-time scores and team news via SMS). What Vodafone is heading towards is the ultimate goal—live video of matches, straight to mobiles, anywhere in the world.

While watching matches, users will be able to view statistics, player biographies, and order merchandise. So what does all this have to do with gambling? Mobility will facilitate an increase in “personalized” gambling, for example, the types of service offered by Eurobet’s Match service, where bettors gamble against each other, rather than the house.

Gambling will become part of the match day experience. A typical scenario might involve a £10 bet with a friend on a weekend football match. The gambler can text the friend via SMS and log on to the betting service to make a bet. If the friend accepts, the gambler has the chance to win (or lose). Football clubs will get a share of the profits from the service. Clubs are keen to get fans using branded mobile devices where they can simply hit a “bet” button and place a wager with the club’s mobile phone partner.

The penetration of wireless gambling will mostly be contingent upon the market penetration of wireless Web users in general. The mobile phone market is already large in many parts of the world. Juniper predicts that by 2009, mobile gambling revenues will be concentrated in Europe (37%) and the Asia-Pacific region (39%). They predict that North America will produce only 15% of global revenues because of government and societal opposition to wireless gambling. If these numbers are combined with the popularity of gambling, it could be speculated that there is the basis for a very profitable enterprise.

As with all new forms of technological gambling, ease of use is paramount to success. In the early days of WAP phones, programming the phone to use the protocol was very difficult. However, mobile phones are becoming more user friendly. Pricing structures are also important. Internet access and mobile phone use that is paid for by the minute produces very different customer behavior to those that have one-off payment fees (e.g., unlimited use and access for a monthly rental fee). The latter payment structure would appear to facilitate leisure use, as consumers would not be worried that for every extra minute they are online, they are increasing the size of their bills.

SOCIAL IMPACT: SOME CONCERNS

As with all new forms of technology—especially when used for gambling—there are some areas of potential concern. These are briefly outlined below (adapted from Griffiths, 2004c).

Access and Convenience

As already (implicitly) mentioned, mobile gambling's greatest advantage (even over the Internet) is its accessibility. Gamblers with mobile phones are no longer bound to computers and Internet access. The only thing that separates a mobile phone gambler from his or her favorite games is network coverage. Regardless of location, anyone can bet on their favorite sporting event or play their favorite casino games via mobile phone. Mobile phone gambling eliminates geographical borders, travel, and queuing up to bet. With mobile gambling, anyone can (theoretically) gamble 24 hours a day, seven days a week from the gambler's preferred location. It could also be argued that mobile phones make "impulse betting" easier. Like Internet gambling, it is also another example of convenience gambling (Griffiths, 2003a, 2005a). Given that prevalence of behaviors is strongly correlated with increased access to the activity, it is not surprising that the development of regular mobile use is increasing across the population. Increased accessibility may also lead to increased problems. Research into other socially acceptable but potentially addictive behaviors (drinking alcohol) has demonstrated that increased accessibility leads to increased uptake (i.e., regular use) and that this eventually leads to an increase in problems (although the increase may not be proportional) (Griffiths, 2003b).

Targeting the Low Earners

A popular claim by anti-gambling campaigners is that the low-limit bets and the relatively low payouts on many types of mobile phone gambling will attract mostly lower-class gamblers. However, most low-income workers are unlikely to own a brand-new high-tech PDA or mobile phone that incorporates such technology and services (although as prices continue to decrease, this may change). According to the gaming industry, mobile phone betting requires a very high standard of security and reliability that can only be reached with the newest (and most expensive) mobile phones. Regardless of disposable income, mobile phone gambling providers must (at the very least) allow gamblers to set pre-determined spending limits. This will help the gambler to avoid chasing losses (a known risk factor that facilitates problem gambling).

Youth Gambling

It has also been claimed that promoters of mobile phone gambling think it will attract a younger breed of gambler. In fact some companies are deliberately targeting the under-16 market with mobile phones specially designed for them, although they are not targeting gambling per se. This is something that needs to be monitored (Smeaton & Griffiths, 2004). Mobile phones that do not implement a user ID program will be very hard to trace and check—in particular when it comes to under-age customers trying to place a bet. However, the industry claims one way to tackle underage use is through a pre-paid card system. Pre-pay systems are bound by the same security and accounting best practices currently employed within the casinos today. This may potentially minimize problem gambling and prevents access to minors since distribution is controlled by the operator.

As we can see, potential social impact always follows new developing markets. Mobile phone gambling is clearly an area that needs in-depth monitoring of the psychosocial impact over the next few years.

CONCLUSION

It is clear that mobile phone gambling is still a relatively untapped area, and the functional capabilities of mobile phones are getting better all the time. Cell phones are rapidly growing in their functional capabilities. Mobile gambling is available on most of the mobile phones that are powered by Windows Mobile, Symbian OS, RIM including Java, and browser-based phones. There are now Internet sites that allow mobile phones to download casino-style games to the gambler's phone, allowing real money betting from anywhere they can get a phone signal. As the new generation of mobile phones accept Java programming, the high-end graphic display can be used to deliver live video feeds for the various casino games.

It appears that sophisticated mobile phone technology is increasingly able to integrate within our culture. This will have implications for the social impact and will need monitoring. The research by both Mintel and Juniper raises the possibility that almost unlimited access to mobile phone gambling will lead to more problem gambling. Like Internet gambling, mobile phone gambling has completely changed the way people think about betting. Mobile phones provide the convenience of making bets or gambling from wherever the person is. On paper, this all sounds relatively simple and is set to get even easier. Many gaming industry observers are claiming that in the not too distant future, people will not go to sporting events like horse races or football anymore. They will simply watch the sport on television and place bets via their mobile phones.

KEY TERMS

Convenience Gambling: Remote forms of gambling such as Internet gambling, interactive television gambling, and mobile phone gambling. Convenience gambling allows the gambler to gamble when he or she wants to without leaving the comfort of home and/or the workplace.

Java: A feature that allows the device to run specially written applications. Java applications can provide specific functions such as games, or they can be custom-written corporate applications. Some phones allow the user to download new applications directly from Internet, while others require a data cable to transfer the applications from a PC.

Mobile Gambling: One of several mobile (cellular) phone activities that are similar to online (Internet) gambling and offer the chance for players to win money on a range of different gambling activities.

Mobile Gaming: Video games played on mobile (cellular) phones. There is no opportunity to win money on these types of game.

Mobile Phone: A wireless telephone that sends and receives messages using radiofrequency energy in the 800-900 megahertz portion of the radiofrequency (RF) spectrum. Also called a cell phone.

Short Message Service (SMS): A service that enables subscribers to send short text messages (usually about 160 characters) to and from mobile phones.

Third Generation (3G): Analog cellular phones were the first generation. Digital marked the second generation. 3G is loosely defined, but generally includes high data speeds, always-on data access, and greater voice capacity. The high data speeds are possibly the most prominent feature and certainly the most hyped. They enable such advanced features as live, streaming video.

Mobile Phone Privacy Issues

Călin Gurău

Montpellier Business School, France

INTRODUCTION

Mobile phones have become a normal feature of our social life. People use them in institutions, on the street, in buses or trains, in restaurants, and even while driving, although in many countries this is a forbidden practice. The ringing of a mobile phone has become a familiar sound, and people have grown accustomed to witnessing loud-voice telephone conversations. However, not everybody is happy about this additional noise, which can be considered as an invasion of the personal privacy (Monk, Carroll, Parker, & Blythe, 2004).

On the other hand, the new generations of mobile phones started to incorporate advanced computing and communication facilities, such as location-tracking or position-aware applications, which can be used by mobile phone companies, relatives and friends, or third parties to identify the specific location of a mobile phone user (Broache, 2006). With the introduction of SMS and mobile Web browsers, the phenomenon of spam has also infected mobile phones. A new generation of hackers started to attack mobile devices, creating specific viruses. Recently, a company called Vervata announced the development of the first spyware for mobile phones—FlexiSPY—which is “absolutely undetectable by the user,” and which can be used to monitor the SMS messages that are sent and received, or to record the duration and the history of these calls. The data captured is then sent to Vervata’s servers, being accessible to customers via a special Web site (Evers, 2006). In some cases, governments have considered the possibility to register and analyze mobile phone conversations in order to track down and prevent harmful activities such as terrorism (Lettice, 2003; Richtel, 2005). All these issues raise important concerns regarding the personal privacy of the mobile phone users.

This article presents an overview of the main privacy problems raised by mobile phones, both for their users and for society in general, and analyzes a series of solutions for reducing their negative impact. After discussing the evolution of private vs. public space in the last decade, the article presents the main privacy concerns related with mobile phone usage. A series of data collected both from mobile phone owners, as well as from people without mobile phones, is analyzed, providing a basis for comparing conflicting opinions related to privacy issues. The article concludes with a series of solutions that already exist or may be available in

the near future, and which can solve or reduce mobile phone privacy problems.

BACKGROUND

The use of mobile phones is becoming truly universal. The average mobile phone ownership in Europe is above 55%, with Spain, Norway, Iceland, and the Czech Republic having more than 90% cell phone coverage in the population, and Luxembourg, Taiwan, Italy, and Hong Kong reaching 100% (Kristoffersen, 2005; Plant, 2001).

The use of mobile phones has determined a series of contradictory changes in the social and work environment (Townsend, 2000). The importance of investigating these changes stems from the fact that the mobile phone represents only the first step toward the introduction of ubiquitous computing, a trend demonstrated by the redefinition of mobile phones from ‘communication devices’ to ‘mobile platforms for computing and networking applications’.

Research conducted into the social impact of mobile phones has identified their multiple functionality—mobile phones are perceived as communication devices, but also as identity signifiers and fashion symbols. People can use them not only to communicate with their friends or relatives, but also to express their identity by choosing the color of phone or a specific ring tone. The mobile phone is considered by many people as a part of their personal identity (Hulme, & Peters, 2001).

Social research has emphasized that mobile phones force people to combine different aspects of their life, as for example when a person receives a call with a subject that is totally at odds with their physical situation. In such a situation the mobile phone user looks embarrassed and ill at ease, and often she or he tries to find an isolated place in which she or he can talk openly (Geser, 2004). Other people become experts in managing and dealing with the two conflicting situations simultaneously, for example riding a bicycle and taking at the same a mobile call (Plant, 2001). From this perspective, mobile phone technology has blurred the boundaries between private and public space, creating situations in which the two co-exist and blend their characteristics (Geser, 2004).

The use of mobile phones changes the social relations among people, and the positioning of a person both towards

close friends and relatives, and toward other citizens. It is easier to contact a friend who has a mobile phone anytime of the day, but on the other hand, the mobile phone might increase the isolation of an individual in a crowd, because s/he will be less inclined to ask information or help from a passerby. As a consequence, mobile phone users might lose some essential social skills, such as their capacity to communicate with strangers (Fortunati, 2002).

Despite the increased interest about the privacy problems raised by mobile phones, most of the existing studies attempt to investigate only one specific privacy issue (Hulme & Peters, 2001; Kindberg, Spasojevic, Fleck, & Sellen, 2004; Minch, 2004), without attempting to provide a clear general overview of the perceived privacy threats. This study attempts to fill this knowledge gap, presenting the results of an empirical research about the perception of privacy problems in two groups of respondents—owners and non-owners of mobile phones.

PRIVACY RELATED TO MOBILE PHONE USAGE

Privacy was constantly considered a central issue in relation to the use of information and communication technologies. However, its meaning has evolved in direct relation to the social transformations determined by the evolution of technology. Palen and Dourish (2003) have analyzed the issue of privacy within a networked environment, using the theoretical framework developed by Altman. Altman (1975, 1977) argues that privacy is not a fixed and immutable concept, but represents a selective control of access to the personal self, regulated through a process of dialectic and dynamic boundary regulation. For Altman, privacy does not simply mean avoiding information disclosure, but rather a selective disclosure of personal information which permits reconciliation of the desire for a private life with the maintenance of an accepted social persona.

The realization and maintenance of this equilibrium between private and social spheres are increasingly complex in a networked society, in which the very existence of a person is linked to some form of information sharing. The extreme case of total privacy control will imply an asocial life, which rejects not only the disadvantages but also the advantages of communication and social involvement.

The case of mobile phones is rather symptomatic for this situation: the use of mobile phones provides clear personal and social advantages, together with a series of threats and problems concerning the management of personal information. The solutions to these privacy issues should be identified and applied intelligently in order to eliminate or reduce the problem, but also to maintain the advantages offered by mobile communication and computing.

The first logical step in solving mobile phone privacy problems is to identify the range and intensity of these issues. The studies investigating these dimensions are few and dispersed, usually presenting a theoretical framework for mobile phone privacy issues, which is often unsupported by empirical evidence and data analysis.

In relation to the use of mobile phones, previous studies' threats have identified the following privacy issues for mobile phone owners and/or for the people from their entourage: (1) location tracking (Minch, 2004); (2) mobile phone conversations that are heard by other people (Geser, 2004); (3) data interception by governmental authorities (Richtel, 2005); (4) data interceptions by third parties—spywares (Evers, 2006); (5) the noise of ring tones and mobile phones conversations (Geser, 2004; Plant, 2001); and (6) the use of mobile phones to take pictures (McLeod, 2003).

In order to identify the perceptions of people regarding these privacy issues, a short face-to-face interview was applied to two groups of people, one comprising mobile phone owners (56 people) and another formed by people who do not own a mobile phone (22 people). The interviews took place between April and June 2005 in Montpellier, France, and lasted about 15 minutes. The respondents were asked to rate the importance they attach to various mobile phone-related privacy issues on a scale from 0 (no importance) to 10 (very high importance). The questions focused on the six main privacy issues already identified in the literature, but at the end an open question was added, asking the respondents to specify any other perceived privacy threat related to mobile phones.

The positioning map reproduced in Figure 1 offers an overview of the number of people concerned about a certain privacy issue and of the intensity of their concern, allowing also an easy comparison between mobile phone owners and non-owners. The numbers before parentheses represent the code of the privacy issue being identified and considered by respondents, while the numbers within parentheses represent the number of people from each of the two groups that have indicated a specific privacy issue as important. Finally, the position of each group of symbols indicates the mean importance of each privacy issue calculated on the basis of the importance levels provided by the respondents (from the two groups) who considered the privacy issue as being relevant for them.

Some of the respondents from the non-owners' group have indicated an additional privacy concern, which, in some respects, can be considered as a derivation of location tracking privacy threats, namely availability. These respondents indicated that the ownership and use of a mobile phone directly indicate the availability to be contacted by various people and organizations, contacts that can impact on the structure and content of your private life, and which, in some cases, can restrict your personal privacy. This concern is a good illustration of the fear of conflict between the private

Mobile Phone Privacy Issues

Figure 1. The spatial representation of various mobile phone-related privacy issues, and of their importance for owners and non-owners of mobile phones

and the public spheres (one respondent gave the example of receiving a mobile phone call while seeing a good movie at a cinema), which forces the user to re-adapt quickly to the requirements of the ‘other sphere’ and neglect the actions/circumstances in which s/he is involved at that moment. The fact that a number of non-owners have indicated this as a fairly important issue may indicate this as a potential reason in their decision to not own a mobile phone device.

It is also interesting to note that the distribution of answers provided by the members of the two groups is clearly different in terms of the perceived importance of various privacy issues. Overall, the non-owners of mobile phones perceive the privacy-related problems as more important than the group of mobile phone owners. The only exception is the issue of ‘data interception by third parties using spywares’, in which both groups give a high score (8.1 by owners of mobile phones, and 9.2 by the non-owners). The more negative perception of the non-owners group can represent a certain bias in their judgment of the privacy risks of using a mobile phone—a bias which may have prevented them from using a mobile device.

FUTURE TRENDS

The future development of information and communication technology and applications clearly indicates that the privacy-related issues will continue to represent an object of debate. On the other hand, the concept is expected to evolve, in line with the social and technological changes in the society and in people’s lifestyles.

The future evolution of mobile telephony and the privacy issues related to the use of mobile phones can be analyzed from three inter-related perspectives: technological, social, and legal.

From a technological point of view, the miniaturization of mobile devices and the integration of multiple functionalities and applications will probably continue. Mobile phones will represent the basis for the new concept of ubiquitous computing. The communication will take place not only between people, but also between humans and intelligent software applications, or through digital intelligent agents that will be stored in the computing devices dispersed in the environment. The main problem related with this technological trend is the need to improve computing and information transfer security. With personal communication flowing among various computing devices, the risk of data interception will be multiplied; therefore better firewalls and encryption programs will have to be implemented. On the other hand, as voice recognition applications will be gradually introduced, biometric security tests based on voice profile will complement the present system of personal passwords. Personal intelligent agents will have the capability to dynamically negotiate the privacy levels offered by various software applications, using the elements provided by their users.

The social landscape of mobile communication will be influenced by the principles of the networked society. The non-owners of mobile phones will limit their capacity of interacting with various computing devices that provide useful services and information. They will be able to preserve their personal privacy, but only with the cost of being discon-

nected from the digital social network. On the other hand, the present problem of having the personal or social space invaded by other people who use their mobile phones will continue, although new solutions can be found to alleviate the discomfort (e.g., the replacement of ring tones with more discrete methods to indicate an incoming call).

Some sociologists (Geser, 2004; Plant, 2001) believe that the increased use of mobile phones will accelerate the dissolution of the traditional family. Using mobile phones, the members of a family will be able to communicate easier with their closer or distant relatives, but on the other hand, they will develop an independent communication network, linking with friends and participating to spatially dispersed communities of interest. Nowadays children already use mobile phones as an expression of their communicational independence, because the personalized number allows them to reduce the transparency of their communication networks to parents.

Finally, at a legal level, the use of mobile phones and the privacy problems developed in relation to this use often determines the introduction of new legislation, which has a large potential impact on all forms of communication. Following the introduction of digital cameras in mobile devices, and some serious offences against privacy, Victoria and Western Australia introduced new surveillance devices legislation that restricts how photographs of private activities may be taken and/or used. Many voices have even asked for bans on the use of phone-cameras, but any wrong initiative can have an impact not only on the use of mobile phones, but also on the way information is transmitted and used. For example, the way in which the press is taking and using pictures of people and events can be fundamentally transformed by such legal initiatives (McLeod, 2003).

In many countries, restrictions have been imposed for the use of mobile phones in specific places. Trains in Britain, Japan, Switzerland, and the U.S. now have quiet carriages; and restaurants in cities as diverse as Cairo and Chicago have introduced 'no-mobile' policies, or 'mobile-free' zones in order to protect the privacy and personal space of their customers (Plant, 2001).

In other situations, governments have attempted to introduce legislation that permits the police or the security forces to intercept and analyze mobile phone conversations in order to prevent criminal or terrorist acts (Perera, 2001). Although the legislative bodies have sometimes approved such legislative initiative, the measures have been received by the population with an increased concern regarding the limitations of personal privacy (Richtel, 2005).

The regulation of mobile phone use will continue to evolve, illustrating the conflict among the free use of mobile phone technology, the requirements for personal privacy, and the governmental surveillance for crime prevention purposes.

CONCLUSION

This article attempted to present a general overview of the main privacy issues raised by the increased use of mobile phones in modern society. Both the examples and the empirical study provided in this article indicate that mobile phone privacy-related problems are complex and multifaceted. The large-scale introduction and use of mobile phones change the way in which people and institutions interact, and modify accordingly the relation between personal and private space. The solutions to the privacy problems introduced or aggravated by the use of mobile phones cannot be rigid and final, but should rather be formulated as a personal attempt of every individual to dynamically balance his/her needs of privacy with the need to participate in networked social interactions.

KEY TERMS

Biometric Security: A security science where body or physical attributes are used for secure identification and authentication, such as fingerprints, voice patterns, face geometry, hand geometry, retinal scans, signatures, and typing patterns.

Hacker: Individual who gains unauthorized access to computer systems for the purpose of stealing and corrupting data.

Intelligent Agent: A specialized software application that automatically collects information or performs another specific task on behalf of a person or a software program.

Location-Tracking Application: A virtual software application that permits third parties to identify the location of mobile phone users/owners.

Position-Aware Mobile Device: Information technology tools that are capable of defining their spatial location.

Spyware: Any technology that allows third parties to collect information about a person or organization without their knowledge and permission.

Ubiquitous Computing: A new information technology paradigm that attempts to integrate computation into the environment, rather than using computers that are distinct objects.

Mobile Phone Texting in Hong Kong

Adams Bodomo

University of Hong Kong, Hong Kong

INTRODUCTION: TECHNOLOGY AND LANGUAGE CHANGE

Mobile phone texting or communication through *short message service* (SMS) has emerged as a frequent daily linguistic, literacy, or general communicative practice in which two or more people exchange messages by coding and decoding texts received and sent from their cell phones. Mobile phone texting is almost now as pervasive and as ubiquitous as mobile phone voice communication. This communication process can be witnessed in buses, at homes, in offices, in restaurants, out in the woods, on the high seas, and even in the air! Hong Kong's main English language newspaper, the South China Morning Post (SCMP), on April 11, 2004, indicated that as huge a volume of 200 million SMS messages are exchanged monthly. SMS has become a multi-million dollar business for service providers.

Along with other kinds of digital technology-mediated communication, SMS seems to be causing a silent revolution with regards to the linguistic and communication habits of people in Hong Kong and beyond. This is especially so among the youth where one can safely say that more than 80% of people between the ages of 12 and 25 frequently use SMS as a mode of communication with their peers.

Given such a huge impact that this mode of communication has on the population, researchers and policymakers ought to turn their attention to this topic and attempt to find answers to questions about the consequences of SMS on various issues including language, communication, and our general social behaviors.

In this article, we focus on the relationship between communications technology and language change. Does the emergence of these new communications technologies affect our language and communication habits? Does it change our language, bringing in new words and structures of expressions, and does it alter our general communication patterns? In short, is technology changing our language?

In examining these questions, based on observation and analysis of issues of language, literacy, and communications technology, we propose a model called *technology-conditioned approach to language change and use* (TeLCU). This approach projects the view that there is a causal relationship between the emergence of new tools and media of communication and the creation of new forms of language and communication. New tools and media of communication

demand the creation of new forms and ways of communication. These new forms compete with existing forms and ways of communication, leading to changes in the way we use language in its various forms, including spoken and written forms.

A potential anti-thesis to TeLCU is that there is little or no causal relationship between the prevalence of new media of communication and changes in the forms of language and ways in which we use human language. While not directly arguing against the idea that there is no causal relationship between the emergence of new technology, in general, and the new ways in which language is used, Kress (1998), for instance, observes that "... when we look at the far-reaching and deep changes in forms of communication which characterize the present-day e-mail and its changing forms of language, for instance, it is tempting to attribute these changes to some technological innovation but erroneous to do so" (p. 53). Luke (2000) also takes a similar position, believing that new forms of literacy practices do not simply emerge with technological change. Rather, "technologies always emerge as products of specific cultural practices, literate traditions, and the interests and desires of those groups who design and name them" (p. 83).

This article builds on this fruitful discussion in the literature on the relationship between new technologies and the way language is used within these technologies, and argues that there is indeed a significant causal relationship between communications technology and new language and communication practices or more specifically the evolution of new ways of using language. As Adams (1996) puts it, "the new technologies are themselves dramatically changing the nature of the language we use." Such an approach is also supported by Baron (1984), who concludes that "[n]o one in the computer industry has any hidden agenda for using hardware or software development to alter human language. Yet technology can indeed drive linguistic and social change" (p. 139).

Indeed, new practices of language and communication may be attributed to a set of unique properties in new communications technology. Modern digital communications technology is characterized by flexibility, connectivity, and interactivity (Blurton, 1999) that traditional forms of technology like radio and TV lack. In other words, it is possible to have many-to-many, many-to-one, one-to-many, and one-to-one modes of communication with modern digital

information and communications technology (ICT). These features of digital ICTs enable them to have a more pervasive influence on forms and uses of language.

In pursuing these questions and research agenda, this article is organized as follows. After giving background statistics and other kinds of information about the evolution of SMS, we introduce and describe our data which comprise a corpus of about 500 SMS messages collected from Hong Kong youth in April 2002. Following this, we introduce the theoretical model of TeLCU, sketching out the ways in which we believe new technologies affect our language structure and use. We then look closely at the linguistic features of the corpus, noting peculiar instances of structure and usage. The article concludes with an outline of the implications for these linguistic and communicative changes in our society with particular reference to social and educational habits, and consequences for the design of new tools of communication.

THE DATA: SMS CORPUS¹

What is SMS?

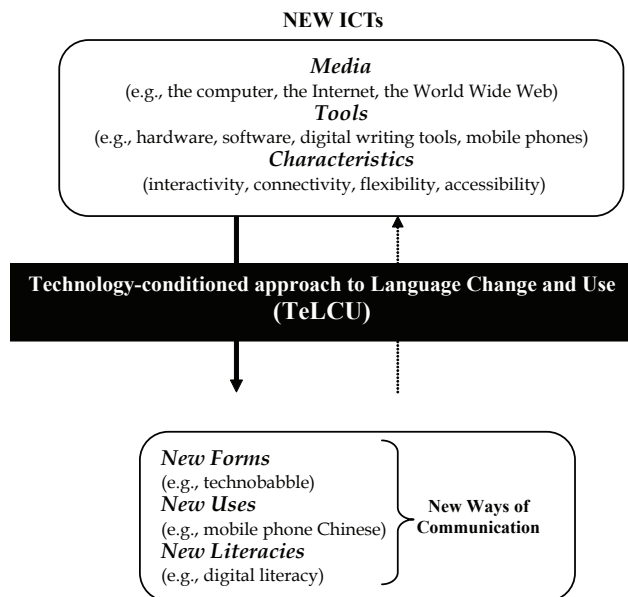

Short message service, first introduced commercially in 1995, refers to the transmission of short text messages between mobile phone users. The first SMS message was a Christmas

greeting sent out in Britain in 1992. Today, SMS has emerged as one of the major digital communication media, with an estimation of over one billion messages exchanged per day around the world. SMS had a slow beginning in Hong Kong, mainly because of the inconvenience of inputting Chinese characters with mobile phone keypads. In addition to that, text messages could only be exchanged between subscribers of the same service provider. However, the SMS market has grown rapidly in Hong Kong. In December 2001, the six major service providers opened their networks to allow message exchanges across networks (SCMP, 2002). As of April 2004, over 200 million messages are exchanged every month in the territory.

Data Collection

The collection of textual data began with a questionnaire survey conducted in April 2002. The target subjects of the survey were Cantonese-speaking youngsters in Hong Kong who use English as a second language. Since text messages involve private correspondences, prior permission was sought from the data providers. At the end of the questionnaire, the respondent was asked whether he/she would be willing to make his/her SMS texts available for the study. The study (Bodomo, 2001-2002) successfully collected 487 messages from 87 out of the 92 respondents who participated in the questionnaire survey. Data providers were asked to write

Figure 2. TeLCU—The relationship between new ICTs and new forms of language and literacy

down at least five messages that were already stored on their mobile phone message in/outbox on a form provided by the investigator (see Figure 1). Since the texts were collected from end users, the corpus may also include messages sent from a non-mobile device/tool, such as ICQ.

THE MODEL: TeLCU

In this section, as discussed earlier, we propose a model called *technology-conditioned approach to language change and use*. We suggest that there is a causal relationship between the emergence of new tools and media of communication in our society and the use of language.

New technologies often require new forms of language and literacy to express new concepts that emerge along with these new media and tools. New media of communication, then, can lead to changes in the way people use their language. In fact, works like Lakoff (1982) and Ong (1982) have discussed the impact of oral media like TV and radio on people’s use of language.

The information age is characterized by the rapid advancement of technology, with the introduction of new tools and media. Among these, ICTs constitute the type of technology that this article is concerned with. ICTs, according to Blurton (1999), are characterized by flexibility, connectivity, and interactivity, which are different from passive, one-way media such as TV and radio. These distinctive features of ICT tools and media allow pervasive changes in language forms

and uses. Apart from these, we believe that the popularity of a particular tool or media can also be a major factor in the discussion of how new ICTs introduce new forms and uses of language. One might expect that the products of the TeLCU model (i.e., new forms of language and literacy) are gradable. That is, the more of the above features a new technology carries, the more likely new forms of language and literacy will be introduced, and the more widespread these new forms will be. Figure 2 illustrates the cause-and-effect relationship between new digital ICTs and new forms of language and literacy.

In this model, we show that new ICTs include all the tools and media along with a bundle of features that act as the ‘inputs’ of this model. These features undergo the main process, TeLCU, and new forms of language and literacy are then generated. This is indicated with the downward arrow in the model. However, we do not eliminate the possibility of a ‘reverse’ process—that is, the possibility where new forms of language and literacy reinforce changes in new technologies. Hence, the upward arrow of the diagram illustrates this process. This process, nevertheless, cannot exist without TeLCU: new ICTs foster changes in language and literacy before new forms of language and literacy can have impact on ICTs.

The TeLCU model as espoused here is a specific model for a technologically deterministic approach to account for the linguistic and communication dynamics that are often observed in the environment of ICTs. As has been noted earlier, this technological determinism is not without its critics. Technological determinism is often juxtaposed with what is called socio-political determinism. Herring (2003) notes: “Many technologically deterministic claims regarding CMC, for example, have been found to make incorrect predictions in specific contexts of use, and a call has gone out for explanations of computer-mediated behaviour that take social and contextual factors into account” (p. 9). In response to this critical evaluation of technological determinism, we believe that there is hardly any need for this juxtaposition at all; indeed, the two approaches do not seem to be mutually exclusive, and certainly the TeLCU approach pursued here is not intended to exclude socio-political factors for language and communication dynamics in the age of IT. It may be true, for instance, that socio-political factors in Hong Kong such as a very high population density may force the youth of Hong Kong to constantly use mobile phone texting to sound each other out in busy malls and in large restaurants (as evidenced by the preponderant use of *nei5 hai2 bin1 aa3*, ‘Where are you?’ in both mobile phone voice and text messages); however, the crispness of the language they use would certainly be constrained by the technology available for decoding the messages.

Having introduced the theoretical framework of TeLCU, we shall discuss in the following sections some of the new forms of language and literacy under the influence of new ICTs.

LINGUISTIC FEATURES OF MOBILE PHONE TEXTING IN HONG KONG

As its name suggests, an SMS text message is indeed very short. It has to be short because users are constrained to input only up to 70 Chinese characters or 160 alphabetic letters. This also imposes some constraints on the basic structure of a message composed with the mobile phone. This section explores the various linguistic features identified in the corpus. The crisp nature of SMS language necessarily raises questions about its morphological and syntactic nature. Given a limited writing space and limited production time, there is logically more need to be as economical as possible than to be as elaborate/expressive as possible. In other words, a principle of economy outranks a principle of expressivity. The questions then are: How is this balanced out? What aspects of the morphology and syntax are retained, and what are given up? We here propose a general principle of economy and try to show how it generally manifests itself in SMS:

Technologically-Conditioned Economy of Expression

Words, phrases, and sentences should be coded with as few symbols as possible without giving up comprehensibility.

1. **Morphology:** Produce words as short as possible.
2. **Syntax:** Produce strings as short as possible.

Morpholexical Features: Shortening

We shall look at some morpholexical features in this subsection. While there are many morpholexical features of mobile phone texting that distinguish it from normal writing, we concentrate on the more salient feature of shortening. Shortening in ICT texts has been widely studied in the literature of computer-mediated communication (CMC). Scholarly research into SMS is still rare, and thus we have identified a set of shortened expressions in the corpus. We use the term here as a general cover word for the various strategies for shortening words, including acronymy, abbreviation, and so on. Table 1 is a list of common ways for shortening and abbreviating lexical items and the number of times this happens in the corpus.

The following example from the corpus illustrates the use of shortenings in the real messaging context:

r u 3 2nite? izit possible 2 hv dinner 2getda? call me (1)

Most (though not all) morpholexical items, as seen above, are thus produced in accordance with the economy principle: produce words as short as possible. We now turn to the syntactic aspects of the economy principle.

Syntax: Economy of Expressions vs. Expressivity

Although there exists a wealth of studies on the linguistic features of ICT texts, the aspect of *syntax* is rarely mentioned. This subsection is an attempt to take into account the syntactic nature of shortened expressions in SMS. The assumption here is that, in shortening a sentence, functional items such as tense and aspect are dropped, while lexical categories such as nouns and verbs are allowed to stay; in fact, this is more of a tendency than absolute adherence to the principle. So while in the morphology lexical items are more susceptible to reduction, in the syntax functional items are more susceptible to reduction or even dropping. Next we list each group of items likely to be retained or dropped.

- **What is retained**
 - lexical items
 - the most essential piece of information:
 - lunch? (2)
 - SLEPT? (3)
 - QUIZ (4)
 - exams finished la. now coming (5)
 - in ikea,thinking of u... (6)
- **What is left out**
 - Pro-drop
 - miss u terribly! wanna c u & hold u so much. (7)
 - will hv quite a bz wk. =((8)
 - MISS U VERY VERY MUCH DUNNO (8)
 - HOW TO TELL U (8)
 - Tense
 - YES I RECEIVE (9)
 - My friend ask me to go taiwan (10)

The above are ways in which mobile texters attempt to satisfy the principle of economy over and above that of elaborate expressivity.

Phonological Features: Homophony

Some interesting morphophonological and phonosemantic features also characterize the language of mobile texting. In this article, I will focus mainly on the concept of homophony. One of the creative practices of mobile phone texters (Bodomo 2002) lies in their ability to substitute shorter (forms of) words for longer words that are homophonous or near-homophonous. While there are not that many examples in this particular corpus, we have found a very interesting one:

3 for 'free' as in

r u 3 2nite? (11)

Here, the homophonous word *three* (its shorter form being the numeral 3) is used to represent *free*.

The Omission of Tone

Another of the crisp nature of mobile phone text is the explicit omission of tone markings in the Cantonese romanization. The Linguistic Society of Hong Kong (LSHK) has an elaborate romanization system, including tone markings², but this is hardly used in mobile texts. We list below a number of sentences showing various ways of romanization, especially in the rendition of final particles, which are very much a characteristic feature of the language of ICTs like mobile phone and ICQ texting (Lee, 2002a, 2002b).

exams finished la. now coming (12)

Where R U worry ar me (13)

Heavy raining wor... but u still need to go rite?
Be careful ar :p (14)

Romanization of Common Cantonese Expressions

Ai Ya... ho sun fu ar... the ref bk is very difficult...
can't understand a word ar! @-@ ho mun! (15)

Hey bei sum gei la... (16)

Lo lic... everything will be fine again (17)

Emoticonomy

Unlike face-to-face talk where emotions can be expressed visually (by facial expressions) or auditorily (by stress and loudness), text-based CMC mainly takes place without any face-to-face interactions between participants. Therefore, emotions are often expressed by graphical means. The introduction of the so-called *smileys* or *emoticons* has facilitated electronic communication to a large extent.

By emoticonomy, we mean “a subfield of CMC which involves the analysis and practices of employing smileys and related icons for conveying emotions and other linguistic and kinesic features intended by the author” (Bodomo & Lee, 2002, p. 35). Emoticons (emotional-icons) are also used to avoid misunderstanding in the interpretation of a message. For instance, a smiling face like :) is often used to indicate a joke or that the message sender is happy about something. Emoticons are usually placed at the end of a sentence, as in “I am so sorry :-(.” Most emoticons are created with different combinations of punctuation marks (colon and a closed bracket form a smiling face). This is further illustrated as follows:

Ladies hockey champion! Yeah >:D (18)

Tmr 記得 交essay ^v^ (19)

tmr gei3 dak1 gaau1 essay (20)

tomorrow remember submit essay (smiles) (21)

Don't forget to hand in your essay tomorrow. (22)

Mode-Mixing

Apart from emoticons, there also exist combinations of codes and symbolic systems in the messages. As Kress (2000) suggests, ‘The appearance of modes other than language in the centre of the domain of public communication has several aspects: new, or newly prominent modes appear: texts, textual objects are more clearly seen to be multimodal, that is, to be constituted by a number of modes of representation’ (pp. 183-184). So what is happening in SMS? In our corpus, we can identify a combination of words/letters and numbers, and graphic and alphabetic symbols. These are illustrated as follows:

- Words/letters + Numbers

r u 3 2nite? izit possible 2 hv dinner 2getda?call me
(Are you free tonight? Is it possible to have dinner together? Call me.) (20)

- Graphical + alphabetic

()”“()

(|’|o|’|)”)

(.) /

Happy New Year

(Punctuation marks to visualize ‘fireworks’) (21)

U :) = I :) U :(= I :(+ WORRY TAKE CARE

(When you're happy, I am happy too. When you are sad, I also feel sad and worried. Take care.) (22)

New Varieties of English

In this section we have examined specific features of written language on the mobile phone. The constraints of time and space force users to invent diverse and new ways of shortening or even leaving out entire words, and adding new signs and icons to make themselves comprehensible.

We believe that the media of the mobile phone and other ICTs, such as the ICQ that is popular in Hong Kong, are changing our language use in profound ways, and making Hong Kongers and the youth in other parts of world evolve different ways of using language. New varieties of written English thus seem to be evolving. This new variety involves a mixture of English and Chinese signs, characters, words, and expressions. Even though some features may seem spontaneous and playful at first glance, some features and patterns are used quite consistently and repeatedly by different users. Indeed, these new varieties of written English are finding their way into school writing and are the source of worry for school teachers, but this is the topic for another study (Bodomo, 2002).

SUMMARY AND CONCLUSION

In this article, we have attempted to take stock of language structure and use within the technological environment of new media of communication such as the mobile phone. Drawing from different arguments and points of view within the literature, we have highlighted the important debate as to whether the linguistic and communicative transformation that we are witnessing is one of *technological determinism* or *social determinism*. The position espoused in this article is that while technological determinism cannot be divorced from social determinism, one has to tease out the two and look concretely and specifically at the immediate ways in which language functions and changes in the environment of new ICTs. We have proposed a specific technologically deterministic model known as TeLCU. As has been proposed, users of language are forced to abide by a quite stringent *economy principle* in mobile phone texting. This has resulted in different ways of experimenting with language structure and use—phonologically, morphologically, and syntactically. The attendant innovations at these various levels of linguistic analysis seem to be creating new varieties of language and new ways of communicating.

Modern ICTs such as computers, the Internet, and mobile phones seem to be profoundly transforming our language structure and general communicative patterns so much so that linguists and other language and communication professionals who turn a blind eye to this (r)evolution risk being accused of professional negligence.

KEY TERMS

Digital Literacy: “The ability to understand and use information in multiple formats from a wide range of sources when it is presented via computers” (Gilster, 1997, p. 1).

Hong Kong ICT Corpora: Developed at the University of Hong Kong, the Hong Kong ICT corpora is a database of texts collected from various modes of ICTs, including computer-mediated communication such as ICQ and e-mail, and mobile phone texting.

Information and Communications Technology (ICT): The use of technology to communicate and process information.

Literacy: The ability to code and decode linguistic and other symbolic systems for communication and information processing (Bodomo, 2000).

Mobile Phone Texting: The transmission of short text messages between mobile phone users.

Short Message Service (SMS): See *Mobile Phone Texting*.

Technobabble: A language characterized by the pervasive use of technical jargon, or a speech or a piece of writing characterized by the pervasive and extreme injection of technical jargon to the extent that the language is barely comprehensible to non-specialist speakers of the particular language.

Technology-Conditioned Approach to Language Change and Use (TeLCU): The central claim of TeLCU is that there is a causal relationship between the introduction of new tools and media of communication and the emergence of new forms of language and communication.

ENDNOTES

- ¹ This SMS corpus is part of the Hong Kong ICT-corpora (Bodomo, 2000) developed at the University of Hong Kong. Some texts of the corpora are available online from <http://www.hku.hk/linguist/research/bodomo/QEF/>
- ² Tones in Cantonese are marked as follows: Tone 1: high level, Tone 2: high rising, Tone 3: mid level, Tone 4: low falling, Tone 5: low rising, and Tone 6: low level.

Mobile Phones for People with Disabilities

Hend S. Al-Khalifa

Southampton University, UK

AbdulMalik S. Al-Salman

King Saud University, Saudi Arabia

INTRODUCTION AND BACKGROUND

Nowadays, the demand for mobile phones by people with special needs is evolving. Disabled people can utilize mobile phones for personal communication, security, social integration, and autonomy. Personal communication is one of the most important reasons that disabled person uses a mobile phone. For example, people with motor disabilities cannot easily reach the wired telephone within a limited period of time when it rings. Security is another reason that most disabled people strive for. In case of emergency, illness, or accident, mobile phones are considered a fast communication channel. Furthermore, to keep in touch with society and to feel autonomous, people with special needs think that the mobile phone is a good medium for social integration and self-independence (Abascal & Civit, 2000).

Enrico and Stephen (2003) stated that mobiles could also be used as an aid to carry out everyday activities, as though they were not disabled—for example, using the mobile phone to remotely instruct PCs, lifts, doors, and ATMs. Abascal and Civit (2000) emphasize Enrico and Stephen's (2003) argument on the use of mobile phones to control other devices by saying “with the emerging Bluetooth standard, a user will be able to use her/his mobile phone controlling it from any other device including not only PDAs and notebooks but also Assistive Technology devices such as communicators and wheelchair controllers” (Abascal & Civit, 2000, p. 264).

Common problems of existing mobile phones arise from small print on mobile phone controls and screens, hard-to-press buttons, complexity of use, no audio battery limit indicator, no caller identification, and no specially designed keys for emergency and easy access to specific functions (Lee, 2003). Another problem is the limitation of some software programs that only work on specific phone brands and operating systems. Also, there is no standardization between mobile phone companies in terms of design and functionality. Furthermore, as stated by Baker and Bellordre (2004), the barriers to access/use of mobile phones can be classified into three factors: awareness and proficiency factors, economic barriers, and incompatible technologies. Therefore, the lack of standardization imposes the proposal of strict rules and regulations for designing accessible telecommunication devices by the Federal Communications Commission (FCC); these

rules are called “Telecommunications Act of 1996, Section 255” (Chen, 1999; Telecommunications Act of 1996¹). The FCC has rules requiring telecommunications manufacturers and service providers to make their products and services accessible to people with disabilities, if readily achievable. These rules implement Section 255 of the Communications Act. Where it is not readily achievable to provide access, Section 255 requires manufacturers and providers to make their devices and services compatible with peripheral devices and specialized customer premises equipment that are commonly used by people with disabilities, if such compatibility is readily achievable.

Finally, many disability-centered organizations worldwide perform regular reviews and tests on the latest mobile phones in the market and publish the result online for free. As an example, *Accessworld*, a publication of AFB (American Foundation for the Blind), is carrying out regular mobile phone reviews and evaluations to test the accessibility and usability of several off-the-shelf cellular telephones and add-on software applications. These reviews can be accessed online at <http://www.afb.org/>.

TECHNOLOGIES, SERVICES, RESEARCH, AND PROJECTS

Using mobile phones is challenging for the movement impaired and physically challenged, the blind and visually impaired, the elderly and arthritic, and those with any of many immune and neuromuscular disorders. In order to make mobile phone technology accessible for those people, this may require augmentative communication devices with expensive customized hardware and software interfaces to support their interaction with mobile phones. Moreover, there is a need for a standard universal design of cell phones that includes features such as infrared ports, volume range, speakerphones, matrix displays, EZ buttons, voice dialing, and messaging (Bryen, 2004). Also, there are many services and much research currently taking place to bridge the gap of the mobile divide. In this section, we will present the various trends and technologies that are developed to help people with special needs cope with the new stream.

Figure 1. Owasys 22C mobile phone

Figure 2. ALVA MPO

Technologies

Technologies used in mobile phones can be classified into three types: software technologies, which will handle all aspects of integrating software functionality into a mobile phone; hardware technologies, which will focus on the different devices that can be added to a mobile phone to make it more accessible and the variant kinds of newly designed mobile phones devoted for the use by people with special needs; and hybrid technology, which combines both software and hardware into a single device.

Software Technologies

Most mobile phones that operate using the Symbian operating system can easily install third-party software like screen readers and screen magnifiers, which provide further accessibility to mobile phones. On the other hand, off-the-shelf mobile phones have limited speech output capabilities (Burton, 2005). In this subsection, we provide the reader with accessible software applications that work on Symbian-based mobile phones.

SpeechPAK TALKS is a product from ScanSoft² Company. It converts the display text of a cellular handset into speech, making the phone accessible for visually impaired people. *SpeechPAK TALKS* runs on Symbian-powered mobile phones. It speaks to the user either in English, German, or another language. The user can change ring tones for different callers, check who dialed the number, hear spoken voice messages, write and send an e-mail or a fax, and manage PDA functions. A portable Braille display can also be attached.

*Mobile Speak*³ is another screen reading software that can be installed on a mobile phone. It is available in many languages including Arabic.

*Talks*⁴ is also a screen reader for mobile phones. It supports Arabic and English languages. A trial version of this software is available through the Internet.

*Mobile Magnifier*⁵ is language-independent software that enlarges and enhances all items of the mobile phone display. It provides six different color schemes (from black and white up to 4096 colors). *Mobile Magnifier* automatically detects and magnifies the area of interest as the user

navigates through the phone's user interface. It supports a range of mobile phone brands like Nokia and Siemens.

*The vOICe MIDlet for Mobile Camera Phones*⁶ is seeing-with-sound technology for the totally blind. It is available for most camera phones and PDAs. The *vOICe MIDlet* software runs on both Symbian and non-Symbian devices, and it is free of charge and can be downloaded from the Internet.

*Mobile Color Recognizer (MCR)*⁷ is software that was developed to work with *Mobile Speak* and *Mobile Accessibility*. It can be installed in camera phones that are Symbian compliant. *MCR* can be used to determine the color (or different colors) of an object by taking its picture. *MCR* also can be used to know the level of light.

Hardware Technologies

Many major telecommunication players in the market have a department devoted to accessibility research. Nokia, Sony Ericsson, and Samsung, to name just a few, are all working on making their products more accessible for various types of disabilities. In this subsection, we provide the reader with accessible hardware technologies that can be used as a replacement/companion to a mobile phone and are tailored to the needs of a person with a disability (i.e., blindness, deafness, or motion impairments).

*Owasys 22C phone*⁸ (Figure 1) is a cell phone that is designed specifically for blind and partially sighted people. The phone does not include a visual display; instead it uses speech synthesis technology to read everything that would normally appear on the screen. It has an ergonomic design with tactile keys. It also has a dedicated key to access the phonebook and an information key that verbalizes the user position within the phone's menu system. It gives audio feedback from the press of a button.

*ALVA MPO*⁹ (Figure 2) is a Braille-based mobile phone. Besides making calls using the phone, it also has many integrated functionalities like a text-to-speech engine, organizer, and note-taker.

*Mobile Screen Magnifier*¹⁰ (Figure 3) is a piece of a magnifier lens that is placed on top of a mobile display to magnify the text displayed on the screen up to 100%.

Voice activation/recognition is built into most mobile phones. A blind person can activate the mobile phone by dictating commands. Yet, a major disadvantage of this

Mobile Phones for People with Disabilities

Figure 3. Mobile screen magnifier

Figure 5. Mobile phone attached to TTY device

Figure 4. From (a)–(d): Nokia Loopset, SonyEricsson Handset Adapter, HATIS, and HITEC

functionality is the interference of the background noise and the battery power requirements. The Samsung P207 phone is a new phone that uses voice-recognition technology to allow users to create text messages by simply speaking into the phone.

Most telecommunication companies like Nokia and SonyEricsson have designed some of their mobile phones with a feature of amplifying or attenuating the sound frequency and volume to fit the hearing-impairment needs—that is, *adjustable audio*. Such phones, like the Nokia 3300, have this built-in feature.

Almost all mobile phones in the market have some sort of vibrating sense and flashing displays feature for helping hearing-impaired people to have some kind of *tactile and visual feedback*.

*Hearing accessories*¹¹ (Figure 4) include, for example, Loopset, which is a special device that someone can wear around his or her neck with built-in microphone for hands-free operation. It prevents the mobile phone from interference with the hearing aid used by hard-of-hearing people. Another accessory from SonyEricsson is the cellular phone handset adapter that links mobile phones with 2.5mm jacks to any TTY/TDD that has acoustic cups. HATIS (Hearing Aid Telecommunications Interconnect System) from SonyEricsson is another accessory that includes a silhouette induction loop that connects with a T-Coil in a hearing aid. It also includes a throat microphone that helps hands-free operation. In addition, the HITEC under-the-chin binaural headset works in a similar way as HATIS, with binaural

sound for improved hearing and a microphone incorporated into the “Y” junction.¹²

TTY¹³ (Figure 5) an acronym for teletype (also known as Telecommunications Device for the Deaf or TDD device). It is a special teletypewriter device with a screen to display typed text electronically that is connected to the mobile phone to type and read the conversation during a call, rather than using speech and hearing. Furthermore to benefit from these devices there must be telecommunication relay services (TRS is an operator service used by deaf persons and those with other hearing difficulties, to allow them to place telephone calls as voice messages by a TRS operator, and vice-versa) that support this technology.

Another available hardware technology is the *snap-on/wireless keyboard*¹⁴ (Figure 6). Nokia wireless QWERTY keyboard is a small, foldable, lightweight keyboard that operates using A3 batteries. It is designed for disabled people who find pressing the buttons on the mobile phone awkward. A similar product is the Sony Ericsson T28 snap-on keyboard (Figure 6).

Hands-free accessories (Figure 7) are usually used by car drivers to make driving safer. On the other hand, people with motion impairments can benefit from such a technology.

The *voice-activated communication system*¹⁵ Liberty Bell VAS allows individuals with minimal or no use of their hands the ability to communicate without any assistance. The user may initiate a call and answer a call, as well as adjust the volume simply by speaking into the mobile phone.

Figure 6. Nokia Wireless keyboard (left) and Ericsson T28 with an attachable QWERTY keypad (right)

Figure 10. Ubinetics GC201 GSM PCMCIA phone card for laptops

Hybrid Technologies

Hybrid technologies are those technologies that integrate both hardware and software on the same device and designed for the people with special needs. This subsection lists some of these technologies.

*RNID Mobile TextPhone*¹⁶ (Figure 8) is a combination of the Nokia Communicator 9210i and RNID's (the Royal National Institute for the Deaf's) mobile textphone software. The device enables deaf, hard of hearing, or speech-impaired people to make or receive telephone calls in text format.

The *BlackBerry 7290 Wireless Handheld*¹⁷ (Figure 9) is a mobile phone with many advanced features like e-mail,

SMS, Bluetooth support, and organizer applications. Also, it has an integrated QWERTY keyboard. This device is capable of communicating with TTY or TDD terminals.

The *Ubinetics GC201 GSM PCMCIA phone card for laptops*¹⁸ (Figure 10) can help a disabled person to deal with laptops instead of mobiles. Therefore, he/she can make calls; send and receive e-mails, faxes, and SMS messages; as well as browse the Internet. This card is a dual-band GSM Type II PC card, supporting voice, data, fax, and SMS. It can be used within any laptop that has a PC card slot and supports MS-Windows.

SERVICES

Many telecommunication companies support a wide range of services to help people with special needs cope with the digital divide. TTY, GPS, SMS, MMS, WAP, and mobile e-mail are types of services that can be used by both regular people and those with special needs (Høeg, Rasch, Ruud, Jynge, & Zäll, 2004).

TTY service is devoted mainly to deaf people. To benefit from this service, four groups are responsible for making TTY service worthwhile: the wireless network provider in a country, the mobile phone manufacturers, wireless service providers who provide the connection between the mobile phone and network system, and the TTY manufacturers who modify their TTYs so they can work with the handsets (Harkins & Barbin, 2002).

Mobile phones that are equipped with built-in or external GPS (global positioning system) receivers can pick up navigation signals from satellites and convert these signals into an accurate position in the phone (Makino, 1996). By calling the phone, its position is returned to a control center, where the exact position of the phone can be detected. The Nokia 9210/9210i with GPS module is equipped with a graphic color screen that shows the user's position. This type of phone is ideal for wheelchair users and others who need to call for help and tell people exactly where they are. Moreover, these phones can be used as a personal safety alarm (Høeg et al., 2004).

SMS (short messaging service) is a service for sending and receiving text messages on all modern mobile phones. A new trend is to use a phone with predictive text. This service is called T9.¹⁹ This means that the phone 'guesses' which word the user is trying to type, which can make it easier and faster to use. This service is useful for deaf and motion-impaired people.

MMS (multimedia messaging service) is similar to SMS; it allows sending text, speech, images, sound, and video clips from one mobile to another. MMS also supports e-mail addressing, so that messages can be sent by e-mail. A mobile phone with WAP facility enables accessing information and services stored in WAP format on the Internet (Høeg et al., 2004; Ovum²⁰).

WAP (wireless access protocol) is designed to access the Internet from mobile phones and PDAs using wireless communication. The use of the Internet is expected to increase rapidly even among disabled and elder people (Abascal & Civit, 2000).

MobileMail, a type of *mobile e-mail*, can be accessed via the Internet, WAP, SMS, or a mobile answering service. MobileMail can be printed out as a fax, or read out from the mobile answering service (mobile answering service e-mail). When activating the mobile answering service e-mail, the entire e-mail can be read out, including the sender name and the subject (Høeg et al., 2004).

RESEARCH AND PROJECTS

Since the introduction of mobile phones, many research and projects were conducted to potentially benefit from the different features a mobile phone can provide (Fernandez & Roa, 2003). As an example, in Japan, Katuhiro and Iwao (2004) from Tokyo Gakugei University, used a mobile video-phone to deliver e-learning service for a student with severe physical impairment. Also, Fujitsu's company designed an easy-to-use mobile phone with a universal design and user-friendly interface that makes full use of speech synthesis and voice recognition technologies. The phone is called Raku Raku PHONE and is dedicated for elderly persons, persons unfamiliar with mobile phone operation, and persons with physical disabilities, for example, persons with visual disabilities (Toru, Keigo, & Yukinori, 2005).

In Slovenia, a project called GOVOREC is a system to automatically convert any Slovenian text into speech. "Currently, several leading Slovenian telecommunication companies are testing the system for providing information (e-mail, short messaging service—SMS, weather reports, traffic information) through mobile phones" (Sef & Gams, 2003, p. 227).

In the United States, "Mobile Wireless Technologies for Persons with Disabilities," a dedicated center at Georgia Institute of Technology, has been established to design wireless aids that target different disabilities, including mobility, vision, and hearing. It also tries to influence wireless-device manufacturers to make their existing products accessible to disabled people (Anonymous, 2004).

In Finland, there is ongoing research by VVT Institute about using video messaging as a way of communication. Kasesniemi, Ahonen, Kymaelaeninen, and Virtanen (2003) state that video messaging was the first possibility for the deaf to use signing in mobile communications, in their own language.

In Spain, the CONFIDENT project, partially funded by the European Commission, is a system to support disabled people managing their daily life by means of IT-based services. The platform of the system is based on the so-called "access from anywhere paradigm" and is built on a distributed and collaborative architecture based on Web services. This structure provides secure access to a service network from various devices for people with special needs (Cabrera, Arredondo, & Villalar, 2004).

In Europe, a consortium of researchers from Germany, Spain, Sweden, and the UK are working together on a project called WISDOM (Wireless Information Services for Deaf People on the Move). This project will enable hearing-impaired users to call up news, weather, and sports information in sign language from a video server via 3G (third-generation) phones, give commands to their phones in sign language, and access a real-time interpretation service to aid them in communicating with hearing people (Britta & Karl-Friedrich, 2001)

Much research has been conducted to discuss mobile phone design issues for people with special needs. As an example, Smith-Jackson, Nussbaum, and Mooney (2003) developed and used a framework called NARA (needs analysis and requirements acquisition) based on the universal design principles, to help suppliers and telecommunication companies construct mobile phones tailored to the requirements of people with disabilities.

The largest obstacle to mobile phone use by people with severe disabilities is the lack of a suitable interface system that would allow the user to operate the phone. Building interfaces to make mobile phones more accessible is another important theme that the augmentative and alternative communication (AAC) research project is tackling. The research is trying to build an interface system that bridges the gap for AAC device users and their mobile phones. A prototype interfacing system was demonstrated at the Australian Rehabilitation & Assistive Technology Association National (ARATA) Conference 2004 (Nguyen, Garrett, & Downing, 2004)

A personal navigational aid attempts to address many of the problems faced by persons who are blind. This aid incorporates many of the features of a PDA, cellular phone, wireless Internet access, and GPS (Szeto, 2003).

Finally, many guides have been compiled to help disabled people choose the suitable mobile phone with accessibility features; examples include those by Høeg et al. (2004) and Nguyen (2002).

CONCLUSION

As new technologies emerge and as the number of users grows, it is incumbent on technology developers to enhance their systems to help people with disabilities. One of the most important technologies in this respect is the mobile phone. There are many international worthwhile efforts to enhance the use of technology to people with special needs. This survey shows the great efforts from technology developers to assist people with different types of disabilities. In this article, we presented an overview of the existing hardware/software technologies that improve disabled people accessing mobile phones. The review takes into account the various developments oriented to people with disabilities, including software technologies, hardware technologies, hybrid technologies, services, research, and projects.

However, still much work can be done to improve the functionality/operation of mobile phones for people with special needs. This might include making mobile phones smarter, by tracing eye movements as an indicator of a dialing pattern, enabling the use of breath (puff and sip) controllers for people with movement impairments, operating a mobile phone by brain (e.g., dialing memorized numbers), or even enhancing the overall design of the handset to fit the disabled

needs. So, as mobile phones are getting smarter and smarter everyday, we might soon see people with disabilities fully immersed in the telecommunication world.

KEY TERMS

Braille: A writing system using a series of raised dots to be read with the fingers by people who are blind or whose eyesight is not sufficient for reading printed material.

EZ Button: A special button on a mobile phone that allows the reading of the label for any key, as well as the contents of the display and all menus and features of the phone.

MIDlet: A Java program for embedded devices, more specifically the J2ME virtual machine. Generally, these are games and applications that run on a cell phone.

Personal Digital Assistant (PDA): A small handheld computer that acts as a personal organizer.

QWERTY Keyboard: A name for the standard computer keyboard, named by the first six keys from the left on the top alphabetic row.

TDD Device: Stands for Telecommunications Device for the Deaf; allows a person to transmit typed messages over phone lines to another person with a TDD.

TTY: Abbreviation for teletypewriter. Machinery or equipment that employs interactive text-based communications through the transmission of coded signals across the telephone network.

Mobile Processes and Mobile Channels

INTRODUCTION

Since the late 1990s there has been an explosion of new Internet technologies, making the Internet a primary medium for academic, business, and focus interest groups. As a result, new applications are constantly emerging and evolving. Couple this with the concept of mobility, something that is all around us today, and it can be seen that new applications require vastly different characteristics to those envisioned by the original Internet architects. For example, point-to-point IP traffic was designed to allow stationary parties to communicate, but when one of these parties becomes mobile with a wirelessly enabled mobile device, the original models become more difficult to implement.

This trend is a direct result of the fast development of mobile and wireless technologies, and it brings with it new problems. A nomadic user, equipped with a laptop or personal data device with wireless Internet connectivity, still requires and expects seamless communication while they migrate between locations. To overcome this and other issues, mobility is generally tackled at a hardware level, using and modifying existing underlying network techniques to accommodate this new mobile aspect. Designing a truly mobile system, however, also requires mobile software—software components that have the same freedom of movement as the hardware they are executed on.

BACKGROUND

Recent advances in programming frameworks, such as Microsoft's .NET framework and Sun Microsystems's Java platform, provide a number of mechanisms allowing applications to not only be portable between devices, but for applications to actually move from one device to another during runtime (Brooks, 2004; Delamaro & Picco, 2002). These types of systems fall under the general heading of code mobility platforms (Fuggetta, Picco, & Vigna, 1998), the same category as mobile agents and remote invocation systems. These interactions are usually modeled using more

traditional techniques such as UML, but this does not truly allow us a very high-level view of how a mobile system actually behaves, being based on architectures aimed at much more static, single machine systems. Therefore a different paradigm should be employed, and here we examine mobile processes and mobile channels. Viewing a mobile component as a mobile process and a communication between them as a mobile channel, a much broader viewpoint of system mobility can be achieved, facilitating development, understanding, and maintainability.

Mobility

Mobility is all around us today. Wireless technology and mobile phone ubiquity have brought about a technological landscape that is no longer bound to a specific site, but can be carried globally from location to location moving around as we do. The trouble is we still expect to have the same level of service as we migrate as we get when we are stationary. This is of course difficult (imagine trying to hop from one moving train to another instead of having stations), and research into how seamless communication can occur is ongoing in such fields as mobile IP (Johnson & Perkins, 2004; Perkins, 2005) and migratory TCP (Sultan, Srinivasan, Iyer, & Ifode, 2002).

Here, we consider mobility more at the software level, although the basic concepts can be utilized for modeling lower level interactions. Indeed, most of the ideas presented are based on a more formal model—the π -calculus (Milner, 1999)—which has been used to model hardware processes such as mobile phone migration between base stations (cells). We do not, however, use this more formalized style here, but adopt a much softer view of mobility.

In the following paragraphs we will describe what mobile processes and channels are, and how they can be used to model some basic systems. These simple yet powerful building blocks are available in the JCSP (Communicating Sequential Processes for Java) package (Welch, Aldous, & Foster, 2002), which is based on yet another formal model, Communicating Sequential Processes (Hoare, 1978). Recent

Table 1. Symbols

| Symbol D | escription |
|---|------------------------|
|  | A (stationary) channel |
|  | A (stationary) process |
|  | A mobile channel |
|  | A mobile process |

work (Chalmers & Kerridge, 2005) has simplified the usage of the mobility constructs within this architecture, allowing many interesting approaches to system development to occur, some of which shall be described presently.

SYMBOLS USED

Before moving on, we will define in Table 1 some basic symbols that shall be used.

SIMPLE PROCESS NETWORK

Processes communicate to each other using channels; synchronizing during a read-write operation (i.e., when a read occurs, the process waits until the associated write operation occurs, and vice versa). A set of processes interconnected by channels is generally referred to as a process network. Also of note is the fact that messages travel in one direction on a channel, as opposed to the two-way viewpoint normally thought of when considering network connections. For example if we consider a client-server application, using channels to model the connection, two separate channels will be created, one from the client to the server, and one from the server to the client. Using this level of interaction allows some interesting models to be built, especially related to events generated by messages being sent across a channel, which allows distributed event-based systems to be simply developed. Remember that channels synchronize on communication also, adding more interesting models.

Process and channel networks can be built up to a very high level of complexity if required, but individual processes themselves are generally quite simplistic with simple input and output interfaces. Processes can also contain other processes and channels operating within them, permitting the detail of a process network to be viewed at differing levels if required.

MOBILE CHANNELS

A mobile channel can be viewed in simple terms as a channel object that can be sent across a communication channel. This could be another channel altogether, or the channel input end could send its opposite output end if necessary (although the need for this is questionable). Milner (1997) considers this ability of communication a sign that it is sufficiently adult, in that it can utilize a property of itself. In other words the answer to the question *Can a communication communicate a method of communication?* is yes. Usually, only a single end (the input or output) is sent, allowing another process to communicate with the sender, or another process, over the received channel. If, for example, we examine a streaming server system, it is possible to create a client-server communication by the server sending a mobile channel end to the client, as in Figure 1.

The client process can now communicate back to the server using the mobile channel end. Mobile channels, just like normal channels, can also communicate channel ends. Or channels can be passed much further down a chain of connected processes, allowing remote systems to start communicating without prior knowledge of one another. This allows such network application interactions as peer-to-peer to be modeled. This would simply involve a peer requesting the output end for another peer from a central server, and the opposite doing the same for a connection back to it. This allows the two peers to communicate with each other without knowing where they specifically were before the interaction.

When we talk about a mobile channel end, we do not necessarily mean that the underlying software component is actually migrating around a distributed environment. This kind of interaction is possible, but it is also true to say that the location of the channel end can be passed and the necessary channel created dynamically when this location is received. If we consider channel mobility to also include this, then we can see that simply typing in the channel location (a URL for example) becomes a simulated mobile channel. In short, almost every distributed connection can be modeled as a mobile channel. What the more structured mobile channel enables is the movement of a connection without losing any sent or received messages, while still providing

Figure 1. Mobile channel

a synchronized message transfer handshake. This higher level abstraction is much more useful to the software practitioner, allowing channel movement to occur transparently in a single instruction. This is in contrast to the four-stage interaction of get location, send location, receive location, and create channel.

So, as can be seen, the ideas behind mobile channels have been present in systems for a long time; the viewpoint is just rarely taken, if at all. Modeling generally happens at an object level in most modern systems, but this tells us little about how distributed systems communicate or the structure of the communicating components. To illustrate how versatile this approach is, we will examine a much more common networking interaction, the three-way handshake.

Example: Three-Way Handshake

The three-way handshake occurs whenever a client-server communication is initiated within a TCP/IP environment. The three stages (hence the name) of the handshake are as follows:

1. The server creates a server socket to allow client connections.
2. The client connects to the server socket.
3. The server accepts the connection and obtains a new socket unique to that specific client-server communication.

By performing these three stages, a TCP connection provides the guaranteed transmission and reception of traffic that is a property of this protocol. Actually, we have already modeled this in Figure 1, although the three-way handshake is the reverse of this. The client has a connection from itself to the server this time, and the client sends a mobile channel end to the server to provide the unique connection. This interaction is currently being investigated in channel-based systems to allow multiple mobile clients to request services from a server when they enter the location of a wireless access point. As the server will not know about the devices until they request a service, and since each service requires its own access channel, then using mobile channels provides an easier level of interaction. The same interaction is also used to request channels from a server, an interaction that can be seen in the previous description of the peer-to-peer system previously discussed.

What people might argue here is that this does not accurately model a network connection, as a network stream generally allows two-way traffic. This is correct, but we view each channel as a one-way transmission method only. To provide a two-way method, a separate channel connection would be created. By viewing a connection as one-way only also provides a lot more control in a distributed environment, and multiple channel connections do not necessarily

mean multiple sockets. For example, sockets are related to a different inter-node connection in JCSP, whereas channels are related to processes (nodes can be viewed as individual runtime environments or distributed machines). This allows multiple distributed processes to communicate back to a server using the same channel (an Any-2-One connection), even though they are using separate underlying sockets. This Any-2-One configuration can allow a number of interesting configurations, such as a formalized print spooler that can handle multiple users using multiple printers or a server that can handle multiple clients on the same input channel.

MOBILE PROCESSES

A simple way to view a mobile process is as a more state-conscious and controlled version of a mobile agent (White, 1994). Indeed, mobile agents and mobile processes tend to share many common properties, the ability to migrate from system to system being the one of prime importance. This requires some form of code mobility system that allows code accessible on one machine to be loaded onto another during runtime for execution by the receiving machine. A mobile process differs from an agent in that it can be much more sophisticated, possibly including internal processes or even being almost a full-scale application. Compare this to a mobile agent, which is usually a small task-orientated software component. That is not to say that a mobile agent is not a useful tool, but that it could not be used to model a mobile process, whereas a mobile process can model the mobile agent.

To allow a truly mobile process, it has to be possible for the receiving node to request and load the necessary data required to invoke the process. In JCSP for example, this is handled by dynamic loading of Java class data, but any form of class loading, or even scripting, could provide the same result. The advantage of using a compiled language, such as Java or a .NET derivative, is that the system will run faster than its scripting counterparts. This code loading can be hidden inside a channel (as is the case in JCSP), meaning that the developer does not have to consider it, merely accepting that if an object is sent between nodes then the class data will be loaded as required. As an example of how a mobile process would behave, we will look at how a simple task-orientated mobile agent is modeled.

Example: Task-Orientated Mobile Agent

The task-orientated agent design pattern (often called the master-slave agent design pattern (Ariador & Lange, 1998)) involves the sending of an agent from a master (or host) system to a slave (or client) system. Figure 2 illustrates this interaction.

Figure 2. Mobile process

All the master process simply does is connect to the slave and send the mobile process down the previously created channel. When the slave process receives the mobile process, it need only invoke it (by calling a method on the process to run it) and the slave will then execute the task. Again, this simple interaction can be built upon to provide much more complex systems, including mobile processes that can create and distribute mobile processes themselves. Any required class loading is handled within the underlying channels, providing a viewpoint that appears to simply be two distributed nodes passing an object between them. And this is basically what is happening in the underlying interaction.

COMBINING PROCESSES AND CHANNELS

The previous example does not really provide an accurate model of how a mobile agent would behave in practice. Really what would happen is that the agent would return after performing its task, carrying with it some data relevant to the executed task. Or it may be in constant communication with the master process, providing feedback on its execution as required. This is easily modeled by combining both mobile processes and channels together, and therefore we will look at this to provide a means of modeling a more accurate mobile agent.

Example: Returning Agent

The model for a returning mobile agent is provided in Figure 3. As we can see, all that needs to be added is a mobile channel end within the mobile process that connects it back to the master process. Whenever the mobile process needs to communicate back to its master, it can do so using this channel end. The mobile process can also return to the master by writing a copy of itself back down the channel, then destroying the version left on the slave.

It is also possible to model a traveling mobile agent using these techniques, by having the mobile process carry multiple mobile channel ends within it, and using these to send it to different nodes as required. This allows the agent

Figure 3. Returning agent

to migrate around a distributed environment, executing tasks at the required nodes.

FUTURE WORK

The ideas presented here are currently being used to develop location-enabled (site-specific) services to mobile devices by using connection migration and class loading techniques. The hope is that it will be possible to provide a service to a mobile device when it enters a location, without the device requiring any prior knowledge of the service. The service itself could be as simple as a text message that appears on entry into a wireless access point's coverage area, or as complex as allowing interaction with local hardware components (projector, printer, etc), providing location-specific games or site-specific services. These services are of particular interest, especially within the ubiquitous computing community (Toye, Sharp, Madhavapeddy, & Scott, 2005), as they are powerful yet easy to understand for the common user (an electronic ticket machine at a train station is a site-specific service). By allowing multiple users to use a service such as this via their mobile phones, we remove the need for queues, easing our everyday lives. All this can be done with the mobile device having minimal prerequisites, all necessary software being loaded dynamically as required then disposed of when finished. The hope is to provide an inroad into more universal ubiquitous interaction between devices, without forcing them to behave in a certain way.

An easy way to envision how this works is to consider how two people communicate in comparison to how two devices communicate. Humans have various methods of communication, such as writing and speech. However, if two people do not understand each other's language, then much more primitive methods of communication need to be used, such as hand signals. This continues until one or the other learns enough of their opposite's language to allow a higher level of communication.

Looking at mobile devices, they generally share some method of primitive communication via a wireless network interface. But they can rarely truly interact with one another, as they do not talk the same language. Yes, simple data can be passed, and XML can provide some structure to this; but to truly interact, one device must teach its language to another—and that can be viewed as one device passing a mobile process to another. By doing this, it would be pos-

sible for two devices to spontaneously interact, allowing, for example, two people to play a networked game with only one actually requiring the game on his or her device. Or it could spell the end to remote controls for each different device in the home. For example, a TV could send its remote control interface to a mobile phone, allowing the mobile phone to control the TV without any prior knowledge. In short, providing a framework that can load processes and create dynamic connections is a step towards a truly ubiquitous computing landscape, as envisioned by Weiser (1991).

SUMMARY

In summary, we have examined the interactions possible when viewing mobility at the level of channels and processes. This higher level view aids the understanding of how mobile systems interact, and aids our ability to design interacting systems such as those required for ubiquitous computing. Modeling systems in such a way allows mobile systems to be envisioned in simpler terms, taking the process view as opposed to the object view. Ideas from mobile agents to simple network interactions have been examined, providing a broad view as to what is possible when utilizing this viewpoint.

KEY TERMS

Code Mobility: Code that can be dynamically loaded into another runtime environment during execution. This is essential for mobile processes and mobile agents.

Communicating Sequential Processes for Java (JCSP): A Java implementation of the formal model communicating sequential processes (CSP), which also incorporates features of the formal model the π -calculus.

Mobile Agent: A task-specific mobile process.

Mobile Channel: A communication construct that is able to be sent via another communication element.

Mobile Process: A process with the ability to migrate from one runtime environment to another.

Node: A runtime environment within a network. Nodes may exist on a single machine or may be distributed around a network.

Site-Specific Service: A service that is based in a particular location. In physical terms this could be considered as an electronic ticket machine.

INTRODUCTION

During the last decade we have witnessed the widespread penetration of mobile communications infrastructures and services (Chochliouros & Spiliopoulou-Chochliourou, 2005a) together with a great expansion of various information terminals such as cell phones, notebook computers, and personal digital assistants (PDAs). Broadband facilities (Chochliouros & Spiliopoulou-Chochliourou, 2005b) have also forwarded evolutionary processes and promoted the role of the mobile sector. In particular, improved performance of cell phones and their enhanced Web-based features have resulted in their use as personal trusted devices (PTDs), in order to perform tasks such as mobile banking, stock brokering, mobile ticketing, mobile shopping, access of corporate databases, and handling of e-government procedures (e.g., completing various types of documents) (May, 2001). These must be completed in a secure and safe environment that will guarantee protection from malicious or illegal actions like spoofing—namely, stealing information concerning financial transactions (such as passwords, bank account numbers, and credit card accounts), tampering with significant documents, and so forth.

From today's perspective, network and information security (European Commission, 2001) is about ensuring the availability of services and data; preventing the disruption and unauthorized interception of communications; confirming that data sent, received, or stored is complete and unchanged; securing data confidentiality; protecting information systems against unauthorized access; and protecting against attacks (involving malicious software and securing dependable authentication—that is, the confirming of an asserted identity of entities or users). Specific security measures therefore should be taken in order to establish an appropriate environment.

BACKGROUND

PKI Technology as the Means to Ensure Security

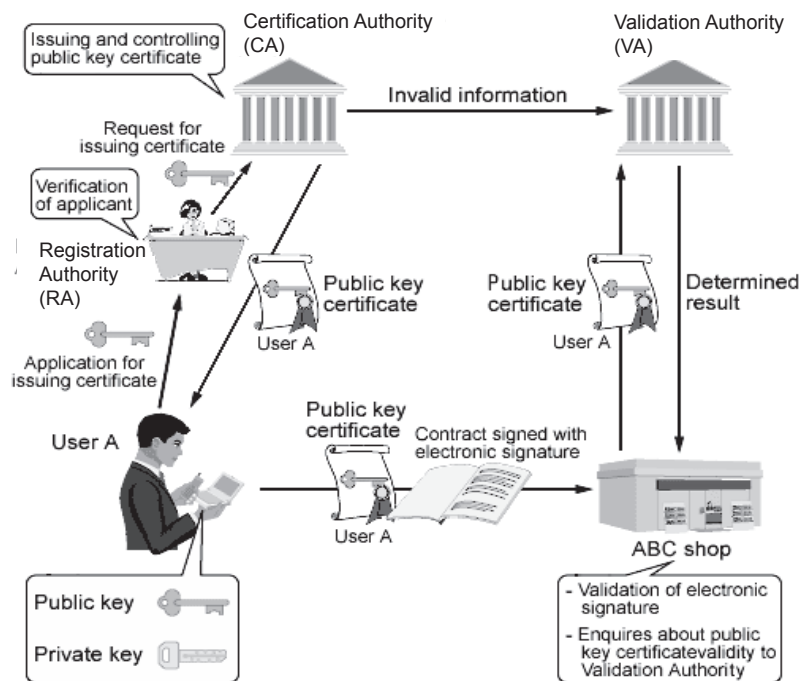

“Secure mobile transactions” implicates that, at least, the following specific features must be ensured satisfactorily:

1. **Confidentiality:** The “assurance” that information is accessible only to those parties/entities that are appropriately authorized to access it.
2. **Integrity:** The assurance that information (either stored or transmitted) has not been altered (with or without intention) between two communication points or at a given time gap.
3. **Authentication:** The assurance that the source of information is “who” it claims to be.
4. **Non-Repudiation:** The assurance that communication parties remain honest about their actions—that is, that they cannot falsely deny having originated or received information.

Public key infrastructure (PKI) is able to offer (IETF, 2005) all the above security services for the case of mobile transactions. In the following sections, we provide a more detailed explanation of PKI.

PKI is based on a main tool for encrypting and decrypting data (Adams & Lloyd, 2003), which is called a “key.” In fact, public key cryptosystems use two kinds of keys: a “public key” and a “private key.” The latter is held by one (legal or physical) person and is for that person's unique use only; in contrast, the former is open to the public for widespread use. In the case of authentication by a public key cryptosystem, the “person”/“entity” subject to authentication starts by encrypting the transmitted data with his private key; resulting data

Figure 1. A fundamental PKI infrastructure

cannot be read, unless a great deal of complex decryption is done; in fact, it cannot even be read by the person who encrypted it. Next, the “entity” realizing authentication uses the public key for data to decryption, and so information returns to a “readable” status. If data is correctly decrypted, the performer concludes that the key used for the encryption purposes was the private key that corresponds to the public key; consequently, the “person” who encrypted the data must be the holder of the private key. A fundamental question that raises here regards the case in which the entity performing the authentication mistakes the holder of the private key. Whether the encrypted transmitted data can be decrypted correctly simply depends on the specific nature of the public key corresponding with the private key. On the other hand, if the public key belongs to a complete “stranger” but does correspond to the proper private key, the stranger can decrypt the encrypted transmitted data. Therefore, authentication of a legitimate person can be mistaken, and it is possible that someone can pretend to be someone else.

The above-described scenario means that in the case of authentication through a public key cryptosystem, it is extremely important to correctly connect the right person and the public key. Consequently, it has become essential to devise a system that can certify, by means of utilizing a third-party organization with no direct connection to the person undergoing authentication, whether the person in question is unmistakably the person holding the corresponding private key or whether that person is a malicious “stranger” intending

to spoof the cryptosystem. This scheme is called PKI, which practically constitutes a core technology that configures the security infrastructure for protecting electronic commerce (e-commerce), especially in the mobile sector (Lalopoulos, Chochliouros, & Spiliopoulou-Chochliouros, 2005).

A Social System for Supporting PKI Implementation

A commonly accepted configuration of a proper social system for the efficient support of PKI perspective is described (Kaji, 2004) in Figure 1.

Figure 1 shows the separate roles of various organizations, authorities, and other entities involved in authentication and certification procedures within a PKI system.

The first key-concept, a so-called certification authority (CA), confirms “who” is the owner of the private key corresponding to the public key and fixes the “prescribed” correspondence between them. According to existing regulatory provisions and practices (European Parliament and Council of the European Union, 2000), CAs can be public or private organizations. The CA then issues (and controls) an “electronic certificate” as the authorization of this correspondence. A registration authority (RA) is an organization responsible for verifying the identity of the key holder and checking his certification with the CA.

The second key-concept is the validation authority (VA), a body for checking the legality of electronic certifi-

cates—namely, whether a certificate is valid and whether a trustworthy CA issued this. Since the PKI is a system to prevent spoofing, such a validity checking procedure is considered of basic importance among all operations.

The Concept of PKI in the Mobile Environment

From a technical point of view, mobile transactions over wireless networks are inherently insecure compared to electronic transactions over the Internet. The main reasons are:

- **Integrity:** Interference and fading make the wireless channel error-prone. Frequent handoffs and disconnections also degrade the security services offered.
- **Confidentiality:** The broadcast nature of the radio channel makes it easier to tap. Thus, communication can be intercepted and interpreted without difficulty if no security mechanisms (such as cryptographic encryption) are employed.
- **Authentication:** The mobility of wireless devices introduces an additional difficulty in identifying and authenticating mobile information terminals.

Therefore, specific measures are necessary to provide for enhanced security (European Commission, 2001), especially if considering the high penetration of mobile applications, both for corporate and residential users. On the other hand, there are several mobile transactions that do not require high security, like micro-payments and/or traditional Web-browsing. (For example, buying refreshments from a vending machine via the use of a cellular phone does not require an electronic signature.) The demand for strong authentication, however, becomes drastically higher in the case of mobile banking. One has therefore to make sure that his mobile banking transactions are safe, with no risk of a “third party” using his mobile phone illegally to “conduct” the activity.

PKI has proven itself a reliable solution for providing the necessary security frame. In fact, it can be used in mobile environments by security protocols in the same way as it is used in a fixed network. However, a specific adaptation of PKI is needed, so as to cope with the inherent limitations of mobile technology (e.g., processing power, memory size, communication bandwidth, and battery power). Two wire-

less communications solutions were developed in order to facilitate mobile transactions through Internet access: (a) the i-mode, and (b) the wireless application protocol (WAP). Since i-mode is a proprietary NTT DoCoMo scheme, our effort will focus on WAP (Open Mobile Alliance, 2002), which is a publicly available solution and a *de facto* standard for wireless communication.

THE WAP ENVIRONMENT

WAP is an industry-wide specification for developing applications that operate over wireless communication networks. It bridges the gap between the mobile and the Internet, as well as corporate intranets, and offers the ability to deliver a wide range of mobile value-added services to subscribers (information, location-based services, corporate information, interactive entertainment, etc.). The WAP specification defines an open, standard architecture and a set of relevant implementation protocols. WAP has a layered architecture (see Figure 2).

In the following paragraphs, we examine separately the features of each layer in the protocol stack.

Wireless Application Environment (WAE)

The WAE defines the user interface on the phone—that is, the application development environment to facilitate services supporting multiple bearers. To achieve this, the WAE contains: (1) a microbrowser for the wireless handset; (2) the Wireless Markup Language (WML), a presentation language for rendering WAP through the microbrowser; (3) WMLScript, a scripting micro-language similar to JavaScript; and (4) the wireless telephony application (WTA) that provides access to traditional telephony services (such as call-forwarding through WMLScript). These are the tools allowing WAP-based applications to be developed.

Wireless Session Protocol (WSP)

WSP is an intermediate layer that links the WAE to two session services: one connection-oriented operating above the wireless transaction protocol (WTP) and a connection-less service operating above the wireless datagram protocol (WDP).

Wireless Transaction Protocol (WTP)

WTP is a transaction layer providing transport services. It runs on top of a datagram service such as user datagram protocol (UDP); it is a part of the standard suite of TCP/IP (transport control protocol/Internet protocol) protocols, to provide a simplified one suitable for low-bandwidth

mobile stations. Interestingly, WTP supports protocol data unit (PDU) concatenation and delayed acknowledgement to help reduce the number of messages sent. This protocol therefore tries to optimize the user experience by providing the necessary information, when it is needed. By stringing several messages together, the end user may well be able to get a better “sense” more quickly for what information is being communicated.

Wireless Transport Layer Security (WTLS)

The WTLS protocol (Open Mobile Alliance, 2002) is a PKI-enabled security protocol, designed for securing communications and transactions over wireless networks. It includes data integrity checks, privacy on the WAP gateway to client support, and authentication. It is used with the WAP transport protocols to provide security on the transport layer between the WAP client in the mobile device and the WAP server in the WAP gateway. Applications can selectively enable or disable WTLS services, depending on their security requirements and the characteristics of the underlying network. WTLS provides functionality similar to the Internet secure socket layer (SSL) and transport layer security (TLS) systems, but it has been optimized for use over narrow-band communication channels and incorporates datagram support. WTLS is being implemented in all major microbrowsers and WAP servers.

Wireless Datagram Protocol (WDP)

WDP is a connectionless transport layer allowing WAP to be bearer-independent (by adapting the transport layer of the underlying bearer). WDP presents a consistent data format to the higher layers of the WAP protocol stack, thereby conferring the advantage of bearer independence to application developers.

The WAP has evolved in various versions: WAP 1.0 → 1.1. → 1.2 → 1.3 → 2.0. The latest (WAP 2.0) release (Open Mobile Alliance, 2002) has one significant difference from the previous ones. In particular, WAP 1.x releases make use of a component called the WAP Gateway (or WAP Proxy) in order to translate Web-based protocols to/from WAP-based ones. However, the WAP 2.0 protocol does not require the WAP Gateway, since the mobile WAP 2.0 browser supports HTTP and standard Internet network and transport protocols (i.e., TCP/IP). By adding these protocols-standards and providing interoperable optimizations suitable to a wireless communications environment, the WAP specifications make available an appropriate framework that permits wireless devices to utilize existing Internet technologies. However, deploying a WAP Proxy in WAP 2.0 can optimize the communications process and may offer mobile service enhance-

ments, such as location, privacy, presence- based services, and “push” functionality.

WAP 2.0 adopts the eXtensible HyperText Markup Language (XHTML) developed by the World Wide Web Consortium (W3C) as the language for rendering content, irrespective of whether it is created for the Internet or otherwise. XHTML provides a universal format for structured documents and data on the Web, while it has been extended to offer PKI-based functionality. A key management framework has been introduced, and standards for encryption and generation of signatures have been applied. The idea of key/certificate management in XML is to source out some of the functionality that is usually done by the client to a trusted party. This allows developers to build up only one version of content. WAP 2.0 is backwards compatible because WML (the language used by WAP 1.x) is a subset of XHTML. Some additional features of WAP 2.0 are:

1. **WAP Push:** This service allows content to be sent or “pushed” to devices by server-based applications via a “push” proxy. This capability is critical in delivering important information and alerts to the mobile devices without the user initiating a request.
2. **Provisioning:** This provides a standard approach to supply WAP clients with information needed to operate on the wireless network(s). It permits the network operator to use a common set of tools.
3. **MMS (Multimedia Messaging Service) Support:** WAP 2.0 has built-in relevant support, which allows MMS to seamlessly integrate with the wireless Internet interface. WAP 2.0 supports SyncML, the XML protocol that allows synchronization for all devices (particularly mobile).

VARIOUS ASPECTS OF THE WAP SECURITY

In this section we examine the security components of the WAP, recent developments, and possible future directions.

WTLS/TLS

WTLS/TLS is the basis of WAP 1.x security in the WTLS protocol, a transport-level security protocol (Grech, 2005). The WTLS specification allows for three classes (levels) of relevant implementation:

- **Class 1: Anonymous Encryption:** Data is encrypted, but certificates are not exchanged between the client and the gateway.
- **Class 2: Encryption with Server Authentication:** Data is encrypted and the client requires a digital

certificate from the server. Server-side authentication is performed using public key certificates similar to the SSL/TLS protocol. The WAP Gateway uses a WTLS certificate (a particular form of X.509 certificate compressed to save on bandwidth).

- **Class 3: Encryption with Client and Server Authentication:** Data is encrypted and the client and the server exchange digital certificates. Clients are able to authenticate, using proper certificates. These are of regular X.509 format and can be stored either on the client or on a publicly accessible server (where a pointer to the certificate will be stored on the mobile device).

WAP 2.0 uses TLS instead of WTLS due to requiring end-to-end security with all-IP-based technology in order to overcome the WAP gateway security breaches. For example, sensitive information can be translated into clear texts, so the operator may read it at the gateway (the “WAP gap”). A possible solution is to make the WAP Gateway resident within an enterprise (server) network, where heavyweight security mechanisms can be enforced. The WAP 2.0 overcomes this problem by using TLS tunneling to support end-to-end security at the transport level. TLS is a PKI-enabled protocol that provides services such as authentication (by using digital signatures and public key certificates), confidentiality (by encrypting wireless data), integrity (by employing hashing of wireless data for detecting data modifications), and denial-of-service protection (by detecting and rejecting data that has been replayed or not successfully verified).

WMLSCrypt

WML script crypto (WMLSCrypt) is an application programming interface (API) that allows access to basic security functions (Ashley, Hinton, & Vandenwauver, 2001) in the WML script crypto library (WMLSCLib), such as key-pair generation, digital signatures, and the functions that process objects commonly found in the PKI (e.g., keys and public-key certificates). WMLSCrypt allows WAP applications to access and use the security objects and basic security services managed by other WAP security standards. WML Script can utilize an underlying WIM Module to provide the crypto-functionality.

WAP Identity Module (WIM)

The WIM is a tamper-resistant computer chip that optionally resides in WAP-enabled devices (such as mobile phones and PTDs). It can store key material like the PKI root public key and the user’s private key. WIMs are most commonly implemented using smart card (Chochliouros & Spiliopoulou-Chochliourou, 2002) chips that have memory and storage for data and programs. A secure solution is to

integrate WIM functionality into a SIM (subscriber identity module) card, resulting to the SWIM (Subscriber WAP identity module) card.

The SIM card is by itself a smart card, and the reader for this is already in place. It works as follows: When a mobile user wants to sign a transaction, a SMS with a signing request is sent to his phone from the institution he has business with (e.g., public department). To proceed, he only enters the signing PIN (personal identification number) code that activates the private keys and the signature function for the received SMS. The returned signature SMS is verified by the business by retrieving the certificate. If needed, transactions can be time-stamped and stored into the database, accessible by all parties involved in the procedure (i.e., both users and merchants), to assure the non-repudiation feature. Similar functions are available for mobile Web browsing, as the same signature function can be used when logging into some protected Web page. Such solutions are already deployed in Scandinavian countries (like Norway and Finland). Furthermore, it seems a preferred authentication/signature method in the wider European Union (EU) territory.

Wireless Public Key Infrastructure (WPKI)

WPKI is not an entirely new set of standards for PKI; it is more an “optimized” extension of traditional PKI for the wireless environment. Both WPKIs and PKIs implement mobile commerce businesses by managing relationships, keys, and certificates. WPKI is concerned primarily with the policies that are used to manage electronic businesses and the security environment by WTLS/TLS and WMLSCrypt. In the case of wired networks, IETF PKI standards are the most commonly used; for wireless networks, WAP’s Forum WPKI standards are the most widely used.

WPKI requires (Yeun & Farnham, 2001) the same components as a traditional PKI—that is, an end-entity application, a RA, a CA, and a PKI repository. However, in WPKI, the end-entities and the registration authority are implemented differently, using the PKI portal. The latter is a network server, like the WAP Proxy. It typically functions as the RA and is responsible for translating requests made by the WAP client to the RA and CA. (It interoperates with WAP devices on the wireless network and with the CA on the wired network). The end-device application in WPKI is implemented as optimized software (based on WMLSCrypt API) that runs in the WAP device and performs the same functions as in traditional PKI. Moreover, it includes relevant functionalities. WPKI has optimized the PKI protocols, the certificate format, and the cryptographic algorithms and keys with respect to mobile environments. Compared to a PKI, WPKI applications have to work in an environment with less powerful CPUs (central processing units), less memory, restricted power consumption, smaller displays,

and diverse input devices. Despite these shortcomings, the wireless equipment must be able to generate and register keys; manage end user mobile identities; encrypt and decrypt messages; and receive, verify, store, and send certificates/digitally signed data. In many cases, ordinary PTDs are not able to fulfill all these requirements, as they do not possess sufficient memory. Sometimes, a client's functionality has to be implemented outside the mobile equipment. Therefore, some WPKI solutions are very likely to employ "network agents" to perform some of these tasks. The PTDs must at least be able to perform a digital signature function to permit the establishment of a WPKI. Network agents can perform all other PKI-related tasks such as validation, archiving, or certificate delivery—that is, an implementation in which private keys are stored in a proxy server or alternatively, embedded into the tamper-resistant modules (like WIM/SWIM) of PTDs. Unfortunately, such solutions require more improvements, particularly in the area of key-pairs generation by end users, rather than being assigned by the network operators. In addition, a lack of standardization presents a major barrier in the development of wireless PKI. In other words, establishing trust in a WPKI is crucial for the success of applications that will exploit probable opportunities created by PTDs. Trust is based on the reliability of the technology, but also on a carefully implemented system of laws, policies, standards, and procedures (Chochliouros & Spiliopoulou-Chochliourou, 2003), which includes the management of certificates by trusted certificate authorities. The questions of anonymity, privacy, government surveillance, and industry-based policies (and standards) represent challenges that all parties involved have to face, if they plan to strengthen the level of trust that recent legislation efforts have already made possible throughout the world.

CONCLUSION

The high penetration of wireless devices paves the way for mobile commerce. Such devices have begun to transform into PTDs, suitable for applications like mobile banking, mobile shopping, citizen services, and so forth. A secure mobile infrastructure needs to ensure that such transactions are confidential, that all parties involved are clearly identified, and that the relevant agreements are non-reputable. This establishes a reliable and convenient framework for valid contracts, signed with digital signatures. Consequently, PTDs will be able to generate legally binding digital signatures and to enable a user to authenticate him remotely over the underlying networks. Such moves will quickly make mobile commerce a part of our everyday life. In particular, businesses are expected to extend their services to customers on the move.

To this aim, PKI can play an important role in meeting the corresponding security requirements. In a mobile environ-

ment, a special type of PKI (called WPKI) is used, in order to deal with the inherent limitations of wireless devices. WPKI includes most of the concepts that are present in traditional PKI. The combination of WPKI and the widely adopted standard WAP can offer users a platform for trusted and secure services, and significant new revenue opportunities for authentication, payment, and validation services.

In the near future, mobile operators face the challenge of providing secure authentication and value-added services between the PTDs and service/content providers. Their task will be to perform fundamental functions such as encryption/decryption, certificate validation, and key generation. Moreover, manufacturers also face the challenge of making wireless devices that are compact, powerful, easy to-use, and with single log-on security mechanisms. Each of these factors will contribute to the success of WPKI, and companies that are to develop, produce, and sell these products inexpensively (with the required quality), and will play an important role to gain an extremely large market.

Collaborative projects (WPKI Non-Profit Association, 2005) can perform prime actions towards developing a framework for stimulating the mobile market and establishing the appropriate environment for WPKI security promotion. Some significant factors for the development of WPKI are issues regarding WIM/SWIM cards, in combination with 3G technology, and the management of certificates via the CAs. To this aim, root certificate authority services and certificate chains are being used in the verification procedure (Developer Connection, 2005). Establishing a WPKI will generate potential for additional services (like those required for managing the financial risk involved in certification practices). Another major area of potential business can be found in offering and packaging a variety of certificate-related services like directory services, a notary service, or services for key generation or archiving. Others will be involved in monitoring technical compliance with policies and regulations.

The future challenge is to establish adequate trust in WPKI as a "new" medium, while the success of wireless applications will depend on their usefulness. The easy-to-use solutions are more likely to succeed than complicated ones. Governments, businesses, and end users can benefit from this. In order to enable secure mobile commerce solutions, qualified legal expertise needs to be considered in every environment (European Commission, 2004), together with the continuous enhancement of the WPKI standards throughout the world (Funk, 2003; Costello, 2002).

KEY TERMS

Certification Authority (CA): An entity that issues/updates/revokes public-key bearing certificates in response to authenticated requests from legitimate registration authorities.

Public Key Infrastructure (PKI): Allows users to exchange data securely over an unsure network (such as the Internet), and involves the use of a public and private cryptographic key pair, which is obtained through a *trusted authority*. PKI provides for digital certificates that can identify individuals or organizations, and directory services that can store and revoke them.

Registration Authority (RA): An entity authorized to make requests to issue/revoke/update certificates to a CA. The registration authority can be considered similar to an account manager in function and is responsible for member enrollment and/or attribute assignments.

Trusted CA Information: Information that is stored by a PKI entity and indicates that a given certification authority is trusted as a root CA by that entity. This has to include a public key, which typically also includes a name and a validity period (often stored in the form of a self-signed certificate).

WAP Identity Module (WIM): Used in performing WTLS and application-level security functions, and especially to store and process information needed for user

identification and authentication. WIM may be used by WPKI for secure storage of certificates and keys.

Wireless Application Protocol (WAP): A secure specification allowing users to access information instantly via handheld wireless devices such as mobile phones, pagers, two-way radios, smart phones, and communicators. WAP is a widely used set of protocols that standardize the manner in which wireless devices are able to access parts of the Internet (e.g., e-mail and the Web).

Wireless Public Key Infrastructure (WPKI): An optimized extension of traditional PKI for the wireless environment. Both WPKIs and PKIs support mobile commerce by managing relationships, keys, and certificates. WPKI is concerned primarily with the policies used to manage electronic businesses and security environment.

Wireless Transport Layer Security (WTLS): A security layer of the WAP, providing privacy, data integrity, and authentication for WAP services. It is needed because the client and the server must be authenticated in order for wireless transactions to remain secure and because the connection needs to be encrypted. WTLS is based on the widely used TLS v1.0 security layer used on the Internet.

Mobile Serverless Video Communication

INTRODUCTION

Voice and video conferencing have been well established as regular communication services within the wired Internet. Facing the paradigm of ubiquitous computing and mobile communication, they are on the spot to be launched within a wireless Internet infrastructure. Following an 802.11, 802.16 or 3G standard, wireless networks provide enough bandwidth to support data intensive communication services such as videoconferencing. The vision of nomadic users at roaming devices performing synchronous communication, such as voice or videoconferencing over IP (VoIP/VCoIP), is around, but raises new challenges for the Internet infrastructure.

In conferencing scenarios addressability raises the first major issues. To globally call a device, a routable IP address must be in use. On a large scale such address space is only provided by IPv6. To identify a communication partner's current device, a supplementary global user locating scheme is needed. In wireless infrastructures, where users share limited bandwidth from a restricted frequency space, multicasting is needed to enable group conferencing compliant to transmission resources and without placing the burden of dedicated group-server infrastructure.

At the same time, synchronous real-time applications, such as VoIP and VCoIP place new demands on the quality of IP mobility services: packet loss, delay and delay variation (jitter) in a constant bit rate scenario need careful simultaneous control. A spoken syllable is about the payload of 100 ms continuous voice traffic. Each individual occurrence of packet loss above 1%, latencies over 100 ms or jitter exceeding 50 ms will clearly alienate or even distract the user. Audio and visual streams in video conferencing additionally require tight synchronization. Inter-stream latencies should remain below 30 ms for audio arriving ahead, 40 ms for audio being behind. While uni-directional distribution may compensate quality deficits by buffers, available techniques of hiding packet loss at the cost of delay and jitter or vice versa are of limited use in conferencing. Their requirements impose strong challenges on a mobile Internet scenario. Challenges are even tightened by multicast-based group communication,

since in conferencing scenarios each member commonly operates as receiver and as sender. Real-time requirements consequently are a major driving force for the development of a seamless mobile Internet layer.

In concordance with communication capabilities, video coding techniques have evolved, as well. The latest standard for video coding H.264/AVC (ITU H.264, 2005), although designed as a generic standard, is predestined for applications like mobile video communications (Stockhammer, Hannuksela, & Wiegand, 2003). Besides enhanced compression efficiency, it delivers also network friendly video representation for interactive (video telephony) and non-interactive applications (broadcast, streaming, storage, and video on demand). H.264/AVC provides gains in compression efficiency of up to 50% over a wide range of bit rates and video resolutions compared to previous standards. While H.264/AVC decoding software has been successfully deployed on handhelds, high computational complexity still prevents pure software encoders in current mobile systems. There are, however, also fast hardware implementations available (see a list in Wikipedia, H.264, 2006). Next generation codes, like scalable video coding (SVC) are already in a design state (Reichel, Schwarz, & Wien, 2005; Schwarz et al., 2004). The main new feature, scalability, addresses schemes for delivery of video to diverse clients over heterogeneous networks, particularly in scenarios where the downstream conditions are not known in advance. The basic idea is that *one* encoded stream can serve networks with varying bandwidths or clients with different display resolutions or systems with different storage resources, which is an obvious advantage in heterogeneous networks prevalent in mobile applications.

BACKGROUND

Video conference communication is a person-oriented, session-based service. A caller requesting contact to one or several partners will expect to address a personal identifier, but establish the corresponding conference session with the devices currently in use by the callees. Unlike in mobile

telephony, the Internet architecture is required to locate users and mask the user-device mapping, following the paradigm of location transparency, like in e-mail services. Once established, sessions need to persist while mobile devices roam. Intermediate handovers thereby should unnoticeably comply with quality of service measures for real-time communication. Operating on portable devices with limited capacities of CPU, batteries and displays, a video conferencing solution needs to balance out network efficiency and adaptability versus coding complexity. Lightweight flexible software systems as introduced by Cycon et al. (2004) are preferably employed in mobile communication.

Conference Signaling

The traditional, ISDN compatible architecture of VCoIP systems has been defined in the standard ITU H.323 (2000). Central parts of this model are derived from a client-server principle with a Gatekeeper, providing connection control and address translation, and a multipoint control unit (MCU) serving video streams in multipoint conferences. The H.323 architecture must be considered local and immobile in the sense that all participants need to agree on common MCU and pre-configured Gatekeeper servers, which, at least for the MCU, suffer from severe scaling deficiencies.

A flexible, fairly general Internet signaling solution has been presented with the session initialization protocol (SIP) (Rosenberg et al., 2002). Beside user localization, SIP covers negotiations about user capabilities, user availability, the call set-up by session description protocol (SDP) data and the handling of the calls itself. SIP introduces its own infrastructure of servers, which actively perform a peer-to-peer routing by using SIP-URLs. SIP is based on an extensible method framework and open to store persistent data. SIP liberates the rigid addressing scheme of telephone numbers used in H.323, proposing addresses of the “e-mail-like” form <user>@<SIP-server>. A basic interaction with IP multicast is defined in SIP through the *maddr* address attribute in the VIA header.

Mobility Management

As an application layer protocol SIP provides some mobility support to session-based services (Wedlund & Schulzrinne, 1999), which requires implementation at the application layer. Employing the regional SIP server as an application specific home agent, handoff notifications are traded via regular SIP messages to the home server (register) and the correspondent node (re-invite). As SIP mobility operates above the transport layer, it remains self-consistent and transparent to the Internet infrastructure, but inherits all underlying delays in addition to its own signaling efforts.

The fundamental approach to mobility management in the next generation Internet is the Mobile IPv6 (MIPv6) RFC (Johnson, Perkins, & Arkko, 2004). MIPv6 transparently operates address changes on the IP layer as a device moves from one network to the other by sustaining original IP addresses in a home address destination option and hiding the different routes to the socket layer. In this way, hosts are enabled to maintain transport and session connections when they change locations. An additional infrastructure component, the MIPv6 Home Agent, preserves global addressability, while the mobile node is away from home.

Local handovers in MIPv6 are rapidly completed. In the presence of layer 2, triggers for movement detection, the time needed for address reconfiguration and local updates remains well below 10 ms (Schmidt & Wählisch, 2003). Distributed Mobile IPv6 scenarios, though, inherit strong topology dependence from binding updates with the Home Agent and correspondent nodes. To resolve topologically originated delays, Hierarchical MIPv6 (Soliman et al., 2005) has been introduced for micro mobility scenarios and Fast Handovers (Koodli, 2005) for delay hiding by means of handover predictions. Even though an expected disappearance of predictive handover delays does not hold in practice, these accelerating schemes arrive at real-time compliant handover performance (Schmidt & Wählisch, 2005).

IP layer handovers thus can be considered capable of a mobility management for real-time voice and video communication. SIP application layer handovers have been found by Kwon, Gerla, Das, & Das (2002) to significantly fall behind Mobile IPv4, which itself is largely outperformed by MIPv6. Handoff disruptions of the underlying layer 2 add to service degradation, admitting vendor specific, but large values in 802.11 systems (Mischra, Shin, & Arbaugh, 2003). Further quality of service issues of wireless transmission technologies and of the general IP routing layer need consideration, as well.

Video Coding

H.264/AVC, or MPEG-4 Part 10, (formally, ISO/IEC 14496-10) is a digital video codec standard. It was defined by a collective effort of the International Telecommunication Union - Telecommunication Standardization Sector (ITU-T) Video Coding Experts Group (VCEG) and the International Organization for Standardization/International Electrotechnical Commission (ISO/IEC) Moving Picture Experts Group (MPEG) known as the Joint Video Team (JVT). The final drafting work on the first version of the standard was completed in May of 2003.

H.264 is a name related to the ITU-T line of H.26x video standards, while AVC (advanced video coding) relates to the ISO/IEC MPEG side of the partnership project that completed the work on the standard. H.264/AVC has also been referred

to as “the JVT codec”. The intent of H.264/AVC project has been to create a standard that would be capable of providing good video quality at bit rates that are substantially lower than what previous standards would need (e.g., relative to MPEG-2, H.263, or MPEG-4), and to do so without much of an increase in complexity (Wiegand, Sullivan, Bjøntegaard, & Luthra, 2003; Ostermann et al., 2004). An additional goal was to work well on a very wide variety of networks and systems (e.g., mobile network systems).

H.246/AVC, as almost all conventional video codecs which are in use today, is not in a simple, efficient, application-friendly way scalable, that is, it encodes video content using a fix bit-rate tailored to a specific application. Video streaming in heterogenic networks today is realized by parallel encoding the video data into different compression/quality stages depending on the available bandwidth of the client (multibit streaming, sure stream, etc.). The disadvantages of those methods are obvious: unreasonable large memory and processing power is needed. Current digital video applications require at least three types of scalability features: quality scalability, spatial resolution scalability, and temporal (frame rate) scalability. Next generation codecs like scalable video coding (SVC) promise to solve this problem. The Moving Picture Experts Group (MPEG) started to work on (SVC) in December 2001. The goal was to provide scalability at the bit stream level, with good compression efficiency, allowing free combinations of scalable modes (such as spatial, temporal and SNR/fidelity scalability). In October 2003, MPEG issued a “Call for Proposals on Scalable Video Coding Technology”. It was widely believed that the so-called 3-D wavelet coding will solve the problem efficiently (Choi & Woods, 1999; Ohm, 2002; Flierl, 2003). But it turned out that extensions of H.264/MPEG-4 AVC outperformed all other proposals and subjective tests for different scalability scenarios verified their superior coding efficiency (Wiegand et al., 2006). In January 2005, MPEG and the Video Coding Experts Group (VCEG) of the ITU-T agreed to jointly finalize the SVC project as an amendment of their H.264/MPEG-4 AVC standard, and the scalable coding scheme (Schierl, Schwarz, Marpe, & Wiegand, 2005; Schäfer et al., 2005; Schwarz, Marpe, & Wiegand, 2004).

MOBILE CONFERENCING SUPPORT

Locating Nomadic Users

A video conference is a synchronous form of communication, requiring online presence of its participants. These commonly register at some SIP server. The device a user is currently located at then can be easily identified by searching this SIP server’s session directory. Locating a nomadic user therefore can be considered equivalent to identifying its SIP or session directory server. It can be easily achieved when

addresses of the form <user>@<SIP-server> are employed. However, it is desirable and has been foreseen by SIP to allow for virtual addresses, which do not reflect existing machine infrastructure. Virtualization is not only demanded when telephone numbers are used, but has proven relevant within the global e-mail system.

In contrast to e-mail, though, conference sessions services are not built onto a DNS infrastructure like the MX record, which translates any virtual name into its e-mail server on duty. To enable virtual session naming services, Rosenberg and Schulzrinne (2002) propose to rely on DNS extensions, the SRV and NAPTR record, which are capable of encoding a service-to-server name mapping. This approach—even though technically irreproachable—suffers from a limited pervasiveness of DNS extension records. In practice, the allocation of DNS SRV records is very rarely seen. To overcome these obstacles, Schmidt, Wählisch, Cycon, and Palkow (2003) propose to restrict call-names to e-mail addresses and take advantage of the globally established MX server record infrastructure by applying a name convention to session servers. This allows for a rollout of session server infrastructure in concordance with e-mail services. In proceeding along this line, session-oriented service support for nomadic users can be easily established, while Internet infrastructure remains unchanged.

Serverless Group Communication

An important application scenario for video communication is given by multi-party conferences. Ranging from a small group of few partners up to very large conventions, video conference technology faces the need to provide seamless, mobility transparent services to all of these assignments. The simple, server-centric approach of H.323 to group communication thereby is easily ruled out by scalability and flexibility issues.

Instead, as a complex and data intensive application video group conferencing requires relying on multicast distribution techniques, which have to account for media distribution as well as inter-party signaling. While the RTP architecture initially provides flexible multicast support for media streaming, a call control for multi-party usage of SIP is currently under development (Mahy et al., 2005). Major focus is donated to unicast-based overlay multicast, introducing the function of “mixing node”. Such mixers arrange group management and signal distribution substituting stationary servers and thereby attain a role incompatible with mobility constraints.

The basic SIP RFC 3261 already defines a message exchange using IP layer multicast: a client wishing to initiate or join into a multi-party conference sends its INVITE request to a multicast group by employing the *maddr* attribute in

the SIP VIA header. Group members subsequently indicate their presence by responding to the same group. Suitable for large, loosely coupled and mutually unknown parties, this simple scheme only operates through any source multicast (ASM). Due to its routing complexity and security threads, ASM deployment mostly remains restricted to single management domains. It is the general belief that a large-scale inter-domain deployment will be reserved to the emerging source specific multicast (SSM) (see mobile multicast).

To enable group communication by source specific multicast, SIP dialogs need alteration in the following way: a new conferencing member willing to join a previously established group conference invites any party and receives response including multicast session descriptions via unicast. In parallel, the invited party has to repeat its response to the previously established SSM signalling domain, in order to trigger an active source subscription with respect to the newly established caller at all previous group members. All additional group members subsequently will advertise their session affiliation, while the initially called party will signal a turnover of its newly established SIP signalling channel to SSM multicast. As soon as the new conferencing member has completed its subscription to SIP signalling and media sessions for all conference party's addresses, a source specific multicast group conference is fully established among peer-to-peer members in the absence of any coordinating instance (Schmidt, Wählisch, Cycon, & Palkow, 2006).

VIDEO CODECS FOR MOBILE SYSTEMS

H.264/AVC or MPEG-4 Part 10 contains a number of new features that allow it to compress video much more effectively than older standards and to provide more flexibility for application to a wide variety of network environments. In particular, such key features include (Richardson, 2006):

- Multi-picture motion compensation using previously encoded pictures as references in a much more flexible way than in past standards, thus allowing up to 32 reference pictures to be used in some cases.
- Variable block-size motion compensation with block sizes as large as 16×16 and as small as 4×4 , enabling very precise segmentation of moving regions.
- Quarter-pixel precision for motion compensation, enabling very precise description of the displacements of moving areas.
- An in-loop deblocking filter, which helps to prevent the blocking artifacts common to other DCT-based image compression techniques.
- An exact-match integer 4×4 spatial block transform (similar to the well-known DCT design).

- Context-adaptive binary arithmetic coding (CABAC), which is a clever technique to lossless compression of syntax elements in the video stream, knowing the probabilities of syntax elements in a given context (Marpe, Schwarz, & Wiegand, 2003).
- Context-adaptive variable-length coding (CAVLC), which is a lower-complexity alternative to CABAC for the coding of quantized transform coefficient values.
- A network abstraction layer (NAL) definition allowing the same video syntax to be used in many network environments that provide more robustness and flexibility than provided in prior designs.

These techniques, along with several others, help H.264/AVC to perform significantly better than any prior standard can, it often performs radically better than MPEG-2 video—typically obtaining the same quality at half of the bit rate or less (Compression Links, 2006).

The standard includes six sets of capabilities, which are referred to as *profiles*, targeting specific classes of applications and some fidelity range extensions (Marpe, Wiegand, & Sullivan, 2005). We mention only three of them, which are relevant for mobile applications:

- **Baseline Profile (BP):** Primarily for lower-cost applications demanding less computing resources, this profile is used widely in videoconferencing and mobile applications.
- **Main Profile (MP):** Originally intended as the main-stream consumer profile for broadcast and storage applications.
- **Extended Profile (XP):** Intended as the streaming video profile, this profile has relatively high compression capability and increased robustness to data losses.

The next coding generation, scalable video coding (SVC) is defined as a codec architecture which is based on a layered representation (Wiegand et al., 2006, Schwarz, Marpe, & Wiegand, 2005, 2006). The design builds upon an H.264/AVC-compatible base layer, and re-uses existing elements such as motion-compensated prediction, intra prediction, transform coding, entropy coding, and deblocking filter while only a few components have been added or modified. Different scalable modes (such as spatial, temporal and SNR/fidelity scalability) can be combined to obtain much more flexibly as compared to scalable tools of previous standards.

Key features are:

- hierarchical prediction structure;
- layered coding scheme with switchable inter-layer prediction mechanisms;

- fine granular quality scalability using progressive refinement slices;
- usage and extension of the NAL unit concept of H.264 / MPEG-4 AVC.

FUTURE TRENDS

Infotainment has been well established within the mobile world. Digital radio telephony and (unidirectional) digital video broadcasting still govern the majority of mobile devices today, but emerging standards of a next-generation mobile Internet envision a network layer, which unifies hardware abstraction and offers scalable and flexible services at decreasing costs. Mobile video communication will be one foreseeable service of ubiquitously available Internet devices, superseding today's static multimedia messaging. Communication protocols and standards are rapidly evolving towards this vision.

Video encoding capabilities still are a major barrier today. SVC, though, as defined for the new generation standard based on the H.264/AVC will get in more efficient and less complexity versions hardware and also software implementations. This will be the basis software for a large variety of mobile video-capable communication gear. Application fields will be video streaming over heterogeneous IP networks, surveillance systems, mobile streaming video, wireless LAN video, multi-channel video production and distribution, layered protection of content, multi-party video telephony/conferencing and wireless broadcasting (Ohm, 2005).

CONCLUSION

Multimedia communication is a challenge to both the stationary and the mobile Internet; video conferencing simultaneously raises issues of system, network and protocol performance. In this overview we discussed mobility-related aspects of conference signaling and network performance, nomadic user and group management, as well as emerging capabilities of adaptive, scalable video coding. The combination of these ingredients, current or future algorithms and technologies are likely to provide a firm basis for the procurement of widely favored mobile video services.

KEY TERMS

Any Source Multicast (ASM): The distribution of packets from an arbitrary source to a group of receivers. Receivers are addressed by a delocalized group address and remain unidentified by the source.

DCT: Discrete cosine transform.

H.264/AVC: Video compression/decompression (codec) international standard.

ITU-T: International Telecommunication Union—Telecommunication Standardization Sector.

ISO/IEC: International Organization for Standardization / International Electrotechnical Commission.

JVT: Joint Video Team.

MPEG: Moving Picture Experts Group.

NAL: Network abstraction layer.

Mobile Serverless Video Communication

Nomadic User: A term for the user behaviour of switching devices.

Real-Time Transport Protocol (RTP): Internet protocol standard for the transmission of real-time data, providing media sessions, timestamps, order and media-specific metadata encoding.

Session Initiation Protocol (SIP): Internet protocol standard for managing session-based network communication.

Signal to Noise Ratio (SNR): The common quality measure in signal encoding.

Source Specific Multicast (SSM): The distribution of packets from an initially specified source to a group of receivers. Listeners must actively subscribe by address to each source they want to receive traffic from.

SVC: Scalable video codec.

VCEG: Video Coding Experts Group.

Mobile Sports Video with Total Users Control

Dian Tjondronegoro

Queensland University of Technology, Australia

INTRODUCTION

Sports video is very popular thanks to its in-progress (live) information and entertainment values. Many users are motivated to access sports video using mobile devices, since they often cannot watch the game on their sofa due to a busy life and inability to cope with lengthy games. The current generation of mobile video services has only focused on supporting the when and where consumers can watch their favorite sports matches. Since total control over playback and content is neglected, users often have to settle with low-quality videos and static content, which have been pre-processed. This limitation slows down the progress towards an era in which users are comfortable using their mobile devices to enjoy sports broadcasts while gaining total control over what they can watch at their most convenient time and place. In this article, we will describe a mobile video system which offers users full support over the when, where and how they want to watch sports video. The main new features offered are: (1) non-linear navigation within single and/or multiple documents; (2) customizable and personalized summaries; (3) multimodal access and video representation.

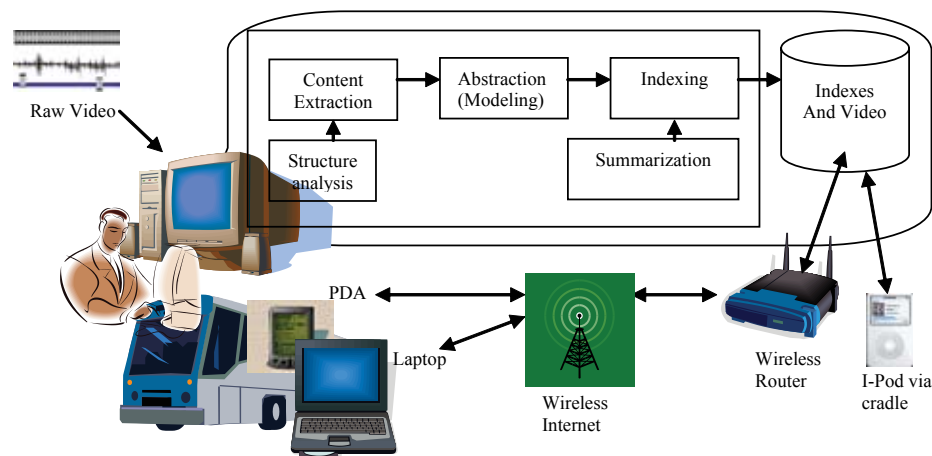

BACKGROUND

With the ongoing growth of mobile and hand-held video-enabled devices such as PDAs, smartphones, and iPods,

users are increasingly able to afford video on-demand at their most convenience. Sports video is particularly popular for mobile consumption, thanks to its in-progress information (live) and entertainment values. Consumers are at the most convenient level if they have total control over the “when, where and how” they can access the video. The following will describe two scenarios that show how users can benefit from total control over mobile sports video. Figure 1 gives an overview of the descriptions.

- Scenario 1:** A soccer fan does not want to miss two important live matches, one in the morning (7 a.m.), and another one in the evening (7 p.m.). Thus, he schedules the recording of both broadcasts on his home PC with TV tuner. While the video is being recorded, he wants to watch it on his laptop during a one-hour trip to work. Unfortunately, the bus is full and he has to stand with noisy and squeezed passengers. Thus, he uses his PDA that is connected via wireless network to listen to the audio and occasionally look at the live images. As soon as he arrives at work, he has to attend meetings and finish many tasks, which are due on that day. During this time (8 hours), his PC has finished the match recording and indexing process. At 6:30 p.m. he finishes work, and during his bus-trip from work he must watch the first match while skipping many boring tracks (i.e., those without any interesting events), so that he can watch the first 30 minutes of

Figure 1. Mobile sports video architecture

the second match live on his laptop (by using wireless broadband to access his PC via remote desktop). As soon as he arrives at home, he must cook dinner, thus he uses his PDA in his pocket to listen to the match. During dinner, he cannot watch the game since it is a special time for his family, hence he settles with audio commentaries being turned on only when there is a goal scored. At 8:30 p.m., he can relax and watch the rest of the live match using the media center in his living room. In this scenario, we assume that all devices are connected with a wireless network and all have access to broadband Internet. This setup allows each device to inform the server (in this case the home PC) the current time-stamp in which the user stops each playback.

- **Scenario 2:** A casual sports viewer does not usually watch live broadcasts since she likes to follow various sports and has a very busy life. However, she does not want to wait and follow static summaries from TV and Internet. Instead, she prefers to be able to watch the personalized summary of each sport video every day or at least three times in a week during her trip from-and-to work. She likes the contents to be pre-recorded on her home PC, indexed, and prepared according to her personal preferences so that she can store them in her iPod. For swimming and other racing sports, she likes to watch every race in real-time while skipping the interviews. For soccer, basketball, and other score-based games, she only wants to see all key events (i.e., goal and goal attempts), as well as any interesting segments in which her favorite players appear. For tennis, badminton and other set-point based games, she wants to see only the key events, such as long rally and service ace, as well as the last portion of play just before each set is won by the player. Due to the unpredictability of public transport (e.g., lighting, crowd, etc.), she needs each segment to be available in multimodal forms so that she can listen or see the key audio or images. Moreover, when she has too many videos to be watched, she needs the video segments to be presented in key frames in order to choose which clips she wants to play.

The two scenarios demonstrate that mobile video interaction increases the necessity for more effective content-based retrieval. Mobile devices have limited capabilities in supporting users watching the full contents of a sports video due to their small screen size and restricted battery life. Since local storage in mobile devices is relatively small, costs of downloading streaming content is also a major issue. Thus, users need to selectively watch particular segments they want to watch to reduce the time and costs of downloading full-video content. Current solutions for streaming video content have not fully exploited the power of content-based

indexing to enhance users' experiences. For example, UEFA.com via RealPlayer 10 only allows users to watch a fixed set of soccer video segments which are compiled as a 15 minute highlight. To improve the flexibility of content access, the system must more adaptive to a user's requirements. A study on users' requirements on mobile TV content has found that viewing was most likely to be transient and low commitment, as people are worried about getting too absorbed and are distracted with other tasks (Knoche & McCarthy, 2005). One of the biggest challenges in mobile sports video streaming is how to repurpose TV-quality videos for mobile devices to meet the tolerable downloading time, color depth, and available network bandwidth (Lum & Lau, 2002). Traditional approaches have simply sacrificed the video quality and produce distorted pictures and audio, which are not necessarily acceptable for small screen and speakers. Hence, users should be able to select which key segments (highlights) to watch, thus content-based analysis of sports video is needed to extract the important content automatically. Automatic sports video highlights extraction has been a major issue, which has been addressed by researchers world-wide (Babaguchi, Ohara, & Ogura, 2003; Duan, Xu, Chua, Qi, & Xu, 2003; Ekin & Tekalp, 2003; Rui, Gupta, & Acero, 2000); therefore it will not be the focus of this article.

The scenarios also show the importance of context awareness as an integral feature in mobile computing, which means that applications should react according to the circumstances in which they operate (Wikipedia, 2006). Almost any information available at the time of an interaction can be seen as context information (Korkea-aho, 2000), thus its long list can be categorized into: user-, physical-, computing- and time- contexts (Chen & Kotz, 2000).

Based on these discussions, Table 1 summarizes the requirements for sports video viewing on mobile devices. In this article, we will propose a content-based video indexing and retrieval that supports a total control over the video accessing (i.e., M1-M4) and how it can meet all the other requirements (i.e., T1-T4, and S1-S4). To demonstrate the look-and-feel of the system, we have implemented a Web-based video retrieval system that can be accessed by desktop and mobile devices; thus supporting multi-platform access (S1). Figure 2 depicts the system's interface.

TOTAL CONTROL ON PLAY-BACK

It should be noted that all video playback tools, such as Windows Media Player and Apple QuickTime, support total control over: *play*, *pause*, and *rewind* during live streaming video (T1). Fast forward is only available when the future content is already available; for example, play-back is delayed after the video is recorded (T2). While play and pause are very straight forward operations, fast forward and rewind should be achieved in a more elegant manner, rather than

Figure 2. Web-based video retrieval system accessible for desktop and mobile devices

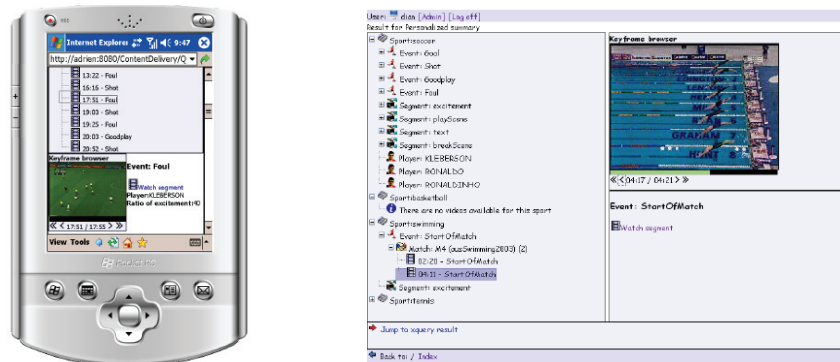

Table 1. Requirements for most-convenient mobile video viewing

| WHEN (Temporal) | WHERE (Situation) | HOW (Access Method) |
|---|--|--|
| T1: During (real-time): contents are presented as-it-is. Indexing can benefit from Web sites that offer real-time content annotation | S1: Seamless multi-platform access: users share familiar GUI and data on desktop as in mobile devices | M1: Total control on the video playback: pause, rewind, fast-forward, and so forth |
| T2: After (Recorded): there is time for processing content extraction and indexing. Often we don't want a summary of the content (ruining the excitement). | S2: <i>User context:</i> profile (identity), activity, and varying pace of interaction, Surroundings (including people nearby), social situations, schedules and agendas. | M2: *Non-linear (hyper) navigation within single and/or multiple documents |
| T3: Before (Preview or build-up): Team and player introductions, score predictions, supporters' comments | S3: <i>Physical context:</i> lighting, noise, temperature | M3: *Customizable and personalized summaries: users should not write their own queries. |
| T4: <i>Time context:</i> time of a day (morning/night), week, month, season, and so forth | S4: <i>Computing context:</i> adaptive to hardware (platform) and network resources | M4: *Multimodal access: key representations for low-bandwidth, using sound/image |

* M1 – M4 represents requirements for total control over the playable contents

just jumping several frames. In fact, content-based intelligent fast forward should support smart skimming, which allows users to skip uninteresting segments without missing too much of information. This means that a user would be able to recognise the aim of the video's contents via a shorter version of the original video. Intelligent fast-forward (or skimming) supports a varying pace of interaction, which is often determined by users' contexts, including activity, schedules and agenda (S2). During mobile video consumption, users will benefit from fast skimming especially if the current content is boring or when the playing device is running out of battery, which part of computing context (S4).

In order to achieve a successful skimming, the system should exploit the fact that users unintentionally embed their understanding and interests of the video content through their interaction with computers. Thus, video skimming

for future users can be based on modeling previous users' experiences and attention with the video. One method is to use *browsing behavior* since intelligent skimming can be achieved by delivering shorter video clips which are personalized based on users' preferences. Common tracking of video usage can be achieved by examining a usage log to determine the number of times a video (segment) has been accessed. For example, a shot rank calculation framework can be used to measure the subjective importance of video shots by unifying low-level video analysis and user-browsing-log mining (Yu, Ma, Nahrstedt, & Zhang, 2003). Since usage log is not always sufficient to reveal user interests, a statistical model such as Hidden Markov Model can be used to analyze the potential browsing states while users are watching videos, such as "aimless browse," "looking for something," and "found what I wanted" (Syeda-Mahmood &

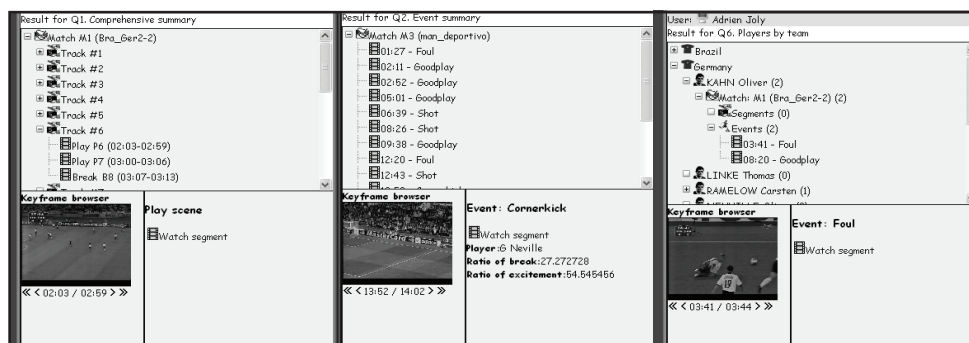

Poncelson, 2001). Thus, interesting segments can be defined as the segments “played” by users in an “interested” state. Unstructured video contents should be therefore managed by standard meta-data. Another method is to use *user attention model* to presents contents that would be generally interesting for users. While watching a video sequence, human attention is generally attracted by various information channels including image sequence, audio track, and text information. A complete user attention model should be fused using machine learning or linear combination from the user attention model of each modality. For example, by combining audio and visual models, video skims can be produced without interrupting sentences in the audio channel (Ma, Lu, Hong-Jiang, & Li, 2002) developed. Thus, video skims can generally generated by selecting particular visual objects and audio keywords (Smith & Kanade, 1998). For example, as soccer video contains many global shots, users will find it easier to follow the action if the regions of interest are zoomed-in (by cropping) on small devices in real time (Seo & Kim, 2006).

NON-LINEAR NAVIGATION

Current mobile video players have yet to fully support non-linear navigation of video contents within a single and/or multiple documents. This feature is particularly useful if users are presented with a large collection of videos. For example, users can benefit browsing on the contents within a single video according to the topics (e.g., soccer goals), or within multiple documents according to subjects, topics classification and taxonomy. To support this feature, content extraction and summarization processing are required. In this section, we will describe some video summarization schemes that enable non-linear navigation.

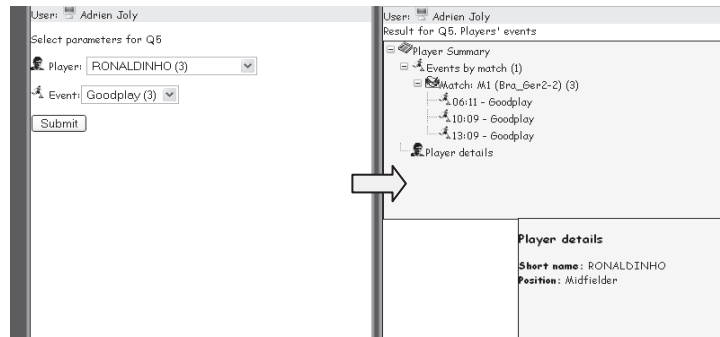

- Comprehensive Summary:** We have applied a hierarchical structure to organize a sports video summary that consists of integrated plays, breaks and highlights as shown in *Figure 3a*. Using this summary structure, users can easily choose to browse a sports video either by play-break sequences (like audio tracks), or collection of highlights (based on the categories such as goals and fouls). When a particular collection is selected, users can select the particular highlight segment. Each highlight segment will consist of *play* and *break* shots. Most sport viewers prefer to focus their attention to events within play segments. It is due to the fact that most sport videos contain many events that cause a game to stop, such as foul, goal celebration and end of playing period in soccer. In most cases, even a sports fan does not want to spend their time waiting for the game being resumed again. On the other hand, if users prefer to browse by sequences, they can check whether the sequence contains a highlight. Thus highlight can be a subset or the whole length of a sequence. Users can watch the entire sequence or watch the highlight only for a shorter version. Based on a user study reported in Tjondronegoro, Chen, & Pham (2004), we found that most sports fans would rather watch the entire sequence to fully understand the context of the highlight, while most casual viewers chose to watch just the highlights to save some viewing time. However, both user classes liked the idea of skipping play-break sequence, just like they can skip a track in audio compact disc (CD), since each sequence is “self-consumable.” Generally, a play-break sequence contains events which can be classified based on the sports genre, while play segments describe the cause (of each event), and break segment describes the outcome (of each event). This model has some obvious benefits. First, users can watch all play and break scenes or just the ones that

Figure 3. (a) comprehensive summary, events summary and team summary; (b) user preference-based summary; (c) player’s summary; (d) favorite match summary

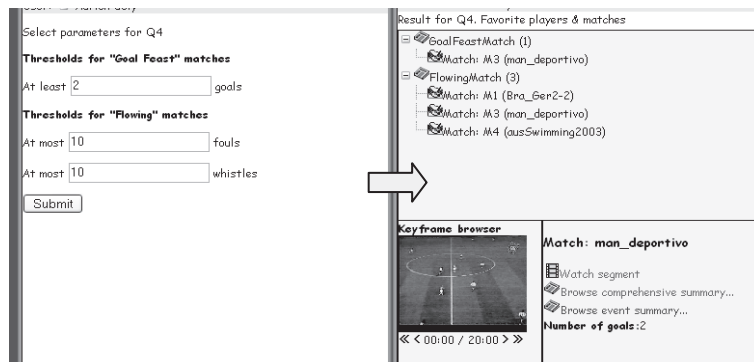

(a)

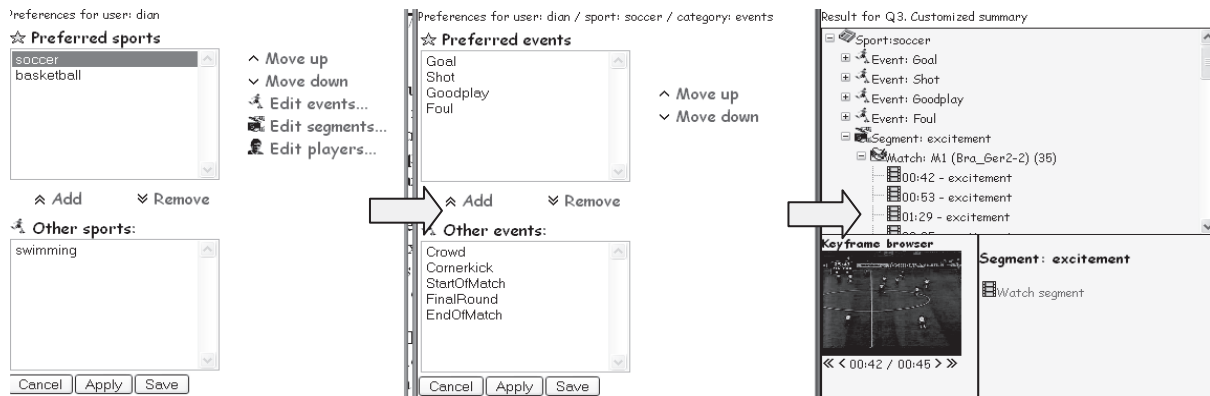

Figure 3. continued

(b)

(c)

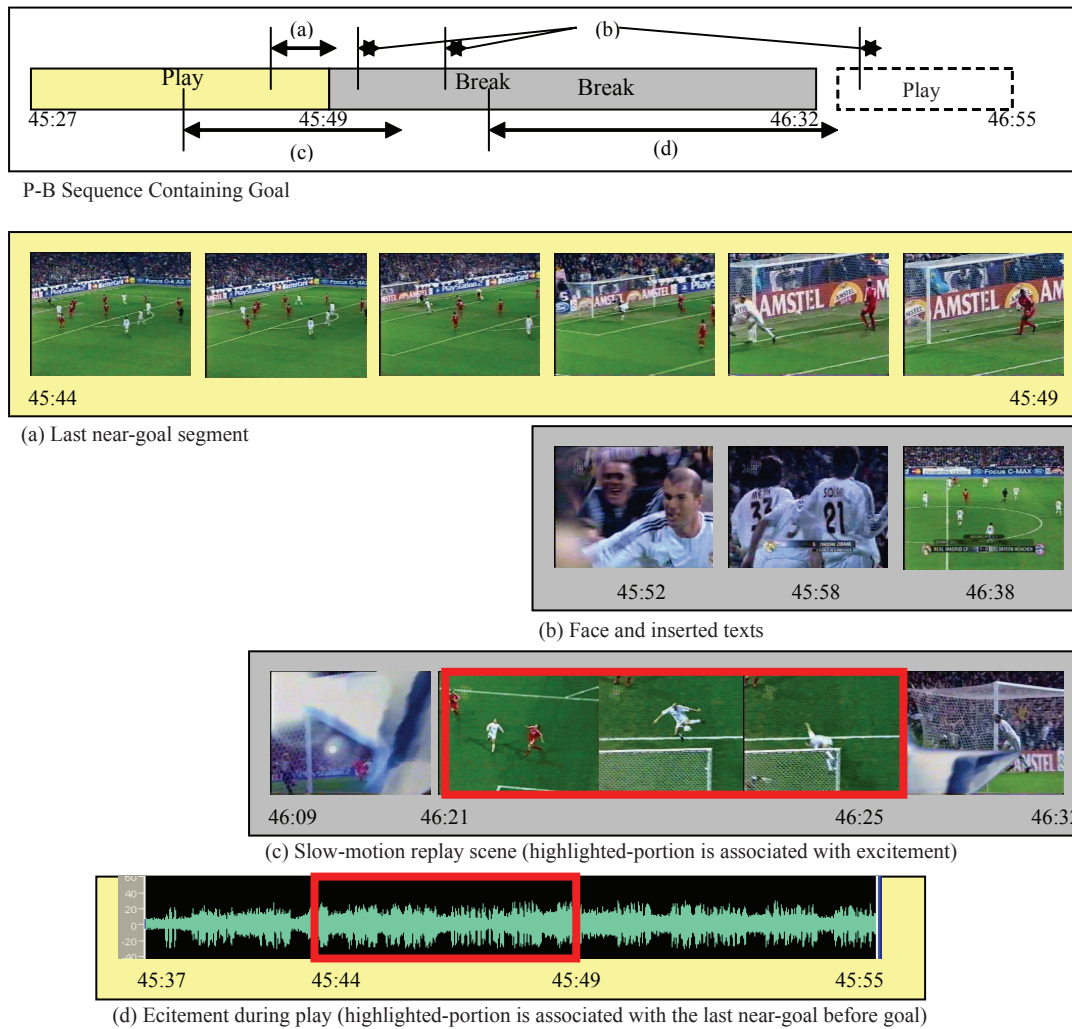

(d)

have a certain number of highlights. Second, users can refer back to the whole play or break scene and thus answer: What happens before and after a highlight? Or what causes a highlight? Third, the model lets viewers have one or more highlight collections for a sports video and structures them in a hierarchical scheme. Thus, users can build their own highlight collection on top of existing or system-generated collections.

- **Events Summary:** Event-based indexing can be used as the potentially most suitable indexing technique for sport videos, since sport highlights on TV, magazine or Internet are commonly described using a set of events, particularly the important or exciting events (i.e., key events or highlights). The first reason is the fact that a sports match can be naturally decomposed into specific events. For example, soccer videos may

Figure 4. Multimodal representation of sports video

contain players kicking the ball, scoring goals, and so on. Secondly, sport viewers remember and recall a sport match based on the events, especially the most exciting events. For instance, viewers will remember that a goal is scored during the first playing period of a soccer match after watching the video. Thus, when he/she wants to play that goal event again, the query can be based on the particular period of play within the soccer match. Thirdly, events can assemble, describe and summarize specific audiovisual features in soccer videos. Thus, events can serve as an effective bridge between low-level features and high-level features in sports videos. Finally, events occurrence and its order during a specific soccer/sport match can be predicted based on the specific domain knowledge and therefore can be detected automatically.

- **Players by Team Summary:** Most sport fans support particular teams and players. Thus, this summary pres-

ents all video segments in which players that belong to particular teams appear. This summary has an apparent entertainment value since users can easily see all the videos in which their favorite teams are involved. Figure 3(a) depicts the screen captures of players by team summary and match events summary.

Players by team summary can be used to construct a *preview clip* (T3) that shows the performance of two competing teams. It is obvious that non-linear navigation of video content supports a varying pace of interaction (S2). Users do not need to follow the standard pace of each match since they can easily browse certain topics or events, move between contents easily within one video and between videos interchangeably. Moreover, depending on users' regularity in accessing the summarized contents (T4), they can choose to watch summaries at any particular time. For example, after a competition like FIFA (soccer) World Cup, users

can view all events that belong to the team and players that have competed.

CUSTOMIZED PERSONAL SUMMARIES

While using mobile devices, users have a limited capability in entering complex queries. Thus, content-based and personalized summarization that creates browseable, dynamic event structures will make users feel in total control. Using customized and parameterized summaries, we can support users' context including personal profile (S2). Personalized summary can be constructed using:

- **Parameterized Queries:** Users need to understand the query's syntax language and the data indexing schema before they can write queries of their retrieval requirements. A better alternative is to assist users in selecting what they want to watch by constructing "queries-generated" dynamic summaries, event structures, and customized summaries. Thus, users only need to "fill-in-the-gaps."
- **Users' Preferences:** Users should be able to explicitly specify what they want to store and watch.
- An automatic personal summary can be constructed based on search (retrieval) and accessing history (log). This has been discussed previously in the "total playback control" section.
- **Annotation and Metadata:** Users can share their preferences for future searches. For example, each individual user may have favorite and past searched and played clips. Based on annotation by community, popular and top-rated clips can be determined.
- **Parameterized Summary 1—Player's Summary:** (Figure 3b) This query is able to list a certain player's (e.g., Ronaldo) details, such as full name, short name, position, and any event segments that related to him regardless of in which match. It determines all specified event segments in all matches in which the selected player appeared and displays a count on that event (e.g., goals) too. This query facilitates a user tracking a certain player's performance, such as how many goals he scores and how many fouls he made, in all matches in the video database.
- **Parameterized Query 2—Favorite Players and Matches Summary:** (Figure 3c) In this query, users can specify the type of their favorite match and/or players. For example, some users only like to watch a "goal feast" match, which is a match with > N number of goals.
- **User Preference-Based Summary:** (Figure 3d) Users can explicitly choose their favorite type of events, players and segment in this preference. This summarization

is particularly useful when users want to specify the total duration of the summary while having total control on the segments, events and players that they will be able to watch.

MULTIMODAL ACCESS

Since video contains a synchronized content of audiovisual modalities, it is naturally larger than other media types such as image and sound. To reduce bandwidth and produce a more compact representation, video can be represented by "lighter" media and smaller clips, including scenes, shots, frames, images (mosaic, multi-frames capture), sound, and text. Multimodal access supports physical context (S3); for example, users may prefer to watch (image-only) for a noisy environment (unless users have headphones), or "audio-only" while standing on a crowded public transportation. Video playback can also be difficult to watch when the lighting is too bright. Multimodal also allows users to multi-task in a busy lifestyle (S2), as described in Scenario 1. For instance, users may only be able to listen to the audio while looking at the full video during key events only. Multimodal video indexing will be adaptive to different hardware and network resources. Unlike most of the current solutions for mobile video playback, which sacrifice video quality over lower-bandwidth and smaller screen, multimodal access can allow users to preview a particular video segment (in the form of image and text) and choose to play a particular clip in a high-quality format.

Our system constructs the sports video index using two main abstraction classes, namely, *segment* and *event*. Each segment is instantiated with a unique key of segment ID into either video, visual, or audio segment. An event can be instantiated into generic (e.g., interesting event), domain-specific (e.g., soccer goal), or further-tactical (e.g., soccer free kick) semantics. Events and segments are chosen as they can provide an effective description for many sport games. For example, most users will benefit from watching soccer goals as the most celebrated and exciting event. Segments can be used as the text-alternative annotations to describe the goal. As shown in Figure 4, the last near-goal segment in a play-break sequence containing goal describe *how* the goal was scored. Face and text displays can inform *who* scored the goal (i.e., the actor of the event) and the updated score. Replay scene shows the goal from different angles to further emphasize the details of how the goal is scored. In most cases, when the replay scene is associated with excitement, the content is more important. Excitement during the last play shot in a goal is usually associated with descriptive narration about the goal. In fact, we (humans) often can hear a goal without actually seeing it.

CONCLUSION

In this article, we discussed some methods that enable users to have total control over the contents of mobile sports video access. The key requirement is content extraction and indexing, as the system can present results according to how users want it, anywhere and at anytime. Full play-back control is achieved by supporting the traditional play and pause operations, plus an intelligent fast-forward or skimming that helps viewers to get an overview of the video's contents. Non-linear navigation within single and/or multiple documents is supported by comprehensive summary of a single match containing play-break and events segments summary in a game containing the highlights, as well as a summary that puts together all segments from the database in which a users' favorite players and teams appear. Customizable and personalized summaries can be achieved manually by allowing users to enter parameters on dynamic summaries and specify their preferences in a stored user profile, or automatically by allowing the system to learn from the usage history and behavior. Multimodal access is achieved by representing video with other modalities such as key frame or image and audio.

ACKNOWLEDGMENT

The authors would like to sincerely thank Adrien Joly who developed the Web-based system during his stay at QUT for exchange program with INSA de Lyon, France.

KEY TERMS

Break: A break is similar to play, except it happens when the game is stopped or paused due to specific reasons such as foul and goal.

Browsing Behaviour: Browsing behaviour is the way users typically look for the desired information.

Event: An event is a special type of video segment that contains a particular theme or topic such as a soccer match, goal, and foul. An event includes (a) temporal textures such as flowing water: indefinite spatial and temporal type, (b) activities such as a person walking: temporally periodic but spatially restricted and (c) isolated motion events such as smiling: no repeat either in space or in time.

Multimodal: Multimodal means that a system utilizes more than one mode or modality (as of stimulation or treatment) to transfer information. This term is often called multimedia since video appeals to more human senses than an image.

Object: An object is either an abstract or visible entity that appears in a video segment; therefore it can be regarded as the actor of the segments and events.

Play: A play is a specific type of video segment in a sports match, which shows events when the game is still flowing, such as when the ball is being played in soccer.

Preview Clip: A preview clip is a prepared clip that shows the contents of a future program by collating existing clips which have similar topics of interests. For example, a soccer match preview can show preview clips that contain the key players from each team.

Queries Generated Summary: This is the type of summary that is not predefined statically or prepared manually by collating certain video segments. Instead, it is constructed using a query formula on video indexes.

Segment: A segment is an audio, visual, or audiovisual portion of video that contains index-able contents such as whistle, slow motion replay, close-up players' face and near goal area.

User Attention Model: User attention model is the predictable area of interests from users while watching each video modality, such as a particular spatial area in an image.

Mobile Telephony in Sub-Saharan Africa

M

Princely Ifinedo

University of Jyväskylä, Finland

INTRODUCTION

A mobile telephone is a telecommunications device that connects its user to a network using a wireless radio wave transmission technology. In some parts of the world, mobile phones are known as cellular phones. Mobile telephones were first introduced in the mid-1980s (Marcussen, 2002; Sadeh & Sadeh, 2002; Sarker & Wells, 2003). Mobile telephony is diffusing globally due to a variety of reasons, including cost advantages in setting up the system compared to landlines, its small-sized nature, portability, and its ability to foster and enhance social relationships, among others (Plant, n.d.; Marcussen, 2002; Sadeh & Sadeh, 2002; Sarker & Wells, 2003; ITU, 2004; Anonymous, 2006). According to reports by ITU (2004), the percentage of total telephone subscribers that are mobile telephone subscribers has been increasing over the last five years. In 2005, mobile telephone subscribers were approximately 62% of total telephone subscribers for the five regions of the world (see Table 1).

The data in Table 1 shows that Africa has the lowest connectivity rate (i.e., 9 per 100 people), but with the highest number of mobile telephone users as percentage of the total telephone subscribers for 2004 (WEF, 2003; ITU, 2004). The current trend suggests that this will be the case for some time (BBC News, 2002a; WEF, 2003; ITU, 2004). For example, BBC News (2002a) reported that “the popularity of wireless communication is soaring. More mobiles were connected in

Table 1. Mobile telephony (cellular) subscribers per 100 people 2004 (ITU, 2004)

| Region | CAGR | Per 100 2004 | As % of total telephone subscribers 2004 |
|----------|------|--------------|--|
| Africa | 59.7 | 9.14 | 75.1 |
| Americas | 22.9 | 42.74 | 55.8 |
| Asia | 34.4 | 18.72 | 56.8 |
| Europe | 25.9 | 71.61 | 63.6 |
| Oceania | 20.7 | 61.71 | 59.2 |

* CAGR (Compound Annual Growth Rate)

the past five years than landlines installed in the last century.” Similarly, a recent report by the World Economic Forum (WEF, 2003) on ICT status in Africa indicated that the number of mobile telephone subscribers in Africa now numbers around 23 million and the demand is expected to grow in the future. Furthermore, the WEF report also provided the growth estimate for other information and communication technology (ICT) products in Africa which is reproduced in Figure 1. Clearly, the number of mobile telephone users is the highest of the three ICT products compared.

Given the encouraging statistics seen with mobile telephones user in Africa, the following questions are posed:

Figure 1. Growth in the number of ICT users in Africa

- Can Sub-Saharan African countries exploit the diffusion of mobile telephones to create or engage in m-business?
- Why would such a facility be useful for them?

THE REGION OF SUB-SAHARAN AFRICA

Africa, with its population of about 880 million people, is the poorest continent in the world (World Bank, 2001a, 2001b; Ifinedo, 2005a, 2005b; CIA, 2005). In terms of geography, Africa tends to be described as comprising two regions—North Africa and SSA. The northern part is comparable to the Middle East economically and culturally (Ifinedo, 2005b). Further, South Africa (also known as the Republic of South Africa [RSA]) tends to be excluded from the rest of SSA because of its relative high socio-economic indicators. In brief, SSA is associated with poverty, a high illiteracy rate, civil strife, and chronic under-development (World Bank, 2001b; ITU, 2004; CIA, 2005). In this article, the northern part of Africa and RSA are excluded, because these parts of Africa have better indicators for ICT use and are richer than the rest of the continent (Ifinedo, 2005b). Put differently, the conditions in SSA are different from those in the excluded regions, and the region of SSA typifies perceptions of Africa more than do the excluded regions. For example, in a recent report, the World Bank (2001b, p. 38) states: “In Africa, slow growth increased both the share and the number of the poor over the 1990s; Africa is now the region with the largest share of people living on less than US\$1 per day.” The conditions in SSA, it appears, are more consistent with the foregoing observations than for any of the countries in North Africa and RSA.

With about 10% of the world’s population living in the SSA (CIA, 2005), it is sad to note that only 0.2% of the world’s one billion fixed telephone lines are located in the region (WEF, 2003, p. 2). Indeed, the current statistics for Africa with regard to the pervasion of mobile telephony in the region is welcoming. However, one of the main questions for policymakers in the region is: how should the advent and spread of mobile telephony in the region be exploited to improve the livelihoods of its inhabitants? Answers to such a question are pertinent because development research and reports have suggested that ICT adoption, diffusion, and usage in the developing countries (including SSA) could hasten socio-economic development in such disadvantaged regions of the world if concerted efforts are made to harness the power of such ICT products (Avgerou, 1998; Castells, 1999; Singh, 2000; G8 DOT Force, 2001; UN ICT TASK Force, 2004; Ifinedo, 2005b). Recently, during an ICT task force meeting at UN headquarters in New York, the UN Secretary General Kofi Annan remarked: “Information and communication technologies can help us turn this potential

[of using ICT for socio-economic development] into concrete opportunities that will help the poor work their way out of poverty” (BBC News, 2002a). The UN Secretary General added: “It is not, of course, a magic formula that is going to solve all the problems, but it is a powerful tool for economic growth and poverty eradication, which can facilitate the integration of African countries into the global market.”

Along a similar line of reasoning, Singh (2000) discussed how the use of ICT products in developing nations can improve the chronic socio-economic conditions in such regions. He stated, “For firms [and people] in the developing countries dealing in the global market some of the common problems are [as follows:] lack of market knowledge, poor communication, cumbersome procedures, delays and uncertainties in supply, poor quality and excessive stock.” He noted that e-commerce (the buying and selling over the Internet) “can help solve some of these through better knowledge management, communication and automated supply procedures leading to higher profits and enhanced competitiveness” (p. 23). It is important to add that the foregoing issues and problems identified by Singh are inhibitors to socio-economic development in developing parts of the world even when the emphasis or bias is not the global market. In other words, poor supply chain management and poor organization could stifle economic development in local trade as well when information does not get to the people that require it.

At this juncture, it is vitally important to investigate if the ongoing positive pervasion of mobile telephony in SSA can facilitate m-business among the people and businesses in the region. Next, we discuss the concepts of mobile business at a general level, and present a summary of how such concepts have been implemented in one SSA country—Senegal—to improve the lot of some citizens in that country.

WHAT IS M-BUSINESS?

Simply, m-business, which is also known as mobile business, can be defined as doing business using wireless services. This is the mobile equivalent of e-business. A clear picture of m-business emerges by understanding e-business. Zwass (1996) defines e-business as “the sharing of business information, maintaining business relationships, and conducting business transactions by means of the telecommunication networks.” Similarly, m-business can be defined as the sharing of business information, maintaining business relationships, and conducting business transactions using a wireless radio wave transmission technology. Just as researchers (e.g., Turban, Lee, King, & Chung, 2000) have argued that there is a difference between e-commerce (buying and selling of good and services online) and e-business (a broader term that includes e-commerce and the servicing of customers, collaborating with entities both within an organization and

outside it), this article distinguishes between m-business and m-commerce. Broadly speaking, m-commerce is the next-generation e-commerce; it refers to the buying and selling of goods and services through a network of wireless radio wave transmission technology (Sadeh & Sadeh, 2002). The buyers and sellers may use mobile phones (cellular telephones) and/or personal digital assistants (PDAs). Wireless application protocol (WAP) is the emerging technology behind m-commerce and m-business (Anonymous, 2006).

Further, many handset manufacturers, including Nokia, Motorola, and Ericsson, having realized the potential for m-business and m-commerce worldwide, have initiated partnerships with carriers such as AT&T Wireless to develop WAP-enabled smart phones. Another telecommunications industry specification that is increasingly being mentioned in connection with the emerging m-business initiatives is Bluetooth. Essentially, this technology describes how mobile or cellular phones, PDAs, and computers can easily be interconnected using a short-range wireless connection (Anonymous, 2006). M-business and m-commerce issues seem to be diffusing at different rates across the world. Europe and some parts of Asia (notably, South Korea and Japan) appear to be leading the rest of the world on such fronts (Marcussen, 2002; Sadeh & Sadeh, 2002; McKinsey Quarterly, 2006). As would be expected, the diffusion of m-business in SSA is marginally low. However, we present a case study of m-business in Senegal in the next section.

M-BUSINESS IN SSA: A CASE STUDY

M-business in Africa is beginning to be discussed, and development from Senegal seems to be pioneering such initiatives in the SSA region (e.g., Annerose, 2001). Mobile services have been used to improve commercial activities in the country (Annerose, 2001; Manobi, 2003). Like many countries in SSA, Senegal is poor: about 70% of its population lives in rural communities where most of them make their living by farming and fishing (Annerose, 2001; CIA, 2005). However, fallouts from the increasingly globalized world, Annerose (2001) noted, have reached the peoples of SSA, including Senegal. He comments:

Like many developing countries, Senegal in recent decades has deregulated and liberalized its economy to adapt to the demands of globalization. In rural areas, this has brought the gradual disappearance of government mechanisms that managed production and prices. Small-scale farmers and fishermen have had great difficulty adapting to a purely market-driven economy, and rural incomes have dropped. One of the key challenges is that farmers and fishermen have no way of determining market prices before they sell their crop or catch to middlemen, many of whom take advantage

of this ignorance and offer prices much lower than market prices.

To assist, the fishermen and farmers in one Senegalese town, Niayes, sell their wares at lower losses, compared to previous times when huge losses were incurred due to the poorly organized supply chains that are commonly seen with businesses in developing parts of the world such as SSA; Manobi, a local private telecommunications company, came up with an initiative using mobile technology to help them gather information about market prices. The first phase of the project commenced in 2001; it involved Manobi and some fruit and vegetable farmers of Niayes. The chief executive officer of Manobi, Annerose, reported that as a result of using the mobile phone-based market price system, farmers were able to increase their prices by over 50% (Annerose, 2001). In summary, farmers use their mobile phones from their homes and farms to check price levels, and the information they garner permits them to make better decisions regarding what to sell, when to sell, and even what to grow. BBC News (2002b) reports: “Even though Manobi is only being tested [in 2001], it is already having an effect on the way farmers grow crops.” The report continued by citing quotes from the CEO of Manobi who asserted that: “For a farmer it is very interesting to note that price is not something stable; a price is living data and is changing very quickly.” (Figure 2 shows a farmer using a mobile phone from his farm.)

Following the success of the pilot project, the initiative expanded, and in 2003, Manobi (the firm)—in partnership with three local fishing unions, two telecommunications companies (Alcatel and Sonatel), and the Canadian International Development Research Center (IDRC)—started another project that aims to support the livelihoods and improve the safety of Senegalese fishermen through the provision of timely information on market prices, weather reports, and other information services via mobile phones using WAP and SMS (short messaging services) technologies. The

Figure 2. An African vegetable farmer using a mobile phone (Photo Source: Messrs Ololube, & Ifinedo)

fishermen are provided with training on how to retrieve the information they require (Manobi, 2003). In brief, the project uses three data collectors who are stationed in markets of the participating cities and towns, including Dakar and Kayar. The information they collect is captured in a Psion computer and is then transmitted by a mobile phone to a central database and Web site. This arrangement ensures that market information is available real time to fishermen. In addition, the fishermen also get access to up-to-date weather reports. The project has been a success, and several individual users (fishermen and artisans) joined by the end of 2003 with a higher number of subscribers expected in the future. BBC News (2002b) also reported:

Now Manobi is talking to professional organisations that represent more than 250,000 people who work in Senegal's agricultural industry. Prices [of using the services] are kept low and farmers pay for the service as part of a deal between Manobi and the national telephone company.

The future of the initiative seems to be secured because Manobi, the national government of Senegal, and other private-sector partners are developing a detailed plan to extend the service to farmers and fishermen across Senegal (Annerose, 2001; Manobi, 2003).

THE USEFULNESS AND CHALLENGES OF M-COMMERCE DIFFUSION IN SSA

To some extent, some aspects of the sorts of problems hampering commercial activities in developing countries that Singh (2000) discussed in his report can be ameliorated through the engagement of m-business. For example, m-business could provide a good opportunity to solve entrenched problems of poor supply chain management that manifest in several ways, including a lack of market knowledge, uncertainties, and/or instability in supply due to poor communication systems and excessive stock. When these kinds of problems are tackled, it is likely that farmers, fishermen, and other artisans that require access to better information can improve their competitiveness, which will invariably lead to higher profits for them and subsequently a higher quality of living standard. M-business and m-commerce may provide an opportunity in this regard. It is likely that such an ICT-enabled initiative could make a positive impact on the lives of the people and businesses in SSA. The diffusion of the basic device for m-business, namely, mobile telephones, could be interpreted to mean that the opportunity to deliver quality information in a real-time fashion is enhanced.

The Manobi projects in Senegal offer support for the preceding statement with concrete examples as to how such changes can be brought about. In the first phase of the Manobi

project, farmers increased their returns by over 50% from a mobile phone-based market price system. The quality of lives (i.e., safety) of the Senegalese fishermen using the Manobi system was improved through the availability of up-to-date weather information. The fishermen also have the opportunity to increase their earning through quality information about market prices. Additionally, according to Manobi (2003), the project was able to persuade Sonatel to install a cell phone base station near the beach at Kayar. This benefits the fishermen as well as the neighboring communities.

There are, however, several challenges facing the emergence of m-business and m-commerce that policymakers in the region must address. A few of these are briefly discussed as follows.

Technology

Policymakers in the SSA region must continue to encourage the deregulation of the telecommunications industry. Studies show that teledensity (number of telephone users per 100) tends to be higher where governments are not involved in the provision of telephony to their citizens (Ifinedo, 2005a, 2005b). SSA countries wishing to adopt m-business must be aware of developments in the technology and must be willing to accommodate new concepts that may emerge with the initiative. Bluetooth is one example that is diffusing in the developed West which is relatively unknown in SSA. To ensure a smooth diffusion of m-business and m-commerce, governments in the region must invest in building related infrastructure. Telephony must be extended to both rural and urban centers in SSA to avoid the inadequacies that were seen with landlines, which tend to be concentrated around urban centers (Okoli, 2003; Ifinedo, 2005a). When m-business emerges fully in SSA, policymakers must not downplay security and legal issues often accompanying the use of such technologies. A lack of attention in such areas might negatively affect peoples' attitudes toward the initiative.

Illiteracy

This is a major challenge for any emerging m-business initiative in SSA. The region has the highest rate of illiteracy in the world (Ifinedo, 2005a; CIA, 2005). In order to fully reap the benefits of ICT products for improving economic conditions, efforts must be directed toward improving the literacy levels in SSA.

Costs

Efforts must focus on making mobile telephones (handsets) available to more people in SSA. The current statistic of nine mobile phone users per 100 persons could be improved.

Governments may consider subsidizing such facilities for poor farmers and artisans in underserved communities.

Health Concerns

Governments in SSA must follow developments regarding health concerns that have been linked to the use of mobile telephones (ARPNSA, 2005). For example, the preceding report states:

Concerns have been raised about the normal mobile phone, which has the antenna in the handset. In this case, the antenna is very close to the user's head during normal use of the telephone and there is concern about the level of microwave emissions to which the brain is being exposed.

Culture

Governments in the SSA region must begin to sensitize their populace about the benefits of using ICT products to improve their quality of life and living standards. Efforts must be directed at instilling a new way of thinking about m-business and related initiatives. Arguably, m-business might be facing an uphill task spreading in SSA if the cultural undertones are not conducive for digital transactions. Okoli (2003, p.16) comments that "Africans do not have the culture of buying a product without [having] tactile contacts." For m-business to thrive, a change of culture may be necessary.

KEY TERMS

Bluetooth: This technology describes how mobile or cellular phones, PDAs, and computers can easily be interconnected using a short-range wireless connection.

Information and Communication Technology (ICT): Information systems and communication technologies that allow data to be processed, stored, shared, and transmitted over networks.

Mobile Business (M-Business): The sharing of business information, maintaining business relationships, and conducting business transactions using a wireless radio wave transmission technology.

Mobile Commerce (M-Commerce): The buying and selling of goods and services through a network of wireless radio wave transmission technology.

Mobile Telephone: A handheld device used in mobile telephony; it is also sometimes known as a handset.

Mobile Telephony: The use of wireless transmission technology to connect users.

Personal Digital Assistant (PDA): A handheld device that organizes personal data; includes an address book, task list, memo pad, and calculator, among others.

Short Message Service (SMS): A content delivery technology introduced in 1997 that permits the sending of short texts between users in a mobile telecommunications environment.

Sub-Saharan Africa (SSA): The region of Africa excluding the northern part of the continent and the Republic of South Africa.

Supply Chain Management: Management of the value-added chain, from the supplier of goods and services to the final consumer.

Mobile Television

INTRODUCTION

During the last 10 years, the TV landscape has changed quite significantly. With a relatively low investment, consumers can get access to several hundreds of TV channels. Free TV stations are trying to establish new revenue sources in order to become less dependent on revenues from advertisements. FreeTV and PayTV service providers operating via cable or satellite networks are faced with competition from IPTV service providers, which are offering video-on-demand services to broadband Internet users.

An important emerging trend is Mobile Television (MobileTV). The basic idea of delivering TV services to mobile users has been around for quite some time. Between 1982 and 1985 Seiko sold a wristwatch including a small TV screen, which had to be connected to an external receiver carried at the belt. The display size was very small, roughly half the size of a modern smartphone, and also the quality of the monochrome display was limited. Later, when LCD displays became available at cheap prices, several manufacturers started to build handheld TV receivers. However, this approach failed for a number of reasons: First the additional TV reception equipment was often too large and heavy to be carried around all the time. Secondly, it was often difficult to receive noise-free pictures, simply because terrestrial TV networks had not been engineered for portable reception.

Nowadays, mobile phones with multimedia capabilities and excellent display qualities have become commodities (Lee, Byun, Lee, & Kim, 2003; Koike, Matsumoto, & Kokubun, 2006), and third-generation (3G) cellular networks like UMTS provide sufficient capacity and data rates to deliver multimedia services to mobile users. Those networks also provide very good coverage, which gives mobile users access to MobileTV services wherever they are. Upcoming mobile broadband technologies like HSDPA will give further quality improvements due to increased data rates. With 3GPPMBMS and 3GPP2 BCMCS, broadcast/multicast

extensions have been added to 3G standards and will become commercially available during 2007/2008 (Toenjes, 2004; Bakhuizen & Horn, 2005).

Apart from the cellular broadcast/multicast evolution, also digital TV transmission standards have produced variants addressing broadcast delivery to mobile devices (Weck & Wilson, 2006). DVB-T for instance has produced a variant called DVB-H, where the *H* stands for *handheld*. Even the digital transmission standard DAB, originally developed as a digital replacement for analog FM radio, developed a variant called T-DMB, which allows broadcasting of multimedia content to mobile devices.

This article gives an overview of the main technology and service trends in MobileTV. We start with an overview about existing MobileTV services. We then discuss the various transport options for delivering MobileTV services. At the end we go through some important service layer components.

MobileTV

MobileTV Services Today

During 2004 and 2005 many mobile operators launched commercial MobileTV services. In the simplest case, this is just a re-broadcast of existing TV channels.

In order to get access to a MobileTV offering, users have to pay a monthly fee. The basic package contains access to live TV channels; for on-demand premium content (for instance, sports channels), end users must pay separately.

However, existing TV channels are using formats that are not adapted to the behavior of mobile users. Studies have shown that mobile users consume MobileTV services in a very different way than fixed TV services (Södergard, 2003). Most noticeable, they spend less overall time per viewing session. The time spent per session is typically around 5

minutes in the mobile case. Likewise the time spent on individual programs is around 1-2 minutes. This behavior makes it necessary to develop new content formats, better tailored to the needs of mobile users. This was addressed during 2005 by some operators, which started to add mobile-specific content provided by existing TV channels to their offerings. An example is a 20-minute summary with the highlights of the week combined with the latest news which is looped over the day and updated once or twice per day.

The services provided by mobile operators today also show a clear trend towards combined offerings including not only live channels, but also personalized video-on-demand content.

Delivering MobileTV services to the mobile phone as an interactive communication device opens up a lot of opportunities for creating new services around the TV experience, and novel services emerge (Rauchenbach, 2005).

An example is interactive MobileTV. Already today there are many formats in traditional TV allowing users to interact with a TV show by sending back SMS for voting, chatting, purchase of ring tones, and so on. Those formats are often used by music stations, targeting younger people. On a mobile device, it is possible to seamlessly integrate the interaction and the program. For instance, a voting request can be presented as an interactive menu from which the user can easily make his selection. By browsing to the right answer and confirming the choice, voting services becomes much more convenient to use, compared to creating and sending an SMS which requires a lot of typing. This demands for advanced user interfaces (e.g., Knoche, 2005).

Systems for Delivering MobileTV Services

Commercial MobileTV services today are delivered over cellular networks. In particular, 3G cellular networks like UMTS provide sufficient capacity and data rates to achieve a good quality of experience. Those networks also provide very good coverage, which gives mobile users access to MobileTV services wherever they are. Upcoming mobile broadband technologies like HSDPA will give further quality improvements due to increased data rates.

Most of the existing MobileTV services are built upon the packet-switched streaming service (PSS) as it was standardized by 3GPP (3GPP TS 26.234, 2004; Elsen, Hartung, Horn, Kampmann, & Peters, 2001). The advantage of 3GPP PSS is its wide availability and support in existing mobile multimedia phones, and some effort has been made to bring PSS's services to unidirectional links (Yoshimura & Ohya, 2004). Since PSS uses a point-to-point connection between each client and a media server, it does not scale very well with an increasing number of simultaneous users.

Therefore, in 2003 3GPP and 3GPP2 started to address broadcast/multicast services in GSM/WCDMA and

CDMA2000, respectively. In 3GPP the work item is called Multimedia Broadcast and Multicast Service (MBMS) (3GPP TS 23.246, n.d.; 3GPP TS 26.346, n.d.). In 3GPP2 it is called Broadcast and Multicast Service (BCMCS). The specifications of cellular broadcast services were functionally frozen during 2004. 3GPP MBMS and 3GPP2 BCMCS have many commonalities. Both of them add the following capabilities to cellular networks:

- A set of functions that control the broadcast/multicast delivery service; MBMS uses the term Broadcast/Multicast Service Center, whereas in BCMCS it is called "BCMCS Controller."
- Broadcast/multicast routing of data flows in the core network.
- Efficient radio bearers for point-to-multipoint radio transmission within a cell.

Both MBMS and BCMCS are introducing only small changes to the existing radio and core network protocols. In the higher protocol layers, the same media codecs and associated transport protocols as for packet-switched streaming are used. This reduces the implementation costs both in terminals and in the network, and makes cellular broadcast a relatively cheap technology. Another advantage of cellular broadcast is that mobile operators can retain their established business models. Current services, such as MobileTV, will greatly benefit from the capacity-boosting effect of broadcast capabilities. Certainly cellular broadcast will also stimulate the development of new, mobile, mass-media services. Likewise, cellular broadcast will enable operators to provide a full triple-play service offering—telephony, Internet, and TV—for mobile handheld devices in a cost-effective way over a common service and network infrastructure.

Not only cellular networks have addressed mobile broadcast services, also digital TV transmission standards have produced several variants addressing mobile broadcast extensions.

One of them is DVB-H (Digital Video Broadcasting for Handheld—Faria, Henriksson, Stare, & Talmola 2006; ETSI EN 302 304, 2004), which can be regarded as an extension to DVB-T (Ladenbusch, 2006), an European standard for conventional terrestrial video services. DVB-H adds new features to the physical and link layer to reduce the power consumption in the receiver and to allow for a more robust transmission as it is needed for mobile devices. DVB-H may reuse the frequencies of old analogue television services, but competes with digital non-mobile television services for the spectrum.

T-DMB (terrestrial digital multimedia broadcasting) is a Korean extension of the digital audio broadcasting (DAB) standard for digital radio. Many countries allocated radio frequencies for DAB, but in most countries the commercial success was limited. This spectrum can now be reused by

T-DMB—that is, it could be deployed quickly. A companion standard S-DMB offers the same service over satellite links, and it is possible to use both DMB standards jointly. For example, the reception quality can be optimized by using S-DMB for large-area coverage and add T-DMB for improved indoor coverage.

T-DMB was called DMB-T for a long time. However, China decided to name its conventional digital TV standard DMB-T, and therefore the Korean standard was renamed. Though not specially tailored for mobile television, DMB-T is able to compete with other approaches for unidirectional transport.

First concepts are underway to integrate DVB-H, DMB, and 3G mobile networks under a common system concept. For example, DXB (digital extended broadcast) tries to establish a common IP-layer and common source coding recommendations for all mentioned transport options (Schäfer, 2003).

Common to non-cellular, broadcast-only systems is the lack of an additional interactive channel, which can be used for feedback or personalized services. This has been recognized as a potential drawback, and integration between broadcast-only and cellular networks has been proposed in the past (Tuttlebee, Babb, Irvine, Martinez, & Worrall, 2003; Pangalos, Chew, Aghvami, & Tafazolli, 2004). However, there are certain co-existence issues that need to be addressed. For instance, in Europe the upper part of the digital TV spectrum, which could be used for DVB-H, is close to the GSM900 uplink. This might lead to interference problems in a combined DVB-H/GSM900 system. Also the business model becomes more complex since an interactive broadcast service provider has to make business agreements with both the DVB-H and the cellular network operator.

MobileTV Service Layer Standardization

The existence of many similar yet different MobileTV standards has been recognized as a disadvantage, especially for service providers that want to distribute their services over different networks supporting different standards. The Open Mobile Alliance (OMA) has at least defined a service layer system called OMA mobile broadcast services, which allows service providers to better separate service generation and management from actual broadcast distribution.

Apart from media transport, which can be realized over different access systems based on already existing standards, OMA BCASST addresses more service-related components of MobileTV service. An example is the machine-readable metadata that is necessary to receive the service, and its transmission. Such metadata is called electronic service guide (ESG), and is for example used to convey information about upcoming services and shows. Interactivity, typically also an important component, enables interaction between the end user and the service provider and its service, enabling func-

tionality like voting or spontaneous purchase of goods.

A very important area in OMA BCASST is content and service access protection. In a commercial MobileTV offering for which a mobile operator wants to charge its customers, it is required to restrict the access to only those services a user has subscribed to. Service access protection is achieved by encrypting the audiovisual data, using strong stream ciphers with adequate key lengths. The keys used to decrypt the data are usually conveyed in a key hierarchy. That means a shared secret key is somehow established between the transmitting server and receiving client. There are different ways of establishing this shared secret, and in fact the different service access protection systems differ most in the principle of how this is done. Changing long-term keys are then encrypted with the shared secret key and transmitted to the receiving client. Such keys do not change too often, maybe in the order of hours or days. They are not directly used to encrypt the media data; rather they are used to encrypt frequently changing short-term keys, which are broadcast together with the protected audiovisual data. Those short-term keys change often, for example in the order of seconds, to avoid that possibly compromised keys are published and used by unauthorized parties. The short-term keys are used to decrypt the audiovisual data. Thus, the key hierarchy consists of a shared secret, which is used to protect long-term keys, which are used to protect short-term keys, which are used to protect the audiovisual data. In 3G MBMS, a service access protection mechanism has been defined that uses the smartcard present in GSM and 3G mobile phones to establish a mutually trusted shared secret. In DVB-H, a service access protection mechanism has been defined that uses special pre-shared keys that are designed for secure content exchange using DRM (digital rights management) systems (Hartung, 2004). Another service access protection mechanism in DVB-H specifies just an interface to proprietary service access protection systems, a model that has long been used in legacy Pay TV systems.

FUTURE TRENDS

In order to attract more and more mobile users, new content formats, better tailored to the needs of mobile users and in particular produced for mobile channels, will evolve. The similar holds for advertisements. The interaction and mobile positioning capabilities will trigger many new personalized add-on services. For example, it is very likely that both the offered programs and the inserted advertisements will be tailored to the user and the context, like location. Further, services will evolve from pure audiovisual services with real-time video and audio tracks, to feature and media-rich services, containing for example embedded pictures, text pages, clips, executables, and graphical navigation possibilities, like in a computer game or interactive Web page

today. Mass content and personalized content will exist side by side.

Aggregation of highly personalized channels, be it in the network or in the terminal, will soon complement the linear TV programs provided today. Content is aggregated based on personal preferences and no longer controlled by content aggregators like TV stations.

Also, TV services and communication services will converge, for example there might be multi-player shows with virtual teams of several players, all sitting at home, but virtually connected via their keyboards and voice connections. There will also be a convergence between fixed and mobile services.

In general, MobileTV services will become rather integrated and bundled with other services, like Internet access, telephone, videophone, and mobile communication services. In order to exploit synergies, it is very likely that these different services will use more and more common components, and they might for example all be based on IP-based protocols and technologies, irrespective of the underlying access technology.

CONCLUSION

Although TV is a service known for many years, delivering TV services to mobile devices is still a comparatively new area, and the design requirements are just emerging (Knoche & McCarthy, 2005). However, there is a strong end user interest in those services. The mobile distribution channel will open new revenue streams for TV content owners and service providers.

Commercial MobileTV services have already been launched in several cellular networks. For mobile operators, MobileTV could become the looked-for killer application, and upcoming broadcast extensions like 3GPP MBMS and 3GPP2 BCMCS will help to further increase the capacity of cellular networks for delivering mass content.

There are also non-cellular standards like DVB-H and T-DMB evolving from existing digital broadcast systems. However, those standards are pure broadcast distribution systems, lacking support for on-demand and personalized services. However, in order to provide more than plain TV services, they need to become tightly integrated with cellular networks, which could then be used for service interaction and delivering personalized content.

The development of a common service layer, which can be used to achieve a good integration between different access technologies, is addressed by the Open Mobile Alliance forum (OMA, 2005).

In the future we will see new content and advertisement formats, better tailored to mobile users. The interaction and mobile positioning capabilities will trigger many new personalized add-on services. Highly personalized chan-

nels, compiled in the network or in the terminal, will soon complement the linear TV programs provided today.

KEY TERMS

BroadCast and MultiCast Service (BCMS): Extension of 3G mobile networks by multicast/broadcast techniques. Standardized within 3GPP2.

Digital Multimedia Broadcasting (DMB): Extension of the Digital Audio Broadcasting (DAB) standard for TV content distribution. Variants for terrestrial distribution (T-DMB) and satellite distribution (S-DMB) exist. Mainly exploited in Korea.

Digital Video Broadcasting for Handheld (DVB-H): Extension to DVB-T for broadcasting of TV content to mobile terminals. Special techniques for low power consumption in the receiver are included.

Digital Extended Broadcast (DXB): System concept for an integrated mobile TV delivery solution for DMB, DVB-H, and 3G mobile networks.

High-Speed Downlink Packet Access (HSDPA): Packet-based data service in 3G networks with data transmission up to 8-10 Mbit/s.

Multimedia Broadcast and Multicast Service (MBMS): Extension of 3G mobile networks by multicast/broadcast techniques. Standardized within 3GPP.

Open Mobile Alliance Broadcast (OMA BCAST): Working group within the standardization body OMA defining the service layer system, “OMA Mobile Broadcast Services.”

Packet-switched Streaming Service (PSS): 3GPP standard for streaming of multimedia content over mobile networks. Used for the distribution of MobileTV over 3G networks

3GPP (3rd Generation Partnership Project) /3GPP2: Standardization bodies for the specification of mobile networks, especially 3G mobile networks.

Uni-/Bidirectional: Unidirectional networks act like conventional broadcast stations where data can only be transmitted in one direction to the viewer. Bidirectional networks or links can transmit feedback from the user and allow for interactivity.

Uni-/Multicast: A unicast transmission is directly sent to one receiver, hence a TV program seen by n users is transmitted n times. In a multicast network data is transmitted to a group of receivers jointly.

Mobile Text Messaging Interface for Persons with Physical Disabilities

INTRODUCTION

Morse code has been shown to be a valuable tool in assistive technology, augmentative and alternative communication, and rehabilitation for some people with various conditions such as spinal cord injuries, non-vocal quadriplegics, and visual or hearing impairments. In this article, a mobile phone human-interface system using a Morse code input device is designed and implemented for the person with disabilities to send/receive SMS (simple message service) messages or make/respond to a phone call. The proposed system is divided into three parts: input module, control module, and display module. The data format of the signal transmission between the proposed system and the communication devices is the PDU (protocol description unit) mode. Experimental results revealed that three participants with disabilities were able to operate the mobile phone through this human-interface after four weeks' practice.

BACKGROUND

A current trend in high-technology production is to develop adaptive tools for persons with disabilities to assist them with self-learning and personal development, and lead more independent lives. Among the various technological adaptive tools available, many are based on the adaptation of computer hardware and software. The areas of application for computers and these tools include training, teaching, learning, rehabilitation, communication, and adaptive design (Enders & Hall, 1990; McCormick, 1994; Bower et al., 1998; King, 1999).

Many adapted and alternative input methods now have been developed to allow users with physical disabilities to use a computer. These include modified direct selections

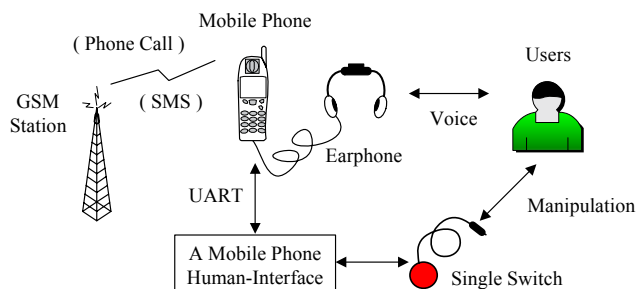

(via mouth stick, head stick, splinted hand, etc.), scanning methods (row-column, linear, circular), and other ways of controlling a sequentially stepping selection cursor in an organized information matrix via a single switch (Anson, 1997). However, they were not designed for mobile phone devices. Computer input systems, which use Morse code via special software programs, hardware devices, and switches, are invaluable assets in assistive technology (AT), augmentative-alternative communication (AAC), rehabilitation, and education (Caves, 2000; Leonard, Romanowski, & Carroll, 1995; Shannon, Staewen, Miller, & Cohen, 1981; Thomas, 1981; French, Silverstein, & Siebens, 1986; Russel & Rego, 1998; Wyler & Ray, 1994). To date, more than 30 manufacturers/developers of Morse code input hardware or software for use in AAC and AT have been identified (Anson, 1997; Yang, 2000, 2001, 2003; Yang, Chuang, Yang, & Luo, 2002, 2003; see also <http://www.uwec.edu/Academic/Outreach/Mores2000/morse2000.html>). In this article, we adopt Morse code to be the communication method and present a human-interface for persons with physical disabilities.

The technology employed in assistive devices has often lagged behind mainstream products. This is partly because the shelf-life of an assistive device is considerably longer than mainstream products such as mobile phones. In this study, we designed and implemented an easily operated mobile phone human-interface device by using Morse code as a communication adaptive device for users with physical disabilities. Experimental results showed that three participants with disabilities were able to operate the mobile phone through this human-interface after four weeks' practice.

SYSTEM DESIGN

Morse code is a simple, fast, and low-cost communication method composed of a series of dots, dashes, and intervals

Figure 1. System schematics of the mobile phone human-interface

in which each character entered can be translated into a pre-defined sequence of dots and dashes (the elements of Morse code). A dot is represented as a period “.”, while a dash is represented as a hyphen, or minus sign, “-”. Each element, dot or dash, is transmitted by sending a signal for a standard length of time. According to the definition of Morse code, the tone ratio for dot to dash must be 1:3. That means that if the duration of a dot is taken to be one unit, then that of a dash must be three units. In addition, the silent ratio for dot-dash space to character-space also has to be 1:3. In other words, the space between the elements of one character is one unit while the space between characters is three units (Yang et al., 2002).

In this article, the mobile phone human-interface system using a Morse code input device is schematically shown in Figure 1. When a user presses the Morse code input device, the signal is transmitted to the key scan circuit, which translates the incoming analog data into digital data. The digital data are then sent into the microprocessor, an 8051 single chip, for further processing. In this study, an ATMEL series 89C51 single chip has been adopted to handle the communication between the press-button processing and the communication devices. Even though the I/O memory capacity of the chip is small compared to a typical PC, it is

sufficient to control the device. The 89C51 chip’s internal serial communication function is used for data transmission and reception (Mackenzie, 1998). To achieve the data communication at both ends, the two pins, TxD and RxD, are connected to the TxD and RxD pins of an RS-232 connector. Then the two pins are connected to the RxD and TxD of an UART (universal asynchronous receiver transmitter) controller on the mobile phone device. Then, persons with physical disabilities can use this proposed communication aid system to connect their mobile communication equipment, such as mobile phones or GSM (global system for mobile communications) modems, and receive or send their messages (SMS, simple message service). If they wear an earphone, they might be able to dial or answer the phone. SMS is a protocol (GSM 03.40 and GSM 03.38) that was established by the ETSI (the European Telecommunications Standards Institute). The transmission model is divided into two models: text and PDU (protocol description unit). In this system, we use the PDU model to transmit and receive SMS information through the AT command of the application program (Pettersson, 2000). Structurally the mobile phone human-interface system is divided into three modules: the input module, the control module, and the display module. The interface framework is graphically shown in Figure 2. A detailed explanation is given as follows.

Input Module

A user’s input will be digitized first, and then the converted results will be sent to the micro controller. The signal processing circuit can monitor all input from the input device, the Morse code. The results will be entered into the input data stream. When the user presses the input key, the micro-operating system detects new input data in the data stream, and then sends the corresponding characters to the display module. Some commands and/or keys, such as *OK*, *Cancel*, *Answer*, *Response*, *Send*, *Receive*, *Menu*, and *Exit*, have been customized and perform several new functions in order to accommodate the Morse code system. These key modifications facilitate the human-interface use for a person with disabilities.

Figure 2. Interface framework of mobile phone for persons with physical disabilities

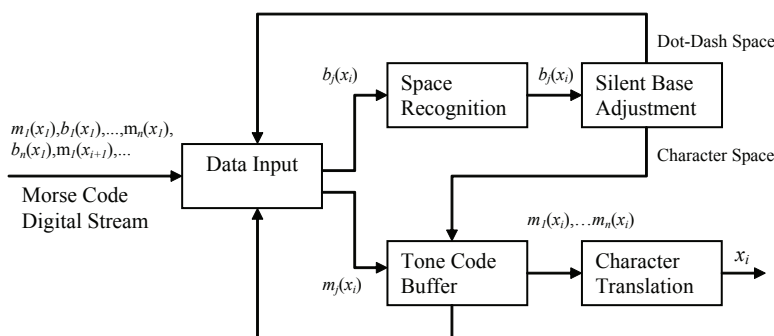

Figure 3. Block diagram of the Morse code recognition system

Control Module

The proposed recognition method is divided into three modules (see Figure 3): space recognition, adjustment processing, and character translation. Initially, the input data stream is sent individually to separate tone code buffer and space recognition processes, which are based on key-press (Morse code element) or key-release (space element). In the space recognition module, the space element value is recognized as a dot-dash space or a character space. The dot-dash space and character space represent the spaces existing between individual characters and within isolated elements of a character respectively. If a character space is identified, then the value(s) in the code buffer is (are) sent to character translation. To account for varying release speeds, the space element value has to be adjusted. The silent element value is sent into the silent base adjustment process. Afterwards, the character is identified in the character translation process.

A Morse code character, x_i , is represented as follows:

$$m_1(x_i), b_1(x_i), \dots, m_j(x_i), b_j(x_i), \dots, m_n(x_i), b_n(x_i)$$

where

$b_j(x_i)$: j th silent duration in the character x_i .

n : the total number of Morse code elements in the character x_i .

$m_j(x_i)$: the j th Morse code element of the input character x_i .

Display Module

Since users with disabilities have, in order to increase the convenience of user operations, more requirements for system interfaces than a normal person, the developed system shows selected items and system condition information on an electronic circuit platform, which is based on LCD (Liquid

crystal display). The characteristics of the proposed system can be summarized as follows: (1) easy operation for users with physical disabilities with Morse code input system, (2) multiple operations due to the selection of different modes, (3) highly tolerant capability from adaptive algorithm recognition, and (4) system extension for customized functions.

RESULTS AND DISCUSSION

This system provides two easily operated modes, the phone panel and LCD panel control mode, which allow a user with disabilities easy manipulation. The following shows how the proposed system sends/receives an SMS message or makes/responds to a phone call.

SMS Receiving Operation

First, when users receive a message notification and want to look at the content, this system will provide phone panel and LCD panel control modes to choose from. In the phone panel mode, users can directly key-in Morse code “...” (as character ‘S’). The interface system will go through the message recognition process, then exchange the message into the AT command “AT+CKPD=‘S’, 1”, to execute the “confirm” action of the mobile phone. The purpose of this process is the same as users keying-in “yes” on the mobile phone keyboard, then keying-in Morse code “. - . .” (as key ‘↓’). The system will recognize the message, then automatically send the “AT+CKPD=‘↓’, 1” instruction. The message cursor of the mobile phone is moved to the next line, or keys-in Morse code “. - . .” (as key ‘↑’) for moving it to the previous data line. Finally, if users want to exit and return to the previous screen, they only need to key-in Morse code “. . - .” (as character ‘F’), and start the c key function on the mobile phone keyboard. If LCD panel mode is selected, one can directly follow the selected items

on the LCD crystal, to execute the reception and message reading process.

SMS Transmitting Operation

Message transmission services are provided in two modes: phone panel and LCD panel. In the phone panel mode, continually type two times the Morse code “. - . - .” (as key ‘→’). The system will be converted into AT Command and transferred into mobile phone to show the selection screen of the message functions. Then continuing to key-in three times the Morse code “. . .” (as character ‘S’), one can get into the editing screen of message content, and wait for users to input the message text data and receiver’s phone number. The phonebook function can be used to directly save the receiver’s phone number. After the input, press the ‘yes’ key to confirm that the message sending process has been completed. In addition, if the LCD panel mode is selected, one can follow the LCD selection prompt to input the service selection of all the action integrated in the LCD panel. Then the user goes through the interface and translates to a series of AT command orders, and batch transfers these into the mobile phone to achieve the control purpose.

The selection command “Answer a phone” displays on the menu of the LCD screen and can be constructed using Morse code. The participants could press and release the switch and input the number code “. - - - .” (as character ‘1’) or hot key “. - .” (as character ‘A’). The mobile phone is then answered automatically. Problems with this training, according to participants, are that the end result is limited typing speed and users must remember all the Morse code sets of commands.

Three test participants were chosen to investigate the efficiency of the proposed system after practicing on this system for four weeks. Participant 1 (P1) was a 14-year-old male adolescent who has been diagnosed with cerebral palsy. Participant 2 (P2) was a 14-year-old female adolescent with cerebral palsy, athetoid type, who experiences involuntary movements of all her limbs. Participant 3 (P3) was a 40-year-old male adult, with a spinal cord injury and incomplete quadriplegia due to an accident. These three test participants with physical impairments were able to make/respond to phone calls or send/receive SMS messages after practice with the proposed system.

FUTURE TRENDS

In the future, a Morse code input device could be adapted to several environmental control devices, which would facilitate the use of everyday appliances for people with physical disabilities considerably.

CONCLUSION

To help some persons with disabilities such as amyotrophic lateral sclerosis, multiple sclerosis, muscular dystrophy, and other conditions that worsen with time and cause the user’s abilities to write, type, and speak to be progressively lost, requires an assistive tool for purposes of augmentative and alternative communication in their daily lives. This article presents a human-interface for mobile phone devices using Morse code as an adapted access communication tool. This system provides phone panel and LCD panel control modes to help users with a disability with operation. Experimental results revealed that three physically impaired users were able to make/respond to phone calls or send/receive SMS messages after only four weeks’ practice with the proposed system.

KEY TERMS

Adaptive Signal Processing: The processing, amplification, and interpretation of signals that change over time through a process that adapts to a change in the input signal.

Assistive Technology (AT): A generic term for a device that helps a person accomplish a task. It includes assistive, adaptive, and rehabilitative devices, and grants a greater degree of independence to people with disabilities by letting them perform tasks they would otherwise be unable to perform.

Augmentative and Alternative Communication (AAC): Support for and/or replacement of natural speaking, writing, typing, and telecommunications capabilities that do not fully meet a communicator's needs. AAC, a subset of AT (see above), is a field of academic study and clinical practice, combining the expertise of many professions. AAC may include unaided and aided approaches.

Global System for Mobile Communications (GSM): The most popular standard for global mobile phone communication. Both its signal and speech channels are digital, and it is therefore considered a second-generation mobile phone system.

Morse Code: A transmission method implemented by using just a single switch. The tone ratio (dot to dash) in Morse code has to be 1:3 per definition. This means that the duration of a dash is required to be three times that of a dot. In addition, the silent ratio (dot-space to character-space) also has to be 1:3.

Simple Message Service (SMS): A service available on digital mobile phones which permits the sending of simple messages between mobile phones.

INTRODUCTION

Constant technological advances are making *pervasive computing* (Weiser, 1991) a reality. Such advances have been enabling the rise of devices increasingly smaller, with larger storage space, novel wireless interfaces, and lower battery consumption. These innovative technologies are contributing to the emergence of a new sort of personal portable device, as well as a large number of sensors and actuators. Sensors and actuators are embedded into objects spread across the environment, while portable devices quietly inform such environments how users wish to interact with them. Therefore, personal mobile devices stand out currently as the interface between people and smart spaces.

A basic requirement in the context of pervasive computing is to allow users to access services seamlessly as they move across environments. This requirement demands from the underlying infrastructure the ability to transfer user sessions among access points (*handoff*), which is a well-known concern in the context of pervasive computing (Cui, Nahrstedt, & Xu, 2004; Banerjee, Das, & Acharya, 2005). Nevertheless, the effective delivery of services in smart spaces requires conceiving mechanisms for handling localized scalability, availability, and redundancy of services; load balancing among providers; and on-demand content transformation for different devices (Sathanarayanan, 2001; Raatikainen, Christensen, & Nakajima, 2002; Raman et al., 2002), henceforth *QoS issues*. These requirements rise as fundamental for promoting transparency and invisibility to the service usage, as well as delivering some level of QoS and optimized resource utilization (Kalasapur, Kumar, & Shirazi, 2006).

Currently, there are still no efforts for conceiving solutions to provide ubiquitous access and seamless usage of services while taking into account QoS issues. In this context, we define the dynamic provision of services as a set of requirements relevant to the seamless provision of services for mobile users plus mechanisms for dealing with QoS issues.

In this article we define and present the basis of our work about dynamical services provisioning for mobile users in

smart spaces. We present an overview about our envisioned service provision infrastructure, as well as the main research challenges related to it. Finally, we discuss issues related to the current state of our research and point out research directions in this field.

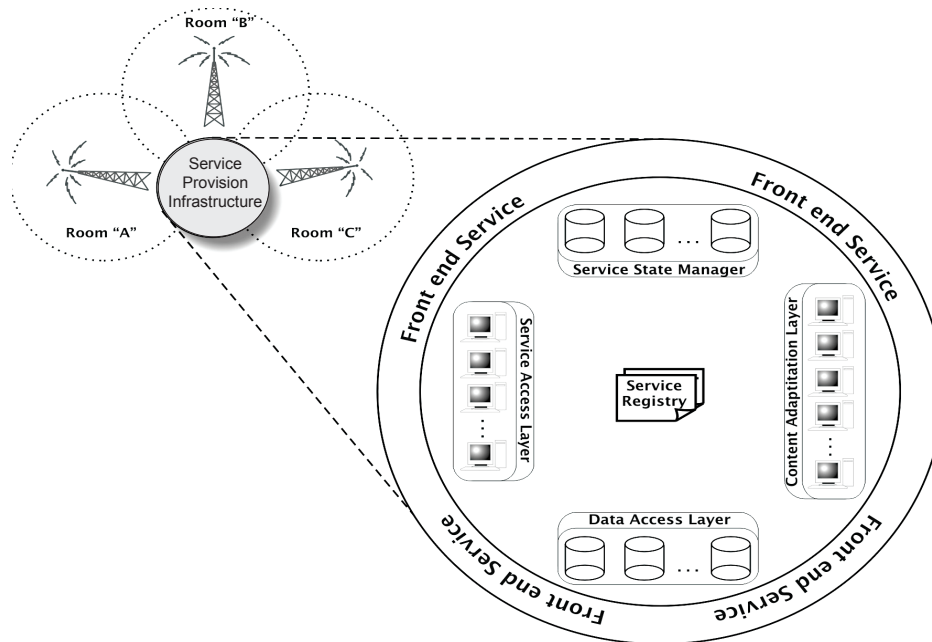

BACKGROUND

The interaction between users' devices and smart spaces occurs primarily through services advertised in those environments. The *service-oriented paradigm* (Papazoglou & Georgakopoulos, 2003) is especially suitable due to the dynamics of smart spaces, where resources may exist anywhere and applications running on mobile devices must be able to find out and use them at runtime.

In the context of smart spaces, user mobility is the main cause of such disturbances, but other factors may also cause temporary unavailability or degradation of services, for example, crash failures in the service providers, temporary network congestion, or peaks of overload on service providers. Smart spaces are primarily service-oriented environments, where part of the application logic is at the client side (e.g., in the form of helper applications for user profiles) and part at the server side (e.g., in the form of services offering some extra features for the users). When losing network connection, client applications also lose part of their capabilities, which are deployed as services in these environments. This scenario illustrates the first requirement of the applications aimed at smart spaces: the ability to switch between connected and disconnected modes. Applications and service implementations may utilize this connectionless period for performing some sort of preparation for when the connectivity is reestablished (Sairamesh, Goh, Stanoi, Padmanabhan, & Li, 2004).

When able to cope with off-line operations, both applications and the underlying infrastructure need to provide means for bringing transparency to the service usage, even when users move across access points. Sessions specify which client is using which services in a given access point.

Figure 1. Conceptual infrastructure for dynamic provision of services

When users move across access points, sessions need to be transferred between them, service providers need to be contacted, and the use of services needs to be reestablished from the point at which they were interrupted due to the change of location (handoff).

Currently there are several alternatives for dealing with application mobility, such as mobile IP (in short MIP), hierarchical MIP, cellular IP, teleMIP, and dynamic mobile agent (Saha, Mukherjee, Misra, Chakraborty, & Subhash, 2004). All these alternatives are suitable for IP-based applications and are embedded in the transport layer of the IP protocol stack. The major issue of these solutions is their unsuitability for dealing with *real-time traffic* management (Saha et al., 2004). In the context of smart spaces, this is an important limitation since these environments have many multimedia services, such as video and/or audio streaming services. New mechanisms need to be developed for providing multimedia services for mobile users (Cui et al., 2004; Banerjee et al., 2005).

Nevertheless, a great many issues may affect the quality of the provided service, such as adaptability to changes in the execution and communication environments, efficient use of communication resources, and high *availability* and stringent *fault-tolerance* (Raatikainen et al., 2002). The requirements for data accessed by these applications are quite similar. The underlying infrastructure must provide consistent, efficiently accessible, reliable, and a highly available information base (Raatikainen et al., 2002).

Presently, there are many approaches to deal with QoS issues in the context of smart spaces (Kumar & Song, 2005;

Panagiotakis et al., 2003; Hingne, Joshi, Finin, Kargupta, & Houstis, 2003). However, current efforts focus on the implementation of mechanisms for only coping with QoS issues in isolation, that is, they do not provide any support for handoff. In the same manner, current solutions for dealing with handoff focus only on the handoff mechanisms and neglect other aspects that also impact the quality of the provided services.

The fact that distinct solutions regarding handoff management and *QoS assurance* for service provision are available does not imply that it is possible to aggregate these two features into one unique solution. Bridging two distinct solutions may be prohibitively burdensome, may introduce bugs and/or restrict interaction between the two software modules, and after that may also perform poorly because the two software modules were not designed for working together. Therefore, designing and implementing infrastructures able to not only deal with handoff, but also capable of delivering extra levels of QoS, is certainly the next step towards conceiving service provision infrastructures that better approximate from the pervasive computing principle of invisibility (Satyanarayanan, 2001).

DYNAMIC PROVISION OF SERVICES

We define dynamic provision of services as a set of requirements relevant to the seamless provision of services for mobile users plus mechanisms for dealing with QoS issues. The goal is to conceive an infrastructure for dealing

Table 1. QoS features

| Feature | Expected Behavior |
|--|---|
| Seamless handoff scheme for both kinds of applications | When moving across access points, users consuming both RPC and stream-based services will not experience interruptions at service usage, of course, only if users experience short times of disconnection. |
| Data throughput | Data throughput is granted, through resource reservations, for different kinds of data transfer, such as streamed video or file transfers. |
| Availability of data and services | We achieve better availability of services and data through redundancy, performed by the service and data access layers. |
| Dynamic content adaptation | Data transformation is performed on-demand in order to accomplish both static and dynamic requirements. For instance, the data throughput requirement may trigger a content adaptation process according to current network conditions. |
| Policies for data delivery | Users may specify which policies the underlying infrastructure must assume when necessary. For instance, users may wish to automatically reduce streamed video quality if the network gets congested instead of experiencing freezing in playback. |

with both handoff management and availability issues of computational resources at the server side. In the next sections we present a conceptual architecture of our envisioned infrastructure, along with some discussions regarding open issues and challenging aspects of our work.

Infrastructure Overview

In Figure 1 we present the conceptual architecture of our vision of a dynamic service provision infrastructure.

Client applications interact with the service provision infrastructure through a front end service. The front end service publishes an interface through which client applications can search/select/use services, and specifies QoS constraints of the required services. In Table 1 we briefly depict the QoS features we intend to address.

The front end service is also responsible for the authentication/authorization of the users. During this process, the front end service can also obtain information pertinent to eventual opened sessions and may use this information to execute part of the handoff procedure. Other relevant information can also be gathered during the authentication/authorization process, such as client profiles and device features (e.g., memory, CPU speed, display size/colors, and network technology). Some kind of network evaluation process can be coupled with the data exchange of the authentication/authorization process, so that instantaneous information regarding delay, bandwidth, and jitter may be identified in advance. This information, along with user profiles, device features, and defined QoS constraints, is used for applying on-demand data transformations, making the service usage as close as possible to clients expectations.

All complexities behind locating and controlling QoS parameters are tasks of the front end service and remain modules of the infrastructure. The front end service queries the service registry about the existence of providers for the needed services. The service registry can return a service handle or an error message. The error message can assume two meanings: there is no provider for a needed service or QoS constraints cannot be assured. Since a service handle is returned, the front end service uses it for contacting the service provider.

The access to service providers is mediated by a service access layer. The role of this layer is managing computational resources (essentially sets of computers), allocating and freeing them as the current workloads demand and/or permit. The service access layer also controls service instances, creating and destroying them dynamically according to the demand of such services and availability of computational resources. Therefore, the service access layer is also responsible to distribute workload among service providers.

In order to accept client requests, the service access layer must negotiate with the data access layer access to needed data according to client-defined QoS constraints. Just like the service access layer, the data access layer arbitrates and manages the access to data providers. It must control workload balancing among data providers and manage data copying/moving among providers. New resources can be allocated or freed as the current load conditions demand and/or permit.

The service state manager is only a symbolic entity. It denotes the need of providing means for reestablishing services interrupted due to user mobility. For instance, most RPC-based applications can be handled in a mobile envi-

ronment through transport layer solutions, such as MIP. In this case, the “service state manager” can be mapped into the network elements required by MIP. On the other hand, stream-based services require some kind of collaborative cache scheme, where local buffers in the client side work together with cached data in the server side in order to deliver transparency to the handoff process.

The last major role of our infrastructure is the on-demand content adaptation. Client devices may drastically range in aspects such as processing power, storage space, user interface, and network connectivity, among others. These are some examples of static features that require some level of personalized content adaptation. Moreover, some dynamic features, such as network congestions, also demand personalized content. Dealing with such distinct constraints, both static and dynamic, requires delivering content using protocols and data formats best suited for each kind of device, according to their specific constraints and needs.

Technical Issues

A number of issues are identified in the context of the discussed infrastructure. Below we discuss some of them.

- **QoS Constraints:** Modeling user behaviors, computational resources, and expressing QoS constraints is yet an open issue in our work. Alternatives range from mathematical models, using matrixes and systems of equations (Sauvé et al., 2006), to queue systems along with simulation tools (Urgaonkar, Pacifici, Shenoy, Spreitzer, & Tantawi, 2005).
- **Security:** Normally, mobile devices are not shared among different users, and this property is used for recognizing users based on their portable devices. This authentication proceeding could raise problems, for example in the case of device thefts (Tatli, Stegmann, & Lucks, 2005). Security issues also cover data propagation over wireless medium (Grosche & Knospe, 2002) and authorization/authentication procedures in order to avoid opening the system ports for untrusted parts.
- **Creating and Destroying Service Instances on Demand:** Managing service instances can be split into two problems: how to develop services and how to monitor them. These problems create a set of questions that must be answered, such as: What are the requirements for writing services? What are their limitations? How do we deal with different underlying architectures? Does the service middleware have expressiveness enough for addressing different kinds of applications? What is the impact of the monitoring protocol over resource utilization? How do we estimate threshold values? Are static triggers enough? What happens with client requests interrupted due to server failures?
- **Access Layers:** Access layers encapsulate the access to sets of computational resources, acting as both resource schedulers and monitors of current demand vs. remaining computational power. If they are centralized entities, they become single points of failures, and if they fail, the access to all computational resources is lost. On the other hand, how do we contact them if they are distributed entities? What are the drawbacks of using hardcoded references? These remarks are also applicable to the front end service, which has the same properties as the access layers.
- **Distributed Databanks:** Conceiving distributed databanks is not a novel issue but is still a challenging task. Challenging issues include: data fragmentation and distribution, query processing and optimization, distributed concurrency control, reliability and commit protocols, and replicated data management. Techniques and algorithms for managing replicated data is also a concern, such as dealing with clocks, deadlock detection, and mutual exclusion.
- **Different Handoff Schemes:** User mobility may manifest itself in different faces and thus different kinds of handoffs. For instance, host-level (both user and device move) and user-level (only the user moves) handoffs concern how to identify the occurrence of handoff. Horizontal (handoff without changing in the underlying network technology) and vertical (handoff with changing in the underlying network technology) handoffs concern eventual changes in the underlying network technology. Providing transparency to the service usage requires definition of which kinds of mobility the underlying infrastructure will support.
- **Dynamic Content Adaptation:** Developing mechanisms for delivering personalized content for different kinds of applications—that is, different data formats—is an important open issue. On-demand data transformation may require considerable processing power, which implies distributed computation. This can be a challenging task since not all data formats can be processed in a parallel fashion (e.g., video rendering). Dynamic content adaptation may also require stringent integration with other software modules. For instance, when consuming streamed data, a cache adjustment may be necessary for hiding the extra time used for transforming data.

FUTURE TRENDS

The idea of dynamic service provision is still in its early days, and there is a lot of work still needed to implement a software infrastructure to promote such a scenario. The definition of which QoS parameters must be added or removed to the ones presented before is still source of discussion.

Since the requirements are well bounded, the next steps include directing efforts towards the issues depicted in the previous section. Only when we have a complete knowledge of the mechanisms we need for solving these issues will we be able to design and implement a prototype system.

CONCLUSION

In this article we presented our vision of a dynamic service provision infrastructure aimed at users of mobile devices. A high-level overview of our envisioned infrastructure was presented, including depiction and discussion of its major modules. We presented the main open issues and challenging tasks regarding the implementation of the introduced infrastructure.

We believe that the major contribution of this work is to make available a first discussion about all issues related to the subject. Our first efforts to specify such infrastructure, and the related open issues and challenging tasks, can serve as guidelines for research groups planning to propose new solutions in this field.

KEY TERMS

Helper Application: Small software deployed on resource-constrained devices. Helper applications implement only small sets of functionalities. They combine resources of other computers (e.g., advertised as services) to provide more powerful functionalities.

Portable/Mobile Device: Any low-sized device used to interact with other small devices and resources from smart spaces. Examples of portable/mobile devices are cellular phones, smart phones, PDAs, notebooks, and tablet PCs.

Proxy: A network entity that acts on behalf of another entity. Proxies' roles vary since data relays to the provision of value-added services, such as on-demand data adaptation.

Real-Time Traffic: Any data flow with stringent restrictions of throughput, such as maximum delay and jitter, and minimum bandwidth. Examples of real-time traffic are video broadcast or audio streaming.

Service-Oriented Computing (SOC): Distributed computing paradigm whose building blocks are distributed services. SOC stands out as the effective choice for advertising services to mobile devices in smart spaces.

User Profile: Set of information regarding user preferences when interacting with computational systems. Possible information of a profile of smart space users includes commonly used services and QoS constraints for such services.

Workload: Abstract notation for expressing the amount of work being performed by computational resources. Workloads indicate, for example, the number of requests being served by a certain host at a certain moment, which peripherals they are using, and how much CPU and memory they demand.

Mobile Video Transcoding Approaches and Challenges

Ashraf M. A. Ahmad

National Chiao Tung University, Taiwan

INTRODUCTION

Mobile access to multimedia contents requires video transcoding functionality at the edge of the mobile network for interworking with heterogeneous networks and services. Under certain conditions, the bandwidth of a coded video stream needs to be drastically reduced in response to changes in a highly constrained transmission channel, such as mobile.

Therefore, to guarantee quality of service (QoS) delivered to the mobile user, a robust and efficient transcoding scheme should be deployed in a mobile multimedia transporting network. In this article, we review several typical video transcoding architectures and major applications of video transcoding. We identify issues involved in accessing video streams through handheld devices and wireless networks. This article examines the challenges and limitations that face video transcoding schemes in a mobile multimedia transporting network. Then we explore different approaches for video transcoding schemes in a mobile multimedia transporting network.

BACKGROUND AND RELATED WORK

Current advances in mobile communications and portable client devices enable us to access multimedia content universally. However, when multimedia content becomes richer, including video and audio, it is difficult for wireless access because of many restrictions. On one hand, wireless connections usually have a lower bandwidth compared to wired ones and communication conditions change dynamically due to the effect of fading. On the other hand, portable client devices only have limited computing and display capabilities, which are not suitable for high-quality video decoding and displaying.

Concerning the heterogeneity issue, the previous era has seen a variety of developments in the area of multimedia representation and communication. In particular, we are beginning to see delivery of all types of multimedia data for all types of users in all types of conditions. In a diverse and heterogeneous world, the delivery path for multimedia content to a multimedia terminal is not straightforward, especially in the mobile communication environment. Access networks are various in nature, sometimes limited, and differ

in performance. The characteristics of end user devices vary increasingly, in terms of storage, processing capabilities, and display qualities, as well as the natural environment (e.g., position, elucidation, temperature, changes). Finally, users are different by nature, showing dissimilar preferences, special usage, disabilities, and so forth.

The advance of multimedia systems has had a major influence in the area of image and video coding. The problem of interactivity and integration of video data with computer, cellular, and television systems is relatively new and subject to a great deal of research worldwide. As the number of networks, types of devices, and content representation formats increase, interoperability between different systems and different networks is becoming more important. Thus, devices such as gateways, multipoint control units, and servers must be developed to provide a seamless interaction between content creation and use.

The transporting of multimedia over wireless channels to mobile users is becoming a research topic of rapidly growing interest (Han et al., 1998; Warabino, Ota, Morikawa, & Ohashi, 2000; Mitchell, Pennebaker, Fogg, Chad, & LeGall, 1996; Shanableh & Ghanbari, 2000; Correia, Faria, & Assuncao, 2001). With the emergence of small wireless handset devices such as PDAs, video mobile, and so forth, it is expected that interactive multimedia will be a major source of traffic to these handset devices. These devices could be carried by users inside buildings when they are connected by a wireless local area network (LAN) or in vehicles when they will be connected to the cellular network, such as GPRS (Eleftheriadis & Anastassiou, 1995; Keesman, 1996). Wideband mobile communication systems such as IMT-2000 have also emerged, and there should be a mechanism to cope with a variety of media such as video provided to a mobile terminal.

Wireless transmissions use radio channels as the transmission media. Generally, radio links connect users to base stations which are connected to routers using wired links. The wireless segment “cells” provide mobility to a user while using the network. In contrast to wireline transmission links where the bandwidth can be easily increased and the channel quality can be guaranteed, the bandwidth of a wireless channel is limited because of spectrum allocation and physical limitations. The transmission quality of radio is easily affected by environments such as buildings, moving

objects, and atmosphere, as well as shielded obstacles and so forth. Moreover, because of the mobile nature of the users, the access point of a mobile user changes continuously. All these factors in wireless networks give rise to issues such as effective bandwidth allocation, high channel bit error rate, and user handover.

Moreover, because of its high traffic characteristics such as high bit rate, video will be the dominant traffic in multimedia streams and hence needs to be managed efficiently. Obviously for efficient utilization of network resources, video must be compressed to reduce its bandwidth requirement. Although there exist several compression techniques, MPEG [1, 2, and 4] is one of the most widely used compression algorithms for networked video applications. A wireless handset device, for instance a personal data assistant, can integrate voice, video, and data in one device. In contrast to solely text information, multimedia data can tolerate a certain level of error and fading. Therefore, although a wireless network has a high bit error rate when compared to a wireline network, it is possible to cost effectively transmit multimedia over wireless networks with acceptable quality.

For instance, the MPEG-2 compressed digital video content is being used in a number of products, including DVDs, camcorders, digital TVs, and HDTVs. In addition, tons of MPEG2 data have been stored already in different accessible multimedia servers. The ability to access this widely available MPEG-2 content on low-power end user devices such as PDAs and mobile phones depends on effective techniques for transcoding the MPEG-2 content to a more appropriate, low bit rate video.

Therefore mobile access to multimedia contents requires video transcoding functionality at the edge of the mobile network for interworking with heterogeneous networks and services, changing bit rates, and so forth. This transcoding mechanism should tackle the aforementioned issues in transmitting video in a mobile and wireless network.

FUNCTIONS OF TRANSCODING TECHNIQUES

Building a good video transcoding for mobile devices poses many challenges. To meet these challenges, a various kind of transcoding function is provided. This paragraph will describe these functions in detail.

The first function is bit rate adaptation. Bit rate adaptation has been the most significant function of video transcoding techniques. The idea of compressed video bitrate adaptation is initiated by the applications of transmitting pre-encoded video streams over heterogeneous networks. When connecting two transmission media, the channel capacities of the outgoing channel may be less than those of the incoming channel, so that bit rate adaptation is necessary before sending the video

bitstream over heterogeneous channels. In applications such as video on demand, where video is off-line encoded for later transmission, the channel characteristics through which the resulting bitstream will be transmitted might be unknown. Through video transcoding, the bit rate of pre-encoded videos can be dynamically adapted to the obtainable bandwidth and variable communication circumstances. In most bit adaptation cases, a pre-encoded video with high bit rate and fine visual quality will be converted into low bit rate video with elegantly degraded visual quality.

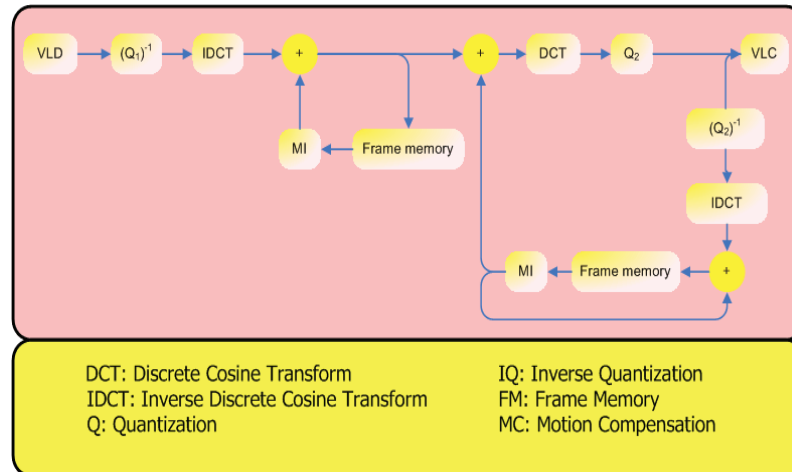

The second function is frame size conversion. Video spatial resolution downscaling is significant since most current handheld devices are characterized by limited screen sizes. By inserting a downscaling filter in the transcoder, the resolution of the incoming video can be reduced. For downscaling the video into lower spatial resolution, motion vectors from the incoming video cannot be reused directly, but have to be resampled and downscaled. Based on the updated motion vectors, predictive residues are recalculated and compressed.

The third function is frame rate conversion. To transcode an arriving compressed video bitstream for a low-bandwidth outgoing channel, such as a wireless network, a high transcoding percentage is often necessary. However, high transcoding ratios may result in intolerable video quality when the arriving bitstream is transcoded with the full frame rate as the arriving bitstream. Frame-rate conversion or frame-dropping is often used as an efficient scheme to assign more bits to the remaining frames, so that acceptable quality can be maintained for each frame. In addition, frame-rate conversion is also needed when an end system can only play video at a lower frame rate due to the processing power limit. Frame rate conversion can be simply accomplished by random frame dropping. For instance, dropping every other frame in a sequential order leads to a half rate reduction in the transcoded sequence. When frames are dropped, motion vectors from the arriving video cannot be directly reused because they are pointed to the immediately previous frame. If the previous frame is dropped in the transcoder, the link between two frames is broken and the end decoder will not be able to reconstruct the picture by these motion vectors. Therefore, the transcoder is in charge for calculating new motion vectors that point to the previous un-dropped frames.

TRANSCODING ARCHITECTURES

Generally speaking, transcoding can be defined as the manipulation or conversion of data into another more desirable format. Depending on the particular strategy that is adopted, the transcoder attempts to satisfy network conditions or user requirements in various ways. In the context of video transmission, compression standards are needed to reduce

Figure 1. Cascaded pixel domain transcoder

the amount of bandwidth that is required by the network. Since the delivery system must accommodate various transmission and load constraints, it is sometimes necessary to further convert the already compressed bitstream before transmission.

The simplest way to develop a video transcoder is by directly cascading a source video decoder with a destination video encoder, which is called the cascaded pixel domain transcoder (Youn, & Sun, 2000). Without using common information, this direct approach needs to fully decode input video and re-encode the decoded video by an encoder with different characteristics as described in Figure 1. Obviously, this direct approach is usually computationally intensive. The architecture is flexible, because the compressed video is first decoded into raw pixels, hence a lot of operations can be performed on the decoded video. However, as we mentioned earlier, the direct implementation of the cascaded pixel domain transcoder is not desirable because it requires high complexity of implementation.

The alternative architecture for transcoding is an open-loop transcoding in which the incoming bit rate is downscaled by modifying the discrete cosine transform (DCT) coefficients. For example, the DCT coefficients can be truncated, requantized, or partially discarded in the optimal sense (Sun, Vetro, Bao, & Poon, 1997; Eleftheriadis & Anastassiou, 1995) to achieve the desirable lower bit rate. In the open-loop transcoding, because the transcoding is carried out in the coded domain where complete decoding and re-encoding are not required, it is possible to construct a simple and fast transcoder. However, open-loop transcoding can produce “drift” degradations due to mismatched reconstructed pictures in the front-encoder and the end-decoder, which often result in an unacceptable video quality.

MOBILE AND WIRELESS VIDEO TRANSCODING SYSTEM ARCHITECTURE

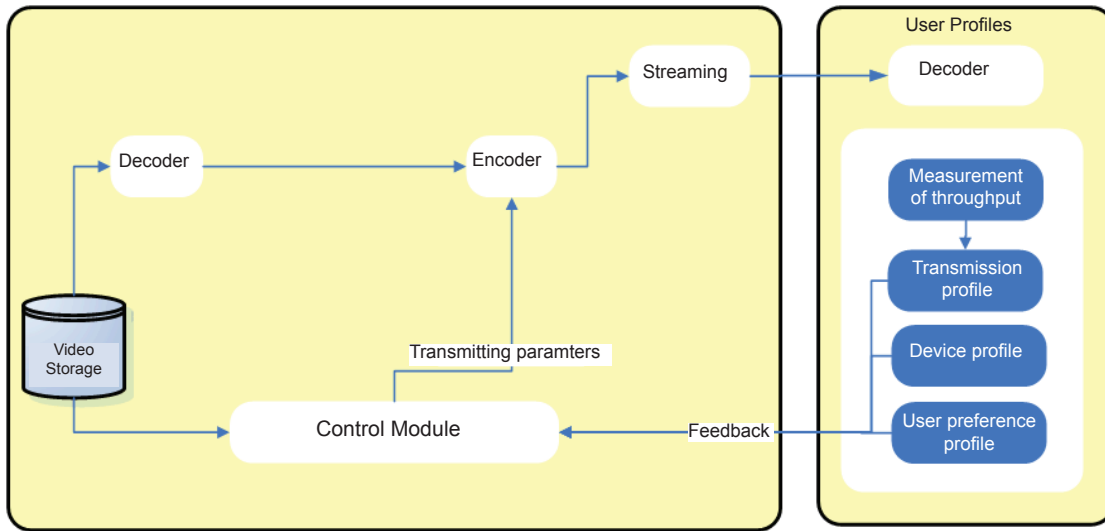

In order to state the mechanism to deploy a transcoding scheme for high-performance transcoding in mobile or wireless communication, we propose a general system architecture for mobile and wireless video transcoding.

In order to enable users to access video through wireless network and handheld devices, we propose using a transcoder as an intermediate node to dynamically convert the video according to user devices and network connections. In this approach, a content provider provides only one video stream, which is pre-encoded at high quality. The video transcoding performs transcoding dynamically for each user and provides converted video streams. The architecture of the video transcoding system is illustrated in Figure 2, as the proposed system contains four important parts: user profile, video transcoder, control module, and pre-encoded video content. In this system, the transcoder is integrated into the video streaming server. It can also be placed as an intermediate node along the transmission path.

User Profile

The user profile maintains several profile modules. The handheld device profile includes hardware and software information on the devices, such as display size, processing power, storage capability, and decoder information. The user preference profile includes user preference information such as user-preferred display size, user-preferred video presentation, and user-preferred video player behavior. The communication profile will measure the download

Figure 2. Overview of mobile and wireless video transcoding system architecture

throughput and update the communication conditions. The information included in the device profile and user profile will be transmitted to the video stream server before the start of the video transmission session. The information included in the transmission profile will be sent to the stream server periodically to control the bit rate adaptation in the transcoder. All information in the user profile is used for parameters in the transcoding process. Table 1 is a clear example for user profile information.

Video Transcoder

The video transcoder is the actual conversion engine of a video stream. It decodes a video stream, which is pre-encoded at high quality and stored in the video source, and then performs transcoding according to our proposed

scheme. Our results show that our proposed scheme has very high performance in terms of visual quality. They are comparable to results which can be achieved by full-scale motion estimation-based transcoding. When fast transcoding architectures are used, it is possible to execute transcoding in real time. Thus we can provide the handheld device user a smooth, online video presentation.

Control Module

The control module is responsible for creating a transcoding scheme according to the user profile and other information. The transcoding scheme will include some transcoding parameters. In order to decide appropriate transcoding parameters, decisions must be made by considering all of the factors adaptively. For example, when connection throughput is low, the bit rate of the video needs to be converted. At the same time, in order to ensure video quality, the frame rate of the video also needs to be reduced. This way, each frame will have enough bit budgets to maintain tolerable visual quality.

CONCLUSION

In this article, several typical video transcoding architectures and major applications of video transcoding have been reviewed. We identify issues involved in access video streams through handheld devices and wireless networks. We state that the main functions of this transcoding include frame size downscaling, frame rate conversion, bit rate adaptation, color conversion, and so forth. To handle these issues, a few

video transcoding system architectures have been proposed; in particular we introduce a system architecture recently suggested by us for intelligently transcoding pre-encoded video for different user devices and network connections in a wireless network environment.

KEY TERMS

Bit Rate: The transmission speed of binary coded data.

CODEC, Decoder, and Encoder: A device or program capable of performing transformations on a data stream or signal. Codecs can both put the stream or signal into an encoded form (often for transmission, storage, or encryption) and retrieve or decode that form for viewing or manipulation in a format more appropriate for these operations.

Discrete Cosine Transform (DCT): An algorithm that is widely used for data compression. Similar to Fast Fourier Transform, DCT converts data into sets of frequencies. The first frequencies in the set are the most meaningful; the latter, the least. To compress data, the least meaningful frequencies are stripped away based on allowable resolution loss. DCT is used to compress JPEG, MPEG, and H.263 frames.

Mobile Network: The network through which mobile devices communicate. This contains base stations, also known as cell sites, which are in turn linked to the conventional telephone network.

MPEG: The Moving Picture Experts Group is a working group of ISO/IEC charged with the development of video and audio encoding standards.

Multimedia: The use of several different media data elements (text, audio, graphics, animation, video, and interactivity) to express information.

Quality of Service (QoS): The probability of the telecommunication network meeting a given traffic contract, or in many cases, the probability of a packet succeeding in passing between two points in the network.

Mobile Virtual Communities

Christo El Morr

York University, Canada

INTRODUCTION

The adoption of mobile phone technology on a large scale in today's societies turned mobile phones into a universal tool. Phone companies are deploying 3G mobile technology and planning for 4G; nevertheless, the "killer" applications are yet to be developed. Meanwhile, *mobile virtual communities* (MVCs) are emerging, and their applications are diverse: they range from education, to entertainment and lifestyle. Our vision is that mobile virtual communities will be a major trend and could create a momentum for 3G and 4G mobile phone applications. In this article we analyze the different types of mobile virtual communities, and we draw some research perspectives and applications.

BACKGROUND

Computer-supported collaborative work (CSCW) is a multidisciplinary field of research that incorporates people from computing, sociology, psychology, economy, as well as other fields. CSCW research goes back to the 1980s; indeed the first CSCW conference goes back to 1986 (Grudin, 1994). CSCW research aims to study the different human aspects of a group of people working together (a community). Research in CSCW strives to understand how people collaborate together in groups and organizations, and to analyze how computers affect their way of work and how computing can support collaboration between members of a community.

Online communities emerged in beginning of the 1990s with the development of the World Wide Web. Online communities are part of the CSCW field of research, and they can be considered as a kind of a social system. In general, we can identify two types of *social systems* (Preece, 2000): the organization type and the association type. The organization type is designed for a specific aim, and the association type is formed out of individuals' dedication for shared objectives or beliefs. An *online community* is a kind of social system that consists of: (a) socially interacting people; (b) performing special roles or satisfying their needs; (c) a purpose, which is the reason behind the community; (d) policies to govern people interaction; and (e) a computer system that supports social interaction (Weissman, 2000).

Virtual communities (VCs) are online communities where the meeting place is virtual; in fact, the community

members in a virtual community are not in the same physical place, rather they are "associating" in a virtual space that is the Internet. *Mobility* emerged in the 1990s and added other aspects to virtual communities. People started to use mobile technology to communicate, to notify each other about events, and to collaborate on common objectives while they are on the move—mobile virtual communities (MVCs) emerged. Mobility shaped new challenges on the technological level and opened new opportunities on the application level; furthermore it incurred new aspects/changes in the community environment that impact the way people interact together and collaborate. The need to understand the types of mobile virtual communities and to explore their application perspectives is of major importance, and a lot of effort is still to be done in this regard. In the next two sections we will first define the different types of virtual communities and then draw some suggestions on pending questions and research perspectives.

TYPES OF MOBILE VIRTUAL COMMUNITIES

To determine the different types of mobile virtual communities, we will begin by looking into the different research areas in the field. Obviously, an overview of MVC research cannot be exhaustive but mostly indicative of the research directions that are taking place. Indeed, MVC research does cover a wide variety of areas such as the infrastructure needed to enable MVC applications, the diverse applications that can serve mobile users/consumers, and the user needs elicitation and user experience analysis.

Some research projects cover the *technology needs* of virtual communities and are concerned with investigating the right hardware and software technologies that could help in establishing a rich and seamless mobile practice in a community. This research area is involved in establishing the infrastructure requirements such as the network and services design, as well as the platform design (Kaji, Ragab, Ono, & Mori, 2002; Pedro Sousa & Garlan, 2002). It also tackles the user interface usability, the wearable devices' impact on the field, and the opportunities that intelligent mobile agents' technology can offer to the MVC experience. *Work-related* research is more oriented towards determining the impact of mobility on the ways people conduct collaboration at work

and the kind of influence it has on their workflow (Geisler & Golden, 2003). Other research interest relates to *education* and is concerned with mobility impact on the learning experience. Even though e-learning has been around for a while, mobility added a component to e-learning communities that is pushing learners to further their educational experience, since it enables learners to have access to information while they are on the move (e.g., in the case of field trips) (Farooq, Schafer, Rosson, & Carroll, 2002). In this respect, researchers investigate the way in which collaborative and matchmaking tools can support e-learning. Recently we have witnessed a very promising research orientation in the *entertainment* field. One thinks of mobile gaming, which started to take more and more interest in the last few years; and the huge success of the Apple iPod shows the potential of music virtual communities, while emergence of the interactive TV (iTV) as a community support is opening the way for new opportunities (CHI2006, 2006). Another type of research activity is *lifestyle*-related research that strives to organize and simplify users' daily activities. Visiting a city (tourism), collaborating with colleagues (study, work), and organizing leisure time with friends are all examples of such lifestyle communities (Brown et al., 2005; Silverstone & Sujon, 2005). The most recent aspect of virtual communities is in health care. Indeed, *health* collaborative communities such as the COSMOS project are very recent in MVC research. COSMOS, for example, proposes to build a virtual community to support cancer patients (Leimeister, Daum, & Krcmar, 2004), though mobility is not envisaged yet in the project. Research in the health field is very promising (Johnson & Ambrose, 2006). Finally, *security* as well as trust models are still a universal concern in virtual communities and more specifically in health (Sillence, Briggs, Fishwick, & Harris, 2004).

These different research domains suggest that virtual communities have evolved and are now covering diverse areas such as entertainment and health. While virtual communities emerged from the CSCW field of research, it is becoming a standalone field. The complexity of today's environment at work, the lifestyle that is pushing towards more and diverse entertainment experience, the strive of governments to reduce health care cost, the evolution of the tele-worker concept, as well as the strive of communication companies to generate profit (especially after the stock market crash in 2001)—these are all factors pushing research in different areas of interest. We believe that mobility is a major investigation field for the coming years; indeed, young generations are technology savvy, and mobile technology is widespread driving communication demand. The future picture is one where the mobile environment permits mobile access anytime, anywhere to communities of interest (entertainment, health, education).

RESEARCH PERSPECTIVES

MVCs represent a great potential for mobile network companies; indeed companies are searching for the “killer” application—that is, the application that will embrace the 3G and 4G mobile market; we believe that MVC applications can provide potential services that may drive the demand for the next mobile technologies.

Nevertheless, overcoming the screen size is an issue in mobile devices; this fact is fueling research for a “suitable” graphical user interface and the most appropriate way to organize the letters on the keypad. Mobile usability will continue to stimulate research, but beyond the device the usability of mobile virtual communities is still in its infancy since mobile virtual communities are still emerging.

Several research opportunities in MVCs are still ahead. One can think of the health-related (mobile) virtual communities to see the tremendous potential of MVCs: patient support communities and health promotion communities are only two examples of such potential applications of MVCs; we expect the impact of MVCs in the health field to be tremendous.

The study of members' motivation in order to understand participation and interaction dynamics is still evolving. In this context, artifacts such as the value of the contribution of a member is being proposed to enhance participation (Rashid et al., 2006), and longitudinal studies of newsgroup members' behavior are performed in order to draw conclusions on possible tools to enhance community interaction (Arguello et al., 2006).

Questions related to security and privacy are under investigation; nevertheless we believe that beyond the traditional approach to security and privacy, new research directions related to policymaking (in case of health for example) are still not investigated due to the relatively recent emergence of MVCs and the lack of mobile applications in real life.

We believe that MVC research is an emerging field that needs to be tackled in a multidisciplinary way; notably a joint approach from the CSCW area and the Usability area can lead to several innovative solutions. MVC research is promising to lead to innovative applications if intertwined with upcoming technologies such as 3G/4G mobile phones and pervasive computing.

KEY TERMS

Computer-Supported Collaborative Work (CSCW):

A multidisciplinary field that studies the aspects in which computer systems can support people working in collaboration.

Health Promotion: An approach that aims to improve the health of a population by providing information that allows on to make informed decisions about one's own health.

Mobile Virtual Community (MVC): A virtual community where members are on the move.

Online Community: A community where members are communicating using Web-based technology.

Tele-Worker: A worker that is able to perform his or her job tasks remotely (off-site), as in the case of people working at home for a company.

3G/4G: Third-generation and fourth-generation mobile communication technologies that enable access to high bandwidth over mobile phones.

Virtual Community: A community where members are not present in the same physical place.

Mobile-Based Advertising in Japan

Shintaro Okazaki

Autonomous University of Madrid, Spain

INTRODUCTION

The Internet-enabled mobile handset has rapidly achieved worldwide penetration. Combining personal telephony and sophisticated technologies, the mobile Internet has opened new opportunities for offering a diverse range of services, including interactive advertising. In Japan, D2 Communications offers various forms of mobile advertising services delivering promotional information from advertisers.

For example, Message F (Free) delivers text-based information to a designated inbox of registered users, who are exempt from the normal packet transmission charges. It can enable highly effective communication due to its ability to target selected demographic segments by region, gender, age, and so forth. In July 2005, D2 Communications began an image attachment service for users of Message F, supporting the transmission of images, logos, and other visual effects, up to 8KB (192 × 192 pixels in JPEG or GIF), as well as text.

This was to be enhanced further in 2006, when Japanese broadcasters began mobile digital broadcasting. The major carrier, NTT DoCoMo, already announced the development of the 3G FOMA(R) P901iTV, which will be “DoCoMo’s first mobile handset to receive terrestrial digital broadcasting signals, in addition to conventional analog signals” (NTT DoCoMo, 2005). Therefore, leading mobile advertisers will take advantage of three basic elements in PC-based interactive advertising in mobile devices: static, animated, and broadcast images.

Pull-Type Advertising

In pull-type advertising, messages are displayed to users who voluntarily enter sites (Andersson & Nilsson, 2000) and

Figure 1. Tokusuru menu

decide whether to access further information. Consequently, wireless advertisers must improve consumer response and acceptance (Carat Interactive, 2002) because users are unlikely to click banners unless they believe that the content will prove useful, credible, and valuable. Consumers’ acceptance, and their perceptions of the delivered content of wireless advertising, are crucial (Carat Interactive, 2002).

In this vein, D2 Communications offers a pull-type advertising platform called “Tokusuru Menu” (which means “beneficial menu” in Japanese), which provides various text banner ads for promotional campaigns, discount coupons, presents, and so forth. This service requires no registration, and any mobile users can freely access it by selecting No. 4 on the i-menu of an i-mode phone (one of DoCoMo’s official sites). Then, they can click and go to the detailed information site. As a result, click-through and call-through rates (almost 15%) are much higher than those of the wired Internet (2-3%) (D2 Communications, 2003; Mizukoshi, Okino, & Tardy, 2001). This popular site attracts an average of 3.5 million people monthly.

Push-Type Advertising

Message F (Free)

This push advertising delivers selected promotional information from advertisers, exclusively to users who have opted in to receive the service. It is delivered to a designated

Figure 2. Message F

Figure 3. Mobile mail advertising

Figure 5. Toku number

“Message F” inbox, and users are exempt from the normal packet transmission charges. It can enable highly effective communication, due to its ability to target selected demographic segments by region, gender, age, and so on.

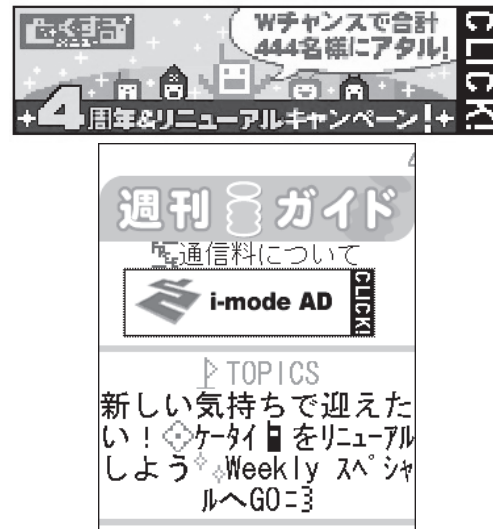

Mobile Mail Advertising

This advertising is delivered in text format and inserted into mail-magazines’ headers. The target customers are “opt-in” users who have registered their regular subscription. User responses often follow directly upon delivery. This category of advertising elicits a high level of response.

Banner Advertising

In this form of advertising, advertisers can send a static image as banner to the sites linked with i-menu. This banner ad occupies approximately one-quarter of a micro-browser screen. Usually it provides a good exposure of logos and other visual elements, and can thus be used as an attention-grabbing tool. According to the most recent statistics, approximately

Figure 4. Mobile picture advertising

1.8 billion advertising banners have been sent so far, with an average click-through rate of 4.6%.

Toku Number

This advertising has been developed as one of the direct marketing strategies via mobile devices. Basically, this is a short code (or “number,” as reflected in its name) that enables users to connect directly to a designated mobile campaign site or clients’ mobile site. In Japan, each mobile operator carries an informative site, such as *Tokusuru Menu* for i-mode, *Tokusuru Info* of EzWeb, or *Tokusuru Information Board* of Vodafone Live, but users can insert this code in any of these Internet sites, because it is a standardized form or common campaign code. This code is frequently used in a cross-media campaigns: a given campaign’s Toku number appears in television or print media so that mobile users can input the code to their mobile handsets directly.

Electronic Wallet

In July 2004, NTT DoCoMo’s new i-mode service “FeliCa” became available. FeliCa is a multi-functional electronic wallet with contactless electronic IC chips developed by Sony. In combination with NTT DoCoMo’s “i-appli” (Java-based applications), users can use FeliCa for diverse transactions, such as commuter pass, electronic money, membership card, and movie tickets, among others, simply by waving their phone in front of enabled sensors (IT Media Mobile, 2003). Figure 2 shows some micro-browser screens of FeliCa. FeliCa combines a wireless Internet service with electronic financial transactions, and offers three principal functions in its main menu: e-Wallet, e-Card, and e-Ticket.

This breakthrough technology is expected to expand greatly the uses and productivity of wireless advertising platforms by enabling users not only to access promotional benefits in banner ads, but also to make use of them. For example, when advertisers display discount coupons in a wireless advertising platform, users can browse the information, transfer it to FeliCa with one click, and then redeem the coupon at a point of purchase using FeliCa. At convenience stores, payments can be made using electronic money, "Edy" (developed by Bit Wallet, Inc.), simply by waving the handset at the cash register (IT Media Mobile, 2004a). In July 2004, "Toho Cinemas," a movie theater chain, started a wireless ticketing service through FeliCa-enabled mobile handsets (IT Media Mobile, 2004b), while NTT DoCoMo and two international payment companies, JCB and AEON Credit Service, announced that they are jointly to develop a quick payment solution for FeliCa-enabled handsets (NTT DoCoMo, 2004).

Furthermore, FeliCa technology can also enhance the feasibility of applying the global positioning system (GPS) to the wireless Internet service. For example, on an extended menu of i-mode, "i-area" includes a diverse range of location-based services: weather news, restaurant guide, local hotel information, zoomable maps with an address-finder function, and traffic updates and estimation of travel times (Sadeh, 2002). In the future, advertisers will be able to beam "real-time offers" to subscribers in targeted, location-specific campaigns, with benefits redeemable in a quick and timely manner.

CONCLUSION

This article summarizes the current practices of mobile advertising in Japan. These services are mainly offered through i-mode of NTT DoCoMo, which has been "exported" to European countries, as well as the United States. Although the level of acceptance of mobile advertising remains limited, the use of mobile advertising has become increasingly popular among consumer goods manufacturers. At the same time, the information provided in this article will be a useful reference for international advertisers and marketers, given that the mobile Internet has been achieving a high penetration worldwide. In Japan, major mobile advertising agencies started an image attachment service to their messaging services in 2005, supporting the transmission of images, logos, and other visual effects. In 2006, mobile carriers will begin to launch a mobile handset which can receive terrestrial digital broadcasting signals, in addition to conventional analogue signals, enabling firms to take advantage of three basic elements in PC-based interactive advertising in mobile devices: static, animated, and broadcast images. This terrestrial digital broadcasting is expected to

be a breakthrough change in terms of the advancement of mobile-based advertising strategies in Japan.

KEY TERMS

Electronic Wallet: In July 2004, NTT DoCoMo's new i-mode service "FeliCa" became available. FeliCa is a multi-functional electronic wallet with contactless electronic IC chips developed by Sony. In combination with NTT DoCoMo's "i-appli" (Java-based applications), users can use FeliCa for diverse transactions, such as commuter pass, electronic money, membership card, and movie tick-

ets, among others, simply by waving their phone in front of enabled sensors (IT Media Mobile, 2003).

Message F (Free): A push-type advertising offered in i-mode which delivers promotional information exclusively to users who have opted in to receive the service. It is delivered to a designated “Message F” inbox, and users are exempted from the normal packet transmission charges.

Mobile Banner Advertising: A static or animated image can be used as a banner to the sites linked to the i-menu. Generally, it provides a good exposure of logos and other visual elements, and thus can be used as an attention-grabbing tool.

Tokusuru Info: An equivalent service to Tokusuru Menu in EZWeb.

Tokusuru Information Board: An equivalent service to Tokusuru Menu in Vodafone Live.

Tokusuru Menu: A pull-type advertising platform offered by D2 Communications. This is one of the “official” i-mode sites, which provides various text banner ads for promotional campaigns, discount coupons, presents, and so forth. This service requires no registration, and any mobile users can freely access it by selecting No. 4 on the i-menu of an i-mode phone. “Tokusuru” means “beneficial” in Japanese.

Mobile-Based Research Methods

Mamoru Nishiyama

Dentsu Communication Institute Inc., Japan

INTRODUCTION

The Internet-enabled mobile handset has rapidly achieved worldwide penetration. Combining personal telephony and sophisticated technologies, the mobile Internet has opened new opportunities for offering a diverse range of services, including online surveys. In particular, the mobile-based messaging service can be used as a practical tool for transmitting questionnaires and collecting responses (see Figure 1). This method also offers a solution to researchers who have begun to recognize that an important question remains unanswered in mobile research: How can we actually “capture” mobile Internet users? So far, the majority of empirical studies in this area have used the traditional pen-and-pencil survey method, while little care has been taken to ensure that the respondents are actual mobile Internet adopters who are capable of evaluating such a new medium. Because of the ubiquitous nature of the mobile device, a conventional questionnaire may be inappropriate for capturing “true” targets, and unlike PC-based e-commerce research, there are several factors to be considered in terms of survey planning and executions.

The aim of this article is to propose a framework of mobile-based survey methodology. Specifically, we attempt to establish guidelines for a questionnaire survey via the mobile device, in terms of cost, questionnaire format, incentives, target respondents, response rate, and data quality.

CRITICAL ISSUES TO BE CONSIDERED

Cost

Prior research indicates that the total cost of Internet-based surveys requires a higher set-up cost in designing, programming, and hosting sites, in comparison with paper-based surveys. However, Internet-based surveys demand neither paper nor postage, thus reducing overall costs by 30-60% (Hanna, Weinberg, Dant, & Berger, 2005). Furthermore, typical online surveys require no expenses related to photo-

copying, clerical support, and data entry, since the responses can be input into the data analysis software automatically (Llieva, Baron, & Healey, 2002).

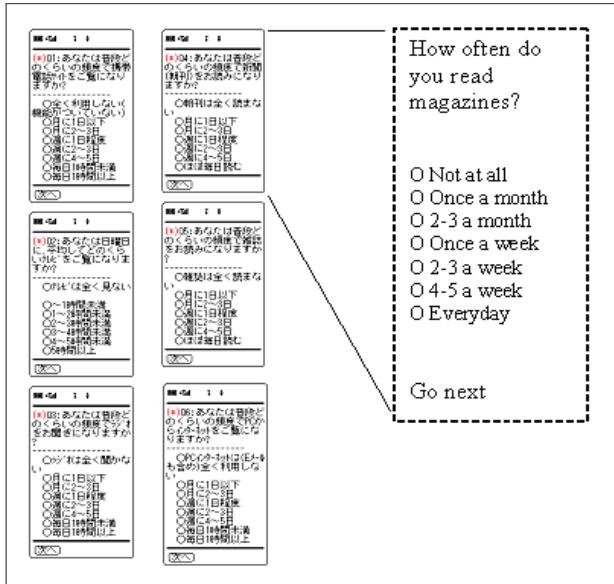

While similar benefits can be expected from mobile-based surveys, the wireless device requires a higher connection cost in data collection. This is particularly an issue, because although mobile penetration has been growing worldwide, Internet connection capacity still varies between countries in terms of both infrastructure and handset functionality. For example, SMS seems comparable to the Japanese e-mail service in terms of cross-carrier compatible, text-based, and immediate send-and-deliver, but the simple SMTP-based mail used by DoCoMo, KDDI, and Vodafone offers more practical advantages. With regard to pricing, Scuka (2003) notes:

It costs 0.3 yen to send 1 packet on DoCoMo's 2.5G i-mode network in Japan; 1 packet is 128 bytes, so a typical simple e-mail might only cost 1 yen (and even cheaper on 3G, where the average packet price is around 0.06 yen/packet). SMS messages, in contrast, cost 19 Euro cents to send 160 characters on all four carriers in Germany (T-Mobile, Vodafone, E-Plus, and O2).

Response Format

The choice of response format is another important question. Here, two basic issues must be considered: (1) dichotomous vs. multichotomous scale formats, and (2) the wording of the response scale points (Netemeyer, Bearden, & Sharma, 2004). Dichotomous scales have practical advantages, in that they take less time for a respondent to fill in and, therefore, allow more items to be responded to in a short time. However, they have been criticized for their tendency to have highly unbalanced response distributions—that is, all individuals always answering “true” or all individuals always answering “false” (Comrey, 1988). Furthermore, any one item for a dichotomous scale produces only limited covariance with any other item because of the binary format, and overall scale variance will be very limited. Multichotomous scales overcome these shortcomings, in that they create more

Figure 1. Example of mobile-based online questionnaire (Source: D2 Communications). An English translation is shown on the right side.

scale variance relative to a dichotomous scale with a similar number of items.

For these reasons, academic researchers tend to prefer multichotomous formats, while practitioners are more likely to adopt dichotomous formats. For example, our depth-interview with an agency practitioner reveals that the reason for the exclusive use of dichotomous response format was its ease of use and minimum response time, which agencies believe are closely related to data quality (Fukada, 2005).

Type of Incentives

In general, it is agreed that the use of monetary incentives has positive effects in increasing the response rate, in both online and off-line surveys (Church, 1993; Yammarino, Skinner, & Childers, 1991). However, what “type” of incentives could increase the response rate seems unclear. For example, Ray, Griggs, and Tabor (2001) found that as much as 57% of the respondents agreed to an exchange for a draw/raffle inclusion, while Comley (2000) reports that such an incentive has little impact in e-mail surveys. A recent experimental study shows that a shorter questionnaire with small lotteries with higher winning chances would produce a higher response rate, but a longer questionnaire also could generate a reasonable response rate if vouchers were promised (Deutskens et al., 2004).

In the case of a mobile-based survey, a barcode coupon has been widely used in various cases of push marketing

(Senden Kaigi, 2004). Furthermore, a free download of screen images, ring-tones, online games, product samples, electronic coupons, and a sweepstakes competition have been tested as effective incentives to encourage participation (Senden Kaigi, 2004). In particular, the free content download (in particular, ring-tone and screen image) and sweepstakes competition offer practical and economical solutions, given that they represent two of the most popular mobile Internet usages in many markets (Dano, 2002; Kim et al., 2004; Harris, Rettie, & Kwan, 2005).

Target Respondents

One of the major problems in m-commerce research is that researchers are often unable to ensure whether target consumers actually have sufficient experience and are capable of providing reliable responses. Empirical studies that used “general” consumer samples seldom conditioned their experience in accessing the mobile Internet, and did not ensure that the target respondents had actually adopted the mobile device for Internet connection. Also, we need to cover a wider range of consumer groups, in both demographic and socioeconomic characteristics. In particular, in an m-commerce context, it is extremely important that the survey examine those who regularly access the mobile Internet, read promotional messages, and even access the linked sites to obtain further information, on a daily basis (Okazaki, 2005). This clearly relates to the respondents’ perceived ability to use the mobile Internet, because mobile-based questionnaires can only be returned from those who are willing to reply via mobile device. This is significantly different from PC-based online surveys, where researchers can offer alternative response options such as fax or postal mail (Truell, 2003).

Response Rate

The response rate of surveys has often been used to assess data quality (Shermis & Lombard, 1999). According to Comley (2000), the overall response rate of all virtual surveys in 1999 ranged from 15% to 29%. However, considerable discrepancies have been found between similar studies in similar periods (Ray et al., 2001; Virtual Surveys, 2001; Wygant & Lindorf, 1999). In many cases, the response rate was found to depend upon the researched topic, which may or may not encourage active participation (Sheehan & McMillan, 1999; Ray et al., 2001).

These figures have an important implication for the computation method of response rate, since a mobile-based questionnaire is normally sent via a push messaging service to the “opt-in” users. Therefore, the target base is a total population of a given area, and whether recipients actually click and open the questionnaire is crucial. At the same

Table 1. Principal component analysis results

| | Factor 1 | Factor 2 | Factor 3 | Factor 4 | Factor 5 | Factor 6 | Factor 7 |

| Well-crafted | | | | | | | .743 |

time, empirical evidence shows that the click-through rate of push-type messages has been quite stable (D2 Communications, 2005). A question then arises as to the base on which we should compute the response rate. Should the response rate be calculated on the basis of the total population or on those who actually click the message? The former method seems inappropriate, because we would include in the calculation of the response rate those who are unlikely to open the questionnaire.

PILOT STUDY

A pilot study was carried out in July 2005 in an attempt to examine the respondents' perceptions of mobile-based advertising campaigns. Forty thousand mobile users were randomly chosen from the agency's customer database, to which a structured questionnaire was sent directly via

mobile device. As an incentive, a book coupon was offered. The questionnaire consisted mainly of 23 adjectives that represent consumers' psychological motivations to willingly receive, open, and read mobile-based advertising campaigns. In addition, media habits as well as demographic information were collected. In all question items, the dichotomous response format was used, and consumers were asked to check the appropriate box to indicate whether an adjective appropriately expressed his or her motivation to accept mobile-based advertising campaigns.

As a result, 1,401 people responded to the survey. The results were converted into fictitious variables, by assigning 1 to "checked" (which means "yes") and 0 to "unchecked" (which means "no"). A principal component analysis with Varimax rotation was then performed. The results are shown in Table 1. The analysis produced a clear-cut seven-factor solution, with 50% of the total variance explained. Creativity, entertainment, and convenience were the three

Table 2. Summary of two-step cluster analysis

| Cluster | Characteristics |
|-----------|--|
| Cluster 1 | This cluster mainly consists of male white-collar workers between the 20s and early 40s. Their occupations include administrative, research, and professional workers. |
| Cluster 2 | This cluster consists of students who are under 25 years old. The proportions of female and male respondents are almost equal. |
| Cluster 3 | This cluster mainly consists of housewives between early 20s and early 30s, including some part-time workers. This cluster is least willing to accept mobile-based advertising campaigns. |
| Cluster 4 | Three-quarters of this cluster consist of "working women" who are between early 20s and early 30s. More than half of this cluster has occupations such as sales and service (30%), administrative, clerical, and office jobs. This cluster is most willing to accept mobile-based advertising campaigns. |

most accentuated factors, which seems to corroborate prior e-commerce research on users and gratification theory (Lin, 1999). Speed, pragmatism, curiosity, and trust were the remaining factors.

Next, to identify possible segments of mobile Internet users, we performed two-step cluster analysis via SPSS 13.0. We included respondents' media habits and demographic variables in the analysis. As a result, we extracted four clusters, the major characteristics of which are summarized in Table 2. Clearly, gender is a key factor in differentiating mobile Internet behavior, in terms of the willingness to accept mobile-based advertising campaigns.

IMPLICATIONS

E-mail or Web-based questionnaire surveys have been widely used by marketing researchers because of their low costs and high response quality. Similar benefits can be expected in mobile-based surveys. Although important differences exist across markets in terms of mobile Internet technology and penetration, a mobile messaging service can be effectively used as a carrier of structured questionnaires. Researchers should take into consideration various factors influencing the response rate and data quality, such as cost, choice of response format, type of incentives, and so forth. In particular, future research via mobile device should consider the inclusion of multichotomous response format, so that researchers can apply sophisticated multivariate analysis.

KEY TERMS

Barcode Mobile Coupon: Mobile barcoding can be used in the form of a picture SMS which is delivered to a mobile phone. Recipients save the image, arrive at the destination, and present their barcode SMS to be scanned.

i-mode: A broad range of Internet services for a monthly fee of approximately 3 euro, including e-mail, transaction services (e.g., banking, trading, shopping, ticket reservations, etc.), infotainment services (e.g., news, weather, sports, games, music download, karaoke, etc.), and directory services (e.g., telephone directory, restaurant guide, city information, etc.), which offers more than 3,000 official sites accessible through the i-mode menu.

Opt-In: Process of actively soliciting a permission from a user to which an advertiser sends a promotional message or to collect personal information for marketing purposes.

Opt-Out: Process of giving an explicit notification that a user does not wish to receive any promotional messages or does not wish to have his or her personal information collected for marketing purposes.

Push Messaging Service: Various forms of messaging services are generally offered in the mobile Internet. For example, SMS and WAP push messaging generally allow users to send 100-160 characters, while mobile e-mail in Japanese i-mode allows up to 1,000 characters.

Short Message Service (SMS): A service for sending messages of up to 160 characters to mobile devices.

Mobility and Multimodal User Interfaces

Christopher J. Pavlovski

Stella Mitchell
IBM T. J. Watson Research, USA

INTRODUCTION

Traditional user interface design generally deals with the problem of enhancing the usability of a particular mode of user interaction, and a large body of literature exists concerning the design and implementation of graphical user interfaces. When considering the additional constraints that smaller mobile devices introduce, such as mobile phones and PDAs, an intuitive and heuristic user interface design is more difficult to achieve.

Multimodal user interfaces employ several modes of interaction; this may include text, speech, visual gesture recognition, and haptics. To date, systems that employ speech and text for application interaction appear to be the mainstream multimodal solutions. There is some work on the design of multimodal user interfaces for general mobility accommodating laptops or desktop computers (Sinha & Landay, 2002). However, advances in multimodal technology to accommodate the needs of smaller mobile devices, such as mobile phones and portable digital assistants, are still emerging.

Mobile phones are now commonly equipped with the mechanics for visual browsing of Internet applications, although their small screens and cumbersome text input methods pose usability challenges. The use of a voice interface together with a graphical interface is a natural solution to several challenges that mobile devices present. Such interfaces enable the user to exploit the strengths of each mode in order to make it easier to enter and access data on small devices. Furthermore, the flexibility offered by multiple modes for one application allows users to adapt their interactions based on preference and on environmental setting. For instance, hands-free speech operation may be conducted while driving, whereas graphical interactions can be adopted in noisy surroundings or when private data entry, such as a password, is required in a public environment.

In this article we discuss multimodal technologies that address the technical and usability constraints of the mobile phone or PDA. These environments pose several additional challenges over general mobility solutions. This includes computational strength of the device, bandwidth constraints, and screen size restrictions. We outline the requirements

of mobile multimodal solutions involving cellular phones. Drawing upon several trial deployments, we summarize the key design points from both a technology and usability standpoint, and identify the outstanding problems in these designs. We also outline several future trends in how this technology is being deployed in various application scenarios, ranging from simple voice-activated search engines through to comprehensive mobile office applications.

BACKGROUND

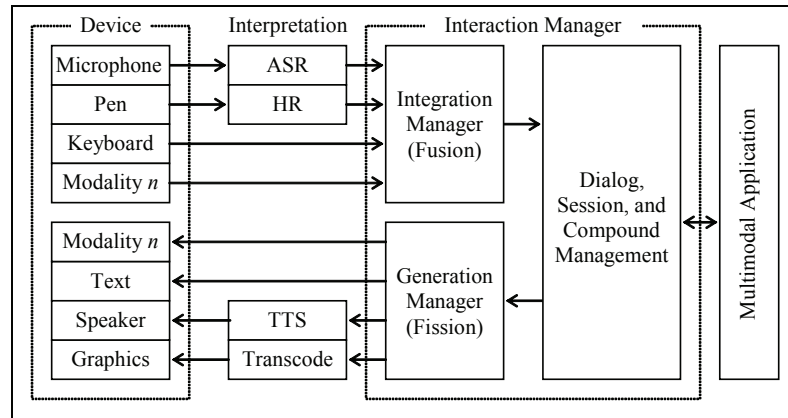

Multimodal interaction is defined as the ability to interact with an application using multiple sensory channels (i.e., tactile, auditory, visual, etc.). For example, a user could provide input by speaking, typing on a keypad, or handwriting, and receive the subsequent response in the form of an audio prompt and/or a visual display. Useful multimodal applications can cover a broad spectrum including tightly synchronized, loosely synchronized, and complementary modes of operation. Synchronization behavior must be defined both for input (the way in which input from separate modes is combined) and for output (the way in which input from one mode is reflected in the output modes). The W3C distinguishes several types of multimodal synchronization for input as follows (W3C, 2003a):

- **Sequential:** Two or more input modalities are available, but only a single modality is available at any given time.
- **Simultaneous:** Allows input from more than one modality at the same time, but each input is acted upon separately in isolation from the others.
- **Composite:** Provides for the integration of input from different modes into one single request.

A general framework for multimodal systems is depicted in Figure 1. This diagram elaborates further on several fundamentals positioned by W3C.

The interaction manager is responsible for combining multiple requests, dialog management, and synchronization. The function of receiving and combining multiple inbound

Figure 1. Multimodal framework

requests is the responsibility of the *integration manager* subcomponent. Conversely, the generation manager is responsible for distributing multimodal output to all of the respective output channels (modes) via an interpretation layer, which may involve text to speech (TTS) conversion or transcoding of graphical content to accommodate the needs of the target modality. Earlier work in multimodal systems referred to the integration tasks relating to composition and decomposition of requests as *fusion* and *fission* respectively (Coutaz, Nigay, & Salber, 1993).

Speech-based telephone interfaces currently available in the commercial market commonly use varying levels of directed dialog. Directed dialog, as the name implies, employs a style of system prompts that helps to “direct” the user in what to say next. Users are often presented with spoken menu options from which they can make a selection, thus navigating in a controlled manner until the task is completed. Much of the naturalness and power of speech is undermined when the application relies too heavily on the use of directed dialogs. A Natural Language speech interface, which allows the user to phrase their request in a wide variety of ways, reduces the cognitive load since there are no commands to memorize or hierarchies to navigate. A mixed-initiative interface allows the user to share control over the direction of the dialog, making the interaction more efficient for the user.

Device manufacturers can install specialized software or firmware on handsets to enable distributed speech recognition (DSR). DSR technology digitizes the speech signal and sends it over an error-protected data channel to a speech recognizer on a server. Thus the processing is distributed between a terminal client and a server. The accuracy of speech recognition can be better when using DSR because the degradations associated with sending speech over the mobile network, such as low bit rate speech coding and channel transmission errors, are avoided. In addition, DSR

allows for the implementation of a multimodal, speech and data, application on devices which do not support simultaneous voice and data connections.

MULTIMODAL TECHNOLOGY IN MOBILITY SYSTEMS

Multimodal applications for small mobile devices must overcome several technical challenges; these include device capability and computational strength, functional and bandwidth constraints of the network, and limitations of the user interface. Present work in multimodality is focused upon the support of two modes of interaction, most typically data (graphics or text) and speech (Kondratova, 2004; Pavlovski, Lai, & Mitchell, 2004a; Hastie, Johnston, & Ehlen, 2002; Kvale, Warakagoda, & Knudsen, 2003). Future trends support additional modes that include visual gesture, lip reading, and haptic responses. In this section we present advances in multimodality supporting speech and data entry, outlining the current state of the technology used and the outstanding challenges yet to be addressed.

Multimodal Architectures

Due to the need to support two or more modes of input and output, the solutions to support multimodal systems are more complex than unimodal systems. Additional capabilities are required to support composite input and output requests, manage multiple application states, and perform session management between devices and the multimodal application services.

There are fundamentally two architectural approaches to constructing multimodal solutions for mobile devices such as mobile phones and PDAs. The most widely investigated architecture appears to involve deployment of an application

Figure 2. Distributed client multimodal architecture

onto the mobile device, using distributed speech recognition (DSR) and a GUI client application. Such a solution may be categorized as *distributed client architecture* (i.e., thick client architecture). The alternative employs the *browser-based architecture* (thin client), where a standard Web browser is the only client software used.

Several proposed solutions have been studied that support distributed client architectures (Kvale, Narada, & Warakagoda, 2005; Klante, Krösche, & Boll, 2004). Figure 2 provides an overview of the key sub-systems and components of the distributed client architecture. The device is required to host several components of the solution, generally including a multimodal client application and distributed multimodal processing technologies. This may include automated speech recognition (ASR), text to speech (TTS), and handwriting recognition (HR); however, typical distributed client designs to date have such components on the server. Communication between the client and server occurs over a single channel; hence the multimodal input is marshaled (encoded) into one communications stream.

There are several advantages of this type of architecture including true synchronicity in delivery of the multimodal output, distributed processing, and richer user interface. Since the multimodal output is combined before transmission to the client, the client application is able to ensure media synchronization—that is, synchronized presentation of content to the user; this is a key problem to address in multimodal systems. The presence of a client application also provides a richer graphical user interface and consistency in user interface output. Additionally, the capability to distribute some processing tasks to the client provides greater flexibility for multimodal applications, particularly in relation to response time. For instance, a multimodal short message service is able to perform speech recognition locally within the device, rather than returning to the server, and display the utterance to the user before sending as a short text message.

A key drawback to distributed client architectures is the need to manage the client software to be deployed to the

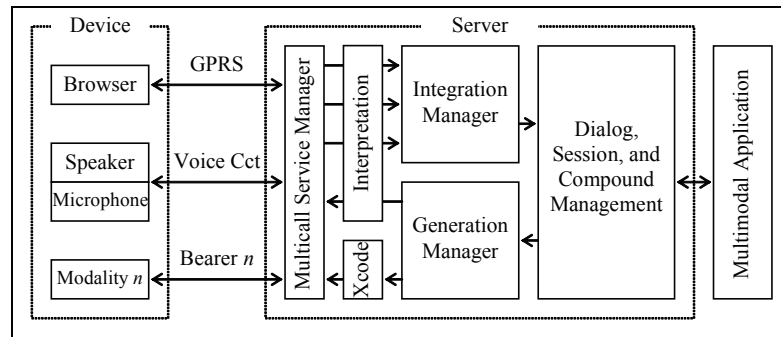

mobile device. This appears to be of particular concern to mobile operators for several reasons. Given the significant numbers of mobile phones in use, software distribution and management to the device is costly. The majority of mobile phone plans are 12 or 18 months, hence new devices are acquired rapidly and continual support becomes cost prohibitive. Additionally, it may not be practical to support all devices available on the market.

Further research suggests that while a limited graphical user interface is of concern to users, in fact the major contributor to improved usability of multimodal user interfaces is the speech interface (Hastie et al., 2002; Pavlovski et al., 2004a). There is also much work on the notion of speech-centric multimodal user interfaces (Johnsen & Kvale, 2005). These observations also support the notion that alternative architectures require consideration.

An alternative approach is a class of multimodal system that does not require client applications to be deployed to the mobile device. Such a framework is also termed a browser-based, or thin client, architecture—only requiring a standard browser on the mobile phone. In order to support the multiple channels, typically speech and data, use is made of a 'Class A' mobile phone and the multi-call supplementary service, which is only available in 3G networks. Specifically, each device establishes several bearer channels with the server, one per mode of user interaction. For example, simultaneously a voice circuit is established for speech and a data bearer service for the browsing graphical and text content (see Figure 3).

Thin client architectures have been studied for mobile devices. An initial set of building blocks to support browser architectures for sequential multimodal processing was outlined in Niklfeld, Finan, and Pucher (2001). The approach in Chou, Shan, and Li (2003) and Li, Wong, and Guo (2004) supports a thin client architecture, where use is made of the multi-call supplementary service for simultaneous connections between the mobile phone and the multimodal application server; however, only sequential multimodal input and output is supported. A further solution solves the

Figure 3. Browser multimodal architecture

problem of supporting composite multimodal output response (Pavlovski, Wood, Mitchell, & Jones, 2004b), however only sequential simultaneous multimodal input is supported. The MONA project provides a similar capability for thin client, and extends the device range to support both mobile phones and PDA devices using a multimodal presentation server (Anegg, Dangl, & Jank, 2004).

The browser-based architecture would naturally seem more attractive to mobile phone operators given the dynamic and rapid turnover of mobile phones, hence eliminating the need to manage software distribution and complexity attributed to supporting numerous mobile devices. The disadvantage of course is that coordinating additional channels increases the complexity and introduces the possibly of latency or synchronization errors. One paper points out that media synchronization is an impact to multimodal applications (Pavlovski et al., 2004b). This may be accommodated by delaying one of the responses so that both arrive simultaneously at the client device. However, complex multimodal applications are yet to be studied to comprehensively assess the impact of synchronization.

Several key challenges remain for browser-based multimodal architectures. This includes management of channel latency and media synchronicity. A full implementation that supports both input and output multimodal composite requests remains as an outstanding problem. And, support for three or more multimodal channels is yet to be explored. These problems may be solved by using the distributed client architecture and have been demonstrated (Johnsen & Kvale, 2005)—however, at the cost of introducing additional software management overheads and restrictions on device supportability.

Standards and Technology

The W3C organization has defined several multimodal standards, including interaction requirements and an interaction framework (W3C, 2003b). We briefly summarize some

further technologies that are specific to multimodal solutions, outlining their applicability to mobile devices.

Extensible Multimodal Annotation (EMMA)

EMMA is a set of XML specifications that represents multimodal user input including speech, pen, and keystroke. The XML is intended to be generated automatically, hence is suitable for use between recognition engines and the interaction manager.

Multimodal Presentation Markup Language (MPML)

The MPML Language is designed for presenting multimodal output on browsers supporting XML. The limited processing capability of phones is accommodated, with a mobile edition defined for J2ME applications (Saeyor, Mukherjee, Uchiyama, & Ishizuka, 2003). As such, the architecture resembles a distributed client solution.

Speech Application Language Tags (SALT)

SALT is a set of extensions to HTML (or XHTML and WML) adding speech capability to these mark-up languages. While it is suggested to support the thin client architecture, applicability to mobile phones is limited due to the requirement of browsers' support for SALT. The need to manage multiple application versions, one for each device, is also observed as a drawback (Kondratova, 2004).

XHTML+Voice (X+V)

X+V is a proposed standard for multimodal markup. Designed for clients that support spoken and visual interaction, X+V technology furnishes traditional Web pages with further voice tags for input and output speech tasks. A goal is to support thin client, however in its current form this technology is

most suited to the distributed client architecture. Use of VoiceXML has also been studied (Niklfeld et al., 2001).

Synchronized Multimedia Integration Language (SMIL)

SMIL is a relevant standard to managing media synchronization, an important multimodal problem. However, the standard is largely aimed at conventional browser technology that supports XML, DOM, and XHTML. Hence, it is restricted to browsers that may not be deployed to mobile phones.

User Interface Design

There is some work treating multimodal user interface design in mobility. A framework for multimodal interface design has been proposed in Baillie, Simon, Schatz, Wegscheider, & Anegg, (2005). The authors suggest the need to study user behavior in the natural environment. This follows the observation that user behavior differs considerably when comparing a controlled environment to the general freedom of use that mobile devices provide (Baillie & Schatz, 2005). A key feature of the method is a table designating the context in which the multimodal system is used and the users' preferred mode of interaction. Further work extends these concepts by proposing a tool to more fully analyze user behavior over an extended period of time (Salembier, Kahn, Calvet, Zouinar, & Relieu, 2005).

Given that there is little data on user behavior in a mobile environment, early design efforts will require careful consideration with users on how to maximize multimodal capabilities. Several key factors determine user behavior including response to error recovery, the course of action context, and properties of the implementation of each modality (Calvet, Julien Kahn, Pascal Salembier, & Zouinar, 2003). Further work shows that the speech interface appears to be the major contributor, when complementing a text or graphical interface, to the improvements bestowed through multimodality (Pavlovski et al., 2004b).

Summarizing the literature, the key features that a multimodal user interface design must address include the capability to dynamically alter modes, support for simultaneous composite output, and the ability to review the output request on one mode, using an alternative mode prior to actioning the request; for example, users who may dictate a message would prefer to see a transcript of the message prior to sending.

FUTURE TRENDS

There are several industry trends and future areas of research including the extension of multimodal solutions to

accommodate haptic response, visual gesture recognition, lip reading, and speech technologies that support natural language understanding. Oviatt (2003) reviews several of these emerging technologies.

The idea of haptic response is already in use with present-day mobile phones, where mobile phones offer a silent mode that alerts the user with a vibration event. Such stimuli has been in use for some time and appear with early flight control systems that provide feedback to the pilots' control system indicating turbulent flight conditions. More recently, gaming controllers use such feedback. There is some recent work on the design of haptic response (Kaaresoja & Linjama, 2005) in mobile devices, while other work focuses on haptic input to control a mobile device (Oakley & O'Modhrain, 2005). The notion of extending applications in mobility with such haptic responses is relatively new. To extend such a capability to multimodal applications, access to native mobile services such as vibration is required to initiate a haptic response.

Lisetti et al. (2003) describe research progress on a multimodal emotion recognition system. They have developed a prototype that takes input from multiple modes (i.e., camera, microphone, wearable computer) and includes both subjective, as expressed by the user, and physiological components as inputs to its model. Lip reading technology, as an alternative interaction mode, may be used to improve speech recognition. Prior research suggests that bimodal audiovisual speech recognition can improve as much as 40% in accuracy (Chan, 2001), in comparison with using audio input alone. Additional work on the use of Natural Language understanding to augment the multimodal user experiences has been proposed and studied (Pavlovski et al., 2004b).

A final observation is required regarding security and privacy. Traditionally, voice communications are considered relatively secure, due to the transient nature of circuit establishment between parties and the real-time exchange of data between two peer entities. This is no longer the case for multimodal application, where the utterances are digitally recorded and stored. Furthermore, in order to improve the speech accuracy and fault resolution, there is a desire on the operators' part to store such data for a perceived user benefit. Of course the storage of personal conversations and requests for information raises several security and privacy issues that have yet to be addressed.

CONCLUSION

The literature has shown that multimodal user interfaces are able to provide a superior user experience when interacting with multimodal applications on mobile devices such as cellular phones. Furthermore, the applicability of multimodality is extending beyond traditional mobile Web applications to a greater range of domains. For instance, due to the plural-

ity of user interface modes, multimodal systems provide a natural improvement for people with disabilities (Kvale et al., 2005). Although studies demonstrate that multimodal user interfaces provide a superior user experience on a mobile phone, it remains unclear whether such an improvement remains consistent for all types of applications.

Distributed client architectures are able to overcome several problems identified in the literature, however the practicality of deployment for mobile phones requires consideration. Browser-based multimodal architectures overcome deployment issues and provide an alternative and easier mechanism for allowing mobile devices to access services. In order to support multimodal applications that make use of three or more interaction modes, the use of thin client architecture is as yet unproven. In addition, further capabilities that may not be inherent within the devices are required, such as local composite management. Hence, distributed clients would seem a necessary choice to support these capabilities and appear most appropriate to address the needs of the increasing complexity due to several modes of interaction, particularly as the media synchronization of modes becomes more complex.

KEY TERMS

Automated Speech Recognition (ASR): The use of computer processing to automatically translate spoken words into a text string.

Directed Dialog: Speech interface where the user receives system prompts that direct the user on available options that usually require a response with simple spoken words.

Fission: The decomposition of output from a multimodal application, to be distributed to the different modalities.

Fusion: The composition of input from multiple modalities into one input request to the multimodal application.

Multi-Call Supplementary Service: Enables several simultaneous circuit-switched calls to the same device, each call using its own dedicated bearer. Only one circuit-switched bearer can be used for speech at any one time.

Multimodal Interaction (MMI): W3C term for a class of human to computer interaction that involves multiple modes of user interaction, such as speech, writing, text, and haptics.

Text To Speech (TTS): The use of computer processing to transform text into spoken words.

Modular Sensory System for Robotics and Human–Machine Interaction Based on Optoelectronic Components

Milan Kvasnica

Tomas Bata University, Zlin, Czech Republic

INTRODUCTION

Presented here is a new unified modular sensory system. The subject of the article is the sampling and information processing used in the conversion of a 2-D CCD array image into three axial and three angular displacement values. The CCD array image consists of four light spots produced by four light beams (planes) from laser diodes. These light beams (planes) form the edges (faces) of a pyramidal shape, with the 2-D CCD array forming its base and the origin of the laser sources forming its apex. The algorithm for the computation of the location and orientation is based on the inverse transformation of the final trapezoidal light spots position, related to the original square light spots position on the 2-D CCD array. This algorithm determines the relative location and orientation of a floating 2-D coordinate system (corresponding to the 2-D CCD array) against a fixed 3-D coordinate system (corresponding to the apex of the pyramidal shape). The modular design presented here enables easy customizing of this sensory system for a wide variety of applications. Various combinations of the modular components enable tailoring of the sensory system properties for applications such as:

- portable modular system for the six-component dynamic measurement in general anisotropic construction in 3-D space,
- detection of microelastic or macroelastic deformation,
- six-DOF force-torque sensors of various properties,
- active compliant links,
- haptic interface,
- multi-DOF hand controllers,
- signature scanners for banking,
- keyboards for blind people,
- tactile sensors,
- range-incline finders-positioners,
- chaser systems,
- accelerometers,
- dynamic weighing, and
- artificial limbs.

In general, this modular design concept allows:

- maximization of service life because of ease of repair and the use of universal modular components for various types of sensors;
- environmentally friendly design, because the modular components are recyclable; and
- customization for a wide variety of design requirements.

Examples include various levels of resolution and operating frequency, enhanced demands for safety and reliability in space robotics, operation in dangerous areas and medical use with supporting self-checking and self-correcting algorithms, and low-cost design for manufacturing. In conclusion, regarding industrial relevance, many fields could benefit from the use of such a sensory system: robotics, telerobotics, rehabilitation robotics, intelligent automation, manufacturing and materials handling, automotive, marine and aerospace industry, medicine, ergonomics, safety accident prevention, defense, and banking.

The function of these sensors is based on the six-DOF system for the scanning of axial shifting and angular displacement. This simple construction enables low-cost customization, according to the demanded properties by means of the modular sensory system consisting of the following basic modules:

- A: Stiff module of two flanges connected by means of microelastic deformable medium;
- B: Compliant module of two flanges connected by means of macroelastic deformable medium;
- C: The module of square CCD elements;
- D: The module of the insertion flange with basic light sources configuration and focusing optics;
- E: The module of the insertion flange with auxiliary light sources configuration and focusing optics;
- F: The module of the plane focusing screen;
- G: The module of forming focusing screen;
- H: The module of the optical member for the magnifying or reduction of the light spots configuration;

- I: The module of switchable muff coupling for changing the scanning mode for the micromovement and the macromovement-active compliance; and
- J: The module for the preprocessing of scanned light spots configuration.

The problem of the customization of six-DOF sensory systems according to the enhanced accuracy and operating frequency of scanning of the six-DOF information is possible to improve by means of the modules:

- K: The module of insertion flange with the configuration of light sources with strip diaphragms, creating the light planes with strip light spots;
- M: The module of the single or segmented linear or annular CCD or PSD elements with higher operating frequency; and
- N: The module of two, parallel working, concentric CCD annulars with higher reliability.

BACKGROUND

The results of our research program concerns the task of how to use a robot to imitate the human activity, as for example inserting a peg in a hole by means of the six-component force-torque sensor. The first robotic systems able to manage this task used a six-component strain gage wrist sensor developed at Stanford University, MIT, and C. S. Draper Laboratory (1960-1970). Using a robot to imitate a human activity in this way marked a historic step in human creative thinking. Recently, several implementations of sensory systems using optical imaging of six-DOF information on a CCD or PSD array have been proposed. An example is the project NASA in the cooperation with the DLR project ROTEX (1993).

SIX-COMPONENT FORCE-TORQUE SENSOR

The explanation of the activity of the majority of sensors described here is introduced with the six-component force-torque sensor (see Figures 1 and 2) composed from modules A,C,D,F,H, of the intelligent modular sensory system. Laser diodes 1 emit the light beams 2 creating the edges of a pyramid intersecting the plane of the square CCD element, here alternatively the focusing screen 8 with light spots 3. The unique light spots configuration changes under axial shifting and angular displacements between the inner flange 5 and the outer flange 6 connected by means of elastic deformable medium 7. An alternatively inserted optical member 9 (for the magnification of micromovement or the reduction

Figure 1. The approach of six-DOF scanning

of macromovement) projects the light spots configuration from the focusing screen onto the square CCD element 4. Four light beams simplify and enhance the accuracy of the algorithms for the evaluation of six-DOF information. The algorithms for the evaluation of three axial shiftings and three radial displacements are based on the inverse transformation of the final position of points A,B,C,D, related to the original basic position of points A₀,B₀,C₀,D₀,S₀ of the plane coordinate system x_{CCD}, y_{CCD} of the square CCD element (see Figures 1 and 2).

The information about axial shiftings caused by forces F_x, F_y, F_z and angular displacements caused by torques M_x, M_y, M_z are sampled and processed according to a calibration matrix. The intelligent modular sensory system enables us to compose in a customized way the various modifications of the multi-DOF force-torque sensors and compliant links for artificial arms or legs, range incline finders, hand controllers for wheelchairs, tactile sensors, keyboards for blind people, and handwriting scanners.

HUMAN ARTIFICIAL LIMBS

The effort to imitate by means of robot the human behavior of inserting a peg in a hole for the purposes of automatic assembly led to the development of the six-component force-torque sensor. For the scientist it is more satisfying to

Figure 2. Six-component force-torque sensor

utilize such sensors to substitute for the missing limbs of the human body by an artificial limb of higher quality. Universal, low-cost, intelligent modular sensory systems enable us to evaluate a man's hand or leg dynamics while in motion. A part of the artificial leg consisting of the joint 10 connecting a shin with a foot 11 is depicted in Figure 3. The motion of the joint 11 is controlled by means of the six-DOF information gained from two six-component sensors. The joint's 10 drive transmission is switched by means of the coupling muff 9 in order to control the dynamics of the motion.

The six-component information about the leg's dynamics processed from two force-torque sensors enables us to use the drive power intelligently, even to convert the damping of the joint 10 motion for energy recuperation into the battery. The joint 13 connects the foot 11 with the toes part 14. The angular displacement (here for example a, b) of the joint 13 is used for accommodation to the ground's incline 12a, 12b, according to the information from the range-incline finder.

RANGE-INCLINE FINDER

The ground's incline under the artificial leg is scanned by means of the range-incline finder mounted in a heel (see Figure 3) consisting of the modules A, C, D, H. The light spots 3 from the light beams 2 on the ground 12a, 12b create the configuration scanned by the square CCD element. The processing of this information enables us to evaluate the incline of the ground in two perpendicular planes. Real-time algorithms are suitable for the single cheap microprocessor. An acoustic signal as indicator of the ground's incline helps the user to keep stability. The range-incline finder mounted on a wheelchair helps to keep the desired distance from a wall.

Figure 3. Six-component force-torque sensors mounted in artificial leg and the range-incline finder built in the heel

CUSTOMIZED DESIGN OF A DEXTEROUS HAND

In rehabilitation robotics and in health care, many tasks occur frequently for example at the feeding of disabled people:

- the approaching of the artificial hand with the feeding utensil into the required position in front of a target object,
- the sequence of the operations until the time instant of the first contact with the target part of the body, and
- the inserting into a target part of a body.

Following this is the force-torque manipulation with a target object, with the aim here, for example, to load the food into the mouth and to protect the hurt.

Intelligent sensory systems for the solution of these tasks may be implemented instead of a missing part of a human hand or as a part of a robot's hand. In addition there is a possibility to evaluate the weight of gripped food in a dynamic way, while the robot's hand is in motion, in order to check the caloric limit.

Figure 4. Customized design of dexterous hand

A simple solution of an universal dexterous hand consists of three sensory systems with two independently working CCDs (see Figure 4).

The first sensory system is the range-incline finder-positioner, composed of three modules C, D, H, alternatively working into the CCD element 4b. The range-incline finder-positioner consists of two pairs of mutually perpendicularly situated cross-light beams (planes) 2a radiated from the laser diodes 1a situated on the gripper. The configuration of the light spots (strips) 3a on the surface of the target object is projected by means of the zoom optical member 9a into the CCD element 4b. This multi-laser scanning equipment is used in the approach of the robot's gripper to the target and for simplifying some tasks in recognizing three-dimensional backgrounds.

The second sensory system is a six-component stiff force-torque sensor, composed of three modules A, C, D, alternatively working into the CCD element 4b. The laser diodes 1b fastened on the outer flange 6b radiate the light beams (planes) 2b against the CCD element 4b, fastened on the inner flange 5b. The unique light spots (strips) configuration 3b is changed under the force-torque acting between flanges 5b and 6b, both mutually connected by means of microelastic deformable medium 7b.

The third sensory system is the six-component active compliant link composed of six modules B, C, D, F, H, I, working into the CCD element 4c. The laser diodes 1c emits the light beams (planes) 2c against the focusing screen 8c. An optical member 9c mediates the reduction of the macro-

Figure 5. Multi-DOF hand controller

movement of the light spots (strips) 3c. The unique light spots (strips) configuration 3c is changed under the force-torque acting between flanges 5c and 6c, connected by means of the active compliant medium 7c. An active compliance is solved by means of pneumatic, programmable switched, segmented hollow rubber annulars 7c. Alternative use of the six-component stiff force-torque sensor or the active compliant link is switched by means of coupling muff 10.

Dexterous fingers 13 are equipped by two force-torque sensors for the motion control of the finger's joints by means of the six-component information. The top of every finger is equipped by elastic rubber cushions 14 and by nails 15. The unified modular intelligent sensory system enables customized design for a wide variety of tasks in rehabilitation robotics.

HAND CONTROLLER

Efficiency in using a wheelchair depends on the user's effectiveness in communicating with the driving gear. A low-cost six degrees-of-freedom hand controller means for many users not luxury, but the possibility for personal autonomy in their daily activities. A multi-DOF hand controller is possible to use for the control of the feeding utensil combined with a simple mechanism. The multi degrees-of-freedom hand controller (low cost) or of enhanced reliability is depicted in Figure 5, under the influence of the acting force $+Fz$. This device consists of the module C of the square CCD element, or of the module N, for example in medical use of enhanced reliability for surgeons with two independently parallel working CCD annulars 4, fastened in mutually opposite directions in front of the (module D) modules K of the (light beams) light planes 2. The configuration of the (light beams) light planes 2 of the pyramid shape is radiated from the laser di-

Figure 6. Keyboard for blind people

odes 1 fastened on the outer flange 6. The configuration of light (beams) planes 2 creates in the plane of (square CCD elements) the CCD annulars of the configuration of light (spots) strips 3. The inner flange 5 is fastened on the stand 8 and connected by means of the elastic deformable coupling balks 7 with the outer flange 6. The design of the outer flange 6 is shaped for a human-hand-friendly form.

KEYBOARD FOR BLIND PEOPLE

Six-component force-torque sensors that make it possible to pass judgment about the heterogeneity of a man's hand dynamics, for example the handwriting of two different persons, may be used like a keyboard for blind people. Because of the lack of place for the six-component force-torque sensor between a nib and a penholder, the configuration seen in Figure 6 was used, where the inner flange 5 is put on the end of a penholder 8. The outer flange creates a steady mass. This handwriting scanner is possible to use as a keyboard for blind people in order to improve their communication with a computer. Another configuration of the handwriting scanner, where the six-component force-torque sensor is inserted between the writing plate 6 and the support 8 of the writing hand, is depicted in Figure 7. This device may be used as a signature scanner in banking.

Figure 7. Six-DOF signature scanner

Figure 8. Six-DOF hand controller with haptic interface

HAND CONTROLLER WITH HAPTIC INTERFACE

Adding haptics to an interface can enhance human-computer interaction. A haptic interface enables software to utilize a new class of operations, including cursor-controlled feedback through dynamic force-torque responses from virtual objects displayed on screen. It also allows novel hardware interfaces, for example in the handling of fragile materials or assembly operations in telerobotics or in space robotics. In rehabilitation robotics, it is possible to use a multi-DOF hand controller with haptic feedback as a human-machine interface, for example for the control of a feeding utensil. A six-DOF hand controller (see Figure 8), with the same basic structure as shown in Figure 2, shows the inner flange 5 fastened on the stand 8 and connected by means of the elastic medium 7, with the outer flange 6, which is shaped

Figure 9. Six-DOF head controller with haptic interface

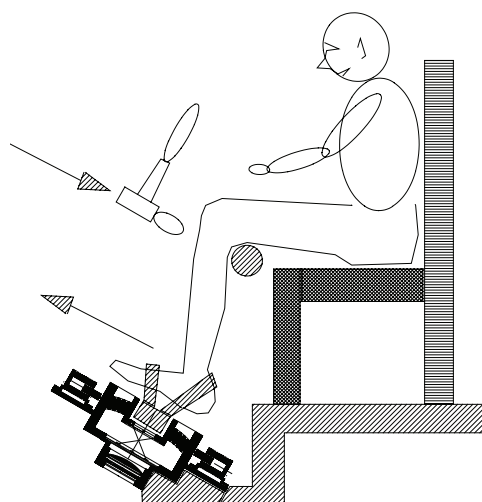

to be grasped comfortably. One end of the Bowden cable 9 is fastened on the outer flange in the point 10 and inserted in the hole 11 in the inner flange 5 and in the stand 8. The other end of the cable passes through the elastic medium 7 and the wheel 12, and is fastened to the movable core 13 of electromagnetic actuator P. The pressure sensor 15 for the calibration of haptic forces is inserted between the foot of the cable 9 and the movable core 13.

HEAD CONTROLLER WITH FORCE INTERACTION

For 3-D tasks in space robotics, telerobotics, or surgery, a head controller can be useful. A six-DOF head controller with force feedback interface is depicted in Figure 9. The modular design allows this device to be constructed identically to the above hand controller, but uses larger parts, with the exception of the attachments of the inner and outer flanges. The inner flange 5 is fastened on the human head, and the outer flange is fastened to the stand 8 from the chair. The inner flange 5 is connected by means of the elastic medium 7 with the outer flange 6.

Another possibility of how to use the head controller with force interaction is depicted in Figure 10. There is an application for the examination of the patellar reflex response in neurology by means of the hit of the reflex hammer, connected by means of the force sensor with computer. The examination of the patellar reflex response using the leg's dynamics movement scanner is evaluated from the course of the dynamic characteristic by means of the computer. Another application is possible like the leg's controller.

Figure 10. The examination of the patellar reflex response by means of the leg's dynamics movement scanner

SIX-DOF SENSORY SYSTEM FOR INTERACTIVE POSITIONING IN SURGERY

Some applications of multi-pod's parallel structures frequently need the six degrees-of-freedom (DOF) force torque feedback between the multi-pod's platform with a patient and a robot's effector at robotic-aided therapy. A six-DOF force-torque transducer is inserted between the multi-pod's platform with a patient and a stand (see Figure 11). The difference between the actual, measured, and computed position of both platforms changes during the manipulation. The first difference arises under the influence of interpolation of the positioning algorithm, elasticity of materials, temperature dilatation, inaccuracy of incremental sensor, and servo drivers. The second difference is caused by the functional elasticity of the body of an inserted force-torque transducer, and both have an additive course.

The multi-pod's motion sensing system is derived from the pyramid modular sensory system for the sampling of information about six-DOF displacements (see Figure 12). The subject of this modular sensory system is based on the conversion of four 2-D PSD (CCD) array images into three axial shifting and three angular displacement values. Every 2-D PSD (CCD) array image consists of one light spot produced by light rays from four laser sources. These light rays form the edges of a pyramidal shape, with four 2-D PSD (CCD) arrays forming its base in the vertex of the square shape. An origin of the laser sources 9 is forming its apex P.

The sampling of the configuration between two platforms by means of two universal modules is depicted in Figure

Figure 11. Multi-pod's parallel structure combined with the six-DOF force-torque transducer

Figure 12. Multi-pod's parallel structure equipped by the module Ap of four lasers and four modules Cp for direct sampling

11. Here the position of movable platform 2 is sampled by the module Ap of four laser 3a radiated light rays 2a with presetting control 1a of the angle 2σ against four modules Cp mounted on the stand 1. Modules Cp are situated in the corners of a square shape on the multi-pod's stand. The module Cp for direct sampling of measured values fluctuation of the light spot 3c position consists of the 2-D PSD (CCD) array 6c with focusing optics 5c and the flange 1c. The light spot 3c from the laser light ray 2c is imagined on the translucent screen 4c.

Figure 13. The module M of segmented linear CCD or PSD arrays intersected by structured light planes for enhanced scanning frequency

Figure 14. The module M of segmented annular CCD or PSD arrays intersected by structured light planes for enhanced scanning frequency

THE ENHANCEMENT OF THE SAMPLING FREQUENCY

The problem of the customization of six-DOF sensory systems according to the enhanced accuracy and operating frequency of scanning of the six-DOF information is possible to improve by means of the modules:

- K: Module of insertion flange with the configuration of light sources with strip diaphragms, creating the light planes with strip light spots;
- M: Module of the single or segmented linear or annular CCD or PSD elements with higher operating frequency; and
- N: Module of two, parallel working, concentric CCD annulars with enhanced reliability.

Figure 15. The module N of two parallel working concentric annular CCD or PSD arrays intersected by structured light planes for enhanced scanning frequency and enhanced reliability

CONCLUSION

The modular design presented here enables easy customizing for a wide variety of applications. Various combinations of the modular components enable tailoring of the sensory system properties, including the use of the haptic interface for applications such as detection of microelastic or macroelastic deformation, active compliant links, multi-DOF hand controllers, signature scanners, keyboards for blind people, tactile sensors, and range finders-positioners. In general, this modular design concept allows maximization of service life because of ease of repair and the use of modular components for various types of sensors, and customization for a wide variety of design requirements, for example, various levels of resolution and operating frequency, enhanced demands for safety and reliability in space robotics and medical use, and low-cost design for manufacturing.

In conclusion, many fields could benefit from the use of such a sensory system: robotics, telerobotics, measurements in engineering constructions, intelligent automation, automotive and aerospace industry, medicine, defense, and banking.

INTRODUCTION

Advances in mobile and ubiquitous computing, wireless communications and mobile positioning have given a rise to a new class of mobile information systems and services, called location-based services (LBS) (Schiller & Voisard, 2004). Such services, like fleet management, cargo tracking, child-care, tourist services, transport management, traffic control and digital battlefield rely on the tracking of the continuously changing positions of entire populations of moving objects. LBSs are becoming ubiquitous. A traffic service may inform its users about traffic jams, traffic accidents and weather situations that are expected to be of relevance to the service user. A friend finder service may inform each user about the current whereabouts of friends. Other services may monitor and track the positions of emergency vehicles, police cars, security personnel, hazardous materials, or public transport. A more advanced location-based game service may allow a group of users to play and try to surround and catch “hostile” players. Monitoring and tracking moving objects require continuously registering the positions of mobile objects, and at any instance in time to know whether those objects are

within the specified area, or a specified distance from known mobile/static objects, or which are its k nearest neighbors (k -NN). To provide monitoring and tracking of moving objects in mobile application environments, it is highly desirable and sometimes critical for the service efficiency to provide accurate results to these requests and update them in real time, whenever moving objects enter or exit the regions of interest, or become the closest neighbors to the objects of interest.

Monitoring and tracking LBS applications require database and application support to model and manage moving objects in both database and application domains. Such services must also provide efficient processing of continuous queries over moving objects. In contrast to regular queries that are evaluated only once, a continuous query remains active over a period of time. At any time there will be a number of continuous queries simultaneously running at the server. Each of these queries needs to be periodically re-evaluated as the objects and/or queries move. A major challenge for this problem is how to provide efficient processing of continuous queries with respect of CPU time, I/O time and network bandwidth utilization. The architecture of the monitoring and tracking LBS system is given in Figure 1.

Figure 1. The architecture of monitoring and tracking LBS

BACKGROUND

Monitoring and tracking moving objects in mobile environments by processing continuous queries over moving objects is an active area of research, resulting in the proposal of many query processing methods, techniques and indexing schemes. One of the challenges in monitoring and tracking LBS development is how to handle different types of queries in a mobile environment, where both queries and objects can be moving. Different types of location dependent queries are significant for the monitoring and tracking purposes, such as range queries, k -nearest neighbor (k -NN) queries, reverse neighbor queries, distance joins, closest pair queries and skyline queries. The most important type of query for the purpose of monitoring and tracking moving objects is the range query. The range may represent a user selected area, a map window, a polygonal feature, a part of the road segment or an area specified by the distance from a reference point. The map window of the LBS client application represents the simplest continuous range query that must be supported in monitoring and tracking LBS application. Using such a query, up-to-date information about moving/stationary objects in a user's surrounding is continuously represented in the map window, as he/she, as well as objects of interest, move.

Continuous query processing in a location-aware environment is an active area of research, resulting in the proposal of many query processing methods, techniques and indexing schemes. In Prabhakar et al. (2002), velocity constrained indexing and query indexing (Q-index) has been proposed for efficient evaluation of stationary continuous range queries. According to the proposed method, in-memory data structures and algorithms are developed and presented (Kalashnikov et al., 2004). By indexing queries, and not moving objects, the Q-index method avoids frequent updates of the index structure and thus expensive maintenance of this structure. The MQM method presented (Cai et al., 2004) focuses on stationary continuous range queries. It is based on partitioning the query space into rectangular sub-domains, and the assignment of the resident domain to each moving object. A moving object is aware only of the range queries intersecting its resident domain, and reports its current location to the server only if it crosses the boundary of any of these queries. Gedik and Liu (2004) propose a method and a system for distributed query processing, called Mobieyes. Mobieyes ships some part of the query processing to the mobile clients while the server mainly acts as a mediator between moving objects. The method tries to reduce the load on the server and save communication costs between moving objects and the server. In the paper by Gedik et al. (2004), the authors propose a scheme called motion adaptive indexing (MAI), which enables optimization of continuous query evaluation according to the dynamic motion behavior of the objects. They use the concept of motion sensitive bounding boxes (MSB) to model

and index both moving objects and moving queries. Mokbel et al. (2004a) present SINA, a server-side method based on shared execution and incremental evaluation of continuous range and k -NN queries. Shared execution is achieved by implementing query evaluation as a spatial join between the moving objects and the queries. Incremental evaluation means that the query processing system produces only the positive or negative updates of the previously reported answer, not the complete answer for every evaluation of the query. Both the object and query indexes are implemented as disk-based regular grids. The same authors in Mokbel et al. (2004b) present a continuous query processor that extends a relational database management system and a data stream management system, to support efficient continuous query processing of spatiotemporal streams. They implemented the proposed query processor inside the PLACE (pervasive location-aware computing environments), scalable location-aware database server. Based on the authors' previous work, the proposed continuous query processor provides incremental evaluation of continuous queries, shared and scalable execution of a set of concurrent continuous queries and integration of data streaming management and semantics to support location-aware environments.

Hu et al. (2005) propose a generic framework for monitoring continuous spatial queries over moving objects, both range and k -NN queries. The work of Tao et al. (2002) focuses on continuous k -NN query evaluation, for moving queries over stationary objects. They propose an algorithm for precalculating k nearest neighbors with a line segment representing the continuous motion of the object.

Koudas et al. (2004), propose a method, called DISC, for approximate processing of k -NN queries over streams of multidimensional points, where the returned k th NN point is further than the actual k th NN point, within a specified distance threshold. Yu et al. (2005) describe a method for continuous monitoring of k -NN queries. Their method uses a main memory grid as an index structure and utilizes two algorithms using grid indices. The first one is based on object indexing, and the second is based on query indexing. Each k -NN query is evaluated for the first time by a two-step NN search technique, and is further re-evaluated every T time units. The initial step visits the cells in squares around the cell covering the query point until k objects are found. The second step refines the search by examination the cells outside the examined squares in order to determine the actual k -NN set of objects and remove false candidates appearing in the initial step.

Xiong et al. (2005) propose the method SEA-CNN for monitoring changes in the k -NN set, assuming that the initial result of a query is available. Objects are indexed by a regular grid on the disk. The method defines the answer region of a k -NN query as the circle centered at the query point with radius the distance to the current k -th NN, and the cells that intersect the answer region hold information about

it. When the data or query objects update their locations, the SEA-CNN algorithm is used to determine the new k -NN set based on the new circular search region.

MONITORING AND TRACKING MOVING OBJECTS

The methodology for processing continuous range queries in a mobile environment is developed as a part of ARGONAUT, a service platform for moving object data management (Predic et al., 2005). We base our approach on the application scenario appropriate in LBS for monitoring and tracking moving objects. In this scenario, users have wireless devices (e.g., mobile phones or PDAs) that are online via some form of wireless communication network. We assume that users can obtain their positions using global positioning system (GPS) technology. A setting is assumed in which a central database at the LBS server stores a representation of each moving object's current position. Each moving object stores locally the representation of its current position assumed by the server. Then, an object updates the database whenever the deviation between its actual position (as obtained from a GPS device) and the local copy of the position that the central database assumes exceeds the uncertainty threshold (Civilis et al., 2005).

In most real-life monitoring and tracking applications, the object movement is constrained by an underlying spatial network, that is, objects can not move freely in space, and their position must satisfy the network constraints. Network connectivity is usually modelled by a graph representation, comprising a set of nodes (intersections) and a set of edges (segments). In order to perform tracking with as few updates as possible, the LBS server must match the position of the moving object sent in the form of (X, Y) coordinates to the underlying network segment. Map matching is a technique that positions an object on a network segment, at some distance from the start of that segment, based on location information from a GPS device. Knowing the moving object's speed (also sent by the moving object along with position) and the time of position update, the server can predict the current and the near future position of the object until the next junction (node) assuming that it moves at a constant speed (Civilis et al., 2005). Reduction of updates reduces communication between clients and the server and server side update and query processing.

The ARGONAUT methodology employs an incremental continuous query evaluation paradigm similar to Mokbel et al. (2004a, 2004b). Thus the server reports to the clients only the changes of the answer from the last evaluation time of their continuous queries. This significantly saves the network bandwidth by limiting the amount of transmitted data to the updates of the answer only rather than the whole query answer. Two types of updates are distinguished: positive

updates and negative updates. The positive/negative update indicates that a certain object needs to be added/removed to/from the query answer.

As mentioned in the previous section, most query processing methods index either objects, queries or both in main memory. Thereby, efficient query processing and minimization of CPU time are achieved, both necessary for real-time applications. Since the object movement is constrained by the underlying transportation network, the methodology maintains two representations of the network data. The first representation organizes network segments according to Euclidean distance in a main memory R^* -tree index structure (Beckmann et al., 1990), that stores MBR (minimal bounding rectangle) representation of segments belonging to a spatial network.

The graph representation of a spatial network is maintained by the network connectivity table (NCT) data structure, which stores information about the connectivity of network segments. Both network representations are interconnected, that is, there is a reference from R^* -tree segment representation to the corresponding NCT segment representation and vice versa. For each segment, two lists are maintained: the list of objects IDs (*Olist*) and queries IDs (*Qlist*) that move along or reside on that network segment. Both segment representations have pointers to these lists.

A moving object ID is inserted in the *Olist* that corresponds to the network segment at which such object resides or currently moves according to map matching technique. The moving/stationary query is determined by the reference object and query condition (range, distance, k -NN, etc.). The stationary/moving query is inserted in each *Qlist* that corresponds to the network segments whose MBR representation is intersected by the query range (for Euclidean metric space), or which are in specified network distance from the reference object of a query (for network metric space).

By inserting the objects IDs and queries IDs in appropriate lists related to network segments, the matching between moving objects and moving/stationary queries according to their spatial relations is performed. This matching provides the filter step of continuous query processing. The ARGONAUT query processing methodology involves an additional step in the query processing strategy. The pre-refinement step is performed to further refine the initial query result set regarding object and query temporal information, as well as exact locations and query ranges. The pre-refinement step creates data structures in main memory to support incremental refinement steps.

The two tables and associated lists are created in main memory by the pre-refinement step. *Continuous query table* (CQT) stores information related to continuous queries. A CQT entry is described as $(QID, OID, range, resultSet)$ and stores information related to a continuous query. The table is indexed on the *QID* attribute, which is the unique query identifier. *OID* is the identifier of the reference object

Figure 2. Changing the status of a moving object in a continuous query result

of the query; *range* defines the shape of the spatial query range around the reference query object. *resultSet* is the query result set obtained by the pre-refinement step with additional, temporal information about satisfaction of a query. The result set is a list of elements defined as $(RID, OID, resPeriod, status)$, where *RID* is the result identifier, *OID* is the unique identifier of the object, which is the result of the query during period *resPeriod*, while its status in the query result is described by the *status* attribute. The values of the *status* attribute are INIT_RESULT, NEW_RESULT, OLD_RESULT, NO_RESULT. In the simplified case, when the resulting period is single time period, the resulting object, during its motion and/or query motion, change all status values sequentially (Figure 2).

For each moving object in the system, an in-memory mobile object table (MOT) is created and maintained. The moving object entry is described as $(OID, loc, time, speed, IDseg, querySet)$, where *OID* is the unique moving object identifier, *loc* is the last received location update, *time* is the timestamp of the location update and *speed* is the last received speed. The *IDseg* attribute is the identifier of the current network segment. *querySet* attribute represents the list of queries in which such object participates, either in a query result, or as a reference object of a query.

The pre-refinement algorithm examines the set of moving objects obtained by the filter step, and creates *CQT* and *MOT* along with corresponding lists. For each query in the set, the pre-refinement algorithm generates the result of the query along with the validity period of the resulting object in that result. For each moving object in the system, the pre-refinement algorithm generates the set of queries in whose results it participates.

The incremental evaluation (refinement step) is performed periodically and evaluates the validity periods of query results in regard to current time. It determines the incremental result containing only the changes of the results from the last evaluation, that is, only positive and negative updates. This enables fast query evaluation and saves the network bandwidth by limiting the amount of data transmitted to the client.

The most challenging part of the query processing methodology in such real-time settings is to update the data and index structures upon receiving location/speed/segment update of the moving object. When a moving object sends its location/speed update to the server, when its actual location differs from the server-predicted location by the specified threshold, the methodology needs to update the validity periods for all queries in whose result the particular object participates. If the moving object is the reference object of the query (-ies), the validity periods for all resulting objects must be updated accordingly. For the case of range queries, this update is represented by simple algebraic expressions. But, when a moving object changes its underlying network segment, the *OID* of the object must be deleted from previous *Olist* and entered in the new one associated to the new network segment. Thereby, the object can participate in the query results of the new set of continuous queries (new *Qlist*), and must be added in their *resultSet*s, along with updating of its *querySet* accordingly. The complete algorithms for the query processing methodology and performance study for moving objects that know its destination in advance and thus their route/path in the network (public transport, fleet management, etc.) are given in Stojanovic et al. (2005). The improvement of such algorithms and experimental evaluation of our continuous query processor for objects moving freely on the network is presented in Stojanovic et al. (2006). The experimental results show that the performance of the ARGONAUT query processing methodology is satisfactory for real-world settings in LBS applications for monitoring and tracking moving objects. We plan to further extend and improve our methodology for query processing of continuous *k*-NN queries.

FUTURE TRENDS

The application of continuous query processing techniques to the monitoring and tracking of moving objects is a very active area for both research and practice. One of the future directions in the field represents continuous query process-

ing over moving objects regarding their trajectories as data streams and incorporating data streams techniques in such process. Also, with the advancement of mobile computing/communication devices, distributed and mobile query processing techniques become more important. Such techniques ship some part of query processing to the moving objects, which have the computational and storage capabilities to perform some part of the query processing algorithms. The next step is to distribute data management, as well as query processing functionality required for monitoring and tracking moving objects to the mobile peer-to-peer networks, where moving objects communicate with each other via short-range wireless transmission. In such environments, moving objects serve as both clients that monitor and track other objects, and routers of queries and answers on behalf of other clients.

CONCLUSION

The wide-spread of smart cellular phones, personal digital assistants and GPS technology enables a mobile environment where objects are continuously moving and are aware of their locations. During the past few years, we have witnessed the emergence of location-based services field as a novel research area, investigating interesting problems and developing real-life applications and services related to monitoring and tracking moving objects.

Services such as these rely on the efficient management of moving objects' location and processing of continuous queries. Since most of these services have real-time constraints and are mission critical, it is of great importance to effectively process continuous queries and generate incremental results, which must be delivered to clients across a wireless/wired communication channel.

The field provides many attractive topics for both theoretical and engineering achievements and it is expected to be one of the key fields in mobile and ubiquitous computing research for the years ahead.

KEY TERMS

Continuous Query: Query that needs to be evaluated at every time instant in order to ensure the correctness and validity of the query answer

Incremental Evaluation: Query evaluation that determines the incremental result containing only the changes of the results from the last evaluation.

K-Nearest Neighbors Query: Spatial query whose condition is given as a k nearest neighbors to the specified spatial object.

Location-Based Services (LBS): Services that deliver geographic information and geo-processing services to the mobile/stationary users taking into account their current location and references, or locations of the stationary/mobile objects of their interests.

Moving Object: Spatial object that continuously changes its location and/or other spatial properties: shape, dimensions, orientation, and so forth.

Negative Update: The update to the previous query answer containing objects that need to be removed from the query answer.

Positive Update: The update to the previous query answer containing objects that need to be added to the query answer.

Range Query: Spatial query whose condition is given by a spatial range or a distance from the specified spatial object.

Multilingual SMS

Mohammad Shirali-Shahreza
Sharif University of Technology, Iran

INTRODUCTION

In 1985, Ernie made the first telephone call on the mobile phone in Britain. In less than two decades, however, the mobile phone has turned into a necessary device for people, and now one out of every six individuals throughout the world has a mobile phone.

With the expanding use of mobile phones and the development of mobile telecommunications, telecommunication companies as well as companies manufacturing mobile phones decided to add additional features to their telephone sets in order to attract more customers. One of the services that were provided on the mobile phone was the SMS.

The SMS (short message service) is the transfer and exchange of short text messages between mobile phones. The SMS is defined based on GSM digital mobile phones. According to the GSM03.40 standard (GSM, 2000), the length of the exchanged message is 160 characters at most which are saved in 140 bytes depending on how information is saved according to the standards. These messages may be a combination of digits and letters or saved in non-text binary form. Using the same binary messages, one can also send pictures as well. The pictures, however, are two color and have a low quality (Shirali, 2006).

SMS messages are exchanged indirectly and through a component known as the SMSC. SMS messages have the following advantages:

- Communication is possible when the network is busy.
- We can exchange SMS messages while making telephone calls.
- We can send offline SMS messages.
- Various services are provided such as e-commerce.

One can also receive reports on the status of the SMS message or define a validity period for the SMS message (Nokia, 2001).

SMS PICTURE MESSAGE

The size of the SMS picture message is 72×28 pixels and it is two color. The saving format of the SMS picture is OTA. The structure of this format is as follows (Nokia, 2001).

The header of this format containing four fixed bytes is as follows:

Byte 1) 0000 0000 (→ 0)

Byte 2) 0100 1000 (→ 72)

Byte 3) 0001 1100 (→ 28)

Byte 4) 0000 0001 (→ 1)

As you can see in the above header, the second and third bytes indicate the height and width of the picture.

The structure of the body of the picture contains the pixels in 0 and 1. The amount of each pixel is saved in one bit. In each bit, 0 indicates the black and 1 the white color. Thus, every 8 pixels are saved in one byte. The order of saving of the pixels is from the left to the right and from the top to the bottom of the picture. Considering the size of the picture, the entire size of an SMS picture message is 256 bytes (see Figure 1).

SENDING SMS IN LOCAL LANGUAGE

Using SMS is not limited to the subscribers inside a country, and all mobile phone owners in other countries can also receive SMS.

In the early days, mobile phones supported limited languages such as English, but gradually other languages were also added to the potentialities of mobile phones. Today, mobile phone producers offer support of local language of the country where the phone set is to be supplied. For example, the mobile phones supplied to the Iranian market support Persian and Arabic languages as well. Thus, it is possible to send SMS in local languages. Anybody can send SMS in his own language and not need to use English (Stuiver, 2006).

Figure 1. Size of an SMS picture message

Image Size: $((72 \times 28 \text{ bit}) \div 8) \text{ byte} + 4 \text{ byte} = 256 \text{ byte}$

Multilingual SMS

However, as already states, the mobile phones only support the English language plus the language of the concerned country (and sometimes a limited number of other languages). Thus, a person who lives outside his native country where the language spoken is different from his native language is not able to send or receive SMS in his mother tongue. In the same manner, those who live in a given country cannot send SMS in their local language to their friends in other countries, because the mobile phones of their friends may not support their local language, and therefore they have to send SMS in English. In some cases, people send their messages in their local language typed in English letters. For example, “place” is the English word for Arabic «مكان» “Makan.” An Arab may type “Makan” (a transcription of the Arabic word in English characters) and send as SMS. This forces undesirable changes to the local languages and may, in the long run, destroy the language.

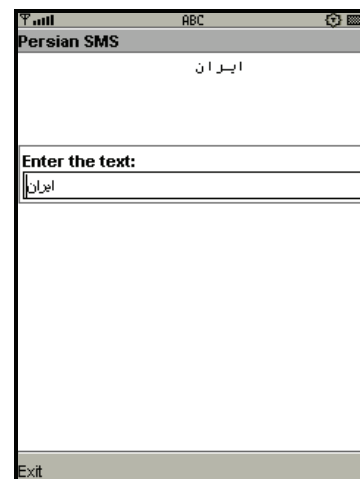

MY PROPOSED IDEA

In this article, I am presenting a solution to this problem. As indicated earlier, two-color pictures can be sent by SMS. Therefore, SMS picture messages can be sent to convey SMS in local languages. Thus, there will be no problem in view of support of the local language by the mobile phone of the person who receives the message. The details and procedure of this method are as follows.

First, the input text is received from the user. As the size of SMS is limited to 72×28 pixels, a limited amount of text can be incorporated into the picture. This amount differs for different languages. As the size of letters in Persian and Arabic is not identical, a precise size cannot be defined, but on average, two lines and in each line 9 Persian or Arabic letters can be accommodated. That is, a total of 18 Persian or Arabic characters can be placed in each picture. In case the mobile phone of the sender did not have the capability of entering text in the local language, a program can be developed to receive the texts in a local language. The possibility of supporting local language can be also added by installing some programs available in the market. For example, the Arabic/Farsi/Urdu Localization program produced by Psiloc Mobile Solution Company (Psiloc, 2006) can be used for Persian and Arabic languages. Of course, the text can be received from the user in the form of English characters and then converted into the local language, as done by the ArabTex program (Lagally, 2006). In this case, there is no need for a mobile phone capable of supporting the local language. However, this method is not recommended due to the defects previously indicated.

After receiving the text from the user, a certain number of letters depending on the language in use (due to limited size of the picture) are separated and saved in the picture of

Figure 2. The program for converting text to picture SMS on the mobile phone

an SMS. This action is repeated until the entire text is saved in SMS picture messages. Then, these pictures are sent.

This idea has been implemented by J2ME (Java 2 Platform, Micro Edition). This language is a version of the Java programming language specially developed for small devices such as pocket PC computers, PDAs, mobile phones, and so on. As mobile phones extensively support the Java language, this method can be executed on a large range of mobile phones. It can also be executed on PDAs. A sample of this program for Persian and Arabic languages is shown in Figure 2.

ADVANTAGES

All mobile phones, even the black-and-white models and the old models, are capable of displaying picture SMS. Therefore, this method can be used without any hesitation. The cost of sending SMS is very low and sending a message in the form of a few SMS picture messages is not costly. This method is not only useful for sending SMS to another country. Even inside a given country, some old mobile phones do not support local language, and this method can solve their problem.

My proposed method has high security. For identification and tracing messages, an optical character recognition (OCR) program is needed to extract the text of the message and then to study the text. This process needs too many calculations and, considering the large volume of SMS exchanged daily, it is a difficult and time-consuming work.

In this method, special fonts of each language which may not be installed on the phone set of the receiver can be used to add to the beauty of the text.

INTRODUCTION

Electronic mobile devices are becoming more and more powerful in terms of memory size, computational speed, and color display quality. These devices can now perform many multimedia functions, including rendering text, sound, images, color graphics, video, and animation. They can provide users with great entertainment values, which were only possible with more expensive and bulky equipment before.

Technological advances in computer and telecommunications networks have also made mobile devices more useful for information exchange among users. As a result, a number of new mobile products and services, such as multimedia messages services (MMSs) and online games, can be offered to users by the industry.

It is commonly believed that “contents are the king” for multimedia products and services. As the mobile handsets and networks become more and more advanced, there is a stronger and stronger demand for high-quality multimedia contents to be used in new hardware systems. Content creation involves both computer technology and artistic creativity. Due to a large number of users, mobile entertainment has become an important part of the so-called creative industry that is booming in many countries.

In this article, we provide an overview of multimedia contents for mobile entertainment applications. The objective is for the readers to become familiar with basic multimedia technology, and the concepts and commonly used terms. Our focus will be on multimedia signal representation, processing, and standards.

SOUND

The original sound, such as speech from humans, can be represented as a continuous function $s(t)$. The sound can be recorded using electronic devices and stored on magnetic tapes. It can also be transmitted through telecommunications systems. The traditional telephone is used to send and

receive waveform information of sound signals. The function $s(t)$ here is called an analog audio signal. This signal can be sampled every T seconds, or $f_s = 1/T$ times per second. The output signal is called a discrete-time signal. Each data sample in a discrete-time signal can have an arbitrary value. The sample values can be quantized so that we can represent them using a limited number of bits in the computer. These two processes, sampling and quantization, are called digitization, which can be achieved using an analog-to-digital converter (ADC) (Chapman & Chapman, 2004; Gonzalez & Woods, 2002; Mandal, 2003; Ohm, 2004). A signal $s(n)$ that is discrete both in time and in amplitude is called a digital signal. To render a digital sound signal, we must use a digital-to-analog converter (DAC) and send the analog signal to an electronic speaker.

The parameter $f_s = 1/T$ is called the sampling frequency. For telephone applications, usually $f_s = 8000\text{Hz}$, and for audio CD usually $f_s = 44100\text{Hz}$. To achieve stereo effects, the audio CD has two channels of data. There is only one channel in telephone applications. The sampling frequency f_s must be greater or equal to twice the signal bandwidth in order to reconstruct or recover the analog signal correctly. This is called the Nyquist sampling criterion. In telephone systems, a sound signal may have to be filtered to remove high-frequency components so that the sampling criterion is satisfied. This is why audio CDs have a higher sound quality than telephones.

The sound information can be stored as raw digital data. Some sound files, such as WAVE files (with extension “.wav”) used on PCs, store raw sound data. This kind of format requires large storage space but has the advantage, since there is no information loss and the data can be accessed easily and quickly. To reduce the amount of data for storage and transmission, sound data are often compressed. Commonly used sound data compression methods include the m-law transformation, adaptive differential pulse code modulation (ADPCM), and Moving Picture Experts Group (MPEG) audio compression (Chapman & Chapman, 2004; Mandal, 2003; MPEG, n.d.; Ohm 2004).

Currently, MPEG Audio Layer 3 (MP3) is a very popular sound data compression technique for mobile devices. MP3 is also a well-known sound file format. During data compression in MP3, a sound signal is decomposed into 32 frequency bands, and psychoacoustic models are used to determine the masking level and bit allocation pattern for each band. Modified discrete cosine transform (MDCT) is used to compress the data. The discrete cosine transform (DCT) has the so-called energy compact property—that is, it is able to pack most of the energy of a signal in a small number of DCT coefficients. For example, if $s(0) = 2$, $s(1) = 5$, $s(2) = 7$, and $s(3) = 6$, then the DCT coefficients are $S(0) = 10$, $S(1) = 3.15$, $S(2) = 2$, and $S(3) = 0.22$ (Mandal, 2003). In this case, from $S(0)$ to $S(3)$, the coefficients become smaller and smaller. We can simply retain the low-frequency components $S(0)$ and $S(1)$ and discard high-frequency ones $S(2)$ and $S(3)$ to obtain an approximation of the original signal. In practice, we can allocate more bits to code $S(0)$ and less and less bits for $S(1)$ to $S(3)$ to achieve a high compression ratio and at the same time maintain good signal quality.

Short sound files can be completely downloaded to mobile devices before being played. To reduce waiting time for downloading long sound files, audio streaming technology can be used (Austerberry 2005). In a streaming system, audio data is transmitted through a network and played by a mobile device as the data become available. That is, a sound does not have to be completely stored in the mobile device before being played. Streaming is useful if a large amount of data need to be received by a mobile device or live broadcasting is required.

We have focused on how to process sound waveform information above. In fact, sound can also be generated according to its parameters or a set of instructions. The musical instrument digital interface (MIDI) standard is used for such purpose (Chapman & Chapman, 2004; Mandal, 2003). A MIDI file contains information on what kind of instruments, such as different types of pianos, should be used and how they should be played. Several instruments can be arranged in different channels and played at the same time. MIDI files are much smaller than waveform-based sound files for music and is widely used for ring tones on mobile phones.

IMAGES

The imaging ability of mobile devices has been improved rapidly in recent years. Now most new mobile phones are equipped with digital cameras and can take pictures with millions of pixels. Software programs are available to edit an image, such as to enhance its contrast and change its color appearance. Mobile devices can also be used to send or receive images and browse the Web.

An important parameter for images is the resolution, which is closely related but should not be confused with

the image size. Image resolution is usually measured by dots per inch (dpi). Higher resolution for the same physical area of an object would generate a larger image than lower resolution, but a large image does not necessarily mean a high resolution as it depends on the area that the image covers. The concept of resolution is often used in image printing and scanning. Typically, laser printers have a resolution of 300dpi or 600dpi and fax documents have resolutions from 100dpi to 300dpi.

A digital image can be considered as a two-dimensional (2D) discrete function $i(x, y)$. Like sound data, images need to be compressed to save storage space and transmission time. There are a number of methods that can be used to compress an image. Most methods are designed to reduce the spatial redundancy so that an image can be represented using a smaller amount of data. The most popular technique used for image compression is the Joint Photographic Experts Group (JPEG) standard (Gonzalez & Woods 2002). In JPEG-based compression, an image is divided into small, square blocks, and each block is transformed using the two-dimensional DCT (2D-DCT). Similar to audio data compression, the energy of a smooth image is concentrated in low-frequency components of the 2D-DCT coefficients. By allocating more bits to a small number of low-frequency components than to a large number of high-frequency components, we can achieve effective data compression.

In the JPEG2000 standard, the 2D discrete wavelet transform (2D-DWT) is used for image compression. In this method, an image is decomposed into several sub-bands, and different quantization schemes are used for different sub-bands. The 2D-DWT usually performs better—that is, it can provide a higher quality for similar compression ratio or a higher compression ratio for similar image quality than the 2D-DCT.

The JPEG and JPEG200 standards are usually used to provide lossy compression with a high compression ratio, although they can also be used for lossless compression. In lossy compression, the decompressed image is only an approximation of the original one, and as a result the image may appear to be blocky and blurred. The quality of an image from lossy compression can be improved using a number of techniques (Liew & Yan, 2004; Weerasingher, Liew, & Yan, 2002; Zou & Yan, 2005). In lossless compression, we can reconstruct or recover the original image exactly. Commonly used lossless compression methods include graphic interchange format (GIF), tagged image file format (TIFF), and portable network graphics (PNG). A GIF image can only show 256 colors and is especially useful for logos, buttons, borders, and simple animation on Web pages. GIF is a patented technology. In TIFF, image information is associated with different tags, which can be defined by users. TIFF is widely used for scanned office documents. PNG, which can support true colors, has been developed to be a royalty-free alternative to GIF. Similar to GIF, PNG

can provide background transparency, but PNG does not support animation.

GRAPHICS

An image can also be generated from a set of drawing operations, similar to the way music is generated from MIDI instructions. Images represented by pixel values are called bitmaps, while those obtained from drawings are called vector graphics. The bitmap format is better for natural objects, such as human faces and outside sceneries, whereas the vector format is better for computer-generated objects, such as line drawings and industrial designs.

On computers and mobile devices, different operating or window systems provide different graphics utilities as software development tools. In general, they should all have graphics functions for drawing line shapes, such as lines, polygons, and circles, and displaying bitmaps. Some systems provide more advanced functions, such as geometric shape transformations, color gradients, and spline curve and surface displays. Currently, there are many proprietary mobile operating systems developed by different manufacturers. This makes it difficult to port graphics applications from one phone model to another model. However, a few systems have been adopted by more and more manufacturers. They include Symbian, Microsoft Windows Mobile OS, and Linux-based mobile OS.

There are also several graphics formats that are supported by many mobile operating systems. They include proprietary formats Java 2 Micro Edition (J2ME) and Flash, and royalty-free and open standard scalable vector graphics (SVG). J2ME is a general purpose programming language for small electronic devices and contains many useful graphics functions (Edward, 2003; Wells, 2004). It has gained widespread use in mobile phones, especially for games.

Flash was developed by Macromedia, which is now part of Adobe Systems. In addition to graphics, Flash can also be used to present other types of multimedia data, such as text, sound, and animation. The output file of Flash is called an SWF movie, which contains definition tags and control tags. The definition tags describe the objects in a movie, such as text, shapes, bitmaps, sound, and sprites. The control tags define how and when an object should be transformed and displayed. SWF movie files use a very compact binary format, so they can be transmitted over the Internet quickly. They have found many applications to Web page design and are now used more and more in mobile phones. Macromedia Flash provides an authoring tool to design SWF movies. One can also create a SWF movie using a computer program according to the SWF file format.

SVG is an open graphics standard developed by the World Wide Web Consortium (W3C). It is royalty free and vendor independent. SVG uses text format and provides a language

to define graphics display, in a way similar to the HyperText Markup Language (HTML) that defines text display. SVG can be used to describe vector shapes, text, bitmap images, and animation. Since vector graphics can be easily scaled larger or smaller, SVG files can be used for different resolutions, such as in printing which requires a high resolution, and in displays on mobile devices which have low resolution. A number of graphics software packages, such as CorelDraw and Adobe Illustrator, can output SVG files.

VIDEO

A digital video contains a sequence of images $v(x, y, n)$, where x and y are spatial coordinates and n represents time. For each n value or a time sample, we have a frame of video or an image. In video compression, we can explore both spatial or intra-frame redundancy and temporal or inter-frame redundancy. Spatially, a frame can be compressed just like an image. Temporally, a frame is similar to its proceeding frame, so we can expect a higher compression ratio for video than for each image separately and independently.

A straightforward way of reducing the temporal redundancy is to use the proceeding frame and approximation of the current frame. A better approximation can be achieved if we take into account movements of the objects in the image sequence. We can divide an image into small blocks and search in the proceeding frame for a closest shifted version of each block. Then, we only need to code the difference between the block under consideration and its closest match in the previous frame, and the shift between the two blocks. This procedure is called motion estimation.

Extensive research has been carried out in the field of video processing on how to estimate and compensate motions efficiently.

A series of MPEG standards have been developed for video compression (MPEG, n.d.; Watkinson, 2004). MPEG-1 was developed for coding of moving pictures and associated audio for digital storage media, such as video CD and MP3, at up to 1.5 Mbit/s. It uses block motion compensation and the DCT to code the residual image. MPEG-2 provides generic coding of moving pictures and associated audio information for bit rates from 1.5 to 80 Mbit/s. It is an extension of MPEG-1, allows combinations of video and audio streams, and supports different packet formats for data transmission. MPEG-2 products include digital TV setup boxes and DVDs. MPEG-4 provides standardized technology for video and audio data storage, transmission, and content access and manipulation on digital TV, interactive graphics applications, and the World Wide Web. In addition to video and audio coding, it supports creation of synthetic objects. For example, mesh models can be used for human face animation. MPEG-7 is a standard for describing multimedia content, including images, graphics, 3D models, audio,

speech, video, and the way various data should be combined in a multimedia presentation. MPEG-21, which is still under development, defines the multimedia framework for different users, including content creators, producers, distributors, and service providers, to access, exchange, manipulate, and trade a large variety of multimedia items.

The International Telecommunication Union (ITU) Telecommunication Standardization Sector (ITU-T) has developed a series of standards H.26x for video phone and videoconference applications. H.261 supports data rates as multiples of 64Kbit/s, that is, $p \times 64\text{Kbit/s}$, where $1 \leq p \leq 30$. H.261 only supports two image frame sizes, common interchange format (CIF) or 352×288 pixels, and quarter common interchange format (QCIF) or 176×144 pixels. H.262 is the same as the video part of MPEG-2. H.263 provides a number of improvements over H.261, MPEG-1, and MPEG-2. For example, it uses better methods for motion compensation, offers higher video quality, and supports more image sizes. H.264 is the same as MPEG-4 Part 10, advanced video coding (AVC), and is jointly developed by the ITU-T Video Coding Experts Group (VCEG) and MPEG. H.264/MPEG-4 AVC employs a number of new techniques, such as variable block-size motion compensation (VBSMC), to improve the compression performance. It is also more flexible under a variety of network environments. H.263 and H.264 have been used in 3GP movies for second-generation (2G) and third-generation (3G) mobile phones.

Similar to audio, video can also be streamed (Austerberry, 2005). This is especially useful for video phone calling, videoconferencing, and live broadcasting. Current 3G mobile networks already offer video calls and many video-based entertainment programs, such as news and sports, which were only possible through TV before.

ANIMATION

Animation means presentation of a sequence of artificially created images. In video, the images are obtained from a camera, while in animation, the images are drawn by hand or generated by the computer. Moving pictures in animation are often synchronized with audio to create movies.

Cartoon movies had been used for entertainment long before the digital computer was invented. A cartoon film must contain 24 picture frames every second to show smooth motions (Chapman & Chapman, 2004). This means 86,400 pictures for a one-hour movie; obviously it is very labor intensive. The labor cost can be reduced using cel animation and key-frame animation techniques. In cel animation, the still background is drawn only once and the moving part is drawn frame by frame, each on a cel, a sheet of transparent material, which is placed on the background picture. In key-frame animation, a motion is decomposed into important key frames and in-betweens. Experienced animators are

assigned to draw the key frames and junior animators the in-betweens. Now using the computer, the in-betweens can often be generated using pattern matching and interpolation techniques.

Simple animation can be displayed on the computer or mobile devices by simply going through a sequence of images. GIF provides such function. It is useful for small animated pictures, which does not require many colors or audio. It is widely used for Web page design and for MMS on mobile phones.

Simple animation can also be generated using morphing techniques. In Macromedia Flash, one shape can be morphed to another shape specified by a set of parameters. Each shape is described by its edges and color information. In this method, key frames are drawn according to shape specifications, and in-betweens are automatically generated by the computer through the morphing process.

Three-dimensional (3D) animation has been used in many digital entertainment products and services. In 3D animation, an object is often represented using a mesh model. It is shaded according to light and camera settings, and may be superimposed with a texture. Now there are a number of 3D design packages available for PCs as well as powerful workstations. Virtual reality (VR) systems make extensive use of 3D graphics and animation. The Virtual Reality Modeling Language (VRML) was developed to support VR on the Web (Ames, Nadeau, & Moreland, 1997).

An interesting and challenging task in computer animation is to automatically animate the human and animal faces (Huang & Yan, 2002, 2003; Parke & Waters, 1996; Yan, 2001). This involves synchronizing the mouth movement with voice and generating different facial expressions. We have recently developed a real-time lip synchronization and facial animation system, which has already been used by several Internet and communications companies for 3G and MMS applications on mobile phones (Tang, Liew, & Yan 2005). Our system can create many virtual characters with different styles. It can match voice signals with lip/mouth shapes smoothly and automatically. The lip-sync can be done in real time (e.g., 20 frames per second) for several languages, including Chinese (Cantonese and Mandarin), English, French, German, Japanese, and Spanish. In addition, a virtual character can express his/her emotion with different kinds of facial expressions. Examples of the movies produced by our system can be found on <http://www.HyperAcademy.com> or simply <http://www.hy8.com>.

TECHNOLOGY TRENDS

Mobile technology is rapidly advancing. We expect to see many new or enhanced mobile entertainment products and services in the next several years. First of all, future mobile devices will have higher computational power for its proces-

sors, higher resolution for digital cameras, and higher data rates through the telecommunications network. Currently, there is criticism for 3G mobile phones that the battery does not last long for displaying movies. To support multimedia functions for a longer period of usage, mobile devices need improved technologies for reduced power assumption and better batteries.

Traditionally, most multimedia contents based on graphics, video, and animation are produced for TV and other large display screens. Simple image down sampling of the images can cause visibility problems. So future multimedia editing and authoring tools should take into account the legibility of the material for mobile devices. An interesting research topic in image processing and pattern recognition is how to reduce the size of a bitmap image optimally so that the output is most legible. This requires sophisticated algorithms for feature detection and pattern extraction from the image.

More and more multimedia contents will become available for mobile devices in the future. Mobile gaming is one of the rapidly growing areas. There will also be increased use of mobile phones for music, movies, advertisements, news reports, storytelling, finance, weather and traffic information, and educational and training programs, and for access to the Web, most of which are similar to the capabilities and functions provided by TV and desktop computers. For Web applications, better user interface and page layout will be needed so that the users can find information needed easily. We also expect increased applications of video phone calls, videoconferencing, and video e-mail messages.

A more challenging task for a mobile device to perform is to recognize its user's voice, speech, face, and even facial expressions and emotions, and interact with the user. Considerable progress has been made in the past in these areas, but the recognition reliability still needs significant improvement. These problems can be solved to some extent under restricted conditions. For mobile phones, it is difficult to control the background noise or appearance for normal usages, so more robust pattern recognition techniques must be developed to solve these problems.

KEY TERMS

Audio Signal Processing: Acquisition, compression, enhancement, filtering, transformation, and transmission of sound data.

Computer Graphics: Modeling and rendering of two-dimensional or three-dimensional objects on the computer.

Digital Entertainment: Providing multimedia materials, such as music and movies, on digital devices, such as computers and mobile phones.

Facial Animation: Modeling and displaying talking human faces with different expressions.

Image Processing: Acquisition, compression, enhancement, filtering, transformation, and transmission of pictures.

Lip-Synchronization: Matching the mouth shape created by the computer with the voice signal.

Multimedia Content: Digital data of text, music, graphics, images, and video

Video Processing: Acquisition, compression, enhancement, filtering, transformation, and transmission of movies.

Multimodality in Mobile Applications and Services

INTRODUCTION

Multimediality and multimodality are concepts with multiple meanings. In Van den Anker and Arnold (1997), multimediality is defined as a way to present and convey information using several different media. Multimodality provides the user with multiple modalities of interacting with a system, beyond the traditional keyboard and mouse.

Both multimediality and multimodality refer to more than one communication channel. The diffusion of mobile devices and the development of their services and applications is connected with the natural communication approach preferred by users, which combines several modalities (speech, sketch, etc.) in order to communicate. It is therefore necessary to integrate the diverse modalities so that the features of the mobile device are more similar to the paradigm of human communication, making it simpler to use.

W3C (World Wide Web Consortium) activities have solved various mobile Web problems affecting the diffusion of mobile devices, such as practice Web navigation from mobile devices, multimodal interaction for the mobile Web, and multimedia and graphics for multimedia messaging. Diverse W3C working groups are involved in the discussion about device independence, multimodal Web access, and type of content for multimedia messaging. Characteristics identified by W3C according to the power and extensibility of XML (eXtensible Markup Language) enable the exchange of rich multimedia content and promote inter-user communication.

The greater opportunity to access and exchange information according to the content and opportunities offered by mobile devices are the two main elements of the growing interest in added-value services in different social environments. In fact, the opportunities offered by multimedia and multimodal technologies are important for any type of communication services, and as these technologies allow new ways of communicating, particular attention can be devoted to people with no technological ability or those with disabilities. This article introduces and discusses the

problems and future scenarios and prospects of multimodality and mobile communication, analyzing the multimodal dialogue systems.

BACKGROUND

Multimodal applications combine visual information (involving images, text, sketches, and so on) with voice, gestures, and other modalities to provide powerful mobile applications, giving users the flexibility to choose one or more of the multiple interaction modalities. These systems break down the barriers in adopting mobile devices for added-value services.

Mobile applications and services generally involve both multimodality and multimediality, using different modalities and (as specified below) different communication channels. Two typical cases of mobile multimedia use are person-to-person communication and person-to-content communication (Ericsson, 2004). In addition, several applications require multimedia data, and numerous studies have been devoted to developing new ideas for methodologies, technologies, and algorithms for indexing, retrieving, compressing, transmitting, and integrating different types of data (Pham & Wong, 2004).

The use of multimodality and multimediality in mobile devices allows a simple, intuitive communication approach and generates new, richer services for users (Colby, 2002). When developing multimodal services, it is essential to consider perceptual speech, audio, and video quality for optimum communication system design and effective transmission planning and management in order to satisfy customer requirements (Kitawaki, 2004).

The following parameters should be considered when characterizing quality in advanced mobile devices: (1) wideband speech, audio, and video for multimedia; (2) noise reduction; and (3) speech recognition-synthesis for hands-free communication.

Multimedia and multimodal systems use different channels of communication, and specific devices are developed to increase the information flow between user and system. Nigay and Coutaz (1993) distinguish between the two, observing that a multimodal system is able to automatically model information content through a high level of abstraction. This difference leads to the definition of two main characteristics of multimodal interfaces:

- fusion among different data types and different input/output devices; and
- temporal constraints, imposed by information processing to and from input/output devices.

A multimodal system is an hw/sw system that allows one to receive, to interpret, and to process input, and that generates as output two or more interactive modalities in an integrated and coordinated way.

Communication among people is often multimodal, and it is obtained combining different modalities. Multimodal interfaces allow several modalities of communication to be harmoniously integrated, making the system's communication characteristics more similar to the human approach.

Multimodal interfaces provide the user with multiple interaction paradigms through different types of communication input. Data fusion is one of the main problems in human-computer interaction, where each datum is generated through a distinct interaction mode. Furthermore, the management of these multiple processes includes synchronization and selection of the predominant mode. Consequently, an important issue in multimodal interaction is the integration and synchronization of several modalities in a single system. In literature two approaches are often used: signal fusion, and information fusion at the semantic level.

The first approach is preferred for matching and synchronizing modalities as speech and labial movement. The semantic fusion is used for modalities that differ in a temporal scale. In this approach, time is very important because chunks of information with different modalities are considered, and integrated if they are temporally close. The integration can be carried out using an intermediate approach between the signal integration and the semantic fusion.

The relation among modal components can be classified as follows (Bellik, 2001):

- **Active:** (Act in following tables)—when two events, produced by two different devices, cannot be completely and correctly interpreted without ambiguities if one of the two events is unknown.
- **Passive:** (Pas in following tables)—when an event produced by a given device cannot be completely and correctly interpreted without ambiguities if the state of the other devices is unknown.

The input synchronization of a multimodal system can be defined as:

- **Sequential:** (Seq in following tables)—if the interpretation of the interactive step depends on one mode and the modalities can be considered one by one.
- **Time-Independent Synchronized:** (TIS in following tables)—if the interpretation of the interactive step depends on two or more modalities and the modes are simultaneous.
- **Time-Dependent Synchronized:** (TDS in following tables)—if the interpretation of the interactive step depends on two or more modalities and the semantic dependence of the modalities has a close temporal relationship.

There are several levels of synchronization (W3C):

- **Event-Level:** If the inputs of one mode are received as events and immediately propagated to another mode.
- **Field-Level:** If the inputs of one mode are propagated to another mode after a user has changed the input field or the interaction with a field is terminated.
- **Form-Level:** If the inputs of one mode are propagated to another mode after a particular point of the interaction has been achieved.
- **Session-Level:** If the inputs of one mode are propagated to another mode after an explicit changeover of mode.

The semantic fusion of modal input occurs in two steps: (1) the first matches the modalities to obtain a low-level interpretation module, by grouping the input events in multimodal events; and (2) the second transfers the multimodal inputs to the high-level interpretation module, in order to obtain the meaning of their events. This high-level interpretation defines the type of actions that will be triggered by the user and the used parameters. These parameterized actions are passed to the application dialog manager to start their execution.

MAIN FOCUS OF THE ARTICLE

There is an emerging need for integration among the various input modalities, through signal integration and semantic fusion, and an additional need to disambiguate the various input modalities and coordinate output modalities, to enable the user to have a range of integrated, coordinated interaction modalities.

Martin and Toward (1997) proposed a theoretical framework for studying and designing multimodal systems based on a classification of six basic types of cooperation between modalities:

Table 1. Correspondences among types of cooperation, relation among modal components, and input synchronization

| Types of Cooperation | Relational Among Modal Components | Input Synchronization |
|----------------------|-----------------------------------|-----------------------|
| C | Act, Pas | TDS, TIS |
| E | No relation | Seq |
| R | Act | TDS, TIS |
| T | Pas | Seq |
| CC | No relation | No synchronization |
| S | No relation | Seq |

- **Complementarity:** (C in following tables)—different chunks of information comprising the same command are transmitted over more than one mode.
- **Equivalence:** (E in following tables)—a chunk of information may be transmitted using more than one mode.
- **Redundancy:** (R in following tables)—the same chunk of information is transmitted using more than one mode.
- **Transfer:** (T in following tables)—a chunk of information produced by one mode is analyzed by another mode.
- **Concurrency:** (CC in following tables)—independent chunks of information are transmitted using different modalities and overlap in time.
- **Specialization:** (S in following tables)—a specific chunk of information is always transmitted using the same mode.

Benoit, Martin, Pelachaud, Schomaker, and Suhm (2000) have advanced several proposals for integrating different modalities. Table 1 presents correspondences among types of cooperation, input synchronization, and relation among modal components.

An approach for classifying multimodal applications considers the services provided. Aslan, Xu, Uszkoreit, Krüger, and Steffen (2005) classify services into three groups: information services, transactional services, and composed services. Information services can provide the user with information such as air travel info, city info, and so on. Transactional services, such as travel planning services, involve a much closer engagement and a greater degree of two-way interactivity. Composed services integrate various services and information for complex situations. Starting from the multimodal applications taxonomy introduced in Benoit et al. (2000) based on several proposals for multimodal systems in different application domains, Table 2 provides a classification of services by input mode, domain of application,

cooperation between modalities, type of multimodal fusion, input synchronization, and relation among modal components. It considers the following input modalities (Benoit et al., 2000): automatic speech recognition (ASR), gesture recognition (GR), hand-writing recognition (HR), pointing (P), eye tracker (ET), gaze tracking (GT), keyboard (K), 2D or 3D controller device (2D and 3D), object recognition (OR), speaker verification (SV), and face recognition (FR).

The application domains more frequently involved in the information services include road maps, geographical maps, tourist information, and so on. These often involve the integration of automatic speech recognition and gesture recognition—that is, these two modalities can be fused at a semantic level.

Transactional services often involve speech, gesture, and handwriting recognition; cooperation between these modalities is complementary and equivalent. Multimodality provides end users with the option to move among different modalities. They might send a message by voice or text, using a mobile phone or personal digital assistant (PDA). Users can dynamically select the most appropriate interaction mode for their needs by multimodal services, improving service accessibility and usability, especially for people with disabilities.

Table 2 highlights the fact that mode fusion can take place at the semantic level, intermediate level, or signal.

The synchronization level depends on the temporal granularity of the multimodal interaction. Diverse modalities can be combined, using several levels of synchronization according to the expected temporal granularity. Table 2 therefore does not include the level of granularity synchronization.

In literature there are several approaches to represent the events of multimodal inputs:

- **Typed Feature Structures** (Cohen et al., 1997; Johnston et al., 1997): In this approach, multimodal inputs can be transformed into typed feature structures that represent the semantics attributed to the various modalities. These feature structures are combined by unification (QuickSet).
- **Syntactic Representation** (Faure & Julia, 1993): The input multimodal events are represented as a triplet {verb, object, location}. This representation is sufficient for input in the form of speech with deictic references, but it is not clear how this approach can be extended to deal with several modal events.
- **Melting Pots** (Nigay & Coutaz, 1995): A melting pot encapsulates types of structural parts of a multimodal event. The content of a structural part is a time-stamped piece of information. The melting-pots are constructed by events in elementary inputs with different mechanisms of fusion: micro-temporal, macro-temporal, and contextual fusion.

Table 2. Classification of services by domain of application, input modalities, cooperation between modalities, type of multimodal fusion, relation among modal components, and input synchronization

| | Application/Domain | Input | Cooperation | Fusion | Relation among Modal Components | Input Synchronization |
|------------------------|----------------------------------|-----------------------|-------------|------------------------------------|---------------------------------|-----------------------|
| Information Services | Air Travel Info | ASR, P, K | C, E | semantic | Act, Pas | Seq, TDS, TIS |
| | Web Navigation | ASR, P, K | E | n/a | | Seq |
| | Geographic Maps and Blocks World | ASR, 2D-GR, 3D-GR, GT | C, E | semantic | Act, Pas | Seq, TDS, TIS |
| | Tourist Information | ASR, 2D-GR and P, HR | C, E | semantic | Act, Pas | Seq, TDS, TIS |
| | Office Assistance | ASR, 2D-GR and P, HR | C, E | semantic | Act, Pas | Seq, TDS, TIS |
| | Tourist Map | ASR, P, K | all forms | semantic | Act, Pas | Seq, TDS, TIS |
| | Consumer Information | ASR, K | n/a | n/a | | |
| | Product Information | ASR, K, GR | E, R, C, S | semantic | Act, Pas | TDS, TIS |
| | Information Retrieval | ASR, 2D-GR, K | C | semantic | Act, Pas | TDS, TIS |
| | Campus Information | ASR, GR | E, C, S | semantic | Act, Pas | Seq, TDS, TIS |
| | Notebook | ASR, P, K | C, E | semantic | Act, Pas | Seq, TDS, TIS |
| | Talking Agent | ASR, GR | n/a | signal intermediate semantic | | |
| | Train Scheduling | ASR, GT | R | intermediate | Act, Pas | TDS, TIS |
| | Road Maps | ASR, P | E, S | semantic | | Seq |
| Transactional Services | Notebook | ASR, P, K | C, E | semantic | Act, Pas | Seq, TDS, TIS |
| | Videoconferences | ASR, FR | E, R, C, S | semantic | Act, Pas | Seq, TDS, TIS |
| | Train Scheduling | ASR, GT | R | intermediate | Act | TDS, TIS |
| Composed Services | Interactive TV | ASR, 3D-GR | S | n/a | | |
| | Robot Control | ASR, 2D-GR and P, HR | C, E | semantic | Act, Pas | Seq, TDS, TIS |
| | Image Analysis | ASR, 2D GR and P, HR | C, E | semantic | Act, Pas | Seq, TDS, TIS |
| | Emergency Dispatch | ASR, 2D GR and P, HR | C, E | semantic | Act, Pas | Seq, TDS, TIS |

- **Micro-Temporal Fusion:** Combines two information units produced concurrently or very close to one another. *Macro-Temporal Fusion* combines sequential or temporally close information units, when these units are complementary. *Contextual Fusion* combines information units according to semantic constraints.
- **Partial Action Frame** (Vo & Wood, 1996; Vo & Waibel, 1997; Vo, 1998): The input of each mode is separately interpreted and then analyzed and transformed into a semantic frame containing slots that specify the control parameters. Information in the partial action frames can be incomplete or ambiguous. Each sequence of grouped input events has a score based on their mutual information.

Semantic fusion is not further defined by the characteristics of the events because the above approaches can be used indifferently. For example, speech and pen fusion can be achieved by both Typed Feature Structures and Partial Action Frame. In literature, events for fusing gesture and speech have been represented by Typed Feature Structures or Syntactic Representation. The Melting Pots approach can be used to fuse speech, keyboard, and mouse.

The diffusion and implementation of multimodal services is supported by the activities of the World Wide Web Consortium (W3C), aimed at extending the modalities of interaction for mobile devices and particularly devoted to solving various mobile Web problems:

- minimization of costs for mobile devices,
- practice Web navigation from mobile devices,
- multimodal interaction for the mobile Web, and
- multimedia and graphics for multimedia messaging.

Some W3C working groups focus their activities on issues such as independence from devices, multimodal Web access, and types of content for multimodal messaging. These specifications allow rich multimodal contents to be transmitted and are based on the power and extensibility of XML (eXtensible Markup Language).

W3C has defined specific modal languages for developing Web-based applications. The W3C groups voice browser and multimodal interaction are working to standardize these languages. VoiceXML and speech application language tags (SALT) are valid instruments to support the implementation of visual-representation-enriched systems and visual browsers, with instruments such as eXtensible Hypertext Markup Language (XHTML), Cascading Style Sheet (CSS), Synchronized Multimedia Integration Language (SMIL), and scalable vector graphics (SVG). In addition, new trends are outlined to allow intermodal interaction by instruments as Ink

Markup Language (InkML), which captures pen movements and enables data exchange by “digital ink.” Another interesting language is extensible multimodal markup annotations (EMMA), used to implement semantic interpretations of a great variety of inputs, such as voice, text languages, and digital ink. The Speech Services Control (SpeechSC) working group of the Internet Engineering Task Force (IETF) develops protocols to support distributed speech recognition, speech synthesis, and speaker verification services, and expects to take advantage of W3C’s work on speech recognition grammar specification (SRGS), Speech Synthesis Markup Language (SSML), and semantic interpretation (SI).

FUTURE TRENDS

The trend toward converging various methodologies and technologies has created new mobile devices, which make available complex services and contribute to the sharing of experiences and the inclusion of people as members of the community. The usability, accessibility, portability, wearability, and power of future mobile devices thus give rise to important perspectives for the evolution of services in different application domains.

When considering future trends, it is important to consider the developments offered by methodologies and technologies on the semantic fusion of modal inputs. There are several approaches for representing events of modal inputs: melting pots, partial action frame, syntactic representation, and typed feature structures. Other approaches may be defined for future multimodal systems adapted to the next generation of mobile devices. Research into the integration of different interaction modalities is of great interest for the diffusion and connectivity of mobile devices.

CONCLUSION

The development of multimodal tools is producing notable interest in mobile devices, especially for accessing information and performing transactions. This article discussed the methods and future prospects of mobile multimodal applications and services. These are divided into three groups: information services, transaction services, and composed services, which are then further classified into some important characteristics, such as application domain, input and output modalities, type of cooperation between modalities, and type of multimodal fusion.

Finally, special attention is dedicated to the activities of the World Wide Web Consortium (W3C) devoted to extending multimodal services on the Web and on mobile devices.

KEY TERMS

Extensible Multimodal Annotation (EMMA): This markup language is a W3C recommendation based on XML used for information automatically extracted from the user input. This language is focused on annotating interpretation of information in input.

InkHTML: A markup language devoted to describing ink data acquired with an electronic pen.

Internet Engineering Task Force (IETF): Activity devoted to promote and develop Internet standards.

Mobile Device: A pocket-sized computer device used for managing and accessing information and communicating in the different context of life.

Personal Digital Assistant (PDA): A mobile device used as a personal organizer, a data book, a task list, a clock, and a calculator.

Scalable Vector Graphics (SVG): A W3C Markup Language describing a two-dimensional vector graphic. It allows shapes, raster graphics images/digital images, and text.

Speech Application Language Tag (SALT): A markup language used for adding voice recognition to HTML and XHTML files.

Speech Synthesis Markup Language (SSML): A W3C recommendation based on XML used for speech synthesis.

Synchronized Multimedia Integration Language (SMIL): A W3C recommendation based on XML used for multimedia presentation.

VoiceXML: The W3C standard XML format used for specifying voice dialogues between a human and a computer.

Multi-User OFDM in Mobile Multimedia Network

Ibrahim Al Kattan

American University of Sharjah, UAE

Habeebur Rahman Maricar

American University of Sharjah, UAE

INTRODUCTION

The optimization of resource allocation in multi-user orthogonal frequency division multiplexing (OFDM) has been of great concern to the mobile commerce. The major concern is the allocation of subcarrier and power to different users in order to minimize the total transmitted power, consequently increasing the total data rate and improving the performance of the wireless communication system. Multi-user OFDM systems have been in use recently and seem promising for future mobile network applications. This research would mainly focus on modeling and improving the wireless communication system with multi-user OFDM. The proposed optimization techniques for OFDM wireless communication will be conducted in two phases. Phase one is to optimize the subcarrier allocation to mobile hosts, and the second phase is to optimize the power allocation (depends on the number of transmitted bits) in a multi-user OFDM system.

A wireless and mobile multimedia network has become challenging in the cutting-edge technology of today's global market economy. Some current applications include mobile computing, mobile phones, satellite communications, radio stations, and so forth. An efficient communication plays a very important role in any wireless and mobile network. Global system for mobile communications (GSM) and code-

division multiple access (CDMA), commonly known as the second-generation (2G) mobile systems, are being widely used all over the world and have been constantly developing over the last decade (Zheng, Huang, & Wang, 2005). These developments have led to the growth of third-generation (3G) and fourth-generation (4G) mobile systems. Among the many technologies proposed for 4G systems, orthogonal frequency-division multiplexing (OFDM) has been of great interest over the past decade (Gross, Geerdes, Karl, & Wolisz, 2005). The major reason is that it can provide high data rates over a wireless channel and it divides the bandwidth into subcarriers (Gross et al., 2004).

OFDM is defined as a multi-carrier transmission technique that has been recognized as an excellent method for high-speed bi-directional wireless data communication. OFDM effectively squeezes multiple modulated carriers tightly together, thus reducing the required bandwidth. The modulated signals overlap with each other, but they do not interfere with each other since they are kept orthogonal (Intel in Communications, n.d.). Figure 1 shows a conventional frequency division multiplexing (FDM) with nine subcarriers using filters, while Figure 2 shows an OFDM with nine subcarriers. The quality remains the same, but the bandwidth required and consequently the cost has been reduced tremendously. Resource allocation problems are of

Figure 1. FDM with 9 subcarriers using filters (Intel in Communications, n.d.)

Figure 2. OFDM with 9 subcarriers (Intel in Communications, n.d.)

great concern to wireless communication networks dealing with a multiple-user OFDM system (Shen, Andrews, & Evans, 2003).

The major concern is the allocation of subcarriers and power to different users in order to minimize the total transmitted power, increase the total data rate, and maintain an acceptable quality.

BACKGROUND

Mobile and wireless communication networks are growing both in size and complexity and hence the use of OFDM has increased over the past few years. With this tremendous growth, engineers are facing challenges in deciding the allocation of subcarrier, bit, and power to multiple users in an OFDM system. While OFDM-based multi-user systems have been proposed, subcarrier and power allocation for these systems is still under investigation (Kivanc & Liu, 2000). The wireless communication network using OFDM is described as follows (Shen et al, 2003):

- OFDM divides the entire transmission bandwidth into a number of orthogonal subcarriers.
- The set of subcarriers is adaptively assigned to different users. Some subcarriers are inadequate for some users but good for others. Hence by adaptive assignment, we can ensure that all the subcarriers will be used effectively.
- The second issue would be to determine the power level transmitted on each subcarrier in order to minimize the total power transmitted (to reduce cost of transmission) and attain acceptable quality.

Since both the issues are correlated, they must be solved together using a single model (Gross & Karl, 2004).

The problem of optimizing subcarrier and power allocation in a multi-user OFDM system is studied by Kivanc and Liu (2000). Their work explains the importance of the problem and gives a detailed model for the problem. They define two greedy algorithms and claim that they give optimum solutions. The approach is appropriate, but a method such as a greedy algorithm does not guarantee an optimum solution, though the method has less computations and the solution is reached quite fast. The study also includes an application for a small-scale problem using Excel. Using integer programming would yield optimum results as compared to greedy algorithms. A similar approach has been conducted by Wong, Cheng, Letaief, and Murch (1999) and Kivanc and Liu (2000). However, Wong et al. (1999) developed an algorithm for a single-user system, and then they extended the algorithm for a multi-user system. The results are compared to other static allocation schemes and have proved the algorithm to be better than static allocation schemes. Another

approach developed by Shen et al. (2003) employs methods like Newton-Raphson and Quasi-Newton. The drawback of the method is the high complexity involved in the computations. Their primary focus is on proving a multi-user OFDM system to be better than the other conventional methods. Their secondary focus is on the optimization technique. Mohanram and Bhashyam (2005) have explored this area and have used suboptimal techniques to solve the problem.

Furthermore, integer programming could be used to solve the problem. In this proposal, the steps required in achieving the optimum solution using integer programming are analyzed. Integer programming gives us the optimal solution, unlike greedy algorithms. However, when the number of design variables increase (a large-scale system model), the time to solve the problem using integer programming is high, and at some point it becomes impossible to solve using integer programming. Thus, an alternate algorithm would be developed for the system, and this algorithm would be tuned to get the same solution as obtained with integer programming. This tuned algorithm can be used for larger models where integer programming could not work. A comparison would be done between the developed algorithm to the existing greedy algorithm in terms of optimality and number of iterations.

When an optimization problem has some variables that can be only integer, then integer programming can be used to achieve the optimum solution (Wolsey, 1998). Evidently, integer programming becomes complex when the number of design variables increase. However, the advantage as compared to heuristic algorithms is that integer programming results in optimum solution. Optimization deals with problems of minimizing or maximizing one or more functions subject to equality or inequality constraints. The major fields of optimization are global, constrained, combinatorial, and multi-objective optimizations (Gen & Cheng, 2000).

- *Global optimization* is maximizing or minimizing a function in the absence of constraints.
- *Constrained optimization* deals with optimizing an objective function subject to equality or inequality constraints.
- *Combinatorial optimization* is used to determine either a permutation or a combination of some items associated with a problem or both. It could also be used to determine the above subject to some constraints.
- *Multi-objective optimization*, as the name suggests, deals with optimizing multiple objective functions simultaneously.

PROPOSED OPTIMIZATION MODEL

A subcarrier and power allocation problem could be classified as a combinatorial optimization problem. The objective

of this model is to minimize the total power transmitted and the cost of transmission while maintaining acceptable quality. However, when using integer programming, one of the objectives is made to be a constraint, and hence the problem becomes a constrained optimization problem. In order to develop the algorithm, we must have a complete model for the multi-user OFDM system. The system under consideration is a multi-user OFDM system. Wong et al. (1999) and Kivanc and Liu (2000) have assumed a perfect channel state at both the receiver and the transmitter. The other assumption is that one subcarrier can only be used by one user.

Phase one of this research considers a system with K users and N subcarriers. R_k would be the data rate for the k th user, which means the user k would receive R_k bits. The number of bits of the k th user to the n th subcarrier can be represented by $b_{k,n}$ (Wong et al., 1999). Since our assumption is that one subcarrier can only be used by one user:

for all n , if $b_{k,n} \neq 0$, then $b_{k,n} = 0$ for all $k \neq k'$

$G_{k,n}$ is the magnitude of the channel gain of the n th subcarrier as seen by the k th user. $P_{k,n}$ is defined as the power spent by the transmitter to transmit to the k th user in the n th subcarrier, whereas $p(b_{k,n})$ is the signal power required at the receiver side for reliable recovery of $b_{k,n}$ bits (Wong et al., 1999). Therefore:

$$p(b_{k,n}) = G_{k,n} \cdot P_{k,n} \quad \text{for all } k, n$$

Phase two is to minimize the overall power transmitted. The objective function would be to minimize the overall power transmitted in order to minimize cost of transmission. This could be achieved by minimizing the summation of $P_{k,n}$ for all k, n . The constraints would be that only one user can use one subcarrier, and the total number of bits transmitted to the k th user through all subcarriers must equal the data rate. Accordingly, the number of bits for each subcarrier must be assigned. The problem can be seen as an assignment problem where we have to assign the number of bits for each user for each subcarrier minimizing the objective functions. If a particular user is not using a subcarrier, then the number of bits assigned is zero. To summarize the model, we have K users and N subcarriers. The notations used are:

- R_k : Data rate for the k th user, which means the user k would receive R_k bits.
- $b_{k,n}$: The number of bits of the k th user assigned to the n th subcarrier.
- $U(b_{k,n})$: Indicates whether or not subcarrier n is used by user k .
- $U(b_{k,n}) = 0$ only if $b_{k,n} = 0$.
- $G_{k,n}$: The magnitude of the channel gain of the n th subcarrier as seen by the k th user.

- $P_{k,n}$: The power spent by the transmitter to transmit to the k th user in n th subcarrier.
- $p(b_{k,n})$: The signal power required at the receiver side for reliable recovery of $b_{k,n}$ bits.

Hence, the objective function is:

$$\min \sum_{k=1}^K \sum_{n=1}^N \frac{p(b_{k,n})}{G_{k,n}}$$

Subject to:

$$\sum_{n=1}^N b_{k,n} = R_k \quad k=1 \text{ to } K$$

$$\sum_{k=1}^K U(b_{k,n}) = 1 \quad n=1 \text{ to } N$$

$$b_{k,n} = 0 \text{ to } M \text{ for all } k, n$$

APPLICATION USING SOLVER

The proposed model is tested using Excel Solver for a different combination of number of users and subcarriers. The number of bits of the k th user assigned to the n th subcarrier ($b_{k,n}$) is marked as the changing variables. Usually it takes a value from zero to the maximum capacity of the channel. Using Solver, it is changed from zero to one and then multiplied by the maximum channel capacity in order to simplify the run. The sum of the number of bits ($b_{k,n}$) for each user is added and verified that the sum equals the data rate for the k th user (R_k).

$U(b_{k,n})$ indicates whether subcarrier n is used by user k or not. It is marked as changing variables and is restricted to be binary. The assumption that one subcarrier can be used by only one user is satisfied by adding $U(b_{k,n})$ for each subcarrier under the condition that the sum remains binary. Hence, as per the proposed model, all three constraints are satisfied. Now in order to achieve the objective function, the proposed method assigns random numbers (between zero and one) to the channel gain. In practice, modeling of the channel is a separate research area. Regardless of the model, the channel gain would always take a value between zero and one. The best channel would have a gain of one, which means that the power transmitted is received in full. On the other hand, the worst channel would have a gain of zero, which means that all the power transmitted is lost.

The signal power required at the receiver side for reliable recovery of $b_{k,n}$ bits ($p(b_{k,n})$) is modeled as square of the

number of bits transmitted. Since the relationship between the power and the bits is normally proportional to its square, the proposed method is reasonable. However, the power calculation could be different, but in testing the proposed model, it is irrelevant since the power would always be a real number.

$$p(b_{k,n}) = b_{k,n}^2$$

Now, the power transmitted can be calculated by dividing the power required at the receiver side by the channel gain, assuming that the channel gain ($G_{k,n}$) is non-zero. However, it could have a very low value resulting in a huge $P_{k,n}$. The objective function in solver would be to minimize the total power transmitted (sum of all $P_{k,n}$).

$$P_{k,n} = \frac{p(b_{k,n})}{G_{k,n}}$$

TESTING THE MODEL

A pilot scheme for the model is tested on a small scale using Solver for three users and three subcarriers, and the optimum

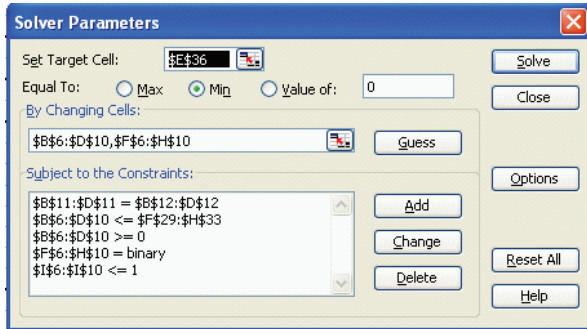

results were achieved. The three-user model was then run for four and five subcarriers, and optimum results were obtained. When the model was run for four users and four subcarriers, Solver could not find a feasible solution. Since the model returned results for the smaller system, we can conclude that bigger models cannot be tested using Solver because of the restriction of the number of constraints in Solver. Figures 3 and 4 shows the Excel and the Solver screenshot for the 3×5 model respectively.

FUTURE TRENDS

The result obtained using Solver is optimum. However, we cannot use Solver for larger scale models. Hence, an algorithm representing the proposed model using integer programming could be formulated which could be run using programming languages C and MatLab. An alternate approach is that the algorithm could be heuristic. The idea of heuristic algorithms is to “find a good feasible solution quickly” (Wolsey, 1998). Greedy algorithms, genetic algorithms, taboo search, and so forth are some examples of heuristic algorithms. In solving the allocation problem in a multi-user OFDM system, two features could force the use of a heuristic algorithm (Wolsey, 1998):

Figure 3. Excel screenshot for the 3×5 model

Figure 4. Solver screenshot for the 3×5 model

1. The solution is required quick since the subcarrier and power allocation is done for a dynamic system.
2. The system could become large and complicated where the use of conventional optimization technique is not possible.

Using integer programming to adjust the heuristic method would ensure that the solution is closer to optimal. Genetic algorithm would be a good approach since it has proved to yield faster results than greedy algorithms in some areas. In the proposed optimization problem, the design variable is $b_{k,n}$, whereas we have $p(b_{k,n})$ in the objective function which makes the model nonlinear. However, the signal power required at the receiver side for reliable recovery depends only on the number of bits. For example, to receive one bit, the signal power required at the receiver is the same irrespective of the subcarrier and the user of the incoming signal. Thus, it is possible to remodel the problem, making it linear, and then we can apply linear programming to solve the problem to obtain an optimum solution. The drawback of the linear model is that the system would become more complex. The power required for reliable recovery of bits and the channel gain are not modeled perfectly. Hence, further study in this area would reinforce the proposed model.

CONCLUSION

In this research, a multi-user OFDM system with the challenge of assigning bits and subcarriers to the users while minimizing the overall transmit power is considered. The main purpose is to illustrate the use of integer programming that would simplify the problem in attaining the optimum allocation. Integer programming is used in Solver to achieve optimum solution. However, the limitation of solver is that larger models cannot be tested due to computational restriction in the number of constraints. Other software like C and MatLab could be used to program the model using integer programming. As an alternate solution, the use of genetic algorithms could be considered.

Mutual Biometric Authentication

Mostafa El-Said

Grand Valley State University, USA

INTRODUCTION

Cell phone fraud accounts for more than a billion dollars in lost revenue in North America (Rose, 1999; Wingert & Naidu, 2002). Therefore, one of the largest problems in cellular communication systems is the security of cellular phones and the authenticity of cell phone base stations. Caller authentication and voice encryption (CAVE) is the currently used algorithm in cellular systems for authentication and data integrity (Cryptome, 1997; Korzeniowski, 2005; Cellular Technologies, 2006). It was developed by Committee TR45.3 of TIA/EIA under the auspices of the NSA. Gauravaram and Millan (2004) presented two crypto methods to exploit the security vulnerabilities in the CAVE algorithm, and proposed two attack methods that demonstrated that the CAVE is insecure. Another attempt to crack the CAVE is conducted by a research team at the University of California at Berkeley. David Wagner, a member of this research team, announced the CAVE algorithm can be cracked in a matter of minutes or at most hours (Monitoring Times, 1997).

Other attacks on the cellular systems can take place through the RF interface or through the interconnecting wireline networks, including the radio network controller switch and the PSTN network. The RF interface attack is the most severe attack on the cellular systems. Several well-known RF attacks are recognized by the cell phone industry including:

- **Cell Phone Cloning:** The cell phone cloning problem is created because illegal users can capture a cell phone's pair of uniquely assigned numbers—ESN (Electronic Serial Number) and MIN (Mobile Identification Number)—when sending the information to the tower. Then, those illegal users can bill time to a user's account. The cell phone industry solved this problem by encrypting the cell phone number and the pair of ESN and MIN when sending the information to the tower (Hai-Ping Ko, 1996; Landmark Communications, 1996).
- **SMS Messages Flood Attack:** The SMS messages flood attack was a direct result of the shortcoming of 3G cell phone design where the same control channel is used for both call setup and sending SMS messages. An attacker can exploit this vulnerability and use free SMS Web sites to send a large number of anonymous text messages to a cellular phone tower. This could eventually jam up the cellular tower, block any new

telephone calls from going through, and result in a denial of service (DoS) attack on the cellular system. The SMS message attack problem was discovered by accident, and some of the European networks have already been jammed when the volume of SMS messaging reached an unexpectedly high level. This problem is still under research (McMillan, 2005).

- **Hash Function Attack:** Gauravaram, McCullagh, and Dawson (2006) investigated several legal and practical implications of attacks against various 128-bit hash functions, and in particular MD5 due to its wide usage. They claim that MD5 can be a single point of failure in various applications. Also, they suggested that new hashing algorithms should be developed in order to avoid new attacks in the future (Gauravaram, Millan, & May, 2004).

This article addresses another severe threat affecting the security of cellular systems, called *pilot aliasing attack*. This problem occurred due to pilot code reuse among different cellular carriers.

In the forward link direction, the base station transmits a dense pack of codes which assists the mobile terminal in performing vital operations such as system synchronization, system acquisition, cell search, and monitoring strong pilots in its serving zone. In general, the CDMA cellular systems have a total of $(2^{18} - 1)$ scrambling codes available in the downlink path. These codes are arranged into blocks of 512 coding sets, which are sufficient for a cellular carrier to start deploying a new service. Each cellular tower is allocated one and only one scrambling code, which serves as a unique identifier for the tower and used for cell separation.

These code sets can be reused over and over again within the same carrier's network, and in different carrier networks provided that they will interfere with each other as little as possible (Calhoun, 2003). All 512 cells have the same pilot waveform (same code). They can be differentiated from one another by their pilot signal phase offset. The pilot phase offset is always assigned to the base stations in a multiple of $(2^6 = 64)$ chips, such as that shown in Figure 1.

Due to the carriers' interoperability nature of the cellular networks, the cell phone may receive two identical pilot signal phase offsets (PN offsets) from two distinct carrier networks at any moment in time. This phenomenon is even worse in the presence of non-homogeneous geography and high-dynamic RF multi-path environments. The mobile

Mutual Biometric Authentication

Figure 1. Base stations pilot code phase offset

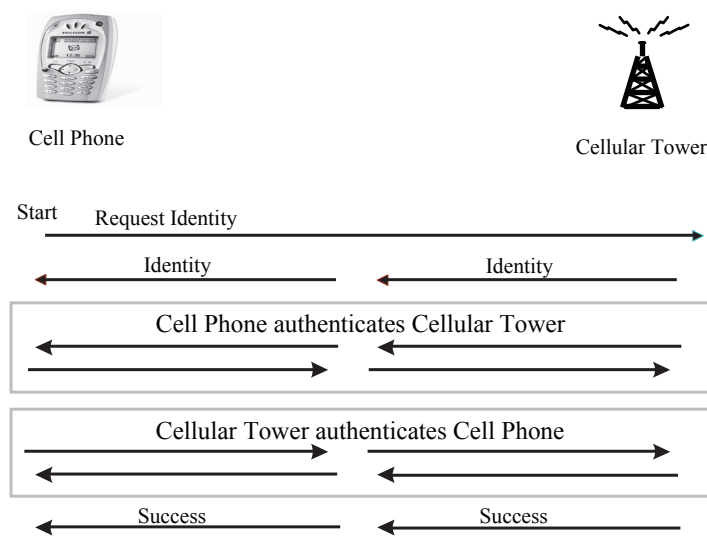

Figure 2. MBA interaction algorithm

receiver became confused and cannot distinguish between the two pilots. One of the pilot signals may be sent from a fake malicious tower that hunts for cell users, which results in *pilot aliasing attack*.

In this article, I use a mutual biometric authentication (MBA-) based solution to allow the cell phone device to authenticate the cellular phone tower before using it as a serving base station. This solution allows the cell phone to detect the existence of pilot aliasing attack. The proposed solution stems from authenticating the cellular tower based on a combined key that consists of the TowerID and the CarrierID's fingerprint. This is a significant step towards creating a robust mutual biometric authentication technique in the cellular system.

PROPOSED SOLUTION

The proposed MBA solution relies on having the tower and the cell phone devices passing each one's credentials before engaging in a communication scenario, such as that described in Figure 2.

The following section describes the proposed MBA interaction algorithm.

MBA Algorithm Assumptions

- The cell phone's Electronic Serial Number: ESN
- The cell phone's Mobile Identification Number: MIN
- The cell phone's public Number: PPN
- The cellular tower has an ID: TowerID
- The cellular tower Broadcast its PilotID: PilotID
- The CarrierID is kept at the tower and at the cell phone station and acts as a shared secret key between the cell phone and the carrier tower. (See Diagram 1.)

PERFORMANCE MEASUREMENTS AND KEY FINDINGS

To test the applicability of the proposed MBA solution, I use and compare the two hashing algorithms, called MDS and SHA1. To do that, the simulation experiments are carried out 10,000 times. I computed the time that the cell phone

Diagram 1.

| Phase I. One-Way Authentication (cellular tower to cell phone station) | |
|--|---|
| Steps | Events |
| Step 1: At the carrier's tower | The tower hashes its (TowerID+CarrierID+ PilotID) and sends the hash value (Hash1) along with the PilotID and the TowerID in clearText periodically. |
| Step 2: At the cell phone station | When the cell phone station receives the Hash 1 value, TowerID, and the PilotID, it extracts the TowerID and the PilotID. Then it performs a hash on the (received TowerID + received PilotID + stored CarrierID), called Hash 2. The cell phone station compares the two hashes (Hash 1 and Hash 2). if (Hash 1 == Hash 2) { The tower is legitimate. } else { The tower is a malicious tower and should be avoided } |
| Phase II. Second-Way Authentication (cell phone station to cellular tower) | |
| Steps | Events |
| Step 3: At the cell phone station | The cell phone hashes its (ESN+ MIN+ PPN+ CarrierID) and sends the hash value (Hash3) along with the (ESN+ MIN) in clearText to the tower. When the tower receives the Hash 3 value and the (ESN+ MIN), it extracts the (ESN+ MIN) and looks up the PIN value associated with the received (ESN+ MIN). Then it performs a hash on the (received (ESN+ MIN) + retrieved PIN+ CarrierID), called Hash 4. |
| Step 4: At the carrier's tower | The tower compares the two hashes (Hash 3 and Hash 4). if (Hash 3 == Hash 4) { The cell phone is legitimate. } else { The cell phone station is bad and should be denied access. } |

Table 1. Summary of the system performance analysis

| | Hash time using (MD-5) in milliseconds | Hash time using (SHA-1) in milliseconds |
|---------------------------|---|--|
| At the Cellular Tower | 0.031090 | 0.035366 |
| At the Cell Phone Station | 0.032482 | 0.036561 |
| Session Hash Time | 0.063573 | 0.071927 |

station took to hash the incoming message from the tower using MD-5 and SHA-1. The process is repeated at the cellular tower to compute the time that the cellular tower took to lookup the PIN value and hash the incoming message from the cell phone using MD-5 and SHA-1. Table 1 summarizes the simulation results for MD5 and SHA-1.

The results shown in Table 1 comply with the theoretical foundation of the cryptology science, where MD-5 generates a hash value of 128 bits length and the SHA-1 5 generates a hash value of 160 bits length. Therefore, MD-5 should take a shorter amount of time to hash the message compared to SHA-1. The session hash time is very short, especially if

Mutual Biometric Authentication

we use MD-5 (0.08 ms), and can be reduced if we use high-speed cellular tower stations. The session hash time can be further reduced if we use one-way authentication (cellular tower to cell phone), which guarantees avoidance of the pilot aliasing attack.

FUTURE TRENDS

An effective solution for cell phone security in 3G and 4G wireless systems should investigate the utilization of the asymmetric RSA encryption algorithm as well as the symmetric encryption algorithm. Therefore, the approach proposed in this article can be applied easily to the existing cellular infrastructure.

CONCLUSION

In this article, a mutual biometric authentication has been developed to solve the pilot aliasing attack problem in cellular systems. The proposed solution relies on hashing credentials using MD-5 or SHA-1. The proposed solution is very efficient, especially if we use MD-5, which provides shorter session hash time (0.08 ms) compared to SHA-1 (0.11).

KEY TERMS

Caller/Cellular Authentication and Voice Encryption (CAVE): The name of an encryption algorithm used by global cellular phone manufacturers.

Cell Phone Cloning: A mobile phone can be programmed with a stolen or duplicate electronic serial number (ESN) and mobile identification number (MIN). After cloning, both cellular telephones have the same ESN/MIN combination; the cellular systems cannot distinguish between the cloned cellular telephone and the legitimate one.

Cellular Tower's Biometric Authentication: The verification of a tower's identity by means of a physical trait or behavioral characteristic that cannot easily be changed, such as a tower's fingerprint.

Electronic Serial Number (ESN): A unique identification number embedded in a cellular phone by the manufacturer. Whenever a user places a phone call, the ESN is sent to the cellular tower so the wireless carrier's mobile switching office can check the call's validity.

International Mobile Equipment Identifier (IMEI):

A unique 15-digit number that acts as a serial number for the mobile handset unit. The IMEI is automatically transmitted by the phone to the network. The cellular carrier can use the IMEI to determine if a mobile unit is stolen or if it is in fault.

Mobile Identification Number (MIN): Uniquely identifies a cellular phone unit within a wireless carrier's network infrastructure. The MIN is assigned by the cel-

lular carrier and often can be dialed from other wireless or wireline networks.

Pilot Aliasing: Term referring to the reception of two identical PN offsets from two distinct CDMA networks, provided that the difference between the pilots' propagation times is less than half of the mobile search window. The mobile receiver becomes confused and cannot distinguish between the two pilots.

INTRODUCTION

As the mobile database permeates into today's computing and communication area, we envision application infrastructures that will increasingly rely on mobile technology. Current mobility applications tend to have a large central server and use mobile platforms only as caching devices. We want to elevate the role of mobile computers to first-class entities in the sense that they allow the mobile user work/update capabilities independent of a central server. In such an environment, several mobile computers may collectively form the entire distributed system of interest. These mobile computers may communicate together in an ad hoc manner by communicating through networks that are formed on demand. Such communication may occur through wired (fixed) or wireless (ad hoc) networks. At any given time, a subset of the computer collection may connect and would require reliable and dependable access to relevant data of interest.

Peer-to-peer (P2P) computing is basically an ad hoc network, and it can be built on the fixed or wireless network. With P2P, computers can communicate directly and share both data and resources. So far, many applications such as ICQ, which allows users to exchange personal messages, and Napster and Freenet, which allow exchange of music files, have taken advantage of P2P technology. However, data management is an outstanding issue and leads directly to the problem of low data availability. Thus, data availability is the central issue in P2P data management. The most important characteristic that affects data availability in the P2P environment is the nature of the network. For the case of the ad hoc network, hosts are connected to the network temporarily. Furthermore, hosts also play the role of router, and they communicate with each other directly without any dedicated hosts. Since there are no dedicated hosts that act as a router, obviously the network connections are prone to get disconnected. Thus, it is difficult to guarantee one-copy

serializability since we rely on the mobile hosts, not the fixed hosts, in order to communicate with other hosts not reachable directly (Bhargava, 1999). When hosts are disconnected more often and the applications have high transaction rates, the deadlock and reconciliation rate will experience a cubic growth (Bhargava, 1999), the database is in an inconsistent state, and there is no obvious way to repair eventually. For the case of the fixed network, the network connection is relatively stable, but the availability of sufficient computing resource depends on the strategies of replication.

Walborn and Chrysanthis (1996) describe the use of mobile computers in the trucking industry. Each truck has a computer with a satellite or radio link and interacts with the corporate database. Other applications involving remote or disaster areas and military applications have mobile computers forming ad hoc networks without communications with stationary computers. Faiz and Zaslavsky (n.d.) discuss the impact of wireless technologies and mobile hosts on a variety of replication strategies. Distributed replicated file systems such as Ficus and Coda (Agrawal & El Abbadi, 1996) have extensive experience with disconnected operations.

In this article, we consider the distributed database that can make up mobile nodes and the peer-to-peer concept. These nodes are peers and may be replicated both for fault-tolerance, dependability, and to compensate for nodes that are currently disconnected. Thus we have a distributed replicated database where several sites must participate in the synchronization of transactions. The capabilities of the distributed replicated database are extended to allow mobile nodes to plan disconnection, with the capability of updating the database on behalf of the mobile node by using a fixed proxy server to make these updates during the mobile disconnection, once a mobile reconnects automatically, synchronously, and integrates into the database.

By using the notion of planned disconnection MTCO, we present a framework to allow the replicated data of mobile nodes available to access and update at low cost for reading and writing.

MODEL

A distributed database in a P2P environment consists of a set of data objects stored at different sites (fixed network) and nodes (mobile network) in a computer network. A site (node) may become inaccessible due to site (node) or partitioning failure. No assumptions are made regarding the speed or reliability of the network. Users who interact with the database by invoking transaction must appear atomic: a transaction either commits or aborts (Pitoura & Bhargava, 1995; Dunham and Helal, 1997).

In a replicated database, copies of a data object may be stored at several sites as nodes in the network. Multiple copies of a data object must appear as a single logical data object to the transactions. This is termed as one-copy equivalence and is enforced by the replica control technique. The correctness criteria for replicated database synchronously (fixed network) is one-copy serializability (Dunham & Helal, 1997), which ensures both one-copy serializability and one copy equivalence, while the correctness criteria for replicated database asynchronously (at mobile network) is a timestamp order, which ensures serializability into mobile transactions; a replicated data object may be read by reading a quorum of copies, and it may be written by writing a quorum of copies. The selection of a quorum is restricted by the quorum intersection property to ensure one-copy equivalence: For any two operations $o[x]$ and $o'[x]$ on a data object x , where at least one of them is a write, the quorum must have a non-empty intersection. The quorum for an operation is defined as a set of copies whose number is sufficient to execute that operation.

The environment has two types of networks—the fixed network and the mobile network. For the fixed network, all sites are logically organized in the form of two-dimensional grid structure. For example, if the network consists of 25 sites, it will be logically organized in the form of a 5x5 grid as shown in Figure 1. Each site has a master data file. In the remainder of this article, we assume that replica copies are data files. A site is either operational or failed, and the state (operational or failed) of each site is statistically independent of the others. When a site is operational, the copy at the site is available; otherwise it is unavailable.

The logical structure for fixed and mobile networks is as shown in Figure 1. The circles in the grid represent the sites under the fixed network environment, and a, b, \dots , and y represent the master data files located at site $s(1, 1)$, $s(1, 2)$, \dots , and $s(5, 5)$ respectively. The circles in the oblong shape are sites under the mobile network.

The Technique

In the fixed network, the data file will replicate to diagonal sites according to the DRG technique, discussed in Dircke and Gruenwald (2000), while in the mobile network, the

data file will replicate asynchronously at a number of mobile nodes based on the most frequently visited node, and these mobile nodes are not fixed.

For the fixed network, a site s initiates a DRG transaction to update its data object. For all accessible data objects, a DRG transaction attempts to access a DRG quorum. If a DRG transaction gets a DRG write quorum without non-empty intersection, it is accepted for execution and completion, otherwise it is rejected. We assume for the read quorum, if two transactions attempt to read a common data object, read operations do not change the values of the data object. Since read and write quorums must intersect and any two DRG quorums must also intersect, then all transaction executions are one-copy serializable.

For the mobile network, a node will replicate the data asynchronously analogous to the concepts of *checked-out*, proposed in Cetintemel and Kelender (2002). The ‘commonly visited node’ is defined as the most frequent node that requests the same data at the fixed proxy server (the commonly visited nodes can be given either by a user or selected automatically from a log file/database at each center). This node will replicate the data asynchronously, therefore it will not be considered for the read and write quorums.

Definition 1: Assume that the mobile environment consists of n mobile nodes. All nodes are labeled $N_1, N_2, \dots, N_n, 1 \leq i \leq n$.

Definition 2: Assume the mobile disconnection consists of a pre-committed transaction and request transaction for maintaining data replicate.

*Definition 3: Assume that the limitation amount of data object $X = \Delta$, where Δ calculates from $\Delta_x = f(x, N_x) = [((1/2) + (0.1*r)) x/N_x]$.*

In Definition 3:

- r = the number of reconnection of replicated data file, and also consider the time by changing the order of data amount: $N_x =$ number of replication and $N_x \leq x$,
- x = value amount of data object x and $x > 0$, we chose 0.5 to keep some x amount to request transaction,
- pre-committee = transaction process locally at mobile nodes during disconnection depended on the limitation amount of data object x ,
- request transaction = transaction process at fixed proxy server because the limit amount of data object x less than the request.

We are using r for considering the time by changing the order of data amount, so that in the first disconnection, r will start (0), then $(0.1*r)$; we chose the amount of $(1/2)$ in order to save half of the data object amount at fixed proxy server for new disconnection mobile node. After the first

Figure 1. Peer-to-peer environment

Figure 2. Replicate of data object amount at mobile nodes

disconnection, in any disconnection the fixed proxy server will save less than the half of data object amount depending on the number of ($r \cdot 0.1$), so that the amount of data object at mobile node will increase depending on the number of r , and also the fixed proxy server can allow for the multi-mobile node to disconnect at a different time.

As an example, assume a data object X representing the total number of movie tickets, and N_x is the number of replicas of X among mobile nodes. Initially $x = 180$ and $N_x = 3$. X is replicated at N_1, N_2, N_3 . The function that defined in Definition 3 is $\Delta_x = f(x, N_x) = [(0.5 + 0.1r)x/N_x]$; note to keep in first time half of X the amount at fixed proxy server for the request transaction; we are using r to consider the new mobile node wish to disconnect and also from r considering time by changing the orders amount as shown in Figure 2.

Consider the scenario that N_1 and N_2 wish to disconnect and check-out the data object x , so according to the function in Definition 3 $\Delta_x = 45$, that means mobile nodes N_1 and N_2 will take privilege to maintain locally update less than or equal to the limitation Δ_x and in this case, the mobile node

will make pre-commit and when reconnecting to the fixed proxy server will serialize with other transactions depending on timestamp ordering for each transaction and the fixed proxy server will commit as shown in Figure 3.

If the request transaction greater than limitation of Δ_x , in this case, mobile node cannot update data object x locally, when reconnecting it will send the request transaction to the fixed proxy server to process it and send the report to the mobile node, whether abort or commit, depending to the amount of data object X and the transaction arrival time to fixed proxy server.

Consider during mobile nodes N_1 and N_2 disconnect, mobile N_3 wish to disconnect and check-out the same data object X ; the fixed proxy allow mobile node N_3 to check-out the data object X according to Definition 3 and will consider the new mobile that wishes to disconnect after N_1 and N_2 as a reconnect mobile, so making $r = 1$, as shown in Figure 4.

Thus, N_3 will disconnect with privilege update to the data object X less than or equal to the new limitation $\Delta_x = 18$; otherwise, it will send request transaction.

Figure 3. Replication at two mobile nodes

For the multi check-out in the mobile network, if nodes N_1, N_2, N_3 want to disconnect and be able to update the same particular data object, it declares its intention to do so before disconnection and “check-out,” or “takes” the object for writing.

This can be accomplished by obtaining a lock on the item before disconnection. An object can be checked out to more than one node at a time. In order to maintain serializability in multi check-out mode, we will use timestamp ordering to serialize the mobile transaction at the fixed proxy server. The fixed proxy server will process two types of transactions—pre-committed transactions and request transactions are executed locally at a mobile node and serialized on the fixed proxy in the order of their timestamp order arrival. The request transaction is a mobile transaction that sends the transaction(s) to a fixed proxy server to update the amount of data because the amount of data at the mobile node is less than the request of transaction and the mobile node cannot update the amount of data locally. So, after the mobile node reconnects to the fixed proxy server, it will send the request transaction to the fixed proxy server asking for an update of the data amount if the amount at fixed proxy server is greater than the request transaction; in this case

the fixed proxy server will update the account, commit the transaction, and transfer the committed transaction to the mobile node or abort and send the abort transaction to the mobile node.

The pre-committed transaction is also a kind of mobile transaction, but this transaction can update the data amount at the mobile node; we call this case *pre-committed transaction*. When reconnected, the pre-committed transaction will be transferred to the fixed proxy server to update it, and it will send the committed transaction to the mobile node. But this kind of transaction is different from a request transaction because it can update the data locally.

By using timestamp order, the nodes that wish to disconnect, say N_1, N_2, N_3 , acquire a write lock on the same object at different times or the same time to update while disconnected. The disconnect procedure is as follows:

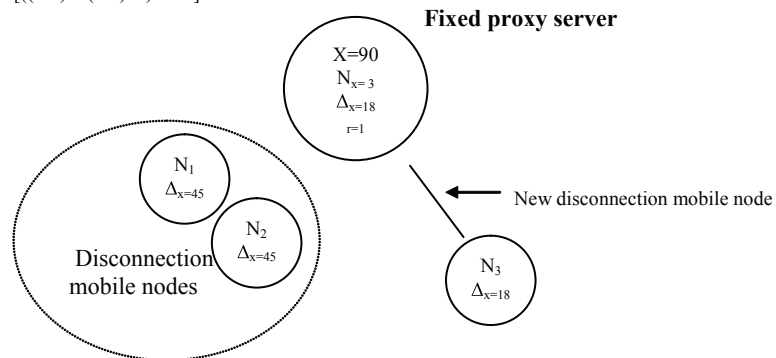

1. $N_1, N_2,$ and N_3 tell the nearest “fixed proxy server” from the fixed network to check-out the same data object at any point in time.
2. At the same time, $N_1, N_2,$ and N_3 initiate a transaction to obtain locks on the object depending on the limitation amount that gives equivalence to each mobile node participating.
3. If the transaction is successful, $N_1, N_2,$ and N_3 are disconnects with update privileges on the same object. Otherwise, $N_1, N_2,$ and N_3 try again.
4. $N_1, N_2,$ and N_3 can make local transaction and pre-commit during the limitation amount given to them; if the transaction is greater than limitation, the mobile node will send a request transaction to the fixed proxy server when connected.

The reconnect procedure is as follows:

1. When $N_1, N_2,$ and N_3 reconnect, it contacts the fixed proxy server from the fixed network.

Figure 4. New mobile node wishing to disconnect

$$\Delta_x = (90,3) = [((1/2) + (0.1)*1) 90/3] = 18$$

2. N_1 , N_2 , and N_3 will transfer the pre-commit transaction and request transaction to the fixed proxy server. The pre-committed transaction will transfer the transaction(s) that were updated during mobile node disconnection, while the request will transfer the transaction(s) that were not updated during mobile disconnection because the transaction request was greater than the data amount at the mobile node.
3. The fixed proxy server applies the DRG to replicate to diagonal sites at the fixed network only.
4. N_1 , N_2 , and N_3 release the corresponding lock.
5. The fixed proxy server sends the data with the latest updated version to N_1 , N_2 , and N_3 .

In order to preserve correctness, it must be possible to serialize all of the transactions executed by N_1 , N_2 , and N_3 during disconnection at the point in time of reconnection. This can be done if:

1. Objects not write locked by transaction at disconnect time are treated as read-only by N_1 , N_2 , and N_3 during disconnect.
2. The object process at the fixed proxy server depends on the transaction time arrived.
3. Timestamp ordering serializes all mobile transactions.

This will guarantee serializability because each transaction at a disconnected node respects the timestamp ordering.

Since the data file is replicated to only the diagonal sites at the fixed network, then it minimizes the number of database update operations, misrouted and dropped out calls. Also, sites are autonomous for processing different query or update operations, which consequently reduces the query response time. The data files are proved in Dircke and Gruenwald (2000).

PROOF OF CORRECTNESS AND PROPERTIES

In this section, we prove the correctness of our new technique for requested transactions; multi check-out timestamps order—that is, the MCTO technique—ensures serializability for request transaction. In the correctness proof, we prove that all committed schedules S produced by the requested transaction MCTO technique are serializable. In other words, the serialization graph $SG(S)$ does not contain any cycle (Forman & Zahorjan, 1994). The SG is a directed graph $G = (N, E)$ that consists of a set of nodes $N = \{T_1, T_2, \dots, T_n\}$ and a set of directed edges $E = \{e_1, e_2, \dots, e_n\}$. There is one node in the graph for each transaction T_i in the schedule. Each edge

e_i in the graph is of the form $(T_i \rightarrow T_j)$, $1 \leq i \leq n$, $1 \leq j \leq n$, where T_i is the initial node of e_i and T_j is the end node of e_i . Such an edge is created if one of the operations in T_i appears in the schedule before some conflicting operation in T_j .

Serializability is a widely used correctness criterion of database consistency (Unland & Schlageter, 1992). It is more difficult to maintain serializability of mobile transactions than that of traditional distributed database transactions.

Lemma 1

Let T_i and T_j be two committed transactions in a schedule S produced by the MCTO technique. If there is an edge $T_i \rightarrow T_j$ in $SG(S)$, then $TS(T_i) < TS(T_j)$.

Proof

If there is an edge $T_i \rightarrow T_j$ in $SG(S)$, there must exist one or more conflicting operations of one of the following types on data object x .

In the MCTO technique, the serialization order among transactions may not be the same as the chronological order of transaction commitment T_j may commit before T_i does. Therefore, two possible cases of commit order must be considered.

Case 1: $r_i[x] \rightarrow w_j[x]$

T_i commits (read) before T_j reaches fixed proxy server. When T_j reaches the fixed proxy server, for $w_j[x]$, the timestamp interval of T_j will be adjusted: $TI(T_j) = TI(T_j) \cap [RTS(x), \infty]$. It ensures that the final timestamp interval of T_j , $TS(T_j)$, which is obtained by adding a sufficiently small value to the lower bound of $TI(T_j)$, is greater than $RTS(x)$, which is equal to or greater than $TS(T_i)$ or T_i aborts if the interval shuts out. Therefore, if T_j can be committed, then $TS(T_i) \leq RTS(x) < TS(T_j)$, thus $TS(T_i) < TS(T_j)$.

Case 2: $w_i[x] \rightarrow r_j[x]$

T_i commits (write) before T_j reaches fixed proxy server. This case happens when T_i commits before T_j reads x . When T_j reads x , the timestamp interval of T_j will be adjusted: $TI(T_j) \cap [WTS(x), \infty]$ where $WTS(x)$ is equal to $TS(T_i)$. It ensures that $TS(T_j)$ is greater than $TS(T_i)$ or T_j aborts if the interval shuts out. Therefore, if T_j can be committed, then $TS(T_i) < TS(T_j)$.

Theorem 2

If S is a committed schedule produced by the MCTO technique, then S is serializable.

Proof

Consider there is an edge in SG (S), $T_i \rightarrow T_j$, then there must exist conflicting operations $p_i[x]$ and $q_j[x]$ in S, such that $p_i[x]$ precedes $q_j[x]$. Hence, by Lemma 1, $TS(T_i) < TS(T_j)$. If a cycle $T_1 \rightarrow T_2 \rightarrow \dots \rightarrow T_n \rightarrow T_1$ existed in SG (S), then by induction, $TS(T_1) < TS(T_1)$. This is a contradiction. Therefore, SG (S) is not cyclic and thus S is serializable.

Lemma 3

All transactions that are committed by the DRG technique are also committed by the MCTO technique.

Proof

Assume a transaction T_i is committed by the DRG technique but is aborted by the MCTO technique. Let $RC(T_i)$ be the set of recently committed transactions that are committed between the time when T_i starts its execution and the time at which it reaches the fixed proxy server phase. Since T_i is committed by the DRG technique, it must be true that $RS(T_i) \cap WS(T_{RC}) = \emptyset$ for each transaction $T_{RC} \equiv RC(T_i)$. If T_i is aborted by the MCTO technique, it implies that T_i shuts out and T_i must read some data objects written by at least some transaction $T_{RC} \equiv RC(T_i)$. Hence, $RS(T_i) \cap WS(T_{RC}) \neq \emptyset$, which is in contradiction to the assumption, $RS(T_i) \cap WS(T_{RC}) = \emptyset$, that T_i is committed by the DRG technique. Thus, Lemma 3 follows.

Lemma 4

All transactions that are aborted by the MCTO technique are also aborted by the DRG technique.

Proof

Assume a transaction, T_i is aborted by the MCTO technique but is committed by the DRG technique. Since T_i is aborted by the MCTO technique, it must be true that $TI(T_i)$ shuts out and T_i read some data objects written by at least some transactions $T_{RC} \equiv RC(T_i)$. That is, $RS(T_i) \cap WS(T_{RC}) \neq \emptyset$ where $T_{RC} \equiv RC(T_i)$. If T_i is committed by the DRG technique, it must be true that $RS(T_i) \cap WS(T_{RC}) = \emptyset$ for each transaction $T_{RC} \equiv RC(T_i)$, which is in contradiction to the assumption that T_i is aborted by the MCTO technique. Thus, Lemma 4 follows.

Theorem 5

The set of transactions committed by the DRG technique is the subset of transactions committed by the MCTO technique.

Proof

The theorem follows directly from Lemma 3, Lemma 4, and Example 1 in which T_2 is aborted by the DRG technique, but is committed by the MCTO technique.

CONCLUSION

Transaction management in mobile databases has the same behaviors as those in multi-database systems in many aspects. Many approaches in multi-database systems can be extended to a mobile multi-database environment. The differences in mobile databases are that transactions in mobile databases have mobility and long-lived nature. In this article we have developed a mobile transaction model that captures data and movement nature of mobile transactions. This model is based on multi check-out. The model describes a mobile transaction *Management by Timestamp Order*. Based on this mobile transaction model, we have presented a serializability theory of mobile transactions in mobile databases. In addition, the correctness of the technique was discussed.

INTRODUCTION

Mobile communications and the Internet have experienced rapid and largely unexpected growth during the last decade of the 20th century. Consequently, the mobile triple-play services (voice, video, data) will be the major demand drivers for the emerging 21st century networks. In this view, the convergence of mobile communications, multimedia, and the Internet would produce innovations, novel applications, and new services that would not otherwise be possible (ITU, 2002). Rapid technological innovations have successfully characterised and encouraged the evolutions of various mobile access technologies, leading to the development of various interworking solutions across heterogeneous networks, as well as the transformation of the market structure and business model. The interworking of heterogeneous networks and technologies is where convergence is really exploding, and it is part of the Internet and multimedia movement that has shaped the future world more than the invention of the automobile (Vanjoki, 2005).

This article aims to present the trends of convergence of different mobile technologies in order to meet the requirements in the provisioning of wireless broadband services, followed by an assessment of its impact to the telecommunications community. The discussions will include an insight into the potential collaborations between various technologies, as well as an exploration of possible technical and economical challenges along the convergence trail.

BACKGROUND

Towards the 21st century, there is a strong need to bring the desktop experience to a mobile environment that allows freedom of movement at any speed while connected to the best network. While the advances of Internet have motivated the research and development (R&D) of wireless technologies that adopt network architecture based on Internet protocol (IP), migration of telephony from circuit-based to voice-over IP (VoIP) might transform the traditional telephony business

and change the economics of carrying voice traffic. The emergence of various innovative technologies that support VoIP applications would allow service providers and operators to penetrate into the voice market that was previously inaccessible. In addition, the increased demands for mobile entertainment have motivated the evolution of revenue-producing and bandwidth-hungry multimedia applications such as the digital TV, mobile TV, and Internet (or IP) TV [e.g., TV data, TV telephony (Nortel, 2005)]. Mobile entertainments enable an increasingly compelling content offering as well as new methods to deliver video programming and advertisements to mobile consumers, introducing new business models for both live and on-demand video content. These enhancements are changing how telecommunication networks can be used to enrich subscribers' quality of living as well as to generate additional revenue streams for content providers and network operators. It can be foreseen that the emerging technologies would support various high-end communications, where the requirement of full support for mobile triple-play services is of the ultimate importance.

Following that, various new broadband technologies have been (or are being) developed to address the demands of high-definition multimedia services in future wireless environments. These technologies include Wi-Fi¹, WiMAX², 3G evolutions (HSDPA³/HSUPA⁴, and EV-DO⁵), FLASH-OFDM⁶, Mobile-Fi, DVB-H⁷, DMB⁸, FLO⁹, ISDB-T¹⁰, and so forth, to name a few most popular ones. Wireless operators have been spending billions to upgrade their infrastructure and networks, especially during the period of analog-to-digital transition. Today, in order to counter the threats from new technologies like WiMAX particularly in terms of coverage range and data rates, Wi-Fi players are now deploying the mesh topology to enlarge their hotspot coverage range for the deployment of citywide wireless network (MuniWireless, 2006). The Enhanced Wireless Consortium (EWC, 2006) has also published the high-throughput (over 100 Mbps) specifications for the physical and medium access control layers of the Wi-Fi system. It is likely that the IEEE 802.11n standard will be based on the EWC proposals. Further, the IEEE 802.11e standard has also been developed to improve

the quality of service (QoS) of the legacy Wi-Fi system in provisioning multimedia services, which in turn is able to challenge the QoS-guaranteed technologies like WiMAX and evolved 3G from securing a leading market position in multimedia last mile delivery.

The high demand for mobile broadband and the rapid adoption of multimedia applications have motivated service providers and operators to deploy various networks to cater to the needs of tomorrow. To some extent, some may believe that these technologies are competing with each other, as many of them have been developed or customised to support a same application category or service offering. Technological wars are likely to be waged over the next few years, especially between WiMAX and evolved 3G, as well as between DVB-H and FLO, although no technology is yet in a leadership position. Moreover, as mobile operators have made vast investments in 3G spectrum, they do not wish to see other technologies penetrating into their cellular territories, cannibalising their revenue and profits, especially in the voice markets. However, some parties actually believe that these technologies could complement and strengthen each other in many aspects (Tan et al., 2006). These technologies can run alongside one another bridging the gaps of applications and services rather than overlapping with neighbouring technologies. With careful planning, different technologies can be deployed to demonstrate the interworking and convergence of various service functionalities, and hence interacting in ever more important roles.

The common goals and functionalities of these technologies include the supports for mobility, QoS, ubiquitous access (large coverage range), low error rates, high-speed connections, seamless handover between cells or base stations, and high capacity for simultaneous users. Although these technologies have different capabilities and marketplaces, the convergence of different networks is not far off as most advanced technologies are (being) developed to address data-centric and IP-based applications. The convergence phenomenon is not just in terms of similarity in functionalities, it is also about several networks coming together to further enrich user experience for “always-on” data and multimedia content delivery. This must also be complemented by enhanced user device capabilities, such that a basic device like a mobile phone can become an all-in-one telecommunications, media and computer handheld machine. Carrier operators and service providers all recognise that to sustain their business long-term, they need to devise the right mix of technologies at the right price to lock in subscriber loyalty, entice new customers and increase their average revenue per unit. The shift to new generation networks for mobile entertainments will take this phenomenon even further, and will essentially involve convergence and interoperability in terms of harmonisation and consolidation of technological strengths, functionalities, service offerings, and mobile broadband market segmentation.

CONVERGENCE PHENOMENA

The activities along the convergence trails have revolutionised and created many new technologies, and the wireless R&D community has already begun to glue the broadband Internet, high-definition multimedia, and mobile communications onto a more common ground. On a technical level, the viability of next-generation networks will rely on continued efforts towards the provisioning of ubiquitous access, definite guarantees on QoS supports, high transmission speeds for downlink and uplink, and evolution to IP-based core networks. Despite the availability of various wireless technologies, it can be observed that most technologies have been developed (or upgraded) to fulfill the above requirements, that is, the convergence of technical trends. In order to offer ubiquitous access, Wi-Fi coverage areas are being expanded to form a metropolitan network via the mesh topology. The process is being accelerated with the aid of WiMAX that supports point-to-multipoint architecture and serves as wireless backhaul for several Wi-Fi access points (Intel, 2004a). The rapid growth of VoIP and multimedia applications has placed QoS issues to be part of the network selection criteria, and hence all new technologies in the future would somehow incorporate QoS supports into the system.

In terms of radio access, the design of the latest wireless air interface can be seen to be gradually converging to the use of orthogonal frequency division multiplexing (OFDM) (Intel, 2004b) technology as the preferred radio transceiver technique. The phenomenon can be observed in various systems such as Wi-Fi, WiMAX, FLASH-OFDM, DVB-H, FLO, ISDB-T, and so forth. Further, it is anticipated that future releases of 3G standards would adopt OFDM technology, where the move can be seen in various proposals amongst the industries. These include the high-speed OFDM packet access (HSOPA) by Nortel (Duplessis, 2005) and the Super 3G vision [or long-term evolution (LTE), 3.99G] by NTT DoCoMo (3G Mobile, 2005). In addition, in order to address the problems of bandwidth and transmission speed limitations, most new wireless technologies have been adopting multiple-input multiple-output (MIMO) and smart antenna techniques. It can be foreseen that future consumer devices would employ multiple antennas as one of the key solutions to boost data rates, transmission reliability, and spectral efficiency.

At the service level, convergence between various wireless networks is already happening through new technologies such as unlicensed mobile access (UMA), interworking and interoperability solutions for co-existing networks (“always-on” communications), mobile TV, interactive end-user applications via alternative networks, and so forth. Currently, this form of convergence is at the height of its technology and is strengthening with further developments and innovations. With the advent of VoIP applications, the threats of mobile operators suffering from falling revenues for voice

services have prompted them to strive to encourage the use of convergent technology such as the UMA. Cellular community has already started to collaborate with the wireless local area network (WLAN) operators (public and private) to enable subscribers to make voice calls using UMA-enabled mobile phones (e.g., BT Fusion, DT Dual-Phone, KT One-Phone) within the WLAN (mainly Wi-Fi-based) environments, while at the same time providing transparent and single-billing facility. The increased demands for low-cost voice applications would assemble several networks of different technologies towards the convergence into a common service platform.

On another hand, it is envisioned that most wireless users will hook up to applications offering triple-play services of multimedia, broadband Internet and telephony by the end of the decade. The proliferation of mobile entertainments is also following a similar trajectory as that of the VoIP, where the mobile phones will be used to receive live TV programmes. Exploiting high-definition multimedia applications across the cellular core will require high levels of investment, possibly higher than the migration from 2G to 3G and beyond. This is mostly due to the inherent limitations of 3G networks for carrying “unicast” video traffics (highly bandwidth-intensive). In order to avoid overloading 3G traffics with videos, technologies like DVB-H, FLO, and DMB have been developed to allow mobile networks to broadcast live TV shows to consumer devices (e.g., mobile phones) nationwide. This capability of convergence has incorporated both on-demand contents from 3G networks and live programming over the digital broadcast channels. It enables the handset to transcend from traditional real-time voice communication gadget to an instrument facilitating a greater interaction between telecommunications, multimedia, and information technology, revolutionising the handset to be a new generation pocket TV. The lesson learned from the success or failures of new technologies is that timely availability of consumer devices with simple and convenient interfaces will be the key to future service development, revenue generation, and establishment of leading market position. Devices capable of supporting high-quality multimedia combined with additional functionalities, such as VoIP, broadband Internet, interactive gaming, and location technologies, will further enhance the user experience.

Moreover, the realisation for “always-on” radio communications is around the corner. This can be seen in the Network Working Group of the WiMAX Forum that is currently investigating the WiMAX-3GPP interworking solutions, as well as the IEEE 802.21 Task Group (IEEE 802.21, 2006) that is looking into seamless handover solutions across heterogeneous networks. This convergence scenario would eventually encompass complimentary and alternative network technologies, such as UMA and fixed-mobile convergence, where advanced mobility and radio resource management would be considered in their global

context. The collaborations between several technologies allow mobile users to stay connected with the best network while roaming from one base station to another. For example, the video telephony applications can be delivered via 3G networks, while heavy files uploading or downloading can be accomplished simultaneously via global broadband access networks like WiMAX and Wi-Fi.

Furthering this, the collaborations between heterogeneous networks have also allowed different systems to coexist and collocate at a same site. This phenomenon is now actively promoted within the Open Base Station Architecture Initiative (OBSAI, 2006), especially regarding WiMAX and 3G cellular systems. From the perspective of OBSAI’s open specifications, vendors can now build multimode base station components and module cards supporting the standard hardware of several variants of cellular technologies and WiMAX. This change, impelled by market’s demands, has prompted different networks to band together to prevail. It has shaped the way telecommunication services are provided, enabling the coexistence and interoperability across heterogeneous networks, and hence gradually driving several technologies towards a converged marketplace. The future will see the service providers or operators offering more functions comprising more technologies and applications. It should be noted that despite the on-going competition amongst different wireless technologies, none of them should be considered as a substitute for others, as most technologies complement one another rather than competing with each other (Tan et al., 2006).

CHALLENGES

While there are numerous benefits of having a converged communications network, most of the convergence phenomena discussed above represent only a theoretical observation and finding under ideal circumstances. Along the convergence trail, several technical, regulatory, and business issues are still unresolved. Due to the existence of a plethora of wireless technologies, each having its own relative strengths and weaknesses, the crowded technical environment might result in a highly fragmented, unpredictable, confused, and more competitive marketplace. This is especially so as most operators, content and service providers would like to recoup their investments on current technologies (3G in particular) before migrating to yet another new network architecture aiming for convergence. Before 3G communications were deployed few years ago, some parties have been talking about “4G,” which is still in principle a buzz word as nothing solid has been specified so far. Initially, a 4G system is supposed to partly address the convergence issues, as some parties have been looking into software defined radio (SDR, 2006) as the core for next-generation systems. It is a pretty ambitious type of network, as ultimately it intends to integrate several

networks together using software control so that users can move between cells of different types of radio technologies seamlessly. While the existing technologies (e.g., HSDPA, EV-DO, WiMAX, Wi-Fi mesh) are still being deployed, not much effort has been placed into the so-called “4G,” as this requires huge amounts of innovations and investments. It seems that the entire industry is not fully prepared for the convergence yet, not until at least they have firmly secured individual marketplace for the current technologies.

Another greatest challenge will lie with the power consumption issue. It is envisaged that the converged communication platform in future would require multiple processing and additional communication elements, further draining the battery life of the mobile devices. Most mobile devices available today fail to offer sufficient battery life for continuous intensive usage of more than 3 hours. As digital broadcast TV moves to mass market in near future, it is possible that the battery life of a handset to be measured in TV-time, not just talk-time and standby-time (Texas Instruments, 2005). Advanced power management solutions must therefore be in place. Moreover, the mobile device manufacturers and silicon solution providers must be able to balance the increased functionalities with what consumers have been expecting—small designs, reliable communication services, and ease of use. These include the considerations of bigger and higher contrast display screen for the handset, as well as stylish antenna design. Compact size antenna must be able to receive live TV broadcast and wireless communication services (e.g., 3G, WiMAX) in all on-the-go scenarios, whether travelling on a train through a tunnel or sitting still at a desk in an interior office of a high rise (Texas Instruments, 2005). Handset manufacturers will have to satisfy all these requirements while lowering the production costs. The availability of appropriate mobile devices at affordable prices will be a prerequisite for users.

In addition, multimode technology in a convergence scenario means the ability to perform seamless handover between different types of radio access technologies. Towards this end, there are significant software, billing, carrier and enterprise interoperability challenges. The next-generation mobile communications will not be driven by a single entity or organisation. It requires a tremendous number of partnerships and a robust ecosystem in order to fully exploit the ultimate capabilities of all wireless systems. Given the sweeping changes in the world of technology, it is really going to require multiple standardisation bodies, corporations, industries, and government entities to come together to drive open standard-based interoperability, interworking, and opportunity to enable triple-play merged services. Simple and transparent billing models across several parties are required, taking into account the differences between voice and data services and the growing importance of contents.

Further, the transition from circuit-switched networks to all-IP networks faces different challenges of packet

acceleration, traffic management, data integrity, security, and QoS. Next-generation security will have multiple elements, much more than just delivering encrypted traffic at faster rates across the converged networks. It is also about denial of service attacks and digital right management. The improved QoS support is required to identify and prioritise data packets in order to offer uninterrupted service flows while accessing multiple networks simultaneously (Perkins, 2005). For example, the mobile device must be able to receive uninterrupted live TV shows in real-time, while simultaneously receiving voice calls from multiple parties and downloading large data files from office servers.

Clearly, the mobile industry will have to look into these challenges, as solving these potential problems is at the forefront of convergent mobile technologies. With that, it may be difficult to expect the commercial fruit of the converged mobile communications within the next 10 years or so.

CONCLUSION

This article has discussed the trends, future scenarios, and challenges regarding the convergence of next-generation mobile communications, where the collaboration and interworking between heterogeneous networks and technologies have been specially highlighted. It is shown that the convergence phenomenon is not just in terms of similarity in functionalities or technical requirements, it is also about several networks of different technologies and standards merging together to further enrich user experience in a more efficient manner. It is expected that the integration of mobile entertainments, Internet, and wireless technologies would give birth to a whole new family of services and applications, as well as opportunities for revenue generation. Towards the convergence path, a new era of pervasive computing is dawning with huge implications for consumer's lifestyles and values, where each may own some sort of miniaturised mobile communication devices (e.g., multimode pocket computer with multimedia and telecommunication functionalities) that are always best connected. This emerging trend is mostly driven by wide range of requirements, where the appetite for seamless mobility with an all-in-one mobile device is of the ultimate importance.

However, the convergent marketplace is still in its infancy, and a realistic business case that is both commercially available and overwhelmingly profitable is still yet to be defined. It is anticipated that business models based on partnerships will be the cornerstones for the continued success of the convergent mobile industry to generate opportunities for all players and foster innovations. A significant level of investment, support, understanding, and cooperation between various parties is needed in order to satisfy various requirements of a converged next-generation mobile network. Proper measures to resolve the foreseen challenges are also

vital to achieving the ultimate success of the converged next-generation wireless architecture.

KEY TERMS

DMB: A Korean standard for mobile digital broadcast TV, which provides a direct satellite to mobile phone feed.

DVB-H: An open technical specification for bringing digital broadcast services to battery-powered consumer handheld receivers.

FLASH-ODFM: A proprietary wireless communication scheme developed by Flarion (acquired by Qualcomm) that supports high data rates at very low latency over a distributed IP-based mobile network.

FLO: A proprietary standard from Qualcomm designed specifically for multicasting significant volume of rich multimedia content cost effectively to wireless subscribers.

EV-DO: A wireless radio broadband protocol standardized by 3GPP2 for high-speed data transmission.

HSDPA: A packet-based data service in 3GPP system that can achieve data rates of 3-14.4 Mbps (or over 20 Mbps for MIMO systems) over a 5 MHz downlink channel.

HSUPA: An emerging packet-based data service in 3GPP system that can transmit data up to 5.8 Mbps over a 5 MHz uplink channel.

ISDB-T: A standard used in Japan to deliver digital TV services to subscribers.

Mobile-Fi: Nickname for IEEE 802.20 specifications, also known as mobile broadband wireless access.

MIMO: Refers to communication systems that employ multiple antenna elements at both the transmitter and receiver for improved spectral efficiency and channel reliability.

OFDM: A wireless transmission technique that uses many narrowband sub-carriers which are orthogonal to each other in the frequency domain.

QoS: Refers to the capability of a network to provide better service to selected network traffics over various traffic conditions. It is a generic term for measuring and maintaining quality of network characteristics such as error rates, jitter, and latency.

SDR: A communication system that uses software for the modulation and demodulation of radio signals.

UMA: A technology to provide access to cellular networks (2G, 3G) over unlicensed spectrum technologies like Bluetooth and Wi-Fi.

Wireless Fidelity (Wi-Fi): Another name for WLAN based on IEEE 802.11 family of standards.

WiMAX: A trademark refers to broadband metropolitan area network that is based on IEEE 802.16 or HiperMAN standards.

NFC–Capable Mobile Devices for Mobile Payment Services

Stamatis Karnouskos
SAP AG, Germany

INTRODUCTION

An old saying coming from the telecom world states that nothing can be really considered as a service unless you are able to charge for it. As we move towards a service-oriented society, the necessity to pay in real time for a variety of services via different channels anywhere, anytime, in any currency increases. According to Gartner (www.gartner.com), worldwide mobile phone sales totaled 816.6 million units in 2005, a 21% increase from 2004. Due to the high penetration rates of the mobile devices, they pose an interesting candidate for the real-time payment scenarios. Several efforts have already been done (Karnouskos, 2004), but as new technology comes aboard, new capabilities are also brought along. Near Field Communication (NFC) is such a technology, which due to the industry support and its low cost (in comparison with similar ones) may become dominant in short-range communication among a variety of devices, including mobile phones. NFC is well equipped in order to facilitate mobile payments with little interference from the user side.

Mobile Payment

People today use their mobile devices to pay for a variety of mostly intangible goods such as ring tones, games, digital content, and so forth. However existing solutions are confined usually within one service provider and usually consist of local island solutions. The promising trend is to mainly use mobile devices at physical points of sale (POS) and additionally expand the payment capabilities in virtual ones. We consider as mobile payment, any payment where a mobile device is used in order to initiate, activate, and/or confirm this payment (Karnouskos, 2004). A global study by Arthur D. Little Consulting (Taga & Karlsson, 2004) estimates that m-payment transaction revenues will increase from \$3.2 billion in 2003 to \$37.1 billion in 2008 worldwide. There is evidence of the need for real-time, open, and trusted payment services that can support in a more efficient way the processes evolved in existing electronic and mobile commerce scenarios. Although in the last few years we have witnessed several standardization efforts, the rise and fall of some mobile payment services, promising technologies, ongoing trials, predictions for the future,

investments on startup companies, and so forth, there is still no solution that is open, widely accepted, and acknowledged as a clear market leader.

Several reasons exist as to why the mobile payment has not become mainstream such as user friendliness, security, cost, high learning curve for users, lack of the right business models, lack of advanced technology in devices and mobile networks, non-existent cooperation among the key players, and so on. Implementation of mobile payment services is more complex than originally thought and to provide a viable solution has been proven challenging both at the technology and business level. NFC could be one of the enablers that can lead us into effectively tackling some of the issues that have hindered other mobile payment approaches; therefore it is interesting to look at its capabilities and the context of its usage in mobile payment scenarios.

Near Field Communication

NFC is an interface technology for exchanging data between electronic devices. It represents the second generation of the proximity contactless technology, which supports peer-to-peer communication and enables access to services, anytime, anywhere, with any type of NFC-enabled stationary or mobile device. As NFC-compliant devices are brought close together, they detect each other and begin to communicate. This is done at small distances of about 10 cm (4 inches). NFC is based on RF technology at 13.56 MHz, is standardized ISO 18092, and is backwards compatible with ISO 14443. The data exchange rate can be up to 424 Kbit/sec (while 1 Mbit/sec is planned). NFC was designed with the goal to be easy and intuitive to use, in order to be successful also among the technology illiterate users.

NFC devices operate in two different modes:

1. **Reader Mode:** This mode allows the communication with other tags which effectively transforms any device to a fully capable tag reader.
2. **Card Emulation Mode:** This enables the device to behave like a tag itself which can be read by other devices in reader mode.

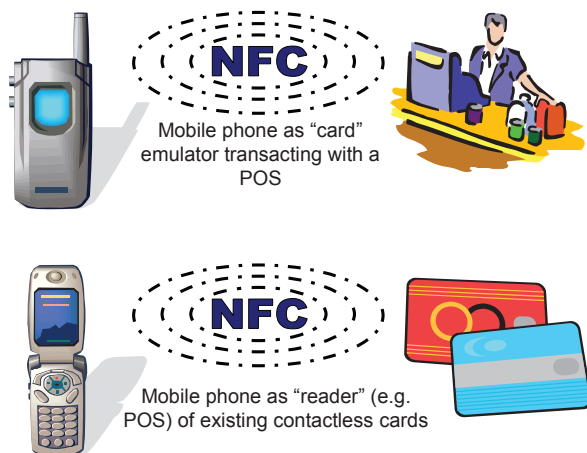

Standardization of NFC is done within the NFC Forum (www.nfc-forum.org), which was launched in 2004 and in

the meanwhile has more than 70 members, many of which are key players in their domains and drive the consortium to success. The Nokia 3220 mobile phone (Nokia, 2004) was the first NFC-enabled device that was brought to the market and delivered all the services envisioned by the NFC forum including service discovery, ticketing, and payment. Today other mobile phones also exist such as the Samsung SGH-X700. NFC is compatible with Sony's FeliCa card (<http://www.sony.net/Products/felica/>) and the broadly established contactless smart card infrastructure based on ISO 14443A, which is used in Philips' MIFARE technology (<http://www.semiconductors.philips.com/products/identification/mifare/>). This backwards compatibility with the existing infrastructure will ease the introduction of NFC-related services, as not everything has to be done from scratch.

COUPLING NFC WITH MOBILE PAYMENT SERVICES

NFC can be used as a communication protocol for mobile payment applications. In a typical scenario, the user would simply bring in-contact his mobile device with the payment point of sale (POS), and the payment transaction would occur. NFC-enabled devices (e.g., mobile phones) provide an additional security layer since they can transmit encrypted payment information to a POS in a way similar to that used with RFID-enabled credit cards. Furthermore, beyond the existence of an NFC-compliant tag capable of storing a unique ID and transmitting encrypted data at 13.56 MHz using the ISO-19082 air interface protocol, NFC devices also feature a smart card microcontroller. The last can be used as a secure storage for applications and credentials that can be used in payment applications. This allows NFC devices

Figure 1. The double mode of NFC-enabled devices in payment scenarios

to store data on multiple payment options which provides a flexible base for several business scenarios. Apart from that, the ISO-18092 standard used is also compatible with the ISO-14443A standard, which is currently used by RFID-enabled POS currently installed in several merchants.

NFC devices can technically operate in two different modes which allows NFC-enabled phones the capability to:

- Fully replace the existing contactless smartcards (when functioning in "card emulation mode"), business and technology wise. All existing business cases that use such cards can now include NFC-enabled mobile phones, which can act as authentication tokens for any transaction.
- Act as a "reader," therefore any reader/POS in the merchant side can be replaced with a mobile phone. Furthermore, the mobility advantage will make it possible to extend existing business cases.
- Make possible new business cases, due to the ability of an NFC-capable device to slip into both modes. For instance in "reader" mode, information can be obtained from a smart advertisement about a concert and the video could be downloaded online from the Internet address specified by the smart tag. The user can pay online and receive the ticket on the mobile phone. Later in "card emulation mode" the user can enter the concert hall by simply waving his mobile (which now has the authentication token stored) from the respective reader.

There are numerous scenarios where NFC-enabled mobile payments can be applied such as gaming, ticketing, purchase of goods, real-time money transfer, and so forth. NFC mobile phones can fully substitute all form of cards as we know them today (credit, debit, prepaid, etc.) and flexibly enable more flexible business models and services to be built.

A number of trials using an NFC mobile phone in order to realize applications that can be hosted under the mobile payment umbrella started within 2005/2006. Most notably:

- In the city of Caen in Normandy, France, trials began in October 2005 (and initially for six months) on NFC-based mobile payments (Caen, 2005). The 200 volunteers in the trial are able to pay with their mobile phone in selected stores (retail), for parking, in tourist sights, and so on. This is the world's first large-scale trial of this emerging technology, and valuable feedback will be obtained from mobile operators, retailers, and consumers. The solution used in this trial incorporates secure, over-the-air (OTA) download of applications on a GSM network and automatically recognizes the appropriate application to launch when an NFC connection is made. The Samsung D500 mobile phone that

is used incorporates a Philips smart card chip, enabling users to make payments and use banking applications securely. The process is straightforward: to make a purchase, the customer indicates to the cashier that s/he would like to pay using the phone. The cashier prepares the register to receive payment information via NFC, and then the customer simply waves the phone in front of the terminal.

- In Atlanta's Philips Arena in the United States, season ticketholders had the chance in December 2005 to pay for purchases at concession stands and access mobile content via their Nokia 3220 phones (Philips, 2005).
- In the same spirit, Royal Philips Electronics and Telefonica Moviles España have demonstrated NFC technology at the 3GSM World Congress (www.3gsmworldcongress.com) in Barcelona, by providing 200 selected attendees with NFC-enabled Samsung SGH-X700 mobile phones to be used in a variety of transactions during the event, including secure mobile payment (Philips, 2006). Each phone comes equipped with e-money that can be spent at a specially equipped kiosk at the Philips booth. By using the touch-screen kiosk, users select and pay for their choice of CDs, DVDs, and books using the NFC-enabled phone. After the transaction, the money is deducted from the purse and a message pops up on the phone screen indicating the balance account.
- In Hanau, Germany, the trial "NFC Handy Ticketing" was initiated in April 2005. It enables 200 people who are equipped with the Nokia 3220 mobile phone to use it as an electronic ticket. The customers interact with the electronic legacy ticketing machines that were established in 2002 for RFID contactless tickets, and the data are stored in the mobile phone. The last five trips can be seen anytime, while the NFC function can also be deactivated on demand. The charging is done via the post-payment method, at the end of the month. Controlling the passenger's ticket form is easy, since the controller now equipped with a similar mobile phone simply queries the last ticket data from the passenger's phone (RMV, 2005).

FUTURE TRENDS

The future for NFC looks promising. However there are still several challenges to be mastered before the NFC finds its way into modern application scenarios. NFC brings the promise of gluing the virtual and the real world, and give rise to new innovative services. Coupling it with the mobile phone and a secure environment such as the SIM (Subscriber Identity Module) card, new business cases will emerge which will integrate more mobile phones into our life, eventually even possibly replacing all other tokens that we use today for

authentication and payment. Mobile phones could emerge as a global platform and be the common denominator via which service providers will be able to charge for their products in a massive way. However in order for this to be done, new business models need to be developed and new strong partnerships need to be formed. Standardization ensuring interoperability at all levels is crucial when we consider the heterogeneity in hardware and software available in the mobile world. The NFC Forum was founded exactly for this reason and has a promising future.

By coupling NFC with mobile phones and especially the SIM card, network operators (the owners of the SIM) come into an advantageous position. Furthermore, more dynamic and better management of the authentication token can be done since now these tokens can be installed, updated, or revoked via OTA interface. Additionally, if this is coupled with mobile presence information, new security models and risk management mechanisms could emerge. For instance the credit card (stored as authentication token in the mobile phone) could be valid within a geographical area set by its owner. Even more interesting might be cooperative scenarios among such smart tags and context-based services.

NFC can also be used for initial communication, which can eventually result in configuration and further usage of other communication protocols or technologies. Therefore, NFC could be used as a means to initiate mobile payments that can be finalized, such as via instant messaging (Karnouskos, Arimura, Yokoyama, & Csik, 2005). For instance in a taxi-payment scenario, the taxi driver simply touches the taximeter, which registers the amount to be paid in the payment application and provides to the customer all the necessary information (e.g., IM credentials, fare, etc.) for the transaction to continue via an instant messaging platform.

As mentioned NFC-devices can function as "readers" or "card-emulators." However in the middle term, "peer-to-peer" functionality is expected to be added. In that way the reading and/or writing mode would be possible which practically empowers the realization of direct data exchanges (and not via a server) between mobile phones; therefore applications such as file exchange, business cards, and so on would become a reality. For the mobile payment domain, this simply means that payment tokens can flow anonymously from one mobile phone to another. Therefore this form of e-cash (e.g., e-coins), which can be moved among devices via local interaction (no centralized server communication infrastructure needed), has the potential to eventually substitute cash as we know it today.

Security and privacy concerns will have to be fully tackled before NFC-based mobile payment services become mainstream. However, contrary to the traditional payment instruments such as credit cards, mobile devices allow more efficient risk management solutions to be deployed since now, depending on the transaction, password-code or biometric characteristics could be required for high-volume

transactions. Furthermore the mobile device can be turned on/off, and the relatively short operational range of NFC at approximately 10 cm constrains (but does not eliminate) possible remote attacks. The security required will be tailored to each service, depending on the risk management and the service's respective business model.

Currently NFC supports ISO 14443A, but ISO 14443B does not. This limits the scenarios where NFC could be used. Mobile phones depend heavily on their batteries. However there are several scenarios where we can use the mobile phone as a simple token and this should not be dependant on its battery status. In other words, in order to cover all possible payment scenarios, we need a technology that does not require that the phone is switched on or its battery charged. ISO 14443B supports such scenarios, but 14443A does not. The extension of the NFC standard to include this capability could expand the use-cases that NFC could play a critical role.

NFC is expected to be complementary to existing protocols (e.g., IrDA, Bluetooth, etc.). Its low cost (around 20¢) is still significantly less, for example, compared to Bluetooth at \$5 per item. Due to cost efficiency, as well as the compatibility with existing RFID infrastructure and the large base of smart cards, NFC creates the potential to deliver services effectively anytime, anywhere, and in a variety of channels. Effectively NFC could act as an abstraction layer that would ease the initial communication among devices and bring the vision of easy ubiquitous access to services one step closer to reality. In a service infrastructure, where tangible and intangible goods are offered and can be immediately charged for, mobile payment is expected to be highly integrated and flourish.

CONCLUSION

NFC technology is carefully taking its first steps. Standardization activities have been carefully carried out, and ongoing work within the NFC Forum looks promising. Although there are some prototype mobile phones out there, NFC technology is expected to be integrated in most mobile phones of the near future. "By 2010, we expect that over 50 percent of all mobile handsets will incorporate near field communication chips to enable short-range, easy and secure transactions," points out Erik Michielsen, director at the market analyst firm, ABI Research (www.abiresearch.com). If this will hold true, then mobile payment via NFC has the potential to reach the critical mass rapidly and emerge as an integral part of our future everyday transactions. The first commercial platforms such as the one offered by MobileLime (www.mobilelime.com) are already underway. NFC has learned from previous efforts on new protocol introduction such as Bluetooth, which looked promising but was complex and low on execution. NFC is compatible with existing infrastructure (i.e., Felica

and MIFARE) which may give it a significant advantage. Also its nature—such as the short-distance communication and user-friendliness—has an initial positive effect on security and privacy issues, which in any case need to be further investigated. Finally it is pointed out that NFC, amalgamated with mobile payment services, could realize a universal "touch-and-pay" approach anywhere, anytime, in any currency, which in its turn may form the core of more sophisticated business cases. From the market point of view, commercial rollouts could be realized as early as in 2007.

KEY TERMS

Mobile Commerce (M-Commerce): Electronic commerce transactions realized via mobile devices (e.g., mobile

phones, PDAs, etc). The term “m-commerce” was coined in the late 1990s during the dot.com boom.

Mobile Device: Any device that can be easily carried around and communicate via mobile/wireless technology. The terms *mobile phone* and *mobile device* are interchangeable in the context of this article.

Mobile Payment: Any payment where a mobile device is used in order to initiate, activate, and/or confirm that this payment can be considered as a mobile payment.

Mobile Ticketing: The realization of a service where virtual tickets are purchased and validated with the help of mobile devices and their authentication capabilities.

Near Field Communication (NFC): A short-range communication technology that can also be used in mobile payment scenarios.

Point of Sale (POS): A location where a transaction occurs. This may be a real POS (e.g., a checkout counter) or a virtual POS (e.g., an e-shop on the Internet).

Subscriber Identity Module (SIM): A smart card that securely stores the key identifying a mobile phone service subscriber, as well as subscription information, preferences, and text messages.

Notification Services for Mobile Scenarios

Michael Decker

University of Karlsruhe, Germany

INTRODUCTION

In this article we introduce the concept of generalized notification services (NSs). NSs are a simple class of services for mobile and wireless terminals, but nevertheless there are many useful services which can be modeled as NSs. Mobile and wireless terminals (MWTs) in our sense are handheld computers with a wireless interface for data communication (e.g., GPRS, UMTS, or WiFi); examples of MWTs are cellular phones, personal digital assistants (PDA), and smart phones. Mobile services are functionalities offered by one or more remote computers (server or back-end systems) to a MWT (client). Because of the mobility of the MWT, at least the first part of the route for the necessary data communication with the server is realized using wireless standards like GPRS, UMTS, or WiFi.

The motivation for giving an exact description of a class of mobile services comes from the fact that in literature there are many descriptions of platforms or technical frameworks for mobile services, but often there is no precise definition of what kind of services are supported by these platforms; these descriptions are more concerned with architectural aspects or how to deal with context information. Also the prevailing paradigm for the realization of mobile services is the Web-like delivery of pull-documents (e.g., iMode) which is not ideal for mobile scenarios, because poor connection quality impairs the user experience (necessity of sending requests again, long waiting times) and push messages are more appropriate for many mobile scenarios.

The remainder of this article is structured as follows: in the next section we cover our understanding of context-awareness. We then explain the basic principle of NSs and argue why they are suitable for mobile scenarios. To show that NSs are a versatile class of mobile services, we mention several examples from different areas of application. Before we summarize, we sketch a protocol for the implementation of NSs.

CONTEXT-AWARENESS OF MOBILE SERVICES

Context-awareness of mobile services (and applications) is an important concept of mobile computing. Context is defined as: “information that can be used to characterize the situation of an entity” and “is considered relevant to the

interaction between a user and application” (Dey, 2001). Since almost everything can be considered as an entity at some level of abstraction, we focus more on the purpose of context: to support a user when interacting with a service, for example, displaying information relevant to his or her current situation, or reducing the amount of data to enter manually. The context information has to be available in an explicit form during the runtime of the system. As discussed below in more detail, mobile services have several restrictions with regard to ergonomic aspects, so context information is crucial for the user experience of mobile services.

For the description of NSs, we need to distinguish how critical a given type of context information is with regard to data protection. Context information that is critical for the user’s privacy is denoted as “personal context,” otherwise as “public context.” An example for personal context would be the current location of a user, because people do not like the idea of having their position tracked. “Time” or “weather” (e.g., a mobile service should not recommend outdoor activities when it is raining all day long) are public context parameters because they are not person-related data (but to interpret them, it could be necessary to have personal context information, e.g., the user’s location to find out the correct time zone or weather).

BASIC PRINCIPLE

The basic idea behind notification services is that users in mobile scenarios do not want to browse for the information they need in longish sessions and thus push mode for information delivery is preferable. A notification service sends push messages to users based upon an initial configuration and public as well as private context information. Munson and Gupta (2002) already mentioned the idea of generalized notification services, but they considered only location information as a context parameter and their discussion of details concentrated on how to provide location information for a large number of clients.

Our definition of NS demands a special client application on the MWT and a machine-readable service description file for each type of NS. Using the service description the client application can guide the user through the configuration of the NS without any network interaction. The description file also specifies which personal context parameters the client application has to provide (e.g., current location of

the user retrieved from a GPS module, profile information, battery level).

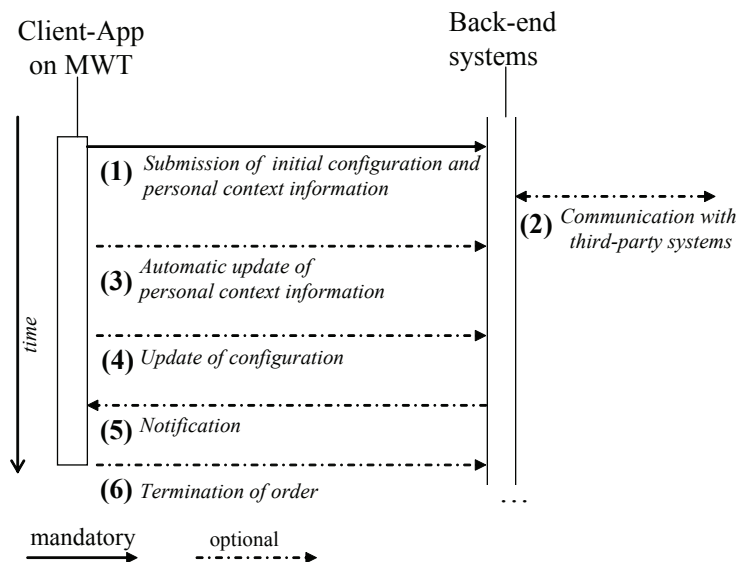

A configured instance of an NS is denoted as “order.” The order is submitted to the server where the actual business logic of the NS is running. If certain events occur, the server will send push messages (notification) to the MWT (e.g., SMS/MMS, e-mail, or a client-specific channel based on TCP/IP connection). The content of the push message might lead to further interaction (e.g., the message might contain a link to a WAP-document with further information), but this is beyond the scope of the NS. Depending on the type of order, it might be allowed to reconfigure the order using the client application; also the client application might submit updates of the personal context information (e.g., new position of user) to the server.

To illustrate this concept we consider the example of location-based advertising (Kölmel & Alexakis, 2002). In this scenario a mobile service sends advertisement messages to a user’s MWT if the user approaches stores with offers matching his wish list (configuration) and his profile. If implemented as NS, the configuration would describe which offers the user is interested in (e.g., clothes, entertainment, restaurants, etc.); according to his or her current position and profile information (personal context information), the user could receive notifications (advertising messages), for example, about a restaurant not far away from his or her current position.

In Figure 1 we illustrate the messages exchanged between the client on the MWT and the back-end systems of a generic order as a UML sequence diagram (Fowler & Scott, 2000). Steps 2-6 might occur several times, the order may vary:

1. **Submission of Initial Configuration and Personal Context Information:** This step is the only mandatory one. If the NS needs personal context parameters, these are automatically filled in by the client application (e.g., current location of the user or profile information).
2. **Communication with Third-Party Systems:** The back-end systems of the NSs may communicate with third-party systems (e.g., databases to query data or public context information). If the third-party systems proactively send information to the back-end systems (which do not query if they need information), the NS is following the publish/subscribe paradigm which is considered suitable for mobile services (Huang & Garcia-Molina, 2004).
3. **Automatic Update of Personal Context:** If during the lifetime of an order a relevant personal context parameter should change (e.g., location of user, battery level), the client application automatically sends an update to the back-end system.
4. **Update of Configuration:** The user can change the configuration of the order at any time; this might not be reasonable for all kinds of NSs.
5. **Notification:** If the business logic of the NS on the back-end systems detects an event, it dispatches a push message to the MWT. A push message is a message sent to a user without being perceived as being directly requested. There might be multiple notifications or not a single one depending on the type of service.
6. **Termination of Order:** Orders might terminate themselves (e.g., based on configuration parameter “expiry date”) or be terminated by the user manually.

Figure 1. Sequence diagram for a generic NS

An important feature of an NS is that both directions of message exchange (upstream: from mobile client to back-end; downstream: notifications from back-end to client) are not coupled, as are services based on document pulls. This feature makes it easy to hide temporary connection drop-outs, but seems to limit the application examples to simple alert services at first glance.

SUITABILITY FOR MOBILE SCENARIOS

Before we can discuss why NSs are particular appropriate for mobile scenarios, we must look at the specific limitations of MWTs (Forman & Zahorja, 1994):

- **Limited Connectivity:** When designing mobile services, possible connection drop-outs, limited capacity, and high latency should be taken into consideration.
- **Limited Ergonomics:** Due to their limited size, MWTs only have a small display, and it is cumbersome to enter data because there is no full keyboard or a “mouse.” So a mobile service should not require a lot of data input from the user.
- **Limited Resources:** MWTs possess only limited energy supply, so mobile services cannot perform extensive computations and transfer data over the wireless interface all the time. While currently the available CPU-power and memory on MWTs are still growing, we cannot assume a significant growth of battery capacity in the near future.
- **Privacy Concerns:** Since MWTs can be located by the MNO—he knows always the position(s) of the base(s) station used by the MWT—people are afraid of being “tracked” (Junglas & Spitzmüller, 2005). People also store personal data on their MWTs and do not want to share that data with everyone.

NSs give consideration to these four characteristics:

1. During the configuration, no interaction with the remote server is required; should a connectivity failure occur, the client application will try to resubmit the order later. When using mobile services based on pull documents, the user experience will be impaired by poor connection quality (necessity to manually resubmit request, significant waiting times between pages).
2. NSs require only a minimum of user input; after the initial configuration it usually is sufficient to read incoming notification messages.
3. Due to limited resources, the NS approach does not require extensive computations on the MWT since the actual business logic of the services is operated on a

stationary server. Most NSs generate a data volume of a few KBytes per day, even if there are frequent updates of the personal context parameters “location.” Only in cases where the notification messages contain extensive multimedia elements (movie sequences, high-quality sound clips) is there a significant amount of data traffic generated by NSs; this might be the case for m-advertising implemented as NS since advertising often uses multimedia elements.

4. Regarding privacy concerns, in the section “NS and Privacy” we show that it is simple to implement NSs in a way to ensure certain requirements with regard to end user privacy.

EXAMPLE SERVICES

We now give examples for mobile services that could be modeled as NSs; for each example we state the required configuration and context parameters, as well as the content of the notification. The example services are not new services; the novelty is their consideration as generalized notification services.

Tourist Guide

This service is for visitors to new places; as they wander around, they receive notification messages with explanations concerning the sights and places in their nearer surrounding. The required personal context parameters are location and profile (e.g., consider age to deliver explanations adequate for children). The time as public context parameter could be considered to mention if the facilities are open or not. See also Sampat, Kumar, Prakash, and McCrickard (2005) for a discussion of a notification system in this usage scenario.

Alert Services

Alert services send notification to users when a time-critical external event was detected, for example, significant changes of stock quotes, emergencies, news, announcement of exam results, or inventory of a certain item got below the minimum threshold (Adya, Bahl, & Qiu, 2002). The configuration describes the event the user is interested in and might also contain a pass phrase, because not everybody is allowed to know about the inventory of a certain firm or the exam results of a certain student. There are even examples of location-aware alert-services, which warn users (e.g., outdoor sportsmen, homeowners, motorists) when a dangerous weather situation is about to appear at their current location. The notifications provide the time-critical information.

Online-Banking Support

To secure online banking in the Internet against so called ‘phishing’ attacks—the user erroneously enters the secret transaction number (TAN) into the Web site of the attacker—a bank could also utilize the MWT as additional credential for the transaction. This is a form of two-factor authentication (2FA) since the user needs two things—this TAN and his MWT—to prove that he or she is authorized to perform the transaction (Wüest, 2005). The Web site of the bank displays a challenge code after the user has entered the transaction details, which are amount of money, recipient, and TAN. This challenge code is the configuration parameter for an NS, and the network authentication is a context parameter; the notification is a summary of the transaction details and a response code. To complete the transaction the response code from the MWT must be entered into the online-banking Web site. The idea behind this authentication method is that it is very unlikely that the attacker compromises not only the user’s PC, but also his MWT. This is an example for an NS where no updates of the configuration or context parameters are allowed. The instance is also terminated automatically after dispatching the response code.

Virtual Memo

Users can deposit “virtual memos” or “virtual graffiti” at their current position (Persson, Espinoza, Fagerberg, Sandin, & Cöster, 2002) with messages like “don’t visit the museum in this street.” The content of the messages is specified in the configuration (with optional expiry date). If other users of this service approach the location of the memo, they will receive notifications with the content of the deposited memo.

Community Support

Groups of people agree on a group-identifier and an optional pass phrase (configuration). A user now can configure a “Buddy-Finder” NS by providing the identifier and the pass phrase. He or she will receive a notification if another user of that group approaches his or her current situation. If instead of a group-identifier with pass phrase, the profile of people is used, we obtain a “blind-date” finder with notifications like “someone matching your profile is around less than 100 meters.”

Mobile Payment

Mobile payment (m-payment) is the usage of a MWT by at least the payer to make a payment (Pousttchi, 2004), for example, payment at a point-of-sale like a vending machine or a supermarket. Configuration parameters are the amount to pay, a pass phrase for authentication, and an identifier

of the recipient (e.g., alphanumerical code displayed). The notification would be a confirmation of the payment.

Call-a-Taxi

This location-aware service (also termed “call-an-ambulance” or “call-a-squad-car”) calls a taxi to the current position of the user at each invocation of the service; the notification in this case is the confirmation of the order with an optional estimation of the time to wait. This is helpful because tourists or people in emergencies often do not know their location with the accuracy required to be found by a motorist.

Mobile Ticketing

The idea behind m-ticketing is to use MWTs for the distribution and presentation of electronic tickets. A ticket is something that certifies that the owner of the ticket has the right to claim a certain service like public transport (e.g., Böhm, Murtz, Sommer, & Wermuth, 2005) or permission to entertainment events. To hinder fraud, electronic tickets usually have some kind of digital signature. If implemented as NS, a mobile ticketing service sends the tickets as notifications. The configuration of the NS may specify the category of the ticket to buy, for example, seat category for entertainment events or number of zones for public transport tickets.

NOTIFICATION SERVICES AND PRIVACY

As discussed above users have concerns with regard to privacy when using MWT. We make the assumption that there is a trusted zone between MWT and the actual service provider (SP). Using public key encryption (Schneier, 1996), it is simple to state a protocol for the implementation of NS that guarantees the following two properties:

- The trusted zone cannot learn more than necessary about the details of the orders and thus compiles no profile about the fields of interest of the user.
- The SP cannot learn more about the user’s identity than necessary for the execution of the service. In particular he or she cannot learn his or her end address, which avoids the danger of unsolicited push messages (“spamming”).

Although a single trusted zone between MWT and SP represents a single point of attack, this model is a realistic one and is used by several authors (Bettini, Wang, & Jojodia, 2005). We interpret the trusted zone as the core network of the mobile network operator (MNO), because this part of the network is no public network and a user has to trust

the MNO to a certain degree because he or she can track the position and knows when (but not necessarily what) data is transmitted. The actual business logic of the NS is operated by the SP; we assume that MNOs do not provide mobile services because their core business is the provision of wireless communication capacity. It is also assumed that the standard for wireless data transmission provides encryption so the data exchange between MWT and MNO can be considered as secure.

We denote the result of a message m encrypted with the public key of participant a by $[m]_a$. X is the configuration of an order along with the personal context information, SID is a randomly chosen identifier, and ad the user's end address. If the MNO has to provide context information, this is mentioned in Z (e.g., location information if the MWT has no GPS receiver attached) and thus the MNO has to provide the location information. The responsible service provider is specified by i , the public key $SP(i)$ is included in the service description file. The client application on the MWT sends an order (or update of an order) in the following form to the MNO:

$$i, Z, [X, SID, [ad]_{MNO}]_{SP(i)}$$

The MNO (he or she cannot decrypt X) evaluates Z (fills in requested values) and forwards this message to the responsible SP. The SP obtains X and SID by decryption with his or her private key and creates an order instance (if SID is hitherto unknown) or updates the instance with identifier SID . If an order instance has to dispatch a notification message Y to the end user, the SP sends $Y, [ad]_{MNO}$ to the MNO. He or she can decipher ad and thus knows to whom he or she must send the notification message Y . Not all notification channels like SMS/MMS or WAP-Push allow encryption, so the MNO who has to dispatch the notification will see Y in clear text and maybe can draw conclusions about the order. If the notification channel allows symmetric encryption, Y can be decrypted with a symmetric algorithm and a key derived from SID since the MNO cannot read SID .

SUMMARY

We introduced generalized notification services (NSs), a class of services suitable for scenarios with mobile and wireless terminals. Several examples from different fields of applications were mentioned to show that despite their simplicity, NSs are versatile. A protocol was sketched which helps to guarantee privacy.

Based on the precise description of NSs given in this article, a software framework could be designed. Frameworks represent generic applications of a specific domain and help to develop applications of that domain with reduced effort.

KEY TERMS

Context: Information deliberately used to support a user during his interaction with an application or service; must be available at runtime in explicit form.

Mobile Payment: Procedure where at least the payer uses a mobile and wireless terminal to process a payment.

Mobile Service: A set of functionalities offered by a fixed computer (server) to mobile and wireless terminals (client), whereas the mobile client uses wireless data transmission to communicate with the server.

Notification Services: Class of mobile services where the user receives notification messages in push mode based on a manual configuration and provision of personal context information.

Order: Configured instance of notification services.

Push Message: A message sent to a user which is perceived as not being directly requested. The opposite is “pull message.” Push messages are essential for notifications concerning time-critical events, but also bear the risk of being annoying.

Sequence Diagram: One of the diagrams of the Unified Modeling Language (UML) which depicts the temporal order of the messages exchanged between a system's components.

An Ontology-Based Approach for Mobile Agents' Context Awareness

Nejla Amara-Hachmi

University of Paris 13, France

Amal El Fallah-Seghrouchni

University of Paris 6, France

INTRODUCTION

Mobile agents are software agents that can travel among computers under their own control. They can be applied with significant advantages in many domains like network management, information filtering, and electronic commerce. They are especially attractive for performing complex, tedious, or repetitive tasks in open and dynamic systems (Fugetta, Picco, & Vigna, 1998).

Nowadays, mobile agents' applications have to operate within environments having continuously changing execution conditions that are not easily predictable. They have to dynamically adapt to changes in their environment resulting from others' activities and resources variation. To survive, mobile agents have to be aware of their execution context and to have flexible architecture enabling them to envisage an adaptation easily. To do so, it is necessary to have an architecture with two clearly decoupled parts: the mobile agent functional compounds and those ensuring the context handling.

In a previous work (Amara-Hachmi & El Fallah-Seghrouchni, 2004), we proposed a component-based generic adaptive mobile agent (GAMA) architecture that exhibits a minimal mobile agent behavior. In this article, we will focus on GAMA's awareness of their execution context. Thus, we propose a formal model of context to be used in a semantic approach for checking agents' compatibility with new execution contexts.

The remainder of this article starts with definitions of context and context-awareness for GAMA mobile agents. We then introduce our context model and detail the proposed approach, before concluding the article.

MOBILE AGENTS: CONTEXT AND CONTEXT-AWARENESS

Definitions

As stated in Dey (2001), context consists of "any information that can be used to characterize the situation of an entity" where an entity is "is a person, place, or object that is considered relevant to the interaction between a user and

an application, including the user and applications themselves." This definition stresses the relation between the system, the context, and the user. In our work, by context we mean information about the current execution environment of the mobile agent, and we focus rather on how the context influences the agent behavior when executing its assigned tasks. This can be illustrated by a failure of the agent execution process if it moves to a host where the context attributes do not fit the agent's requirements. According to these considerations, we propose a definition of the GAMA agents' context-awareness as follows:

Definition 1. A mobile agent GAMA can be context-aware if it is able to detect contextual situations that affect its behavior aiming to achieve its tasks.

According to these definitions, developing context-aware mobile agents requires facilities for recognizing and representing context in order to enable agents to reason on it and make decisions about their execution process (adapt, inform the user, etc.). For GAMA agents, sensing and structuring context information is performed at the hosting platforms. Every interaction between agents and the operating systems (of computers and the network) as well as those between agents and their owners (human users) are achieved by the platform.

The Context Elements

To describe the agents' context, we identify three specific context levels: physical context, social context, and user context. Physical context refers to physical devices the mobile agent is running on, for example, the host's processing power and the network bandwidth. This information is sensed using different probes installed on each operating system. Social context refers to the local multi-agent system (deployed on the platform) with whom the incoming agent has to interact. For instance, information about this context includes the local interaction and coordination protocols. User context refers to the agent's owner preferences, such as restrictions about the exchanged files' size or type, the display quality, and so forth. The user expresses his or her preferences through the platform graphical user interface.

How To Achieve Context-Awareness

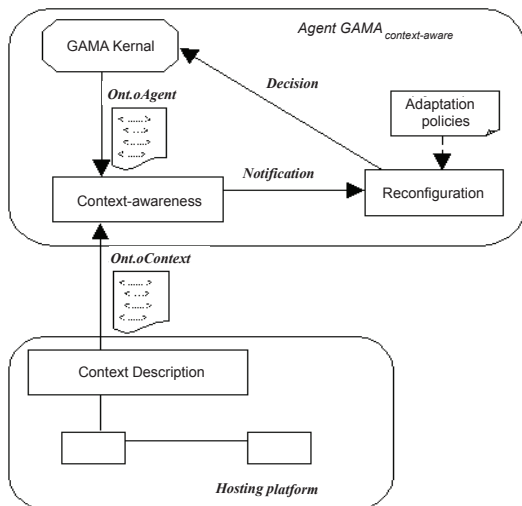

Developing context-aware mobile agents needs capacities to:

1. Capture of the contextual parameters by the means of some physical sensors, graphic interfaces, and the deployment platform. Currently, this step is outside the focus of our work.
2. Model the context by providing formal models of the rough contextual parameters in order to be available for use by the agents.
3. Reason on the context model in order to be aware of it. The reasoning will enable the mobile agent to check if it is able, using its current configuration, to achieve its goals in the new contextual situation to which it moves.

The result of this process is a notification that enables the agent to make a decision about the behavior to adopt in the new context: adapt itself to continue its execution, or alert the user if the adaptation is not possible. Thus, the agent needs not only a model of its context entities, but also a comparable model of its own components. Mapping these models onto one another allows checking their compatibility degrees.

Assuming these requirements, we propose to extend the GAMA architecture with a new component called 'context-awareness'. This component processes the context model provided by the component 'context description' of the platform, and the agent model provided by the component agent profile of the agent. The GAMA architecture is baptized from now up to $GAMA_{\text{context-aware}}$ (see Figure 1).

Figure 1. From GAMA to $GAMA_{\text{context-aware}}$

ONTOLOGY-BASED CONTEXT MODEL

To model context, a number of formal and informal approaches exist. We quote specially attribute-value tuples (Dey, Salber, & Abowd, 2001), entity-relationship models (Henricksen, Indulska, & Rakotonirainy, 2002), and first-order predicates (Ranganathan & Campbell, 2003). These representations have the advantage of addressing a certain level of context reasoning, but they offer a weak support for knowledge sharing and are deprived of semantic.

In our work, we need a context representation that: (1) can define common vocabularies to be shared by different agents, and (2) provides a context description at a semantic level in order to enable agents to reason on it. Ontologies seem to be a reasonable solution that meets these requirements. Thus, we propose to develop two distinct ontologies: the first models the context entities *OntoContext*, the second represents the agent components *OntoAgent*. These application ontologies are built using the Web Ontology Language OWL, the latest standard of the Web-Ontology Working Group.

A Uniform Frame for Ontologies

If we consider the scenario of a coordinating GAMA mobile agent, an example of contextual attributes that influence its execution process is the type of the negotiation protocol used by the multi-agent system hosted at the visited platforms. The agent must be able to check if it uses the same type of protocol by comparing the parts of two ontologies, *OntoAgent* and *OntoContext*, describing the used protocols.

Thus, in these ontologies, the components providing the negotiation features (of the agent and the hosting platform) must be modeled in a uniform way in order to be able to test their compatibility. Indeed, we consider that compatibility between the agent and its context is ensured whenever the agent's required services (respectively, provided) are provided (respectively, required) by its context. That is why we need a generic and uniform representation of the different agent components and the context entities. Genericity is motivated by the need to model all the entities whatever their origin, and the uniformity aims at facilitating the process of mapping the ontologies.

Representing Entities

Within our working ontologies, we propose to model each component of the agent and each entity of its context by a concept (class, in OWL). These concepts have properties (in OWL, *DatatypeProperty*) that represent their general characteristics such as the identifier and whether the entity is replaceable or not (in the case of the agent components). Thus, we propose to define a generic concept, #ENTITY, having common properties of the agent components and

the context entities. Thereafter, each concept modeling a component in *OntoAgent* or an entity in *OntoContext* will be a subclass of the concept # ENTITY.

An additional requirement mentioned when we defined the GAMA agent's context-awareness was the need to verify if the agent shares with its context common knowledge of the world at a semantic level. The idea is to match only parts of the two ontologies that are semantically close. Therefore, we propose to associate to each entity in the application ontologies a reference to a kind of "mediator" that represents information characterizing a particular domain. This mediator, represented by a taxonomy, plays the role of a domain ontology, and it is used as reference for the semantics of the application ontologies concepts. Taxonomy is a set of hierarchical concepts connected with is-a relationships. It can be represented by an acyclic directed graph, where the concepts are represented by the nodes of the graph connected by directed *is-a* edges. In our work, we use a taxonomy of reference per domain such as the FIPA coordination protocols taxonomy. Considering this, we assign to the concept #ENTITY a new datatype property *Taxo_ref* with an *xsd:string* range.

Finally, the generic concept # ENTITY will have the following datatype properties:

- **E_Id (range xsd:string):** Indicates the identifier of the modeled entity;
- **Is_replaceable (range xsd:Boolean):** Allows, when an adaptation of the agent structure is considered, to know if the modeled component can be replaced by another; and
- **Taxo_ref (range xsd:string):** Indicates the taxonomy to which the concept refers.

Representing Attributes

In addition to these properties, each component in the agent (or entity of the context) has a set of provided and required services. In the case of *OntoContext*, the values of these services represent the contextual attributes characterizing the agent execution context. The services of agent components correspond to their interfaces and can be classified as functional and operational. Functional services represent those produced and consumed by the component, while operational services are necessary to connect the component to its hosting architecture. This distinction of services is fundamental to the matching process aiming to test the agent and context compatibility.

To model these services, we define another generic concept #ATTRIBUTE having the following datatype properties:

- **At_Id (range xsd:string):** indicates the identifier of the service;

- **At_Type (range Any):** allows at the instantiation consideration of various datatypes such as string, date, integer, etc.;
- **Is_Prov (range xsd:bool):** indicates if the service is provided (at instantiation will have as value, true) or is required (value to false); and
- **Is_Func (range xsd:bool):** indicates if the attribute models a functional service (its value is true) or operational (its value is false).

Each service in *OntoAgent* and *OntoContext* will then be represented by a concept that is a subclass of the generic concept #ATTRIBUTE. These concepts modeling the services are connected to the concepts representing entities via *ObjectProperties*.

OntoAgent and OntoContext

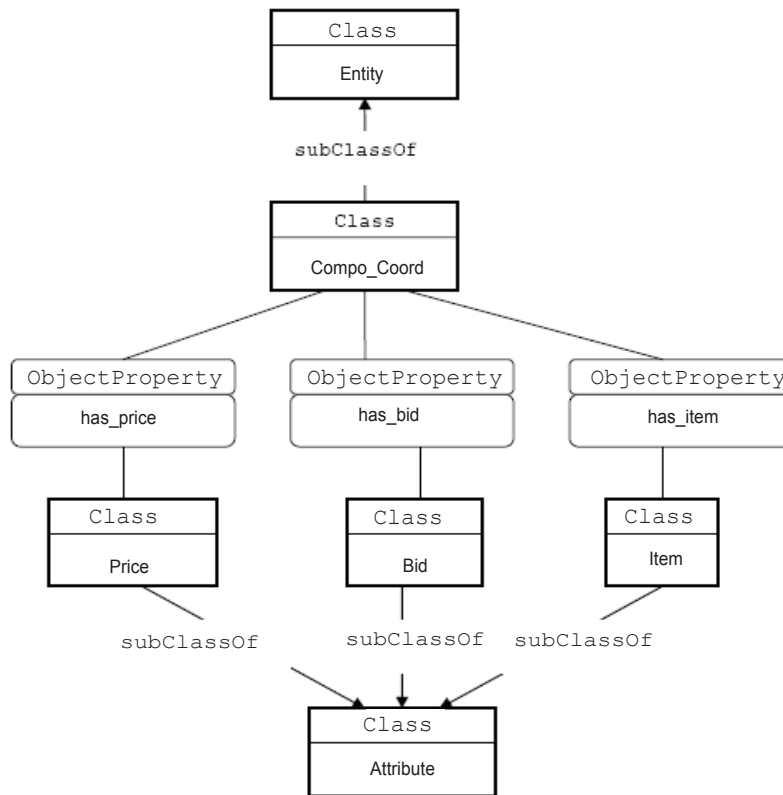

OntoContext is the context ontology. Its class definition begins with the class *Context* that represents an abstraction of the agent execution context. This class is on the top of the hierarchy of subclasses characterizing the agent context. *OntoContext* defines three subclasses of the *Context* class—*PhysicalContext*, *SocialContext*, and *UserContext*—in order to represent the several context aspects. Each one of these subclasses is related to a set of classes that characterize the correspondent context features. For example, the *PhysicalContext* class is related to the classes *ComputerMemory*, *ComputerCPU*, and *NetworkBandwidth* to express that the system level of the agent context can be described by the features of the current host, such as its memory size and CPU power, and the bandwidth of the used network.

OntoAgent is the agent profile ontology. Since a GAMA agent is built by assembling software components, its profile can be described by an ontology including descriptions of all its components. The top-level class of the *OntoAgent* ontology is *AgentProfile*, which represents an abstraction of information about the agent structure. It has several subclasses describing the different functional components of the agent and properties representing relations between these classes. For instance, the coordination component of a GAMA agent can be modeled using the introduced generic concepts as depicted in Figure 2.

SEMANTIC WEB TECHNIQUES FOR GAMA AGENTS' CONTEXT-AWARENESS

The third step in the GAMA agents' context-awareness process is the reasoning upon the context and the agent ontologies in order to check their compatibility on each visited host. The main rationale behind this reasoning is

Figure 2. Model of the agent coordination component

to first, map parts of *OntoAgent* and *OntoContext* that are semantically related, and check after that the compatibility of services required and advertised by the mobile agent and its context. To do so, we propose a two-step semantic approach based on a lightweight method for mapping ontologies and a matching algorithm of the mapped concepts.

In this section, we describe first the proposed semantic approach. Then we present the mapping method and the matching process.

Method

In this work, we assume that for being aware of its execution context, a GAMA agent must be able to answer the following questions: (1) Does it share with its context a common knowledge of the World at a semantic level? (2) Is it able to provide adequate services to interact correctly with its context? (3) Is it possible to meet, on the new visited context, the suitable services required for its execution? In a nutshell, a GAMA agent is expected to be able to “understand” new contexts that it visits and decide whether they are adapted for its execution.

To satisfy these desiderata, we propose a reasoning process to be held by the mobile agent component, called

“context-awareness.” The reasoning is triggered at each migration of the agent and takes as input instances of the ontologies *OntoContext* and *OntoAgent*. The output is a notification sent to another component responsible of making a decision concerning the following agent behavior. This notification aims to specify if the agent is able to correctly continue its execution on the host on which it arrives and otherwise to detail causes of their incompatibility. In this last case, the agent can envisage a dynamic reconfiguration of its structure in order to adapt to the new context.

To achieve the stated goal, we introduce a canonical reasoning process that uses the working ontologies to produce the desired notification. Processing ontologies consists first in mapping concepts’ modeling entities supposed to have semantic relationships. After that, computed concepts are analyzed in order to detect coherent ones. Finally, the resulting pairs of concepts are matched to check their compatibility.

Mapping Method: LiteMap

To map our ontologies, we are interested in 1:1 relations and will refer to existing mapping approaches that operate according to a common general process (Ehrig & Staab, 2004). Inputs are two ontologies O1 and O2, and the mapping tries

to seek for each concept of O1 the corresponding concept in O2 which has the same intended meaning. There are several techniques for mapping ontologies such as terminological, structural, or semantic techniques (Euzenat, Le Bach, Barasa, Bouquet, De Bo, Dieng, et al., 2004).

The method we propose, LiteMap (for Lite Mapping), accommodates this general mapping process to our problem, and combines semantic and syntactic approaches. However, we use a selection strategy making it possible to simplify and gain efficiency for mapping our ontologies. LiteMap is composed of two macro steps:

1. **Selection of Mapping Candidates:** In many mapping approaches, this step is costly and represents a major source of complexity. This is due to the number of concepts to compare in order to find eventual mapping candidates. Naïve mappings have to compare all concepts of O1 to all concepts of O2. Fortunately, a significant feature of our work is the use of reference taxonomies that ensures a shareable vision of the world to both mobile agents and hosting platforms. This consideration enables reducing considerably the number of concept pairs of *OntoAgent* and *OntoContext* that ought to be investigated. Indeed, we need to compare only concepts that are likely to have close semantics. Moreover, contrarily to usual mapping methods, this step is based on semantic relations holding between concepts and not labels. Our mapping candidates will then be pairs of concepts that have the same reference taxonomy. Let S be the set of mapping candidates:

$S = \{(A_i, C_j), i \in \{1..n\} \text{ and } j \in \{1..m\}\}$, where:

- A_i is a concept of *OntoAgent*.
- C_j is a concept of *OntoContext*.
- A_i and C_j have the same **Taxo_ref**.
- n is the number of *OntoAgent* concepts.
- m is the number of *OntoContext* concepts.

2. **Computing Relations:** When two concepts of *OntoAgent* and *OntoContext* are candidates for mapping, we then seek to explore the degree of their coherence at a semantic level. For that, we consider three types of semantic relations between two concepts: equivalence, subsumption, and mismatch. We then define semantic coherence as follows.

Two concepts $C1$ and $C2$ are semantically coherent (the relation is symmetrical) if in the same taxonomy of reference we have:

- $C1 \equiv C2$ when $C1$ and $C2$ are strictly equivalent, or
- $C1$ subsumes $C2$ when $C2$ is a direct son of $C1$ in taxonomy ($C1 \hat{=} C2$), or
- $C2$ subsumes $C1$ when $C1$ is a direct son of $C2$ in taxonomy ($C1 \hat{=} C2$).

We note $C1 \gg C2$ and consider that they mismatch in the other cases ($C1 \wedge C2$).

To compute these relations among the set S of candidate mapping concepts, we use syntactic comparison of concept labels. Indeed, to discover the binding relation R that holds between two mapping candidates concepts from *OntoAgent* and *OntoContext*, we have to compare labels of these concepts to labels of the reference taxonomy concepts. Label comparison is held by measuring linguistical closeness between concept labels. Various measures and metrics can be used to compute string similarities, such as Hamming distance, substring similarity, or N-gram distance. At this stage of work, we use naïve string equality. The output of this step is $S\text{-co}$, a subset of S composed of concept pairs that are semantically coherent:

$$S\text{-co} = \{(A_i, C_j) \text{ such as } (A_i, C_j) \in S$$

and

$$R \in \{\equiv, \hat{=}, \hat{=}\}$$

These concepts will be then used in a matching process to check the agent and context compatibility. However, pairs of concepts that mismatch are an immediate cause of incompatibility, thus the implied agent concept is added to the notification set.

Compatibility Test: The Matching Process

The main idea behind the compatibility test between a $GAMA_{\text{context-aware}}$ agent and its context is to conduct a matching process between their provided and requested services. Indeed, a key observation we already stated is that mobile agents have to respect the subsequent condition to ensure awareness about their context, provide adequate services to interact correctly with the visited host, and meet the suitable services required for its execution. We propose here a matching algorithm that strives to meet these requirements.

Let $\#E$ be a concept of *OntoAgent* or *OntoContext*. This concept will be a subclass of the generic concept $\#ENTITY$. Moreover, it is connected (by means of *ObjectProperties*) to a set of concepts $\#t_1, \dots, \#t_n$ that are subclasses of the generic concept $\#ATTRIBUTE$, representing services of the entity modeled by concept $\#E$. We note $T(E)$ the set of these concepts, $T(E) = \{t_1, \dots, t_p\}$ where p is the number of services of $\#E$. For each service t_p , we define the two following predicates:

- **is_func** (t_i), whose value is *true* if t_i is a functional attribute and *false* if t_i is operational.
- **is_prov** (t_i), whose value is *true* if t_i is a provided attribute and *false* if t_i is required.

By using these predicates, we can define the following sets:

- $Prov(E) = \{t_i \in T(E) \mid is_prov(t_i) = true, i \in \{1..p\}\}$ that represents the set of provided services of #E.
- $Req(E) = \{t_i \in T(E) \mid is_prov(t_i) = false, i \in \{1..p\}\}$ that represents the set of required services of #E.
- $Func(E) = \{t_i \in T(E) \mid is_func(t_i) = true, i \in \{1..p\}\}$ that represents the set of functional services of #E.
- $Opr(E) = \{t_i \in T(E) \mid is_func(t_i) = false, i \in \{1..p\}\}$ that represents the set of operational services of #E.

Using these sets we can define for *OntoAgent* and *OntoContext*:

- The set of functional provided services: $FP(E) = Func(E) \cap Prov(E)$.
- The set of functional required services $FR(E) = Func(E) \cap Req(E)$.

Considering these sets, we can now define semantic compatibility (*S-Compatibility*) between concepts. The key idea underlying this definition is to express that a concept A of *OntoAgent* is semantically compatible with a concept C of *OntoContext* when the services provided by A (respectively C) are used by C (respectively A).

Definition 2. Let A be a concept of *OntoAgent* and C a concept of *OntoContext*. We define the predicate *S-Compatibility* (A,C) having Boolean values as follows:

$S-Compatibility(A,C) = true$ if and only if $FP(A) \supseteq FR(C)$ and $FR(A) \supseteq FP(C)$.

Assuming this, we can precisely note required conditions for compatibility between an agent and its context. A $GAMA_{context-aware}$ agent is compatible with the visited context if the corresponding *OntoAgent* and *OntoContext* ensure the subsequent criteria:

For each concept pair $(A,C) \in S-co$, such as $A \in OntoAgent$ and $C \in OntoContext$, then $S-Compatibility(A,C) = true$.

CONCLUSION

In this article we proposed an approach to address mobile agents' context-awareness using techniques derived from the semantic Web domain. To validate it, we proposed a prototype of a GAMA mobile agent and a hosting platform simulating a pervasive execution environment, implemented with Enterprise Java Beans of Sun. We also have edited the ontologies *OntoContext* and *OntoAgent* using Protégé2000

(<http://protege.stanford.edu/>), an open source ontology editor and knowledge-base framework. We are actually testing the developed prototype with a use case concerning assistant agents in virtual libraries.

KEY TERMS

Component: Component-based software engineering is a product of the natural evolution of object-oriented languages with assembly capabilities beyond inheritance. While objects are expressed on the language level, components are expressed principally by exploring their public interface and promoting black box reuse.

Context: Consists of any information that can be used to characterize the situation of an entity where an entity is a person, place, or object that is considered relevant to the

interaction between a user and an application, including the user and applications themselves.

Mapping: Two ontologies O1 and O2 try to seek for each concept of O1 the corresponding concept in O2 which has the same intended meaning.

Mobile Agent: Software agent that can travel among computers under its own control.

Ontology: A data model that represents a domain and is used to reason about the objects in that domain and the relations between them.

Taxonomy: A hierarchical taxonomy is a tree structure of classifications for a given set of objects.

An Optimal Timer for Push to Talk Controller

Muhammad Tanvir Alam
Bond University, Australia

INTRODUCTION

The push-to-talk over cellular (PoC) application allows point-to-point or point-to-multipoint voice communication between mobile network users (Balaz, 2004). The communication is strictly unidirectional, where at any point of time only one of the participants may talk (talker), and all other participants are listeners. In order to get the right to speak, listeners must first push a “talk” button on their mobile terminals. Floor control mechanisms ensure that the “right to speak” is arbitrated correctly between participants. The PoC application may become a highly popular service for the mobile telecommunications market if its responsiveness and voice quality meet end-user expectations. In the autumn of 2003, Ericsson, Motorola, Nokia, and Siemens submitted their jointly defined PoC specifications to the Open Mobile Alliance (OMA, 2005) to facilitate multi-vendor interoperability for push-to-talk products. The specification is based on the Third Generation Partnership Project’s (3GPP’s) IP Multimedia Subsystem (IMS) architecture (3GPP, 2005); PoC is to bring the first commercial implementations of the IMS architecture into mobile networks. A discussion on strategic actions related to standardization, system architecture, and service diffusion of PoC has been discussed by Vehmas and Luukkainen (2005). An exploratory study of college-age students using two-way PoC cellular radios has been shown by Woodruff and Aoki (2003).

One wireless carrier, Nextel Communications (2002), provides mobile phones with conventional features such as voice telephony and voicemail; the same network and handsets also support a two-way, push-to-talk service called Direct Connect™. This service is very popular, having 10 million subscribers and supporting nearly 50 billion Direct Connect calls in 2001, predominantly for business use (according to a report of Nextel Communications, 2002). Competitors are attempting to introduce similar services based on packet (IP) networking; the top four U.S. carriers have all announced plans for similar services in the very near future, and separate service providers such as fast-mobile (www.fastmobile.com) are also appearing, particularly in Europe.

“Equally important is the fact that push-to-talk is a forerunner to peer-to-peer services over IP, for which IMS provides the capabilities and foundation. PoC is the first commercial application based on IMS” (Northstream, 2004). The driving forces behind the operators’ push-to-talk initiatives are the search for new revenue opportunities and finding

ways to increase subscriber acquisition and reduce churn. In this article, we depict some of the potential problem areas of a PoC server and provide an analytic model to ameliorate dimensioning of a PoC controller.

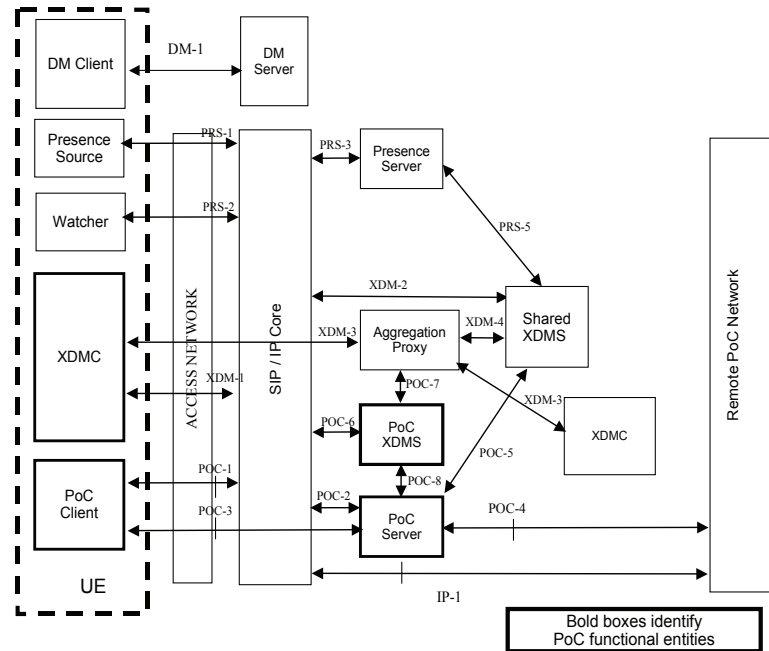

BACKGROUND

PoC is a warm topic today for the researchers. An architecture for enabling PoC services in 3GPP networks has been furnished by Raktale (2005). Similar work is reported by Parthasarathy (2005). The design of a PoC service operated over a GPRS/UMTS (general packet radio service/universal mobile telecommunications system) network is also depicted by Kim, Balazs, Broek, Kieselmann, and Bohm (2005). The basic architecture of PoC is provided in Figure 1. The common terms related to PoC have been furnished in the Key Terms section. The PoC server implements the application-level network functionality for the PoC service. It performs a controlling PoC function and/or participating PoC function (OMA, 2005). The controlling PoC function and participating PoC function are different roles of the PoC server.

The determination of the PoC server role (controlling PoC function and participating PoC function) takes place during the PoC session setup and lasts for the duration of the whole PoC session. In case of *1-1 PoC session* and *ad-hoc PoC group session*, the PoC server of the inviting *user* performs the controlling PoC function. In case of the *chat PoC group* and *pre-arranged group session*, the PoC server owning/hosting the *group identity* performs the controlling PoC function. The PoC server performing the controlling PoC function has N number of SIP (session initiation protocol) sessions and media and talk burst control communication paths in one PoC session, where N is number of participants in the PoC session. The PoC server performing the controlling PoC function will have no direct communication to the PoC client for PoC session signaling, but will interact with the PoC client via the PoC server performing the participating functioning for the PoC client.

The PoC server performing the controlling PoC function normally also routes media and media-related signaling such as talk burst control messages to the PoC client via the PoC server performing the participating PoC functioning for the PoC client. However, local policy in the PoC server performing the participating PoC function may allow the PoC server performing the controlling PoC function to have

Figure 1. PoC architecture (OMA, 2005)

a direct communication path for media and media-related signaling to each PoC client. A PoC server performing the participating PoC function always has a direct communication path with a PoC client and a direct communication path with the PoC server performing the controlling PoC function for PoC session signaling.

The basic challenges that affect the end-to-end service performance for PoC are:

1. network configuration and *dimensioning*;
2. timer settings in terminals and networks;
3. traffic handling priorities used; and
4. service option choices such as early media session establishment.

In this short article, we focus on the issue of *optimized lifetime* of a session provided by the PoC controller. The lifetime of a session is crucial since the server capacity is always fixed. Thus, the lifetime of a session must be set carefully based on the available resources, number of clients willing to talk, network topology, and so forth.

PROPOSED OPTIMAL TIME

Dimensioning and optimizing networks is a mature topic today (Ghaderi & Boutaba, 2006; Vacirca, Vendicits, & Baiocchi, 2006). An optimal design for a multi-rate ATM

loss network is provided by Mitra, Morrison, and Ramakrishnan (1996). We use the square root dimensioning method to compute the optimized timeframe for a session of PoC controller. The mechanism is based on the mean service rate of the controller, number of current sessions, and the controller capacity. Let, T_i be the average session time encountered by a job i and C_i the capacity allotted for session i . Also, let λ , λ_p , and μ be the total PoC session arrival rate, arrival rate of specific session PoC i , and mean service rate of PoC sessions respectively.

If the stability condition $\lambda_i < \mu C_i$ for $i=1,2,\dots,N$ holds, then:

$$T_i = \frac{1}{\mu C_i - \lambda_i} \quad \forall i = 1, 2, \dots, N \quad (1)$$

Thus the average PoC session time of a PoC messages

i is (assuming $\rho_i = \frac{\lambda_i}{\mu}$):

$$T_i = \sum_{i=1}^N \frac{\lambda_i}{\lambda} \left(\frac{1}{\mu C_i - \lambda_i} \right) = \frac{1}{\lambda} \sum_{i=1}^N \frac{\rho_i}{C_i - \rho_i} \quad (2)$$

The stability condition now reads $\rho_i < C_i$ for $i=1,\dots,N$. Therefore, our threshold timeframe problem reduces to:

Optimize: T_i
 With respect to: $\{C_i\}_{i=1}^N$

Under the constraint: $D = \sum_{i=1}^N C_i$

Where, D is the total capacity of the PoC controller.

Applying the Lagrange multiplier technique, we define:

$$f(C_1, \dots, C_N) = \frac{1}{\lambda} \sum_{i=1}^N \frac{\rho_i}{C_i - \rho_i} + \beta \left(\sum_{i=1}^N C_i - D \right). \quad (3)$$

Solving the equation $\nabla f(C_1, \dots, C_N) / \nabla C_i = 0$ for every $i=1, 2, \dots, N$; we obtain:

$$C_i = \rho_i + \sqrt{\frac{\rho_i}{\lambda \beta}} \quad i=1, 2, \dots, N. \quad (4)$$

From the constraint $\sum_{i=1}^N C_i = D$ and equation (4) we get:

$$\frac{1}{\sqrt{\lambda \beta}} = \frac{D - \sum_{i=1}^N \rho_i}{\sum_{i=1}^N \sqrt{\rho_i}} \quad (5)$$

Introducing the value of equation (5) into equation (4) yields:

$$C_i = \rho_i + \frac{\sqrt{\rho_i}}{\sum_{i=1}^N \sqrt{\rho_i}} \left(D - \sum_{i=1}^N \rho_i \right) \quad (6)$$

Therefore the optimized timeframe of a PoC session i becomes:

$$T_{opt} = \frac{\sum_{i=1}^N \rho_i}{\lambda \left(D - \sum_{i=1}^N \rho_i \right)} \quad (7)$$

Equation (7) may be used by the PoC controller during heavy traffic to optimize a session. The parameters of the equation will be adjusted accordingly. After the optimized lifetime, a session will be disconnected by the PoC controller.

FUTURE TRENDS

The PoC service has yet to undergo further refinement to overcome all of its shortcomings. A new algorithm for ef-

ficient dimensioning is required to reduce congestion in the network. If PoC is to carry real-time data over packet switching networks, the Internet standard protocol real-time protocol (RTP) can be used. In that case, low latency and in-sequence delivery need to be guaranteed by some algorithm that would synchronize the clock that timestamps the packets. The PoC signaling in circuit-switched networks is limited to SMS (short messaging service) only. In order to use SMS for push-to-talk, signaling will increase the server load and consume more resources. Thus to use SMS capacity for PoC signaling is expensive, as the traditional use brings direct revenues that are now used for PoC. The cost for this signaling should be compared to the price of sending SMS messages for the end user.

The voice quality, presence functionality, and so forth need to be tested under GSM (global system for mobile communications), GPRS (general packet radio service), and EGPRS (enhanced GPRS) technologies. The different codec facilities—for instance, AMR (adaptive multi-rate voice codec), EFR (enhanced full rate), and so forth—are to be studied both in error-free and error-prone states.

New models could be derived based on the cost incurred by the radio access network to implement PoC service. Some necessary cost items are radio network planning activities, transition network, core network planning, number of application servers used, service integration, and marketing activities. Efficient scheduling is always preferable below the MAC (media access control) layer for the PoC sessions to share the timeslots of the server. The future releases of the OMA should refer to the abovementioned areas at least.

CONCLUSION

This research depicts a potential approach to set the timer for a PoC controller. The mechanism can be used in the similar states for the PoC controller for instance, setting an optimized lifetime for dropping a queued message from the server, setting timer for a session to enter idle state from ready state, and so on. Today, major operators are currently evaluating push-to-talk, and a lot of them have some PoC trials with a number of different vendors. Motorola developed its iDen technology with PoC functionality more than a decade back. Ericsson, Motorola, Siemens, and SonyEricsson announced plans for joint interoperability testing for their PoC products. The major handset manufacturers are all active in the area of push-to-talk. Several agreements between PoC vendors and handset manufacturers have been announced already. Clearly, more commercial PoC launchers are underway, and researchers are up to the task of shaping the service further.

KEY TERMS

Application Server: In 3GPP IMS, a functional entity that implements the service logic for SIP (session initiation protocol) sessions.

Controlling PoC Function: Implemented in a PoC Server and provides centralized PoC session handling, which includes RTP media distribution, talk burst control, policy enforcement for participation in group sessions, and the participant information.

Group: A predefined set of PoC users identified by a SIP URI. A PoC client uses the group to establish PoC sessions and to define PoC session access policy.

Home PoC Server: The PoC server owned by service provider that provides PoC service to the user.

On-Demand Session: A PoC session set-up mechanism in which all media parameters are negotiated at PoC session establishment.

Participating PoC Function: Implemented in a PoC Server and provides PoC session handling, which includes policy enforcement for incoming PoC sessions and relays talk burst control messages between the PoC client and the PoC server performing the controlling PoC function. The participating PoC function may also relay RTP media between the PoC client and the PoC server performing the controlling PoC function.

PoC Session Identifier: An identifier in the user plane associated with a PoC session that uniquely distinguishes a particular PoC session from all other PoC sessions, including those that currently exist and those that do not.

Simultaneous PoC Session: When a PoC user is a participant in more than one PoC session simultaneously using the same PoC client.

Talk Burst Control: A control mechanism that arbitrates requests from the PoC clients for the right to send media.

Talk Burst Control Protocol: A protocol for performing talk burst control and defined in these specifications.

User Equipment (UE): A hardware device that supports a PoC client (e.g., a wireless phone).

XML Document Management Client (XDMC): An XML configuration access protocol client which manages XML documents stored in the network (e.g., PoC-specific documents in the PoC XDMS, URI lists used as contact lists in the shared XDMS, etc). Management features include operations such as create, modify, retrieve, and delete. The

XDMC is also able to subscribe to changes made to XML documents stored in the network, such that it will receive notifications when those documents change. The XDMC can be implemented in a UE or fixed terminal.

Optimal Utilisation of Future Wireless Resources

INTRODUCTION

Radio resource management (RRM) is one of the most challenging and one of the most important aspects in the provisioning of quality of service (QoS) for wireless communication systems. Conceptually RRM policies, in tandem with network planning and air interface design, determine QoS performance at the individual user level and also at the network level and hence significantly improve system performance. For the past decade, the confluence of users' demand for personal and technological advances in communication systems has led to a phenomenal explosion and deployment of mobile wireless systems, and at the turn of this century we have been preparing ourselves for future mobile communication systems. Technological buzzwords such as fixed-mobile convergence (UMA, 2006), Wi-Fi (Wi-Fi Alliance, 2006), WiMAX (WiMAX Forum, 2006), 3G evolutions (Thelander, 2005), and Mobile-Fi (IEEE 802.20, 2006), together with the advancement of broadband multimedia services, are poised to permeate into every fabric of our society, taking flight into every possible imagination of mobile users. Hence, in such a rapidly evolving and expanding environment, resource management remains a central issue in the very near and distant future.

With the ever increasing size of the wireless mobile community and its demand for high-speed multimedia communications, efficient resource management becomes a paramount importance due to limited resources available, such as spectrum or bandwidth allocation and power availability. The objective of utilising RRM techniques is of course to maximise the performance of network throughput or total resource utilisation while satisfying the wireless users' or service providers' requirements. From the users' point of view, they want to maximise services, such as getting maximum throughput, lowest block and drop rate. On the other hand, from the service providers' viewpoint, they want to maximise revenue; to serve the maximum number of users as possible at a given time. Meanwhile, the service providers would also

hope to minimise capital and operational expenditure, for example, deployment of base stations and backhaul links. Hence this article will address the issues of RRM problems in future wireless and mobile networks.

Given the fact that both broadband multimedia services and wireless services are the twin engines driving the future growth of telecommunication industry, current RRM techniques are certainly inadequate to face future demands from the wireless community. Hence, there is a need to reform current technologies and invent newer ones so that end-to-end QoS in future wireless mobile systems can be addressed. In the following sections we shall look into certain aspects of RRM schemes that address the provisioning of QoS in future mobile wireless communications.

FUTURE MOBILE COMMUNICATION SYSTEMS

In the context of future networks it is expected that:

- The system is capable of supporting high data rates and users are able to connect to the best network as long as the terminal power is switched on and experience minimal access delay.
- Providing services comparable to wired networks for applications such as interactive multimedia, voice over internet protocol (VoIP), network games, video conferencing, and so forth.
- Providing multi-service ubiquitously and pervasively in diverse environments from indoor, outdoor (low and high velocity), and to global broadband access (satellite).
- Deployment over heterogeneous environments of various access networks.
- Users are always connected to the most efficient and available access networks catering to their specific QoS and mobility requirements.

- The system would be an integral part of Internet infrastructure (based on Internet protocol (IP) technology).

Of course the above key attributes need significant high spectral efficiency and can only be achieved via innovative techniques in air interface design and by implementing coverage enhancement techniques in which current systems might not be able to support fully. Future wireless systems will be expected to comprise multitudes of wireless air interfaces, such as WLAN, 3G cellular, beyond 3G or 4G cellular, peer-to-peer (P2P), multihop relays, and so forth, where different ranges of cell or coverage size are being supported within an integrated wireless access umbrella.

Within the context of cellular systems such a trend is already in place where the former is working seamlessly with WLAN (IEEE 802.11, 1999) to provide ubiquitous and pervasive access to mobile users. As future networks will evolve into an ever integrating environment, the concept of “optimised connectivity,” whereby maximising user experience while minimising radio operator resources, will be the main feature of such an architecture. To exploit the increased capabilities and potentialities of the systems, efficient resource management strategies in key aspects of the evolution need to be taken into consideration. In the next section we will discuss some of the areas in RRM that need to be addressed for providing users with varying QoS requirements.

RESOURCE MANAGEMENT IN FUTURE SYSTEMS

Given the proliferation of Internet and IP technology, which move in parallel with the advancement of mobile communication systems, eventually more and more IP will be adopted in beyond 3G wireless technologies. Future mobility service networks will be Internet-oriented and peer-to-peer architecture with no central mobile switching centre. Hence, we envision that almost all applications in future will be functionally dependent on IP. The main reason for integrating IP with a communication system is that both technologies can enhance heterogeneous support and interoperability of lower-layer technologies, that is, to continue building a network of networks. Since the QoS over IP-based applications is inherently unreliable, here we will look into the additional measures to support existing RRM schemes, which are crucial for providing QoS in such future wireless networks.

QoS Provisioning in IP Networks

To support the provisioning of QoS in an IP-based wireless communication system, the Internet Engineering Task Force

(IETF, 2006) has proposed techniques such as reservation protocol (RSVP), integrated services protocol (IntServ) and differentiated services protocol (DiffServ) for QoS provisioning in IP networks. However, these models have been designed to work for wired networks in static environments and the aim now is to identify modifications to make them suitable for wireless networks. As mobility is becoming more and more popular on a daily basis, modifications to the IntServ and DiffServ models for use with wireless networks are discussed in length in Johnson et al. (2004), Kan et al. (2001), Lopez et al. (2001) and Moon et al. (2004). In addition the IETF Working Group is also aiming to provide seamless mobility across access routers and even domains, and the MIND project funded by the European Commission is also studying open IP-based mobile wireless network architecture to allow inter-operability between networks.

Traffic Control

Traffic control encompasses the application of scientific principles and technology in planning of network capacity under QoS guarantee and efficient transferring of information. The need to allocate and balance resources among different traffic classes to accomplish the best use of network resources is a crucial traffic engineering problem. The major objective of such a problem is to improve network performance while maintaining the QoS requirements through the optimisation of network resources. In order to support end-to-end QoS resources, such as bandwidth, scheduling time and buffer-space, more research needs to look into Internet traffic management schemes.

Presently traffic is usually routed on the shortest path through a network for both “best-effort service” and “guaranteed service.” This is the case even if the shortest path is overloaded and there exist alternative paths that are underutilised. Hence, efficient optimisation techniques can be applied to IP networks in order to better utilise network resources and to avoid congestion by balancing load over several paths (Gunnar et al., 2005). In the context of treating the dynamics of Internet traffic management such as call admission control, self learning techniques (Gallador et al., 2001) could be used for identifying future traffic trends. Such techniques usually correlate current traffic variations of a given parameter to previous records of the parameter, and then predict favourable scenarios for transmission ahead of time.

Spectrum Management

In the future, we envisage spectrum will become an increasingly scarce resource and will force many operators to build unnecessary and expensive infrastructure with many base stations. Moreover, growing wireless users will only aggravate this problem, and hence spectrum shortage will have

the potential to inhibit future growth. Provided governments allocate abundant spectrum to the wireless industry or to unlicensed bands for free use, growth will be slowed. Another way to reduce the problem is to develop new technology, enabling a more efficient use of the existing spectrum.

In the context of spectrum efficiency, several bandwidth partitioning strategies (Iraqi et al., 2000) have been designed to allocate bandwidth “fairly” for different traffic classes. Among them are complete sharing (CS) and complete partitioning (CP) (also known as mutually restricted access or MRA) strategies, and those in between are known as hybrid strategies. In CS schemes, all traffic classes share the entire bandwidth, with the Achilles heel being that a temporary overload of one traffic class would immediately offset and degrade the connection quality of all other traffic classes. As for CP techniques, the bandwidth is partitioned into different portions with each portion catering to a particular class of traffic. However such a technique is not economical feasible if the actual bandwidth demand for a particular traffic class is greater than the predicted bandwidth demand. As a compromise the hybrid CS-CP techniques have been proposed in which the bandwidth can be allocated dynamically to match the varying traffic classes. Nevertheless, finding the optimal partitioning point is not easy since the model is an NP-complete graph colouring problem, and hence only heuristic solutions on homogenous traffic have been proposed (Habib, 1997). In the future the bandwidth allocation problem is becoming even more complex, when wireless multimedia networks would then carry an integrated non-homogenous traffic in a mobile environment and, as such, new techniques have to be discovered to use the radio spectrum efficiently.

As radio spectrum is considered a public resource, an alternate method for government is to introduce spectrum trading (Hills et al., 2004) instead of licensing it to network operators for a certain amount of money. Since spectrum trading would inevitably involve monetary exchange, it can then increase market awareness of prevailing spectrum value. Hence market players can use this information to determine whether they are utilising the spectrum efficiently, whilst government appointed regulators may use prevailing market prices to assess whether spectrum allocations are indeed optimally being used. However, spectrum trading also introduces a host of uncertainties, the most critical of which is political. In the process of assigning spectrum rights, the government surrenders control of the spectrum to the market forces. This allows the possibility of a dominant player accumulating significant amounts of spectrum and therefore controlling the spectrum market.

Mobility Management

As more traffic in future wireless networks are expected to be mostly generated by multimedia applications, hence wireless

networks need to provide adequate support for multimedia services and support user mobility with extended geographic coverage. Unfortunately multimedia applications often require a dynamic amount of bandwidth and, to guarantee QoS for such bandwidth-greedy applications when used over a wireless link, current schemes for supporting such services have to be reviewed and new resource management solutions have to be proposed.

A critical aspect of guaranteeing QoS support in providing seamless access under changing radio resource conditions is handoff or handover between the mobile terminal and the network. As a result handoff is related to access, radio resources and network resources, and has a direct impact on system capacity and performance. Presently most of the handoff techniques (Iraqi et al., 2000; Periyalwal et al., 2003) attempt to anticipate handoffs by using measurements of signal strengths and prior knowledge of mobility patterns and, in essence, have not entirely addressed the QoS requirement end-to-end. It is anticipated that with the profusion of future support services in tandem with the integration of multiple access networks, further standardisation towards an optimal mobility handoff solution is needed for all levels of QoS.

Another critical aspect of mobility management problem is location discovery (Iraqi et al., 2000; Periyalwal et al., 2003), which stems from navigation to context-aware applications in ubiquitous computing. As expected, the location requirements vary across applications, resulting in the development of a host of diverse sets of technologies and algorithms. In cellular telephony systems, for example, knowledge of handset locations is primarily needed for routing calls to other mobile users. Such a location is found either by measuring the received signal strength transmitted by the base stations or by measuring the round-trip signal propagation time between a handset and a set of base stations. Although cell-level localisation is sufficient for routing calls to mobile handset users, future wireless network applications require more precise handset locations to enable RRM schemes to function optimally. Recent research techniques in this direction are described in length in Savides et al. (2004).

Power Control and Antenna Beamforming

The physical layer of all wireless networks embodies a number of parameters that can be controlled for improved performance. Such parameters include modulation, transmit power, spreading code and antenna beams. By controlling these transceiver parameters adaptively and in an intelligent manner, one can increase the capacity of the system tremendously. In this section we only consider two synergistic parameters—transmit power and antenna beamforming—as they are intuitively the easiest to exploit and perhaps the most studied. The benefits of antenna beamforming include

reduced interference due to narrower beamwidth, longer range due to higher signal to noise and interference ratio, and improved resistance to jamming. The benefits of power control on the other hand include reduced interference and lower energy consumption. In short, we envisage future techniques in interference mitigation in wireless networks would combine both power control and antenna beamforming to enable higher capacity due to increased spatial reuse, lower latency, better connectivity, longer battery lifetime, and better security (minimise eavesdropping). However, much work needs to be done in analysing the theoretical network capacity of using both power control and beamforming (Gupta et al., 2000). In addition, a thorough study of other physical layer parameters such as modulation, spreading codes and others can be exploited to be used in conjunction with power control and beamforming, so as to open up new research frontiers.

Channel Allocation and Routing Mechanism

One of the most common resource management issues faced by service providers is channel allocation, which involves frequency planning, channel reuse schemes and network capacity optimisation. Channel allocation on its own influences the network performance as it limits interference while maximising the system capacity. On the other hand, a routing algorithm's main objective is to secure a communication link between the source and the destination nodes. In the future Wi-Fi or WiMAX mesh networks scenario, sources and destinations nodes may not be within direct transmission range of each other, and hence routing algorithms must be able to discover multihop routes between the sources and destinations so that communication between these nodes is possible. Although there are many routing and channel allocation algorithms (Chiasserini et al., 2000; Chuang, 1993) for a variety of topological scenarios, not much study has been done to exploit both channel allocation and routing algorithms as a single entity to serve the needs of future wireless community. Of course it is unlikely that a single algorithm exploiting both routing and channel allocation can solve the needs of every conceivable future wireless network scenarios. Hence, certain algorithms will likely to perform well in networks having a set of key attributes while others will perform better in networks having a different set of key attributes. Such a problem indeed highlights the importance of identifying sets of characteristics of a network in order to maximise the efficiency of the class of algorithms concerned.

CONCLUSION

At the dawn of the new millennium we have witnessed a fantastic growth of mobile communications particularly at the access network level. With the ever integration of Internet access and multimedia services, more and more sophisticated resource management mechanisms are therefore needed to handle the large volume of heterogeneous traffic. In this article we have discussed some RRM issues that are paramount in providing ubiquitous and pervasive mobile broadband wireless access for the future wireless community. Of course there are many more challenging and open issues and we do not claim to have addressed them all. In addition, the popularity of mobile ad hoc wireless networks (Sim et al., 2006) is rapidly increasing and is soon to be a permanent fixture in wireless communication systems. As such it is envisioned that RRM schemes will receive more attention since the QoS provisioning is more challenging in ad hoc wireless networks due to their decentralised nature and lack of infrastructure. Hence, there will be further challenges of coping with uncertainty in wireless networks, such as time varying wireless links, user mobility, routing, traffic loads, security and so forth. It is hoped that future multimedia networking will reach to a point of having the capability of self-organising appropriate RRM schemes optimally to adapt to the required network environment and also to the type of multimedia traffic.

INTRODUCTION

Computing systems are playing an essential role as an indispensable nervous system of modern society. In recent years, peer-to-peer (P2P) computing has gained significant attention from both industry and research communities (Barkai, 2001). A key attraction of P2P systems is their ability to scale without requiring expensive and powerful servers, primarily because P2P systems work by distributing the functionality and harnessing the resources across a large number of independent peers. In addition to having high scalability, such systems are also inherently robust and fault tolerant since there is no centralized server, and the network is inherently self-organized. Today, P2P technology has been widely embraced by Internet users and has seen highly successful applications in such areas as digital data sharing, voice over peer-to-peer, distributed computing, and distributed storage (Miller, 2001). With the advent of wireless technology, the number of mobile users has increased tremendously over the years. It is envisioned that a significant portion of future users of P2P systems would be based on mobile ad-hoc networks (MANETs), which are dynamic networks formed by peers with no support of fixed infrastructure networks (Ramanathan & Redi, 2002; Perkins, 2001). As contemporary P2P models are designed mainly for the Internet, research is needed to examine their viability for P2P computing in a mobile environment.

This article first overviews some of the most common P2P architectures in use today by Internet users, and then proceeds to evaluate and discuss each of their architectural strengths and weakness for MANET through a qualitative complexity analysis.

INTERNET P2P MODELS

Internet P2P systems are a popular paradigm for data exchange in a decentralized manner between computer users across the Internet. A P2P network over the Internet is a highly dynamic overlay network where users join and leave the

network frequently. Numerous P2P systems that have been proposed for the Internet in recent years may be broadly classified into two categories: *unstructured* and *structured* (Lua, Crowcroft, Pias, Sharma, & Lim, 2005).

Unstructured P2P systems do not have tight control of the overlay topology. The network is typically formed by nodes in a random manner, and thus the object or data that one wishes to locate could be anywhere in the system. A query has to be flooded through the network to search for peers that store the desired object. Besides a high amount of signaling traffic, the search may be prematurely terminated if the object could not be found within the query lifetime, often specified in terms of number of hops.

Structured P2P systems, on the other hand, impose a certain structure on the overlay topology and control of data placement to enable more efficient and reliable location of objects in a bounded number of hops through the use of distributed hash table or DHT (Stoica et al., 2003). In DHT, every object is mapped to some peer. A description (key) containing a link (value) to where the object could be found is then stored at the peer to which the object is mapped. This forms a deterministic relationship between objects and peers, and consequently, the query need not be flooded but routed directly to the peer responsible for storing the object location.

Until recently, Internet P2P systems (including both unstructured and structured systems) assumed all peers are equal and uniform in resource capacity. System functionality is thus distributed without considering real-world heterogeneity of peer capabilities. For example, some peers have less memory and slower processor than others, but they perform the same role and responsibility as other peers with higher capabilities. This results in instances of bottlenecks in performance due to very limited resources of these peers. To account for and even exploit the heterogeneity of peer capabilities, the notion of *super peers*, or nodes more well provisioned in terms of resources, have recently been introduced and advocated (Yang & Garcia-Molina, 2003; Singh, Ramabhadran, Baboescu, & Snoeren, 2003). Super peers take on a greater role and responsibility by serving as local

search hubs that manage (receive and resolve) object queries of ordinary peers. Each super peer in turn communicates with other super peers as equals in a pure P2P way. As a result of clustering heterogeneous devices and elevating certain well-provisioned nodes to the role of super peers, the impact of performance bottlenecks presented by some less capable peers could be minimized.

P2P IN MANETs: A COMPLEXITY ANALYSIS

P2P systems for the Internet are designed with a decentralized architecture, which makes them potentially suited to the infrastructure-less MANET environment. However, as each overlay link could consist of multiple hops in the underlying physical network, a dynamic MANET topology due to peer mobility could pose significant problems for data management, particularly in structured P2P systems (Hsiao & King, 2005). The lower capacity of MANET compared to the Internet and the resource constraints of mobile devices further limit the usability of P2P architectures that have high traffic overhead.

This section provides a complexity analysis of the asymptotic cost and performance of three popular Internet P2P architectures—unstructured super peer, structured non-super peer, and structured super peer—in a mobile environment. The cost measure is the message complexity, or number of hop-wise message transmissions required to perform a specific operation such as node join, node leave, and object query. The performance measure is the time complexity or number of time steps needed to perform an operation.

Unstructured Super Peer

The popular file-sharing application Kazaa (Liang, Kumar, & Ross, 2005) and voice-over-IP (VoIP) client Skype (Baset, & Schulzrinne, 2006) are prominent examples of commercial-grade P2P systems based on unstructured super peer architecture. As these systems are originally designed for wired networks, as a first step, we need to imagine how such a system may be used in a mobile environment. For super peer-based architectures, we reason that the most natural choice of an underlying physical network would be a cluster-based MANET (Yu, & Chong, 2005), since the cluster-heads are ready candidates for super peers in the P2P system.

We assume each ordinary peer (mobile user) would know a super peer (cluster-head) through the underlying clustering mechanism. When a mobile user u wishes to join, it sends a *join* message to its super peer P with a list of objects it wishes to share, and records P as the super peer through which it joins the system. Upon receiving, P adds the object list of u into its index. When u wishes to leave, it sends a

leave message to its super peer. If the current super peer is not P due to node mobility—that is, u is now associated with a different super peer in another cluster—the super peer forwards the message to P . Upon receiving, P deletes the object list of u from its index. When u wishes to query for an object, it sends a *query* message to its super peer. If the super peer knows the object, it replies to u immediately with the object location. Otherwise, it broadcasts the query to other super peers (via cluster gateways). Assume from the reply, u knows that a mobile user v is holding the object. u then proceeds to contact and retrieve the object from v .

Having outlined the join, leave, and query operation of the unstructured super peer system in a MANET environment, we may now begin our analysis. Consider a network of n nodes, of which a fraction m (where $0 < m < 1$) are super peers. Thus, we have mn super peers and $(1-m)n$ ordinary peers. Let us denote n_s and n_o as the number of super peers and ordinary peers, respectively. If m is a constant, then n_s and n_o would increase in proportion to n . Under constant node density, n itself would increase in proportion to A , the network area—that is, $n \propto A$.

If the communication pattern is generally uniform, the average path length L or number of hops between any pair of nodes is expected to grow with the spatial diameter of the network, which in turn grows with the square root of the area, or equivalently \sqrt{n} (Li, Blake, Couto, Lee, & Morris, 2001). Similarly, we expect path length L_s between any pair of super peers, and path length L_o between any pair of ordinary peers, to grow with \sqrt{n} .

During a join, the *join* message from a mobile user to its super peer travels a path length of c , where c is a positive constant denoting the number of hops to a cluster head, which depends only on the clustering scheme used—that is, 1- or multi-hop clustering (Yu & Chong, 2005). The join process thus has a constant message and time complexity of $O(c)$. During a leave, the *leave* message travels under worst case a path length of $c+L_s$: mobile user \rightarrow its current super peer \rightarrow the super peer that originally hosts its object list, leading to a message and time complexity of $o(\sqrt{n})$ for the leave process.

The analysis for the query process is slightly more involved, thus we present for only the most common case of single-hop clustering: $c = 1$. First, consider a mobile user sending a *query* message to its super peer. If the super peer does not know the object, it broadcasts the query to other super peers. We denote a fraction q of the ordinary peers as gateways that rebroadcast the query to other super peers. If k is the fraction of super peers that reply with the object location, there would be kn_s replies and $(1-k)n_s$ rebroadcast queries by the super peers. Each reply would travel a path length of $L_s + 1$: replying super peer \rightarrow super peer of mobile user \rightarrow mobile user. Summing up, this gives a total message cost of:

$$1+q(1-m)n+(1-k)n_s+kn_s(\sqrt{n}+1) \quad (1)$$

Since n_s is a constant fraction of n , the message complexity of the query process would scale as $O(n^{3/2})$, while the corresponding time complexity would be in the order of $o(\sqrt{n})$.

Structured Non-Super Peer

Distributed lookup service Chord (Stoica et al., 2003) is a prominent example of a system with structured non-super peer architecture. For non-super peer-based architectures, which deem all peers as being equals, the most natural choice of an underlying physical network would be a non-hierarchical MANET. In the following, we outline the steps involved in the join, leave, and query processes of Chord.

We assume each peer knows its 1-hop neighbors, for example via a hello mechanism. When a mobile user u wishes to join, it sends a *join* message to a neighbor v that has already joined the system. Upon receiving, v helps u to find its immediate successor, which may take up to $\log n$ steps to complete, where n is the number of nodes in the network. Upon knowing its successor s , u informs s that it has a new predecessor, and s in turn transfers a portion of its keys (object tuples) to u . On the other hand, s 's original predecessor p becomes aware of u through a stabilize process, and proceeds to inform u that it is u 's predecessor. Having set up its successor and predecessor pointers correctly, u needs to build its finger (routing) table by sending up to $m-1$ discovery messages, where m is the number of table entries and s being in the first entry. u then begins to key-insert (publish) for each object it wishes to share, with each insertion taking up to $\log n$ steps to complete.

When u wishes to leave, it sends a *leave* message to its successor and predecessor. In the message to its successor, it also includes the keys it wishes to hand over. Before leaving, u performs a key-delete (withdraw) for each object it has shared, with each deletion taking up to $\log n$ steps to complete. When u wishes to query for an object, it sends a *query* message to a node in its finger table whose *id* immediately precedes that of the object. This node in turn forwards to one of its own finger nodes in the same way, and repeats until the key is found, which again may take up to $\log n$ steps. Finally, assuming from the key that u knows a mobile user v is holding the object, u then proceeds to contact and retrieve the object from v .

In this analysis, we similarly consider a network of n nodes, with path length L between any pair of nodes growing with \sqrt{n} , under the assumption of constant node density. During a join, the *join* message from a mobile user u may be forwarded $\log n$ times, followed by three message exchanges to configure the successor and predecessor pointers of u .

Next, u sends $(m-1)$ messages to build its finger table, and up to $f \log n$ messages to key-insert its objects, where f is the number of objects. If each of these messages travels a path length of L , this gives a total message cost of:

$$1+[\log n+3+(m-1)+f \log n]\sqrt{n} \quad (2)$$

The message complexity of join process is thus $o(\sqrt{n} \log n)$. To compute the time complexity, we assume the transmission of each key-insert message to be separated by only a small time constant ϵ . The total time incurred is therefore: $1+[\log n+3+(m-1)]\sqrt{n}+\epsilon(f)+\sqrt{n} \log n$, which still has a complexity of $o(\sqrt{n} \log n)$.

During a leave, the total amount of messages and time incurred by u is $(2+f \log n)\sqrt{n}$ and $2\sqrt{n} + \epsilon(f) + \sqrt{n} \log n$, respectively. This results in a message and time complexity of $o(\sqrt{n} \log n)$ for the leave process. For the query process, it could be easily seen that its message and time complexity is also of order $o(\sqrt{n} \log n)$.

Structured Super Peer

This section evaluates a system that combines the super peer concept with structured object location (Mizrak, Cheng, Kumar, & Savage, 2003). In this architecture, the super peers manage data in a structured manner, while ordinary peers query and receive replies from their super peers, similar to conventional super peer systems. As in our analysis for unstructured super peer systems, we assume the underlying physical network would be a cluster-based MANET, where cluster-heads perform the role of super peers.

Similarly, we consider a network of n nodes, of which n_s are super peers and n_o are ordinary peers. During a join, the *join* message from a mobile user to its super peer travels a path length of c . If the message contains a list of k objects to be shared, the super peer may key-insert for up to k times, incurring a total cost of $c + k\sqrt{n}$ messages: mobile user \rightarrow its current super peer \rightarrow the super peer(s) responsible for storing the key(s). Summing up, it could be seen that message complexity of the join process is $o(\sqrt{n})$. In terms of time complexity, we have a total time incurred of $c + \epsilon(k) + \sqrt{n}$. The time complexity is thus also of order $o(\sqrt{n})$.

Since the leave process is similar to the join process—that is, the mobile user sends a *leave* message to its super peer, which may key-delete for up to k times—the leave process is found to have the same message and time complexity of $o(\sqrt{n})$. During a query, both the *query* message and *reply* message may travel up to a path length of $c + \sqrt{n}$: mobile user \leftrightarrow its current super peer \leftrightarrow the super peer that holds the key. Thus, the query process has a message and time complexity of $o(\sqrt{n})$.

Table 1. Summary of message and time complexity

| P2P Models | Message and Time Complexity | | |
|---------------------------|-----------------------------|----------------------|------------------------|
| | Join | Leave | Query |
| Unstructured Super Peer | $O(c)$ | $O(\sqrt{n})$ | $O(n^{3/2})$ (message) |
| | | | $O(\sqrt{n})$ (time) |
| Structured Non-Super Peer | $O(\sqrt{n} \log n)$ | $O(\sqrt{n} \log n)$ | $O(\sqrt{n} \log n)$ |
| Structured Super Peer | $O(\sqrt{n})$ | $O(\sqrt{n})$ | $O(\sqrt{n})$ |

CONCLUSION

Table 1 summarizes the complexity of join, leave, and query processes of three P2P models. Generally it is observed that a super peer model is efficient in its *join* and *leave* process. Thus, it may perform well in a churn-intensive environment—that is, frequent join and leave of mobile nodes. However, without a structured method for object location, its query process is potentially costly since the query message could be broadcast to all super peers. Therefore, it is a challenge for unstructured super peer systems to perform under a query-intensive workload.

On the other hand, with structured object location, the *query* process could be more efficient, since the query message would be ‘directed’ and not ‘flooded’. This is achieved by maintaining some state on each node to serve as ‘direction’ pointers. However, in a high-churn environment, the traffic to maintain state could be high: some state needs to be inserted or deleted whenever a node joins or leaves. Without super peers, this traffic could be even higher, as it takes more steps to find the correct node to insert or delete the state (typically up to $\log n$ steps). Each step traverses an overlay link that potentially spans the diameter of the underlying MANET, leading to a very high forwarding traffic. A recent work (Cramer, & Fuhrmann, 2005) on overlay topology construction based on proximity of nodes in the underlying physical network could potentially address this problem.

The structured super peer model appears to be relatively well performed in all three processes. This could be due to its combining of strengths from both super peer design (efficient join/leave) and structured object location (efficient query), and is thus a promising P2P model to be further explored, particularly for a cluster-based MANET.

KEY TERMS

Asymptotic Cost: The algorithmic cost as the problem size grows very large.

Cluster Gateway: A node that enables communication between two or more cluster heads, either by being a member of more than one cluster, or by being adjacent to a gateway of another cluster.

Complexity Analysis: The analysis of how an algorithm scales, for example, in terms of number of messages and time required, with increasing problem size.

Fixed Infrastructure: A fixed topology of network devices such as routers and base stations that does not change during the lifetime of a connection.

Overlay Network: A logical network of nodes layered on top of a physical network in order to perform application-level services.

Physical Network: A network comprised of nodes and the actual communication links between them.

Query Lifetime: A threshold count often specified in terms of number of hops a query message can be forwarded, beyond which the message is dropped.

Partial Global Indexing for Location-Dependent Query Processing

James W. Jayaputera

Monash University, Australia

INTRODUCTION

Mobile computing devices, which are small-size computers, enable mobile users to run their applications to access information via wireless communication anywhere at anytime (Barbara, 1999; Dunham & Kumar, 1998). Applications such as stock or banking activities, weather forecasting, entertainment, and navigation systems have become increasingly popular in recent years (Mobile Computing Horizontal Applications Index, 2006). This implies that people can still access information through their mobile devices without worry about their current location. This situation enables the capability of mobile users to utilize information services easily. However, these mobile computing devices have limited battery power and bandwidth. Hence, speeding up the processing of information access and retrieval is a major challenge to minimize the utilization of battery power and available bandwidth.

In performing the many popular applications mentioned earlier, location-dependent information services is one type of mobile computing capability for providing information based on the current location of mobile users (Baihua, Lee, Xu, & Lee, 2002; Dunham & Kumar, 1998; Waluyo, Srinivasan, & Taniar, 2005). This means that the relaying back of a query result changes according to the current location of the mobile user. If, for example, a mobile user would like to locate the closest restaurant, a list of the closest restaurants depends on the current location of the mobile user. The records in the list change as the location of the mobile user changes.

The objects residing in several servers are partitioned by their locations. This indicates that every object is unique to every server. The objects can be classified into *static* and *dynamic*. An example of a static object is an ATM (automatic teller machine) or building. In contrast, an example of a dynamic object is a moving car or running thief. In this article, we concentrate on static objects.

To speed up the searching process, these objects are indexed and the indexes are put into a data structure. There are several popular data structures, such as B+-Tree (Elmasri & Navathe, 2004), Quadtree (Samet, 1984; Tayeb, Ulusoy, & Wolfson, 1998), and R-Tree (Guttman, 1984; Manolopoulos, Nanopoulos, Papadopoulos, & Theodoridis, 2005).

In a mobile computing environment, a specific area is called a *cell* and is served by a base station (BS). In a simple

situation, a requested query scope can be differentiated into two types—that is, *within* or *crossing* the current cell. In the former, the access time to process a query within a current cell depends on the queuing and processing times. In the latter, the access time to process a query crossing the current cell is similar to the first case, but the queuing time of each cell varies. Here, the terms *queuing* and *crossing* are used interchangeably.

Figure 1 shows an overview of LDIS in a simple situation. For example, a user sends a *location-dependent query* (LDQ) while driving—that is, it asks for data which can be found within the current location of the user. The requested data is called *location-dependent data* (LDD) (Jayaputera & Taniar, 2005). The LDQ sent is to find some vending machines within 500 meters from the current location.

The query is received by a base station, which forwards the message between the wireless and wired network for a specific area, is called a *cell* (Goodman, 1998). We assume that a BS is connected to a single server. From the figure, the query scope is represented by a circle which shows the search area of the query. Before the server starts the searching process, it needs to know the location of the mobile user from the GPS (global positioning satellite) (Getting, 1993). We assume that the location information taken from the satellite is accurate. Once the recipient's location is received, the searching process begins. In our example, the query scope crosses the area of BS1, which needs to ask for the information from BS2 on behalf of the mobile user. Once BS1 has the requested information, it forwards the information to the mobile user. The correct answer to this query should be the information about vending machines located inside the circle.

Figure 1. Overview of LDIS

In a complex situation, the scope of a requested query might cross a number of cells. The main consideration is that the scope of a requested query in a complex situation clearly differentiates between two types of scopes mentioned earlier: within or crossing the current cell.

This article concentrates on how to reduce the access time to retrieve information about static objects in a complex situation. The aim of this article is not to discuss concurrent search trees with their related problems and solutions, but to investigate how the practice of data/table partitioning in parallel databases can be applied in a mobile computing environment. As an example, the first query would be “Tell me a restaurant within 500 meters” and the second query: “Tell me a restaurant within 400 meters.” Two mobile devices, which are located nearby, receive the results of these two queries, and the queries’ scopes cross the current cell. In this scenario, the BS of the current cell needs to forward the request to the crossing cells. We assume that each BS has knowledge of its own service area and its neighboring cells. Requesting the same data from neighboring cells is not efficient since the process depends on some factors, such as the processing and waiting times on each neighboring cell. In the LDIS environment, a short access time is an important issue since the mobile user moves to a new location very frequently before receiving an answer from a server. We argue that accessing data locally needs to be improved and requesting data from other neighboring cells should be minimized.

The idea of this article is based on the parallel indexing concept (Taniar & Rahayu, 2002) in which an indexed object residing in a BS is either fully, partially, or not replicated to others BSs. Therefore, every server contains either partial or all indexes of other servers. In our proposed approach, whenever the requested results return from neighboring cells, we append the resulting items to the current cell. This implies that when the next user sends a request, the current cell needs to look up its own index first to verify if the data is in its local storage. If the data is not present, the current server sends a request to the neighboring cells on behalf of the client; otherwise, the current server directly sends the requested query to the client. We have evaluated our proposed approach and showed that the access time can be reduced by a factor of two.

The next section of this article describes some related work. We then describe our proposed work and the simulation model, and we compare the performance of our proposed technique to other techniques. Finally, we conclude the article and suggest future work.

RELATED WORK

Jayaputera and Taniar (2005) have shown the efficiency of using a square as a valid scope, which is an area in which

the objects are valid for a certain time. They have shown that a square is the easiest shape to use.

Taniar and Rahayu (2002) discussed global indexing for a parallel database. The purpose of their approach was to have a global index of database servers. Whenever there is an update for an item in one server, the global index needs to be updated in all servers. The updating process for every server will increase the CPU load, where it can affect the performance of processing the LDQ. Therefore, this is not a practical choice to be applied directly for LDIS application.

B+-Tree (Elmasri & Navathe, 2004) has been widely known as one of the data structures for index which contains sub-tree and leaf nodes. A sub-tree is formed by a collection of non-leaf nodes. A non-leaf node contains up to m keys and $m+1$ pointers to the nodes on the next level of the tree hierarchy. All nodes on the left-hand side of the parent node have key values less than or equal to the key value of the parent node. In contrast, the key values of the right-hand side nodes of the parent node are greater than the key values of the parent node. The most bottom nodes are called *leaf* nodes. Each leaf node contains up to m keys where every key has two pointers: to the actual data items and to the right-side neighboring leaf node.

Some researchers (Beckmann, Knegel, Schneider, & Seeger, 1990; Guttman, 1984; Sellis, Roussopoulos, & Faloutsos, 1987; Theodoridis & Sellis, 1994) used R-Tree and its variants to provide an efficient and dynamic index structure for spatial data. Some researchers (Sellis et al., 1987) have applied R-Tree to LDQ processing. R-Tree uses the *minimum bounding rectangle* (MBR) to group the closest objects together into a rectangle where every area has the least enlargement area. This data structure does not have a problem when a query range can be fitted into one rectangle. On the other hand, we need to have multi-way searching if a query range involves some rectangles.

Furthest away replacement (FAR) is one of the cache replacements proposed in Dunham and Kumar (2000). In their approach, they eliminated the data items located furthest away from the user and which will be evicted first since the users no longer need those objects. The other replacement method is using *timestamp*, which is the time at which data items are received by the cell. *Least recently used* (LRU) (Jelenkovic & Radovanovic, 2003) is used to eliminate data items that have the oldest timestamp.

PARTIAL GLOBAL INDEXING FOR OBJECT RETRIEVAL: PROPOSED ALGORITHM

In general, the data items are located in several cells; we assume that every cell has a single server, and users often

Figure 2. The proposed algorithm

```

Algorithm 1. FindNode (Tree, Key, Operation)
N ← a root node of Tree
if key is in the range of node N then
  if N is leaf Node then
    Execute operation insert/delete on local node
    if Node is overflow or underflow then
      Perform split/merge on leaf node
    end if
  else
    Locate child tree
    Perform FindNode(child, key, operation)
    if Node is overflow or underflow then
      Perform split/merge on leaf node
    end if
  end if

  end if
end if
end if
    
```

request data items that are located in a single cell or multiple cells. Retrieving data items from multiple cells shows its limitations when a large number of queries are in queue. However, it is not appropriate to wait to retrieve all data items as the users will be moving to another location.

The proposed strategy is used to store the requested index of data items from neighboring cells during its first-time request. This process keeps going on until the next user requests the same data item that was requested before. When the B+-Tree reaches its maximum, some data items have to be invalidated. We invalidate the index of data items by using three cache replacements: *furthest away replacement*, *least frequently accessed*, and *least recently used*.

To simplify our discussion, we explain our proposed approach in conjunction with the B+-Tree. However, it is not limited with the B+-Tree data structure. It also can be used with variants of the R-Tree data structure. We adopt the insertion, deletion, and modification of the traditional B+-Tree. For further information, interested readers may refer to Elmasri and Navathe (2004).

Our approach is based on the global indexing concept. The original global index is designed based on the B+-Tree data structure in the context of parallel database systems (Taniar & Rahayu, 2002). We store indexes of the requested objects from neighboring cells locally since the size of an index is relatively small. In other words, we partially replicate the index of objects from neighboring cells, but we do not replicate the sub-tree of the remote tree if the index is already replicated. The idea is to store a complete list of indexes of all requested objects, which are located in several servers from neighboring cells. A partially replicated sub-tree can consume more processing time, which slows down the query processing.

Figure 3. Examples of object information retrieval from multiple cells

Figure 2 shows our proposed algorithm. In the beginning, we traverse from the root to the leaf nodes to find whether the index of the requested object is located in the B+-Tree of the current cell. If the index is found, the server forwards the information about the requested object to the user. Otherwise, the current cell forwards the request on behalf of the user to the neighboring cells. These servers search for the requested object in their local indexes. The indexes and information about the requested objects are then returned to the requesting cell.

Once the information about the requested objects is received from neighboring cells, the current cell performs two tasks: storing the indexes of the requested objects and sending the answer to the mobile user. The latter is straightforward, because the current cell sends the information to the mobile user directly. If the mobile user gets disconnected, then the current cell waits for a short amount of time before it resends the information about the object to the users. Otherwise, users need to resend the query again since their current locations might be different from the previous one.

The former task of the current cell is quite complex compared to the latter, since the server needs to insert the new indexes to the B+-Tree index and restructure the tree. The tree is growing when there are new indexes inserted into the tree. Therefore, the physical memory space in a server (cell) will become full, while the process of storing new data items keeps going. It causes the server to run out of space. Therefore, we need to invalidate appropriate data items. In the first place, all objects that have the furthest distance from a cell boundary, rather than from the user, will be evicted. If there is more than one object that has the same distance, the data items that are least frequently accessed will be invalidated. If there are still remaining same numbers of frequently accessed data items, those with the older timestamp will be evicted.

Figure 3 shows a situation where there are three mobile users—A, B, C—that ask the same query, and their locations are close to each other and located in cell 1. The order of arrival time is A, B, and C respectively. When server 1

processes a query *A* (dot line), the server looks up the tree index in cell 1. Server 1 cannot find any requested objects in its tree index and so it checks whether the query scope is crossing the boundary. If it is, server 1 forwards the query to the neighboring cell, server 2. The queried object is located in server 2 and returned to server 1.

Server 1 forwards the results to the user and updates its tree index. For simplicity, the mobile user is connected while receiving the result and there is no failure in updating its tree index. Once processing of query *A* is completed, server 1 continues processing the next query, query *B* (dot). Server 1 only searches its tree index, because the object index is available locally as it was requested before. Thus, server 1 does not need to forward again the whole request from the user to its neighboring cell(s) in order to search the object. Server 1 only needs to request information about the requested object from the neighboring cells whenever they are not available in its tree. Then, server 1 processes the next query, query *C* (solid line). The processing steps for query *C* are similar to those for query *B*.

FUTURE TRENDS

The global indexing approach is often used in distributed parallel databases. However, this approach cannot be applied directly to answer a location-dependent query since a short time is needed to answer this query. Therefore, the partial global indexing approach, as a modification of the global indexing approach, is made to be used in retrieving objects for location-dependent queries. Further investigation will be done on how this algorithm can improve processing time to answer the location-dependent query.

CONCLUSION

This article proposes an approach called *partial global indexing*. Our proposed approach is similar to data/table partitioning in parallel databases. The difference is that we do not replicate database records from one cell to all other cells. The aim is to speed up the retrieval of object information from multiple cells by reducing the waiting time. In this article, we did not discuss concurrent search trees and their related problems.

In our approach, we used indexing to store the requested information from other cells to the cell where the mobile client currently resides. This implies that if there is no information entry in the local index regarding the object requested by a new mobile client, the server needs to retrieve the information from neighboring servers. The next time the same information is requested, the next mobile client only needs to find the items inside the cell where he currently resides.

KEY TERMS

Base Station: Stationary that forwards a message from a wireless to a wired network.

Cell: A specific area served by one base station.

Location-Dependent Information Services (LDIS): A service that gives information based on the current location of mobile users.

Location-Dependent Query (LDQ): A query that includes current location.

Neighboring Cell: Adjacent cell of current cell.

Partial Global Indexing (PGI): Modification of Global Indexing technique used to include indexes of objects from a neighboring cell.

Patterns for Mobile Applications

Markus Alekxy

University of Mannheim, Germany

Martin Schader

University of Mannheim, Germany

INTRODUCTION

The increasing adoption of mobile terminals, together with the progressive development of handheld devices and the simultaneous improvement in the infrastructure of wireless communication plays a more and more important role in the development of new kinds of mobile applications. Applications that are executed on mobile terminals often require both a simultaneous interaction with other users of mobile terminals as well as with fixed or location-dependent services. Although this development is very favorable from the view of the end user, it confronts application developers with the problem that they must manage the growing complexity of the mobile applications.

A main characteristic of mobile applications is their dynamics. It is therefore important that during development of a mobile application, its dynamic adaptability—as one of the most important design criteria—must be taken into account.

In this article, we present a pattern-based structure for the development of mobile applications. After a short description of the concept of patterns, we demonstrate how these may be used in the context of the development of mobile applications.

PATTERNS

Patterns are simple and concise solutions for programming tasks frequently appearing in practice. The architect Christopher Alexander (Alexander et al., 1977; Alexander, 1979) is regarded as being the intellectual father of the patterns movement. The structure of a pattern follows certain rules and is based on the elements listed below (Gamma, Helm, Johnson, & Vlissides, 1995):

- **Pattern Name:** The name of a pattern is usually short yet descriptive and acts as an addition to the design vocabulary.
- **Problem:** Patterns should include a short description of the problem they intend to solve.
- **Solution:** The solution to the problem is described in a generally applicable way. The elements of the solu-

tion are described along with their relationships and responsibilities.

- **Consequences:** While the main consequence of using the pattern is solving the problem, there are often side effects. In order to make it easier to understand the trade-off involved in using the pattern, it is important that the potential drawbacks are explained.

Of course, this is not the only possible structure for describing a pattern. Gamma et al. (1995) also provide an extended schema, and other authors offer alternative descriptions as well (e.g., Fowler, 1997).

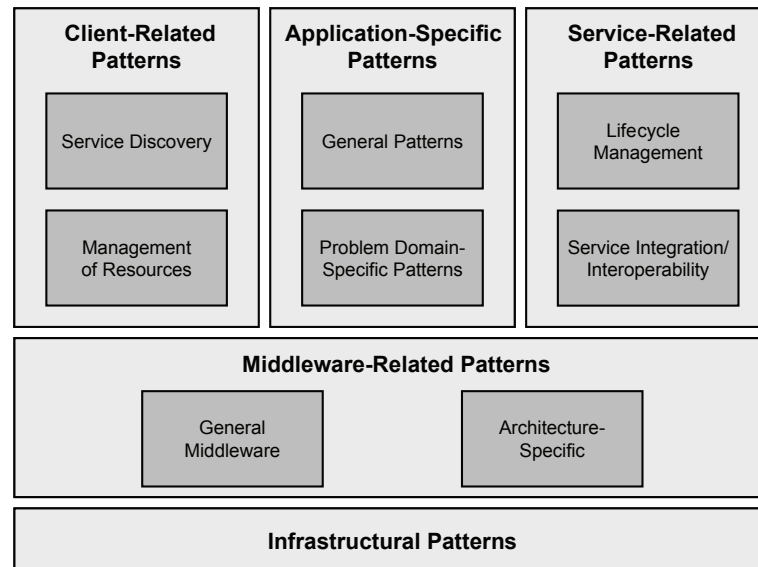

A pattern documents a comprehensive and good solution won from experience to a problem frequently recurring during program design. The engineer-like approach at the design of object-oriented software consists of identifying one or more patterns for a concrete programming task, which helps in coping with this task. The documentation of the patterns supports the development process, from the complete specification of the set task up to its implementation in a concrete programming language; in addition, it supplies a common language frame for the discussion of the envisaged solution between the developers.

The primary benefit of a pattern lies in the description of a solution for a certain class of problems. Additional advantage arises from the fact that every pattern has a name. This simplifies the communication among software developers since one may then discuss a software structure on an abstract level. Thus, patterns are first of all programming language independent. During the design of object-oriented software, they serve as a recognized aid to structuring the outline. A detailed introduction to the concept of patterns can be found among others in Gamma et al. (1995) or Buschmann, Meunier, Rohnert, Sommerlad, and Stal (1996).

PATTERNS FOR THE DEVELOPMENT OF MOBILE APPLICATIONS

When developing a mobile application, a programmer can meanwhile resort to a variety of different patterns. One can distinguish among patterns with a different coverage (see Figure 1):

Figure 1. Patterns for the development of mobile applications

- infrastructural patterns,
- middleware-related patterns,
- client-related patterns,
- service-related patterns, and
- application-specific patterns.

Infrastructural Patterns

Infrastructural patterns describe solutions for the administration of mobility (mobility management functions). They illustrate which elements are needed for the realization of architecture. Andrade, Logrippo, Bottomley, and Coram (2001) identify two types of patterns that fall into this category: *architectural elements* and *functional behaviors*. The patterns *home and visitor databases* as well as *security database* fall into the first category. The first pattern solves the problem of mobility between different local areas (*roaming*) of the same supplier or of different suppliers. The second is aimed at the realization of security and privacy functionality. Besides that, the authors identify broader functional behavioral patterns, such as *temporary identification*, *paging*, *authentication*, *ciphering*, as well as *location registration*.

Middleware Patterns

Building on the infrastructural patterns introduced above, a variety of middleware patterns can be used. Here, middleware functions as the link between different spatially distributed software components. We introduce different middleware-related patterns in the following. These were developed mainly for the realization of non-mobile applications, but

it is possible to transfer them into the domain of mobile computing as well.

Patterns that fall into this category can be classified as *general design patterns*, which can be used for the realization of (almost) all types of distributed architectures, or as *architecture-specific patterns*.

General patterns, which can be used for the realization of a basic infrastructure for object-oriented systems, are described for example by Buschmann et al. (1996), Schmidt, Buschmann, Stal, Rohnert, and Sommerlad (2001), and Völter, Kircher, and Zdun (2002).

Patterns such as the *forwarder-receiver* or the *publisher-subscriber* (Buschmann et al., 1996) may be applied in a variety of applications and architectures.

On the other side, middleware patterns exist which are specific for certain architectures. For example, during the realization of a mobile client-server architecture, the patterns introduced by Völter (2001) can be used on the server side. Aarsten, Brugali, Menga, Brown, and Hirschfeld (2005) present patterns particularly suitable for the realization of three-tier client-server architectures. Another pattern falling into this category is the *broker* pattern (Buschmann et al., 1996), which gained wide popularity in the context of the common object request broker architecture standard (CORBA) defined by the Object Management Group (2004).

Patterns for the Development of Mobile Clients

During development of a mobile application, dealing efficiently with the resources of the mobile client represents

an important challenge. Despite the enormous technological progress, different aspects, such as relatively small memory sizes or comparatively low network capacity, must still be taken into account.

Here, the *virtual proxy* pattern (Gamma et al., 1995) may be applied. Proxy objects are created in the context of the implementation of the mobile client. The use of this pattern has the consequence that “expensive” objects are loaded dynamically—that is, they are only loaded and instantiated if and when required. In this focus, further patterns have been identified such as the *lazy acquisition* pattern (Kircher, 2001), which aims at allocating a resource at the latest possible point in time. Furthermore, with the help of the *virtual component* pattern (Corsaro, Schmidt, Klefstad, & O’Ryan, 2002), aspects like configurability and adaptability of an application can be improved at run time.

Another factor concerns the localization of the services required by the mobile application. So that a mobile client can use a service, it must be able to identify services in a dynamic environment. The offered services can differ from one location to another. It is therefore necessary to decouple the mobile client from the services.

In order to solve the problem, for example, the *lookup* pattern (Kircher, 2001) can be applied. A central instance, the lookup service, functions as a link between mobile clients and the hard-wired services in this case. This approach is also followed in the context of different popular technologies such as CORBA (Object Management Group, 2004). Further patterns, which are related to service discovery, or more exactly a complete pattern language, are described in Pärssinen, Koponen, and Eronen (2004). In this regard, the *naming* pattern (Silva, Sousa, & Antunes, 1998) should also be mentioned.

The dynamics of the mobile clients represent another problem: they may not be “hard-wired” to the services they use. The *service abstraction layer* pattern (Vogel, 2001) can be employed to decouple these possibly heterogeneous mobile clients from the services. This pattern signifies amongst others that an additional layer should be introduced between the client application and the services. It can be realized by means of the *facade* pattern (Gamma et al., 1995). The *service abstraction layer* pattern promotes aspects like separation of concerns, generic request handling, controlled evolution, or communication transparency, for example.

This way, services tailored to the client application can be realized, which, for example depending on location, have different capabilities, such as possibly supplying various quality of service (QoS) features.

By the permanently changing business processes and the regular emergence of new technologies, the “separation of concerns” principle (Völter, 2001) should be stressed. In connection with the patterns introduced here, it may suitably be applied as a basis for the development of platform and programming language-independent mobile applications.

Service Patterns for Mobile Applications

Mobile applications, primarily if these are executed in a location-aware context, require great flexibility. The reason is that the current location of the device decides on the accessible services. Such applications must therefore possess two special qualities: the ability of ad-hoc configuration and the ability of efficiently discovering, adding, using, and administering services.

Although one could think that the aspect of the dynamic adaptability of a mobile client application concerns only the client side, this is normally not the case. The reason is that the flexible detection, use, and administration of services is not alone relevant on the client side, but also requires a flexible infrastructure on the server side. As mentioned above, the ability to efficiently administer services, that is, their discovery, addition, and use, is of essential importance. Several problems must be solved here, including the administration of no-longer-needed services or the selection of a service provider. In the following sections, we will present different patterns that are of importance for the implementation of an administrative infrastructure for the services used by a mobile client.

In the case of mobile clients, the use of the *evictor* pattern (Henning & Vinoski, 1999; Jain, 2001) appears to be the most suitable solution for the administration of services. This approach tries to cope with the aim of efficiently using services by monitoring. Every time an access to a service is carried out, a flag is set. The least recently used (LRU) services or the least frequently used (LFU) services represent candidates for release. The release of the services can happen either periodically or upon request.

It is the principal benefit of this pattern that it is transparent from the view of the client. That is, the mobile client does not have to take care of the release of the services accessed by it, at all. Moreover, the release of no-longer-needed services is ensured even in the case of technical problems, such as interruption of the communication, crash of the mobile client, and so forth. The only disadvantage of this approach is its “ignorance” of the exact time of the services’ release, since the mobile client application cannot take any countermeasures in this situation. However, this disadvantage can be remedied relatively simply by providing corresponding configuration possibilities.

A further problem is the fact that every service is not always attainable. This can either be based on technical causes again or depend on the current location of the mobile client. In this context, the *leasing* pattern (Jain & Kircher, 2000) can be used. This pattern is based on a method that does not assign a service to a user for an indefinite period, but only for a particular timeframe. If the time has run out, different action variants are possible. The leasing concept—which is, for example, of essential importance in the Jini architecture (Sun Microsystems, 2003) and for which Sun Microsystems

even realized an own specification (Sun Microsystems, 1999)—was until now largely neglected in mobile location-dependent applications. The work of Jain and Kircher (2000), who even use the term *leasing pattern*, clarifies that this concept does not have to be limited to Jini only. The authors elaborate the exact details, which are related to the problem definition, the structure, and possible variants of leasing. In technologies that do not directly support leasing, such as CORBA, the concept can nevertheless be realized by means of a dedicated service (Aleksy & Gitzel, 2002).

Furthermore, a number of patterns exist that promote the development of dynamically configurable software components. In connection with this, design patterns such as the *service configurator* (Kircher & Jain, 1997) or the *component configurator* (Schmidt et al., 2001) can be mentioned. Additional patterns that can be used for the dynamic administration of resources are, among others, given in Welch, Marinucci, Masters, and Werme, (2002).

Application-Specific Patterns

Two principally different pattern types can be discriminated in this category: *general patterns* as well as *application-specific patterns*. The first category is domain independent—that is, it can be used in a large variety of applications. This kind of patterns is described, for example, in Gamma et al. (1995).

On the other side, a variety of patterns exists, which very narrowly are connected to a concrete problem domain. In location-dependent mobile applications, the context is of essential importance since it is the determining factor for the range of utilizable services. Dockhorn, Ferreira Pires, and van Sinderen (2005) describe three architectural patterns that can be employed especially in the development of context-specific applications. The *event control action* pattern serves for the decoupling of contexts and the actions being based on them. The use of this pattern promotes the “separation of concerns” principle. The *context sources and manager hierarchy* pattern describes a hierarchical architecture for the processing of context information. The *action patterns* pattern aims at providing a structural schema to enable coordination of actions as well as decoupling of action implementations from action purposes.

FUTURE TRENDS

Although a variety of patterns that can be used in the area of mobile applications was already identified, that process is not completed yet. The increasing popularity of mobile applications is the reason that new applications or types of applications emerge, which in turn can lead to the discovery of new patterns. This development is not surprising since the pattern concept builds on the reuse of solutions already tested successfully. Therefore, it has to be expected that, in

the future, the already-established patterns will be continuously complemented by newly discovered patterns. In this regard, the aspect of the administration and use of the location context is primarily of special importance.

CONCLUSION

In this article, we have introduced different patterns that can be used for the development of mobile applications. These cover different aspects such as the realization of a basic infrastructure, middleware specifics, the development of mobile client applications, as well as patterns supporting the server side of mobile applications.

This way, using existing patterns, a complete basic infrastructure can be realized for the architecture of mobile applications. Based on the patterns introduced here, mobile applications can, in general, be developed faster and more economically, and also their quality may be enhanced by the adoption of “best practice” techniques already tested.

Nevertheless, the domain of mobile applications requires further investigation to identify patterns, which are new and not discovered until now.

KEY TERMS

Client: A computational context that invokes remote operations on a service.

Middleware: The link between different locally distributed software components.

Pattern: A simple and concise solution to programming tasks frequently appearing.

Pattern Language: A collection of related patterns in a certain domain.

Separation of Concerns: A key concept for the development of software systems is the separation of different areas of responsibility. Different aspects of a software system are handled independently of each other and integrated at a later time.

Service: Offers a certain functionality that can be requested by different service users. The type of functionality offered by the service is not relevant and should be regarded as being opaque.

Service Provider: Realizes a certain service at least partially.

Peer-to-Peer Cooperative Caching in Mobile Environments

INTRODUCTION

An infrastructure-based mobile environment is formed with a wireless network connecting mobile hosts (MHs) and mobile support stations (MSSs). MHs are clients equipped with portable devices, such as laptops, personal digital assistants, cellular phones, and so on, while MSSs are stationary servers providing information access for the MHs residing in their service areas. With the recent widespread deployment of contemporary peer-to-peer (known as P2P throughout this chapter) wireless communication technologies, such as IEEE 802.11 (IEEE Standard 802-11, 1997) and Bluetooth (Bluetooth SIG, 2004), coupled with the fact that the computation power and storage capacity of most portable devices have been improving at a fast pace, a new information sharing paradigm known as P2P information access has rapidly taken shape. The MHs can share information among themselves rather than having to rely solely on their connections to the MSS. This article reviews a hybrid communication framework—that is, mobile cooperative caching—which combines the P2P information access paradigm into the infrastructure-based mobile environment.

BACKGROUND

In mobile environments, there are two different types of communication architecture, *infrastructure* and *ad hoc based*. The infrastructure-based mobile communication architecture is formed with MHs and MSSs. The MHs can only retrieve their desired data items from MSSs, either by requesting them over shared point-to-point channels (*pull-based data dissemination model*) or catching them from scalable broadcast channels (*push-based data dissemination model*) or through the utilization of both types of channels (*hybrid data dissemination model*). This type of communication architecture is the most commonly deployed one in real life.

The emergence of the state-of-the-art P2P communication technologies leads to the development of an ad-hoc-based mobile communication architecture, also known as a *mobile ad-hoc network* (MANET). In MANETs, the MHs can share information among themselves without any help of MSSs. This kind of sharing paradigm is also referred to as a *P2P data dissemination model*.

In a pull-based environment, the MHs have to retrieve their desired data items from the MSS whenever they encounter local cache misses. Since the mobile environment is characterized by limited bandwidth, the communication channel between the MSS and the MHs would potentially become a scalability bottleneck in the system, as it serves an enormous number of MHs. Although push-based and hybrid data dissemination models are scalable, the MHs adopting these two models generally suffer from longer access latency and higher power consumption than those adopting the pull-based one, as they need to tune in to the broadcast channel and wait for the broadcast channel index or their desired data items to appear. Furthermore, since the data items are broadcast sequentially, the MHs experience longer access latency with an increasing number of data items being broadcast.

MANET is practical to a mobile system with no fixed infrastructure support, such as battlefield, rescue operations, and so on (Fife & Gruenwald, 2003). However, it is not suitable for commercial mobile applications. In MANETs, the MHs can rove freely and disconnect themselves from the network at any instant. These two particular characteristics lead to dynamic changes in the network topology. As a result, the MHs could suffer from long access latency or access failure when the peers holding the desired data items are far way or unreachable. The latter situation is caused by network partitioning (Wang & Li, 2002) or client disconnection.

The inherent shortcomings of the infrastructure- and ad-hoc-based communication architecture lead to a result that a mobile application adopting either one of these architectures alone would not be as appropriate in most real commercial

settings. In reality, long access latency or access failure could possibly cause the abortion of valuable transactions or the suspension of critical activities, so that it is likely to reduce user satisfaction and loyalty, and potentially bring damages to the organization involved. The drawbacks of the existing mobile data dissemination models motivate researchers to develop a novel hybrid communication framework—mobile cooperative caching—in which a convectional infrastructure-based mobile communication framework is used in combination with a P2P data dissemination paradigm for deploying mobile information access applications in reality.

MOBILE COOPERATIVE CACHING

Recently, mobile cooperative caching has been drawing increasing attention. Several mobile cooperative caching schemes were proposed during the preceding years. These works can be divided into two major categories: *cooperative data dissemination* and *cooperative cache management*. The work of cooperative data dissemination (Lau, Kumar, & Venkatesh, 2002; Papadopouli & Schulzrinne, 2001; Sailhan & Issarny, 2003; Shen, Das, Kumar, & Wang, 2004) mainly focuses on designing protocols for the MHs to search their desired data items and forward the data items from source MHs or MSSs to them in a mobile environment. The work pertaining to cooperative cache management focuses on designing protocols and algorithms for the MHs to manage their cache space, not only with respect to themselves, but also with respect to their peers, in order to improve system performance along such design dimensions as *cooperative data replica allocation* (Hara, 2001, 2002a, 2002b; Hara, Loh, & Nishio, 2003), *cooperative cache invalidation* (Hayashi, Hara, & Nishio, 2003), and *cooperative cache admission control* and *cache replacement* (Lim, Lee, Cao, & Das, 2003; Chow, Leong, & Chan, 2004, 2005).

COOPERATIVE DATA DISSEMINATION

Sailhan and Issarny (2003) propose an intuitive cooperative data dissemination scheme for a MANET environment. If an MH can directly connect to an MSS, it would obtain the required data items from the MSS; otherwise, the MH has to enlist its peers at a distance less than the MSS for help to turn in the required data items. If no such peer caches the data items, the peers route the request to the nearest MSS. A local cache replacement strategy is also proposed for the MH based on the access probability and time-to-live of the cached data items, and the estimated energy cost of retrieving them.

A similar cooperative data dissemination scheme is designed to support continuous media access in MANETs (Lau et al., 2002). Two data location schemes, namely *cache-state*

and *reactive*, are proposed for the MHs to determine the nearest data source that can be either the cache of their peers or the original servers to retrieve their desired multimedia objects. Cache-state is a proactive scheme, whereas reactive is an on-demand scheme. The performance evaluation result shows that the reactive scheme outperforms the cache-state one in terms of network traffic, quality of service (QoS), and access latency.

7DS (seven degrees of separation) (Papadopouli & Schulzrinne, 2001) is another cooperative data dissemination scheme that is used as a complementary component to the infrastructure support with power conservation. When an MH fails to connect to the MSS to retrieve its desired data items, it would attempt to search its neighboring 7DS peers for them. The power conservation scheme adjusts the MHs' degree of activity or participation in 7DS based on their available battery levels.

Shen et al. (2004) propose another cooperative data dissemination scheme with power conservation, called *energy-efficient cooperative caching with optimal radius* (ECOR), in a mobile environment. In ECOR, an optimal radius (in number of hops) is estimated by an analytical model that considers the MH's location, data access probability, and network density for each data item. The MHs exchange the cache content and the optimal radius of each cached data item among themselves. When an MH encounters a local cache miss, if it finds that any peers cache its desired data item, and the distance between the MH and the peer is within the optimal radius based on its local state, the MH sends a request message to the peer that is the closest to the selected holder of the data item. Otherwise, the MH obtains the data items from the MSS.

Yin and Cao (2004) propose three other cooperative caching schemes, called *CacheData*, *CachePath*, and *HybridCache*. The idea of CacheData is that an MH caches a passing-by data item, if the data item is popular and a condition that all requests for the data items are not originated by the same MH is satisfied. For CachePath, the MH caches path information of the passing-by data item instead of the data item. To conserve cache space, an MH does not cache path information of all passing-by data items. It only caches the path information of a data item if it is closer to the requesting MH than the MSS. HybridCache is a hybrid scheme that combines both CacheData and CachePath. An MH either applies CacheData or CachePath based on three factors: data item size, data item time-to-live, and the distance between the MH's distance to the data holder and the distance to the MSS.

COOPERATIVE CACHE MANAGEMENT

All literature related to cooperative cache management can be further divided into four sub-categories: *cooperative*

data replica allocation, cooperative cache invalidation, cooperative cache admission control, and cooperative cache replacement.

Cooperative Data Replica Allocation

Data replica allocation techniques (Hara, 2001, 2002a, 2002b; Hara et al., 2003) are adopted in mobile cooperative caching to improve data accessibility, in order to alleviate the network partitioning problem. Hara (2001) proposes three data replica allocation schemes: *SAF* (static access frequency), *DAFN* (dynamic access frequency and neighborhood), and *DCG* (dynamic connectivity-based group). The MHs applying SAF only consider their own individual access probability to each data item. DAFN extends SAF to take the access probability to each data item of the MHs' connected neighborhoods into account. Finally, DCG groups the MHs with highly stable connection together. A group of MHs possesses high connection stability, as they form a *biconnected component* in the network. DCG considers the access probability to each data item of all MHs in the same group. The performance evaluation result shows that DCG gives the highest data accessibility, but it incurs higher network traffic than the other two schemes. Thus, DCG can be considered as a scheme that trades network traffic for data accessibility.

These three data replica allocation schemes are then adapted to a push-based mobile environment (Hara, 2002a). Other than data access probability, the schemes also consider the latency on accessing data items from the peers and broadcast channel. Furthermore, the proposed replica allocation schemes are further extended, namely, Extended SAF (*E-SAF*), Extended DAFN (*E-DAFN*), and extended DCG (*E-DCG*), to consider periodic data update by allowing the extended allocation schemes to consider the remaining time until next update of each data item (Hara, 2002b). In addition to the access probability, Hara et al. (2003) also consider the stability of radio links. The stability of a radio link is defined as the remaining time period that two MHs will still be connected to each other. The longer the time period indicates the higher the stability of a radio link.

Huang, Chen, and Peng (2003) propose another distributed data replica allocation scheme in MANETs, called *DRAM*, to improve data accessibility and reduce network traffic pretending to the replication mechanism. DRAM extends E-DCG (Hara, 2002b) to consider a group mobility pattern for data replica allocation. It is assumed that some MHs tend to roam together and they share a common access range. To discover the group mobility pattern among MHs, a distributed clustering algorithm is adopted to cluster several MHs who possess a similar mobility pattern into a group. The clustering algorithm is executed periodically to adapt to the changes in network topology. Then, the data replicas are allocated to each group member based on group access probability to the data items and the remaining time until the

next update on them. DRAM is found to perform better than E-DCG in terms of data accessibility and network traffic.

Cooperative Cache Invalidation

Hayashi et al. (2003) propose two cache invalidation schemes, namely *update broadcast* and *connection rebroadcast*. The former is a straightforward, flooding-based scheme. An MH that caches an original copy of a data item broadcasts an invalidation report to other peers when that MH updates the data item. The latter can be referred to as a cooperative cache invalidation scheme. When two MHs are newly connected to each other, they broadcast their collected cache invalidation information to their connected peers. The newly connected MHs and other peers receiving their broadcast information update their own previously received cache invalidation information to identify any obsolete data items in their cache. The performance evaluation result shows that the connection rebroadcast scheme reduces the number of accesses to invalid cached data items, but it incurs higher network traffic than update broadcast scheme.

Cooperative Cache Admission Control and Cache Replacement

Lim et al. (2003) propose a cooperative caching scheme for Internet-based MANETs, namely IMANET. In IMANET, a simple, flooding-based searching scheme is proposed for the MHs to search their desired data items in the network. IMANET also provides two cooperative data management protocols: *cooperative cache admission control* and *cache replacement*. For the cooperative cache admission control protocol, an MH determines whether to cache a data item based on the distance between itself and the data source that can be either other peers caching the data item or the MSS. For the cooperative cache replacement protocol, called *time and distance sensitive* (TDS), a victim data item is selected to be evicted from the cache by an MH based on two factors: the distance between itself and other peers caching the victim or the MSS, and the freshness of the distance information. The distance information is updated when the corresponding data item is accessed by other MHs. Since the network topology changes frequently, the distance information could become outdated, as it has not been updated for a long time.

There is a need for cooperating peers to cache useful data items together, so as to improve cache hit from peers. This could be realized by capturing the data requirement of individual peers in conjunction with their mobility patterns. Two group-based mobile cooperative caching schemes, namely GroCoca (Chow et al., 2004) and DGCoca (Chow et al., 2005), make use of a concept of a *tightly coupled group* (TCG), which is defined as a group of MHs that are *geographically* and *operationally close*—that is, sharing

common mobility and data access patterns. Two MHs are considered to be geographically and operationally close based upon their locations and the set of data items they access respectively.

GroCoca is a *centralized* group-based mobile cooperative caching scheme, in which the MSS uses an incremental clustering algorithm to discover TCGs based on the weighted average distance and data access similarity of any two MHs. In GroCoca, when an MH encounters a local cache miss and its peer can turn in its desired data item to it, it only caches the data item if its local cache has not been fully occupied or the peer is not belonging to its TCG. In other words, the MHs do not cache the data items that are provided by their TCG members, on the belief that the data items can be readily available from the peer if needed.

On the contrary, DGCoca is a *distributed* group-based mobile cooperative caching scheme, in which a stable neighbor discovery algorithm is proposed for the MHs to discover their own TCG's members dynamically without any help of the MSS. The MHs adopting DGCoca not only make use of the cooperative cache admission control protocol proposed in GroCoca, but they also perform cooperative cache replacement to further improve data accessibility. The proposed cooperative cache replacement protocol possesses three important properties. First, the most valuable data items are always retained in the local cache. Second, in a local cache, a data item which has not been accessed for a long period will be replaced eventually. Third, in a TCG, a data item which "spawns" replica is first replaced in order to increase the effective cache size.

FUTURE TRENDS

Mobile cooperative caching is one of the most promising techniques to improve system performance in mobile environments. The future mobile cooperative caching scheme will focus on investigating security and privacy issues. Since an MH can cache outdated, counterfeit, or harmful data items, the access to these data items potentially brings damages to other peers. Therefore, it is necessary to design a mechanism for an MH to ensure the freshness, reliability, and safety of the data items retrieved from other peers. Also, when an MH accesses cached information from others, the MH may tell some personal information about them, for example, personal data, preferences, location information, data access history, and so forth. To resolve this problem, there should be a permission control mechanism on accessing a cached data item, so that the MHs can choose what kinds of information not to be disclosed. Also, an anonymous data sharing protocol should be developed to protect the privacy of the participating MHs in a mobile cooperative caching environment because their personal information may be revealed by other peers through their requests.

CONCLUSION

Mobile cooperative caching is a novel hybrid communication architecture that combines the P2P data dissemination model into a conventional infrastructure-based communication architecture. In mobile cooperative caching, the MHs can retrieve their desired data items not only from the MSS, but also from their peers. The MHs also manage their cache space with respect to themselves and their peers to improve system performance, such as cooperative data replica allocation, cooperative cache invalidation, cooperative cache admission control, and cache replacement. The future trend of mobile cooperative caching will be focusing on how to resolve the security and privacy issues.

KEY TERMS

Biconnected Component: In graph theory, a biconnected component is a maximal subset of edges of a connected graph such that the corresponding induced subgraph cannot be disconnected by deleting any one vertex.

Cache Admission Control: A set of policies for a mobile client to decide on whether to cache a data item.

Cache Invalidation: A mechanism for a mobile client to check whether its cached data items have been updated by someone else.

Cache Replacement: When a cache has no room for storing a data item, the least valuable cached data item is iteratively removed from the cache until there is enough space for caching the required data item.

Data Replica Allocation: An algorithm for allocating some selected data items to a single mobile client or a group of mobile clients based on some prescribed criteria.

Mobile Ad-Hoc Network (MANET): A peer-to-peer mobile communication architecture, in which the mobile clients can share information among themselves without any help of mobile support stations.

Network Partition: There is no mobile client acting as a gateway between two groups of mobile clients in a mobile environment.

Tightly Coupled Group: A group of mobile clients share common mobility pattern and data affinity.

Time-to-Live: The remaining time period of a data item to be updated or evicted from a cache.

Pen-Based Mobile Computing

Bernie Garret

University of British Columbia, Canada

INTRODUCTION

The original idea of a portable computer is credited to Alan Kay of the Xerox Palo Alto Research Center who suggested the idea in the 1970s (Kay, 1972a, 1972b; Kay & Goldberg, 1977). He envisioned a notebook-sized portable computer named the “Dynabook” that could be used for all of the user’s information needs and using wireless network capabilities for connectivity.

BACKGROUND

Origins: Laptop Computers

The first actual portable “laptop” computers appeared in 1979: the Grid Compass Computer was designed in 1979 by William Moggridge for Grid Systems Corporation (Stanford University, 2003). The Grid Compass was one-fifth the weight of any model equivalent in performance and was used by NASA on the space shuttle program in the early 1980s. Portable computers continued to develop in the 1980s onwards, and most weighed around about 5 kg without any peripherals.

In 1984, Apple Computer introduced its Apple IIc model (Abbate, 1999), a true notebook-sized computer weighing about 5 kg without a monitor. The Apple IIc had an optional LCD panel monitor which made it genuinely portable and was therefore highly successful.

In 1986, IBM introduced its IBM Convertible PC with 256KB of memory; it was also a commercial success. By many, this is considered the first true laptop (mainly due to its clamshell design) that was shortly copied by other manufacturers such as Toshiba who were also successful with IBM laptop clones (Allen, 2001; Cringely, 1996). These devices retained the A4 size footprint, full QWERTY keyboards, and weighed between 3 and 4 kg (IBM, 2006). Following these innovations “tablet” PCs with a flat A4 footprint and a pen-based interface began to emerge in the 1990s.

There were several devices in the 1970s that explored the tablet, but in 1989 the Grid Systems GRiDPad was released, which was the world’s first IBM PC-compatible tablet PC that featured handwriting recognition as well as a pen-based point-and-select system. In 1992, Microsoft released Microsoft Windows for Pen Computing, which had an application programming interface (API) that develop-

ers could use to create pen-enabled applications. Focusing specifically on devices that use the pen as the primary input device, this interface has been most successfully adopted in the new breed of small, highly portable personal digital assistants (PDAs).

Personal Digital Assistants

In 1984 David Potter and his partners at PSION launched the “PSION Organiser” which retailed for just under £100 (Troni & Lowber, 2001). It was a battery-powered, 14 x 9cm, block-shaped unit with an alphabetic keyboard and small LCD screen, with 2K of RAM, 4KB of applications in ROM, and a free 8KB data card (which had to be reformatted using ultraviolet light for reuse). Compared to the much larger notebook computers of the time, it was a revolutionary device, but because of its more limited screen size and memory, it fulfilled a different niche in the market and began to be used for personal information management and stock inventory purposes (with a plug-in barcode reader).

In the late 1980s and throughout the 1990s, PSION continued to develop commercially successful small computing devices incorporating a larger LCD screen, and a new fully multi-tasking graphical user interface (before even Microsoft had got Windows up and running). These small devices were truly handheld. The PSION 3c (launched in 1991) dimensions were 165 x 85 x 22 mm, with a 480 x 160 pixel LCD screen, and the device weighed less than 400 g. A small keyboard and innovative touch-sensitive pad provided control of the cursor, and graphical icons could be selected to start applications/functions and select items from menus. The small keyboard proved difficult to use however, and the following 5c model in 1997 used an innovative foldout miniature QWERTY keyboard. These genuinely “handheld” devices with their interface innovations and ability to synchronize data with a host personal computer made the PSION models particularly successful and firmly established the personal digital assistant as a portable computing tool for professionals.

Pen-Based Interfaces for the PDA

The limitations of keyboard-based data entry for handheld devices had been recognized, and following PSION’s lead, Apple Computers introduced the Newton Message Pad in 1993. This device was the first to incorporate a touch-sensitive

screen with a pen-based graphical interface and handwriting-recognition software. Although moderately successful the device's handwriting recognition proved slow and unreliable, and in 1998 Apple discontinued its PDA development. However, the PDA market was now becoming firmly based upon devices using pen-based handwriting recognition for text entry, and in mid-2001, PSION, with dwindling sales and difficulties with business partnerships, ceased trading. US Robotics launched the "Palm Pilot" in 1996 using its simple "Graffiti" handwriting recognition system, and Compaq released the "iPAQ" in 1997 incorporating the new Microsoft "Windows CE/Pocket PC" operating system with the first PDA color screen.

Microsoft's relatively late entry into this market reflected the considerable research and development it undertook into developing a user-friendly pocket PC handwriting recognition interface. This remains a highly competitive field, and from November 2002 PalmSource (the new company owning the Palm Operating System) replaced the Graffiti system with Computer Intelligence Corporation's JOT as the standard and only handwriting software on all new Palm-powered devices. Computer Intelligence Corporation (CIC) was founded in conjunction with the Stanford Research Institute (SRI) based on research conducted by SRI on proprietary pattern recognition technologies (CIC, 1999). The original Graffiti system relied on the user learning a series of special characters, which while simple was irksome to many users. The CIC JOT and Microsoft Pocket PC systems have been developed to avoid the use of special symbols or characters and allow the user to input more naturally by using standard upper and lowercase printed letters. Both systems also recognize most of the original Palm Graffiti-based special characters. In 2006 Palm introduced the Windows Mobile (Pocket PC) operating system on its own high-end devices.

The Thumb Board Text Interface

The arrival of the short messaging service (SMS), otherwise known as text messaging for cellular phones, in the late 1990s led several PDA manufacturers to adopt an alternative Thumb Board interface for their PDAs. SMS allows an individual to send short text and numeric messages (up to 160 characters) to and from digital cell phones and public SMS messaging gateways on the Internet. With the widespread adoption of SMS by the younger generation, thumb-based text entry (using only one thumb to input data on cell phone keypads) became popular (Karuturi, 2003). Abbreviations such as "C U L8er" for "See you later" and "emoticons" or "smileys" to reduce the terseness of the medium and give shorthand emotional indicators developed. The rapid commercial success of this input interface inspired the implementation of Thumb Board "keyboards" on some PDAs (such as the Palm Treo 600) for text interface. Clip-on Thumb Board input accessories have also been developed for a range of PDAs.

Tablet Format PCs

The tablet PC provides a small (usually 10 x 12" screen size) rectangular format device equipped with a sensitive screen designed to interact with a device-specific pen. The pen is used directly to write or tap on the screen. It can be used in place of a keyboard or mouse for data entry; to select, drag, and open files; to draw on the screen; and to handwrite notes and communications. Tablet PCs also incorporate handwriting recognition and conversion to text software. Unlike a touch-sensitive screen, the Tablet PC screen only receives information from the device-specific pen. It will not take information from pressure applied to the screen, so users can rest their hands on the screen and write in a more natural way. Most Tablet PCs also come with optional attachable keyboards and docking stations so they can be used in the same way as a desktop computer.

A pen-based interface for the PC was developed in the early 1990s and was originally envisaged as a challenge to the mouse. Microsoft launched "Pen Extensions for Windows 3.1" in 1991 calling it "Windows for Pen Computing." The system was designed to use plug-in slate and pen systems. However, pen-based systems would take another 10 years to become established. Shortly after its launch a number of companies introduced hardware to support it. Among them were Samsung, Fujitsu, Compaq, Toshiba, and IBM. The original IBM ThinkPad was designed as a pen-based computer. However, these pen-based systems were not well received, as many users found the Windows interface difficult to use with the stylus, and by 1995 sales of pen-based systems failed to support their further mainstream development. Bill Gates remained a strong supporter of the interface, and Microsoft decided to reintroduce pen computers as the "Tablet PC" in 2002. This time the Tablet PC specification was more successful as the use of touch-screen technologies for the pen (not well developed in the 1990s), handwriting recognition, and better integrated smaller devices made the portable tablet more acceptable for consumers.

The tablet PC has proved popular for specialist uses such as in the classroom, for creative artistic use, or more recently as the platform of choice for electronic flight planning/mapping software in aviation. A growing number of manufacturers are now producing Tablet PC hardware. However, the format still retains a far smaller proportion of the mobile PC market compared to laptops and PDAs.

MULTIMEDIA AND WIRELESS INTEGRATION

Current developments in pen-based computer interfaces are exploring the use of multimedia, voice recognition, and wireless connectivity. The expansion of memory capabili-

ties and processor speeds for mobile computing devices has enabled audio recording, digital music storage/playback, and now digital image and video recording/playback to be integrated into these devices. This and the integration of wireless network and cellular phone technologies have expanded their utility considerably.

One of the mobile computer user. Audio is attractive for mobile applications because it can be used when the user's hands and tablet interfaces remains the output display, it can be used in conditions of low screen visibility, and it may consume less power than text-based input in the PDA. The latest PDA interface innovations include voice command and dictation recognition (voice to text), voice dialing, image-based dialing (for cell phone use, where the user states a name or selects an image to initiate a call), audio memo recording, and multimedia messaging (MMS). Several devices (e.g., the new Carrier Technologies I-Mate and Palm Treo) also incorporate a digital camera.

Wireless connectivity has enabled Internet connectivity, enabling users to access e-mail, text/graphical messaging services (SMS and MMS), and the Web remotely. These developments are gradually expanding the PDA's functionality into a true multi-purpose tool.

FUTURE TRENDS

One of the key limitations of PDA and tablet interfaces remains the output display screen size, brightness, and resolution. Issues of resolution and brightness continue to hinder many potential applications for this technology. As input technologies improve, and voice and handwriting recognition come of age, then attention to the display capabilities of these devices will need to be addressed before their full potential can be realized.

Coding PDA applications to recognize handwriting, speech, and incorporate multimedia requires additional code beyond traditionally coded interfaces. PDA application design and development environments need to support this functionality more effectively in order to promote the development of more complex mobile applications.

Data and device security are key areas for highly portable networked PDAs, and the first viruses for PDAs have started to emerge (Melnick, Dinman, & Muratov, 2004; BitDefender 2004). As multimedia interfaces develop, the specific security issues that they entail (such as individual voice recognition and prevention of data corruption of new file formats) will also need to be addressed.

CONCLUSION

Since the early models, manufacturers have continued to introduce smaller and improved portable computers,

culminating in the latest generation of powerful handheld PDAs offering fast (400 MHz and faster) processors, with considerable memory (64MB of ROM and 1GB of RAM or more). This area of technological development remains highly competitive, and by necessity, the user interface for these devices has developed to fulfill the portable design brief, including the use of pen- and voice-based data input, collapsible LCD displays, wireless network connectivity, and now cell phone integration. Modern PDAs are much more sophisticated, lightweight devices and are arguably much closer to Kay's original vision of mobile computing than the current laptop or tablet computers, and possibly have the potential to replace this format with future interface developments. Indeed, if the interface issues are successfully addressed, then it is probable that these devices will outsell PCs in the future and become the major computing platform for personal use.

KEY TERMS

Audio Memo: An audio recorded message of speech digitally recorded as an audio file on a PDA.

Laptop: A portable personal computer small enough to use on your lap.

Media Player: A device or software application designed to play a variety of digital communications media such as compressed audio files (e.g., MPEG MP3 files), digital video files, and other digital media formats.

Multimedia: Communications media that combines multiple formats such as text, graphics, sound, and video.

Multimedia Messaging Service (MMS): An emerging cellular phone service that allows the sending of multiple media in a single message, with the ability to send a message to multiple recipients. As such it can be seen as an evolution of SMS, with MMS supporting the transmission of additional media types, including: pictures, audio, video, and combinations of the above.

Palmtop: A portable personal computer which can be operated comfortably while held in one hand.

Pen Computing: A computer that uses an electronic pen (or stylus) rather than a keyboard for data input. Pen-based computers often support handwriting or voice recognition so that users can write on the screen or vocalize commands/dictate instead of typing with a keyboard. Many pen computers are handheld devices. Also known as pen-based computing.

Personal Digital Assistant (PDA): A small handheld computing device with data input and display facilities with a range of software applications. Small keyboards and pen-based input systems are commonly used for user input.

Personal Information Manager (PIM): A software application (such as Microsoft Outlook) that provides multiple ways to log and organize personal and business information such as contacts, events, tasks, appointments, and notes on a digital device.

Smart Phone: A term used for the combination of mobile phone and PDA.

Short Message Service (SMS): A text message service that enables users to send short messages (160 characters) to other users. A popular service amongst young people, with 400 billion SMS messages sent worldwide in 2002 (GSM World 2002).

Synchronization: The harmonization of data on two (or more) different digital devices so that both contain the same data. Data is commonly synchronized on the basis of the date it was last altered.

Tablet PC: A newer type of format for personal computers. The Tablet PC provides all the power of a laptop PC, but without a keyboard for text entry. Tablet PCs use pen-based input, and handwriting and voice recognition technologies as the main form of data entry, and commonly have an A4-size footprint.

Texting: Sending short text messages by SMS.

Wireless Connectivity: The communication of digital devices between one another using data transmission by radio waves.

Perceived Quality Evaluation for Multimedia Services

INTRODUCTION

The advent of 3G mobile communication networks has caused the fading of the classical boundaries between telecommunications, multimedia, and information technology sectors. The outcome of this convergence is the creation of a single platform that will allow ubiquitous access to the Internet, multimedia services, and interactive audiovisual services, and in addition (and most importantly) offering the required/appropriate perceived quality level at the end user's premises.

In this respect, multimedia services that distribute audiovisual content over 3G/4G mobile communication systems are expected to possess a major part of the bandwidth consumption, making necessary the use of video compression. Therefore, encoding techniques (e.g., MPEG, H-26x) will be applied which achieve high compression ratios by exploiting the redundancy in the spatiotemporal domain of the video content, but as a consequence produce image artifacts, which result in perceived quality degradation.

One of the 3G/4G visions is the provision of audiovisual content at various quality and price levels. There are many approaches to this issue, one being the perceived quality of service (PQoS) concept. The evaluation of the PQoS for audiovisual content will provide a user with a range of potential choices, covering the possibilities of low-, medium-, or high-quality levels. Moreover the PQoS evaluation gives the service provider and network operator the capability to minimize the storage and network resources by allocating only the resources that are sufficient to maintain a specific level of user satisfaction.

The evaluation of the PQoS is a matter of post-encoding procedures. The methods and techniques that have been proposed in the bibliography mainly aim at:

- determining the encoding settings (i.e., resolution, frame rate, bit rate) that are required in order to carry out successfully a communication task of a multimedia application (i.e., videoconference); and
- evaluating the quality level of a media clip based on the detection of artifacts on the signal caused by the encoding process.

The scope of this article is to outline the existing procedures and methods for estimating the PQoS level of a multimedia service.

BACKGROUND

The advent of quality evaluation was based on applying pure mathematical/error-sensitive equations between the encoding and the original/uncompressed video signal. These primitive methods, although they provided a quantitative approach about the quality degradation of the encoded signal, do not provide reliable measurements of the perceived quality, because they miss the characteristics and sensitivities of the human visual system.

The most widely used primitive methods and quality metrics that are based on the error sensitivity framework are the peak signal to noise ratio (PSNR) and the mean square error (MSE):

$$\text{PSNR} = 10 \log_{10} \frac{L^2}{\text{MSE}}, \text{ where } L \text{ denotes the dynamic pixel value (i.e., equal to 255 for 8bits/pixel monotonic signal)} \quad (1)$$

$$\text{MSE} = \frac{1}{N} \sum_{i=1}^N (x_i - y_i)^2, \text{ where } N \text{ denotes the total pixels and } x_i / y_i \text{ the } i^{\text{th}} \text{ pixel value in the original/distorted signal} \quad (2)$$

Currently, the evaluation of the PQoS is a matter of objective and subjective evaluation procedures, each time taking place after the encoding process (post-encoding evaluation). Subjective picture/audio quality evaluation methods require a large amount of human resources, establishing it as a time-consuming process (e.g., large audiences evaluating video/audio sequences). Objective evaluation methods, on the other hand, can provide PQoS evaluation results faster, but require a large amount of machine resources and sophisticated apparatus configurations. Towards this, objective evaluation methods are based on and make use of multiple metrics, which are related to the content's artifacts (i.e., tiling, blurriness, error blocks, etc.) resulting during an encoding process.

These two categories of PQoS evaluation methods will be analyzed and discussed in the following sections.

SUBJECTIVE QUALITY EVALUATION METHODS

The subjective test methods, which have mainly been proposed by the International Telecommunications Union (ITU) and the Video Quality Experts Group (VQEG), involve an audience of people who watch a video sequence and score its quality, as perceived by them, under specific and controlled watching conditions. Afterwards, the statistical analysis of the collected data is used for the evaluation of the perceived quality. The mean opinion score (MOS) is regarded as the most reliable subjective metric of quality measurement and has been applied on the most known subjective techniques.

Subjective test methods are described in ITU-R Rec. T.500-11 (2002) and ITU-T Rec. P.910 (1999), suggesting specific viewing conditions, criteria for the observer, test material selection, assessment procedure description, and statistical analysis methods. The BT.500-11 describes subjective methods that are specialized for television applications, whereas ITU-T Rec. P.910 is intended for multimedia applications.

The most known and most widely used subjective methods are:

- **Double Stimulus Impairment Scale (DSIS):** This method proposes that observers watch multiple references and degraded scene pairs, with the reference scene always shown first. Scoring is evaluated on an overall impression scale of impairment: imperceptible, perceptible but not annoying, slightly annoying, annoying, and very annoying. This scale is commonly known as the five-point scale (where 5 corresponds to “imperceptible” and 1 to “very annoying”).
- **Single Stimulus (SS) Methods:** Multiple separate scenes are shown. There are two different SS approaches: SS with single view of test scenes and SS where the test scenes are repeated. Three different scoring methods are used:
 - **Adjectival:** The aforementioned five-grade impairment scale, however half-grades are allowed.
 - **Numerical:** An 11-grade numerical scale, useful if a reference is not available.
 - **Non-Categorical:** A continuous scale with no numbers or a large range, for example, 0-100.
- **Stimulus Comparison Method:** This methods exploits two well-matched screens, where the differences between scene pairs are scored in one of the two following scoring methods:
 - **Adjectival:** A seven-grade, +3 to -3 scale labeled: much better, better, slightly better, the same, slightly worse, worse, and much worse.
 - **Non-Categorical:** A continuous scale with no numbers or a relation number either in absolute terms or related to a standard pair.
- **Single Stimulus Continuous Quality Evaluation (SSCQE):** According to this method, the viewers watch a program of typically 20-30 minutes without any reference signal. The viewers, using a slider, continuously rate the instantaneously perceived quality using an adjectival scale from ‘bad’ to ‘excellent’, which corresponds to an equivalent numerical scale from 0 to 100.
- **Double Stimulus Continuous Quality Scale (DSCQS):** At DSCQS the viewers watch multiple pairs of quite short (i.e., 10 seconds) reference and test sequences. Each pair appears twice, with random order of the reference and the test sequence. The viewers/subjects are not aware of the reference/test order, and they are asked to rate each of the two separately on a continuous adjectival scale, ranging from ‘bad’ to ‘excellent’, which corresponds to an equivalent numerical scale from 0 to 100. This method is usually used for evaluating slight quality differences between the test and the reference sequence.

The aforementioned methods are described in the ITU-R Rec. T.500-11 document and are mainly intended for televi-

sion signals. Based on slight modifications and adaptations of these methods, some other subjective evaluation methods (namely absolute category rating (ACR), degradation category rating (DCR), etc.) for multimedia services are described in ITU-T Rec. P.910.

OBJECTIVE QUALITY EVALUATION METHODS

The preparation and execution of subjective tests is costly and time consuming, and its implementation today is limited to scientific purposes, especially at VQEG experiments.

For this reason, a lot of effort has recently been focused on developing cheaper, faster, and more easily applicable objective evaluation methods. These techniques successfully emulate the subjective quality assessment results, based on criteria and metrics that can be measured objectively. The objective methods are classified according to the availability of the original video signal, which is considered to be of high quality.

The majority of the proposed objective methods in the literature require the undistorted source video sequence as a reference entity in the quality evaluation process, and due to this are characterized as full reference methods. These methods emulate characteristics of the human visual system (HVS) using contrast sensitivity functions (CSF), channel decomposition, error normalization, weighting, and finally Minkowski error pooling for combining the error measurements into single perceived quality estimation (Wang, Sheikh, & Bovik, 2003).

However it has been reported (VQEG, 2000; Wang, Bovik, & Lu 2002) that these complicated methods do not provide more accurate results than the simple mathematical measures (such as PSNR). Due to this some new full reference metrics that are based on the video structural distortion, and not on error measurement, have been proposed (Wang et al., 2003).

On the other hand, the fact that these methods require the original video signal as reference deprives their use in commercial video service applications, where the initial undistorted clips are not accessible. Moreover, even if the reference clip is available, then synchronization predicaments between the undistorted and the distorted signal (which may have experienced frame loss) make the implementation of the full reference methods difficult and impractical.

Due to these reasons, recent research has focused on developing methods that can evaluate the PQoS level based on metrics, which use only some extracted structural features from the original signal (Reduced Reference Methods—Guawan & Ghanbari, 2003) or do not require any reference video signal (No Reference Methods—Lu, Wang, Bovik, & Kouloheris, 2002).

However, due to the fact that the 3G/4G vision is the provision of audiovisual content at various quality and price levels (Seeling, Reisslein, & Kulapala, 2004), there is great need for developing methods and tools that will help service providers to predict quickly and easily the PQoS level of a media clip. These methods will enable the determination of the specific encoding parameters that will satisfy a certain quality level. All the previously mentioned post-encoding methods may require repeating tests in order to determine the encoding parameters that satisfy a specific level of user satisfaction. This procedure is time consuming, complex, and impractical for implementation on the 3G/4G multimedia mobile applications.

Towards this, recently research was performed in the field of pre-encoding estimation and prediction of the PQoS level of a multimedia service as a function of the selected resolution and the encoding bit rate (Koumaras, Kourtis, & Martakos, 2005; Koumaras et al., 2004). These methods provide fast and quantified estimation of the PQoS, taking into account the instant PQoS variation due to the spatial and temporal (S-T) activity within a given encoded sequence. Quantifying this variation by the mean PQoS (MPQoS) as a function of the video encoding rate and the picture resolution, it finally used the MPQoS as a metric for pre-encoding PQoS assessment based on the fast estimation of the S-T activity level of a video signal.

FUTURE TRENDS

Simultaneously with the development of the aforementioned methods and techniques, research has been focused on developing methods that determine the adequate quality level for a specific multimedia application, taking under consideration not solely the visual estimations, but also a great number of parameters and metrics that depend on the task nature and the user emotional behavior and psychophysical characteristics (Mullin, Smallwood, Watson, & Wilson, 2001). For example, the classification of the task as foreground or background in correlation with its complexity (Buxton, 1995) is a parameter that differentiates the quality demands of a multimedia application. On the other hand, the emotional content of a multimedia communication task alters the required quality level of the specific communication service (Olson, 1994). Due to this, various parameters are measured in order to estimate the appropriate minimum quality level of a multimedia application. Such parameters are:

- the user characteristics (i.e., knowledge background, language background, familiarity with the task, age);
- the situation characteristics (i.e., geographical remoteness, simultaneous number of users, distribution of users);

- the user cost (i.e., heart rate, blood volume pulse); and
- the user behavior (i.e., eye tracking, head movement).

However, these methods still have some issues to solve on the technical, theoretical, and practical levels. A user that participates in such an assessment procedure is so wired (even on the head, he or she may wear the eye tracking equipment) that it causes uncomfortable feelings and affects his or natural behavior. Technical issues, such as the eye tracking loss and the manual calibration/correction by a human operator, affect the reliability of the methods in real-time environments (Mullin et al., 2001).

CONCLUSION

Multimedia applications, and especially encoded video services, are expected to play a major role in third-generation (3G) and beyond mobile communication systems. Given that future service providers are expected to provide video applications at various price and quality levels, quick and economically affordable methods for preparing/encoding the offering media at various qualities need to be developed. There are a number of approaches to this challenge, one being the use of the perceived quality of service concept. The evaluation of the PQoS for multimedia and audiovisual content that has variable bandwidth demands will provide a user with a range of choices covering the possibilities of low-, medium-, or high-quality connections, an indication of service availability and cost. This article outlines the various existing PQoS evaluation methods and comments on their efficiency.

These methods can be mainly categorized into two major classes: subjective and objective. The subjective test methods involve an audience of people who watch a video sequence and evaluate its quality, as perceived by them, under specific and controlled watching conditions. The objective methods successfully emulate the subjective quality assessment results, based on criteria and metrics that can be measured objectively. These objective methods are classified according to the availability of the original video signal to full reference, reduced reference, and no reference.

However, all the aforementioned post-encoding methods require repeating post-encoding tests in order to determine the encoding parameters that satisfy a specific level of user satisfaction, making them time consuming, complex, and impractical for implementation on the 3G/4G multimedia mobile applications. Due to this, lately some new pre-encoding evaluation methods have been proposed that are capable of estimating/predicting the PQoS level of a multimedia service based on the selected resolution, bit rate, and content activity. These methods quickly provide accurate estimations

of PQoS level, alleviating the time and resource requirements that the traditional objective methods consume.

KEY TERMS

Bit Rate: A data rate expressed in bits per second. In video encoding the bit rate can be *constant*, which means that it retains a specific value for the whole encoding process, or *variable*, which means that it fluctuates around a specific value according to the content of the video signal.

Double Stimulus Continuous Quality Scale (DSCQS): A subjective evaluation method according to which the

viewers watch multiple pairs of quite short (i.e., 10 seconds) reference and test sequences. Each pair appears twice, with random order of the reference and the test sequence.

Multimedia: The several different media types (e.g., text, audio, graphics, animation, video).

Objective Measurement of Perceived Quality: A category of assessment methods that evaluates the PQoS level based on metrics, which can be measured objectively.

Perceived Quality of Service (PQoS): The perceived quality level that a user experiences from a multimedia service.

Quality Degradation: The drop of the perceived quality to a lower level.

Single Stimulus Continuous Quality Evaluation (SS-CQE): A subjective evaluation method according to which the viewers watch a program of typically 20-30 minutes, without the original reference shown, and score its quality.

Spatial-Temporal Activity Level: The dynamics of the video content, in respect to its spatial and temporal characteristics.

Pest Activity Prognosis in the Rice Field

INTRODUCTION

In crops management, it is important to estimate the damage effected by pests since the degree of damage will determine the level of pest activity. Pest activity usually involves their life stage and its presence in the field. In addition, pest management in crops is a crucial problem and may yield losses if it is not handled properly. Consequently a forecasting tool is needed to predict the level of pest activity. This is important so that an early treatment or action can be applied before more damage to the plant occurs.

Accordingly, the fuzzy expert system may facilitate the user through a consultation session in order to forecast the pest activity in the rice field. A set of questions will be asked to help users diagnose their given symptom in order to infer such a conclusion. Figure 1 shows the main components of an expert system including inference engine, expert, knowledge base, working memory, and user interface. The consultation performed by the expert system also involves fuzzy logic to deal with the natural and uncertainty data. Besides, all the information and knowledge about the pests, treatment control measures and prevention steps are managed in the specific knowledge base created in the system. This system is able to educate and inform the farmers and smallholders about pests and their activities in the rice field.

BACKGROUND

Sustainable agriculture is a key element of sustainable development and essential to the future well-being of the planet. Sustainability aims to achieve adequate safe and healthy food production, improved livelihoods of food producers, and the preservation of non-renewable resources. The demands of a growing world population for food and fiber require world agriculture to produce higher yields from less cultivated land. Recently, the emerging need for hybrid intelligent systems

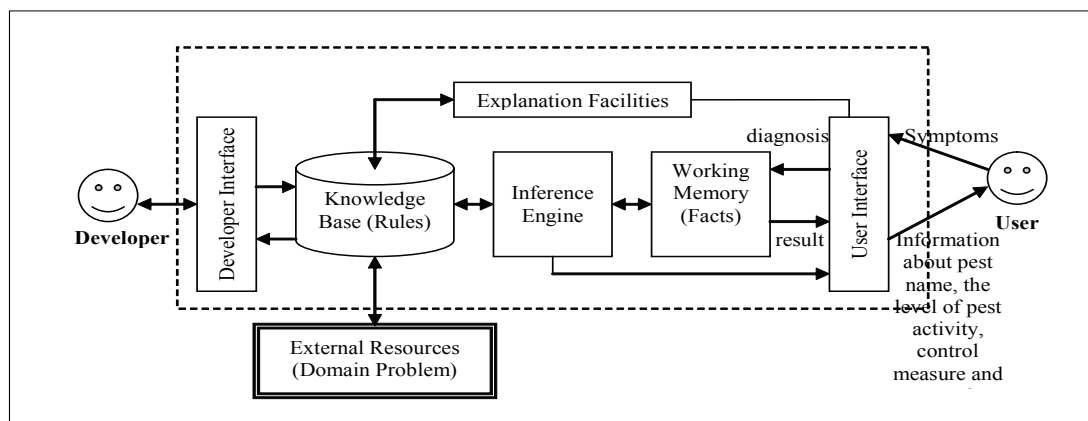

(HISs) is motivating important research and development work. The integration of different learning and adaptation techniques to overcome individual limitations and achieve synergetic effects through hybridization or fusion of these techniques has in recent years contributed to a large number of new intelligent system designs (Abraham & Nath, 2001). This integration aims at overcoming limitations of individual techniques through hybridization or fusion of various techniques.

In the past decade, a great many expert systems—such as office automation, science, and medicine including agriculture—were developed and applied to many fields. At the initial stage of agriculture expert system development, the focus was on diseases diagnosis and pests of various crops. In recent years, research and development of the expert system fields of the agriculture domain received much attention by many countries. The difficulty of problems confronting farmers are yield losses, soil erosion, diminishing market prices from international competition, increasing chemical pesticide costs, pest resistance, and economic barriers. Hence, farmers need such an application or tools to assist with various knowledge and information, especially in their farming operations.

PEST ACTIVITY PROGNOSIS

Pest management in agriculture is a pest control strategy that coordinates and uses a combination of methods to meet individuals' production goals in the most economical and environmental manner. In short, it is based on understanding the farm's ecology. The basic components of pest management include acceptable pest levels, preventive cultural practices, monitoring, mechanical controls, biological control, and chemical control. It is apparent that that farm's monitoring and prevention endow with significant contribution to reduce losses.

Figure 1. Expert system components

The management of pests in crops is a highly challenging problem and may yield losses if not handled properly (Saini, Kamal, & Sharma, 2002). Potential losses of up to 55% before harvest have been estimated, but these estimates often represent the worst case or highest levels of loss. Consequently, different technologies are needed as well as awareness programs for effective, economical, environment-friendly control of pests (Singh & Singh, 1990). Besides, the appropriate and optimal combination of control measures are used for cost-effective and environment-friendly control of pests (Atwal & Dhaliwal, 1997).

It is important to manage and control the pest occurrences and their activity in the crop fields. Pests in crop management involves birds, snails, worms, rats, and others. Good field practices to protect and sustain the field require proficient knowledge and information. Here, farmers are encouraged to learn their farm, observe and monitor, and use their knowledge and experience to decide on actions. They may also seek advice from farm experts (researchers and governmental representatives). Consequently, the transfer of expert knowledge and extension information to the farmers plays a key role in educating this community. The understanding of the farmers is further increased through experimentation and knowledge sharing. For that reason, an expert system seems to be beneficial to vary the knowledge sharing and reasoning. Expert system offer a program that uses available information, heuristics, and inference to suggest solutions to problems in a particular discipline. While such systems do not often replace the human experts, they can serve as useful assistants. Expert systems will play a major role in the dissemination and application of useful knowledge leading to economic growth and higher standards of living.

It is not only providing expert knowledge, but potentially become learning resources to help farmers develop their own expertise.

On the other hand, as knowledge involved in pest management is imperfect and fuzzy logic has been successfully used for approximate reasoning in such cases, its application becomes mandatory to manage the uncertainty in the expert system (Zadeh, 1983). Appearance of damage at a farm does not always promise identification of the pests. Crop damage is never complete and usually expressed linguistically as very low, low, medium, high, and very high. Moreover, the partial truth values of existing pest symptoms may strengthen pest identification. The value of pest occurrence symptoms is also captured in fuzzy terms such as few, many, light, and many more. Due to the imperfect, vague, and not completely reliable knowledge involved in pest activity and damage level in the rice fields, it is difficult to measure the symptom occurrences with simply yes or no, or absence and presence notation. The crisp rules may not be precisely appropriate for pest identification (Pasqual & Mansfield, 1988). For instance, the existence of larvae in the leaves cannot be simply expressed by the 'yes' or 'no' value.

However, the existing expert system allows the user to answer the set of questions using the rigid crisp values (Saini et al., 2002). In crops management, it is important to estimate the damage that has been affected by pests, since the degree of damage will determine the activity of pests (Atwal & Dhaliwal, 1997). Therefore, there is need for a forecasting tool that can predict the level of pest activity so that early treatments can be applied to crops before the damage becomes worse. Hence fuzzy logic helps to cope with the precise damage symptoms for pest activity estima-

tion, which is proportional to the level of damages. Fuzzy modeling techniques such as fuzzy sets, fuzzy logic, and fuzzy expert systems are used to capture vague concepts and process imprecise information, and can further implement and express human knowledge and inference capability in a natural way. The design of a fuzzy system mainly involved two operations: the derivation of the knowledge base, and the selection of the fuzzy inference with a defuzzification process that the system will use to perform the fuzzy reasoning (Cordon, Herera, & Peregrin, 1994).

In order to develop such an intelligent system embedded with some prediction and forecasting ability, a lot of effort is needed. The advantage of fuzziness is that dealing with imprecision fits ideally into decision systems. The vagueness and uncertainty of human expressions is well modeled in the fuzzy sets, and a pseudo-verbal representation, similar to an expert's formulation, can be achieved (Hasiloglu, Yavuz, Rezos, & Kaya, 2003). Garibaldi (1997) stated that in multi-valued logic, truth values are represented by a single real number in the interval $[0,1]$, where 0 represents false, 1 represents true, and values between 0 and 1 represent partial truth, whereas in fuzzy logic, true and false are represented by fuzzy subsets over the interval $[0,1]$, with arbitrary fuzzy subsets representing other intermediate truth values.

Fuzzy Expert System

Hybrid systems composed of artificial intelligence (AI) approaches have shown quite remarkable results in diagnosis (Herrmann, 1995). A fuzzy expert system is an expert system that uses fuzzy logic instead of Boolean logic, and a collection of membership functions and rules that are used to reason about data. Unlike conventional expert systems, fuzzy expert systems are oriented toward numerical processing. This expert system is extended to incorporate explicit handling of imprecision in the input data and uncertainty in the embedded knowledge. The system formed the basis of the fuzzy expert system. The existent crisp rule set was used to derive the initial fuzzy rule set and to guide the initial choice of location of membership function for each fuzzy term (Garibaldi et al., 1999).

In contrast with conventional AI techniques, which only deal with precision and uncertainty, the guiding principle of hybrid systems is to exploit the tolerance for imprecision, uncertainty, low solution cost, robustness, partial truth to achieve tractability, and better understanding with reality (Zadeh, 1998). However, although the theoretical properties of fuzzy systems have been extensively investigated, the implementation of a fuzzy expert system in practice involves a great deal of pragmatic choices. This includes considerations for the type of inference methodology, rule set, and fuzzy operators to determine an appropriate fuzzy model of the expertise for a particular application.

Moreover, the prognosis term has been used widely in medical applications and defined as a forecast of course of disease (Coulson, Carr, Hutchinson, & Eagle, 1990). Since prognosis requires forecasting ability as well as the ability to explain why a phenomenon occurs, AI techniques that are required to perform prognosis must be able to forecast and provide reasoning. AI techniques that are suitable for prediction are neural network, fuzzy logic, and case-based reasoning. On the other hand, expert system and case-based reasoning are good at providing explanation to intelligent system. In this study, techniques which have the forecasting and explanation abilities are required. For this purpose, fuzzy logic and an expert system have been chosen to be integrated into a Web-based environment to demonstrate the used of a hybrid system on pest activity in rice field data.

MOBILE COMPUTING AND CELLULAR TECHNOLOGY

Wireless technologies represent a rapidly emerging area of growth and importance for providing ubiquitous access to the network for various communities. The most related network technology with wireless technology is the mobile computing environment. Mobile computing systems are computing systems that may be easily moved physically and may be used while users are on the move. Examples of mobile devices are laptops, personal digital assistants (PDAs), and mobile phones.

The initiation of portable computers and handheld devices simultaneously with Internet technology has led to mobile computing. The growth of mobile devices has tremendously increased its usability and provides more easy access. As devices become smaller and more portable, the demand for computing and networking solutions while on the move has increased steadily. In the mobile computing environment, users can perform online transaction processing independent of the physical location. Geographical constraints can also be eliminated from data processing activities. Accordingly, data and information stored in a certain database can be accessed widely, using mobile technology and devices. This is important to disseminate information and knowledge among the users.

However, mobile computing environments must deal with limited and dynamically varying resources, in particular, the network quality of service (Bharghavan & Gupta, 1997). This shows that, to facilitate the success of mobile computing application, many factors should be considered. These include slow networks, wasteful protocols, disconnections, weak terminals, operating systems (OSs), and many others (Satyanarayanan, 1995). Nevertheless many efforts have progressed to improve the constraints and increase the usability. For example, enhancements in applications and devices and

increasing of data rates will drive to the implementation of the most efficient solution such as 3G. New devices will be introduced and existing devices will evoke to provide more enhanced wireless data experience.

Mobility applications enable the data transmission and user interaction between wireless devices and a central repository. Data transmission is handled by synchronization applications in situations where the user is not connected to the central database on a real-time basis (Ramadhani & Siddiqi, 2003). Facilitated with numerous handheld devices, the data transmission through these devices extend the mobile application, especially in distributing information among citizens.

Basically, a cellular network is a radio network made up of a number of radio cells, each served by a fixed transmitter known as a cell site or base station. These cells are used to cover different areas in order to provide radio coverage over a wider area than the area of one cell. The most common example of a cellular network is a mobile phone (cell phone) network. A mobile phone is a portable telephone that receives or makes calls through a cell site (base station) or transmitting tower. Mobile phones are becoming more powerful and are equipped with additional large memory, networking interfaces (i.e., IrDA, Bluetooth, and GSM/GPRS), and can reconcile packets between the different networks. Hence, to being able to connect to the network operator, modern phones must have network connection facility. Different hardware manufacturers usually provide different device features (i.e., operating and middleware systems) to the users. Therefore, such particular features are important to support the deployment of the system application using a mobile phone's capability.

FUZZY EXPERT SYSTEM APPLICATION USING MOBILE PHONE

This study focuses on the software development using hybrid AI technology and the employment of a fuzzy expert system

Figure 2. Set of expert questions

| No. | Question | Answer | Why Ask? |
|-----|---|--------|----------|
| 1 | Is adult in appearance of slender and green? | Yes | WHY |
| 2 | Is there a large butterflies with patterns of eye spots on the wings? | No | WHY |
| 3 | Is adult color brownish black with yellowish brown body? | No | WHY |
| 4 | Is there any borers observed at the plants? | No | WHY |
| 5 | Is there any bugs with slender and brown green appearance? | No | WHY |

| No. | Question | Answer | Why Ask? |
|-----|---|--------|----------|
| 1 | Is adult's head rounded or pointed with or without black bands? | Yes | WHY? |
| 2 | Can you find a pair of black spots that is either present or absent on the forewings? | Yes | WHY? |

in the agriculture domain typically in Malaysia. Therefore it emphasizes data acquisition and mapping of uncertainty into fuzzy values, which consists of labels and confidence values. The application offers a computerized fuzzy expert system in dealing with uncertainty information in a way to identify the kinds of pests that attack the rice plant derived from the symptoms given by the farmers. The system helps the user by managing the consultation session in order to forecast the pest activity. With reference to Figure 2, the user has given answers to the related questions and the system will invoke the knowledge base to find the conclusion based on the given answer.

This will help the user diagnose his or her given symptom in order to infer such a conclusion. The consultation performed by the expert system also involved fuzzy logic when dealing with the natural and uncertainty data. The occurrences of pests in the rice field and crop production may affect the field yields. Pest management is needed where losses are much higher, resulting in complete damage. These pests attack the crop from the time of sowing through to harvest and beyond, often causing significant economic losses. Therefore a forecasting system is intended to facilitate the warning system so farmers can apply early treatment to avoid high losses resulting from complete damage.

Even though such a prognostic system has been developed, it is important to distribute and make the application accessible by these farmers. Consequently, this system will facilitate as well as educate the farmers to possess their awareness in their own field management. Moreover, this prognostic application can be accessed using an affordable mobile device. The mobile devices equipped with minimal 2.5G application (GPRS connection) will support the prognostic application. Figure 3 shows the access of prognostic application through mobile phones.

Thus, the prognostic system should be made more accessible to the farmers using mobile devices. Mobile users are able to access and exchange information while they are on the move. Meanwhile, mobile devices need a mobile computing technology to wirelessly connect and use centrally located information and application software. Mobile phones, for instance, are easy to use and equipped with minimal setting of wireless network configuration. Availability and network coverage in these devices depend upon the carrier and the

Figure 3. Accessing from mobile phone

geographic scope of international roaming agreements. Therefore it can allow for a more effective, convenient, and timely use of computing and communication. It is expected that the wireless technology will play an important role in the acquisition and dissemination of new knowledge and technologies to motivate the involvement of youth in the agricultural sector. It is also anticipated to redress the digital divide between the farming community and others.

FUTURE DIRECTIONS

This study attempts to explore the employment of a fuzzy expert system in the agriculture domain typically in Malaysia. Previous study performed by Saini et al. (2002) has been developed to provide pest management to the farmers through the Internet. Saini et al. (2002) have also improved the existing expert system they developed by applying fuzzy logic to handle the uncertainty involved in damage forecasting. Since the system produced is a prototype, the system needs more enhancement and improvements in order to get better results and performance. For the forecasting tasks, if more historical data can be captured, it is beneficial to integrate neural network and fuzzy logic. Neuro-fuzzy systems are known to mitigate the limitations and take advantage of opportunities to produce more powerful hybrids than those that could be built with stand-alone systems where it facilitates fast learning and online adaptability, and achieves a global error rate and computational inexpensive.

On the other hand, an intelligent agent approach can be applied to support Web facilities as well as provide further explanation for expert system. It is a possible way to increase explanation facilities by integrating an intelligent agent into this system, perhaps using case-based reasoning. This indirectly will enhance the support desk facilities for the users. Further enhancement can also be expanded to the other crop management systems. The same engine still can be used, however the database for other crops needs to be developed. In other words, community users will be able to benefit from the system.

CONCLUSION

This study focuses on the employment of a fuzzy expert system in order to make a prognosis on the pest level of activity in the rice fields. Since the rice industry has been and is likely to continue to be one of the most important economic sectors of the company, there is a need to help enhance the competitiveness and profitability in agriculture and forestry in this country. The crop is labor intensive and needs some portion of expenditure to manage this sector. Recently, most of the farmers in this region are gradually

moving away from the image of the traditional farmer to that of an entrepreneur farmer. This success technology can be implemented in some areas to gain benefits from that.

Furthermore, the prognostic application can be accessed using a mobile phone. This is important to disseminate agriculture's knowledge among farmers through mobile devices. This will also facilitate farmers with such an assisting prognostic tool to help manage their fields and to develop awareness of field monitoring from threats and disease. The prognostic system's application allows users to input a percentage of symptoms in uncertainty forms (high, very high, medium) rather than the common form of yes/no or absence/presence form. The system enables the users, particularly the farmers and the governmental representatives, to identify the pest that damages the plant. The system also allows the users to forecast a pest activity level in the rice field and provide the treatment information before the pest activities become worse. In addition, all the information and knowledge about the pests, treatment control measures, and prevention steps are managed in the specific knowledge base. Apart from identifying the pest and its activity level, the system can be used as part of portal development for agricultural agencies in particular and the farmer community as a whole.

Positioning Technologies for Mobile Computing

Michael J. O’Grady

University College Dublin, Ireland

Gregory M. P. O’Hare

University College Dublin, Ireland

INTRODUCTION

Mobility is, as the name suggests, the defining characteristic of mobile computing and the primary differentiator between it and other computer usage paradigms. Traditionally, computers were used in what may be termed a static context. However, when computers are used in a mobile context, a number of difficulties that challenge traditional assumptions emerge. Not least amongst these are those difficulties that arise in delivering a service that is relevant and consistent with the situation in which the end-user find themselves. Should a person be waiting at a bus stop, he or she does not wish to go online and browse a bus timetable. Rather, he or she wishes to know when the next bus will stop at his or her particular stop. Thus location and time would be fundamental to the provision of such a service. Capturing time provides no major difficulties. However, identifying the physical location of a service subscriber may prove problematic.

In this review, we summarize some of the key technologies that enable the position of a mobile computer user to be determined.

BACKGROUND

Research in mobile computing and associated disciplines (Vasilakos, 2006) began in earnest the 1990s as the feasibility of the paradigm became increasingly clear. As the various research issues began to crystallize, researchers became aware of the desirability of using additional known facts of the end user’s prevailing circumstances as a basis for customizing or personalizing the service for the individual end user. The term *context-aware computing* was coined to conceptualize these ideas. Pioneering research in this area was conducted at Xerox Parc in California by Schilit Adams, and Want (1996). The Oxford Concise dictionary defines context as “the interrelated conditions in which something exists or occurs.” Intuitively, everybody understands what context is. Almost paradoxically, this has made the derivation of an agreed definition almost impossible, leading some researchers to reconsider its philosophical roots (Dourish, 2004) and

inherently dynamic nature (Greenberg, 2001). One issue commonly agreed is that a person’s location or physical position forms an indispensable aspect of his or her context—so much so that Schmidt, Beigl, and Gellerson (1999) almost remind researchers that there are other aspects of context that should be considered. The reasons for researchers’ enthusiasm are understandable. In the mid-1990s, the global positioning system (GPS) was deployed, making it possible to determine position to within 100 meters for those people equipped with a GPS receiver. Thus the technological issues were being addressed in a meaningful way. However, it was developments in wireless telecommunications that provided the spur for the upsurge in business interest in what would be termed location-aware computing (Patterson, Muntz, & Pancake, 2003).

In 1996, the Federal Communications Commission (FCC) in the United States announced the E-911 directive. In brief: this obliged public telecommunication network operators to provide the position of those people making emergency calls, thus enabling police, medical, and other personnel to react quicker. It soon became clear that this facility could have other uses for commercial purposes as, in principle at least, the location of any subscriber could be identified. Thus an era of location-aware services was anticipated. This era has yet to materialize, but as outstanding technological issues are continually being addressed, it is only a matter of time before a suite of location-aware services are available for subscribers.

To deliver location-aware services, it is necessary that an appropriate technology be selected that will provide a subscriber’s position within a certain range. In the next section, some of the principal technologies for determining position are described.

TECHNOLOGIES

Various technologies and techniques are described in the academic literature for determining user position. Naturally, each has its respective advantages and disadvantages. For the purposes of this discussion, it is useful to classify them as

satellite techniques, cellular network techniques, and hybrid. Each classification is now considered briefly.

Satellites Technologies

Trilateration is the basic principle for determining position using satellites. In short, the time taken for a signal to travel from a satellite at a known position to a receiver is calculated. This process is repeated for three satellites and a solution can be generated. In practice, a fourth measurement is necessary to account for the lack of synchronization between the atomic clocks on the satellite and the receiver's internal clock. The accuracy of the resultant calculation may vary due to a number of factors, including atmospheric conditions and the satellite constellation configuration. However, a reading within 20 meters of the receiver's exact geographic position may be realistically expected.

At present, there are two satellite systems in operation that broadcast signals:

1. *Global positioning system* was deployed in 1996, covers the entire earth, and is freely available. It remains under the control of the United States military. It is currently the de facto standard with specialized receivers on the market for all kinds of purposes including aviation, maritime, and leisure. To use GPS, a mobile computer user would acquire a receiver, usually in the form of a Compact Flash (CF) card. More recently, receivers are sold as separate devices that can interface with any device that supports the Bluetooth protocol stack. Interestingly, a significant number of mobile phones on the market support Bluetooth, thus offering one scenario for providing location-aware services to mobile phone users.
2. *GLONASS* was developed and deployed by the former USSR in competition to GPS. For a number of years, it was not adequately maintained. However, this situation has changed recently, and GLONASS is currently being overhauled and restored to its former state. There are very few commercial products available that use GLONASS at present.

A third satellite navigation system is scheduled for launch in 2008. *GALILEO* is an initiative by the European Union (EU) that seeks to deliver a similar service to GPS and GLONASS, but with adequate guarantees regarding signal reliability. It is designed for purely civilian and commercial use, and unlike GPS and GLONASS, it is not controlled by defense or military groups. However, the signal broadcast will be compatible with GPS and GLONASS, and it is hoped that receivers that can utilize all three systems will be developed.

Cellular Network Techniques

E-911 obligated network operators and, implicitly, telecommunications equipment manufacturers to facilitate the determination of a subscriber's position within an emergency call context. A number of *cellular network techniques* were proposed as a result of ongoing research, and Zhao (2002) provides a useful overview of these. The Third Generation Partnership Project (3GPP) proceeded to standardize on four different techniques for third-generation (3G) UMTS (Universal Mobile Telephone Networks) networks (3GPP, 2005):

1. In *cell-ID*, the geographic coordinates of the base station serving the subscriber are identified. The position of the subscriber must be within the radius of this cell. Though this method is easy to implement, its principle limitation concerns the variability in cell size. Thus the precision with which the subscriber's position is calculated may range from tens to hundreds of meters.
2. *Observed time difference of arrival (OTDOA)* requires the handset to measure the time taken for a signal to arrive from three separate base stations. Hyperbolic curves must be constructed, and their intersection indicates the position of the subscriber. Though computationally expensive, a particular difficulty involves guaranteeing that the subscriber can see three base stations simultaneously. OTDOA is highly susceptible to fading and interference.
3. *Assisted GPS (A-GPS)* involves the handset measuring GPS signals from satellites. Initially, the handset is informed as to where to look for the signals, thus minimizing delay in signal acquisition. The signal measurements are then returned to the appropriate component on the network where the position is calculated. Though increasing power consumption on the device, users can expect position readings comparable with GPS.
4. *Uplink time difference of arrival (UTDOA)* is similar in principle to OTDOA, but in this case, the signals are generated at the handset and measured at a number of base stations. As the geographic positions of the base stations are known, the position of the subscriber can be calculated using hyperbolic trilateration.

With the exception of A-GPS, the accuracy of a position obtained using these techniques is variable and unpredictable. In the case of the cell-ID method, urban areas will have a concentration of base stations so the method may work well. In contrast, the diameter of cells in rural areas may be several kilometers, thus rendering the method ineffective. In the case of OTDOA and UTDOA, accurately measuring

the time it takes the signal to travel between the subscriber's handset and surrounding base stations, and vice versa, is essential. Yet the signal may be subject to interference and fading, depending on the vagrancies of the immediate physical environment.

Hybrid Techniques

A scenario can be envisaged where a number of techniques may be combined, with each remedying their respective deficiencies in certain situations. For example, in an urban area, base stations are relatively plentiful, and in certain cases, a number may be deployed in individual streets. Thus techniques like cell-ID, OTDOA, and UTDOA will function reasonably well. In contrast, GPS—and implicitly, A-GPS—may not perform satisfactorily, as the high nature of the surrounding buildings, so-called urban canyons, can result in satellites being obscured. In rural areas, the sparsity of base stations may render techniques based on the topology of the cellular network redundant. However, a clear view of the sky is likely, thus GPS and A-GPS should both function satisfactorily.

It should be noted that A-GPS itself could be arguably considered a hybrid technology. However, its close association with and standardization in the telecommunications world result in it being generally considered as a cellular network technique.

The Indoor Scenario

Determining the position of people in an indoor scenario raises particular issues and difficulties. Traditionally, satellite technologies have not operated indoors, as the signal is weak and is subject to additional reflection and fading problems when tracked indoors. A new generation of receivers promises to address this deficiency, with each succeeding generation being incrementally more sensitive. However, the key issues of accuracy and precision remain. This continues to be the case when cellular network techniques are considered, thus making the provision of guarantees concerning the quality of the calculated position exceedingly difficult.

If it is necessary to track a person in an indoor environment with confidence; it is almost essential to consider deploying a dedicated infrastructure, expensive and time-consuming as this may be. However, the required accuracy is a significant determinant. For example, it may be only necessary to track a person to room level. Alternatively, in a museum or art gallery setting, it may be necessary to determine the visitor's position to within one meter so as to determine which artifact is nearest to him or her.

Hightower and Borriello (2001) and Pahlavan, Xinrong, and Makela (2002) provide useful overviews of the issues involved in indoor tracking and positioning. A common approach is to tag the person and place a network of sen-

sors throughout a building. This approach was adopted by Want, Hopper, Falco, and Gibbons (1992) in the pioneering active badge project, and the feasibility of the approach was verified. Systems that use a similar approach today include Cricket (Priyantha, Chakraborty, & Padmanabhan, 2000) and Ubisense (Cadman, 2003). Indeed, given the increased interest in Radio Frequency Identification (RFID), one can easily envisage a solution involving a fixed network of RFID readers and RFID-tagged personnel.

FUTURE TRENDS

One of the key developments currently taking place concerns the deployment of *satellite-based augmentation systems (SBAS)*. Such systems are a satellite-based implementation of the well-known differential GPS (DGPS) method of improving GPS positions to within a few meters. A number of SBAS systems are being deployed, including the European Ground Navigation Overlay Service (EGNOS) and the Wide Area Augmentation System (WAAS) in the United States. More SBAS satellites are expected to be launched for other areas of the world in the coming years. Two methods for accessing SBAS are of interest. The easiest way is to incorporate an appropriate chip in a GPS receiver. In this way, the position is augmented seamlessly and transparently to the user. A second method involves the Internet, via which SBAS signals can also be broadcast. SISNet (Chen, Toran-Marti, & Ventura-Traveset, 2003) is one example of such a system. Indeed, when A-GPS is reconsidered, it can be seen that integrating this approach with a system such as SISNet is relatively straightforward.

Indoors, the situation is more complex. One approach receiving increasing attention by the research community concerns pseudolites (Wang, 2002). Pseudolites (pseudo-satellites) are placed throughout a building and mimic the GPS signal. Naturally, the pseudolite network should be calibrated for the building in question. However, the important issues of interoperability and standardization—issues that have so far been neglected—must also be addressed.

CONCLUSION

A significant choice of technologies is available for aspiring providers of location-aware services. The required accuracy and precision of the resultant subscriber position is a key determinant of the choice of technology. Attitudes of network operators toward independent small businesses seeking to deploy new services are also of critical importance. It is essential that such operators provide an open and transparent mechanism for accessing subscriber position information. Should the operator adopt an attitude of restricting access or charging excess fees for such information, the potential

of location-aware services will be compromised. Overtime, it can be anticipated that a number of mobile phones with integrated GPS and SBAS technologies will be launched on the market. Ultimately, however, it beholds those people designing for mobile users to judiciously consider the merits of the respective positioning technologies in the context of both the application domain and target audience. Only in this way can they be reassured that the needs and expectations of their customers will be addressed.

KEY TERMS

GPS: Global positioning system.

OTDOA: Observed time difference of arrival.

Pseudolite: Pseudo satellite.

SBAS: Satellite-based augmentation system.

SISNet (Signal In Space through the Internet): An initiative by the European Space Agency (ESA) to broadcast corrections to the standard GPS signal through the Internet and in real time.

3GPP: Third Generation Partnership Project.

Trilateration: A method of determining the position of an object using the known position of at least three reference points.

UMTS: Universal mobile telephone system.

UTDOA: Uplink time difference of arrival.

Privacy Concerns for Indoor Location-Based Services

Leonardo Galicia Jiménez

J. Antonio García-Macías

CICESE Research Center, Mexico

INTRODUCTION

Systems that provide location-based services (LBSs) register all available services in a central entity, so users may subscribe to this entity and thus be able to obtain certain services according to their geographic location. Geographic location information—known as geolocation information—may be known through different mechanisms in manual or automatic ways. Most of these mechanisms imply the use of radiofrequency technologies, through the use of devices such as GPSs, mobile telephones, and others, typically using triangulation techniques to determine the position of the device (and the user carrying it). Most of these systems are implemented for users moving outdoors. Also, geolocation information is under the control of the entity that manages the user's subscription, which motivates concerns regarding how this information is used.

LBS systems require servers where geolocation information is stored, and where objects, attributes, and relations are described in different layers or abstraction levels. This geolocation information enables the representation and visualization of maps, political divisions, roads, electrical networks, buildings, lakes, and so forth. This information is thus stored statically and superposed on a geographical zone, forming a complex map with attributes that can be used to perform queries. These systems commonly use a pull-based paradigm, where users make explicit requests to the server, which responds with geolocation information and related services. For instance, a car driver could request information regarding the closest restaurants, shopping centers, and so on. This example also shows another general characteristic of LBS systems: most of the services are static in nature, meaning that usually the services are in the same place and it is the user who actually moves.

Advances in LBS systems and mobile computing technologies have caught the attention of telephone companies, which seek to provide competitive services to their users and differentiate themselves from their competitors.

Being able to locate artifacts and persons can raise privacy concerns. In fact, these privacy concerns represent one of the most important barriers for the adoption of systems providing location-based services. Thus, effective

mechanisms for addressing these privacy concerns should be implemented.

LOCAL MOBILITY

Some of the so-called “knowledge workers” present a high degree of mobility in their daily activities (Bellotti & Bly, 1996). Local mobility refers to dynamic patterns of mobility that take place close to the worker's office, or even within a building, when a worker is carrying out her duties, collaborating with colleagues, and so forth. A clear example of this is the kind of work performed in a hospital, as it involves a high degree of mobility of patients, equipment, resources, and personnel within the hospital facilities. Doctors and nurses frequently move in order to carry out their activities; likewise, hospital personnel transport information and equipment through different areas.

Recent studies (Rodríguez & Favela, 2003; Muñoz, Rodríguez, Favela, Gonzalez, & Martinez-Garcia, 2003; Santana et al., 2005) have aided to characterize hospital work in order to design and evaluate different technologies to support processes in that type of environment. As a result, several requirements and needs have been identified for the development of systems that take into account contextual parameters, such as location. Therefore, these needs and requirements also apply for the design and development of LBS systems in hospitals. Among the requirements for information and services identified, related to the location parameter, are:

- **Location of Artifacts:** In many cases, when doctors or nurses finish using medical artifacts, they do not pay attention to returning them to their original place. As a result, when other persons (or even themselves) need these artifacts, they have to invest some time trying to locate them. Checking the availability of some equipment is also a concern.
- **Location of Persons:** During work shifts, medical personnel require locating a specialist to consult on some particular case, or even to get aid in an emergency.

In this context, the concept of artifacts refers to medical equipment, document, furniture, electronic devices, and any other physical object (static or mobile) that hospital personnel use to carry out or support an activity.

LOCATION OF ARTIFACTS AND PERSONS

In order to provide location-based service discovery, it is first necessary to have some mechanisms to estimate the location of artifacts and persons through some device. Usually, location of devices is basically categorized as device-centered and network-centered. The first one allows the device, through some mechanism, to estimate its own position; that is, it is only the device and no other that can estimate and know its physical location. Meanwhile, network-based mechanisms require that a different entity within the network perform the estimation of a device's physical location; this way, when a device wants to know its location, it has to consult the entity in the network that is in charge of determining it. Some good examples of device-centered systems are RADAR (Bahl & Padmanabhan, 2000), Cricket (Priyantha, Chakraborty, & Balakrishnan, 2000), and AeroScout. In this type of system, a PDA, mobile phone, or some other type of mobile device usually performs the estimation. So, in some way the estimation is person centered, as persons normally carry the devices, but only if the device is fully in control of the calculations for determining the current position; and if the device is turned off for some reason, the location cannot be determined. Some examples of network-centered systems are Active Badge (Want, Hopper, Falcao, & Gibbons, 1992), Ubisense, and Exavera. In these types of systems, objects and persons can carry small devices to aid the network in determining their location.

We think that the network-centered model is more appropriate for the type of scenarios that take place in hospitals, which are our focus for technological development. In a hospital environment some artifacts, such as wheelchairs, stretchers, portable EKG equipment, and others, are good candidates to be located. Moreover, the network-centered model allows the possibility of continuous tracking.

REPRESENTATION OF PHYSICAL SPACES

It is necessary to have a computational model to represent all those artifacts and persons that are moving within a physical space. This model should represent, at least, the physical space, the entities that move within it, as well as those that are static. There are currently different models that allow the representation of physical spaces (Rui, Moreira

Rodrigues, & Davies, 2003), including the geometric model, set theory, graphs, and the semantic model. The geometric model includes definitions based on Euclidian geometry, through coordinates in a Cartesian plane; this plane is a direct consequence of cartographic representation, where information and participating entities are superposed on maps, planes, or images. The semantic model offers descriptive information about the geometric areas that represent physical spaces. Under these considerations, both the geometric and semantic models are appropriate for the requirements and technological needs identified in the type of environments that we are interested in (i.e., hospitals). These models have been previously used in the projects and commercial systems mentioned above, namely Cricket, RADAR, Exavera, Ubisense, and Radianse.

PROXIMITY MODEL

A fundamental concept for proximity-based service discovery is, not surprisingly, proximity. The key for a correct association between services and physical spaces is the geographical criterion to be used when services are searched based on their proximity. Two models are widely used for the selection of services: the distance-based model and the scope-based model. In the distance-based model, clients select the services that are within a certain distance from the current position. Given that proximity is a relative value and what is perceived as proximal can vary drastically according to the activities being performed by the client, some mechanism should be present to dynamically change the proximity range.

In a scope-based model, each service is associated with a scope that explicitly represents the context of use of the service within a physical space. The client selects those services whose scopes include the location of the requesting client; that is, a client can discover services if it is inside a certain scope, as well as the services. The main characteristic of this model is that the correlation between context and proximity is assured. When services are discovered, no matter what their distance, they have a high probability of being relevant for the requesting client.

We consider that the scope-based model better suits our needs, mainly because it allows the representation of physical sub-spaces as geometric shapes; this is very adequate for indoor environments such as hospitals where the definition of rooms, working areas, and so on is very useful.

DEFINITION OF SERVICES

A service is an entity that can be used by a person, a computer program, or any other entity (Johansen, 1999); examples of services are files, a storage device, a printer, a server. When service discovery is performed within a physical space or

scope, it is not enough to know the available services, but also the persons within it, in order to be able to interact with them. Thus, it is convenient to consider artifacts and persons as services associated to a given scope; it should be noted that some of these entities will not strictly provide a service, but it is necessary to know their attributes (type, role, etc.) in order to know what kind of entities there are and where they are in a certain space.

USER IDENTIFICATION

In a ubiquitous computing environment, the search for services responds to contextual variables such as the location of the user and its identification. While the location allows obtaining those services near the user, the identification allows the user to access them. This way, a user could make an anonymous request for available services within a scope, and she may obtain a list of them. However, it could be possible that more services would exist; this is because some of those services may require additional information about the user (such as her role, an ID, etc.) in order to be possible to discover them. This way, services are discovered not only based on their location or proximity, but also based on who is requesting them.

CONTROL OF ACCESS TO LOCATION INFORMATION

In spite of the benefits that ubiquitous computing environments offer, one of the main barriers for the adoption of related technologies is the privacy concerns of users. A clear example is shown in the results obtained by Intel Research Berkeley through a series of interviews and scenarios (Barkhuus & Dey, 2003) where users manifested concerns regarding being located. Recently the IETF, through the Geopriv working group, has been studying privacy issues that arise when the geographical information of people and resources is used. The focus of the group, as stated in their charter, is “to assess the authorization, integrity and privacy requirements that must be met in order to transfer such information, or authorize the release or representation of such information through an agent.” Then, attention is paid to presence and geospatial information, commonly used in instant messaging systems, location-based services, and others. Until now, the Geopriv working group has generated a couple of RFCs (requests for comments) and recommendations aimed at proposing a standard that guarantees the privacy of users. Much of this work is currently under review, but rules and mechanisms have already been defined (represented in XML formats); these control when, to whom, in what place, and under what circumstances geolocation information can be released. The

Geopriv group uses formats and architectures previously approved by the IETF, for instance XMPP (Extensible Messaging and Presence Protocol) or SIMPLE (SIP for Instant Messaging and Presence Leveraging Extensions).

The user should be able to define when (day and time), to whom, where (place), and under what circumstances (status of the user) location information can be released. The mechanisms for this are defined by the Geopriv group and can be easily applied to artifacts, not for protecting their privacy, as this would not make much sense, but for extending service discovery and indicating who and under what circumstances they can be discovered. This way, artifacts and persons (viewed more generally as services) can be discovered based not only on their location, but also taking into account who is requesting them using control policies for service discovery.

These policies are inspired mainly by RFC 3669 of the Geopriv working group, as well as by the policy and common policy working drafts of that same group. RFC 3669 deals with the authorization, integrity, and privacy involved in releasing information about the location of users. The Geopriv group is currently exploring how to represent information about location and presence, as well as how to protect this information.

In its Common Policy draft, the Geopriv group defines the base mechanisms for delivering location information in presence messages; these mechanisms, which allow access control form information regarding presence and location of users, can be extended and translated easily to other application domains. These mechanisms define an XML document that represents policies associated to an entity. Requests from entities contain policy rules, and these are checked against the policies defined in the entity that receives the request; if one or more of the rules match, then the location and presence information are released, else it is denied.

Three sections compose each rule: conditions, actions, and transformations. The conditions section defines all the restrictions that should be satisfied by an entity in order for it to obtain the requested information. The actions section is a set of processes that the user requests an entity to perform; these actions have not been defined by Geopriv and are meant to be defined at the application (and not at the user) level. The transformation section indicates those modifications that should be made to the location information before being released. For instance, even if a user complies with all the rules imposed by an entity, a transformation could be imposed to reduce the precision of the geographic location, or to indicate the floor where the entity is located but without saying in what room it is.

CONCLUSION

We have presented the design considerations that should be taken into account for the design of ubiquitous distributed applications that allow the discovery of service based on their physical proximity and considering important privacy concerns. The use of privacy policies, as proposed by the IETF Geopriv working group, can be applied in order to restrict the way in which services are discovered and the potentially sensitive information is disclosed.

KEY TERMS

Context: Any information that can be used to characterize the situation of an entity. An entity is a person, place, or object that is considered relevant to the interaction between the user and an application, including the user and the application themselves.

Context-Aware Computing: Augments computers with sensors and actuators in order to achieve a better understanding of, and interaction with, the physical environment. Such systems collect sensor data, build a model of the environment or world model, and use the model to provide more useful and intuitive services to users by triggering actuators or automating tasks (Schilit et al., 1994).

Local Mobility: Describes the need of some workers to displace and move around their offices or premises to conduct their work (Bellotti & Bly, 1996).

Privacy: The ability of an individual or group to stop information about themselves from becoming known to people other than those they choose to give the information to. Privacy is sometimes related to anonymity, although it is often most highly valued by people who are publicly known.

Privacy can be seen as an aspect of security—one in which trade-offs between the interests of one group and another can become particularly clear.

Service Discovery Protocol: Computational mechanisms for the provision of adequate support to dynamic changes in the network regarding the services it offers. These mechanisms allow clients to connect to the network and be able to search for a particular service, and also allow entities providing services to announce their capabilities; all these without previous configuration.

Service or Resource: An entity that can be used by a person, by a computer program, or by another service. For instance: a file, a storage device, a computer (Johansen, 1999).

Ubiquitous Computing: A concept proposed by Mark Weiser (1991). Refers to the use of computers embedded in the physical space of the user. Through these computer-saturated spaces, the user has some of them available to support his or her activities (Schilit, Adams, & Want, 1994). These computers are small devices with ample processing power, and given their small size they are used without the user being aware of them.

Protocol Analysis for the 3G IP Multimedia Subsystem

Muhammad Tanvir Alam
Bond University, Australia

INTRODUCTION

In the past few years, the evolution of cellular networks has reflected the success and growth the Internet has experienced in the last decade. This leads to networks where IP connectivity is provided to mobile nodes. The result is third-generation (3G) networks where IP services such as voiceover IP (VoIP) and instant messaging (IM) are provided to mobile nodes (MNs) in addition to connectivity. IP multimedia subsystem (IMS) is a new framework, basically specified for mobile networks, for providing Internet protocol (IP) telecommunication services. It has been introduced by the Third-Generation Partnership Project (3GPP) in two phases (release 5 and release 6) for Universal Mobile Telecommunications System (UMTS) networks. 3GPP was born in 1998 as a collaboration agreement between a number of regional telecommunication standards bodies, known as *organizational partners*. The current 3GPP organizational partners are:

- ARIB (Association of Radio Industries and Business) in Japan,
- CCSA (China Communications Standards Associations) in China,
- ETSI (European Telecommunications Standards Institute) in Europe,
- Committee T1 in the United States of America
- TTA (Telecommunications Technology Association) of Korea, and
- TTC (Telecommunication Technology Committee) in Japan.

Besides the organizational partners, *market representation partners* (the UMTS Forum, 3G Americas, the IPv6 Forum, the Global Mobile Suppliers Association, etc.) provide the partnership with market requirements. 3GPP maintains an up-to-date Web site at <http://www.3gpp.org>.

3GPP working groups do not provide standards. Instead, they produce technical specifications (TSs) and technical reports (TRs). 3G PP Release 5 contains the first version of the IMS. 3GPP release 6 contains enhancements to the IMS. The Third Generation Partnership Project 2 (3GPP2) was born to evolve North American and Asian cellular networks based on ANSI/TIA/EIA-41 standards and CDMA2000 radio access into a third-generation system. An IP multimedia

framework was later introduced by 3GPP2 as the Multimedia Domain (MMD) for third-generation Code Division Multiple Access 2000 (CDMA2000) networks, and finally harmonized with IMS. IMS aims to use Internet protocols. The 3GPP and 3GPP2 established collaboration with the IETF to make sure that the protocols developed there meet their requirements. In this article, we aim to discuss a few potential areas of the IMS that could be improved to provide better quality of service (QoS).

BACKGROUND

The IMS is the technology that will merge the Internet (packet switching) with the cellular world (circuit switching). It will make Internet technologies, such as the Web, e-mail, instant messaging, presence, and videoconferencing- available nearly everywhere.

In brief the IMS concept was introduced to address the following network and user requirements:

- Deliver person-to-person, real-time, IP-based multimedia communications (e.g., voice or video-telephony) as well as person-to-machine communications (e.g., gaming service).
- Fully integrate real-time with non-real-time multimedia communications (e.g., live streaming and chat).
- Enable different services and applications to interact (e.g., combined use of presence and instant messaging).
- Easy user setup of multiple services in a single session or multiple simultaneous synchronized sessions.

Figure 1 depicts an overview of the IMS architecture. The definitions and functions of the common nodes included in the IMS are furnished in the Key Terms section. There are plenty of ways to improve the existing infrastructure and protocols in the IMS. Previously, the performance of the critical protocol SIP (Session Initiation Protocol, Rosenberg et al., 2002) in an IMS environment had never been evaluated. The signaling overhead reaches its peak when a massive number of IMS terminals joins the network at the same time. The minimal discovery time of different CSCFs are crucial for system performance.

Figure 1. 3GPP IMS architecture overview

Session Establishment Scenario for a Mobile Terminal

Every mobile node must register with the visited network in IMS. Re-registration takes place once the timeout occurs. The SIP INVITE request is sent from the UE (user equipment) to S-CSCF#1 (serving call session control function) by the procedures of the originating flow to initiate a session between two nodes. This message may contain the initial media description in the SDP (session description protocol). S-CSCF#1 performs an analysis and passes the request to I-CSCF#1 (interrogating CSCF) and so on. Thus the intermediate nodes analyze and forward the request to the next node until it reaches the destination node. The detail of IMS SIP session set up procedures with MIPv6 can be found in Technical Specification 23.228 of IP Multimedia Subsystems.

If a mobile terminal moves away from its current visited network, it needs to send a binding update (BU) message to the corresponding node. It may move away during the session set up. The issue of sending the BU to achieve better mobility management needs to be addressed thoroughly.

In the existing scenario, the mobile node sends the BU to the corresponding node after the session is set up. This implies that traffic will be routed through the HA (home agent) before being routed directly to the MN (mobile node), even if for a limited amount of time. This can have implications on quality of service, since quality of service (QoS) is initially established only for the route from the MN to the HA and to the CN (correspondent node), whereas QoS for the optimized route is not established.

Presence Service in the IMS

Presence is one of the basic services that is likely to become omnipresent in IMS. It is the service that

allows a user to be informed about the reachability, availability, and willingness of communication of another user.

The presence framework defines various roles as shown in Figure 2. The person who is providing presence information to the presence service is called a presence entity, or for short a presentity. In the figure, Alice plays the role of a presentity. The presentity is supplying presence information such as status, capabilities, communication address, and so forth. A given presentity has several devices known as presence user agents (PUAs) which provide information about her presence. All PUAs send their pieces of information to a presence agent (PA). A presence agent can be an integral part of a presence server (PS). A PS is a functional entity that acts as either a PA or as a proxy server for SUBSCRIBE requests. Figure 3 also shows two watchers: Bob and Cynthia. A watcher is an entity that requests (from the PA) presence information about a presentity or watcher information about his/her watchers. A subscribed watcher asks to be notified about future changes in the presentity's presence information, so that the subscribed watcher has an updated view of the presentity's presence information.

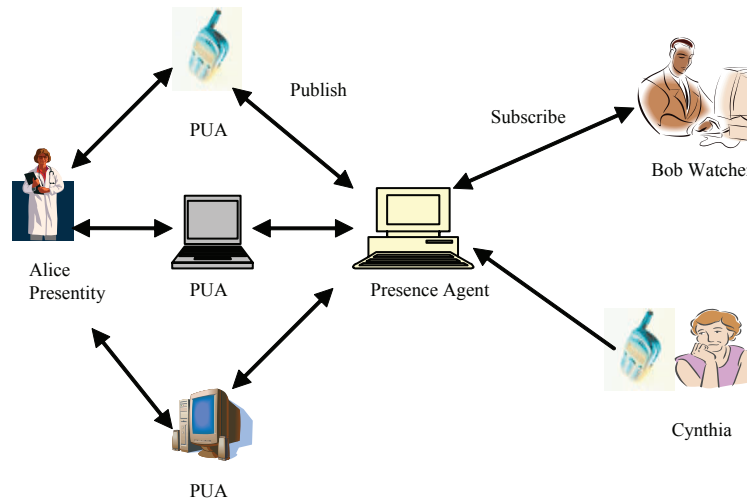

3GPP defined in 3GPPTS 23.141 provides the architecture to support the presence service in the IMS. The architecture indicates that the flow of messages will be massive for a large amount of publishers and watchers joining an IMS system.

P-CSCF Discovery

P-CSCF discovery is the procedure by which an IMS terminal obtains the IP address of a P-CSCF. This is the P-CSCF that acts as an outbound/inbound SIP proxy server toward the IMS terminal (i.e., all the SIP signaling sent by or destined for the IMS terminal traverses the P-CSCF). P-CSCF discovery may take place in two different ways:

Figure 2. SIP presence architecture

1. integrated into the procedure that gives access to the IP-CAN (IP connectivity access network), or
2. as a stand-alone procedure.

The integrated version of P-CSCF discovery depends on the type of IP connectivity access network. If IP-CAN is a GPRS (general packet radio service) network, once the GPRS attach procedures are completed, the terminal is authorized to use the GPRS network. Then the IMS terminal does a so-called activate PDP context procedure. The main goal of the procedure is to configure the IMS terminal with an IPv6 address, but in this case the IMS terminal also discovers the IPv6 address of the P-CSCF to which to send SIP requests.

The stand-alone version of the P-CSCF discovery is based on the use of DHCPv6 (Dynamic Host Configuration Protocol for IPv6) specified in RFC 3315 by Droms et al. (2003) and DNS (Domain Name System, specified in RFC 1034 by Mockapetris, 1987). A suitable procedure is required in order to identify the faster mechanism to discover P-CSCF in IMS.

CHALLENGES OF THE IMS

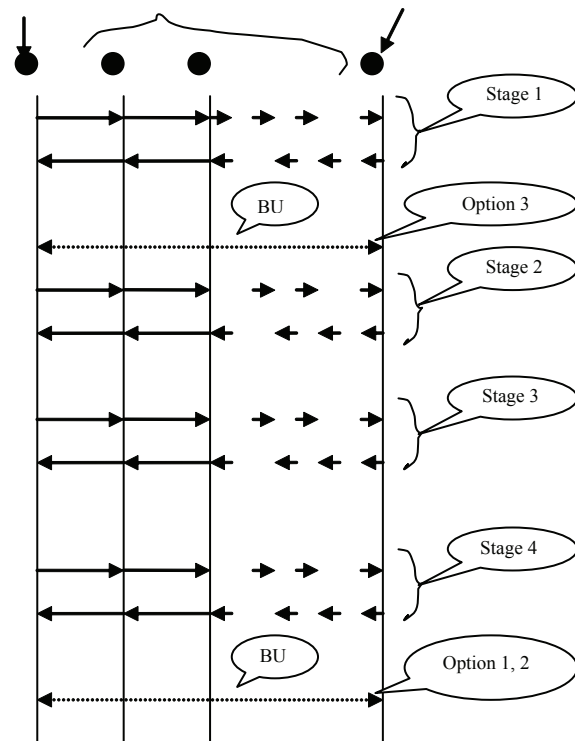

The abovementioned aspects could be potentially reviewed. Following are some proposed approaches to improve some of the IMS services.

Session Establishment Schemes in Mobile Environment

An architecture of mobility and QoS support is provided by Shou-Chih Lo, Lee, Wen-Tsuen, and Jen-Chi (2004). Naka-

jima, Dutta, Das, and Schulzrinne (2003) depicted a handoff delay analysis for SIP-based mobility in IPv6. The whole procedure of session set up in IMS may be divided into four stages as shown in Figure 3. Stage one includes sending of an INVITE message from source to destination and getting a response from the destination back to the source. Stages two, three, and four can be described in the same manner

Figure 3. Three options for IMS session set up

as Response, Reservation, and ACK messages respectively. Note that a session set up may fail anytime due to the different processing complexity. The destination node may send a BUSY message in response to the INVITE request. The message may also be corrupted or lost in the intermediate nodes which raises the possibility for a session to fail at any stage during the period of establishment.

The basic scenario (option 1) (Johnson, Perkins, & Arkko, 2004) is that the MN receives packets from the CN tunneled through the HA, and initiates the route optimization procedure. This implies that traffic will be routed through the HA before being routed directly to the MN, even if for a limited amount of time. This can have implications on quality of service, since QoS is initially established only for the route from the MN to the HA and to the CN, whereas QoS for the optimized route is not established.

A second scenario (option 2) introduces an optimization where the MN sends a BU to the CN immediately after setting up the SIP call, before any traffic is received from the CN. This option was mentioned by Faccin, Lalwaney, and Patil (2004). This requires slight modifications to the implementation of the MN, but benefits from route optimization from the beginning of the communication.

The main difference between options 1 and 2 lies in the data transfer. MN may start sending the data via HA immediately after the session is set up, before the BU has been sent in Option 1. MN waits till the BU has been sent before it starts to send any data in Option 2.

We propose an additional optimization (option 3) by sending the BU message in parallel while the SIP session is still being set up. For example, after the first round trip (which includes the INVITE message reaching the destination and coming back to the source) of messages of a session set up, the source may initiate (by forking) a BU for the destination and try to ensure QoS. Alternatively, the BU message could be initiated after the second roundtrip of a session set up progress. This way, the MN can immediately start to send data once the session has been set up. However, the overhead would be high if a session fails to set up for variable reasons.

Note that options 1 and 2 are applicable only for a successful session set up, while option 3 is applicable to both successful and unsuccessful session set ups. In options 1 and 2, the BU is sent only after the session is set up, while the BU is sent in parallel in option 3. The idea is to compare and contrast the different scenarios with an appropriate algorithm. The overhead and the delay of the schemes need to be identified.

Acquiring an IP for P-CSCF

In GPRS, the IMS terminal first undertakes a set of procedures, globally known as GPRS attach procedures, in order to acquire an IP for P-CSCF. These procedures involve several

nodes, ranging from the SGSN to the HLR and the GGSN. Once these procedures are complete, the terminal sends an activate PDP context request message to the SGSN requesting connection to an IPv6 network. The message includes a request for connectivity to a particular APN (access point name) and packet connection type. The APN identifies the network to connect to and the address space where the IP address belongs. In the case of an IMS terminal, the APN indicates a desired connection to the IMS network and the connectivity type indicates IPv6. The SGSN, depending on the APN and the type of network connection, chooses an appropriate GGSN. The GGSN is responsible for allocating IPv6 addresses. In the case of the IMS, the GGSN does not provide the terminal with an IPv6 address belonging to the IMS address space. Instead, the GGSN provides the terminal with a 64-bit IPv6 prefix and includes it in a create PDP context response message. The SGSN transparently forwards this IPv6 prefix in an active PDP context accept. When the procedure is completed, the IMS terminal has got a 64-bit IPv6 prefix. The terminal is able to choose any 64-bit IPv6 suffix. Together they form a 128-bit IPv6 address—that is, the IPv6 address that the terminal will use for its IMS traffic. During this GPRS attach procedure, the terminal also discovers the IPv6 address of the P-CSCF in a similar fashion from GGSN.

The stand-alone version of discovering P-CSCF depends on DHCP and DNS. In DHCP the terminal does not need to know the address of the DHCP server, because it can send its DHCP messages to a reserved multicast address. In some configurations a DHCP relay may be required to relay DHCP messages to an appropriate network, although the presence of the DHCP relay is transparent to the terminal.

Once the terminal has connectivity to the IP-CAN, the IMS terminal sends a DHCPv6 information-request where it requests the DHCPv6 Options for SIP servers (specified by Schulzrinc & Volz, 2003). In the case of the IMS, the P-CSCF performs the role of an outbound/inbound SIP proxy server, so the DHCP server returns a DHCP reply message that contains one or more domain names and/or IP addresses of one or more P-CSCFs.

At the discretion of the IMS terminal implementation, there are two possible ways in which the IMS terminal can specify the request for the DHCPv6 Option for SIP servers:

1. The IMS terminal requests the SIP server's domain name list option in the DHCPv6 information-request message. The DHCPv6 reply message contains a list of the domain names of potential P-CSCFs. The IMS terminal needs to resolve at least one of these domain names into an IPv6 address. A query response dialog with DNS resolves the P-CSCF domain name, but prior to any DNS interaction, the IMS terminal also needs to get the address of one or more DNS servers

to send its DNS messages. To resolve this problem, the DHCP information-request message not only contains a request for the option for SIP servers, but also includes a request for the DNS recursive name server option. The DHCPv6 reply message contains a list of IPv6 addresses of DNS servers, in addition to the domain name of the P-CSCF. Then, the IMS terminal queries the just learned DNS server in order to resolve the P-CSCF domain name into one or more IPv6 addresses. The procedures to resolve a SIP server into one or more IP addresses are standardized in RFC 3263 (Rosenberg & Schulzrind, 2002).

2. The alternative consists of the IMS terminal requesting the SIP server's IPv6 address list option in the DHCPv6 information-request message. The DHCP server answers in a DHCP reply message that contains a list of IPv6 addresses of the P-CSCF allocated to the IMS terminal. In this case, no interaction with DNS is needed, because the IMS terminal directly gets one or more IPv6 addresses.

Eventually, the IMS terminal discovers the IP address of its P-CSCF and can send SIP signaling to its allocated P-CSCF. However, these procedures do not mention which one is efficient in which environment. For example, if P-CSCF is located in the home network and the CN (IMS terminal) in the visited network, which would be the quicker method for P-CSCF discovery? The performance of network access connectivity in IMS was never analyzed before. An efficient algorithm is needed for an IMS terminal to promptly select the faster method in order to achieve the IP address of a P-CSCF to send SIP messages.

Presence Service during Heavy Traffic

In order to reduce heavy message flows in the IMS presence service, the IETF has created a number of concepts described as follows.

1. Partial notification is one mechanism on which IETF engineers are working to reduce the amount of presence information transmitted to watchers. The mechanism defines a new XML body that is able to transport partial or full state. Thus, the document size is reduced at the cost of information transmitted.
2. An event-throttling mechanism allows a subscriber to an event package to indicate the minimum period of time between two consecutive notifications. So, if the state changes rapidly, the notifier holds those notifications until the throttling timer has expired, at which point the notifier sends a single notification to the subscriber. However, with this mechanism the watcher does not have a real-time view of the subscription state information.

3. Compression of SIP messages is another technique to minimize the amount of data sent on low-bandwidth access. RFC 3486 by Camarillo (2003), RFC 3321 by Hannu et al., (2003a), and RFC 3320 by Hannu et al. (2003b) define signaling compression mechanisms. Usually these algorithms substitute words with letters. The compressor builds a dictionary that maps the long expressions to short pointers and sends this dictionary to the de-compressor. However, the frequency of data transmission is not reduced in such techniques.

Clearly each of the abovementioned works has limitations and tradeoffs. The lifetime of a watcher subscription time has not received any attention so far. An optimal watcher registration time procedure to allow Proxy-CSCF to reassign UE (user equipment) in IMS needs to be considered. Every time, the UE/IMS watcher needs to re-subscribe when its timer (which is kept shorter than the subscription timer in the network) expires. If the UE does not re-register, any of its active sessions are deactivated in IMS. On the other hand, de-registration is accomplished by a registration with an expiration time of zero seconds. A forced de-registration from the network (PA) may occur in case of data inconsistency at node failure. The constant time set may create a bottleneck because of excessive message flow in the network. Especially, if an IMS watcher watches many presentities and if the watcher-subscription-time is not set carefully, it will be notified of any changes made in its presentity list. Both long and short lifetime will introduce overhead in a number of messages and cache respectively. Thus an optimal procedure to set the timer of the watcher subscription lifetime for the IMS node is desirable.

FUTURE TRENDS

The IMS has yet to undergo further refinement to overcome all its shortcomings. New algorithms to reduce latency in session set ups in mobile environments, to balance load efficiently for heavy traffic PS, and to make faster discovery of P-CSCF are required. Besides, there are other potential areas that need to be addressed. IMS provides SIP-PSTN inter-working services. The traditional audio calls in SIP-PSTN inter-working focus on audio-only calls. Although, the video services are included in the inter-working, significant work is required in the encoding and gateway architecture to facilitate video streaming in the IMS. One other problem with the IMS is that SIP does not offer a mechanism for a UA (user agent) to indicate that all proxies in the path must use a transport protocol that implements end-to-end congestion control—that is, SIP derives from the fact that any proxy can change the transport protocol from TCP (transmission control protocol) to UDP (user datagram protocol), SCTP (stream control transmission protocol), or others and vice

versa. UDP is notorious for not offering congestion control, which may affect the Instant Messaging services in the IMS. The IETF engineers are working on an extension to SIP that will allow a UA to request proxies to use a transport protocol that supports end-to-end congestion control. Session-based instant messaging may be a solution to this problem that uses MSRP (message session relay protocol, by Campbell, Mahy, & Jennings, 2005). MSRP is a simple text-based protocol whose main characteristic is that it runs over transport protocols that offer congestion control. However, the complete behavior of MSRP relays is still not well defined. The future releases of the IMS should refer to the abovementioned areas at least.

CONCLUSION

This research depicts some of the potential approaches to some of the shortcomings of the IMS. One of the reasons for creating the IMS was to provide the quality of service required for enjoying, rather than suffering, real-time multimedia sessions. Thus its drawbacks are essential to be overcome in the near future. The proposed Option 3 might reduce delay in session establishment while the IMS terminals are mobile. However, the overhead needs to be tested if a session fails to set up in the first trial. One potential solution for reducing load in the IMS presence service may be to optimize the watcher subscription time—that is, a watcher should not be able to watch its presentities' infinite amount of time during heavy traffic to reduce heavy message flow. Again, the scheme needs to be tested thoroughly in a suitable environment.

KEY TERMS

Breakout Gateway Control Function (BGCF): A session initiation protocol server that includes routing functionality based on telephone numbers.

Call/Session Control Function (CSCF): A session initiation protocol (SIP) server that processes SIP signaling

in the IP multimedia subsystem. There are three types of CSCFs depending on the functionality they provide.

Home Subscriber Server (HSS): Contains all the user-related subscription data required to handle multimedia sessions. These data include, among other items, location information, security information (including both authentication and authorization information), user profile information, and the S-CSCF allocated to the user. The SLF (subscription location function) is a simple database that maps users' addresses to HSSs. Both the HSS and the SLF implement the Diameter protocol.

Interrogating-CSCF (I-CSCF): Provides the functionality of a SIP proxy server. It also has an interface to the SLF (subscriber location function) and HSS (home subscriber server). This interface is based on the diameter protocol. The I-CSCF retrieves user location information and routes the SIP request to the appropriate destination, typically an S-CSCF.

IP Multimedia Services Switching Function (IM-SSF): Acts as an application server on one side, and on the other side, it acts as an SCF (service switching function) interfacing the gsmSCF (GSM service control function) with a protocol based on CAP (CAMEL application part).

Media Gateway (MGW): Interfaces the media plane of the PSTN (public-switched telephone network) or CS (circuit-switched) network. On one side the MGW is able to send and receive IMS media over the real-time protocol (RTP). On the other side the MGW uses one or more PCM (pulse code modulation) time slots to connect to the CS network. Additionally, the MGW performs transcoding when the IMS terminal does not support the codec used by the CS side.

Media Gateway Control Function (MGCF): Implements a state machine that does protocol conversion and maps SIP to either ISUP (ISDN user part) over IP or BICC (bearer independent call control) over IP. The protocol used between the MGCF and the MGW is H.248.

Media Resource Function (MRF): Provides a source of media in the home network. It is further divided into a signaling plane node called the MRFC (media resource function controller) and a media plane node called the MRFP (media resource function processor). The MRFC acts as a SIP User Agent and contains a SIP interface towards the S-CSCF. The MRFC controls the resources in the MRFP via an H.248 interface. The MRFP implements all the media-related functions.

Proxy-CSCF (P-CSCF): The first point of contact between the IMS terminal and the IMS network. All the requests initiated by the IMS terminal or destined to the IMS terminal traverse the P-CSCF. This node provides several functions related to security. The P-CSCF also generates charging information toward a charging collection node. An IMS usually includes a number of P-CSCFs for the sake of scalability and redundancy. Each P-CSCF serves a number of IMS terminals, depending on the capacity of the node.

Serving-CSCF (S-CSCF): A SIP server that performs session control. It maintains a binding between the user location and the user's SIP address of record (also known as public user identity). Like the I-CSCF, the S-CSCF also implements a diameter interface to the HSS.

Signaling Gateway (SGW): Performs lower-layer protocol conversion.

SIP Application Server (SIP AS): The AS is a SIP entity that hosts and executes IP multimedia services based on SIP.

Protocol Replacement Proxy for 2.5 and 3G Mobile Internet

INTRODUCTION

Providing mobile Internet access in GPRS and UMTS networks is not an easy task. The main problem is in rather challenging network conditions (Inamura, Montenegro, Ludwig, Gurtov, & Khafizov, 2003). Latency in these networks could be an order of magnitude higher than in wired networks, with round-trip time (RTT) reaching up to one second. Moreover, there occur delay spikes in the network, when latency can exceed average RTT several times (Gurtov, 2004). Furthermore, in wireless networks, the risk of experiencing packet losses is considerably higher in comparison to that in wired networks. This is because packets can easily be lost due to corruption, either during deep fading leading to burst losses, or cell re-selections, resulting in a link black-out condition. Such characteristics of wireless cellular networks significantly affect performance of the principal Internet protocol—TCP—as it was designed to work in conditions of low-latency reliable networks.

TCP assumes that all segment losses indicate congestion as they are traditionally (i.e., in wired links) caused by buffer overflows in routers. If losses are detected, in addition to retransmitting the lost packet, TCP adjusts the values of sending window size and retransmission timeout (RTO) in order to slow down transmission. Packet losses or even long enough delays can lead to TCP timeouts. However, in both cases the timeouts are not caused by congestion, hence the basic working assumption for TCP is incorrect, and consequently the countermeasures are also not optimal. TCP flow control is achieved by complex mechanisms trying to probe for a data rate as high as possible but backing off as soon as congestion occurs. A TCP sender adapts its use of bandwidth based on feedback from the receiver. The high latency characteristic of cellular networks implies that TCP adaptation is correspondingly slower than in wired networks with shorter delays. Similarly, delayed acknowledgements exacerbate the perceived latency on the link.

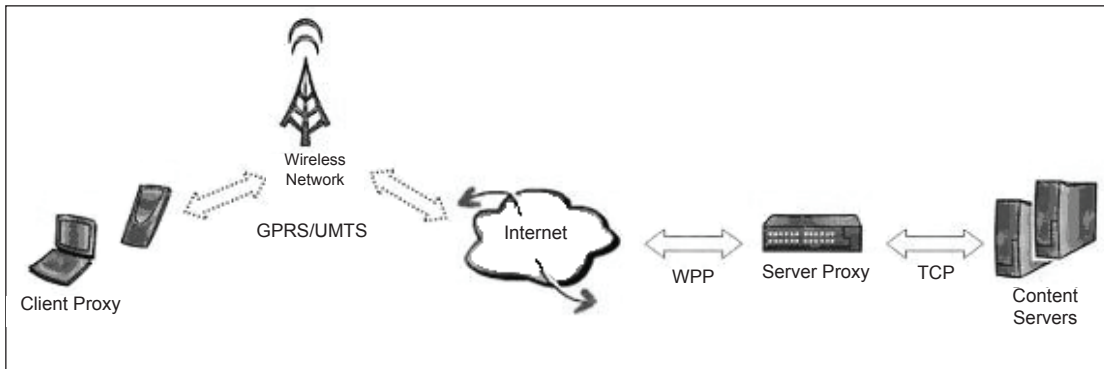

The central performance issues of TCP in wireless cellular networks lie in the inability to correctly detect the nature of the error, and so it is incapable of responding in an appropriate manner (Tsaoussidis & Matta, 2001). In addition, the protocol lacks efficient monitoring of the network conditions, rapid window size readjusting in response to changes in these conditions. Thereby overall performance of TCP is degraded through additional retransmission and wasted opportunities in maintaining the communication pipe full. There have been numerous attempts to improve TCP in wireless environments, for example, Chandran, Raghunathan, Venkatesan, and Prakash (2001), Kim, Toh, and Choi (2000) and Liu and Singh (2001). A standard implementation (Wireless Profiled TCP) is defined by WAP forum, which comprises state-of-the-art works on the subject, and implementation of TCP stack in modern operation systems supports them by default (Macdonald & Barkley, 2000).

As an addition to TCP optimization, the performance enhancing proxy (PEP) concept was developed (Border, Kojo, Griner, Montenegro, & Shelby, 2001) to further improve performance of Internet applications over wireless links. Different types of PEPs are used in different environments to overcome different link characteristics, which affect the performance.

Kustov et al. (2002) proposed an idea for raising efficiency of data transfer over high-latency low-bandwidth links by combining application-level PEP and TCP replacement with a lightweight protocol stack. This approach is called protocol replacement proxy (PRP).

As shown on Figure 1, data transfer over wireless link is performed using WAP peer protocol (WPP). At both ends of the link client and server proxies perform protocol translation between TCP and WPP. For example, when a mobile user downloads a Web page from a content server, the client proxy accepts a TCP connection from the browser, passes the request to the server proxy, which, in turn, establishes a TCP connection to the content server. The content server response is delivered to the browser in the same way.

Figure 1. PEP approach with transport protocol replacement

WPP stack uses UDP as a transport protocol and utilizes WTP and WDP layers of standard WAP protocol stack, with proprietary WPP layer added on top of WTP layer. This scheme makes use of both application-specific optimization techniques (e.g., for HTTP metadata, applets removal, lossy image compression), and transport protocol optimization, which is achieved by reducing overhead and adapting it to wireless link characteristics.

PROBLEM DEFINITION

The concept of PRP, proposed by Kustov et al. (2002) was experimentally studied in Kustov and Lang (2005) for its practical realization (Nokia Wireless Accelerator). The study focused on mobile Internet experience for the two most commonly used Internet protocols—FTP and HTTP—for network technologies ranging from GPRS to UMTS. Application-specific optimization depends strongly on the transferred data; for example, for office documents and HTTP browsing, data reduction was in the range of 60-90%. Transport-level optimization was found to reach 35% in the case of GPRS, which was the main target for PRP.

At the same time, it was found that the wireless accelerator yields negative time savings in the 3G network. Taking into account the fact that compression was applied to the downloaded data, all this indicated inefficient bandwidth utilization of WPP stack compared to that of wireless profiled TCP. The reason was found to be static protocol sending window, decreasing efficiency of WPP at higher data rates. Initially optimized for slower GPRS/EDGE, the same window only allowed partial bandwidth utilization in 3G.

For PRP to work properly in 3G networks as well, WPP protocol stack needs improvements.

DYNAMIC WPP STACK ADAPTATION

In this article we propose the solution to the problem—correction of the WPP protocol stack, allowing the transport layer to adapt in real-time to available bandwidth.

The optimal size of sending window is equal to bandwidth-delay product. As this value can not be measured directly, we have developed the method of adaptation based on adjusting sending window size according to bandwidth utilization feedback. For that, all packets are supplied before sending with time intervals placed in transport information items (TPI) of WTP packet headers. At the receiving side, time intervals between the moments of arrival of two consequent packets are compared to the intervals between the packets departure.

Figure 2 explains the idea in detail. Time interval t_1 between sending of the first and the second packets is conveyed from the sender to the receiver within the second packet. At the receiving side, the interval between times of arrival t_1' is measured and then the difference $(t_1' - t_1)$ is sent as feedback to the sender within WTP ACK packet.

If the difference is positive like in the case (a), this means that packets are sent faster than it is possible to deliver with currently available network bandwidth. In the long run it might result in packet losses and thus retransmissions. To avoid this, sending window size has to be decreased in order to restrict the data-sending rate.

If the difference is negative like in the case (b), the network is capable to deliver packets faster than they are currently sent, so available bandwidth is not utilized fully and sending window size has to be increased.

Figure 2. Window adaptation algorithm for WPP protocol stack improvement

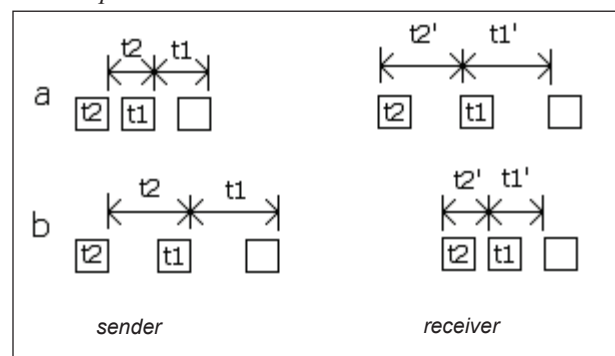

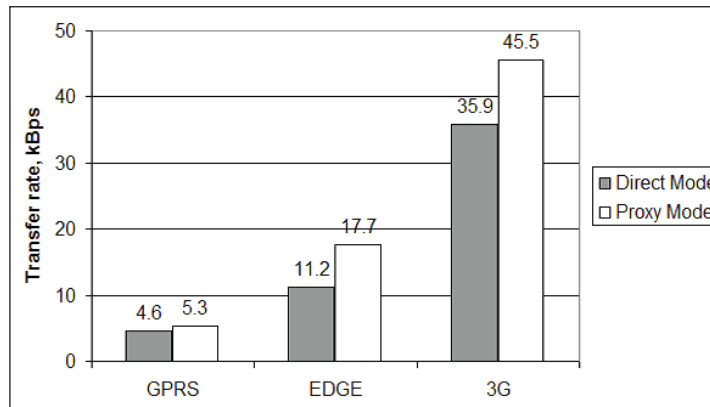

Figure 3. Improved WPP (Proxy) in comparison with TCP (Direct)

To avoid possible oscillations, the feedback values being received at the sending side are smoothed before they are used to adjust sending window size.

Predefined limits of sending window size are set to protect adaptation system from running out of reasonable boundaries.

Besides sending window size, retransmission timeout is adjusted based on current RTT value, which is measured as the time interval between sending a data packet from WTP layer and receiving corresponding acknowledgement packet (ACK) from the peer WTP layer.

EXPERIMENTAL VERIFICATION

We measured efficiency of the improved PRP scheme in GPRS/EDGE and 3G networks. We compared two file downloads: a) in direct mode, where the mobile client directly connects to the origin content server and standard TCP stack is used; and b) in proxy mode, where a tunnel is established between mobile client and PRP proxy over a wireless link and WPP protocol is used (Figure 1). As aforementioned WPP changes don't affect application-specific optimization, we focused on measuring transport protocol efficiency. To minimize the effect of compression performed by the proxy at application level, we downloaded an almost incompressible MP3 file. We have chosen large enough file (>800 KB) for its download to take time long enough to measure it even in the faster 3G network.

Measurements were done in live GPRS/EDGE/3G networks in the downtown of Helsinki. We repeated every measurement until we could reliably identify inconsistent results caused by delay spikes; after dropping them, from the remaining data we calculated average values of downlink transfer rate. Results are shown in Figure 3.

We can see that PRP with improved WPP stack provides data rates higher than TCP for all networks, improvement

being at least 15% (GPRS) and reaching 60% for EDGE, with 3G results being in between (27%). The measurements in proxy mode must be corrected with accordance of data reduction, as proxy compresses all data traversing the tunnel. PRP performs gzip compression on-the-fly on chunks of the data stream, so a compression ratio that is not as high as could be achieved by applying standard archiving programs to the whole file was measured as a ratio of amount of data written to the client application (a browser) to the amount of data counted at WDP (i.e., UDP) layer. For the MP3 file that we used in measurements, PRP compression ratio was only 6%; this proves that the increase in performance gained with PRP is essentially due to more efficient transport protocol.

DISCUSSION

In this article we finalized our study of performance replacing proxy solution for efficient Internet access in mobile networks, which utilizes content optimization at application layer as well as TCP protocol replacement at transport layer with WPP, a lightweight UDP-based protocol.

Kustov and Lang (2005) pointed out bandwidth utilization inefficiency in WPP transport, resulting in low overall PRP performance in a 3G network, although content optimization at the application level is capable of reducing traffic over a wireless link up to 60-90%. This presented a problem when PRP optimization was used in latest mobile handsets, which support multiple network standards and can switch between them automatically.

To overcome the problem, in this article we proposed an algorithm for adapting of the sending window to available network bandwidth and RTT. The algorithm is based on real-time bandwidth probing from data stream, which allows extending the PRP solution applicability from slower 2.5G to faster 3G networks.

We measured the efficiency of improved WPP transport in comparison with TCP, and we have shown that WPP transport outperforms TCP in the whole range of bandwidth; the data rate increase in PRP case was in the range of 15-60%, although the data compression at PRP was only 6%.

Combined with payload reduction, better efficiency of its transportation with WPP makes PRP solution an even more efficient way of improving user experience.

Obviously needed in slower GPRS networks, optimization is also relevant even for relatively fast 3G networks; at least as long as a user is billed for traffic and network coverage restricts data rate at the levels far from theoretical maximum.

KEY TERMS

Bandwidth Utilization: A criterion to measure the ability of a system to efficiently use radio data channel; it reaches its maximum value when data fill the channel as much as possible.

Content Optimization: Minimizing data redundancy by means of, for example, applying compression in order to reduce traffic over wireless channel.

Bandwidth Probing: A method to measure link capacity by sending dedicated test packets, or appending service data to payload.

Sending Window: At the transport protocol layer, amount of data in-the-flight; that is, packets that have been sent but have not been acknowledged by the receiver.

Retransmission Timeout (RTO): It is a time interval for the sender to wait for the packet acknowledgement from the receiver before starting retransmission.

Round Trip Time (RTT): It is a measure of the time it takes for a packet to travel from a mobile terminal, across a mobile network to a server, and back.

Performance Enhancing Proxy (PEP): A technique employed to improve degraded TCP performance caused by characteristics of specific link, for example, in wireless environments.

Providing Location-Based Services under Web Services Framework

Tongji University, China

Shuigeng Zhou

Fudan University, China

Jiaogen Zhou

Wuhan University, China

Fubao Zhu

Wuhan University, China

INTRODUCTION

Location-based services (LBSs) provide personalized services to the subscriber based on his or her current position. By combining information on the location of a mobile user, services can be tailored exactly to the user's situation. These powerful location-based services are the keys to the growth of the mobile Internet in both the consumer and business markets. The geographical location of mobile phones can be used by operators and service providers to create and offer location-based mobile services, which employ accurate, real-time positioning to connect users to nearby points of interest, advise them of current conditions such as traffic and weather, or provide routing and tracking information—all via wireless devices. For subscribers, this means access to attractive, convenient, value-added services that will make their lives easier and more fun, save time, enhance business efficiency, and increase personal safety (Ankar & D'Incau, 2002).

To meet the demands of efficient, stable, and scalable architecture and implementation techniques of location-based mobile services, adjusting for various multi-platforms, multiple applications, and sustainable development environment, we propose an architecture of LBS based on Web services technologies—that is, Web service-based LBS (WS-LBS). WS-LBS has multi-layers and consists of a database server, global spatial information servers, local spatial information servers, and mobile clients. Web services technologies are adopted in WS-LBS. UDDI is used to publish global spatial information services, and URL address is used for local spatial information services publishing. At the mobile client site, SOAP client technology is adopted for end users to access remote spatial information services. Two kinds of WS-LBS clients are implemented: J2ME client and WinCE client. A WS-LBS prototype is implemented by Java and C#

languages, providing transparent access to distributed spatial information services for various mobile end users.

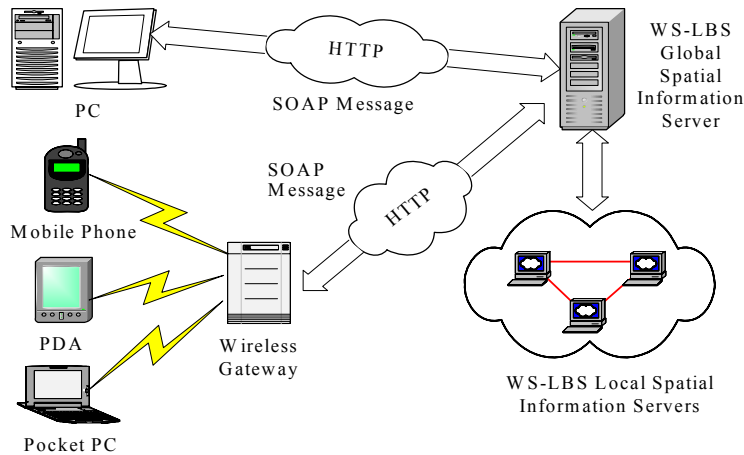

BACKGROUND

Mobile terminals such as cellular phones, PDAs, palmtops, and so forth emerge as a new class of small-scale, ad-hoc service providers and consumers. And location-based services have been a rapidly growing concept in telecommunication industry. Market research companies predict a huge market for services to be delivered to mobile users. Strategy Analytics, a leader in providing strategic and tactical support for business planners, recently concluded that: "Demand for mobile information services is skyrocketing and interest in coupling them with positioning technologies [is] at an all time high" (Raskind, 2000). Location technologies are expected to augment existing wireless applications as well as spawn a host of entirely new services, including alerts, advertisements, and personal location and guidance services. LBSs are services that are triggered by the current geographic location of the mobile user and his surroundings. According to ARC Group Consultants (2003), it is expected that LBSs will be the most widely used mobile services by 2007.

LBSs can be categorized into three main classes (Beinat, 2001):

- **Information Services:** Providing information about objects close to the user—services like "Where is an ATM nearby?" or "Find the nearest parking lot."
- **Interaction Services:** Based on the interaction between mobile users/objects and which do not require a "mobile Internet" component or content sources.
- **Mobility Services:** Supporting smart mobility and revolving around navigation capabilities. An example may be: "How to get to the nearest hospital?"

Figure 1. An overview of the WS-LBS architecture

Location-based services provide personalized services to the subscriber based on his or her current position (Searby, 2003). By combining information on the location of a mobile user, services can be tailored exactly to the user's situation. These powerful location-based services are the keys to the growth of the mobile Internet in both the consumer and business markets. For subscribers, this means access to attractive, convenient, value-added services that will make their lives easier and more fun, save time, enhance business efficiency, and increase personal safety.

Many GIS enterprises bring forth their wireless schemes: ESRI ArcPad is integrated with GPS module to provide mobile users functions similar to desktop GISs; ArcLocation gives a set of wireless solutions; and MapInfo's miAware, Intergraph's IntelliWhere, and Oracle's Mobile Location Services on Oracle8 and Oracle 10g are all conformed with OpenLS specifications of OGC. Mobile terminal providers such as Nokia, Ericsson, and Motorola are also competitive to develop added-value businesses for mobile users. However, the architecture, platforms, standards, and application background of these systems and applications are quite different (Adams, Ashwell, & Baxter, 2003). To keep sustainable development of LBSs, urgent need exists for efficient, stable, and scalable architecture and implementation techniques of location-based mobile services, adjusting for various multi-platforms, multiple applications, and sustainable development environment (Hermann & Heidmann, 2002).

Web services as a language-neutral and platform-independent technology can be adopted in constructing flexible and loosely coupled business systems. It is easy to apply Web services as wrapping technology around existing applications and information technology assets, and new solutions can be deployed quickly and recomposed to address new opportunities under a Web services framework (Gottschalk, Graham, Kreger, & Snell, 2002). Hence, we propose a Web services-based LBS architecture: Web service-based LBS (WS-LBS).

WS-LBS ARCHITECTURE

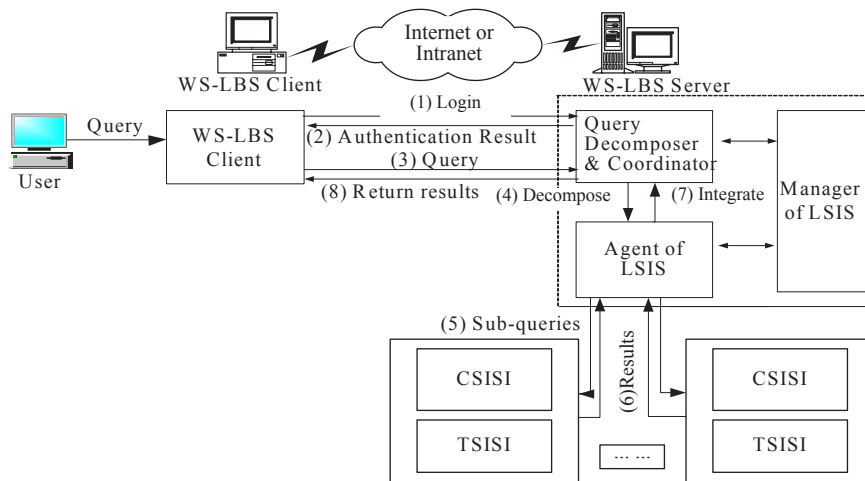

The WS-LBS system consists of four components: client site, server site, Internet or intranet connecting the client sites and server sites, and SOAP messages among the sites. Figure 1 is an overview of the WS-LBS architecture.

In the WS-LBS system, a client is referred to a client machine that can be a desktop or a notebook computer, or a PDA or a mobile phone, which usually does not provide functions of spatial information processing. A user can submit a query request and obtain the final results via a client machine, and only if the user wants to connect to WS-LBS to get spatial information needed, then the client machine can be a part of system. A server in WS-LBS usually refers to a spatial information server that can provide spatial services for local and remote users. When a user submits a query via a client, the query is encapsulated in a SOAP message after initial analysis, and the message is sent to a related server. After receiving this SOAP message, the server makes further analysis and optimization on the requirement, and decomposes the query into sub-queries. Then one or multiple SOAP messages will be sent to related server(s) for the required information or services. The search results will return to the original server within SOAP messages and be merged into final results back to the client.

The Framework of the WS-LBS Server

The framework of the WS-LBS server has two layers: the global spatial information services (GSIS) layer and the local spatial information service (LSIS) layer. GSIS consists of three components: agent of LSIS, manager of LSIS, and query decomposer and coordinator. LSIS is composed of two components: common spatial information services interfaces (CSISI) and thematic spatial information services interfaces (TSISI).

Figure 2. Query handling procedure in WS-LBS

Agent of LSIS in GSIS provides direct proxy for those services with independent functions and no necessity of cooperation with other servers. With the proxy, terminal users need not know the exact providers of such spatial information services. Manager of LSIS is responsible for the management of LSIS, such as registration of new services, or destroy, update, suspend, or activate services, and so forth. The manager also has duties of statistically analysis, tracing, and monitoring the running status of LSIS to improve the holistic quality of services. Query decomposer and coordinator takes charge of the decomposition of the user's query into sub-queries, and the coordination of such sub-queries is sent to corresponding services providers, along with the merge or integration of the searched results so as to return the final result to the user.

CSISI is mainly composed of authentication interface, local metadata interface, map generation interface, non-spatial query interfaces, and so forth. TSISI consists of certain spatial operation service interfaces, such as interfaces of adjacent relationship query, real-time tracing, coverage analysis, route analysis, and so forth.

WS-LBS Client Site

A WS-LBS client is a computer or a mobile device that a user used to access the geographic information services in WS-LBS. Figure 2 shows the request handling procedure of a user's query. At the client site, a user logs into a WS-LBS server and waits for authentication; he or she then submits his or her request to the server. The server will make further analysis, decomposition, and optimization on the query, and take charge of finding, coordinating, merging, and returning the results to the user.

Since WS-LBS is based on Web services technologies to construct and publish geographic information services, at the client site we only need to adopt SOAP client technology to access remote geographic information services.

WS-BASED SPATIAL SERVICES ESTABLISHING AND PUBLISHING

The WS-LBS server mainly aims to effectively provide various spatial information services. For services creation, two approaches can be applied: services defined with WSDL or defined with Java Interfaces description. See examples 1 and 2.

Services can be classified into global or local ones. Considering services publishing in WS-LBS, UDDI is adopted to publish global geographic information services, which

Example 1.

```
// Java Interfaces definition to describe spatial information services
package CAN ;
public class MapService
{ // transform map layer to a SVG document
/* @jws:operation*/
public String Layer2Svg(String strLayer){}
// transform map layer to a GML document
/* @jws:operation*/
public String Layer2Gml(String strLayer){}
// integrate map layers into a SVG document
/* @jws:operation*/
public String IntegrateSvg(String strLayers){}
...
}
```

Example 2.

```
// WSDL based description of spatial information services:
<?xml version="1.0" encoding="utf-8"?>
< definitions xmlns="http://schemas.xmlsoap.org/wsdl/"
  xmlns:conv="http://www.openuri.org/2002/04/soap/conversation/"
  xmlns:cw="http://www.openuri.org/2002/04/wsdl/conversation/"
  xmlns:http="http://schemas.xmlsoap.org/wsdl/http/"
  xmlns:jms="http://www.openuri.org/2002/04/wsdl/jms/"

    </port>
    .....
  </service>
</definitions>
```

have relatively stable interfaces, while URL address is used for local geographic information services publishing, which have more flexible interfaces.

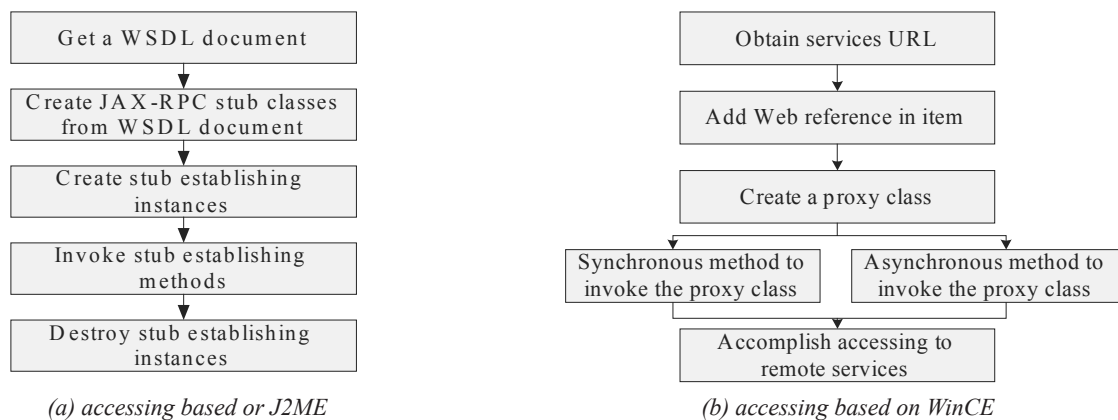

SPATIAL SERVICES ACCESS VIA MOBILE DEVICES

For mobile devices such as cellular phones, PDAs, palm-tops, and so forth, embedded operation systems, application

platforms, and software are used. For example, Symbian, Windows CE, Palm OS, and Linux are such embedded OS, while BREW, J2ME, and .net are the software used often in mobile terminals.

Windows CE is Windows Consumer Electronics or simply WinCE. It is Microsoft's version of Windows for handheld devices and embedded systems that use x86, ARM, MIPS, and SHx CPUs. J2ME stands for Java 2 Platform, Micro Edition. It is a version of Java 2 for cell phones, PDAs, and consumer appliances. J2ME uses the K

Figure 3. Web services accessing under J2ME and WinCE environment

Virtual Machine (KVM), a specialized Java interpreter for devices with limited memory. The connected limited device configuration (CLDC) provides the programming interface for wireless applications. The mobile information device profile (MIDP) provides support for a graphical interface, networking, and storage.

There are three main schemes (WAP, J2ME, or WinCE based) for accessing services via mobile terminals. A WAP-based solution consists of a WAP gateway, WAP mobile phones, and spatial information servers. WAP gateway is applied to bridge the World Wide Web and a mobile network like a protocol translator. The channel width, storage, and process ability that the WAP solution depends on are limited to provide effective multimedia services. In WS-LBS, we design and implement the other two schemes: J2ME- and WinCE-based schemes.

Scheme Based on J2ME Technology

Mobile terminal accessing scheme based on J2ME is neutral to platform, which can provide support for PDAs, cellular phones, TV set top boxes, remote controllers, and other embedded devices. There are WS-APIs provided in J2ME. The client site implementation procedure is shown in Figure 3(a). First, get a WSDL document, next create JAX-RPC stub classes, then through the stub classes the client can access Web services.

Scheme Based on WinCE Technology

WinCE is developed specially by Microsoft to support handsets and information household appliances. A services accessing procedure implemented on WinCE includes these steps: first, obtain the services URLs, and add Web reference in the item, create a proxy class, and use synchronous or asynchronous accessing method to invoke the proxy

class; finally accomplish the access to remote services. The procedure is shown in Figure 3(b). The synchronous method is simple, while the asynchronous one is relatively complex. If there is no response from the Web services for a long time, synchronous invoke will freeze the application, while asynchronous invoke allows users to interact with application during invoke procedure.

WS-LBS PROTOTYPE

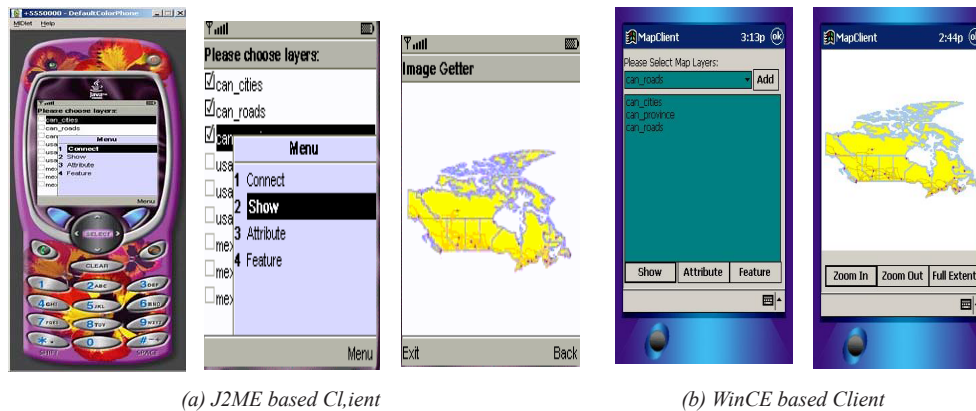

WS-LBS prototype is implemented by Java and c#. The development tools include Weblogic Platform 7, J2ME Wireless Toolkit 2.1, Microsoft Visual Studio 2003, Oracle9i and Oracle9i Spatial, JDK1.4.1, DOM4J, Geotools0.8.0, Batik1.5.1, SQL Server 2000, and Jbuilder. Five desktop computers and one portable computer connected via Internet are designed as servers and clients in WS-LBS, and two kinds of mobile phone simulators are included in the system. The geographic information and some spatial information services are distributed to machines among the WS-LBS system. Users can get some simplified location-based services via mobile phone simulators. The interfaces and menu selection example and a query sample are shown in Figure 4.

CONCLUSION

LBS is an value-added business which gets a user's location information through a telecom provider's network and provides the corresponding services under the support of a digital map platform. In this article, we propose to provide LBS under a Web services framework. We call such services: Web services-based LBS, or simply WS-LBS. The architecture and implementation techniques of WS-LBS are given, and a WS-LBS prototype is developed, which

Figure 4. Query interface and examples at J2ME and WinCE client sites respectively

provides transparent access to distributed spatial information services via mobile terminals.

Research and applications of LBS involve not only spatial information technologies, but also mobile telecom technologies. Furthermore, technologies of wireless markup language, mobile database, mobile localization, mobile network, mobile terminals, wireless application server, mobile connection, as well as appropriate architecture, development platform and software, and efficient data management for LBS are all under deep investigation.

KEY TERMS

Information Services: One of the three main classes of LBSs, providing information about objects close to the user; includes services like “Where is an ATM nearby” or “Find the nearest parking lot.”

Interaction Services: One of the three main classes of LBSs, based on the interaction between mobile users/objects and does not require a “mobile Internet” component or content sources.

Java 2 Platform, Micro Edition (J2ME): A version of Java 2 for cell phones, PDAs, and consumer appliances. J2ME uses the K Virtual Machine (KVM), a specialized Java interpreter for devices with limited memory. The Connected Limited Device Configuration (CLDC) provides the programming interface for wireless applications. The Mobile Information Device Profile (MIDP) provides support for a graphical interface, networking, and storage.

Location-Based Service (LBS): Used to provide personalized services to the subscriber based on his or her current position. By combining information on the location of a mobile user, services can be tailored exactly to the user’s situation.

Mobility Services: one of the three main classes of LBSs, supporting smart mobility and revolving around navigation capabilities. An example may be: “How to get to the nearest hospital?”

Mobile Terminal: Examples include cellular phones, PDAs, palmtops, and so forth; emerging as a new class of small-scale, ad-hoc service providers and consumers in Internet applications, usually connected to the network via wireless connection.

Simple Object Access Protocol (SOAP): A message-based protocol based on XML for accessing services on the Web. Initiated by Microsoft, IBM, and others, it employs XML syntax to send text commands across the Internet using HTTP. SOAP is similar in purpose to the DCOM and CORBA distributed object systems, but is lighter in weight and less programming intensive.

Web Service: Can be seen as an interface that describes a collection of operations that are network accessible through standardized XML messaging. Software applications written in various programming languages and running on various platforms can use Web services to exchange data over computer networks due to the interoperability using of open standards.

Windows Consumer Electronics or Windows CE (WinCE): Microsoft’s version of Windows for handheld devices and embedded systems that use x86, ARM, MIPS, and SHx CPUs.

Web Services Description Language (WSDL): An XML language for describing Web services. This is an XML-based service.

INTRODUCTION

With the opening of the telecommunication market and the emergence of low-cost and heterogeneous wireless access technologies, it is envisaged that next-generation network and service providers will not only vary in the deployed access technology but also in their business models and structures. Such providers will differ from large providers such as the current telecom providers offering multiple services and covering large geographical areas, down to small providers offering certain services such as conferencing or messaging only or covering small geographical areas such as a coffee shop or a shopping mall. Further, while in the current networking environment, a home provider of a user is usually represented by a large telecom provider; in such a heterogeneous environment, any trustworthy entity such as an application provider, a banking entity, or a credit card provider that is capable of authenticating the user and managing his usage profile can act as a home provider. Towards this vision this article discusses the issues that concern the establishment of multimedia applications across heterogeneous networks.

NEXT-GENERATION NETWORKS AND THE ALL-IP CONVERGENCE

Convergence of heterogeneous wireless technologies over a broadband IP core network will allow mobile subscribers to access a new variety of services, over a variety of access networks and by using a variety of devices. This integration will be realized on the network access with devices able to hand off across heterogeneous wireless access technologies, service delivery, and availability (Dagiuklas & Velentzas, 2003). There is no industry consensus on what next-generation

networks will look like but, as far as the next-generation networks are concerned, ideas and concepts include:

- transition to an “All-IP” network infrastructure;
- support of heterogeneous access technologies (e.g., UTRAN, WLANs, WiMAX, xDSL, etc.);
- VoIP substitution of the pure voice circuit switching;
- seamless handovers across both homogeneous and heterogeneous wireless technologies;
- mobility, nomadicity, and QoS support on or above the IP layer;
- provisioning of triple-play services creating a service bundle of unifying video, voice, and Internet;
- home networks opening new doors to the telecommunication sector and network providers;
- unified control architecture to manage application and services; and
- convergence among network and services.

HETEROGENEOUS MULTIMEDIA NETWORKS AND SERVICES

Vision

In order to allow seamless communication and roaming in a heterogeneous wireless environment, one needs to provide an efficient way for coupling multimedia service provisioning, access with fast-handover schemes, and establishing trust relations among service providers and users. This necessitates the provisioning of a framework for establishing security and trust relations among network operators, service providers, and mobile users, allowing thereby smooth roaming among different administrative domains/networks

Figure 1. Inter-domain framework

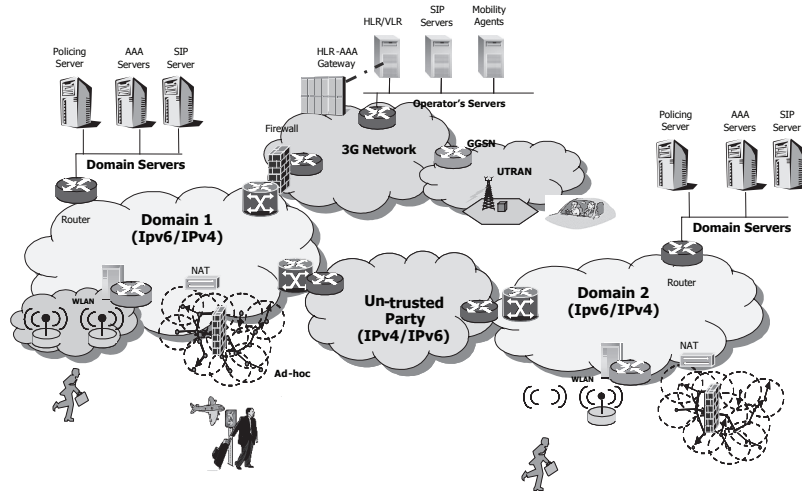

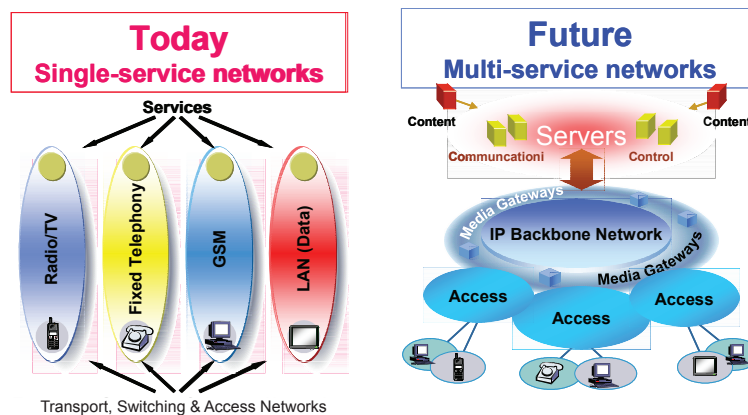

Figure 2. NGN architecture migration (Nokia, 2001)

and seamless provisioning of multimedia services. Such a vision infrastructure is illustrated in Figure 1.

This infrastructure will support the dynamic establishment of trust relations between independent providers (e.g., foreign and home providers) in a distributed manner over hybrid IPv4 and IPv6 networks (Salkintzis, 2004). Moreover, it will provide the required enhancements for providing secure interconnection among different heterogeneous networks, establishing user-provider trust relations, and the necessary means for authenticating users in foreign domains and exchanging their profiles in a secure manner. This would thereby enable users to roam to foreign networks and use the provided services in these networks without affecting their privacy. Finally, to support the smooth and fast handover, efficient and secure context exchange mechanisms will be provided, allowing users to roam among different providers without having to explicitly re-authenticate themselves and establish new trust relations.

It is envisioned that the NGN architecture will be based on packet-based technologies. The most important part of NGN is the division of network functionality into many distributed functions, which fall into the following categories (Dagiuklas et al., 2005):

1. Control, management, and signaling, which provides the intelligence needed for user control of the connection. This intelligence is distributed.
2. Access, routing, switching, and transport, which provides the functions needed for transporting information between end users and other network elements.
3. Convergence with existing legacy networks (PSTN, SS7, mobile networks).

Figure 2 illustrates the transitions from the current scene towards NGN.

To achieve the goal of enabling flexible roaming between different network and services providers in a secure and chargeable manner between providers of different technologies and business models, this article will be addressing the following requirements (Velentzas & Dagiuklas, 2005):

- secure and scalable inter-domain AAA infrastructure for mobile user (secure roaming);
- user access security;
- application level security; and
- concepts for security context transfer while the user hands over among heterogeneous wireless technologies.

INTER-PROVIDER RELATIONSHIP

The establishment of heterogeneous networks aims to import substantial services for the customer through the specification and realizing of infrastructure that enable dynamic trust relation among different providers in a secure and scalable manner. Particular emphasis should be given to roaming business models while the mobile users move across different administrative domains. The possibly very large number of service and network providers as well as home providers makes the establishment of static trust relations between all of those providers tedious and non-economical. Therefore, mechanisms and solutions must be defined that will allow users to roam from one provider (either network operator or service provider or a mixture of both) to the other without having to explicitly subscribe to the services of each provider or assuming some pre-established trust relation between the different providers.

Dynamic Trust Relations

Most current solutions for enabling roaming of users among different network providers assume the existence of pre-established trust relations between the involved partners. Two providers that would like to enable user roaming must be registered at this broker. Currently, the number of network providers is relatively small, with those providers having a large scale in terms of the number of supported users and covered geographical area. Further, the definition of a home provider might change as well, allowing for example a banking unit to act as the home provider of a user and authenticate his identity. Registering all possible providers at a single trust broker would surely not scale. This would then lead to having different brokers each maintaining trust relations to only a small number of providers. To allow for roaming between any two entities, the foreign network needs to be able to discover the home provider of the user and which trust brokers could be used for establishing a trust relation with the home provider. The experience gained for private

key distribution architectures shows that for such schemes to work, they need to be distributed. The work to be done here would include specifying a distributed trust infrastructure and investigating its applicability and performance with the increasing number of providers in NGN.

Identity Management

Identity management is best defined as “those IT and business processes, organizations, and technologies that are applied to ensure the integrity and privacy of identity and how it translates to access.” This results in its effective use as a crucial element of IT security infrastructure. Recently, identity management has been elevated within many IT organizations to be a formal program consideration by several business drivers.

The Liberty framework, developed by the Liberty Alliance project (www.projectliberty.org), comprises an identity management architecture focused on the establishment of secure, consistent, and manageable business relationships and interactions over the Internet. This architecture is realized along circles of trusts embracing affiliated identity providers and service providers. The Liberty framework further defines adequate schemas and metadata for identity management, along with the required bindings to Web-based middleware (SOAP) services.

Current roaming solutions require close interaction between the home and foreign providers in order to gain access to user identity profiles. 3GPP solutions necessitate for example that any signaling messages sent by the user be routed through the home network. This not only increases the set-up delay for establishment of communication sessions, but also complicates the offering of local services in foreign networks. To overcome this problem the home and foreign networks need to be able to exchange user profiles that allow the foreign network to make the decision of whether or not to grant a user access to certain services locally. However, while doing this the privacy of the user’s data and profile need to be guaranteed, and the foreign provider should only be given information that is needed for authorizing the user and providing him with the necessary access rights.

Policy-Driven, Configurable, and Programmable AAA Infrastructures

The exact behavior of AAA infrastructure might vary considerably depending on its location (intra- or inter-domain), functionality (broker, proxy, home, or foreign), supported features (QoS, mobility, multimedia), provider policy, load balancing architectures, or security requirements for example. To ease the replacement of RADIUS protocol-based servers to diameter-based AAA servers, server and network providers need to have powerful and yet simple interfaces

for programming and customizing those servers (Nakhjiri & Nakhjiri, 2005). While Diameter-based AAA technologies are increasingly being considered as the basis for AAA in NGN, there will always be providers relying on proprietary or older solutions. To still be able to communicate with such providers and exchange AAA information with them, some translation mechanisms need to be used to cover the gap.

Reliable and Secure Intra- and Inter-Provider AAA Infrastructure

While attacking a certain server of access router by generating a lot of useless traffic might render part of the network or a certain service useless, attacking the AAA infrastructure would render the complete network useless. Mounting an attack on a trust broker would make any roaming between the networks impossible. Currently, the AAA infrastructure in PSTN networks is not very vulnerable simply because the end systems that are allowed to connect to the network are “dumb.” However, in the open environment of NGN mounting attacks on an AAA server will become easier. Any system can start a large number of authentication requests and occupy thereby not only a substantial share of the network bandwidth but also of the processing resources available to the AAA servers.

Another aspect to be considered here is the reliability of the AAA infrastructure in the face of various failure situations such as software or hardware failures of the AAA servers themselves or the links connecting those servers to the networks. The following points need to be dealt with in future work:

- identification of attack and exploitation possibilities on AAA infrastructures;
- dynamic detection of attacks on AAA infrastructure and devising of mechanisms for defending and protecting against those attacks and reducing their effects; and
- specification and realization of fail-over mechanisms for AAA servers.

Secure Multimedia Service Access

In the literature of node cooperation enforcement, the proposed solutions can be subdivided into two main categories: trade-based schemes and reputation-based schemes. In trade-based schemes, a node that provides some service to a peer node (e.g., packet forwarding) is rewarded by either another immediate service in exchange or some monetary token that he can later use to buy services from another node. In reputation-based schemes each node keeps a reputation metric for other nodes it deals with and provides services only to nodes that exhibit good reputation.

In all reputation-based mechanisms for cooperation enforcement, each node in the network performs two distinct

functions: rating the behavior of neighboring nodes and using these ratings to adjust its own behavior towards them. Rating the conformance of neighboring nodes to a given network protocol is an operation that depends on the specific protocol and network architecture. For instance, in single-channel MANETs, rating the packet forwarding service provided by a node’s neighbors is simply performed through monitoring of the common channel. However, in clustered MANETs, which use different channels in each cluster and bridge nodes to relay packets between clusters (such as Bluetooth scatter nets), a node cannot receive the transmissions of all of his neighbors. Hence, a different technique for rating the forwarding services provided by them is needed. Similarly, rating the conformance to a neighborhood discovery protocol or a Medium Access protocol is fundamentally different than rating packet forwarding.

On the other hand, a cooperation reinforcing reputation mechanism can be easily adapted to use such behavior ratings independently of the rated service. A crucial task for this mechanism is to distinguish between perceived and actual non-cooperative behavior. For example an MT might receive a bad cooperation rating because of link failure or mobility. Misbehaving MTs might also choose to misbehave in a probabilistic way in order to evade detection. If erroneously perceived misbehavior is permitted with a certain probability, then the detection of intentional misbehavior is reduced to an estimation problem.

Secure Service Discovery

The service discovery may be performed using a hierarchical multi-tier approach based on several tiers. A service manager (SM) discovers and manages the services in its corresponding tier and interacts with its upper-tier SM. All the available public and private services provided by foreign nodes, directly attached to the network, or provided by any other kind of infrastructure network will be discovered, subject to authentication and authorization.

In the service discovery architecture, the protocols used for communication are some common service discovery protocols, such as UPnP, Bluetooth SDP, and JXTA. At the highest level, the objective is to create an environment where message-level transactions and business processes can be conducted securely in an end-to-end fashion. There is therefore a need to ensure that messages are secured during transit, with or without the presence of intermediate nodes. There may also be a need to ensure the security of the data in storage. The requirements for providing end-to-end security for the service discovery are summarized as follows:

- **Secure Service Registration and Deregistration:** Service registration and deregistration corresponds to service information management by the SMs. Only authorized service providers should be allowed to

register and deregister a service from the repository. Meanwhile, it is important to maintain the integrity and confidentiality of the registered services in the service registration and deregistration process. Other types of attacks should be mitigated such as message replay and spoofing. Efficient message authentications through signatures or keyed hash-functions are suitable countermeasures for these attacks.

- **Secure Authorization:** Authorized service discovery is needed to control the discoverable services by each entity. On the one hand, users may be authorized to perform a service discovery, but based on their set of credentials, they may only have a controlled visibility of available services. On the other hand, the discovered service must be genuine and trustworthy. Finally, the anonymity of the entity performing the service discovery and confidentiality of the process should also be ensured.
- **Secure Service Delivery/Provisioning:** After a service has been found, it should be securely delivered by the mutual authentication between the recipient of the service and the service provider. Delivery confidentiality and service integrity must also be met so that the genuine and authentic service is only delivered to the intended recipient(s). As for secure service discovery, anonymity with reference to the location and identity can also be required.
- **Dependability:** Dependability can be defined as the property of a system, which always honors any legitimate requests by authorized entities. It is violated when an attacker succeeds in denying service access to legitimate users (e.g., by exhausting all the available resources through the DoS attack).
- **Service Access Control:** Future architectures should contain an AAA component that assigns each service a security profile describing the required security and trust level of the user in order to access the service (Sisalem & Kuthan, 2004)). Profiles determine the access rights for users and contain authorized users, credentials needed, certificates, subscription to groups, and so forth. Profile management can be done by the node, offering the particular service (de-centralized approach) and SM as the service advertiser when evaluating the decision to respond to queries (centralized approach). Using both centralized and de-centralized management methods, it will protect the various access networks (3G, WLAN/WMAN, PAN/PN) from unauthorized use and will keep the management procedure fast and reliable.

Context-Aware Security

One of the basic requirements for B3G is to support seamless mobility, such that the user does not perceive any delay

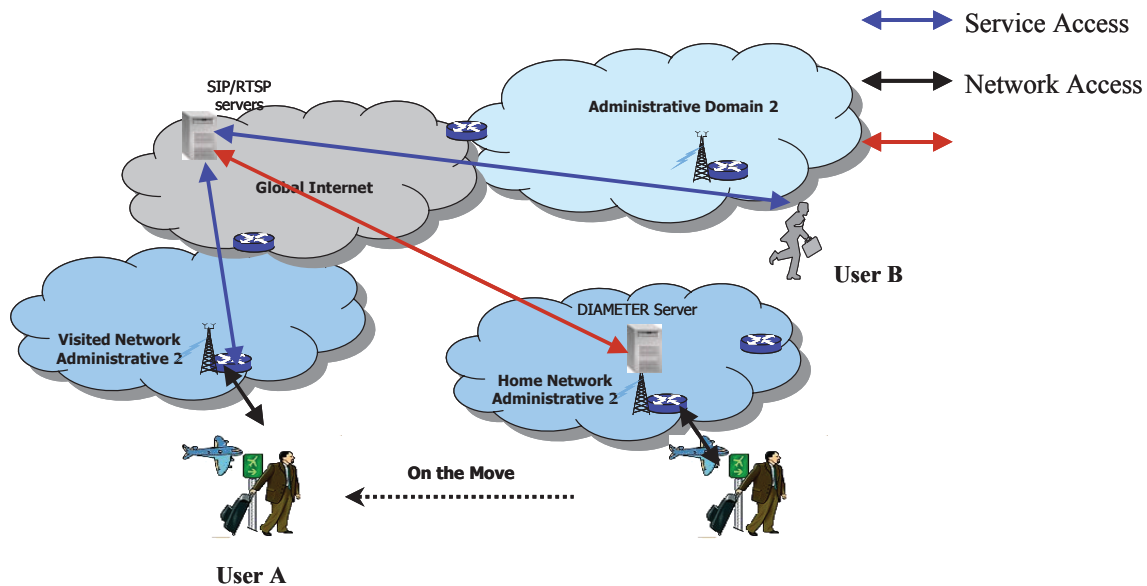

or interruption of service in heterogeneous networks. To provide seamless mobility, handover between networks of either heterogeneous technologies or different administrative domains must be smooth and secure. Because each network may deploy its own security mechanisms that are incompatible with others, seamless handover imposes certain restrictions for maintaining the same security level and minimum delay.

Context transfer aims to minimize the impact of certain transport/routing/security-related services on the handover performance (Loughney, Nakhjiri, Perkins, & Koodli, 2004). When a mobile node (MN) moves to a new subnet, it needs to maintain services that have already been established at the previous subnet. Such services are known as ‘context transfer candidate services’, and examples of these services include QoS policy, AAA profile, IPsec state, header compression, session maintenance, and so forth. Re-establishing these services at the new RAN will require a considerable amount of time for the protocol exchanges, and as a result time-sensitive real-time traffic will suffer during this time. Alternatively, context transfer candidate services state information can be transferred, for example, from the previous RAN to the new RAN so that the services can be quickly re-established. A context transfer protocol will result in a quick re-establishment of context transfer candidate services at the new domain. It would also contribute to the seamless operation of multimedia application streams and could reduce susceptibility to errors. Furthermore, re-initiation to and from the mobile node will be avoided, hence wireless bandwidth efficiency will be conserved (Georgiades, Dagiuklas, & Tafazolli, 2006).

Context transfer requirements should consider the following:

1. **Context Management and User Control:** In many activities in the research community, context information is considered to be important to support usage, operation, and management of heterogeneous wireless network (3G, WLANs, emerging 4G) and service provided by these networks.
2. **Secure Context Transfer of Security Information in Handovers Between Heterogeneous Access Technologies or Network Types:** When a handover occurs, timing constraints may forbid performing a full new access procedure, including authentication and key agreement. Instead, the security context may be transferred between points of attachment in the network which trust each other. The precise nature of the transferred security context must be specified, and the security for the discovery of points of attachment and of the transferred context need to be further studied and researched, especially during vertical handover.
3. **Secure Context Adaptation of Security Information in Handovers Between Heterogeneous Access Net-**

Figure 3. AAA and SIP interworking scenario

works: It may not be sufficient to merely transfer the security context in a handover, but the security context may need to be adapted according to the new environment. For instance, the IP address in an IPsec Security Association may change, or different cryptographic mechanisms or schemes to protect communication traffic may be used.

MULTIMEDIA PROVISIONING

The implementation of demanding services, such as real-time applications and streaming multimedia, in mobile environments using wireless connections has attracted considerable attention over the last few years. Efficient mobility management is considered to be one of the major factors towards seamless provision of multimedia applications across heterogeneous networks (Dagiuklas et al., 2005).

In order to cope with the requirements imposed by the NGN architecture, the IP multimedia subsystem (IMS) has been specified by 3GPP as a comprehensive service framework for both basic calling and enhanced multimedia services (3GPP, 2004). The IMS is the key enabler in the mobile world for providing rich multimedia services to the end users. The IMS enables complex IP-based multimedia sessions to be created with guaranteed QoS for each media component, ensuring that multimedia sessions will be able to reserve the resources they need and are authorized to use in order to perform satisfactorily. The IMS does not standardize any applications, only the service capabilities required to build various services. As a result, real-time and

non-real-time multimedia services can easily be integrated over a common IP-based transport. The functions supported by the IMS include quality of service control, interworking and roaming, service control, and multiple network access. Session initiation protocol (SIP) was chosen as the session control protocol for IMS, which is based on HTTP and uses all service frameworks developed for HTTP. In addition diameter was chosen to be the AAA protocol in the IMS.

Taking into account a mixed environment with both fixed and mobile users and the currently standardized protocols SIP and diameter, several extensions for a complete and integrated security framework with a well-defined identification mechanism and a fully defined intercommunication method with AAA architecture are needed (Camarillo & Garcia-Martin, 2004). Multimedia provisioning across heterogeneous networks should consider the following aspects:

- **Application Level Security:** SIP security mechanisms can be embodied within SIP body message including encryption (enables the possibility to ensure privacy) and AAA.
- **SDP Security and Media Security Extensions:** A number of SDP extensions have been motivated by SIP-based applications, and these need to be accommodated in SDP, which now supports the use of the SRTP/SRTCP protocol. The definition of the SRTP protocol is still in draft phase and under discussion. Features associated with key management attributes need to be included (not just for SIP) and so may need to be general mechanisms to signal security capabilities.

- **SIP Identity Integrity:** The identity information asserted by the sender of a request is the 'From' header containing an URI (like 'sip: ipolitis@ee.upatras.gr') and an optional display name (like "Ilias") that identifies the originator of the request.
- **SIP Privacy:** The privacy problem is further complicated by proxy servers (also referred to in this document as "intermediaries" or "the network") that add headers of their own, such as the record-route and via headers.
- **End-to-End QoS:** Current approaches focus on QoS control in the access part, but the QoS control among service providers is still an open issue (Farkas et al., 2006).

CONCLUSION

In conclusion this article relates the functionalities and AAA infrastructure in order to support the dynamic establishment of trust relations between independent providers in a secure and distributed manner. The support of NGN networks involves research work on vast areas ranging from mobility, quality of service (QoS), roaming models, security, and integration with current networks. Towards the establishment of heterogeneous networks and services, solutions have been presented for supporting the provision of multimedia services over heterogeneous networks, benefiting from the availability of standardized solutions (IMS, Diameter, SIP, etc.) for supporting the operators' needs and solving issues of heterogeneity. Finally, implementing the envisaged conditions, the users' freedom to roam between different networks and use any locally available services in secure and satisfactory manner is increased.

KEY TERMS

Authentication Authorization Accounting (AAA): Provides the framework for the construction of a network architecture that protects the network operator and its customers from attacks and inappropriate resource management and loss of revenue.

Diameter: An AAA protocol for applications such as network access or IP mobility. It is a base protocol that can be extended in order to provide AAA services to new access technologies; it is intended to work in both local and roaming AAA situations.

IP Multimedia Subsystem (IMS): Provides a framework for the deployment of both basic calling and enhanced multimedia services over IP core.

Liberty Alliance: Broad-based industry standards consortium developing suites of specifications defining federated identity management and Web services communication protocols that are suitable for both intra-enterprise and inter-enterprise deployments.

Quality of Service (QoS): The probability of the telecommunication network meeting a given traffic contract, or in many cases used informally to refer to the probability of a packet succeeding in passing between two points in the network.

MANET: Mobile ad-hoc network.

Next Generation Networking (NGN): A broad term for a certain kind of emerging computer network architectures and technologies which generally describes networks that natively encompass data and voice (PSTN) communications, as well as (optionally) additional media such as video.

Remote Authentication Dial-In User Service (RADIUS): An AAA protocol for applications such as network access or IP mobility.

Session Initiation Protocol (SIP): A protocol developed by the IETF MMUSIC Working Group and proposed standard for initiating, modifying, and terminating an interactive user session that involves multimedia elements such as video, voice, instant messaging, online games, and virtual reality. It is one of the leading signaling protocols for voice over IP.

Service Manager (SM): A server that discovers and manages services in its corresponding tier and interfaces with its upper-tier SM.

Triple Play: A term for the provisioning of the three services—high-speed Internet, television (video-on-demand or regular broadcasts), and telephone service—over a single broadband wired or wireless connection.

A QoS Routing Framework on Bluetooth Networking

INTRODUCTION

Bluetooth (2001) is one of the low-bandwidth, energy-efficient wireless technologies designed for mobile devices. As the technology spreads widely in various applications, more and more services and functions are brought to the front, so different types of devices may be equipped with the Bluetooth module and appear in the same area. However, when nodes for different services come together, the need for forming a network comes out.

Actually in Bluetooth technology, there is a kind of basic form of network structure, which is called *piconet*. In a piconet of several nodes, there needs to be a master node and up to seven slave nodes, and all nodes form a star topology centered by the master node. Thus, the piconet is limited by the node number of eight and the communication range of area centered with the master node. To extend the piconet, the scatternet is proposed. In the scatternet, some slave nodes are proposed to serve more than one master. So it can act as a bridge between piconets.

However, the piconet and the scatternet is just the link layer structure. To transmit data between different piconets, in the network layer, a routing protocol is necessary. In addition, the *quality of service* (QoS) is another issue to be solved (Wang & Crowcroft, 1996), because those nodes that are equipped with a Bluetooth module could vary quite differently. Some may be multimedia data, some may be emergency data, and some may be best effort data. When all these services share the same network, the priority shall be different. For this reason, we try to propose some QoS mechanisms in the Bluetooth network.

Bluetooth has a quite unique protocol stack, which has some core layers and the other layers are left to be flexibly customized. To multiplex all above possible services, the QoS routing is proposed to be inserted directly above the core layers of Bluetooth, as shown in Figure 1.

Why shall we propose an improvement to the protocol architecture? It is one of the key points of this article. One

of the reasons is as addressed above, to multiplex and not to be bypassed by upper layers. Another reason is that it can utilize the *energy efficiency* function better, which is provided by the under core layers of Bluetooth.

BLUETOOTH FEATURES AND CHALLENGES

Bluetooth is designed to be the industry standard for low-power mobile devices. Highly integrated chipsets are being developed that provide RF circuitry and protocol processing on a single chip. Current Bluetooth only supports simple services, such as human interfacing, audio/video transmitting, and home network controlling. Most of the cases are one-step communication or the last step to the wired network. Therefore, the Bluetooth network is just as simple as a star topology consisting of a master and several slaves or less. The network range is just the radio transmission range, about 30 feet. In each piconet, the master is limited to have no more than seven active slaves.

To extend the network a little bit further, a multi-hop relay is necessary. Although in Bluetooth, the *scatternet* is designed specially to build the connections between multiple piconets, it is simply a concept of link layer and physics layer, which means it offers the ability to transmit data between piconets but it does not offer the routing function. We need routing algorithms. The general routing algorithms in the wired network or the routing algorithms proposed for the mobile ad hoc networks are not efficient for the Bluetooth scatternet. The power efficiency consideration is necessary.

Bluetooth technology is designed to support 2Mbps at a range of 30 feet. The 2Mbps bandwidth is shared by all the slaves in the piconet. If several slaves try to communicate with the master, the master may share equal opportunity with each slave and the bandwidth is split. If several piconets are overlapped with each other, they will share the same radio spectrum resources as well. Therefore, in each piconet, the

available bandwidth also becomes less. In either case above, each link connection of the multi-hop path is trying to compete for the bandwidth with each other. Thus, if any streaming service runs over the Bluetooth network, the available end-to-end bandwidth will be quite critical. From this viewpoint, a quality of service routing is necessary.

Comparing to others, such as IEEE Standard 802.11 (1997), HyperLan (Z002), HomeRF (Chinitz, 2001), ZigBee (ZigBee Alliance, 2002), and so forth, the advantage of Bluetooth technology is that it offers the power efficiency at a low cost and relatively enough bandwidth. The Bluetooth offers the function of power efficiency by several modes of operation, which is hold mode, sniff mode, and park mode, besides the connection mode. The four modes of operation consume different amounts of energy in different activity states. The sniff mode and the hold mode are not generic device modes. Here we simply consider the connection mode and the parked mode. The connection mode is the mode that the device is working actively, while the parked mode is the mode where the device almost does not work (actually still receiving some messages from the master by a specific channel) and consumes less energy. Normally mobile ad hoc network routing protocols require that all the nodes be in the connection mode. Therefore, the advantage of Bluetooth cannot be explored. We need a routing protocol that can manage the mode of operation to save the energy by sleeping the unused nodes.

NETWORK MODELING

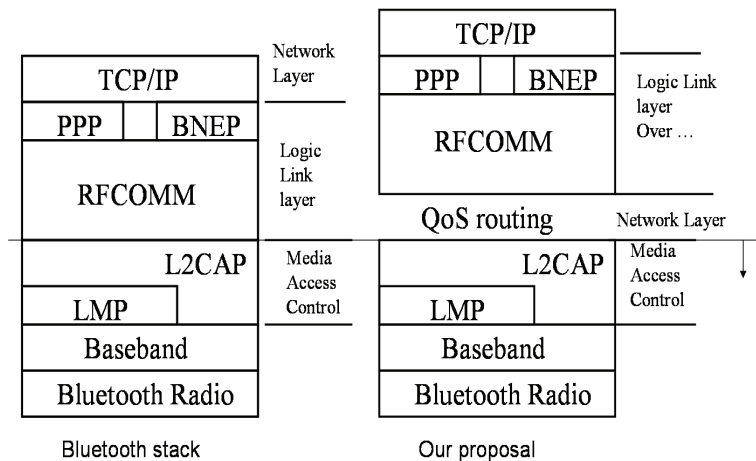

In this section, we compare different applications and different choices of the network model. As a result, it is found that routing on the L2CAP layer is the best choice.

A typical example of the Bluetooth protocol stack is shown in Figure 1. The Bluetooth radio and the baseband consist of the physical layer of the Bluetooth which is implemented by hardware chipsets. The LMP and the L2CAP layer represent the Media Access Control layer of the Bluetooth. The LMP deals with the power management and offers the ACL (Asynchronous Connectionless Link) channel for the communication. The L2CAP layer takes responsibility to multiplex logic transports into the physical channels. By these means, the upper layers can share the bandwidth. Up to the L2CAP layer, the protocols are usually integrated in the hardware. Those protocols built above the L2CAP layer are usually left to be flexibly configured according to the need. The RFCOMM (RFCOMM with TS 07.10, 1999) is protocol emulation to the serial ports. The Bluetooth Network Encapsulation Protocol (BNEP) (Bluetooth Special Interest Group, 2001) is a protocol specifically designed for the Bluetooth to emulate the Ethernet. The PPP (Simpson, 1994) is the simple and useful point-to-point protocol. According to different applications, the choice of these logic link layer protocols varies greatly.

The network model of supporting IP services over Bluetooth has been a warmly discussed issue. The possible network model can be [IP over ACL], [IP over L2CAP], [IP over [BNEP over L2CAP]], [IP over [PPP over RFCOMM]], and [IP over [PPP over L2CAP]].

The L2CAP layer has the segmentation and reassembly (SAR) function and maximum transmission unit (MTU) negotiation, which is done by hardware. Because the SAR function is an unavoidable part in the whole process, hardware implementation of course is better than additional software. Thus we prefer the [IP over L2CAP] to the [IP over ACL] network model. The other three models introduce much overhead and a lot of unnecessary things, although it can improve the compatibility to support many widely used protocols.

Figure 1. Bluetooth protocol stack

The network model of multimedia streaming over Bluetooth is also researched (Wang, 2003). Chia and Beg (2002) proposed and compared HCI, L2CAP, and IP as alternative intermediate protocols for video streaming over Bluetooth. A qualitative comparison of the three intermediate layers is made based on the size of the overheads, the efficiency of segmentation and reassembly processes, and hardware compatibility. Implementation issues of streaming video via different layers over Bluetooth are also discussed in Bilan (2003) and Scheiter et al. (2003). It suggests that video streaming via IP and L2CAP can be achieved using three Bluetooth specifications: the Local Area Network Access Point Profile – LAP, Bluetooth Network Encapsulation Specification – BNEP, and Audio/Video Distribution Transport Protocol – AVDTP (Bluetooth Special Interest Group, 2001, 2002a, 2002b).

Streaming over IP

Streaming over IP can be achieved by using LAP or BNEP. Since the stream is packetized by the IP, it has no problem streaming through the Internet. However, comparing to the streaming over L2CAP, LAP, and BNEP adds an additional encapsulation layer. Thus there are at least three encapsulation layers for an IP Bluetooth solution: L2CAP, BNEP/LAP, and IP.

Streaming over L2CAP

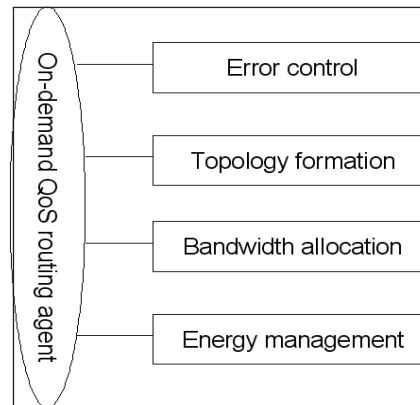

Bluetooth over L2CAP is defined by three specifications: Audio/Video Distribution Transport Protocol, Audio Video Control Transport Protocol (AVCTP), and Generic Audio/Video Distribution Profile (GAVDP). AVDTP suggests that L2CAP channels are best suited for the support of A/V stream data distribution links, because L2CAP can be flexibly configured to enable bandwidth to be shared between multiple A/V content streams.

In summary, we can see that the L2CAP is the simplest and suitable layer to make any routing function. And it shall achieve the least overhead. Although in the IP layer, the routing protocol can be implemented, it is not easy to explore the merits of the lower layer from the IP layer. The routing in the L2CAP could be the optimum choice.

QoS ROUTING

Our routing protocol lies directly above the core layers, which include the L2CAP and the LMP layer, of the Bluetooth technologies. Thus it is easy to control the Bluetooth devices. To maintain a good performance of the whole network, many aspects must be considered, such as error control, topology formation, bandwidth allocation, and energy management, as shown in Figure 2.

Figure 2. The framework of QoS routing

Bluetooth ACL link provides three built-in baseband error correction techniques: 1/3 rate FEC, 2/3 rate FEC, and ARQ. The 1/3 rate FEC scheme is adopted in the header of L2CAP packets. The other two are applied to the payload. In the AVDTP, the upper-layer FEC scheme is proposed to protect video packets. The upper-layer recovery benefits from providing different protection according to the video packet types or contents. We just leave the interface to the application to select the right way of error protection.

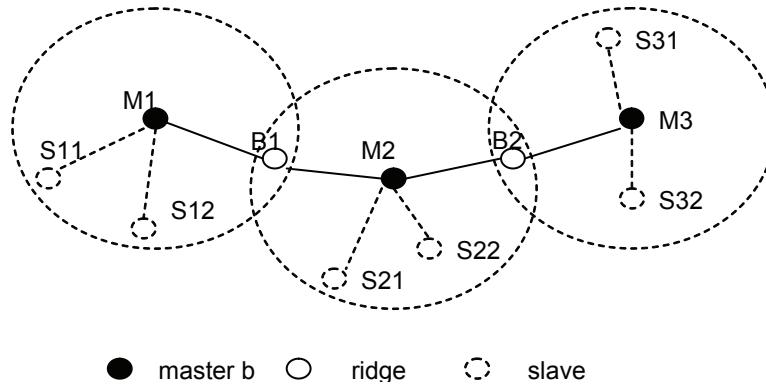

In order to sleep unnecessary nodes, our protocol will form a backbone network to maintain the routing. Other nodes may be put into the parked mode to save energy. Thus the topology formation is triggered by the services.

The bandwidth allocation is one of the key points in our routing protocol. Since all the nodes within a piconet are sharing the same bandwidth, and the master knows the current state of the piconet. It is necessary to send a request to get permission from the master when too many streams of traffic are running in the network. This is described in detail in the following sections.

Backbone Structure Formation

Forming the topology structure is the first step in making a Bluetooth network. Since energy efficiency is one of our goals, in our protocol the key roles of the network are kept awake to maintain the knowledge of the network structure. The key roles are the masters of the piconets and those bridge nodes of the scatternet. Some slave nodes are put into the parked mode when they are not sending data. As Figure 3 shows, the backbone is formed by M1, B12, M2, B23, and M3. Other nodes are parked. Because the master knows well the state of its piconet, it is enough for the master to take charge of routing information. To reduce the interference between the piconets, when forming the structure, the formed piconets need to be overlapped as little as possible.

Figure 3. The structure of Bluetooth network

Routing Identification

In the network layer, each node must have a unique identification to differentiate each other, for instance, the IP address. Here we simply use the Bluetooth device address. However, the Bluetooth device address is not put into any packet header as routing instruction, as the IP does. It is only used while routing at the beginning. After the routing path information is obtained, the tunnel is built from the source to the destination. Thus, there is no need to check the routing table for each packet. Therefore it is desired to avoid any unnecessary overhead, and we use L2CAP channels as tunnels instead of putting an ID on each packet header. As shown in Figure 4, each flow uses a tunnel. There is a default L2CAP channel, which is used as the channel of routing messages. Although there are only a limited number of L2CAP channels offered, the assumption is that we are not going to build any large-scale network or support any complicated traffic scenarios. Thus, the number of L2CAP channels is enough.

Routing Mechanisms

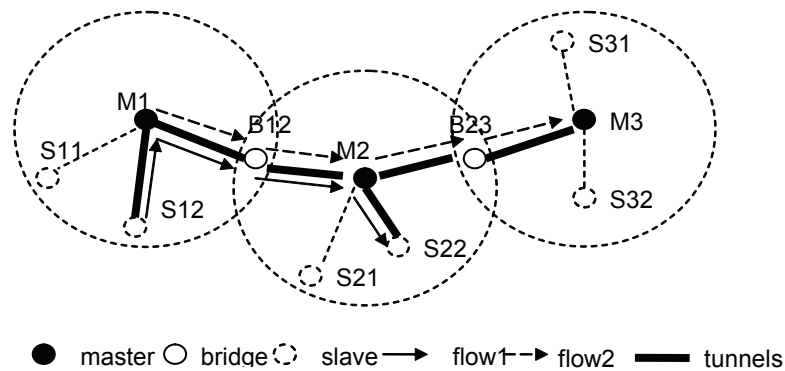

After the structure is formed, the structure information is described as in Table 1, which is the descriptive routing table of the structure in Figure 3. Each row in Table 1 is mapping to a piconet in Figure 3. For instance, the master of piconet 1 (M1) knows its member S11, S12 in parked state and this piconet has a bridge node to piconet 2 (P2). The master also knows how much bandwidth is being used, such as W1 is used in P1, and W1 is used for the bandwidth request process.

The routing procedures can be described as follows. First, as shown in Figure 4, node S12 wants to start a flow, so it wakes itself up and sends a route request message to its master that includes the information of required bandwidth from the application layer. The master checks the value of W1 to see whether there is still enough bandwidth left. If ok, then it forwards the request to the destination according to the routing table. Otherwise, it sends back a route deny message. When the bridge node B12 receives the route

Table 1. The structure information

| Piconet | Used Bandwidth | Members |
|---------|----------------|-------------------------------------|
| P1(M1) | W1 | S11(Parked);S12(Parked);B12(Active) |
| | | B12->P2 |
| P2(M2) | W2 | S21;S22;B12;B23 |
| | | B12->P1;B23->P3 |
| P3(M3) | W3 | S31;S32;B23 |
| | | B23->P2 |

Figure 4. The packet flows

request, the used bandwidth is checked by $W1+W2$ to see if the bandwidth is enough.

If the route request successfully arrives at the destination, the destination will send a route reply back. Any key role players must update their value of used bandwidth at this time. Actually the value is calculated and bound by each L2CAP channel. If any channel is broken, a route error message is sent back and the used bandwidth is updated.

CONCLUSION

In this article, we have presented a routing protocol for Bluetooth networks. Comparing to other general routing protocols, which do not consider the Bluetooth features efficiently, our protocol improves much, in that it can save energy and provide the *bandwidth reservation* function for different services, especially for multimedia services. We suggest building the routing protocol directly over the L2CAP layer of the Bluetooth. By this means, it is able to manage the mode of operation of the nodes, and energy can be saved. In our protocol, we also provide an approach to reserve the bandwidth in order to provide different QoS for different services.

KEY TERMS

Ad Hoc: A network connection method that is most often associated with wireless devices. The connection is established for the duration of one session and requires no base station.

Flow: A sequence of continual data; the content will be anything, such as multimedia or messages.

Link Manage Protocol (LMP): Handles link control, power-sensitive states changing, and data encryption.

Logical Link Control and Adaptation Protocol (L2CAP): Used within the Bluetooth protocol stack. It passed packets to either the Host Controller Interface (HCI) or on a hostless system, directly to the Link Manager. L2CAP provides protocol multiplexing, segmentation and re-assembly, quality of service, and group addressing. Voice packets can bypass the L2CAP.

ZigBee: A published specification set of high-level communication protocols designed to use small, low-power digital radios based on the IEEE 802.15.4 standard for wireless personal area networks (WPANs).

Radio Resource Management in Convergence Technologies

INTRODUCTION

Today we find a large number of wireless networks based on different radio access technologies (RATs) and standards. Furthermore, new RATs will be developed to complement those that exist already today. Each RAT will have its strengths and weaknesses with respect to capacity, cost, achievable data rates, and support for end user mobility. As no single RAT will be able to fully support all service and user requirements, B3G networks will integrate multiple RATs in a common network. It can be anticipated that within a few years' time, a user terminal (UT) will have a choice of access technologies via which it can connect to the fixed communication infrastructure. This paves the way towards new possibilities of managing user service quality as well as radio resource utilization. The idea of multi-access radio resource management (MRRM) handling is to explore these possibilities by co-coordinating radio resource usage of different RATs such that total system capacity as well as perceived performance for individual users is increased. The integration of different technologies with different capabilities and functionalities is an extremely complex task and involves issues at all the layers of the protocol stack. The integrated heterogeneous architecture (Dave, 2005) is shown in Figure 1.

The rest of the article is organized as follows. The internetworking proposals, the challenges while approaching radio resource management, and the RRM functions are discussed. The proposals for vertical handover management are briefed, and finally multi-access RRM distribution in B3G multi-radio access networks is discussed.

INTERNETWORKING PROPOSALS

There are three proposals for internetworking existing networks: tight coupling, loose coupling, and hybrid coupling. *Tight coupling* connects the WLAN network to the rest of the core network in the same manner as other UMTS radio access

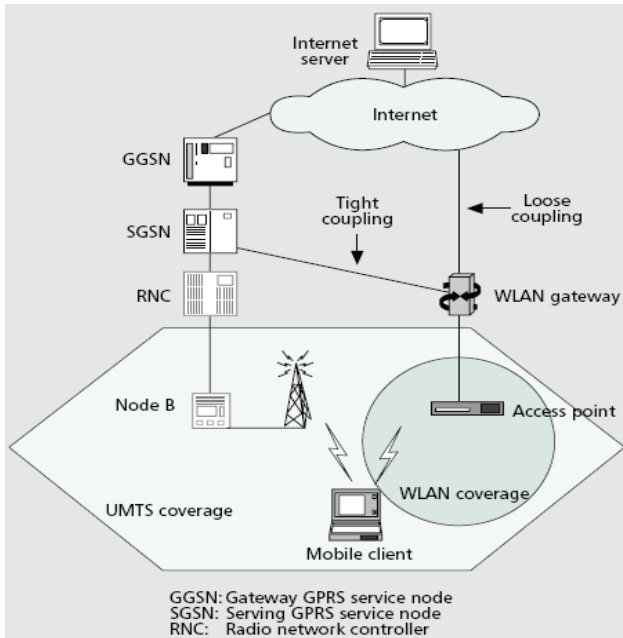

Figure 1. Heterogeneous network architecture

technologies. From the view of the UMTS core network, the 802.11 WLAN service area works like another GPRS serving node (SGSN) coverage area. As a result, all traffic—including data and signaling generated in the WLAN networks—is injected directly into the UMTS core network.

Loose coupling separates the data paths for the 802.11 WLAN and UMTS core networks. The WLAN gateway connects to the Internet, and all data traffic is transmitted into the core network, instead of into the UMTS core network, while signaling may optionally go through either the UMTS network or through the core Internet. *Hybrid coupling* creates a new wireless link between the base station (BS) in a cellular network and the access point (AP) in a WLAN within a same cell area using IEEE 802.16. It has advantages

Figure 2. Internetworking proposals

including dynamically reducing signaling cost and handoff latency due to adoption of the fast handoff techniques, and relieving the burden of core networks through dynamically distributing the traffic.

Both tight coupling and loose coupling increase the burden of core networks (Liu & Zhou, 2004), since all signaling and data transmission pass through the UMTS core network or the core Internet, and even results in bottleneck congestion or reconfiguration of network load when the interchanging traffic is too much. These two proposals are illustrated in Figure 2.

In order to overcome these shortcomings, a priority-based service interworking architecture with hybrid coupling is developed. In hybrid coupling, a new wireless link using the IEEE 802.16 standard is created between the base station (BS) in a cellular network and the 802.11 WLAN within a same cell area. Hybrid coupling has advantages including dynamically reducing signaling cost and handoff latency, relieving the burden of core networks through dynamically distributing traffic in a low-level network, and enhancing the robustness of the integrated networks through adding a new wireless link.

The priority-based service interworking architecture with hybrid coupling is presented in Figure 3. In hybrid coupling, both the cellular network and WLAN are considered as IPv6-based networks, and each element in the interworking networks has a distinct ID number corresponding to the network routing address.

RRM CHALLENGES IN FUTURE

The distribution of RRM (Magnussen, 2004) in existing RATs varies greatly, at least partly because the RATs have been optimized for different purposes. 2.5G and 3G RATs like GSM/EDGE, WCDMA, and cdma2000 have sophisticated network-centric RRM focusing on maximizing the use of available spectrum resources and also supporting mixed traffic types with different QoS requirements (voice, videoconference, Internet surfing, file download, etc.). The basic principle is that RRM decisions are made in a network node1, in most cases based on measurements collected from terminals and other network nodes. In contrast to this, IEEE 802.11 WLAN includes limited RRM support in a terminal-centric fashion, focusing on a simple (low-cost) solution providing high-peak bit rate best-effort data without any QoS. In this case the terminal is making the most of the RRM decisions, for example which access point (AP) to connect to, with some influence from parameters broadcasted by the APs. It has been identified that the simplistic RRM support in 802.11 is an obstruction to large-scale network

deployment. Therefore standardization efforts are ongoing towards more efficient RRM and operation and maintenance in 802.11 networks.

Resource management schemes are strongly related to the traffic. Supporting high bit rate packet-switched traffic over the radio interface puts new requirements on resource management. Moreover, if QoS guarantees shall be provided, this will put requirements on the resource management that cannot be fulfilled by today's high data rate RATs of WLAN type. In a 4G perspective, data rates of 100 Mbit/s for wide area coverage and up to 1 Gbit/s for local coverage are envisaged. Data rates are certainly limited by propagation conditions such as multi-path and so forth, but the primary constraining factor is the terminal transmitter power, which increases linearly with the bandwidth. This means that to be able to cover large areas with high data rates, a dense infrastructure needs to be deployed. Increasing the infrastructure density may cause an increase in complexity of RRM algorithms where distributed schemes will be more and more important. Furthermore, RRM will have to operate across cells and frequencies, and may include mechanisms for dynamical reallocation and/or sharing of spectrum between operators and RATs. The side effect of using multiple RATs within the same spectrum means that the radio link will be subject to interference from other RATs, possibly in an uncoordinated manner. Reliably estimating, for instance, the carrier-to-interference ratio (C/I) as a basis for RRM decisions will be considerably more difficult. This will put requirements on future RRM functions for RATs that may co-exist within the same spectrum.

RRM FUNCTIONS

In a region with multiple independent RATs, one cannot explore the optimal use of available frequency resources and characteristics of each RAT. By coordinating the radio access networks, we can gain:

- increased trunking capacity and grade-of-service (GoS) in the region;
- improved spectrum usage by selecting the best RAT based on radio conditions (e.g., path-loss);
- improved spectrum usage by selecting the most appropriate and efficient radio bearer and RAT for the service;
- minimized inter-system handover latency; and
- preservation of QoS across multiple RATs.

There are also non-performance related gains: greater flexibility for the operator with regard to infrastructure options, reduced signaling and delay due to better coordinated profile handling, and so forth.

Important MRRM functions needed to achieve these gains are:

- access discovery,
- access selection,
- admission control,
- load sharing,
- congestion control, and
- spectrum allocation.

The terminal performs *access discovery* by scanning the assigned frequencies for broadcast channels of other cells. However, to save battery power, network-assisted access discovery mechanisms may support the mobile terminal in detecting cells.

The *access selection* mechanism selects an access based on the discovered accesses, user preferences (QoS, price, etc.), and available system capacity and utilization. Two important functions within access selection are session admission control and load sharing.

Session admission control allocates resources based on QoS (and price) negotiation between the user and the network in a manner that the system load is controlled. A session admission may be followed by RAT-specific link admissions to allocate resources in each RAT.

Access can also be selected based on available capacity and utilization within different RATs—that is, *load sharing*. Intelligent load sharing mechanisms for distribution of terminals and their radio bearers between available RATs have the potential of enhancing overall system capacity.

Congestion control handles overload situations where QoS for admitted users cannot be satisfied with the normal quality agreed for a given percentage of time. The congestion control then invokes procedures that prevent some users from getting their normal QoS, preferably by first removing excess QoS (*soft congestion control*) and then disconnecting already admitted services (*hard congestion control*) based on their GoS—that is, how important different services are.

Spectrum allocation is the mechanism to (re)allocate the spectrum between multiple RATs which can be within the same or different radio access networks. MRRM functions actually needed depend on the following characteristics: support for QoS, spectral efficiency, low complexity, and so forth. The importance of these factors and the potential gain from MRRM differ between particular scenarios considered (combination of RATs, business model, etc.).

VERTICAL HANDOVER MANAGEMENT

In this section the vertical handover management in convergence technologies is discussed. The movement of a user within or among different types of networks can be

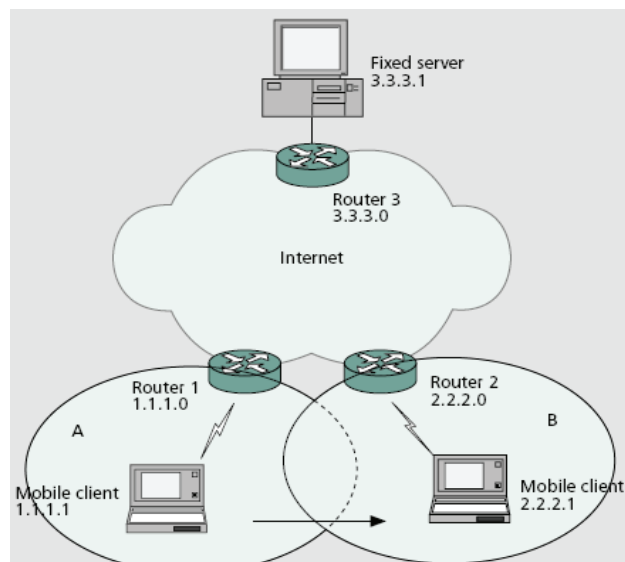

referred to as intersystem or vertical mobility. One of the major challenges for seamless vertical mobility is vertical handoff (Zhang et al., 2003), where handoff (or handover) is the process of maintaining a mobile user's active connections as it changes its point of attachment. Traditionally, handoff research has been based on an evaluation of the signal strength received at the mobile node, followed by a change in access point, if needed, and an updated routing path for the user connection. However, with a vision of a diverse multi-network environment, and considering the goals of transparent universal access, ubiquitous computing, and seamless mobility, traditional signal strength comparisons are not sufficient to make a handoff decision, as they do not take into account the current context or the various attachment options for the mobile user. Another issue in vertical handoff is the timely and reliable transfer of a mobile user's connection(s). While traditional link transfer techniques can achieve fast handoffs, there is now a need to consider the context of the link transfer, including security associations, QoS guarantees, and any special processing operations. Thus, the vision of 4G requires investigation of a more adaptive and intelligent network approach to vertical handoff.

In such a heterogeneous network environment, seamless mobility support is the basis of providing uninterrupted wireless services to mobile users roaming between various wireless access networks. Because of transparency to lower-layer characteristics, ease of deployment, and greater scalability, the application-layer-based Session Initiation Protocol has been considered the right candidate for handling mobility in heterogeneous wireless networks.

However, SIP (Ma, Yu, Leung, & Randhawa, 2004) entails application-layer transport and processing of messages, which may introduce considerable delay. As an application-layer protocol, SIP relies on the protocols and mechanisms in the lower layers to handle the physical network connection. As far as SIP mid-call mobility is concerned, additional procedures are needed to get the MHs attached to the wireless access network infrastructure before the SIP re-INVITE message is sent. For example, an MH attaches to the GPRS radio access network of a UMTS network using the GPRS attach and packet data protocol (PDP) context activation procedures, while it uses DHCP to attach to a WLAN. Therefore, the vertical handoff delay mainly consists of the delay of network attachment as well as that of SIP location update. In the following sections we describe the procedures of vertical handoff and analyze the associated delays. In particular, two cases of vertical handoff are of interest: handoff from a WLAN to a UMTS network, and vice versa.

A new method to facilitate seamless vertical handover between wide area cellular data networks such as UMTS and WLANs is by using the stream control transmission protocol (SCTP) (Wu, Banerjee, Basu, & Das, 2005), as shown in Figure 4.

Figure 4. SCTP support of seamless handover

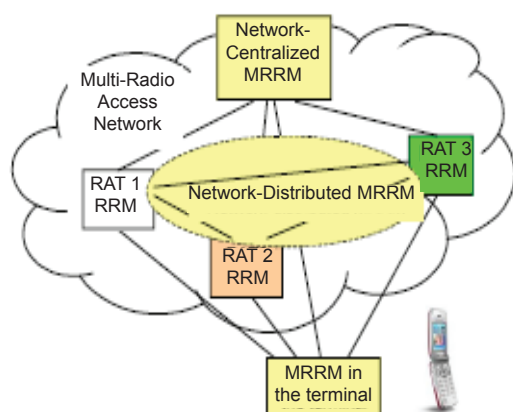

The multi-homing capability and dynamic address configuration extension of SCTP are applied in the UMTS/WLAN overlay architecture to decrease handover delay and improve throughput performance. Unlike techniques based on mobile IP or session initiation protocol, the SCTP-based vertical handover scheme does not require the addition of components such as home/foreign agents or a SIP server to existing networks. Therefore, this scheme provides a network-independent solution preferred by service providers.

MRRM DISTRIBUTION IN B3G MULTI-RADIO ACCESS NETWORKS

When distributing these MRRM functions, it is important to consider not only desired traffic characteristics but also how radio resources, corresponding measurement statistics, and control parameters are distributed throughout the network and in relation to these transport capabilities between the nodes, processing capabilities in the nodes, and so forth. From a control point of view, it is of course beneficial to place the MRRM functions where the measurement statistics and/or control originate. However, there are a number of reasons to place them elsewhere, such as:

- need for coordination of resource usage between multiple resources, such as load sharing between different cells, frequencies, RANs, and so forth;
- need for measurement statistics from multiple nodes for some decisions, such as available capacity in both uplink and downlink;

Figure 5. MRRM distribution alternatives

- CPU processing capacity needed for the RRM function;
- a transmission requirement for input parameters and control updates (periodicity, amount of data and acceptable delay);
- a specific entity wants to control the resource usage, such as the operator or the user;
- extensibility, for instance in terms of possibility for easy integration of new RATs;
- performance, for instance in terms of handover latency, spectrum efficiency, and so forth;
- scalability aspects of the different alternatives;
- possibilities for interaction with other functions, for example mobility management and general QoS control; and
- simplicity and costs, for example in terms of special software, extra nodes, and so forth.

We make a distinction here between three main categories of MRRM distribution between the terminal and the network nodes:

1. network-centralized MRRM functions,
2. network-distributed MRRM functions, and
3. MRRM functions in the terminal.

An overview illustrating these alternatives is given in Figure 5 including all possible interconnections between RRM entities.

The alternative of network-centralized MRRM means that one or more central entities are coordinating different RAT-specific RRM entities. This approach has been proposed and discussed within various forums such as 3GPP. The idea is that the non-RAT-specific MRRM functions are isolated from the RAT-specific RRM functions in one or more centralized network entities, possibly in a hierarchical structure.

In the network-distributed MRRM approach, there is no specific MRRM entity. The corresponding functionality is instead distributed between RAT-specific RRM entities through peer-to-peer relations. This principle is already today supported between WCDMA and GSM/EDGE according to the 3GPP specifications, wherein for example cell load information can be exchanged between WCDMA radio network controllers (RNCs) and GSM/EDGE base station controllers (BSCs).

The third alternative naturally means that MRRM functions and decisions are left to the terminal. This would still typically include some support from the network—that is, each network RRM entity could provide information to the terminal on which it bases its MRRM decisions.

A multi-access network may consist of a combination of these distribution alternatives, that is, some multi-access RRM functions could be centralized (e.g., overall load sharing), others could be distributed (e.g., handover of individual UTs), and some could be located in the terminal (e.g., initial RAT selection). Hierarchical coordination typically scales well. However, it may be difficult for entities high up in the hierarchy to handle detailed RRM decisions concerning individual users or cells. The idea is that the higher in the hierarchy, the less detailed and less time-critical information is handled. Furthermore, a hierarchical structure “creates” border areas where detailed coordination cannot be solved with a non-overlapping hierarchical coordination.

Distributed coordination avoids the coordination problem, but can at least theoretically run into scalability problems, as an increasing number of RRM entities in the network causes the number of interconnections between RRM entities to grow in an exponential fashion. However, in practice, geographical aspects typically limit the number of required interconnections. For instance, only each pair of RRM entities that handle overlapping or neighboring cells actually needs to have a peer-to-peer relation.

A benefit of leaving some MRRM functions to the terminal is that important measurements originate in the terminal such as link quality, and the terminal also contains the application interface, which may provide QoS requirements. In addition, it is often argued that the decision of, for example, which RAT to use should be left to the end user and not to the network operator.

This aspect is very much dependent on the involved business entities (e.g., number of operators) and underlying business model, and it may also be argued that users may not want to make such decisions, but rather just get the best possible connection for its communication needs without having to worry about the technology behind it. On the negative side for terminal control, optimal overall resource utilization is not as easily achieved as through network control. Moreover, the operator network planning becomes a very difficult task if terminal behavior is not consistent

and predictable, meaning that all decision making of the terminal requires strict standardization.

CONCLUSION

This article proposes features relating RRM in convergence technologies. The convergence of all existing networks will provide access to all available services using a single-user terminal. But there are lots of challenges to be addressed in converging all networks. In spite of converging the networks, the RRM of the converged network is more challengeable. This article illustrates some of the challenges, and many more are still open issues. The complexity of radio resource management has to be addressed in the near future.

KEY TERMS

Grade of Service (GoS): A measurement of the quality of communications service in terms of the availability of circuits when calls are to be made. Grade of service is based on the busiest hour of the day and is measured as either the percentage of calls blocked in dial access situations or average delay in manual situations.

Heterogeneous Network: A network that consists of workstations, servers, network interface cards, operating systems, and applications from many vendors, all working together as a single unit.

Radio Access Technology (RAT): Technology or system used for the cellular system (e.g., GSM, UMTS, etc.).

Radio Resource Management (RRM): Efficiently utilizing the available resources.

Wireless Local Area Network (WLAN): Wireless network that uses radio frequency technology to transmit network messages through the air for relatively short distances, like across an office building or college campus.

Wireless Metropolitan Area Network (WMAN): A regional wireless computer or communication network spanning the area covered by an average to large city.

Wireless Personal Area Network (WPAN): Personal, short distance area wireless network for interconnecting devices centered around an individual person's workspace.

Wireless Wide Area Network (WWAN): Wireless network that enables users to establish wireless connections over remote private or public networks using radio, satellite, and mobile phone technologies instead of traditional cable networking solutions like telephone systems or cable modems over large geographical areas.

RFID and Wireless Personal Area Networks for Supply Chain Management

David Wright

University of Ottawa, Canada

INTRODUCTION

Efficient supply chain management relies on knowing where products in the supply chain are located. The ability to track items from manufacturing plant to warehouse to distribution center to wholesaler to retailer is currently provided by RFID, radio frequency identification (Weinstein, 2005). Case examples of commercial applications of RFID in supply chain management are evaluated by Jones et al. (2004). A recent development, low power wireless personal area networking, WPAN, can offer advantages over RFID in certain circumstances. It is the purpose of this article to evaluate RFID and wireless personal area networks with respect to each other and to identify the features that give one an advantage over the other. We first describe the two technologies.

RADIO FREQUENCY IDENTIFICATION (RFID)

RFID tags are of two types: passive and active. A passive RFID tag is a chip incorporating memory and a microwave transmitter that is embedded in a product or in the product's packaging. The memory contains the identification number of the tag and may also contain physical specifications of the product using PML, Physical Markup Language (York, 2003). In order to read the tag an RFID reader sends out a burst of microwave energy, which is picked up by the tag and is sufficient to allow the tag to transmit the contents of its memory, which is received by the reader. Since the tag receives power from the reader, it does not need to have its own battery, and is called a passive RFID tag for that reason. Passive tags cost about US\$0.20 in large volumes, and are used much more widely than active tags.

Active RFID tags incorporate a battery, cost more than passive tags and can be used to track more expensive products. The price of tags is continuously dropping and increasing usage of active tags can be expected over time.

Some tags are read-only in which case the ID is burnt into the tag at time of manufacture. Others are read/write in which case the memory contains not only the fixed identification number of the tag, but may also contain other information such as a physical description of the product (color, size,

etc., in PML format), which is added when the product is manufactured.

Standardization of the identification number, so that it can be read by the many different readers used by organizations in different parts of the supply chain, started at the Auto-ID Center at MIT, and is now being pursued by EPCglobal Inc, an industry consortium that aims to standardize the format of the EPC, electronic product code for use in RFID tags. The current proposal is illustrated in Figure 1 and consists of three parts:

- A 28-bit EPC manager allowing 268 million manufacturers,
- A 24-bit object class allowing 16.8 million products for each manufacturer
- A 36-bit serial number allowing 68.7 billion copies of each product

The specification of the air interface is given by the International Standards Organization (2004). Taken together, the EPC and the air interface are the main standards for RFID.

Automated input of RFID information into a supply chain management system requires RFID readers to be located on shelves in warehouses, distributions centers, and possibly also in retail stores and in delivery trucks. Readers have a range of about one meter so that multiple readers are required. Readers can input information to the supply chain management database via wired connections, for example, using Ethernet, or using a wireless technology such as WiFi or WiMAX (Wright, 2007a, 2007b). The total cost of the system consists of the cost of the tags on each item flowing through the supply chain plus the cost of the readers. Although passive tags cost only US\$0.20, readers cost approximately US\$250.00.

WIRELESS PERSONAL AREA NETWORKS (WPANs)

An alternative to RFID for supply chain management is a wireless personal area network or WPAN, consisting of devices that communicate with each other instead of with a

Figure 1. 96 bit Standard Electronic Product Code, EPC

Figure 2. Wireless personal area network

reader. The word “personal” in the title does not mean that there is always a human user, instead it refers to the limited range of the wireless communications: approximately 1 meter from one device to another. WPANs are of various types and here we focus on the low power version that is standardized by IEEE (2003), and is being commercialized by the industry consortium, the Zigbee Alliance, which has developed a specification for wireless personal area network applications (Zigbee, 2006). WPANs require each device to be powered, typically with a battery, but they transmit low data rates at low power so that battery life can exceed a year. Methods for reducing power requirements are described by Liang (2003) and Rajendran et al.(2006); and the system’s performance is analyzed by Chin et al. (2003). Initially applications of low power wireless personal area networks include interactive toys and industrial control, in which sensors measure temperature, humidity and position of items in a production facility and use the WPAN to communicate this information to a production control system (Egan, 2005). Supply chain applications include embedding WPAN devices with EPCs in products or their packaging and could also include sensors for measuring temperature and humidity, which are important for perishable items such as produce. WPAN devices can be

designed as small as a coin, so as to be easily embedded in products and packaging (Choi, 2003).

The network architecture of a WPAN is illustrated in Figure 2, and is built up of clusters of devices. Each cluster has one device designated as a “cluster head,” and one of these cluster heads is the WPAN coordinator. Although the communications range between one device and another is limited to about one meter, networks of clusters can communicate over a much longer distance. Each device uses wireless communications to communicate with its neighbors, and one device can communicate with a supply chain management system using Ethernet, WiFi or WiMAX. This “upload device” is more costly than the others, however only one is required per WPAN. Actual \$ costs are not available at the time of writing (1Q06) since WPAN devices are at an early stage of commercialization. Practical methods for designing WPAN networks are described by Minami (2004).

In supply chain management, WPAN devices can be embedded in products or in packaging and can communicate with each other in warehouses and delivery vehicles. As items are added to or removed from a stack of shelves in a warehouse, the clusters reconfigure dynamically, and information about the new products is distributed to the

Table 1. Comparative evaluation of RFID and WPANs for supply chain management

| | RFID | WPAN |
|--------------------------|--|--|
| Communications range | ~ 1 meter: tag to reader. | ~ 1 meter: device to device. |
| Networking | N/A | A network can consist of hundreds of devices. |
| Number of devices needed | One tag per product or package. One reader within a meter of each product or package connected to the SCM system. | One device per product or package. One upload device per WPAN, connected to the SCM system. |
| Cost | Very low cost per tag. Higher cost per reader. | Low cost per device. Higher cost per upload device. |
| Environmental monitoring | No standard integration with sensor technology. | WPAN sensors commercially available. |
| Reliability | < 100% reading ratio. | Error control protocol enhances reliability. |
| Stage of development | Established technology. | New technology at early stage of commercialization. |
| Power | Tags derive power from reader. | Devices need batteries or mains power. |

upload device. Each stack of shelves in a warehouse needs an upload device connected to the supply chain management system to forward information it receives from all the other devices on the products stored on those shelves.

COMPARATIVE EVALUATION

A comparative evaluation of RFID and WPANs for supply chain management is summarized in Table 1.

Both RFID and WPANs have a limited communications range of about 1 meter, however the extent of a WPAN can be much greater end to end. In warehousing applications, this allows a WPAN to span an entire stack of shelves, using only a single upload device, whereas multiple RFID readers are required, each having an upload capability. Upload devices and RFID readers cost more than regular WPAN devices and RFID tags, so that using less of them gives a potential cost advantage to WPAN over RFID. Another advantage of WPAN is that additional sensor devices can be added to monitor temperature and humidity, which is important in the case of perishable products. This can be done in a standardized way with WPAN sensors; however sensors interfaced to RFID tags require a proprietary interface (Philipose et al., 2005). The final advantage of WPAN is improved reliability, due to the use of an error control protocol. Any low power wireless communication can be unreliable in the presence of metal, for example, in warehouse shelving and in the products themselves, and read ratios on RFID readers are often <100%. The downside to WPANs is the additional cost of the devices, first due to the fact that it is a relatively new technology, and second due to the requirement for each device to have a battery or mains power supply.

CONCLUSION

RFID is a mature technology that is currently seeing widespread deployment to provide information for supply chain management. WPAN is a more recent development which could provide similar and, in the case of perishable products, improved functionality. As WPAN technology is commercialized and unit prices drop, we can expect cost advantages compared to RFID, since the cost of multiple upload devices can be eliminated in the case of WPANs. In addition WPAN is a more reliable technology than RFID since it incorporates error control.

KEY TERMS

Electronic Product Code (EPC): A code that can uniquely identify each item in the supply chain, by specifying the manufacturer, the product code and the serial number of each item.

Physical Markup Language (PML): A language for describing the physical characteristics of items, including the dimensions, weight and operating specifications of products in the supply chain.

Radio Frequency Identification (RFID): A system consisting of tags containing identification numbers, which can be transmitted to readers over a distance of about 1 meter.

WiFi: A commercial implementation of the IEEE 802.11 standard for wireless communications up to about 100 meters, in which the equipment has been certified by the WiFi Alliance, an industry consortium.

WiMAX: A commercial implementation of the IEEE 802.16 standard for wireless communications with a range of 2-5 Km, in which the equipment has been certified by the WiMAX Forum, an industry consortium.

Wireless Personal Area Network (WPAN): A network consisting of multiple devices communicating using wireless, each within about 1 meter of its neighbor, following standards developed by IEEE 802.15.

Zigbee Alliance: An alliance of companies commercializing WPAN technology by developing specifications for its efficient application in a number of areas of business, home and industry.

Scatternet Structure for Improving Routing and Communication Performance

Waseda University, Japan

INTRODUCTION

As a new promising short-range wireless technology, Bluetooth (Bluetooth; Bray & Sturman, 2001; Miller & Bisdikian, 2000) is designed to enable voice and data communication among various devices. It has received great attention in recent years. Bluetooth SIG develops Bluetooth specifications. By using the unlicensed 2.4 GHz ISM band, Bluetooth devices can communicate within a local area, intended as a replacement of interconnect cable. It supports connection-oriented and connectionless links and thus is suitable for both voice and data communications. The characteristics of low cost and low energy consumption make it not only the ideal technology for wireless local area network but also the best candidate for wireless personal area network (Haartsen, 1998).

When two Bluetooth devices communicate with each other, they must set up a link at first. One device acts as master and the other acts as slave. Actually, Bluetooth specifications can support up to seven slaves for one master. The mini-network constructed by one master and several slaves is called piconet.

Limited to the communication range and slave number, usually, a single piconet is not enough for actual usage. Also, if we permit Bluetooth devices in the same short range to communicate freely, they will influence each other and lower down the whole performance. Fortunately, one Bluetooth device can act as slave in several piconets and master in one piconet simultaneously. Such Bluetooth devices, existing in several piconets, are called relay. Through relay, several piconets can connect and form a scatternet. Scatternet not only provides larger range communication, but also regulates Bluetooth devices' actions to improve the whole performance.

To construct a scatternet, the structure and routing are two major issues. The scatternet structure deals with automated procedures to select master and slaves in a piconet and relays between piconets, and the topologic structure of scatternet

to improve scatternet performance. The routing algorithm deals with delivery of messages in such a scatternet (Sairam, Gunasekaran, & Redd, 2002).

Many scatternet structures and routing algorithms have been proposed in recent years. The following paragraphs will analyze three scatternet structures. After that, we present a new topologic structure, named SolidRing, with its routing algorithm. Finally, there are some discussions on SolidRing's performance.

BACKGROUND

Usually, when designing scatternet, the two issues, structure and routing algorithm, can't be divided absolutely, and influence each other. With a suitable routing algorithm, scatternet performance would be remarkably improved. Of course, to different structures, the meaning of "suitable" is very different. Also, a specific routing algorithm can only be realized in some structures (Prabhu & Chockalingam, 2002; Bhagwat & Segall, 1999; Shih, Wang, & Su, 2003). In a scatternet, the two should be designed appropriate to each other.

In recent papers of scatternet, various structures and routing algorithms are proposed. After studying the papers, two basic routing algorithms and three basic structures can be concluded.

Generally, basic routing algorithms are: proactive and reactive (Royer & Toh, 1999). Reactive routing algorithms find routes only when needed, while proactive algorithms maintain valid routes all the time. So, proactive consumes more energy and memory to win time while reactive contrary. Since Bluetooth initially was designed as a low price and low energy technology, a small Bluetooth device can't accommodate the large table and power consumption needed for proactive. Reactive is not an advisable choice as well. Because Bluetooth can only communicate through comparatively narrow master-slave links, routing data flow and long waiting time can't be tolerant. For our new structure, SolidRing,

Figure 1. Tree structure

we will present a new routing algorithm, a combination of the two. The routing algorithm is simple and fast, but it can only execute in SolidRing for the structure has some special characteristics (Kim, Lai, & Arora, 2003).

THREE STRUCTURES

For scatternet structure, there are three basic types: tree structure, planar structure and ring structure. Each structure has its own merits and demerits.

Tree Structure

The topologic link of tree structure is shown as Figure 1. The merit of tree structure is a very simple routing algorithm, just as described in Sun, Chang, & Lai (2002). The structure is constructed to be regular according to BDAddress (Bluetooth Device Address). Root node is max BD Address device of the scatternet. Its sub-trees have different BD Address ranges, for example, the 1st sub-tree has the range of 100-200, the 2nd sub-tree has the range of 200-500, the 3rd sub-tree has the range of 500-700, and so on. BD Address ranges of sub-trees will not overlap each other. Following the rule, each node has several sub-trees whose BD Address ranges don't overlap. And, each node keeps information about its sub-trees BD Address range.

When a node tries to communicate with another node, it will compare the destination BD Address with its record of BD Address ranges of its sub-tree. If the destination BD Address is out of the range, it will pass a routing message to its father node. Otherwise, it will pass a routing message to the corresponding sub-tree. Each node that accepts the routing message, will act like this. Following the algorithm, the message will arrive at the destination. Then, the message will send back and the routing work finished.

By analyzing the routing algorithm clearly, we can find that the routing message is directly passed from start node to destination node without any unnecessary message. It's a very efficient routing algorithm and should owe to the regular formation. Routing work is sharply reduced. While

the structure has an excellent routing performance, its demerits are critical.

The first problem is serious bottleneck. The structure looks like a pyramid. From bottom to top, the paths become less and less. Even on the top of the pyramid, all communications must pass through root node of the tree. Obviously, it will result in serious bottleneck. The following will give some mathematic calculations to show the bottleneck problem.

Assuming there is a b-branch, n-layer tree and all nodes in the tree communicate with each other once. From root node, the tree can be divided to number of b sub-tree, that each one is a branch with its own sub nodes. The communications related to a sub-tree include two parts: internal and external communications. Internal means the sub-tree nodes communicate with each other. External means the sub-tree nodes communicate with nodes that don't belong to the sub-tree. Then, for the sub-tree, the communications that must pass through root node are just the external communications. The total nodes number is N, and a sub-tree nodes number is B. Then, we can calculate the percent of communications passing through root node.

The total nodes number

$$N = b^n - 1 \tag{1}$$

A sub-tree nodes number

$$B = b^{n-1} - 1 \tag{2}$$

Sum of communications of assumption

$$P_N^2 \tag{3}$$

Total communications for a sub-tree

$$B(N - 1) \tag{4}$$

Internal communications

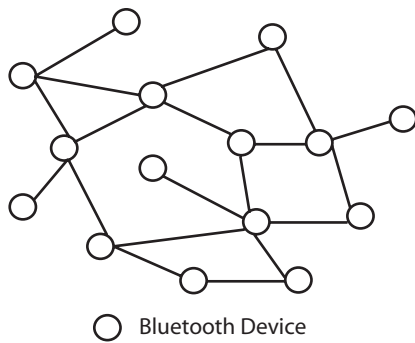

$$P_B^2 \tag{5}$$

Then, percent of communications passing through root node is

$$b \times \frac{B(N-1) - P_B^2}{P_N^2} \times 100\% \tag{6}$$

According to the equation (6), we can calculate that 66.7% communications have to pass root node for 3-branch, 5-layer tree and 51.6% communications for 2-branch, 5-layer tree. That means most of communications must pass through root node. In such situation, root node is very easy to be blocked and bottleneck problem is very serious.

Figure 2. Planar structure

The second problem is that the communication path is so long. There are some comparison results described in Wang, Thomas, and Haas (2002). Although a tree structure could equip with a remarkable routing algorithm, it can't be the main body of a scatternet.

Planar Structure

The topologic link of planar structure is shown as Figure 2. Many papers have proposed various scatternet structures, for example, Wang, Thomas, and Haas (2002) and Wang, Stojmenovic, and Li (2004), and all of them can be concluded to be planar structure. The merits of planar structure are shorter communication paths and some immunity to the bottleneck problem. With the same device number, the layer number of a planar structure is less than those of tree and ring structures, which results in shorter communication paths. Usually, the structure has a multi-path from one node to another. This characteristic makes the structure immunity to bottleneck. In fact, these merits should owe to various rings inside the structure.

As the structure is usually constructed by random algorithms and formed an irregular structure, routing work is complicated and troublesome (Racz, Miklos, Kubinszky, & Valko, 2001). Usually, two basic routing algorithms, proactive and reactive, are often used in planar structure. Reactive routing algorithms find routes only when needed while proactive algorithms maintain valid routes all the time. So, proactive consumes more energy and memory to win time while reactive contrary. Since Bluetooth is initially designed as a low price and low energy technology, a small Bluetooth device can't accommodate the large memory and power consumption needed for proactive. Reactive is not an advisable choice as well. Because Bluetooth can only communicate through comparatively narrow master-slave links, routing data flow and long waiting time would seriously influence WPAN performance. Both algorithms are not suitable for WPAN. As the conclusion, planar structure should be the main body of a scatternet, but it must be improved.

Figure 3. Ring structure

Ring Structure

The topologic link of ring structure is shown as Figure 3. If a scatternet were constructed as a ring, the layer number would be too large. Long communication paths and bottleneck both exist. But, in some situations, a ring will reduce communication paths as well (Lin, Tseng, Chang, & Tu, 2002). For example, if the head node in a chain communicates with the tail node, the communication must pass through the whole chain. Suggesting connect the head node with tail node to transfer a chain to ring structure, the communication path length will sharply reduced to 1. The matter happens not only for head and tail nodes, but also for the whole ring.

Ring structure can also provide various paths from one node to another by adding to other structures (Wang, Thomas, & Haas, 2002). Without rings, planar structure is just some type of tree structure. Although ring structure couldn't be the main body of a scatternet, it would play an important role in scatternet.

SOLIDRING STRUCTURE

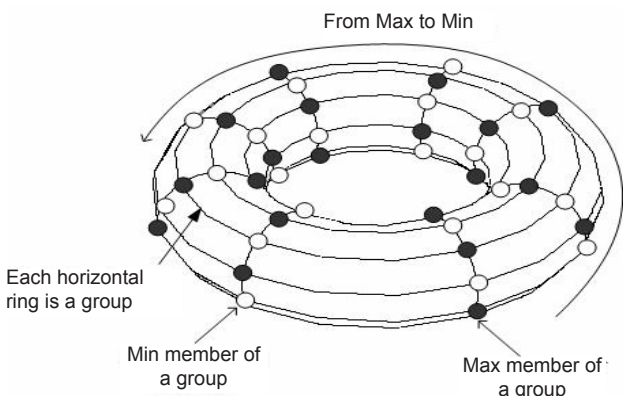

To construct the new structure, some assumptions are made regarding the environment considered herein.

1. All Bluetooth devices are within a range that enables a connection to be established. That means any two devices can receive signals sent out by each other.
2. In the initial stage, no link existed between any two Bluetooth devices.

When designing the new structure, we also take the following notices into account:

1. Avoid forming further piconets inside a piconet.
2. Avoid setting up more than one connection between two piconets.
3. Inside a piconet, the master should have suitable number of slaves.

Figure 4. SolidRing structure

4. Reduce the number of piconets that share a common node.

In fact, the new structure originates from tree structure. As the tree structure has excellent performance for routing, we thought of improving it to avoid bottleneck. From the description about tree structure, a 2-branch tree is better than 3-branch tree on the bottleneck problem. It can be concluded that the less the branch number in a tree, the less the bottleneck problem. Then, a 1-branch tree seems better than 2-branch tree. 1-branch tree is just a chain. So, a regularly formed chain emerges.

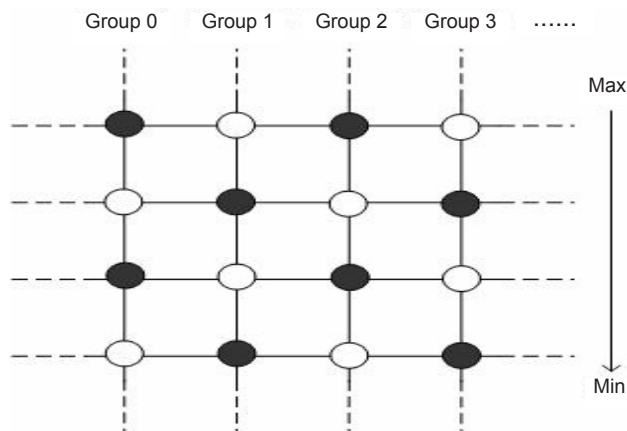

But, if a tree is reformed to be a chain, the layer number will increase and communication path length emerges to be a big problem. In the background section, we have concluded that planar structure has the genius to be the main body of a scatternet structure for its immunity to bottleneck problem and shorter path length. So, we thought of using numbers of such chains to weave a planar structure. To do that, the Bluetooth devices must be assigned to several groups.

For convenience of routing and communication, Bluetooth device assignment should be according to BD Address. Each device divides its own BD Address by group number N and decides which group it should join. The group number N is decided initially. BD Addresses are divided by N and get residual $0, 1, \dots, N-1$. The residual decides which Bluetooth device belong to which group.

After grouping, each group will form a chain following the sequence from larger BD Address to smaller BD Address. The operation reduces members in a chain.

But, from max member to min member in a group, almost the whole chain must be passed through. By using ring structure, the path length in same chain reduces partially. If max BD address member connected to min BD address member, the path length between the two will be only 1. The whole length between members in same group will reduce to

Figure 5. SolidRing section

about half of original. Then, group formation is transformed from chain to ring.

Now, there are N groups, which means N Rings. To form as planar structure, each group ring should connect with its two neighbors. Group 1 connects with Group 0 and Group 2, Group 2 connects with Group 1 and Group 3, ..., Group $N-2$ connects with Group $N-3$ and Group $N-1$, and Group 0 connects with Group $N-1$ and Group 1. The connecting rule is the max members of neighbor groups connect with each other, and along each ring, from max to min, members of neighbor groups will connect one by one.

After all groups connect with each other following the rule, the SolidRing structure emerges, just as shown in Figure 4.

If we split the SolidRing structure, its section will be as shown in Figure 5: just a Planar structure.

ROUTING ALGORITHM

In the SolidRing scatternet, each node records its four (or less) neighbors' BD Address. In the structure, the routing algorithm is very simple and fast. When a node communicates with another one, it divides the destination BD Address by group number and gets the residual. Then, it is clear which group the destination belongs to. The routing message can be directly passed to the destination group. When a routing message arrives to a destination group, no matter which node in the group receives the message, it will pass the message along the group ring. Of course, passing direction is decided by comparison of destination's BD Address and its own BD Address. If the destination exists, the destination can be found sooner or later along the group ring and routing is successful. If not, after circling along the ring, the message will return to the group node that initially received the message. That means the destination doesn't exist and

routing fails. The fail message will be returned. No matter success or fail, the routing message is sent just following a single path. The routing data is sharply reduced and the bandwidth is efficiently used.

It is just a simple example for the routing algorithm. Actually, if we do some modifications on the routing algorithm, the routing procedure will select an idle route to the destination and avoid communication concentrate in some block of the scatternet, which would prevent the scatternet from bottleneck problem. The structure even has the potential to realize multi-path communication.

To realize these functions, we must do some modification for each node. That is, each node must record its own bandwidth occupation ratio during its work. When a new route is setup and asks passing through the node, the node should check its own bandwidth occupation ratio and judge whether it can work for the route. The detailed description is given as following:

- **Step 1:** Each node should record its own bandwidth occupation ratio, which will help nodes to judge whether itself is crowded or not.
- **Step 2:** When start node try to communicate with destination node, it must calculate how much bandwidth it will occupy. Then, it sends the request of communication through the whole path that has been found according to the first routing algorithms.
- **Step 3:** Each node that occurs in the original path will compare its own idle bandwidth with the request bandwidth. The compare result will be recorded inside the request message and then be returned to the start node.
- **Step 4:** After receiving the feedback message, the start node will judge along the original path which node can work for this communication and which node can not. Then, it will send another message to ask nodes along the original path to modify the path.
- **Step 5:** Each node that can not work for this communication will try to find another node or another short path to replace itself. It will send request message around to its neighborhood to ask them to take over the job. If one neighbor is not so crowded, it will take place the node and form a new path.
- **Step 6:** After all crowded nodes find their replace node or path, a new path is generated. Each node along the new path should update its own record on bandwidth occupation. Then, the communication will be carried out along the new path.

Based on this routing algorithm, communication can always choose an idler path. If we do more modification for the routing algorithm, it is also easy to realize multiple-path communication.

CONCLUSION

In the article, we analyze Bluetooth scatternet and conclude which issues are important for constructing scatternet. Based on mathematics, we describe merits and demerits for existing scatternet structures and their routing algorithms. Then, we present a new scatternet structure, named SolidRing, its construction procedure and routing algorithm. We believe SolidRing structure can work better than existing scatternet structures.

KEY TERMS

Bluetooth: A short-range wireless communication technology. The communication range is about 10 meters. The characteristic is low power-consumption. Now, it's widely used in our life.

Bluetooth Device Address: For each Bluetooth device, it has a unique address, which is named Bluetooth device address.

Piconet: The mini-network formation for Bluetooth devices. It can include up to 8 Bluetooth devices. One acts as master and the others act as slaves.

Scatternet: The extended network formation for Bluetooth devices. It can provide extended communication range and include more than 8 Bluetooth devices.

Tree Structure: A common network topologic structure. For Bluetooth scatternet, it's a regularly formed structure.

Planar Structure: a common network topologic structure. For Bluetooth scatternet, it's an irregularly formed structure.

Ring Structure: A common network topologic structure. For Bluetooth scatternet, it's an irregularly formed structure.

Solidring Structure: Our newly developed scatternet structure. It is formed according to Bluetooth device address regularly. We believe solidring structure can work better than existing scatternet structures.

Secure Agent Data Protection for E-Commerce Applications

Sheng-Wei Guan
Brunel University, UK

INTRODUCTION

One hindrance to the widespread adoption of mobile agent technology (Johansen et al., 2002) is the lack of security. SAFER, or Secure Agent Fabrication, Evolution, and Roaming, is a mobile agent framework that is specially designed for the purpose of electronic commerce (Zhu, Guan, Yang, & Ko, 2000; Guan & Yang, 1999, 2003; Yang & Guan, 2000). By building strong and efficient security mechanisms, SAFER aims to provide a trustworthy framework for mobile agents. While such an agent transport protocol provides for the secure roaming of agents, there are other areas related to security to be addressed.

Agent integrity is one such area crucial to the success of agent technology. The integrity protection for agent code is relatively straightforward. A more complex code integrity scheme to handle code-on-demand is also proposed in Wang et al. (2002). Agent data, however, is dynamic in nature and will change as the agent roams from host to host. Despite the various attempts in the literature (Chionh, Guan, & Yang, 2001), there is no satisfactory solution to the problem so far. Some of the common weaknesses of the current schemes are vulnerabilities to revisit attack and illegal modification (deletion/insertion) of agent data.

DESCRIPTION OF SADIS

SADIS has been designed based on the following assumptions:

1. Entities including agents, agent butlers, and hosts should have globally unique identification number (IDs).
2. Each agent butler and host should have a digital certificate that is issued by a trusted CA. These entities will be able to use the private key of its certificate to perform digital signatures and encryption.
3. While the host may be malicious, the execution environment of mobile agents should be secure and the execution integrity of the agent can be maintained.
4. Entities involved are respecting and cooperating with the SADIS protocol.

Key Seed Negotiation Protocol

The proposed key seed negotiation protocol defines the process for key seed negotiation, as well as session key and data encryption key derivation. When an agent first leaves the butler, the butler generates a random initial key seed, encrypts it with the destination host's public key, and deposits it into the agent before sending the agent to the destination host. It should be noted that agent transmission is protected by the agent transport protocol (Guan & Yang, 2002), thereby protecting the system from being compromised by malicious hosts.

The key seed negotiation process is based on the Diffie-Hellman (DH) key exchange protocol (Schneier, 1996) with a variation. The agent will first generate a private DH parameter a and its corresponding public parameter x . The value x , together with the ID of the destination host, will be encrypted using a communication session key and sent to the agent butler.

The agent butler will decrypt the message using the same communication session key (to be discussed later). It too will generate its own DH private parameter b and its corresponding public parameter y . With the private parameter b and the public parameter x from the agent, the butler can derive the new key seed and use it for communications with the agent in the new host. Instead of sending the public parameter y to the agent as in normal DH key exchange, the agent butler will encrypt the value y , host ID, agent ID, and current timestamp with the destination host's public key to get message M . Message M will be sent to the agent after encrypting with the communication session key.

$$M = E(y + \text{host ID} + \text{agent ID} + \text{timestamp}, H_{\text{pubKey}})$$

At the same time, the agent butler updates the agent's itinerary and stores the information locally. This effectively protects the agent's actual itinerary against any hacking attempts related to itinerary, thereby protecting against the data deletion attack.

When the agent receives the double-encrypted DH public parameter y , it can decrypt with the communication session key. Since the decrypted result M is parameter y and some other information encrypted with the destination host's public key, the current host will not be able to find out the value of y and thus find out the new key seed to be used when the

agent reaches the destination host. It should be noted that this does not prevent the host from replacing M with its own version M' with the same host ID, agent ID, and timestamp, but different y . The inclusion of host ID, agent ID inside M can render such attack useless against SADIS. A detailed discussion on this attack can be found in the security analysis section of this article.

Subsequently, the agent will store M into its data segment and requests the current host to send itself to the destination host using the agent transport protocol (Guan & Yang, 2002).

Upon arriving at the destination host, the agent will be activated. Before it resumes normal operation, the agent will request the new host to decrypt message M . If the host is the right destination host, it will be able to use the private key to decrypt message M and thus obtain the DH public parameter y . As a result, the decryption of message M not only completes the key seed negotiation process, but also serves as a means to authenticate the destination host. Once the message M is decrypted, the host will verify that the agent ID in the decrypted message matches the incoming agent, and the host ID in the decrypted message matches that of the current host. In this way, the host can ensure that it is decrypting for a legitimate agent instead of some bogus agent. If the IDs in the decrypted messages match, the decrypted value of y is returned to the agent.

With the plain value of y , the agent can derive the key seed by using its previously generated private parameter a . With the new key seed derived, the key seed negotiation process is completed. The agent can resume normal operation in the new host.

Whenever the agent or the butler needs to communicate with each other, the sender will first derive a communication session key using the key seed and use this communication session key to encrypt the message. The receiver can make use of the same formula to derive the communication session key from the same key seed to decrypt the message.

The communication session key K_{CSK} is derived using the formula below:

$$K_{CSK} = \text{Hash}(\text{key_seed} + \text{host ID} + \text{seqNo})$$

The sequence number is a running number that starts with 1 for each agent roaming session, and is reset to 1 whenever the agent reaches a new host. Each message communicated will therefore be encrypted using a different key. As this means that the butler and agent will not be able to communicate if messages are lost without detection, SADIS makes use of TCP/IP as a communication mechanism. Once the communication is re-established after a send failure, the sender will resend the previous message (encrypted using the same communication session key). The agent and the butler can therefore synchronize on communication session key calculations.

The agent encrypts host information with a data encryption key K_{DEK} . The data encryption key is derived as follows:

$$K_{DEK} = \text{Hash}(\text{key_seed} + \text{hostID})$$

The details on encryption will be discussed in the next section.

Data Integrity Protection Protocol

The key seed negotiation protocol lays the necessary foundation for integrity protection by establishing a session-based key seed between the agent and its butler. Digital certificates also help protect the agent data integrity.

Our data integrity protection protocol comprises two parts: chained signature generation and data integrity verification. Chained signature generation is performed before the agent leaves the current host. The agent gathers data provided by the current host d_i and construct D_i as follows:

$$D_i = E(d_i + \text{ID}_{\text{host}} + \text{ID}_{\text{agent}} + \text{timestamp}, k_{DEK})$$

or

$$D_i = d_i + \text{ID}_{\text{host}} + \text{ID}_{\text{agent}} + \text{timestamp}$$

The inclusion of host ID, agent ID, and timestamp is to protect the data from possible replay attack, especially when the information is not encrypted with the data encryption key, thereby creating an unambiguous memorandum between the agent and the host. The construction of D_i also gives the flexibility to encrypt the data or keep it plain. After constructing D_i , the agent will request the host to perform a signature on the following:

$$c_i = \text{Sig}(D_i + c_{i-1} + \text{ID}_{\text{host}} + \text{ID}_{\text{agent}} + \text{timestamp}, k_{\text{priv}})$$

where c_0 is the digital signature on the agent code by its butler.

One design focus of SADIS is not only to detect data integrity compromise, but more importantly to identify malicious hosts. To achieve malicious host identification, it is an obligation for all hosts to verify the incoming agent's data integrity before activating the agent for execution. In the event of data integrity verification failure, the previous host will be identified as the malicious host.

Data integrity verification includes the verification of all the previous signatures. The verification of signature c_0 ensures agent code integrity; the verification of c_i ensures data provided by host h_i is intact. If any signature failed the verification, the agent is considered compromised.

While the process to verify all data integrity may seem to incur too much overhead and also seem somewhat redun-

dant (e.g., why do we need to verify the integrity of d_1 in h_3 when host h_2 already verifies that), it is necessary to ensure the robustness of the protocol and to support the function of malicious host identification. Although the agent butler can eventually detect such data integrity compromise (since the agent butler must verify all signatures), there is no way to establish the identity of malicious host(s).

Security Analysis

To analyze the effectiveness and reliability of SADIS, a detailed security analysis is performed subjecting SADIS to a variety of attacks. Based on the attack targets, the various attacks to SADIS can be classified into data attack, key attack, signature attack, itinerary attack, and composite attack. Composite attack refers to attacks that are combinations of two or more of the above-mentioned attacks. The security analysis will be organized according to the above classifications.

Data Attack

Data attack refers to any attempt that aims to compromise the data carried by an agent. Compromise can be in the form of data modification, deletion, or insertion.

Considering the data modification scenario, let us assume that the data targeted is D_i provided by host i ; since the agent itinerary is protected by the butler and cannot be changed, only host i can produce a valid signature if the data were to be modified. However, even if the malicious party (or even host i itself) can produce a valid signature c_i' corresponding to D_i' , since c_i is chained to the signature of the next host c_{i+1} , signature verification for host $(i+1)$ will fail. Therefore, in order to perform a successful data modification attack, the malicious host must be able to forge the signatures for all hosts in the itinerary since host i . As the only way to achieve this is to obtain the private keys of all the following hosts, data modification attack is extremely difficult under SADIS.

A number of the existing data integrity protocols suffer from data deletion attack. After analyzing the root cause of the vulnerabilities, it is realized that it is extremely important to protect the agent's itinerary. If the agent's itinerary is closely guarded by the butler, any data deletion will result in modification to the agent's itinerary and thus be detected.

Key Attack

Besides direct attack on data integrity, a malicious host may attempt to attack the various keys in order to compromise data integrity. There are three different types of keys in SADIS. They are session-based key seed, communication session key, and data encryption key.

In SADIS, the key seed is kept by the agent and the butler separately. Attacks to the key seed can only target at the key seed negotiation protocol. As all communication in key seed negotiation is protected by the communication session key, we can safely rule out the possibility of any third-party malicious attempts to break the protocol. We can focus on the scenario where the current host attempts to break the key exchange to obtain the key seed to be used in the subsequent host.

Firstly, as the DH public parameter is encrypted using the destination host's public key, the current host will not, without manipulation, be able to complete DH key exchange to find out the new key seed. Without the private key from the destination host, no one can obtain y to complete the key exchange. Furthermore, as the encrypted message contains the agent ID and destination host ID, the current host will not be able to send a bogus agent carrying this encrypted y to the destination host for decryption.

If the current host attempts to manipulate any one or both of these parameters, it is able to manipulate the key seed derived when the agent reaches the destination host. However, the change in key seed will be immediately detected when the agent communicates with the butler or vice versa. In order to perform a successful attack, the current host must therefore be able to obtain the key seed in the butler so that it can intercept and replace the message communicated between the butler and the agent. Unfortunately, as illustrated earlier, there is no way the current host can find out the value of DH public parameter from butler y . Thus, the key seed will not be compromised.

Besides key seed, SADIS makes use of communication session key and data encryption key in the protocol. These two keys are directly derived from the session-based key seed using a hash function. As far as any third-party host is concerned, attack to communication session key or data encryption key is equivalent to attacking the encryption key given only the cipher text. Even in the extreme case when such a key is compromised, the loss is limited to the message it encrypts.

Signature Attack

Usually a malicious host would need to forge digital signature when it attempts to compromise data integrity. If data integrity is not compromised, there is no need to attack the chained signature at all.

Itinerary Attack

If the agent itinerary is not carefully protected, it may lead to compromise to data integrity, especially in the case of data deletion as illustrated earlier in the section. In SADIS, as the agent updates the butler of its next destination host as part of the key seed negotiation protocol, there is no additional

Table 1. SADIS time efficiency (time taken for operations in milliseconds): Performance without SADIS

| | | | | | | |
|--|----|----|----|----|----|------|
| Key Seed Negotiation (butler timing) | 40 | 50 | 50 | 40 | 40 | 44.0 |
| Key Seed Negotiation (destination host) | 41 | 41 | 40 | 40 | 40 | 40.4 |
| Agent Butler Communication (agent timing - send) | 40 | 40 | 50 | 40 | 40 | 42.0 |
| Agent Butler Communication (butler timing - send) | 30 | 30 | 31 | 40 | 30 | 32.2 |
| Agent Butler Communication (agent timing - receive) | 10 | 10 | 10 | 10 | 10 | 10.0 |
| Agent Butler Communication (butler timing - receive) | 10 | 30 | 10 | 10 | 20 | 16.0 |

overhead related to the itinerary protection mechanism. Therefore, there is no way a malicious host can perform any attack on the itinerary (except, of course, if it breaks into the agent butler).

Composite Attack

At times, in order to perform a successful attack, more than one area is targeted simultaneously. In addition to attacks with specific targets, there are certain general hacking techniques such as man-in-the-middle attack, replay attack. The design of SADIS employs a mechanism to protect the protocol against these hacking techniques. Through the use of communication session key, man-in-the-middle attack can be avoided. On the other hand, the use of sequence number in communication session key generation effectively protects the protocol from replay attack by a third-party host. In addition, the inclusion of host ID, agent ID, and timestamp during the key seed negotiation process prevents the current host from performing a replay attack with the next destination host.

Lastly, the design of SADIS does not have dependency on any specific encryption/hashing algorithm. In an unlikely scenario when one algorithm is broken, SADIS can always switch to a stronger algorithm.

Implementation

In order to verify the design of SADIS and assess its applicability, a prototype of SADIS is developed. The prototyping

language is chosen to be Java, because of its platform-independent feature.

Just like any other security mechanism, there is certain overhead associated with SADIS. The overhead is incurred as additional time required for processing as well as additional data carried by the agent. To assess the efficiency of SADIS, a study is performed on the prototype.

The result of this experimental study on SADIS is broken down based on functionality and is shown in Tables 1 and 2. It can be seen that the bulk of the overhead is incurred during key seed negotiation where the key exchange protocol and the public key operation is performed. Despite the relatively high overhead, this will not impact the overall performance of SADIS significantly because the frequency of agent roaming is low compared to the frequency of some other agent operations (such as agent to butler communication). As a result, the overhead incurred at this stage is 'one-time' in nature.

Other than in the key seed negotiation, the time overhead incurred elsewhere in the protocol is negligible.

Other than overhead in terms of processing time, there is certain overhead to the data size as well. SADIS is designed to produce almost fixed data overhead regardless of the data size. SADIS therefore tends to be more efficient when actual data size is higher. This ability to limit the size of overhead data regardless of actual data size is an improvement in efficiency over existing work. The last and most significant overhead is the digital signature created by the host. The overhead of digital signature is a fixed length of 64 bytes. Altogether, SADIS has a maximum data overhead of 96 bytes.

Table 2. SADIS time efficiency (time taken for operations in milliseconds): Performance comparison with SADIS

| Operation | 1 (ms) | 2 (ms) | 3 (ms) | 4 (ms) | 5 (ms) | Avg (ms) | Overhead (ms) |
|--|--------|--------|--------|--------|--------|----------|---------------|
| Key Seed Negotiation (butler timing) | 250 | 260 | 250 | 220 | 260 | 248.0 | 204.0 |
| Key Seed Negotiation (destination host) | 290 | 281 | 260 | 280 | 290 | 280.2 | 239.8 |
| Agent Butler Communication (agent timing – send) | 60 | 60 | 70 | 50 | 60 | 60.0 | 18.0 |
| Agent Butler Communication (butler timing – send) | 41 | 50 | 40 | 40 | 40 | 42.2 | 10.0 |
| Agent Butler Communication (agent timing – receive) | 10 | 20 | 10 | 10 | 10 | 12.0 | 2.0 |
| Agent Butler Communication (butler timing – receive) | 30 | 30 | 30 | 20 | 20 | 26.0 | 10.0 |

Table 3. SADIS data overhead

| | Original Data Size | Maximum Overhead | Overhead | OKGS Overhead |
|---|--------------------|------------------|----------|---------------|
| 1 | 1800 | 96 | 5.33% | 33.87% |
| 2 | 2001 | 96 | 4.80% | 37.73% |
| 3 | 5000 | 96 | 1.92% | N/A |
| 4 | 10000 | 96 | 0.96% | N/A |
| 5 | 100000 | 96 | 0.10% | N/A |

As the statistics shows, SADIS is optimized to improve both time efficiency and data efficiency compared with related work in the literature. The feasibility and practicality of SADIS is thus demonstrated through the prototype.

IMPACT OF SADIS

Various techniques have been developed to protect agent integrities (Borselius, 2002), based on trusted hardware, trusted host, and conventional contractual agreements. SADIS addresses the problem of data integrity protection via a combination of techniques such as execution tracing, encrypted payload, environmental key generation, and undetachable signature. The security of SADIS is completely based on its own merits without making any assumption about the integrity of external hosts. SADIS also makes use of a negotiated key seed to generate data encryption

key. Therefore, no random value needs to be encrypted and stored with the agent. With SADIS, the data and the communication keys undergo one-time encryption. Thus, even if some of the keys are compromised, the key seed will still remain secret.

CONCLUSION

In this article, a new data integrity protection protocol, SADIS, has been proposed. Besides being secure against a variety of attacks and robust against vulnerabilities of related work in the literature, the research of SADIS includes the objective of efficiency. Unlike some existing literature, the data integrity protection protocol aims not only to detect data integrity compromise, but more importantly to identify the malicious host. With security, efficiency, and effectiveness as its main design focuses, SADIS works with other

security mechanisms to provide mobile agents with a secure platform.

S

KEY TERMS

Agent: A piece of software which acts to accomplish tasks on behalf of its user.

Cryptography: The art of protecting information by transforming it (*encrypting* it) into an unreadable format, called cipher text. Only those who possess a secret *key* can decipher (or *decrypt*) the message into plain text.

Digital Certificate: Certificate that uses a digital signature to bind together a public key with an identity—information such as the name of a person or an organization, their address, and so forth. The certificate can be used to verify that a public key belongs to an individual.

Electronic Commerce (E-Commerce): Consists primarily of the distributing, buying, selling, marketing, and servicing of products or services over electronic systems such as the Internet and other computer networks.

Flexibility: The ease with which a system or component can be modified for use in applications or environments other than those for which it was specifically designed.

Protocol: A convention or standard that controls or enables the connection, communication, and data transfer between two computing endpoints. Protocols may be implemented by hardware, software, or a combination of the two. At the lowest level, a protocol defines a hardware connection.

Security: The effort to create a secure computing platform, designed so that agents (users or programs) can only perform actions that have been allowed.

Secure Group Communications in Wireless Networks

INTRODUCTION

After a decade of exponential growth, wireless technologies have profoundly impacted people’s lifestyles. Wireless networks provide users with greater flexibility and benefit by anytime and anywhere services (Pahlavan & Krishnamurthy, 2002). At the same time, rapid developments in multicast have led to the emergence of many multicast applications, such as stock quoting, multimedia conferencing and network gaming. Therefore it is reasonable to believe that the integration of wireless and multicast will benefit mobile users. Before the customers can enjoy the efficiency and convenience of wireless multicasts, access control must be employed to guarantee that only legitimate users can utilize the multicast services.

BACKGROUND

Access control can be achieved by employing a cryptographic key shared by all group members, which is applied to encrypt the multicast contents. Many group key management approaches (Sherman & McGrew, 2002; Perrig, Song, & Tygar, 2001; Amir, Kim, NitaRotaru, Schultz, Stanton, & Tsudik, 2004; Harney & Muckenhirn, 1997; Steiner, Tsudik, & Waidner, 1996; Mitra, 1997; Banerjee & Bhattacharjee, 2002; Kostas, Kiwior, Rajappan, & Dalal, 2003) have been proposed and most of them are directed toward the wired network. Although the research work done in the wired environment can be applied in wireless networks, the efficiency and security are not the same as that in wired networks. The reason results from not only the limitations of wireless networks, such as high communication error rate and limited bandwidth, but also the properties of light-weight mobile devices, such as limited computational power, insufficient power supply, great mobility and storage limitation.

In order to reduce the communication, computation and storage costs, hierarchical structure (tree structure) is widely applied in the group key management approaches. These schemes utilize all the keys, that is, group key and supporting keys, to construct a balanced key tree.

Figure 1. A typical key management tree

Each node of the tree holds a key. The root node of the tree represents the group key. Each leaf node corresponds to a group member, and possesses a private key associated with the member. The intermediate nodes hold key encryption keys (KEK), which are the auxiliary keys used for the distribution of the group key and other KEKs. Each member needs to store a set of keys in the path from its node to the root of the tree. When a member joins or leaves, the key distributor center (KDC) generates a set of new keys from the leaf node associated with the member to the root, and multicasts this set of keys to all the other group members. For example, as shown in Figure 1, for user 3 joining or leaving, key k_{34} , k_{14} , and k_{18} need to be updated.

For user 3 joining:

$$\text{KDC} \rightarrow u_3: \{k_{34}, k_{14}, k_{18}\}_{k_3}$$

$$\text{KDC} \rightarrow u_4: \{k_{34}, k_{14}, k_{18}\}_{k_4}$$

$$\text{KDC} \Rightarrow (u_1, u_2): \{k_{14}, k_{18}\}_{k_{12}}$$

$$\text{KDC} \Rightarrow (u_5, u_6, u_7, u_8): \{k_{18}\}_{k_{58}}$$

For user3 leaving:

$$\text{KDC} \rightarrow u_4: \{k_{34}, k_{14}, k_{18}\}_{k_4}$$

$$\text{KDC} \Rightarrow (u_1, u_2): \{k_{14}, k_{18}\}_{k_{12}}$$

$$\text{KDC} \Rightarrow (u_5, u_6, u_7, u_8): \{k_{18}\}_{k_{58}}$$

GROUP KEY MANAGEMENT ALGORITHM

Group key management algorithm is core part of multicast security. It maintains the logical key structure and performs the procedures to assign, distribute and update the group key and other KEKs.

Notation

In this section, we depict the notations that we will use in the following sections:

- ▷ u: user
- ▷ bs: base station
- ▷ n: the number of members in the subgroup
- ▷ n_c : the number of the cluster in the subgroup
- ▷ n_s : the number of subgroups
- ▷ m: the number of users in the cluster
- ▷ j: the number of multiple subgroups which user joins and leaves simultaneously
- ▷ α : degree of the balance tree
- ▷ d: the height of the balance tree ($d = \log_{\alpha} n$)
- ▷ k: the encryption key
- ▷ $BS = \{s_1, s_2, s_3, \dots, s_n\}$: the set of the base stations
- ▷ $\{x\}_k$: message x encrypted by the key k
- ▷ $A \rightarrow B: \{x\}$: A sends message x to B via unicast

▷ $A \Rightarrow B: \{x\}$: A sends message x to B via broadcast or multicast

The Proposed Logical Key Structure

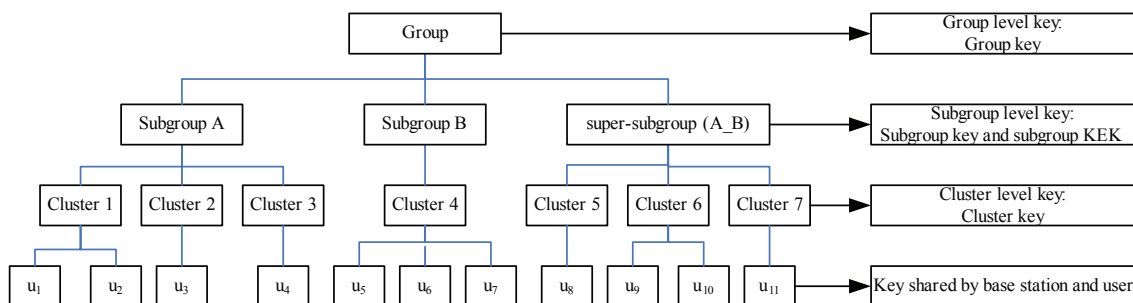

Generally, a large multicast group is comprised of several smaller subgroups. Each member not only joins the group communications but also participates in one or some subgroup communications. Nevertheless the current proposed key tree cannot reflect such a group organization structure. Meanwhile a separate key tree must be constructed for each subgroup. To improve the performance of group key management under such scenario, we propose a new logical group keying structure shown in Figure 2.

From Figure 2, we can see that the proposed structure is a multi-tier model. The root node instigates the group communication session, and holds the group key. Each subgroup represents a multicast session and is associated with two keys: subgroup key and subgroup KEK (key encryption key). Users in the subgroup are divided into several clusters. Each cluster has its own cluster key to distribute other keys in the cluster. In the user level, each user shares a secret key with base station.

It is a common scenario that a user subscribes multiple subgroups simultaneously. To improve the efficiency, we introduce a new concept: super-subgroup, which is a virtual container to accommodate users who participate in multiple subgroups simultaneously. Each super-subgroup is a combination of several subgroups. For example, as shown in Figure 2, super-subgroup (A_B) is a super-subgroup combining subgroup A and B, where users 9 to 11 participate in the subgroup A and B concurrently. Super-subgroup can be a combination of any subgroups. According to the theory of permutation and combination, for a group having n_s subgroups, the total number of super-subgroups is

$$\sum_{i=2}^{n_s} C_n^i$$

Figure 2. Logical key management structure

The Proposed Group Key Management Algorithm

There are three main operations in the wireless group key management (multiple subgroups): member join, member leaving and hand-off. The rekeying procedures of these operations occur independently in each wireless cell. We now illustrate our algorithm in each of these operations in the following subsections.

Member Join

Join is a procedure that is invoked by a user who wants to become a member of a group. Backward secrecy should be achieved to prevent the new member from accessing the previous group communication contents. In the proposal, join is comprised of three steps: registration, key grant and key update. In the registration step, a user submits a join request to the local base station, and the base station forwards this request to upper layer area key controller (AKC) for authentication.

$$u \rightarrow bs: \{JOIN_REQUEST\}$$

$$bs \rightarrow AKC: \{JOIN_REQUEST\}$$

In the second step, after AKC verifies the user, AKC assigns the user into a cluster and sends the relevant keys to the user.

$$AKC \rightarrow bs: \{k_{cluster}, k_{subgroup}, k_{subgroup_kek}, k_{group}\}_{k(AKC_user)}$$

$$bs \rightarrow u: \{k_{cluster}, k_{subgroup}, k_{subgroup_kek}, k_{group}\}_{k(AKC_user)}$$

Finally, AKC invokes a join-key-update procedure to update the affected cluster, subgroup and group key. This updating can be achieved without multicasting rekeying message (Waldvogel, Caronni, Sun, Weiler, & Plattner, 1999). AKC informs the sender to use the new keys to encrypt the data traffic; the members will perceive the key change in ordinary data packets and update their keys locally by passing through a one-way hash function.

$$AKC \rightarrow sender: \{USING_NEW_DATA_ENCRYPTION_KEY\}$$

When a user wishes to join multiple subgroups at the same time, the procedure is the same as mentioned above. The user is assigned into a suitable super-subgroup.

Member Leaving

Leaving is invoked by a user who wants to quit a group or the AKC evicts the user from the group communications.

Forward secrecy must be achieved to prevent the departing user obtaining the forthcoming group communications. There are two steps in this operation: cancellation and key update. In the cancellation, user submits a leaving request to AKC:

$$u \rightarrow bs: \{LEAVE_REQUEST\}$$

$$bs \rightarrow AKC: \{LEAVE_REQUEST\}$$

In the rekeying stage, according to the “bottom to top” principle, rekeying procedure starts from the affected cluster where the departure took place then to the remaining clusters in the affected subgroup, and finally in the entire group. First, AKC generates new keys, and constructs a single message containing all new keys by the *group-oriented* approach (Wong, Gouda, & Lam 2000).

$$AKC \Rightarrow BS: \{new k_{cluster}, k_{subgroup_KEK}, k_{subgroup}, k_{group}\}$$

Each base station searches for the affected cluster members in its cell and delivers the new keys to them. Base station employs *user-oriented rekeying* approach (Wong et al., 2000), that is, for each user the base station constructs a rekeying message that contains precisely the new keys needed by the user.

$$bs u_i: \{new k_{cluster}, k_{subgroup_KEK}, k_{subgroup}, k_{group}\}_{k(bs_user) i(i=1, 2, \dots, m)}$$

To update keys for the remaining clusters in the affected subgroup, the base station multicasts the rekeying message to the clusters members. The new keys are encrypted by the old group key:

$$bs \Rightarrow (cluster)_i: \{new k_{subgroup_KEK}, k_{subgroup}, k_{group}\}_{k(cluster) i(i=1, 2, \dots, n_c)}$$

Finally, the base station updates the group key for the remaining subgroups in the group.

$$bs \Rightarrow (subgroup)_i: \{new k_{group}\}_{k(subgroup_KEK) i(i=1, 2, \dots, n_s)}$$

If a multi-subgroup user leaves, the procedure is same.

$$bs \Rightarrow (subgroup)_i: \{new k_{subgroup}, k_{group}\}_{k(subgroup_KEK) i(i=1, 2, \dots, j)}$$

Handoff

Handoff is a unique operation in the wireless group communications. Several approaches (DeCleene, Dondeti, Griffin, Hardjono, Kiwior, Kurose, Towsley, Vasudevan, & Zhang, 2001; Sun, Trappe, & Liu 2002) have been proposed to address the group key management during the handoff.

We propose a simple and efficient handoff management scheme, which contains three steps: handoff registration, authentication and switching. We assume that the mobile devices can detect signals of the two adjacent base stations on the border of the wireless cell (Chen & Chao, 2004). In the registration step, user switches to the new base station and sends a handoff join message. Then user switches back to the old base station quickly.

$$u \rightarrow bs_{new}: \{HANDOFF_JOIN\}$$

In the authentication stage, new base station contacts the old base station to verify the user:

$$bs_{new} \rightarrow bs_{old}: \{AUTHENTICATION_REQUEST\}$$

$$bs_{old} \rightarrow bs_{new}: \{AUTHENTICATION_REPLY\}$$

In the last step, after a predefined time, user switches to the new base station to finish the handoff. Because the group keying structure is identical in the whole domain, users can move from one cell to another without invoking rekeying operation.

PERFORMANCE DISCUSSION

In measuring the performance of a group key management system, many parameters need to be taken into consideration (Moyer, Rao, & Rohatgi, 1999; Rafaeli & Hutchison, 2003).

However, efficiency is one of the most significant criteria. Communication, computation and storage overheads related to rekeying are the major efficiency measures for a key management algorithm. We take the popular tree-based key management scheme: logical key hierarchy (LKH) (Wong et al., 2000; Wallner, Harden, & Agee, 1999) as the benchmark in our performance analysis.

Communication Efficiency

In order to achieve the best result, the communication during the rekeying and handoff combines the unicast and multicast. Communication overhead is recorded in *big-O* notation as a measure of the number of rekeying messages transmitted per operation. We evaluate the communication overhead for the following three operations: join, leave and handoff.

Join

As described above, when a user joins a group having n_s subgroups, there is no need to multicast rekeying message. The system only needs to inform the sender to apply the new keys. So the communication cost in this situation is

zero. According to the LKH algorithm, the scheme needs to construct separate n_s trees to present all the subgroups. The communication cost of join is d (Wong et al., 2000; Wallner, Harden, & Agee, 1999). When a single subgroup join occurs, there is a join operation and group key updating for the rest (n_s-1) subgroups. So the cost of rekeying communication for LKH is $O(d+n_s)$.

When a user wants to join multiple subgroups simultaneously, with the concept of super-subgroup, the cost of communication in the proposal is still zero. As for the LKH algorithm, multiple trees are affected by the join operation and n_s-j subgroups need to update their group key. So in such scenario, the communication overhead of LKH is the summation of cost of multiple join operation and n_s-j group key updating, that is,

$$O\left(\sum_{i=1}^j d_i + n_s - j\right).$$

Leaving

When a single subgroup member leaves, the proposed algorithm needs to rekey four keys: cluster, subgroup, subgroup KEK and group key. The overhead of rekeying communication is shared by AKC and base station network. AKC is responsible for the generation of new keys. By using the group-oriented approach, all the new keys are contained in a single rekeying message, so the communication cost of AKC is $O(1)$. Base station is in charge of the key distribution in its cell. There are two scenarios in the cell: the leaving user present in the cell or the leaving user not in the cell. In the latter situation, the base station can use multicast for rekeying, the rekeying communication is just one or two messages. Therefore we focus our attention on the former scenario. According to our proposal, first, base station sends the rekeying message to the affected cluster users via unicast, so the cost is $m-1$. Then, base station multicasts the rekeying message to the members of the remaining clusters in the affected subgroup. The overhead of this communication is n_c-1 . Finally, base station needs to update the group key for the rest of subgroups in the group and the cost is n_s-1 . Thus the total cost of rekeying communication of base station is $O(m+n_c+n_s)$. As for the LKH, the leaving cost is $(\alpha-1)d$ (Wong et al., 2000; Wallner, Harden, & Agee 1999). When single subgroup departure happens, the communication cost of LKH is one leaving cost plus group key updating for (n_s-1) subgroups. Therefore the overhead of LKH for single subgroup leaving is $O((\alpha-1)d+n_s)$.

When a member quits multiple subgroups simultaneously, multiple subgroups are affected. Under such scenario, AKC's communication cost is still $O(1)$, because all the new keys are still in one message. By using the subgroup KEK, base station has the same cost as that of single subgroup leav-

Table 1. The communication cost comparison of our proposal and LKH

| | join | | Leaving | | handoff |
|------------|----------------------|--|---|---|---------|
| | Single | Multi-subgroup | Single | Multi-subgroup | |
| our scheme | zero | zero | AKC: O(1) | AKC: O(1) | zero |
| | | | BS: O(m + n _c + n _s) | BS: O(m + n _c + n _s) | |
| LKH | O(d+n _s) | O(∑ _{i=1} ^j d _i + n _s - j) | O((α - 1)d + n _s) | O(∑ _{i=1} ^j (α - 1)d _i + n _s - j) | O(d) |

Note: n_c = the number of cluster of the subgroup; n_s = the number of the subgroups; M = the size of the cluster; α = the degree of the balance tree; j = the number of multiple subgroups which user joins or leaves simultaneously; d = the height of the tree

ing: O(m + n_c + n_s). As we described above, LKH algorithm needs multiple leaving operations. Additionally, the group key of (n_s-j) subgroup needs to be updated. So the overhead of communication of LKH is:

$$O(\sum_{i=1}^j (\alpha - 1)d_i + n_s - j).$$

Handoff

Because of the identical logical keying structure in all the areas, users can freely move from one cell to another without invoking rekeying procedure. As for the LKH algorithm, some handoff procedures at least need a join operation (DeCleene et al., 2001). So the rekeying communication cost is O(d), d is the height of the balance tree.

Summary

We tabulate the efficiency evaluation in Table 1. From the table, we can see that our proposal has advantages over the LKH, especially in the handoff and multi-subgroup join and leaving.

Computation Efficiency

Computation efficiency is to measure the cost of computation during the rekeying process in the wireless devices. Because of the computation limitation of the wireless device, it can not afford the expensive computation function, such as exponentiation, PKI calculation and so on. In our proposal, there are only two kinds of computations performed in the wireless devices: one-way hash function and symmetric encryption/decryption. In reference to the current mobile technology, these calculations were confirmed that they could be operated in a fast and efficient manner in the wireless devices. So the proposed system can achieve good computation efficiency which makes it suitable for the wireless network environment.

Storage Efficiency

The storage efficiency is to measure the number of keys stored in AKC and mobile devices. We compare the key storage cost of our proposal with that of LKH (Wong et al., 2000; Wallner, Harden, & Agee 1999) in Table 2.

From the table, we can see that, on the server side, the keys stored in LKH algorithm are linearly proportional to the number of group users. In the proposal, the key storage cost is proportional to the number of clusters, which is much less than the number of users. On the user side, there are only 4 keys stored for a single subgroup membership and j+3 keys for the multi-subgroup memberships in our proposal. For the LKH, in the same scenarios, users need to store d + 1 and

$$\sum_{i=1}^j d_i + j + 1$$

keys in single and multiple subgroup scenario respectively.

Table 2. The key storage cost comparison of our proposal and LKH

| | Our proposal | LKH |
|-------------------------|---|---|
| KDC/AKC | 1 + ∑ _{i=1} ^{n_s} (n _c) _i + n _s | ∑ _{i=1} ^{n_s} (αn _i - 1) + 1 |
| Users (single subgroup) | 4 | d + 1 |
| Users (multi-subgroup) | j + 3 | ∑ _{i=1} ^j d _i + j + 1 |

Note: N = the number of subgroup members; n_c = the number of cluster in the subgroup; n_s = the number of the subgroups; α = the degree of the balance tree; j = the number of multiple affected subgroups; d = the height of the tree

FUTURE TRENDS

Along with the fast development of wireless communications and fast capacities improvement on mobile devices, more and more multicast group applications and services will be emerging on wireless networks. The future research will focus on the efficiency and security of group key management system. Additionally, new architecture and framework will be proposed to address the wireless multicast security.

CONCLUSION

Here, we present a new group key management solution to secure multicast communications in wireless networks. This proposed solution has distributed two-tier architecture and clustered hierarchical keying structure based on the group organization chart. The group key management system can perform the multi-subgroup access control in an efficient way. Compared with the existing tree-based key management scheme, this proposed scheme can significantly reduce the overhead associated with communication, computation and storage.

KEY TERMS

Backward Secrecy: To prevent new group members from accessing previous group communications, which they may have recorded.

Forward Secrecy: To prevent departing members from decoding future group data traffic.

Handoff: In a cellular wireless network, handoff is the transition of signal for any given user from one base station to a geographically adjacent base station as the user moves around.

Key Encryption Key (KEK): This kind of keys is used to encrypt the other keys for distribution in the multicast group.

Key Management Algorithm: In the group key management system, an algorithm is applied to maintain the logical key structure held by the group members and other entities.

Logical Key Hierarchy (LKH): This algorithm is a tree structure for efficient group rekeying. Each node of the tree represents a key, with the root node representing the group key. Each leaf node represents a group member, and each member knows all the keys in its path to the root.

Multicast: Multicast is communication mechanism to delivery a single message to multiple receivers on a network. The message will be duplicated automatically by routers when multiple copies are needed.

Security Architectures of Mobile Computing

INTRODUCTION

Mobile Internet users expect the same network service quality as over a wire. Technologies, protocols, and standards supporting wired and wireless Internet are converging. Mobile devices are resource constrained due to size, power, and memory. The portability making these devices attractive also causes data exposure and network penetration risks.

Mobile devices can connect to many different wireless network types, such as cellular networks, personal area networks, wireless local area networks (WLANs), metropolitan area networks (MANs), and wide area networks (satellite-based WANs). Wireless network application examples are e-mailing, Web browsing, m-commerce, electronic payments, synchronization with a desktop computer, network monitoring/management, and reception of video/audio streams.

BACKGROUND

Major security threats for mobile computing devices are (Olzak, 2005):

- theft/loss of the device and removable memory cards,
- wireless connection vulnerabilities, and
- malicious code.

Mobile computing devices are small, portable, and thus easily lost/stolen. Most mobile platforms only include support for simple software-based password login schemes. These schemes are easily bypassed by reading information from the device without login. Memory cards are also easily removed from the device.

Mobile devices support wireless network connections such as Bluetooth and WLAN. These connections are typi-

cally by default unprotected and thus exposed to eavesdropping, identity theft, and denial-of-service attacks.

Malware has constituted a growing threat for mobile devices since the first Symbian worm (Cabir) was detected in 2004. Mobile devices can be infected via MMS, Bluetooth, infrared, WLAN, downloading, and installing from the Web. Current malware is focused on Symbian OS and Windows-based devices. Malware may result in (Olzak, 2005):

- loss of productivity,
- exploitation of software vulnerabilities to gain access to resources and data,
- destruction of information stored on a SIM (subscriber identity module) card, and
- hi-jacking of airtime resulting in increased costs.

WIRELESS SECURITY PRINCIPLES

Security Policy

Examples of rules proposed for mobile device end users are:

- I agree to make sure my device is password protected and that latest security patches are installed.
- I agree to keep a firewall/anti-virus client with latest anti-virus signatures installed, and to use a remote access VPN client, if I will connect to the corporate network.
- I agree to use the security policies recommended by the corporate security team.

Examples of rules proposed for administrators of mobile devices in corporate use are:

- End-users get mobile network access after agreeing to the end-user rules of behavior.
- Handheld firewalls shall be configured to log security events and send alerts to *security-manager@company.com*.
- Handheld groups and Net groups shall have restricted access privileges and only to needed services.

Handheld security policies should be automated by restrictive configuration settings for handhelds, firewalls, VPNs, intrusion detection systems, and directory servers (Handheld Security, 2006).

Storage Protection

Mobile device storage protection is online integrity control of all stored program code and all data, optional confidentiality of stored user data, and protection against unauthorized tampering of stored content. Protection should include all removable storage modules used by the mobile device.

The integrity of the operating system code, the program code of installed applications, and system and user data can be verified by checksums, cyclic redundancy codes (CRCs), hashes, message authentication codes (MACs, HMACs), cryptographic signatures, and so forth. However, only hardware protection of verification keys needed by MACs, HMACs, and signatures provide strong protection against tampering attacks. Online integrity control of program and data files must be combined with online integrity control of the configuration of a mobile device for protection against malware intrusion attempts.

User data confidentiality can be granted by file encryption software. Such software also protects integrity of stored information, since successful decryption of an encrypted file is also an integrity proof.

Security Layers

Mobile computing security layers are based on the OSI (Open Systems Interconnection) Security Model. Defined security services are *authentication*, *access control*, *non-repudiation*, *data integrity*, *confidentiality*, *assurance/availability*, and *notarization/signature* (ISO/IEC 7498-1, 1994; ISO 7498-2, 1989).

Specific wireless security architecture issues include Mobile IP security features, and link-level and physical-level security protocols of wireless access technologies like WLAN, GPRS, and Bluetooth

Mobile IP security means that:

- a mobile node, which is a mobile device, has the same connectivity and security in a visited foreign network as in its home network; and

- the home network and visited foreign networks have protection against active/passive attacks.

These security goals require:

- that Mobile IP registration and location update messages have *data integrity protection*, *data origin authentication*, and *anti-replay protection*;
- *access control* to foreign network resources used by visiting mobile nodes; and
- that IP packet redirecting tunnels provide *data integrity protection*, *data origin authentication*, and *data confidentiality*.

Moreover, mobile nodes should have *location privacy* and *anonymity* (Zao et al., 1999).

Replay prevention with timestamps or nonces for all mobile IP messages is specified in Perkins and Calhoun (2000). Other mobile IP security solutions are authentication schemes and protection of data communication (Calhoun et al., 2005; Barun & Danzeisen, 2001; Hwu, Chen, & Lin, 2006).

Identification Hardware

Identification hardware contains user information and cryptographic keys used to authenticate users to mobile devices, applications, networks, and network services.

The following identification hardware types are used:

- subscriber identity module (SIM),
- public key infrastructure SIM (PKI SIM),
- universal SIM (USIM), and
- IP multimedia services identity module (ISIM).

SIM

A basic SIM card is a smartcard securely storing a key (Ki) identifying a GSM network user. A SIM card is a microcomputer executing cryptographic operations with Ki. The SIM card also stores SMS (short message service) messages, MMS (multimedia messaging system) messages, and a phonebook. The use and content of a SIM card is PIN protected (Rankl & Effing, 2003).

PKI SIM

A PKI SIM card is a basic SIM card with added PKI functionality. An RSA co-processor is added for public key-based encryption and signing with private keys. The PKI SIM card stores private keys and certified public keys needed for digital signatures and encryption (Setec, 2006).

USIM

A USIM card is a SIM used in 3G mobile telephony networks. The physical size is the same as for a GSM SIM card, but hardware is different. USIM is actually an application running on a UICC (universal integrated circuit card) storing a pre-shared secret key (Lu, 2002).

ISIM

An ISIM card consists of an application (ISIM) residing on a UICC. ISIM provides secure authentication of handheld users to IMS (IP multimedia system) services (Dietze, 2005).

Wireless Security Protocols

Security protocols are—for wired networks—implemented by (Perelson & Botha, 2004): authentication services, confidentiality services, non-repudiation services, and authorization. Four wireless security protocol types are needed:

- access control to mobile devices,
- local access control to networks and network services,
- remote access control to networks and network services, and
- protection of data communication to/from mobile devices.

Different protocols are presented in Markovski and Gusev (2003).

Access Control to Mobile Devices

Access control must be implemented on a mobile device itself to prevent unwanted access to confidential data stored in the device (see Figure 1). Authentication confirms a claimed user identity.

PIN and Password Authentication

A PIN is four digits from a 10-digit (0-9) keypad. However, PINs are susceptible to shoulder surfing or to systematic trial-

and-error attacks due to their limited length and alphabet. Passwords are more secure than PINs since their length and alphabet are larger (Jansen, 2003).

Visual and Graphical Login

Visual authentication means that a user must remember image sequences to authenticate to a mobile device. A picture password system can be designed to require a sequence of pictures or objects matching a certain criteria and not exactly the same pictures. For example, the user must find a certain number of objects with four sides. This makes the shoulder surfing quite difficult (Duncan, Akhtari, & Bradford, 2004).

Biometrics

Biometric user authentication is a hardware solution for examining one or more physical attributes of an authorized user. Biometric controls, such as fingerprints, are becoming more common in handheld devices (Perelson & Botha, 2004).

Authorization

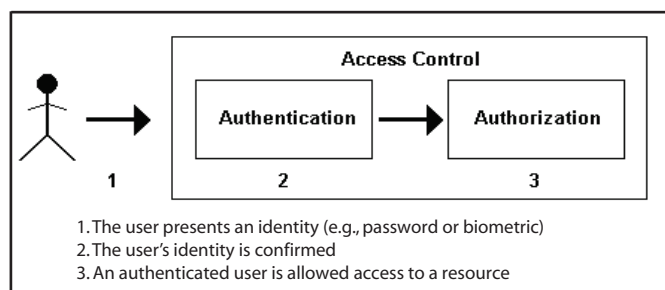

Usually mobile devices are personal, and authentication infers that the user is authorized. A corporate handheld device may however be used by several employees and may contain confidential company information. Needed user authorization features for such mobile devices include (Perelson & Botha, 2004):

- **File Masking:** Some files cannot be viewed by unauthorized users.
- **Access Control Lists:** User-related object permissions.
- **Role-Based Access Control:** User role-related permissions.

Local Network Access

Local network access protocols depend on the wireless access network type (WLAN, Bluetooth, Cellular Network, etc.). A

Figure 1. The access control principle

WLAN is usually an access network to a LAN. Authentication for LAN resources is thus also needed unless WLAN authentication is integrated in a single-sign-on scheme. Local network access protocols are described in later sections.

Remote Network Access

Secure remote network access from a mobile device requires a VPN (virtual private network), which is a protected data path in an existing unsecured network to a private LAN. VPNs can be based on different protocols: IPSec (IP security), SSL (secure socket layer), or SSH (secure shell).

IPSec VPN

IPSec operates at the network layer of the OSI model. IPSec protocols are:

- ESP (encapsulating security payload) for authentication, data confidentiality, and message integrity;
- AH (authentication header) for authentication and message integrity; and
- IKE (Internet key exchange protocol) for encryption key exchange.

IPSec VPNs require VPN client software in mobile devices (Davis, 2001).

SSL VPN

The encrypted tunnel is established at the session layer of the OSI model. SSL VPN clients communicate with the VPN gateway using an SSL-supported application such as a Web browser or e-mail client. No separate VPN client software is therefore needed (Steinberg & Speed, 2005).

SSH

SSH (secure shell) is a protocol for login to and executing commands on a remote UNIX computer. SSH provides between two communicating hosts an encrypted communication channel, which can be used for port forwarding with VPN functionality (Barret et al., 2005).

Protection of Data Communication

Security protocols for protection of wireless data communication are integrated in protocols for local and remote access to networks/network services. In a cellular network a shared secret session key created by the authentication protocol is used for encryption/decryption of data communication. In a WLAN, the TKIP (temporal key integrity protocol) is integrated in the WPA security protocol, and AES (advanced

encryption standard) is integrated in the WPA2 security protocol. The remote access protocols IPSec, SSL/TLS, and SSH also provide end-to-end protection of data communication with secure symmetric encryption algorithms and shared secret session keys created during authentication.

PLATFORMS FOR INTEGRATED ARCHITECTURES

Software signing and binary trust-models do not provide adequate protection against third-party programs. Fine-grained software authorization is emerging into mobile units. Typical examples include Java sandboxing and Symbian platform security. Software-based mobile platform examples are Java Mobile Environment, Symbian OS, Embedded Linux, Windows Mobile, Brew (Binary Runtime for Wireless), Blackberry OS, and Palm OS.

OS implementation vulnerabilities still remain a challenge. Integrated solutions have been proposed for executing trusted code and for secure boot. Standardization efforts are under development (e.g., Trusted Computing Group and Trusted Mobile Platform). There are different embedded on-chip security solutions, but mostly the security solution relies on combining hardware and software. Platform security examples are Texas Instruments OMAP™ Platform (Sundaresan, 2003) and Intel Wireless Trusted Platform (Intel Corporation, 2006b).

The TI platform relies on three layers of security: application layer security, operating system layer security, and on-chip hardware security. The main security features are:

- A *secure environment* provides secure execution of critical code and data by *secure mode*, *secure keys*, *secure ROM*, and *secure RAM*.
- *Secure boot/flash* prevents security attacks during device flashing/booting.
- *Run-time security* is included for security-critical tasks like encryption/decryption, authentication, and secure data management.
- A *hardware crypto engine* is also included for DES/3DES, SHA1/MD5, and RNG with two configuration modes: *secure mode* and *user mode*.

Intel platform building blocks are performance primitives (hardware) and cryptographic primitives (optimized software) for security services. Platform components include

- *trusted boot ROM* integrity validation and booting to a correct configuration;
- *wireless trusted module* processing secrets;
- *security software stack* enabling access to platform resources through standard cryptographic APIs;
- *protected storage* in system flash for secrets; and

- *physical protection* by security hardware in a single device and discrete components in a single physical package.

WIRELESS APPLICATION SECURITY

The risks described above should be addressed in wireless application design. Wireless application security includes (Umar, 2004): application access control, client/server communications security, and anti-malware protection.

Application Access Control

Many mobile platforms lack support for individual user accounts and for operating system-level logon. Mobile applications handling confidential data should require user authentication before application access is granted. In case a mobile device is lost or stolen while the device user is logged in to an application, the application should also support “session timeout.” This means that a limited inactive time is specified for an application before re-authentication is required (Intel Corporation, 2006a).

Client/Server Communication Security

Typical wireless Internet connections are:

1. the wireless connection between a mobile device and an access device, and
2. the Internet connection between the mobile device and the Internet host/server via the access device.

Internet connection security should be provided at the application level.

For Web-based client/server applications, the SSL protocol provides encryption and signing of transmitted data. SSL application examples are:

- Web browsers for secure communications with Web servers,
- e-mail client software for secure reading of e-mail messages on e-mail servers, and
- SETs (secure electronic transactions) for secure financial transactions with credit cards.

For applications using customized protocols, security protocols are also customized. Alternatively, VPN techniques can be used.

Anti-Malware Protection

Most current mobile operating systems lack memory space protection. Malware can access and steal application data,

such as credit card information stored in memory by wireless applications. Time and space for sensitive data in memory should be minimized (Intel Corporation, 2006a).

SECURITY OF MOBILE TECHNOLOGIES

A taxonomy of mobile technologies is:

- wireless cellular networks (GSM, DECT, GPRS, and UMTS),
- wireless long-range networks (WiMax, Satellite Communication Technology),
- wireless local area networks (WLAN, ZigBee™), and
- wireless short-range networks (Bluetooth, Wireless USB).

Wireless Cellular Networks

First Generation

First-generation cellular systems, such as AMPS (advanced mobile phone system) introduced in the early 1980s, use analog transmission and provide no security.

Second Generation

2G cellular systems, such as GSM (Global System for Mobile Communications) introduced in the late 1980s and DECT, use digital transmission.

GSM security is based on a unique IMSI (International Mobile Subscriber Identity) and a unique secret key (Ki) stored in the SIM card of each subscriber. The Ki is never transmitted over the network. Every GSM network has:

- *AUC (authentication center)*, a protected database containing a copy of Ki;
- *HLR (home location register)* for subscriber information;
- *VLR (visitor location register)* for information of each mobile station currently located in the geographical area controlled by the *MSC (Mobile Station Controller)*; and
- *EIR (equipment identity register)* for lists of mobile stations on the network. Stations have unique IMEI (International Mobile Equipment Identity) numbers.

When a mobile station enters a GSM network for the first time, the IMEI is transmitted for determination in which AUC/HLR subscriber data is stored. The MSC/VLR of the visited network asks for and stores a security triplet

(a unique random number RAND, a signed response SRES, a ciphering key Kc) from the AUC/HLR. SRES and Kc are calculated from RAND with Ki.

Subscriber authentication:

- RAND is sent to the mobile station.
- SRES' and Kc' are calculated from RAND with Ki.
- SRES' is sent back to MSC/VLR.
- Authenticated if SRES=SRES'.

Kc=Kc' is used for radio link encryption/decryption.

After the initial registration, IMSI is stored in the VLR. A TMSI (temporary mobile subscriber identity) is generated, transmitted back to the mobile station, stored in the SIM card, and used for future subscriber identification in the visited network.

DECT is a cellular system and a common standard for cordless telephony, messaging, and data transmission standardized by ETSI (European Telecommunications Standards Institute). DECT is similar to GSM, but cell ranges are shorter (DECT, 2006).

DECT uses several advanced digital radio techniques for efficient radio spectrum utilization. It enables high speech quality and security with low radio interference risks and low-power technology. Mobility management, responsible for DECT communication security, consists of procedures for *identity, authentication, location, access rights, key allocation, parameter retrieval, and ciphering* (Umar, 2004).

2.5 Generation

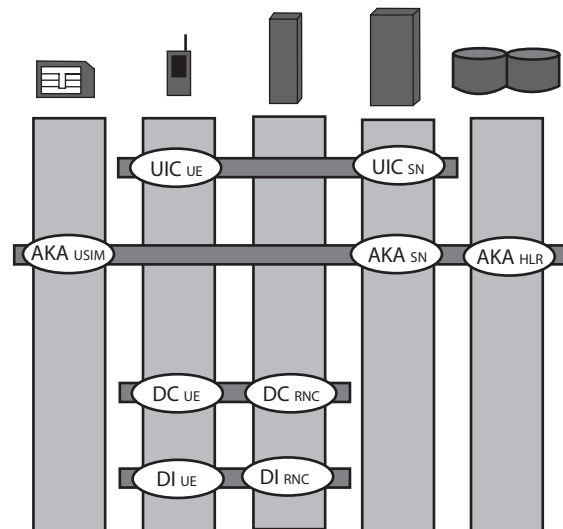

The GPRS (2.5G) infrastructure equals GSM. TMSI is replaced by P-TMSI (packet TMSI) and by P-TMSI signature as alternate identities. Mapping between IP addresses and IMSI is generated in the HLR GPRS Register. GPRS authentication is performed by SGSN (serving GPRS support node). As a consequence, user data and signaling are encrypted all the way from the mobile station to the SGSN. Tunneling, firewalls, and private IP techniques are used. IP addresses are assigned after authentication and encryption algorithm negotiations.

Third Generation

UMTS, Universal Mobile Telecommunications System, a standard for third-generation (3G) systems for mobile communication, referred to as International Mobile Telecommunications 2000 (IMT-2000) and initiated by the International Telecommunication Union (ITU), is presently being developed by the Third Generation Partnership Project (3GPP).

The UMTS security architecture is based on 2G/2.5G security. Some GSM security features have been improved and some new features have been added. The UMTS security

Figure 2. UMTS functional security architecture; UE is user equipment and RNC is radio network controller

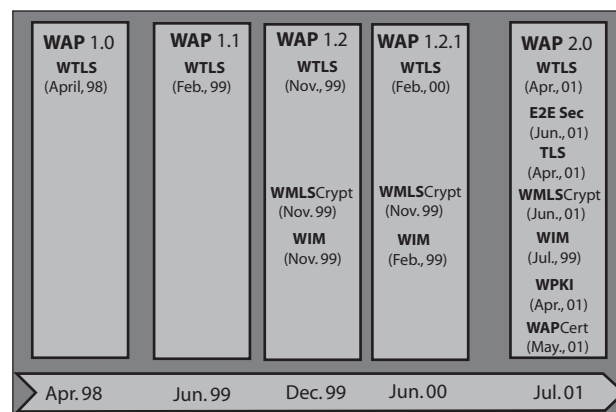

mechanisms are (see Figure 2): user identity confidentiality (UIC), authentication and key agreement (AKA), confidentiality of user and signaling data (DC), and integrity of signaling data (DI). See Lu (2002) for UMTS security details.

WAP

WAP (wireless application protocol) is an open mobile device application standard. WAP security protocols and specifications are being developed by the WAP Forum (Open Mobile Alliance, 2006). The evolution of WAP security specifications is shown in Figure 3.

Figure 3. The development of WAP security specifications

WTLS/TLS/SSL

SSL/TLS are TCP-based security protocols for communication in client/server applications. WAP 2.0 adopts TLS as security protocol and supports the tunneling of SSL/TLS sessions through a WAP/WAP proxy. TLS/SSL in WAP 2.0 is a complement to the similar UDP-based WTLS protocol in earlier WAP versions. Server authentication and mutual authentication are options in WTLS/TLS/SSL-protected WAP applications.

WMLScript Crypto Library, WIM, and WPKI

The lack of non-repudiation services and end-user authentication was addressed in WAP 1.2. The WMLScript (Wireless Markup Language Script) Crypto Library provides cryptographic functionality for WAP clients. WAP identity module (WIM) is used in WTLS and application-level security functions. A WIM stores and processes user authentication information, such as private keys. A WIM implementation example is a mobile phone S/WIM card (combined SIM and WIM). WPKI (wireless public key infrastructure) is a mobile environment PKI supported since WAP 2.0 (Open Mobile Alliance, 2006).

i-mode

i-mode is a Japanese competitor to WAP for m-commerce. i-mode security features are:

- protection of the radio link between the i-mode handset and the base station,
- encryption/authentication of data transmitted between i-mode mobile devices and Web sites, and
- protection of private network links between the i-mode center and special service providers like banks.

The radio link is protected using SSL and other protocols, which are not public. Security of Web site connections and private network links are based on SSL. Mutual certificate authentication is supported (Umar, 2004).

Bluetooth

Bluetooth provides wireless short-distance transmission of data and voice signals between electronic devices. The specifications are defined by Bluetooth SIG (2006). The security is based on *authentication*, *authorization*, and *encryption*. The *security modes* are:

1. no security measures,
2. security measures based on authorization, and
3. authentication and encryption.

Table 1. Bluetooth service levels

| | Authorization | Authentication | Encryption |
|-----------|---------------|----------------|------------|
| Trusted | Yes | Yes | Yes |
| Untrusted | No | Yes | Yes |
| Unknown | No | No | Yes |

Authentication

Bluetooth device authentication is a unidirectional or mutual challenge/response process. Secret keys, called *link keys*, are generated either dynamically or by pairing. For dynamic link key generation, a passkey—the same passkey—must be entered in both connecting devices each time a connection is established. In pairing, a long-term stored link key is generated from a user-entered passkey, which can be automatically used in several connection sessions between the same devices.

Authorization

In authorization, a Bluetooth device determines whether or not another device is allowed access to a particular service. Levels of trust are *trusted*, *untrusted*, or *unknown*. Service levels are shown in Table 1.

Encryption

Bluetooth data transmission uses 128-bit encryption. Encrypted data can only be viewed by a device owning the proper decryption key. The encryption key is based on the link key.

ZigBee

ZigBee is a low-cost, low-power communications standard for wireless data communication in home and building automation. The ZigBee stack architecture is based on the standard OSI model. The IEEE 802.15.4-2003 standard defines the physical (PHY) layer and the medium access control (MAC) sub-layer. The ZigBee Alliance builds on this foundation by providing the network (NWK) layer and a framework for the application layer with: the application support sub-layer (APS), ZigBee device objects (ZDO), and manufacturer-defined application objects.

Security services are defined for key establishment, key transport, frame protection, and device management. The MAC, NWK, and APS layers are responsible for the secure transport of their respective frames. Data encryption uses the symmetric key 128-bit AES algorithm. Frame integrity is protected, since frames cannot be modified by parties without cryptographic

keys. Replayed data frames are rejected by a frame freshness verification function of the NWK layer. Furthermore, the APS sub-layer establishes and maintains security relationships. ZDO manages the security policies and the security configuration of a device. Access control uses a list of trusted devices maintained by a ZDO (ZigBee Alliance, 2004).

WLAN

Broadband mobile communication is supported by a WLAN, which gives mobile users LAN connectivity through a high-speed radio link. Major WLAN security standards are (Pulkkis, Grahn, Karlsson, Martikainen, & Daniel, 2005): IEEE 802.11/WEP, WPA, and IEEE 802.11i.

WEP is not recommended due to security flaws. Data encryption is based on static encryption keys, and no user authentication mechanisms are specified. WPA addresses the WEP vulnerabilities and is based on IEEE 802.11i (see Figure 4).

The main features of WPA are:

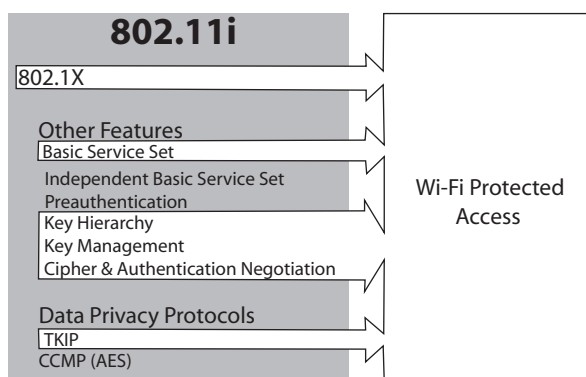

- Temporal key integrity protocol (TKIP) to provide dynamical and automatically changed encryption keys, and
- IEEE 802.1X and EAP (extended authentication protocol) to provide strong user authentication.

CCMP (cipher block chaining message authentication protocol) is an IEEE 802.11i protocol that uses the AES (advanced encryption standard) to provide stronger encryption than TKIP.

WiMax

WiMax is a new technology for wireless broadband Internet access. The MAC layer of the WiMax network stack has a security sub-layer with (Puthenkulam & Yin, 2005):

Figure 4. IEEE 802.11i features in WPA

- a base station device and mobile user authentication capability based on the EAP protocol, X.509 certificates, and AAA servers (Radius, Diameter);
- encryption key management using the privacy key management protocol (PKM) v2;
- AES-CCM authenticated encryption of all data communication—the Encryption Key Refresh Mechanism supports high data rates; and
- CMAC (cipher-based message authentication code) and HMAC (hash-based message authentication code), which handle control message integrity protection.

Wireless USB

An USB wire provides two security services: (1) a wanted interconnection of two devices is created, and (2) all data in transit is protected from casual observation or malicious modification by external parties.

The goal of Wireless USB security is to provide analogous security services. Hosts and wirelessly connected devices are required to authenticate each other to avoid man-in-the-middle attacks. Data communication between a host and a wirelessly connected device is confidential and integrity-checked by AES-128/CCM encryption. Secret encryption keys are shared by mutually authenticated hosts and wirelessly connected devices (Wireless, 2005).

Satellite Communication Technology

A communication satellite permits two or more earth stations to send radio messages to each other over far distances. For satellite communication security it is necessary that earth stations have significant physical security, and RF (radio frequency) communication channels between satellites and earth stations are protected.

Satellite communications are normally secured by scrambling satellite signals using cryptography or transmitting same signals over several frequencies. The data bits are basically transmitted on different signals based on a secret scheme. The receiver of a signal must thus be aware of the secret scheme. Additional security protocols like IPSec can be used to encrypt radio messages. However, such protocols slow down data transmission. The main challenge is thus to find a good balance between performance and security (Umar, 2004).

FUTURE TRENDS

Privacy, security, and trust issues are and will be of major importance. The growth of the Internet and m-commerce will dramatically increase the amount of personal and corporate information that can be captured or modified. In the near

future ubiquitous computing systems will accentuate this trend. We can likewise expect an increase in privacy and security risks, not only with the emergence of mobile and wireless devices, but also with sensor-based systems, wireless networking, and embedded devices. Ubiquitous computing technologies will probably suffer from the same sorts of unforeseen vulnerabilities that met the Internet society.

CONCLUSION

Mobile terminals face security threats due to openness. Platforms are open for external software and content. Malicious software, like Trojan horses, viruses, and worms, has started to emerge. Fine-grained software authorization has been proposed. Downloaded software may then access particular resources only through user authorization. OS implementation vulnerability still remains a challenge because of difficulties in minimizing OS code running in privileged mode. Integrated hardware solutions may be the solution.

Wireless security architectures have many options, and many standards/protocols addressing wireless security are quite recent, especially standards/protocols based on public key cryptography. Therefore more practical experience from the use of these protocols/standards in mobile computing is needed for reliable estimation of the provided security.

KEY TERMS

Bluetooth: A technology standard for wireless short distance communication.

DECT: A cellular system and a common standard for cordless telephony, messaging, and data transmission standardized by ETSI (European Telecommunications Standards Institute).

Mobile IP: Mobile Internet protocol for IP number preservation of a mobile computer.

USIM: A SIM used in 3G mobile telephone networks.

WiMax: A technology standard for wireless broadband Internet access.

ZigBeeTM: A low-cost, low-power communication standard for wireless data communication in home and building automation.

Semantic Caching in a Mobile Environment

S

Say Ying Lim

Monash University, Australia

INTRODUCTION

Mobile computing environments enable the database servers to disseminate data via wireless channels to multiple mobile clients (Chung & Kim, 2001). It has increased popularity with the emerging trend of wireless network and usage of handheld devices, such as PDAs and other portable electronic devices. The typical nature of a mobile environment would include low bandwidth and low reliability of wireless channels, which causes frequent disconnection to the mobile users. Hence due to the constraints of the nature of mobile environment it is important to enhance the performance of the query processing, as well as improve the availability of querying particular data items especially during disconnection (Imelinkski & Korth, 1996; Malladi & Davis, 2002). Often, mobile devices are associated with low memory storage and low power computation and with a limited power supply (Myers & Beigl, 2003). Hence, it is important to help mobile clients to save the usage of its battery.

By introducing data caching into the mobile environment, it is believed to help improve data availability in case of disconnection by retrieving data that has been previously cached in the local memory and to be able to save power by having a lower data transmission. Generally, in data caching, it means the data is cached in the memory storage of the mobile device, and whenever the mobile users want to issue a query, it will first search its cache and if there exists a valid copy in the cache it returns the results immediately. Otherwise the mobile users would attempt to obtain the data from the server either using the server or broadcast strategy. Caching has emerged as a fundamental technique, especially in distributed systems, as it not only helps reduce communication costs but also off loads shared database servers.

In this article, we describe the use of caching, which allows coping with the characteristic of the mobile environment. We concentrate particularly on semantic caching, which is basically a type of caching strategy that is content-based reasoning ability with the ability to—in addition of caching query results—remember the queries that generated these results. Semantic caching provides accurate, semantic description of the content of the cache.

BACKGROUND

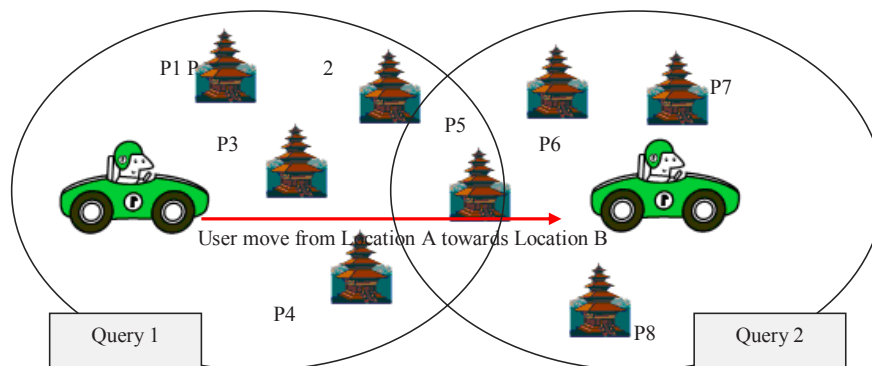

The effect of having the ability to cache data is of great importance, especially in the mobile computing environment than in other computing environments. This is due to the reason that contacting the remote servers for data is expensive in the wireless environment and, with the vulnerability to frequent disconnection, can further increase the communication costs (Leong & Si, 1997). There are many different types of caching strategies that serve the purpose to improve query response time and to reduce contention on narrow bandwidth (Zheng, Lee, & Lee, 2004). Caching mechanisms need to retain the frequently accessed data locally in the mobile device storage to be able to allow users to access server database queries at least partially in cases of disconnections. Hence, the more effective the caching mechanism is in keeping the frequently accessed data will result in more queries that can be served during disconnection.

Due to limitations such as cache space, cache replacement and cache granularity, as well as cache coherence, are the three main issues that characterize caching mechanism. In traditional cache replacement, the most important factor affecting cache performance is the access probability. This refers to replacing the data with the least access probability to free up more cache space for the new data. There is a large variety of caching replacement policies and most of them utilize access probability as the primary factor in determining which data items are to be replaced.

Cache granularity relates to determining a physical form of cached data items. It appears to be one of the key issues in caching management systems. There are three different levels of caching granularities in object-oriented databases, which includes: (a) attribute caching, (b) object caching and (c) hybrid caching (Chan, Si, & Leong, 1998). Attribute caching refers to frequently accessed attributes that are stored in the client's local storage. As for object caching, instead of the attribute itself being cache, the object is cached. In attribute caching, it creates undesirable overheads due to the large number of independent cache attributes. Thus, hybrid caching, which appears to be a better approach, comprises of the combinations of both granularities.

Cache coherence—or known as invalidation strategy—involves cache invalidation and update schemes to invalidate

Figure 1. Overlapping results from two queries issued

and update out-dated or non valid cached items (Chan, Si, & Leong, 1998; Cao, 2003). After a certain period, a cached data may appear as no longer valid and therefore mobile users should obtain a newer cache before retrieving the data (Xu, Tang, & Lee, 2003). There are several techniques that have been proposed to overcome this issue. These include (a) stateful server, (b) stateless server, (Barbara & Imielinski, 1994) and (c) leases file caching mechanism (Lee, Leong, & Si, 2001). Stateful server refers to the server having an obligation to its clients, which means the server has the responsibility in notifying the users about changes, if there are any. In contrast, stateless server refers to the server not aware for its clients, whereby the server broadcasts a report that contains the updated item either asynchronously or synchronously. The leases files mechanism, which is also known as lazy invalidation approach, assigns each mobile user to be responsible for invalidating its cached items.

Consequently, a good caching management strategy is needed to deal with the critical caching issues, such as caching replacement, caching granularity and caching coherence.

SEMANTIC CACHING

A better way of query processing specifically for use in a mobile environment is by allowing the users to specify precisely what data items are missing from its local storage to server the query. This could be achieved by having the previously evaluated query results being cached (Dar et al., 1996; Roussopoulos, 1991).

Using Semantic Caching in a Mobile Environment

A semantic cache is defined as consisting of a set of distinct semantic segments, which can be decomposed into separate components or come together as a whole of the query

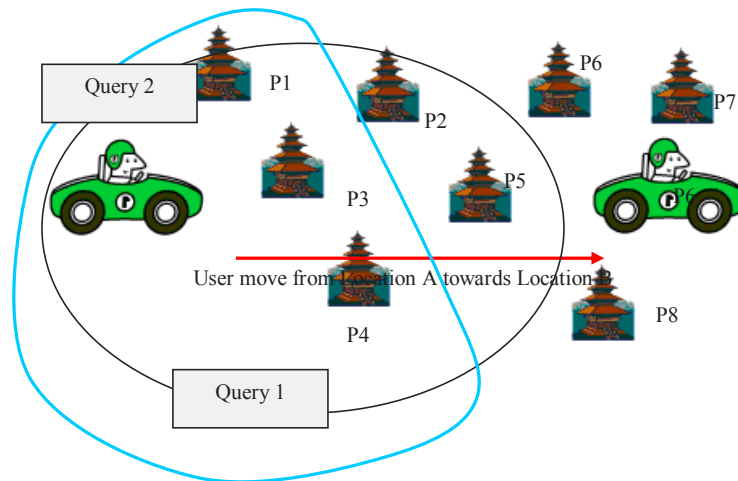

results. A semantic segment S can be specified by having $\langle SR, SA, SP, SC \rangle$ whereby SR and SA define the base relation of relation and attributes in the creation of the semantic segment respectively. SP is to indicate the criteria that S satisfies, and SC indicates the actual content of S , which is represented by pages. (Ren, Dunham, & Kumar, 2003)

Semantic caching stores semantic descriptions and associated answers of the previous queries in the mobile client (Dar et al., 1996). The main feature of semantic caching is the content-based reasoning ability as well as the fact that only the required data, as opposed to a file or pages of data, is transmitted over the wireless channel.

When a new query exists, the mobile client can determine whether should it be totally answered by how much can it be answered and what data are missing. With these abilities, the wireless traffic can be greatly reduced because only the needed data are transferred. This helps with disconnection too, since total or partial results may be obtained even when the server is unreachable (Lee, Heong, & Si, 1999). As a result, if a query can be partially answered from the cache, the volume of missing data requested from the server as well as the wireless bandwidth consumed can be reduced. And if the query could be answered completely based on the cache, then no communication between the client and the server is required at all. This ability is of particular significance during disconnection, which is the main constraint the mobile environment is currently facing. This also leads to reduction of overhead due to redundant computation as the amount of data transferred over the wireless channel can be substantially reduced.

Example 1: Suppose a mobile user who is traveling from one location to another location suddenly wished to find a nearby rest place. So the user issue a query while he is in Location A and the server returns the nearest rest place which is $P1, P2, P3, P4, P5$. But the user is not satisfied with the results. So he re-issued another query while he is moving

Figure 2. Issuing a 3NN query

towards Location *B*. And the query returns another set of results which may contain some overlapping results such as the same *P5* as the user previously received. Hence, the cached results are immediately returned since it has been previously cached. Thus, the user actually only needs to submit the complement of the new query in order to obtain only results that are not the same as the one previously obtained. This example can be illustrated as in Figure 1. This shows that semantic caching not only saves the wireless bandwidth due to less retransmission, but also reduces the query response time since some cached results can be immediately returned.

Benefits and Limitations

There are several advantages that can be gained by using semantic caching, with the main reason that because only required data are being transferred communication cost between the client and the servers would be reduced. Moreover, cache space overhead is low for semantic caching since only the data that satisfy previous queries are being stored. With the ability of semantic caching to keep semantic information, it enables missing data to be exactly determined, which causes easy parallel query processing. Hence, semantic caching is very efficient to be used in the mobile environment since more autonomy is given to the clients and partial results can be derived when disconnections from the wireless channels occur (Ren, Dunham, & Kumar, 2003).

Besides all the benefits semantic caching brings in, there are also limitations and drawbacks that semantic caching brings. Generally, semantic caching captures the semantics of the queries only, and ignores the semantics of the cached objects. Therefore, the granularity is at a query level that helps answering similar queries faster, but cached objects from different types of queries become difficult. (Hu et al.,

2005) In addition, the types of spatial queries supported by semantic caching are rather limited to simple range query and nearest neighbor (NN) query (Ren & Dunham, 2003; Zheng & Lee, 2001). It is difficult to support complex queries such as *k*-nearest-neighbor (*k*NN). Besides that, it also demonstrates complicated cache management. For example, when a new query to be cached overlaps some cached query, a decision has to be made whether to bring these two queries or to trim either of them. When the cache size grows, all these drawbacks would become more remarkable.

Example 2: The same scenario as described in Example 1 but, instead of the user issuing a query 2 in a new location after the query 1 which has been sent, he would like to issue query 2 that is comprised of 3 nearest neighbor (3NN) query. Due to the limitation of semantic caching that is not able to trim a 3NN query from the first query, the user would have to send a full complete query 2 to the server even though the results data *P1*, *P3*, *P4* have been cached as a result of the first query that has been issued earlier on. They are actually partial results of the new query and should have been returned immediately to the user but are not able to do so. This example can be illustrated as in Figure 2. The retransmission of this result to the mobile users has wasted the wireless bandwidth as well as unnecessary transfer and has prolonged the response time (Hu et al., 2005).

Semantic Caching in Query Processing

In order to process a query from a semantic cache, first of all we would check whether the query can be answered locally by the cache. If the answer can be obtained from the cache, the results are locally processed from the cache in the mobile device. However, in cases where the answers are not fully obtainable from the cache, but can only be partially

Figure 3. Semantic caching query processing mechanisms

answered, we will trim the original query by either removing or annotating those parts that are answered and send it over the wireless channel to the server for further processing (Godfrey & Gryz, 1999). In other words, if the answer can be totally answered from the cache a probe query is being issued, whereas a remainder query is being issued to the server when only partial answers are obtainable. Figure 3 shows the semantic caching query processing mechanisms (Waluyo, Srinivasan, & Taniar, 2005).

Example 3: Consider a mobile user who previously issued queries in getting movie information. This information had been cached into his local memory storage previously. Now he would like to send another query obtaining another list of movie information. So, it first processes the query locally via the semantic cache and determines if any of the semantic segments contribute to the query results from the cache index. If the result can be partially answered by the semantic segment then a probe query will retrieve the results that can be obtained locally, and a remainder query will be issued to the server for evaluation to define the other partial results. And then the result for the query is obtained by integrating all the partial results into a single result, which may consist of the results from probe query and remainder query.

Due to the fact that mobile users in a typical mobile environment move around frequently by changing location has opened up a new challenge of answering queries that is dependent on the current geographical coordinates of the users (Barbara, 1999). This is known as location dependent queries (Park, Song, & Hwang, 2005). An example of a location dependent query can be, "Find the nearest restaurants from where I am standing now." This is an example of static object whereby restaurants are not moving. An example of a dynamic object would be, "What is the nearest taxi that will pass by me?"

Queries should be processed in a way that minimizes the consumption of bandwidth and battery power. The problem is challenging because the user location is changing and the results would also change accordingly (Shi, Li, & Wang, 2002). And with the keep on changing location that causes changing results to be downloaded would cause high com-

munication costs if excessive communication is needed to and from the server several times (Seydim, Dunham, & Kumar, 2001). Hence, caching plays a role in location dependent query processing. This allows the queries to be answered without connecting to the server.

In summary, there are a series of steps that can be carried out in answering a query. First of all, when a query has been issued, the local cache is checked to see whether the results can be obtainable locally or not. If there are no suitable answers to the queries that are issued that correspond to the location of the user in cases of location dependent queries, then the information of the location of the user will be transmitted to the server to answer the query and returned back to the user. Otherwise, if there is some related data from the cache itself, then the data can be retrieved directly from the cache and the answer to the query has been completed. For a location dependent situation, by giving the current location of the user as well as the speed, the time when this user will move to another location can be computed and determined. However, before the whole answering process ends, after getting the results from the server, a new cache is inserted into the local cache memory for future use (Ren & Dunham, 2000).

FUTURE TRENDS

There have been several researches done in the area of semantic caching in a mobile environment. The usage of semantic caching has obviously provoked extensive complicated issues. There are still many limitations of the nature of the mobile environment that generate a lot of attention from research in finding a good cache strategy that is specifically designed for use only in the mobile computing environment.

In the future, it is critical to design algorithms for using semantic caching to cope with the low bandwidth of the wireless channel as well as the vulnerable disconnection problem. Applying semantic caching to several different scenarios of location dependent queries, including in a multiple cell environment and a cooperative strategy between multiple clients, is also beneficial. Caching management strategies, which focus on semantic mechanisms that are designed for real mobile queries that will utilize space more efficiently, are also needed in the future.

Besides these, further investigation on other cache replacement policies as well as granularities issues, which exploit the semantics of the caching data in terms of size or access pattern, is desirable. Employing the semantic caching into a broadcasting environment, which reduces the size of a broadcast cycle and improves the tuning time, is necessary.

CONCLUSION

Although there are significant increases in the popularity of mobile computing, there are still several limitations that are inherent, be it the mobile device itself or the environment itself. These include limited battery power, storage, communication costs, and bandwidth problem. All these have become present challenges for researchers to address.

In this article we have described issues of caching in a mobile environment with its advantages and disadvantages focusing mainly on semantic caching. We include adapting semantic caching in both location and non-location dependent queries. This article serves as a valuable starting point for those who wish to gain some introductory knowledge about the usefulness of caching, particularly semantic caching.

KEY TERMS

Caching: Techniques of temporarily storing frequently accessed data designed to reduce network transfers and therefore increase speed of download

Cache Management Strategy: A strategy that relates to how client manipulates and maintains the data that has been cached in an efficient and effective way.

Location-Dependent Queries: A type of query whose results depend on the location of the issuer whereby when the client moves around the results may change accordingly.

Mobile Computing: Mobile computing implies wireless transmission, which enables users to use a computing device while in transit anywhere, anytime.

Semantic Caching in a Mobile Environment

Mobile Query Processing: Database query is being sent by mobile users through wireless communication and being processed by a station server.

Semantic Caching: A type of caching technique that has content-based reasoning ability.

INTRODUCTION

Location-based services (LBS) are considered the most popular mobile telecommunication services besides the traditional ones, for example, SMS and MMS. They are believed to constitute the *killer applications* for next generation mobile networks, since they enable adaptive location-driven content provision. Such services can be provided wherever the location of mobile users can be determined. Nowadays, there is a wide range of methods for estimating the location of users in both *indoor* (i.e., in-building areas) and *outdoor* environments (Schiller & Voisard, 2004).

Outdoor LBS are more developed than their indoor counterparts due to the existence of positioning and topological information systems, GPS (global positioning system) and GIS (geographic information system) respectively. However, almost all known LBS provide their functionality irrespectively of the actual *user context*, which may consist of user's location, physical capabilities, and/or cognitive status. Furthermore, most services ignore the semantic information of the spatial elements (e.g., stairs, elevators, and physical obstacles), other than the Euclidean distance.

In this article, we describe issues related to the development of *intelligent* and *human-centered* LBS for indoor environments. We focus on the navigation service. Navigation is probably the most challenging LBS since it involves relatively complex algorithms and many cognitive processes (e.g., combining known paths for reaching unknown destinations, minimizing path length). With the proposed system, we try to incorporate intelligence to navigation services by enriching them with the semantics of users and navigation spaces. Such semantic information is represented and reasoned using state-of-the-art semantic Web technologies (Berners-Lee, Hendler, & Lassila, 2001).

BACKGROUND

LBS offer location-aware content provision. Apparently, a key enabler of LBS is the positioning infrastructure. As far as outdoor environments are concerned, the most commonly used positioning method is GPS, which provides spatial information with high accuracy and availability at low cost. On the other hand, there exist many alternative positioning solutions for indoor spaces, but with none of them having been standardized yet. Among these solutions are: WLAN (wireless local area network) triangulation, dead-reckoning techniques (implemented with accelerometers and digital compasses), RFID (radio frequency identification) tags, and infrared/ultrasound beacons. The authors in Hightower and Borriello (2001) provide an extensive survey of indoor positioning techniques. A basic assumption for developing our system is that we have an indoor positioning system at our disposal. Such system can locate users with "adequate" accuracy.

This article deals with indoor navigation. Former indoor navigation research focused on robot navigation. As the positioning systems have matured, more effort has been put on developing indoor navigation services for pedestrians, such as museum guides aiding the sightseeing of tourists. An indicative system in this category is CyberGuide (Abowd, Atkeson, Hong, Long, Kooper, & Pinkerton, 1997). Another, more recent and more sophisticated, navigation system is Navio (Gartner, Frank, & Retscher, 2004). Navio aims at developing a route modeling ontology, which provides both outdoor and indoor routing instructions to humans by identifying and formally defining the criteria, the actions and the reference objects used by pedestrians in their reasoning for routes. However, Navio research emphasizes on location fusion (i.e., the aggregation of location information from multiple sensing elements) and user interfaces and, thus, does not contribute significantly to the issue of path selection. This latter issue is of utmost importance for human-centered LBS,

but it is often ignored or handled in trivial ways. In general, such systems focus on the path presentation to users and on the hardware/positioning infrastructure used.

Additionally, some systems have been developed for addressing the special needs of certain user categories, such as navigation for blind people. Such systems, however, lack a holistic approach to the navigation process. This means that their approaches are not considered general enough to address the whole range of potential application requirements. This drawback of existing solutions, as well as their deficiencies that will be identified in the following subsections, have motivated the present research in user- and space-modeling, path selection and navigation algorithms.

Navigation Algorithms

Since navigation is a path-searching algorithmic problem, the decision on the *path-searching* algorithm used is vital for the quality of the provided service. Most of the existing navigation systems, either indoor or outdoor, make use of *traditional* shortest path algorithms (e.g., Dijkstra, A-star), thus, recognizing the minimization of Euclidian distance as the only objective in the path selection process. However, such approach overlooks the significance of other objectives more relevant to the context of the user. Hence, significant research on that topic has identified that pedestrian navigation needs more sophisticated and human-centered path-searching algorithms. Authors in Duckham and Kulik (2003) have proposed the “simplest path algorithm.” In this algorithm, the selected path is the one with the lowest possible complexity in navigation instructions. This work belongs to the category of approaches that introduce modifications of well-known graph routing algorithms like the aforementioned shortest path algorithms. A rather similar approach is discussed in Grum (2005), where the proposed navigation algorithm computes the “least risk path.” The term *risk* refers to the possibility of the user getting lost.

The aforementioned algorithms, although providing more “intuitively-correct” paths than the conventional shortest paths algorithms, do not take into consideration the user semantics, as dictated by the modern design paradigm “Design for All” (European Institute for Design and Disability, 2005) (a.k.a., inclusive design). This paradigm promotes the design and implementation of services and products so that they can be used by any user, without any further adaptation. The implementation of such a paradigm, in the LBS domain, would lead to services that can be consumed (in an optimal way) by any user, regardless of her special characteristics.

Spatial Models and Ontologies

The quality of *path-searching* algorithms also depends on the spatial modeling of the navigation space. Many approaches

have been proposed for spatial modeling with different data representations and expressiveness. Specifically, *geometric* models represent the navigation space using a certain coordination system and mainly support geometric queries (e.g., where is the nearest coffee machine?). On the other hand, *symbolic* models represent the navigation space through sets of symbols (i.e., names) and inter-symbol relationships capturing the topological semantics (e.g., part-of and overlaps spatial relations). Finally, *hybrid* models are combinations of the two former categories, aiming at maximizing the overall expressiveness of the spatial model. An interesting comparison of spatial models is presented in Leonhardt (1998). As far as indoor navigation is concerned, only a few researchers have proposed practical, yet expressive, models. To our opinion, the most important is presented in Hu and Lee (2004). It is a hybrid model, which represents the space as semantic hierarchies of “locations” and “exits” that also carry geometric information (e.g., coordinates).

The use of semantics-based spatial models results in what has been called *semantic location-based services*. However, we claim that actual semantic LBS should not only exploit semantically enriched spatial models (symbolic or hybrid), but also take into consideration the *navigation context* (i.e., user context and instantiation of spatial model). Hence, we propose a refinement of the term *semantic LBS*, or better, *human-centered LBS*, so that it supports the following requirements:

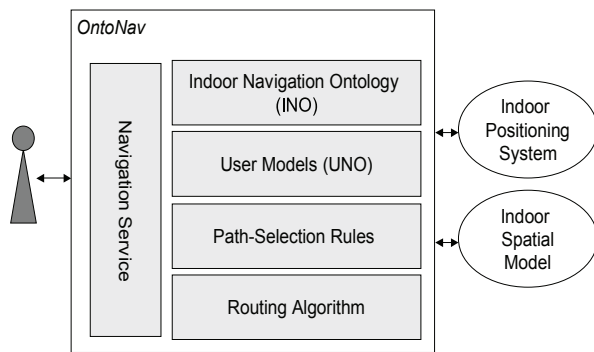

- Awareness of spatial semantics (e.g., hybrid model)
- Awareness of navigation context
- Adherence to the Design-for-All paradigm
- Reaction to dynamic user or space status changes

As will be shown in a following section, such services can be built with a knowledge-based system architecture. This architecture exploits knowledge representation methods to model the various components, and reasoning/inference techniques in order to implement the actual path selection process. The most popular and practical technology for representing models is the ontologies. Ontology is defined as “an explicit and formal specification of a shared conceptualization” (Studer, 1998, p. 185). In other words, it is a method for describing models of application domains that can be understood by machines. Knowledge reasoning is the process of inferring new implied knowledge from explicit knowledge assertions. Such reasoning can be based either on logic-based methods (i.e., resolution) or production rules (Brachman & Levesque, 2004).

SEMANTIC INDOOR NAVIGATION

In this article, we propose a framework for human-centered semantic indoor navigation, which meets the aforementioned

Figure 1. *OntoNav architecture*

requirements. Such framework, named *OntoNav*, is based on a novel combination of practical ontology-based knowledge representation and reasoning technologies, as well as Euclidian path-searching algorithms. The architecture of the implemented navigation system is illustrated in *Figure 1* and can be decomposed to the following basic components:

Navigation Ontology: INO

This spatial ontology, named indoor navigation ontology (INO), describes the basic spatial and structural concepts of indoor environments, as well as the relationships between them. Specifically, it provides a semantic spatial model for reasoning about the selected paths. An extract of the INO taxonomy is depicted in *Figure 2*, illustrating a hierarchy of path elements.

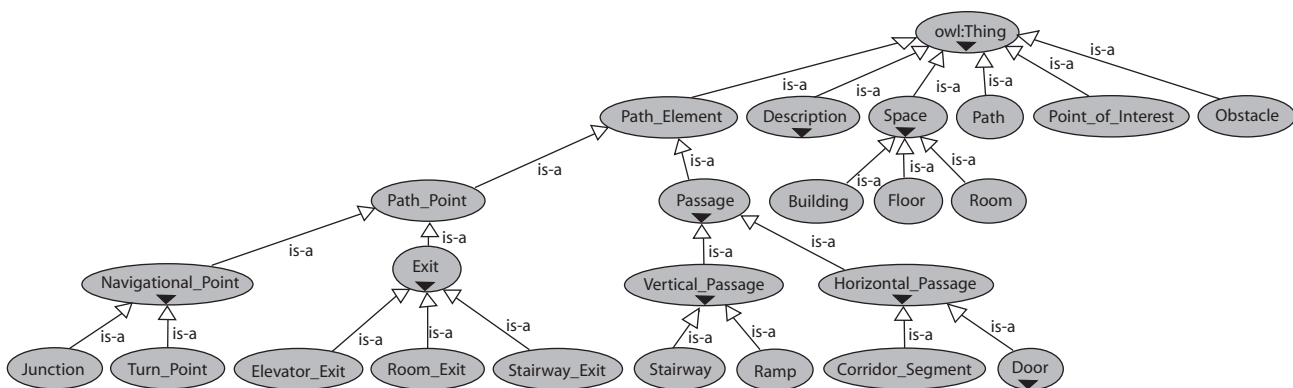

User Model: UNO

In order to describe user context (i.e., profile, capabilities, constraints and navigational preferences), we have developed a minimalistic ontology, named user navigation ontology (UNO). The concepts of such ontology represent user navigation classes. Hence, each user profile is classified into one or more navigation classes according to her characteristics. Indicative user classes are: *HandicappedUser* (users who cannot walk), *BlindUser* (users who cannot see), and *LazyUser* (users who always prefer elevators than stairs). Both INO and UNO have been modeled through the Web Ontology Language-OWL (McGuinness & Harmelen, 2004).

Path-Selection Rules

The path-selection process is performed through sets of production rules. The definition of such rules involves both the spatial semantics (expressed through INO) and the user semantics (expressed through UNO). The rules are applied to the INO instances in order to assert and infer which paths are considered accessible and appropriate for each user request. Moreover, the path-selection rules are further analyzed to *physical navigation rules*, *perceptual navigation rules* and *navigation preferences*. Actually, the physical navigation rules are applied first, in order to discard any paths that are not physically accessible by the user. The *perceptual navigation rules* are related to the user’s cognitive status (e.g., age, education). Finally, paths that are proposed regarding the user preferences (e.g., paths containing elevators) are identified after the application of the navigation preferences. The rules are described through the Semantic Web Rule Language (SWRL) (Horrocks et al., 2004).

Figure 2. *An extract of Indoor Navigation Ontology*

Navigation Service

This service can be defined as the interface between the system and its users. It accepts navigation requests and responds with the optimal path, if any. Path optimality depends on several factors, such as suitability for current user context and length of the selected paths.

Indoor Spatial Model

The INO instances are created by a geometric representation of the indoor topology. Such geometric data may reside in a GIS as building blueprints and are transformed to actual spatial ontology instances. In our framework, it is assumed that such instances are available, (i.e., we do not deal with such data transformation issues).

Routing Algorithm

This algorithm is a central element of the framework and, in combination with the path-selection rules, is responsible for the determination of the optimal path between two given endpoints. The algorithm used in our system was a *k-shortest paths searching algorithm*. Similarly to the approach in Wu and Hartley (2004), we believe that such algorithm facilitates more flexible path selection by enabling us to incorporate additional path finding restrictions, imposed by the user profile. The main idea is that the shortest path may not be

the optimal path, in general. Thus, we compute *k* shortest paths, since path length is always important, although it may not always be the primary selection criterion. More details on the adopted algorithm can be found in Yen (1971).

Indoor Positioning System

OntoNav symbolically locates the users in the navigation space according to the spatial model described by INO. The positioning infrastructure may vary from infrared/ultrasound beacons to WLAN triangulation or dead-reckoning techniques. It is important to note that since the positioning accuracy may be more fine-grained than the location granularity, an approximation error may be introduced in the estimated location of the user. However, this error does not significantly affect the quality of navigation.

Description of System Workflow

The end-to-end functionality of the system is depicted by means of flowcharts in the following figures. Figure 3 depicts the system initialization process, in which the spatial ontology instances are loaded. Figure 4 illustrates the workflow that takes place upon a navigation request from a user. Initially, the user registers her profile to the system, and the destination she wishes to reach. Her current location is determined through the indoor positioning system. If the user has not registered to the system again, then her profile

Figure 3. System initialization

Figure 4. System workflow after a user navigation request has been received

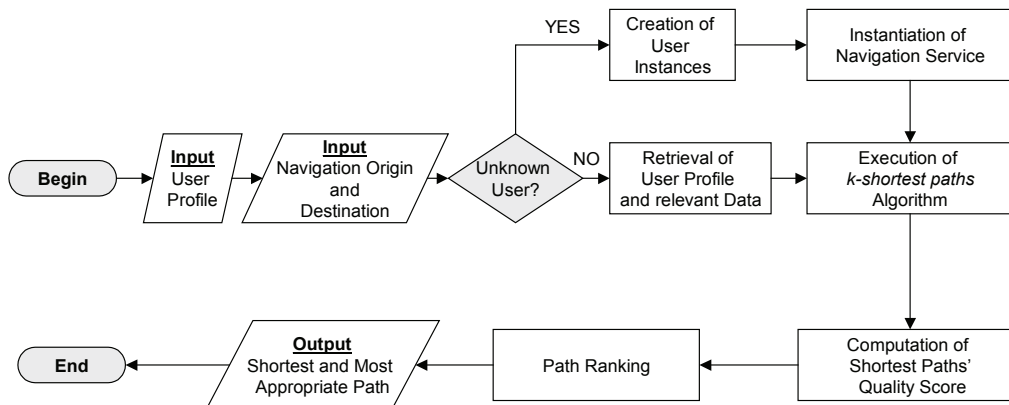

Figure 5. The workflow for the creation of a new navigation service instance

is instantiated in the UNO ontology and a new Navigation Service instance is created. Such an instance mainly consists of the topology-graph associated with the specific user. It should be reminded that this graph is created from the INO instances, after the application of the physical navigation rules. Hence, the graph contains all the path elements that are accessible by that user. Such graph is the basic input to the next task, as illustrated in Figure 4, where the *k-shortest paths* between the user and the destination location are computed. Subsequently, for each path, a total *quality score* is calculated, denoting to which extend a path satisfies the perceptual navigation and preference rules. The path with the highest score is the final selected path that is proposed to the user.

The task that refers to the creation of a new navigation service instance is very important, since it involves the most algorithmic and computational parts of the whole system functionality. In Figure 5, one can see that the UNO instances (i.e., user profile) are the main inputs to that task. Those instances pass through a reasoning engine, which results in the user classification with respect to the UNO classes. Subsequently, all types of rules are applied to the INO and UNO knowledge bases. Specifically, the physical navigation rules “mark” the INO instances for further exclusion from the process, whilst the perceptual navigation rules and navigation preferences reward or penalize certain INO instances pertaining to the specific user. The unmarked elements are used for the creation of the user-accessible topology graph, which is also stored in the user profile for future use.

FUTURE TRENDS

The introduction of knowledge engineering technologies in traditional services and applications is expected in the following years. This “paradigm shift” in system design and implementation is merely “pushed” by initiatives like inclusive design and universal access (Stephanidis & Savidis, 2001). However, there are still a lot of open issues before such approach can be massively adopted in commercial systems. One of the greatest challenges is the common definition and adoption of semantic application domain models (i.e.,

ontologies). In our case, INO and UNO ontologies should have been standardized in some way, so that LBS providers could rely on their specifications in order to develop interoperable semantic navigation services. Moreover, ontological engineering is a very difficult and time-consuming process. Towards simplifying it, there is a great deal of past and current research in developing methodologies and tools for creating, managing, merging, and, updating ontologies (Gomez-Perez, Fernandez-Lopez, & Corcho, 2004). In addition, more and more research projects have commenced to design ontologies for specific application domains. Their attempts, if coordinated accordingly, can result in the creation of an extensible “ontology repository” usable by anyone.

The proposed approach of designing navigation services directly involves human factors. Hence, another issue is the human evaluation of such systems, apart from their performance evaluation. Since semantic LBS are (according to their definition in this article) human-centered, user acceptance and quality assessment are considered as prerequisites before launching them in real-world systems. The parameters that affect the path-selection process should be adjusted carefully by real users prior to system deployment. In the future, we expect to see more research in user evaluation of innovative personalized mobile services. Pervasive computing research has already paved the way for such evaluation frameworks (Scholtz & Consolvo, 2004), but still much progress has to be achieved.

CONCLUSION

This article discusses spatial modeling and processing issues regarding a human-centered navigation service. Such service is mainly targeted to people with navigational limitations, and pursues the vision of context-aware services for ubiquitous computing environments. The main goal of this work is to creatively integrate semantic knowledge engineering technologies with traditional location-based services. In our view, such integration is considered a key enabler for next-generation mobile services that focus on providing advanced user experience.

KEY TERMS

Design for All: A design approach that aims at constructing products and services in a way that no user is excluded from using them, independently of her capabilities or limitations.

Indoor Positioning: The determination of an (moving) object's location in an indoor environment.

k Shortest Paths Problem: The identification of a set of paths $\{p_1, \dots, p_k\}$ between two endpoints s and t (origin and destination, respectively) that satisfy the following criterion: $\text{length}(p_{n-1}) \leq \text{length}(p_n)$, for every $n \leq k$, and p_1 is the shortest path between s and t , as computed by a traditional shortest path search algorithm (e.g., Dijkstra).

Navigation: Q service that finds a path between two locations (origin and destination) and gives appropriate instructions in order for the user to successfully follow it and reach the desired destination.

Ontology: A model representing the main entities and their relationships within a domain of discourse. Although similar to other modeling formalisms, ontologies (and especially those based on subsets of logic) can be more expressive and can represent complex restrictions and axioms that govern the domain entities.

Reasoning: The computational procedure that infers new knowledge from explicitly asserted knowledge (expressed through statements and/or rules). Such new knowledge may

be of the form of new statement assertions or may just give extra information about the consistency and validity of the existing statements.

Semantic Web: the evolution of the current WWW in a way that it is also machine-understandable in addition to being human-understandable. This evolution is based on the annotation of data with explicit semantics (i.e., metadata), which can describe purpose and attributes and classify it according to some knowledge models (i.e., ontologies).

Sensor Data Fusion for Location Awareness

Tei-Athens, Greece

INTRODUCTION

In pervasive computing environments, location is essential information as it is an important part of the user's context. Applications can exploit this information for adapting their behavior. Such applications are termed location-aware applications (e.g., friend-finder, asset tracking). The location of a user is derived by various positioning methods. Especially for indoor positioning, different approaches have been proposed. The majority of indoor positioning systems rely on different technologies, usually of the same kind, like wireless LAN signal strength measurements (Bahl & Padmanabhan, 2000), IR beacons (Sonnenblick, 1998), or ultrasonic signals.

At this point we will quote the definitions of accuracy and precision, the most important characteristics of a positioning system:

- Accuracy denotes the distance within which the system has the ability to locate a user, for example, 1-10 meters.
- Precision denotes the percentage of time the system provides a specific accuracy, for example, 80% of the time the system provides accuracy 1-5 meters (or else accuracy less than 5 meters).

The accuracy and precision are tradable, and it is clear that if we need less accuracy, the precision that the system provides increases.

During the past few years, several location systems have been proposed that use multiple technologies simultaneously in order to locate a user. One such system is described in this article. It relies on multiple sensor readings from Wi-Fi access points, IR beacons, RFID tags, and so forth to estimate the location of a user. This technique is known better as *sensor information fusion*, which aims to improve accuracy and precision by integrating heterogeneous sensor observations. The proposed location system uses a fusion engine that is based on dynamic Bayesian networks (DBNs), thus substantially improving the accuracy and precision.

BACKGROUND

Indoor positioning systems have been an active research area since the Active Badge Project (Want, Hopper, Falcao, & Gibbons, 1992). Since then, several indoor location systems have been proposed. A large number of them use IEEE 802.11 (Wi-Fi) access points to estimate location. RADAR (Bahl & Padmanabhan, 2000) is a radio-frequency-based system for locating users inside buildings. It operates by recording and processing received signal strength (RSS) information. The RSS method is used also by the commercial system Ekahau (Ekahau Positioning Engine).

The Cricket Location Support System (Nissanka, Priyanka, & Balakrishnan, 2000) and Active Bat location system (Harter, Hopper, Steggle, Ward, & Webster, 1999) are two systems that use the ultrasonic technology. Such systems use an ultrasound time-of-flight measurement technique to provide location information. They provide accurate location information, but also have several drawbacks like poor scaling and a high installation and maintenance cost. For these reasons they are rather inaccessible to the majority of users.

Another category of location systems uses multiple sensor readings (Wi-Fi access points, RFIDs) and sensor fusion techniques to estimate the location of a user. Location Stack (Graumann, Lara, Hightower, & Borriello, 2003) employs such techniques to fuse readings from multiple sensors. Another similar approach is described in King, Kopf, and Effelsberg (2005). The drawback of these systems is their inability of supporting mobile devices with limited capabilities (CPU, memory) as the location estimation is performed at the client side; hence devices incur the cost of complex computations.

The location estimation system described in this article relies on data from sensors to determine the location of a user. Our work differs from previous approaches in various aspects. Firstly, we use dynamic Bayesian networks for location inference. By using DBNs, we obtain better location estimation results. Along with heterogeneous sensor data that are processed in real time, we can also "fuse"

past information about the user. Secondly, our system can support a variety of mobile devices (PDAs, palmtops) with low computing power. Location estimation takes place in a server residing in the fixed network infrastructure. Mobile devices are just transmitting observations from sensors to this server and receive the location estimations. Finally, the adopted system architecture has the advantage of easy management and scalability (e.g., the installation of a new access point is completely transparent to users).

POSITIONING TECHNOLOGIES

In this section we present the principal technologies that are used for indoor positioning and describe their characteristics. We also discuss a categorization of the devices.

The most important wireless LAN standard today is the IEEE 802.11 (Wi-Fi) that operates in the 2.4 GHz ISM band or 5GHz band. This technology is used by several positioning systems that measure the signal strength from access points (RSS) to locate a user.

Radio frequency identification (RFID) is the technology used for security tags in shops, ID cards, and so forth. Tags are powered by the magnetic field generated by a reader and transmit their ID or other information. Such tags do not require any battery and can be deployed in a building to detect object and person passing or proximity.

Infrared (IR) beacons are programmable devices that periodically emit their unique ID in the IR spectrum. Usually the range of these beacons is approximately 10-20 meters, and the infrared receiver should have line of sight with the beacon in order to receive its ID.

Ultrasonic signals are vibrations at a frequency greater than 20 kHz. The devices used to receive and transmit ultra-

sonic signals are called transducers and are commonly used for distance measuring. In general, they integrate a sensor that can receive or transmit an ultrasonic signal and another RF transmitter/receiver which is used for synchronization.

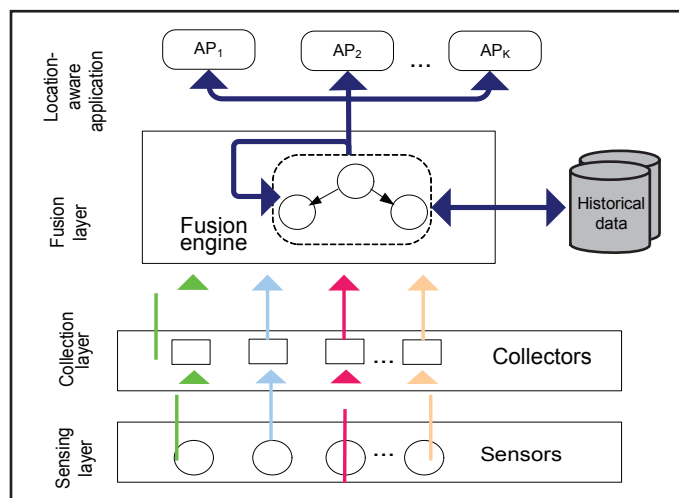

All the previously mentioned devices (elements) of different technologies (access points, beacons, tags, etc.) can be found in indoor environments either deployed in the building or attached to mobile devices. Some of them emit information, and others detect (read) information. According to their position and functionality, the elements can be categorized as follows:

- Portable elements are those carried by users or attached to their mobile devices (RFID tags, Wi-Fi adapters)
- Infrastructure elements are those attached to the building (Wi-Fi access points, IR beacons, RFID tag readers).
- Active elements (sensors) are those which detect a phenomenon or take measurements (RFID tag readers, Wi-Fi adapters).
- Passive elements are those that emit information which is detected by active elements. Wi-Fi access points, IR beacons, and so forth fall into this category.

SYSTEM ARCHITECTURE

The architecture of the proposed location estimation system is organized into three layers: the sensor layer, the collection layer, and the fusion layer. Figure 1 illustrates the generic architecture of the proposed system. In the same figure are also depicted location-aware applications which exploit the location information and databases where the personal profile of users and historical data about their behavior are stored.

Figure 1. Architecture of the indoor location estimation system

The layered approach aims to facilitate effortless inclusion of new elements in order to improve the accuracy and the precision offered by the system. In the following paragraphs we provide a more detailed presentation of each layer.

Sensing Layer

This is the lowest layer of the architecture, comprising sensors of different technologies. Sensors are attached either to the user's mobile device (portable active elements) or to the building (infrastructure active elements). Below, we briefly discuss these two categories.

Portable Sensors

A Wi-Fi adapter can measure the received signal strength (RSS) from a Wi-Fi access point (passive infrastructure element). Similarly, the IR port of a handheld device or a laptop is used as a reader for infrared transmissions from IR beacons that are wall-mounted.

Infrastructure Sensors

RFID tag readers belong in this category. Such readers detect an RFID tag and read its ID when the latter is in proximity. Users can carry RFID tags which have unique IDs. Furthermore, ultrasonic devices, which estimate the distance of a user from a known point, also belong in this category.

Collection Layer

This layer consists of software components called collectors. The role of a collector is to interact with the appropriate sensor and collect measurements or events. Sensors may produce raw data in a variety of formats according to their type. Hence, the output of a Wi-Fi adapter is a stream consisting of RSS measurements from access points; IR and RFID readers generate a stream of proximity events. When such raw data arrive at the collection layer, a preprocessing procedure is performed as described next.

Preprocessing of Raw Data

Assume that a new RSS measurement arrives from a Wi-Fi adapter. Then, the appropriate collector (Wi-Fi collector) quantizes this on N discrete levels (values): $SI, S2 \dots SN$. If, for example, the value from the access point with ID $AP2$ is between -70 dBm and -60 dBm, the value “ SI ” is assigned to this infrastructure passive element. It should be noted that the number N of quantization levels depends mainly on the thresholds (lower and higher) of the access point's transmitted power and the environmental conditions (noise, etc.).

An IR beacon collector, during this preprocessing procedure, operates differently. The two possible states of an IR beacon are: Visible and Not_Visible. Assume that an IR receiver (portable active element) is in the range of the IR beacon with ID IRB3 (infrastructure passive element). This situation will cause a proximity event which will be detected, and thus the collector sets the IRB3 to the value “Visible.” An RFID tag reader collector's functionality is similar to the IR beacon collector's, as RFID tag readers detect proximity events, too.

Tuple Forming

After the preprocessing of raw data from the sensing layer, each collector forms a tuple of the type:

$(user_ID, IE_ID, value)$

where $user_ID$ is the unique identifier of a user, IE_ID is the unique identifier of an infrastructure element, and $value$ is a measurement or an event.

A Wi-Fi collector may form the following tuple:

$(userA, API, SI)$

which denotes that the Wi-Fi adapter (portable active element) of the mobile device of $userA$ measures the RSS from access point API (infrastructure passive element), and the (quantized) RSS has value SI .

A possible tuple generated by a RFID tag reader collector would be:

$(userB, RFRI, Visible)$

which denotes that an RFID tag (portable passive element) worn by $userB$ (or attached to his/her mobile device) is in proximity of RFID tag reader with ID $RFRI$.

These tuples are then forwarded to the upper layer where a location estimation procedure is invoked for each user. In the next section, we will show how such values are exploited for location estimations.

Fusion Layer

As mentioned in the introduction, the fusion engine is based on a dynamic Bayesian network, which is used for location inference. Below, we briefly discuss the basic concepts of Bayesian and dynamic Bayesian networks and discuss the adoption of DBNs in the proposed system. We assume that the reader is familiar with the theory of Bayesian and dynamic Bayesian networks. For a more complete introduction, the reader is referred to Jensen (1996) and Mihajlovic and Petkovic (2001).

Figure 2. (a) A Bayesian network (BN) showing four random variables and their dependencies. (b) A dynamic Bayesian network (DBN) showing dependencies between variables in different time-slots.

Figure 3. DBN for location estimation representing the dependencies between random variables at different time slots

Bayesian and Dynamic Bayesian Networks

Bayesian networks (BNs) present a statistical tool that has become popular in the areas of machine learning. They are well suited for inference because of their ability to model causal influence (cause-effect) between random variables.

A BN (Figure 2(a)) consists of two parts. The first part is a directed acyclic graph (DAG), representing random variables as nodes and relationships between variables as arcs between the nodes. If there is an arc from a node A to a node B , it is considered that B is directly affected by A (A is the parent of B). Each node is conditionally independent from any other node given its parents.

The second part of a BN is a probability distribution associated with each graph node. This describes the probability of all possible outcomes of the variable given all possible values of its parents. The parameters of this probability distribution would be estimated using observed data (Heckerman, 1995). The DAG and probability distributions together define the joint probability distribution.

A DBN extends the static BN by modeling changes of stochastic variables over time. Random variables in a DBN are also affected by variables from previous time slots (see Figure 2(b)). For simplicity, it is assumed that the parents of a node are in the same or in the previous time slot (First Order Markov Chain).

DBN Integration in the Location System

The DBN that is used in our location estimation system is depicted in Figure 3.

The random variables are:

- the location L of the user, which may take values from a set of K locations $\{L1, L2, \dots, LK\}$;
- the N infrastructure elements $IE1, IE2, \dots, IEN$. The range of values of those random variables depends on the type of element. Hence, an access point may take a value from the set $\{S1, S2, \dots\}$ and an RFID tag reader from the set $\{Not_Visible, Visible\}$.

The random variable L at time t , $L^{(t)}$, is directly affected by the random variable L at time $t-1$, $L^{(t-1)}$, so $L^{(t-1)}$ is the cause and $L^{(t)}$ is the effect. This is a reasonable assumption as the location of a user is dependent on his/her previous location. Also, the infrastructure elements at time t are affected by location at time t , $L^{(t)}$; the location of the user affects the value of an infrastructure element (e.g., the signal strength measured from a Wi-Fi access point depends on the location of the user).

The probability distributions that are associated with each node of the DBN are estimated with Bayesian Network learning techniques. In particular, for every infrastructure

element (IE_1, IE_2, \dots, IEN) , we estimate the probability distribution $P(IE_i | L)$. This can be achieved by taking into account the fixed positions of infrastructure elements, the indoor propagation models of RF and IR signals, the time of flight of ultrasonic signals, and so forth. A simpler technique of learning that that we have adopted for our system is the method of sampling (signal, events) at every location for determining the values of infrastructure elements and the frequency of appearance of these values. According to this frequency we are able to form the probability distributions. In Table 1 we present a probability distribution of a passive infrastructure element (Wi-Fi access point) with ID *API*.

Furthermore, the probability distributions $P(L^t | L^{t-1})$ for location transition can be generated according to the structure of the building, the distance between two locations, and the time required by a mobile user to cover this distance (see Table 2). It is important to note here that the determination of probability distributions takes place once, at system initialization (training phase).

Location Inference Queries

After having structured the DBN of the fusion engine, we can use it for location estimations. A location inference query might be: “Where is user *X* given his/her previous location and given the values (observations) of infrastructure elements associated with this user?” To answer this, we calculate for each of the *K* locations $\{L1, L2, \dots, LK\}$ the following conditional probability:

$$P(L^t | L^{t-1}, O^{(t)}) \tag{1}$$

which is the mathematical representation of the location inference query and denotes the probability of being at location L^t at time *t* (the requested location) given the already known value of the previous location L^{t-1} and given the values of the *N* infrastructure elements at time *t*, $O^{(t)}$. For simplicity reasons we write:

Table 1. A possible probability distribution for access point with identifier *API*. It can be shown that the probability $P(API=S2 | L=L1) = 0.3$.

| | | | |
|-----------|------------|------------|-----|
| | <i>L1</i> | <i>L2</i> | ... |
| <i>S1</i> | 0.5 | 0.0 | ... |
| <i>S2</i> | 0.3 | 0.8 | ... |
| ... | ... | ... | ... |

$$\{IE_1^{(t)}, IE_2^{(t)}, \dots, IE_N^{(t)}\} = O^{(t)} \tag{2}$$

Equation (1) can be converted to the following equation:

$$P(L^t | L^{t-1}, O^{(t)}) = \frac{P(L^t, L^{t-1}, O^{(t)})}{P(L^{t-1}, O^{(t)})} \tag{3}$$

Taking into consideration that each node of our DBN is conditionally independent from any other node given its parents, we can compute the joint probability that appears in the numerator of (3). Also, as the denominator of (3) does not depend on the random variable L^t , it can be treated as a normalizing constant. Hence, the following equation is derived:

$$P(L^t | L^{t-1}, O^{(t)}) = \frac{P(L^t | L^{t-1}) * P(O^{(t)} | L^t)}{\sum_{i=1}^K P(L_i^t | L^{t-1}) * P(O^{(t)} | L_i^t)} \tag{4}$$

The probability distributions $P(IE_i | L)$ and $P(L^t | L^{t-1})$ are known from the training phase, so we can now compute the probabilities for each location $\{L1, L2, \dots, LK\}$. Whenever a probability on the numerator of (4) is equal to zero, it is unnecessary to compute the final probability, as it is equal to zero, too. Thus, the calculations are pruned and the overall computation is optimized. The problem of location estimation is to find the location L_i that maximizes the probability.

$$\max \{P(L_i^t | L^{t-1}, O^{(t)})\} \tag{5}$$

The location with maximum probability is stored in the database and the profile of the user is updated. Moreover, the location information is forwarded to location-aware applications for the provision of LBS services. After that the system proceeds to the next location estimation in light of the current observations and the previous estimated location of the user.

Table 2. A possible probability distribution for location transition. The probability of transition from *L1* to *L2* is $P(L^t=L2 | L^{t-1}=L1)=0.1$.

| | | | |
|-----------|------------|------------|-----|
| | <i>L1</i> | <i>L2</i> | ... |
| <i>L1</i> | 0.5 | 0.0 | ... |
| <i>L2</i> | 0.1 | 0.8 | ... |
| ... | ... | ... | ... |

FUTURE TRENDS

Currently we are working on two issues which will have a direct impact on a system's performance and scalability. The first issue is the adoption of a distributed architecture for the system. In this distributed architecture, the building is divided into regions. For each region there is one server responsible for location estimations. Servers of adjacent regions are interconnected in order to interchange information about the users (handovers between regions, etc). The distributed approach of the system will enhance its performance, improve its scalability, and make it more robust in case of server failures.

The second issue that we are working on is the use of "dead reckoning" techniques to improve the precision and accuracy that the system provides. A user's mobile device, which is equipped with an electronic compass and an accelerometer, could provide information about the direction and speed of its owner. Taking also into account the last known position of the user and the time elapsed since then, we can predict the current position and make more accurate estimations.

CONCLUSION

In this article we presented a layered fusion system architecture that exploits information from sensors of different technologies to estimate the location of a user. A key difference from similar systems is the use of dynamic Bayesian networks for location inference. The use of DBNs improves our estimations. Along with sensor information, we take into consideration the previous location of the user thus improving the performance. Additionally, the system supports a variety of mobile devices, including those with restricted computational capabilities (PDAs, etc.) as they do not incur the burden of complex location calculations.

KEY TERMS

Active Element (Sensor): One of the elements that detect a phenomenon or take measurements, like RFID tag readers and Wi-Fi adapters.

Bayesian Network (BN): A directed acyclic graph where nodes represent random (stochastic) variables, and arcs represent dependence relations among these variables.

Data Fusion: The combination of data derived from heterogeneous sources such that the resulting information is better than it would be if these sources were used individually.

Sensor Data Fusion for Location Awareness

Dynamic Bayesian Network (DBN): The extension of static Bayesian network by modeling changes of stochastic variables over time.

Infrastructure Element: One of the elements that are attached to the building, like Wi-Fi access points, IR beacons, and so forth.

Pervasive Computing: The integration of computation into the environment in order to offer a broad range of services to users.

Positioning: The capability to detect the location of a wireless device carried by a user (e.g., cell phone).

Service Delivery Platforms in Mobile Convergence

Christopher J. Pavlovski
IBM Corporation, Australia

Laurence Plant
IBM Corporation, Australia

INTRODUCTION

The demand for enriched multimedia content and entertainment services in mobile networks is being largely driven by the emergence of mobile broadband. A key problem for institutions attempting to capitalize on these new channels for service delivery is a capability to deploy many multimedia services rapidly and cost effectively. Traditional approaches in deploying new services have largely focused on discrete systems for each new service, often termed point solutions or silos. Recent emerging standards coupled with implementation constraints have led to the development of a more strategic approach. Such an approach involves the creation of a service delivery platform (SDP), capable of delivering a broad range of content and services from a host of multimedia applications. Several initiatives are attempting to lay the foundations for the architecture and framework for SDP solutions that support the emerging multimedia and entertainment services for mobile devices. Recent initiatives include platforms based upon the IP multimedia system (IMS), Parlay X, and IT standards-based designs.

A central characteristic of the SDP approach to mobile service delivery is the capability to supply numerous services to mobile users with observed reductions in elapsed effort to bring these services online; this also bestows cost reduction and speed to market. The benefits of a service delivery business model are applicable to the mobile operator, mobile customers, and external third-party developers. Customers are offered more services quickly, while third-party developers are able to focus on core capabilities of their intended service, collectively offering benefits in terms of time to market and reduced cost. The business benefits illustrate why this service delivery approach is recently gaining increased attention by mobile operators globally.

In this article we outline the fundamental principles of a service delivery platform and the business model to be addressed in mobile convergence. The emerging standards and reference architectures are presented, and their shortcomings are discussed. We outline the key requirements that a service delivery platform is expected to address from an operator perspective and summarize the key technol-

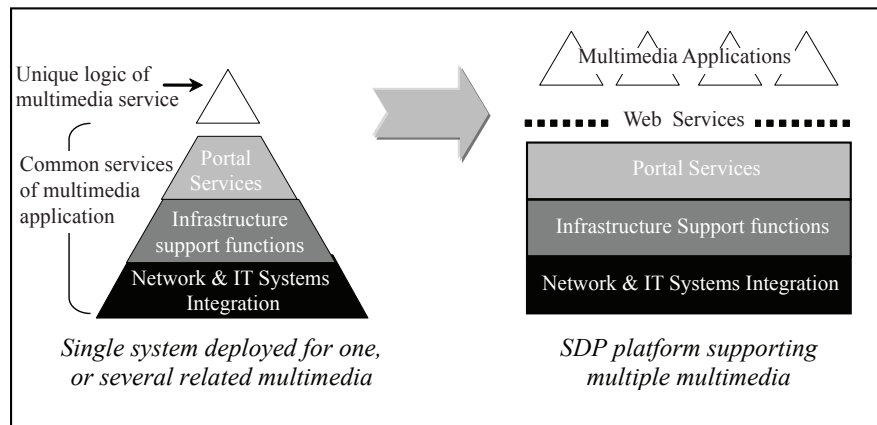

ogy design points. We also outline several future trends in how this emerging mobile technology is being deployed in various application scenarios. This involves straightforward mobile news services, through gaming, and complex interactive multimedia scenarios for the mobile device. These new services make further convergent demands upon three technology domains: the mobile network, IT systems, and the content/media sources.

BACKGROUND

Traditional approaches to deploying new multimedia services involve development of a discrete system to deliver one or a related set of services. This approach involves the development of several common functions required by the multimedia service. A recent trend by many operators globally is deployment of one common service delivery platform that supports multiple applications. The SDP is intended to contain all the common functions and services that a wide range of applications may require in order to deliver its service or function. Figure 1 illustrates the change in design philosophy (Pavlovski & Staes-Polet, 2005), where traditional deployment involves development of common delivery functions for each (or a related set of) multimedia service(s). The SDP approach transforms this by combining the common functions used by multimedia services into one platform that may be exploited by a range of multimedia applications.

Generally, the term convergence, when used in the context of mobile networks, is used to denote the rationalization of internetworking technologies and protocols. An additional form of convergence is related to the convergence of several operational and business domains—more specifically, the convergence of information technology systems, the networks, and media/content applications. Such integration imposes additional complexity, and the service delivery platform is ideally suited to address this type of convergence. This notion of convergence and applicability of the service delivery platform is recently gaining widespread attention, with several aspects of these emerging service delivery

Figure 1. Transformation to service delivery platform

platforms actively studied within research and industry (Hanrahan, 2006; Deckers, 2006; Kimbler, Stromberg, & Dyst Appium, 2006).

Mobile devices such as cellular phones, portable digital assistants, and tablets are becoming increasingly adorned with new services and media format. The fundamental business problem is to successfully integrate the network, information technology, and content applications in a unified manner that ameliorates costs for mobile operators, while supporting rapid deployment of new services in a cost-competitive manner.

SERVICE DELIVERY PLATFORMS

The method used to construct service delivery platforms is based on either a network-centric or an information technology centric (IT-centric) view of the problem domain. Platforms based on the Parlay X or IMS standards and frameworks may be categorized as network-centric; there are several notable examples (Pailer, Stadler, & Miladinovic, 2003; Akkawi, Schaller, Wellnitz, & Wolf, 2004; Magedanz, Witaszek, & Knuttel, 2005; Hanrahan, 2006). In contrast, several broader attempts have been discussed in the literature that apply an IT-centric design (Pavlovski & Staes-Polet, 2005; Hwang, Park, & Jung, 2004; Pavlovski, 2002b). These platform design styles largely reflect the heritage of the originating body. Moreover, IMS and Parlay X have emerged from network standards bodies, while the other works reflect practical IT experiences in building service delivery platforms for mobile operators.

Regardless of the approach taken, the underlying business model remains the same. In this section we first outline this business case, and then present the two strategies in addressing the service delivery model, outlining the benefits and shortcomings of each design viewpoint.

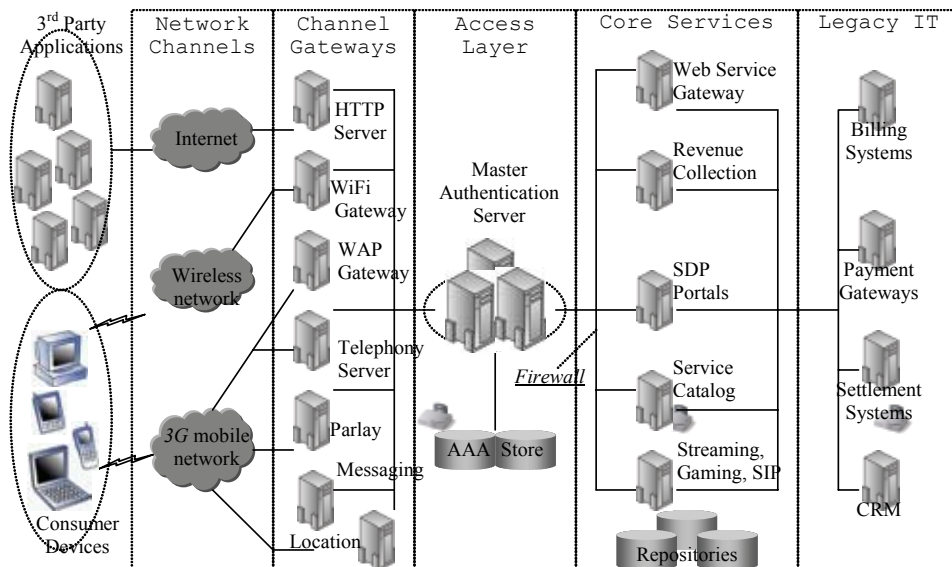

The Service Delivery Business Model

The principle advantage of an SDP for mobile operators is the ability to reduce the cost for deploying new services, while increasing the potential for generating revenue (Deckers, 2006). It is suggested that around one-third of the effort required to introduce a new service is attributed to developing the unique business logic of the service (Pavlovski & Staes-Polet, 2005). This means significant capability is common to a range of services and may be placed into a consolidated platform (see Figure 1). By combining this common functionality within the service delivery platform, the cost for building the platform is amortized since this may now be leveraged by several applications.

Since the SDP is deployed by a mobile operator, external third parties are then able to develop applications that deliver mobile content. The third-party developer may now focus on building the unique business logic associated with the intended multimedia service or content, and is able to reduce the costs by leveraging a set of common capabilities within the service delivery platform.

The service delivery business model for mobile applications has its origins with the *iMode* service (Pavlovski, 2002a), where the platform enables third-party application providers to deliver their content or service, via an iMode service platform, to mobile users. While the technologies have changed considerably over time, the service delivery business model has largely remained constant. The elementary model contains three entities: the mobile network operator, mobile customers, and external third-party developers. The mobile operator (alternatively this may be an MVNO) hosts the SDP and provides a set of common services to the external third-party developer from which to build multimedia applications. The mobile operator owns and maintains the relationship with mobile customers and is able to bring this consumer market to the external third-party developer. A key benefit

Figure 2. IT-centric service delivery platform

of this relationship is that once the platform is constructed, the mobile operator is able to rely on external third parties to build, at their expense, new services. The principle motivation for the external developer, which may be an enterprise, is marketing access to the large customer base owned by the mobile operator. The advantages for the mobile customer is ease of access, a greater range of multimedia and content services, with the payment mechanisms for such access generally viewed as secure (Devine, 2001).

IT-Centric Design Viewpoint

From an IT perspective the key principle is to abstract a range of network and IT services in a way that enables external third-party applications to be developed in a straightforward manner (Pavlovski, 2002a). Such an environment is sometimes referred to as a service creation environment (Schulke et al., 2005). Figure 2 illustrates the topology of an IT-centric SDP.

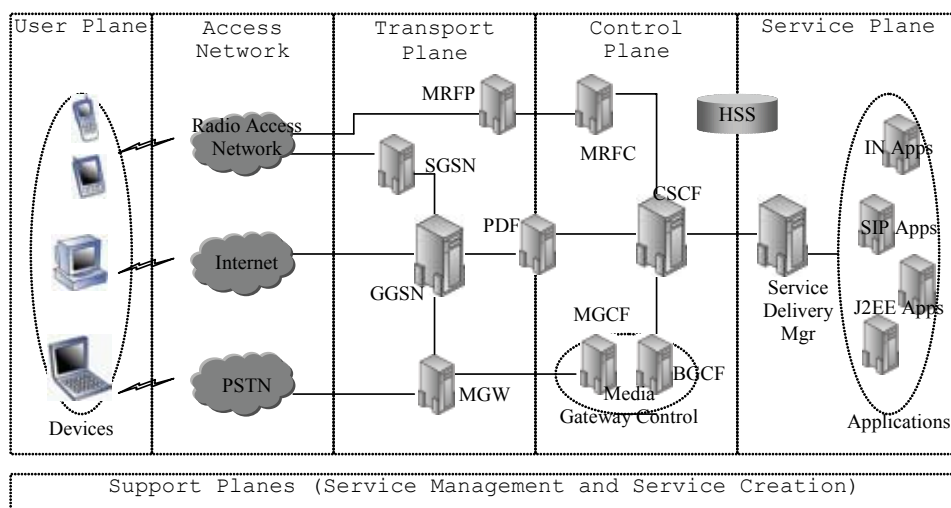

A layered architecture is a key theme of this design, with each layer abstracting the services provided on the preceding layer. This allows the technology to alter without impact to all components within the platform. At the outer most level, the customer and third-party applications reside, external to the platform; note that additional internal applications may also be deployed by the mobile operator. Customers gain access to services provided by multimedia applications via the SDP. The network channel layer defines the various networks used to deliver content and services to consumer devices. The remaining components of an SDP are deployed within the channel gateway, access layer, and core services layer. These layers are now described in more detail.

Channel gateways include those nodes responsible for integration and accessing various mobile and fixed networks. This includes the parlay gateway, messaging gateways (i.e., SMS and MMS), WAP gateways, and location and telephony servers. This underpins the IT-centric view of an SDP by viewing access to the network as an abstract service that the SDP builds upon. These network services are made available to application developers via the Web service gateway. Common services include the ability to send and receive messages, call control, initiating multimedia content downloads, and managing delivery receipt notifications for content delivery.

The access layer hosts the master authentication server. As the central security node, this component conducts authentication of customers accessing the SDP platform and also authenticates access by external third-party applications that make use of the published Web services. In order to provide customers with trusted access to third-party applications, a federated identity management scheme is typically employed, for instance as defined by OASIS. This means that a customer need only login once to the SDP and may then access multiple third-party applications without the need to re-authenticate. Authentication exchange occurs on the user's behalf between the SDP and external third-party application, for example using the Security Assertion Markup Language (SAML).

Core services include streaming and gaming servers, digital rights management, a service catalog that provides a menu on the mobile device for each multimedia service available, several portals, and revenue collections facilities such as billing and payment. A key node is the Web service gateway which typically offers a range of network and IT-

Figure 3. Network-centric service delivery platform

related services to third-party developers. This may include sending messages, prepaid, postpaid charging, payment, and additional authorization services. The portals furnish the visual interface accessed by customers, third-party developers, and internal administrators of the platform. Hence, there are generally several portals available to cater to the needs of each user community. The customer portal provides services to conduct registration, subscribe to services, and manage accounts. A service relationship management (SRM) portal is a vital component allowing third-party developers to register new applications, monitor usage, review revenues due, and provide an environment that facilitates development of new services; this may include testing and development tools (i.e., service creation environment).

While clearer separation between the network and SDP environment is beneficial, particularly as network technologies evolve, there are several drawbacks. The design relies upon a mature network with standardized mechanisms for network access and control. Consequently, deployment under this assumption may be problematic where network access is inconsistent. IT-based SDPs generate billable events but do not themselves manage the balance or prevent access to services based on insufficient funds. Rather, they rely upon external systems for balance management. Furthermore, other than security and Web service definition, the supporting standards and literature are limited and emerging.

Network-Centric Design Viewpoint

Service delivery frameworks that have emerged from standards bodies, such as IMS, Parlay X, and multimedia domain (MMD), largely reflect a network-centric design. In Magedanz et al. (2004, 2005), a service delivery platform

that extends the IP multimedia system has been developed. The authors outline a test-bed architecture that integrates the session initiation protocol (SIP) and Parlay with the telecommunications network to deliver multimedia services. A further platform for delivery of mobile games over the IMS has also been described (Akkawi et al., 2004). While there appears to be more standards work on the network-centric design, the notion of IT-based systems is observed (Magedanz & Sher, 2006).

In broad terms, IMS specifies an architecture that supports IP telephony and multimedia services such as instant messaging, videoconferencing, voice mail, and multiparty gaming (3GPP, 2001). Communications require session establishment between user devices and application servers, and the signaling protocol selected by IMS to establish these sessions is SIP. The architecture defines a layered model for the telecommunications network referred to as planes, similar in concept to the layers of the IT-centric design. These IMS planes are depicted in Figure 3 and include: *access networks*, being the physical network the end user connects to; *transport plane*, which is the common IP backbone network of the telecommunications service provider; *control plane*, which provides key functions of authentication, session establishment, and quality of service; and *service plane*, which houses application servers and provides an abstracted network interface.

The access network connects the cellular, or fixed, network from the physical internetworking equipment to the customer premise or mobile device. For a device to connect to an IMS network, it needs to support an IMS client, providing various functions including the visual and audio presentation of the service to the user. Packets of data which encapsulate the service, such as VOIP from a PC, IPTV to a set top box,

or instant messaging to a mobile device, are all carried on a common transport plane. This plane contains the network elements, the gateway GPRS support node (GGSN) and serving GPRS support node (SGSN), media servers (media resource function processor (MRFP)) for playing announcements, and media gateways (MGW) for interconnecting IP traffic with other networks such as the PSTN.

Control plane authentication of the user's device is achieved by lookup to the home subscriber server (HSS), verifying that the device is enrolled and able to connect to the network and use the requested service. Session establishment is managed by the call session control function (CSCF), which connects the user to the correct application server in the service plane. The policy decision function (PDF) assigns resources to manage quality of service to ensure there is sufficient bandwidth available to deliver the requested service. Several nodes manage the media gateway (MGW) and internetworking between IP and SS7; this includes the media gateway control function (MGCF) and the breakout gateway control function (BGCF), which selects the required (local or foreign) network. As the broker between the MRFP and media applications, the media resource function controller (MRFC) is intended to perform conference, roaming, and media control; however, these capabilities are often developed directly within the applications of the service plane.

The aim of the service plane is to provide an environment for executing various common IP services such as presence, location, messaging, videoconferencing, and multimedia. This is largely where the multimedia and telephony applications reside and is the least defined aspect of the architecture. IMS has to date largely focused upon network convergence, the establishment of IP sessions between users on different networks, how to ensure quality of service, and implementation of heritage features from the mobile phone network such as roaming between networks. As technology migrates to VOIP services, quality of service, mobility, and roaming across different access networks are seen as key features of IMS which will enable the telecommunications service provider to grow the business.

Integral to the network-centric model is near-real-time balance management for the prepaid market, where there needs to be sufficient funds available within the customer account before the control plane grants access to the service being requested. This model becomes complicated when the customer may not select the desired service until the control plane has already allowed access to the service plane, particularly as the customer has access to the shopping portal resident in the service plane. In this instance, like the IT-centric model, the SDP needs to advise the balance manager what service is being requested before the service is initiated.

A drawback of the IMS-based approach is lack of detail for SDP structures such as third-party relationship management, service or device management, and how to deliver

services in the service plane. This reflects the heritage of the authoring body, with specifications emerging from network engineering standards bodies. The focus is upon network application service delivery, omitting detail required for broader IT-based multimedia service delivery. Such capability would be added by introducing a service delivery manager (see Figure 3), which contains much of the detail of an IT-centric design.

FUTURE TRENDS

Mobile devices continue to evolve in capability and computational strength. Together with the increasing reach of mobile networks, access to multimedia content and services will become ubiquitous. These factors contribute to trends in offering an increasing number of multimedia services to mobile customers. This includes gaming, podcasting, telephony services, and broadcast and video on demand. Digital rights management is as yet not aggressively implemented. However, as more content moves to this mobile digital environment, effective protection of digital content will become increasingly important.

Perhaps the key consideration in the evolution of service delivery is the convergence of network IT systems and applications. As mobile networks move towards IP-based telephony, the distinction between the network and IT boundary grows dim, placing greater emphasis on well-defined standards and architectures. For instance, scenarios where users are able to view video content on a mobile device while roaming, pausing this when arriving home, with the ability to continue viewing using the home television, exemplify further the prospective convergence between mobile and fixed networks in the delivery of multimedia services.

Services-oriented architecture (SOA) is emerging as the prevalent cross-industry IT integration regime and is likely to gain favor as a means of integrating components of an SDP. Given that integration of network IT and applications is central to an SDP, SOA may provide a means for IT and network-centric SDP models to converge.

CONCLUSION

The standards for service delivery are still emerging, with specifications providing more detail regarding the network aspects of service delivery. An IT-centric SDP design lends more attention to the detail of integration with IT systems and third-party developers. This is beneficial where many implementations underestimate the effort and complexity of integrating with existing legacy systems. While there is a general lack of SDP standards for an IT-centric approach, Web service standards specified by OASIS in identify management and security exchange may be effectively

applied. A network-centric design is well defined at the network level, offering a greater range of network services. However, these implementations still require the additional consideration for supporting business processes, particularly for third-party service relationship management and application provisioning.

Either approach largely reflects the heritage of the engineering discipline. However, as both the network and IT systems continue to converge, these boundaries will become less visible. Hence the need for clear architectural separation, as layers, becomes more important to ensure technology independence is maintained. Notwithstanding the design style adopted, there are several key considerations in an SDP to ensure the underlying business model is addressed. This includes the provision of an environment for rapid creation of multimedia applications, an intuitive user portal experience as an interface to a full range of content and services, and a comprehensive portfolio of Web services to enable the development of rich multimedia applications and services by external third parties.

KEY TERMS

Federated Identity Management: A standard that enables a user to use one set of credentials to sign on and access the networks of several enterprises in order to conduct transactions.

Multimedia Domain (MMD): Specified by the 3GPP2 group, a set of specifications for the CDMA network based on IMS and Parlay X.

Mobile Network Virtual Operator (MVNO): Being able to sell branded mobile network services without owning a mobile network, through an established relationship with a mobile network operator.

Organization for the Advancement of Structured Information Standards (OASIS): A not-for-profit, international consortium that drives the development, convergence, and adoption of e-business standards.

OSE (Open Mobile Alliance) Service Environment: A reference architecture for how services may be combined to form new services (Schulke et al., 2005). The standard is intended to promote common architectural principles and broadly defines the functional entities, within a telecommunications service environment, for application developers and service providers.

Parlay X: Web service extension to the Parlay APIs that allow developers to build applications using the Parlay API. The Parlay API is an open interface to the mobile and fixed telephone network.

Security Assertion Markup Language (SAML): An XML-based framework that defines an interoperable standard for exchanging security information.

3rd Generation Partnership Program (3GPP): A collaboration between several telecommunications standards bodies to develop 3G GSM technical specifications.

INTRODUCTION

The fast development on microelectronics has promoted the increase on the computational power of hardware components. On the other hand, we are facing a significant improvement on energy consumption as well as the reduction of the physical size of such components. These improvements and the emergence of wireless networking technologies are enabling the development of small and powered mobile devices. Due to this scenario, the so-called pervasive computing paradigm, introduced by Mark Weiser in 1991 (Weiser, 1991) is becoming a reality. Such a paradigm envisions a world where environments are inhabited by computing devices, all of them seamlessly integrated into peoples' lives, and effectively helping to carry on their daily tasks.

Among others, one major characteristic of Weiser's vision is that each device in an environment becomes a potential client or provider of resources. Not surprisingly, pervasive computing environments are becoming dynamic repositories of computational resources, all of them available to mobile users from the palm of their hands. However, devices can unpredictably join and leave such environments. Thus, resources can be dynamically made available or unavailable. Such a scenario has a great impact on the way that resources are found and used. In the case of static environments, such as the Web, it is reasonable to look up and access resources,

such as Web pages, knowing the address of their providers beforehand. On the other hand, for dynamic environments, such as the pervasive computing ones, this is not a reasonable approach. This is due to the fact that one cannot guarantee that the provider of a resource will be available at any moment, because it may have left the environment or simply turned off. A better approach would be to discover these resources based on their descriptions, or any other feature that does not require the client to know the specific address of their providers.

To this end, some of the current pervasive computing solutions, like Wings (Loureiro, Bublitz, Oliveira, Barbosa, Perkusich, Almeida, & Ferreira, 2006), Green (Sivaharan, Blair, & Coulson, 2005), RUNES (Costa, Coulson, Mascolo, Picco, & Zachariadis, 2005), and Scooby (Robinson, Wakeman, & Owen, 2004), are making use of a novel approach from the branch of distributed applications, the *service-oriented computing* paradigm (Papazoglou, 2003; Huhns & Singh, 2005). This is due to the fact that such a paradigm provides a crucial element for pervasive computing systems, the ability for dynamically binding to remote resources (Bellur & Narenda, 2005), which enables mobile devices to find needed services on demand.

However, pervasive environments may be structured in different ways. They can range from wired networks to completely wireless ones, where communication among the

Figure 1. General view of a service-oriented architecture

devices is performed in an *ad hoc* way. Such a characteristic indicates that the way services are provisioned in a pervasive computing environment should fit in its organization, in order to enhance the access to the services available.

Considering the above discussion, in this article we provide a review on service provision and its applicability in pervasive computing. More precisely, we will list the existing service provision approaches and discuss the characteristics and problems associated with each one, as well as their usage in pervasive computing environments. We start by providing introductory concepts of service-oriented and pervasive computing, respectively in the service-oriented computing and pervasive computing sections. Next, we present the service provision techniques available and how they can be applied for pervasive computing environments. The main current solutions within this scope will be introduced in the service oriented technologies section. Some of the future trends associated with research for service provision in pervasive computing environments will be presented in the future research trends section. Finally, in the conclusions section we present the conclusions of this article.

SERVICE-ORIENTED COMPUTING

The service-oriented computing (SOC) paradigm has been considered as the next step in distributed computing (Papazoglou, 2003). In a general way, this paradigm can be viewed as the development of applications through the runtime integration of software pieces named of *services* (McGovern, Tyagi, Stevens, & Mathew, 2003). In this process, three elements are involved: defining what is known as a *service-oriented architecture* (SOA), a *service client*, a *service provider*, and a *service registry*. The former is the one who wishes to use a service. Conversely, service providers are those which offer services for potential clients.

Finally, the service registry is where providers advertise or announce their services (through service advertisements), enabling clients to dynamically discover them. By dynamic, we mean that clients are capable of discovering services at runtime, thus providing a high degree of flexibility for applications. Once clients have discovered a service, they are able to bind to it; that is, to create a link with the service, in order to use it (through a proxy to the real service). This process of advertising, discovering, binding, and using a service is illustrated in Figure 1.

In open environments, the dynamic discovery of services implies that they can be used by heterogeneous clients. Within this scope, heterogeneity is concerned with features like the operating system running in each client and the hardware platform it has been built on. As a consequence of such heterogeneity, for enabling an application to flexibly integrate services, they should present the following features (Papazoglou, 2003):

- **Loose Coupling:** A service must not require from the clients any knowledge about its internal implementation.
- **Implementation Neutrality:** The usage of services must not rely on any specific programming language, operating system, or hardware platform.
- **Dynamically Discoverable:** Services should be discovered at runtime.

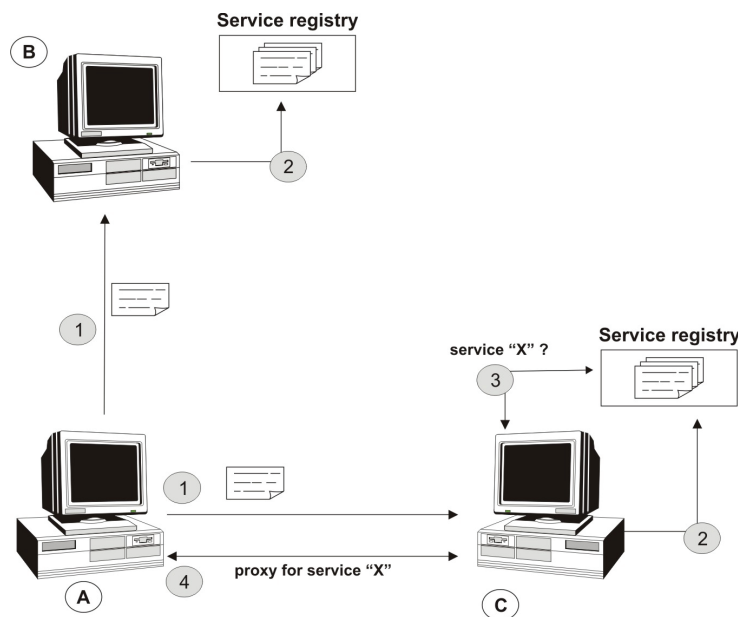

PERVASIVE COMPUTING

The field of pervasive computing has its origins at the Xerox Palo Alto Research Center. The pioneer work that has been led there has culminated in the novel article of Mark Weiser in 1991 (Weiser, 1991), where he describes the first ideas of pervasive computing. Weiser's vision is at the same time revolutionary and simple: a world where computing is embedded in everyday objects, like cars, televisions, and air conditionings, all seamlessly integrated into our lives and performing tasks for us (Turban, Rainer, & Potter, 2005). When Weiser talked about seamless integration, he meant that applications running in these objects should act proactively on our behalf. They should, for example, present us with relevant information, based on what we want/need and the resources (e.g., a printer) available in the environment we are immersed.

SERVICE PROVISION APPROACHES IN PERVASIVE COMPUTING

When provisioning services in a pervasive environment, one aspect to be considered is the way it is organized; that

Figure 2. Example of a push-based service provision

is, whether the environment is based on a wired network infrastructure, whether it is formed in an *ad hoc* way, or both. This is necessary for dealing with the particularities of each environment, and within this scope, we can say that there are two major ways of performing service provision (Nickull, 2005): the *push-based* and the *pull-based* approach. In the next sections we will outline each of these approaches as well as describe how they fit into pervasive computing environments.

Push-Based Service Provision

In this approach, a provider advertises its services directly to potential clients. In other words, it sends service advertisements to all network hosts, either they are interested on the service or not. Such advertisements, when received by a host, will be kept in a local service registry. Therefore, once a client wants to discover some service, it will then look up in such a registry for the services that match its needs. An example of the push-based service provision is illustrated in Figure 2. Note that the provider, host A, sends the advertisement of a service directly to hosts B and C, as illustrated in Step 1. When this advertisement is received, it will be stored on a local service registry at each host (Step 2). Then, once a host, in our example host C, wants to discover a service, it then inquires this registry, as illustrated in Step 3. Finally, considering that a relevant service has been found, it is possible to ask its provider (host A) for a proxy to the service (Step 4), enabling host C to use it.

Using this approach, one major problem to be pointed out is about the validity of the service advertisements. It is concerned with the fact that a service provider can leave the network, but the advertisements associated with its services can still be available. One approach which could be used for solving this problem is to require the provider to explicitly notify the network hosts about its leaving, and consequently its services will be no longer available. The problem is that it is not always possible to do that. For example, if the provider is a mobile device, it may be suddenly run out of energy. To deal with this, providers could be aware of the energy level of the device, in order to notify the network hosts that within some minutes it may not be accessible anymore. However, other factors can be involved in the leaving of a provider from the network. It can be just turned off by its user, or leave the network coverage area. Keeping track of all these factors is a task that certainly overloads the provider. A more reasonable solution would be requiring both providers and clients to cooperate for renewing the service advertisement. Therefore, as long as the advertisements are renewed, it is possible, but not guaranteed, that the service is available. On the other hand, when the advertisement has not been renewed within a time interval, then the service is probable, but also not guaranteed, to be unavailable, either because its provider has left the network or because the service has been unadvertised.

One interesting point to notice is that the push-based service provision does not require any physical infrastructure. This means that such an approach is well suited in decen-

tralized and/or infrastructure-less pervasive environments. One problem, in the scope of pervasive computing, is that the advertisement task can consume a lot of bandwidth if many devices are provisioning services in the environment. Therefore, in environments with very limited wireless links this is certainly a major problem. On the other hand, as services are searched locally, the discovery process does not involve costs of communication.

Pull-Based Service Provision

In the pull-based approach, in order to discover services clients must inquiry remote registries for the needed services. This can be performed in two ways; either using centralized or distributed registries.

Centralized Provision

The centralized service provision consists in scattering service registries in specific servers (i.e., registry servers) of the network. Therefore, for advertising a service, the provider must initially find which of these servers are available in the network. After that, it has to determine in which of them the service will be advertised (instead, the provider could advertise the service in all the available servers). When a client wants to discover services, it must also find the registry servers available in the network, and then

discover the services advertised in them. It is important to notice that, once the registry servers are found, unless they become unreachable, clients and providers do not need to discover them anymore. Jini and Web Services are some of the current technologies that support centralized service provision. In Figure 3 we illustrate an example of such an approach. In such a figure, services are advertised by hosts A and B (Step 1), in a single registry server, host C (we are considering that the clients have already found the registry server). After that, each advertisement is stored in the service registry maintained by host C (Step 2). Also considering that host D has already found the registry server, it is then able to inquiry such server for the advertised services (Step 3). When a relevant service is found (Step 4), host D can interact with its provider, in this case host A, to retrieve the proxy for the service (Step 5).

A problem with this approach is that, if all these servers are off the network, services can not be discovered, even when their providers are available. In these cases a possible solution could be the election of new servers from the moment that is detected that the others are no longer available. Furthermore, the centralized service provision raises the same problem of the pull-based one concerned with the validity of the service advertisements. In this way, the same, or at least similar, solutions can be applied here.

As the centralized service provision requires the existence of registry servers, it is not well suited for highly dynamic

Figure 3. Example of a centralized service provision

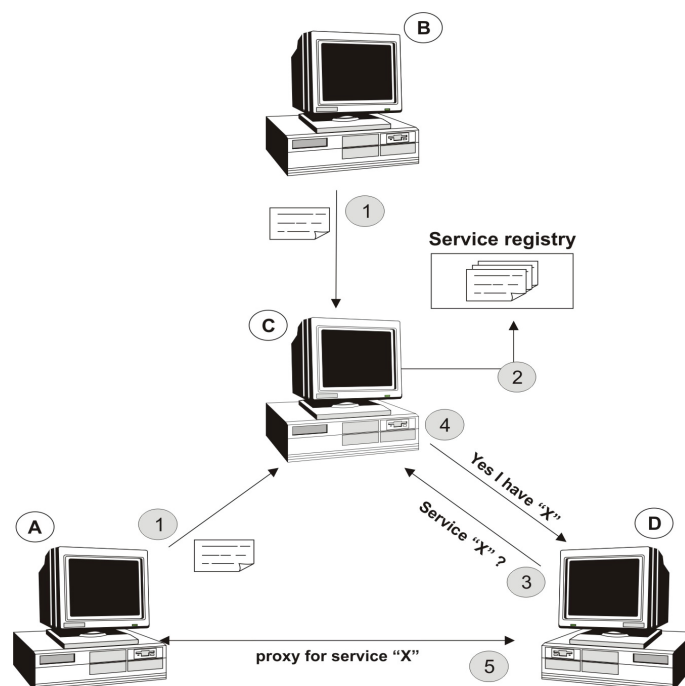

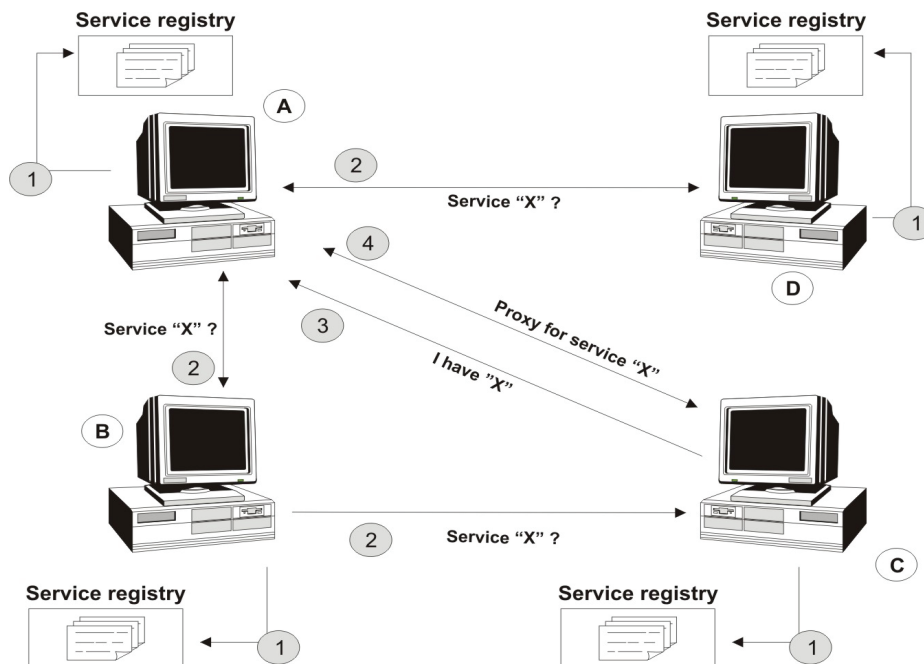

Figure 4. Example of a distributed service provision

pervasive environments. In these cases, as nodes join and leave the environment all the time, there would be too many changes in the current registry servers, which would in turn degrade the provisioning of services. On the other hand, this approach is very useful for environments equipped with wired network. In such environments, services can be deployed in the wired network and thus be accessed by mobile clients through wireless links. In environments populated with lots of mobile clients, this is certainly a good choice, as the bandwidth available in the wired network could support a great number of accesses.

Distributed Provision

In the distributed service provision, services are advertised in registries located in each host. Undoubtedly, in this approach the advertising task is easier to be performed than in the other ones, as it does not involve sending advertisements to central servers or directly to the other hosts. However, service discovery is more complicated, as it must be performed by inquiring each available host for the needed services. As no centralizer hosts are necessary for advertising services, discovery is possible whenever a client and a provider are present in the network. An example of the distributed service provision approach is illustrated in Figure 4. Initially, each host advertises its services (Step 1). Once a client needs to perform service discovery, in our example host A, it asks every host in the network for the needed service (Step 2). It

is important to note the possibility of redirecting the service discovery request to hosts that are not reachable from the client. In Figure 4 this is performed by host B when it redirects the request of host A to C. When a host has a service matching the client's needs, it sends a notification (Step 3). From this notification, the client can then retrieve a proxy to the service (Step 4).

The major problem with this approach is associated with the protocols for performing service discovery. As any node in the network is a potential service provider, the discovery protocol must be well designed, in order to cover all hosts of the network. If any host is missing in the discovery process, it is possible that a relevant service may not be found. In *ad hoc* pervasive environments, one possible solution to this problem is first to discover the hosts in the vicinity, and then to retrieve the relevant services they provide. However this solution only performs well in small networks, where the available hosts can be discovered from any other one. Another point to be considered is about the network congestion that such service discovery protocols can cause. As the search should include all hosts in the network, the protocol must apply techniques for avoiding flooding the network. Obviously, this is not a serious problem in wired networks, but considering the wireless ones, it must be strictly taken into account. A good usage scenario of the distributed provision approach is a decentralized pervasive environment where the edge of the network is formed by mobile clients and its core is populated by service providers connected through a wired network.

SERVICE ORIENTED TECHNOLOGIES

In this section we present the main technologies related to the provision of services in pervasive computing environments.

Universal Plug and Play (UPnP)

The Universal Plug and Play (Richard, 2000) is an open architecture, which uses standard Internet protocols for pervasive peer-to-peer network connectivity (<http://www.upnp.org>). The UPnP protocol defines a set of steps, *addressing*, *discovery*, *description*, *control*, *eventing*, and *presenting*, which enables the automatic network configuration and service provision. Through the addressing, devices get their network address, which is performed by a dynamic host configuration protocol (DHCP). The discovery step consists of notifying the other hosts, through the push-based approach, about the services, and embedded devices, that a joining host provides. The discovery can also be performed in a distributed pull-based fashion. The next step, description, is about the description of a device, stored as an XML document. In such a document, it is kept, among other information, the description of the services that the device provides. Therefore, by discovering a device, it is possible to retrieve the services it provides, and then, through the control step, invoke their actions. Changes in a service can be notified to interested devices through the eventing step. Finally, through the presenting step, it is possible to load a specific URL, specified in the device description, in order to display a user interface for controlling a device.

Jini

Jini is a service-oriented Java technology based on a centralized pull-based approach (Waldo, 1999). Therefore, service

advertisements are stored in central servers, which are named *lookup servers*. Jini uses the RMI (<http://java.sun.com/products/jdk/rmi> - Remote Method Invocation) protocol for all interactions involved in the advertisement, discovery, and invocation of services. When a client discovers and binds to a service, it is incorporated to the client by downloading the code of a proxy to the required service, named *remote control object*.

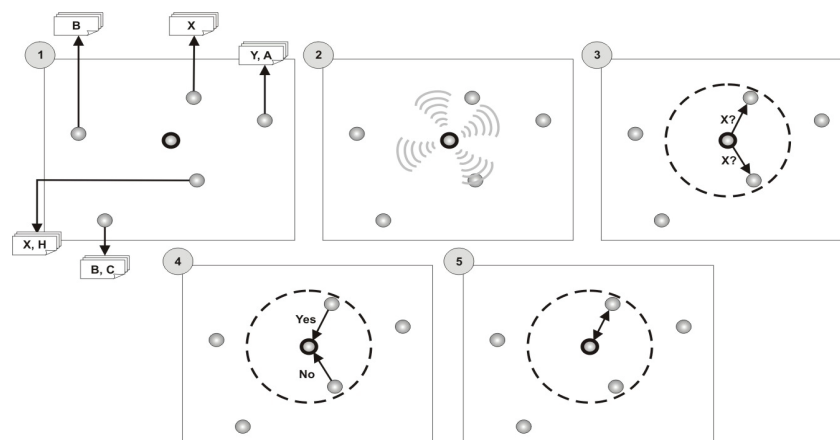

The Jini platform uses the concept of lease for controlling the access to the services. A lease is a sort of warrant that a client has for using a service during a specific period of time. When the lease expires the client needs to renew it with the provider if it wishes to continue using the service.

Bluetooth

Bluetooth is a standard for wireless communication among small devices within short distances (Johansson, Kazantzidis, Kapoor, & Gerla, 2001), defining higher-level protocols for both host and service discovery (<http://www.bluetooth.org>). The discovery of services in the Bluetooth standard is defined by the service discovery protocol (SDP), which enables to enumerate the devices in the vicinity and retrieve the services they provide.

Bluetooth uses a distributed pull-based approach for service advertising and discovery. To this end, each device maintains its own service discovery database (SDDDB), which is a registry where its services are advertised. Therefore, a Bluetooth device performs service discovery by querying the SDDDBs of the devices around. These advertising and discovery processes are illustrated in Figure 5. Notice that, initially, all devices advertise their services on their respective SDDDBs (1). Next, a client searches for all the Bluetooth devices on the range of its wireless interface (2). For each device found, the client sends a query about the availability of an interested service (3). The devices answer these queries

Figure 5. Service discovery in Bluetooth

by informing whether they offer the needed service or not (4). Once localized a device providing the desired service, the client can connect directly to such device and finally use the service (5).

FUTURE RESEARCH TRENDS

Although the first service-oriented pervasive computing solutions have been developed, much work has to be done yet. For example, the matching of the user's needs and the services' functionalities should be enhanced to improve the interaction of the user with the pervasive application. Still, problems remain in the context of service continuity. Solutions to this problem would enable the user to use a service continuously, as he/she walks through different environments. This is important because, sometimes, the service a client was using is not available in the new environment, and thus, some mechanism should allow it to use a similar one without, or at least with a minimum, of interruption.

These, and possibly other problems related to the provision of services in pervasive environments, must certainly be completely solved so that we can enjoy the full potential of merging service-oriented and pervasive computing.

CONCLUSION

The service-oriented paradigm has proved to be an important element in pervasive computing systems, in order to provide anytime and anywhere access to services. Its dynamic binding feature enables to build applications powered with on-demand extensibility and adaptability, two important elements of any pervasive system.

Given this trend, in this chapter we have tried to present an overview of service provision in pervasive computing environments. More precisely, we have showed an introduction to the main characteristics, challenges, and solutions concerning the way that services are advertised, discovered, and used in pervasive environments. Although we presented concepts at an introductory level, we believe they may serve as a good source of knowledge, helping both students and researchers involved with these fields.

KEY TERMS

Pervasive Computing: The vision conceived by Mark Weiser which consists of world where computing will be embedded in every day objects.

Service: a software entity that can be integrated to a remote distributed application.

Service-Oriented Computing: The newest paradigm for distributed computing, where applications should be built by dynamically integrating services.

Service Advertisement: The element used for publishing and discovering a service.

Service Client: The one wishing to use a service.

Service Provider: The one that offers services.

Service Registry: The place where services are published.

Short Message Service (SMS) as an Advertising Medium

S

Shintaro Okazaki

Autonomous University of Madrid, Spain

INTRODUCTION

The proliferation of the Internet-enabled mobile device has extended into many parts of the world. Collectively, the mobile-network operators paid more than \$100 billion for licenses to operate “third-generation” (3G) networks, which were among “the largest bet in business history on the introduction of a new technology” (Economist, 2005). This drastic move has been most illustrated by the use of short message service (SMS) and multimedia messaging service (MMS) by mobile users. For example, a recent survey indicates that SMS in the Asia-Pacific region will increase to up to 75% of mobile subscribers in 2006 (IDC Asia/Pacific, 2003). As a result, marketers and agencies are increasingly interested in taking advantage of this growth, by incorporating SMS advertising as part of an integrated marketing communications (IMC) strategy. However, there has been little academic research on mobile advertising, perhaps because its growth is still in an early stage and the technological infrastructure varies across markets. The study has two objectives: (1) to identify the factors influencing MNCs’ managerial intention to adopt SMS advertising, and (2) to test a statistical relationship between these factors and managerial intention to use SMS advertising. To this end, we conducted telephone interviews of senior executives of MNCs operating in European markets.

CONCEPTUAL FRAMEWORK AND HYPOTHESES

Branding Technique

In an environment where building the brand is a fundamental goal for many managers, the need to build brand equity is likely to be at the center of many marketing decisions. Firms using SMS-based campaigns can attract consumer attention and produce consumer responses to a much greater degree than via other direct marketing channels, because SMS has been claimed to be an effective tool in building and testing customer loyalty by developing demographic databases (Mylonopoulos & Doukidis, 2003). From an industry perspective, McDonald’s conducted a text-messaging campaign in conjunction with a popular TV song contest in the UK,

offering concert tickets and backstage passes, while entry in the Coca-Cola Grand Sweepstakes Competition was offered to U.S. college students who sent a text message to a number printed on a Diet Coke can (Dano, 2002).

Facilitating Conditions

Lu, Yu, Liu, and Yao (2003) suggest that facilitating conditions are one of the most important determinants, along with the ease of using wireless Internet. In this light, the integration of competing standards and fragmented systems across countries, cross-network support for SMS, and higher connection speeds are all necessary conditions for a wider transmission of mobile advertising. In addition, the availability of Web-enabled mobile handsets with 2.5G or 3G functionality would significantly affect the adoption of MMS-based (multimedia message services) campaigns. In this light, a wider selection of handsets must be available, to enable consumers to choose their preferred combination of necessary functions and diverse features.

Location-Based Services

The satellite-based global positioning system (GPS) offers the ability to tailor services and promotional offers to individual consumers’ needs, by locating their position (Sadeh, 2002). Mobile handset makers and content providers are increasingly attracted by the commercial feasibility of applying GPS to their service. For example, on an extended menu of i-mode, “i-area” includes a diverse range of location-based services: weather news, restaurant guide, local hotel information, zoomable maps with an address finder function, and traffic updates and estimation of travel times. This facility would give MNCs strategic leverage in mobile marketing, because individuals’ behavior and receptiveness to advertising is likely to be influenced by their location and time, and marketers can thus induce impulse buying by providing the right information for the right place (Barnes, 2002).

Connection Costs

Another important factor is the concept of connection costs. For example, to send or receive one megabyte of data on 2.5G i-mode costs 32 euros (0.3 yen) per packet. At a rate

of 19 euro cents per 160-character SMS message, European consumers would have to pay 1,356.98 euros to send one megabyte of data by SMS, or approximately 62 times as much as the Japanese pay (Scuka, 2003). In addition, European mobile operators have passed on to consumers the additional costs incurred in obtaining 3G spectrum licenses, and this has made any dramatic price reduction impossible (Baldi & Thaug, 2002). Such cost factors adversely affect mobile players' revenues.

Public Regulation

The idea behind mobile *advertising* is very similar to e-mail on the wired Internet, but with one big difference: it is "opt-in." This function is essential to give users total control over what they receive, because consumers' demand for highly personalized messages has to be reconciled with their desire for privacy (Sadeh, 2002). The Mobile Marketing Association (MMA) has attempted to establish industry guidelines for mobile marketers, as follows: (1) MMA members should not send mobile advertising without confirmed opt-in, and (2) such opt-in subscriber permission is not transferable to third parties without explicit permission from the subscriber (Petty, 2003).

Lifestyle and Habits

In general, European consumers habitually commute by car, and this provides fewer incentives to access the mobile Internet (Baldi & Thaug, 2002). In addition, a systematic "word-of-mouth" helped the rapid diffusion of i-mode in Japan, especially given the "normative beliefs attributed to significant others (friends, colleagues, or family members) with respect to adopting or continuing to use the technology" (Barnes & Huff, 2003). This may partially explain a high subscription rate (almost 75%) to e-mail newsletters among i-mode users, and this makes acceptance of mobile advertising much easier. However, this factor is unlikely to be present in many European countries, which are characterized as more individualist than Asian countries.

On the basis of the preceding discussions, the following hypotheses were formulated to test the principal thesis of the research:

- **H1:** MNCs' intention to adopt SMS-based advertising is directly and positively associated with branding technique.
- **H2:** MNCs' intention to adopt SMS-based advertising is directly and positively associated with facilitating conditions.
- **H3:** MNCs' intention to adopt SMS-based advertising is directly and positively associated with location-based services.

- **H4:** MNCs' intention to adopt SMS-based advertising is directly and negatively associated with connection costs.
- **H5:** MNCs' intention to adopt SMS-based advertising is directly and negatively associated with public regulation.
- **H6:** MNCs' intention to adopt SMS-based advertising is directly and negatively associated with lifestyle and habits.

METHODOLOGY

Questionnaire Items and Measures

A structured questionnaire was prepared, drawing on prior literature. A majority of the items were originally developed for this study, because of the scarcity of empirical research on mobile advertising. Each item was measured on a Likert-type five-point scale. A five-point scale was preferred to a seven-point scale, because telephone interviews were used, rather than a mail or other form of paper-and-pencil survey. This method was considered more appropriate because mobile advertising is still in its infancy, and company executives may not be able to make fine distinctions regarding their attitudes on this topic. During the telephone interview, interviewers followed a script. However, respondents were free to ask questions whenever they encountered definitional problems.

Multinational Corporations

With regard to Japanese firms, the selection was based on the *Multinational Companies Database*. The database was created by the Research Institute for Economics and Business Administration at Kobe University (2003) and includes Japanese companies listed in the first section of the Tokyo Stock Exchange with foreign direct investment in more than five countries (Kobe University, 2003). American firms were chosen from The Forbes 500 (*Forbes*, 2003a). Finally, European firms were singled out from The Forbes International 500 (*Forbes*, 2003b), because this list indicates the nationality of each firm. Regardless of nationality, however, companies associated with aerospace and defense, food and drug retail chains, forestry and fishery, general public utilities, health care providers, heavy machines, industrial goods, local banking and insurance, metals and mining, and oil and gas extraction were excluded. Next, firms operating in Spain were identified. As a result, 43 Japanese, 47 American, and 31 European firms' Spanish subsidiaries were identified.

Table 1. Regression analysis and hypotheses testing

| Hypotheses | Independent Variables | Standardized β | Results |
|------------|-------------------------|----------------------|-----------|
| H1 | Branding technique | .553 ** | Supported |
| H2 | Facilitating conditions | .325 ** | Supported |
| H3 | Location-based services | .023 | Rejected |
| H4 | Connection costs | -.397 ** | Supported |
| H5 | Public regulation | .125 | Rejected |
| H6 | Lifestyle and habits | -.115 | Rejected |
| | | R^2 .598 ** | |
| | | ΔR^2 .013 | |
| | | ΔF 1.509 | |

Note: Dependent variable = MNCs' intention to use mobile advertising

** Significant at $p < .001$

* Significant at $p < .05$

Telephone Interview

Telephone interviewing was considered appropriate because of the novelty of the research subject. It was expected that interviewers would be able to clarify doubts or answer any questions that interviewees might have regarding mobile communications. To this end, four bilingual assistants were employed (two Spanish and two Japanese, all fluent in English). During the second and third weeks of February 2004, intensive training was provided so that the assistants could gain sufficient skills and knowledge to conduct the telephone interview. The actual interviewing was carried out during March 2004, under the supervision of the researcher. It was established that when the target executives were absent or unavailable for interview, assistants had to ask: (1) for an appointment for the next phone call, or (2) about the availability of the person next in seniority in the marketing department to the target executive. As a result, a total of 53 interviews was conducted, with 27, 16, and 10 respondents from Japanese, American, and European firms, respectively. The response rate was 43.8%.

FINDINGS

First, an exploratory factor analysis with Equamax rotation with Kaiser Normalization was carried out. The rotation, converged in 12 iterations, produced a clear-cut six-factor solution with a cut-off value of .50. Only factors with eigenvalue greater than 1 were retained. It should be noted that the proposed construct "connection costs" was merged into a mixed construct "security and costs." However, because

of the exploratory nature of the study, it was considered acceptable to use this six-factor solution for the subsequent analysis. The extracted factors explain 68.6% of the total variance, and the level of loading is consistently high across the six factors. Factor scores were retained as variables with the Anderson-Rubin method to minimize the level of multicollinearity, for the use of regression analysis. The reliability was calculated with Chronbach's alpha for each construct. The scores range from .60 to .85, exceeding the cut-off point of .60 suggested by Hair, Anderson, Tatham, and Black (1998). Next, the hypotheses were tested by performing regression analysis with a step-wise method. Each of six independent variables (i.e., factor scores) was regressed on the dependent variable, "MNCs' intention to use mobile advertising," in order of their expected contributions. The results of regression analysis are shown in Table 1.

DISCUSSION

This study aims to identify MNCs' principal perceptions of SMS-based push-type mobile advertising and their intention to use it. On the basis of the data obtained from 53 MNCs, our principal propositions were tested by multiple regression analysis. The results were mixed: only half of the six hypotheses gained empirical support. The regression analysis identified branding technique, facilitating conditions, and connection costs as the three primary predictors influencing MNCs' intention to use mobile advertising. The contribution of branding technique in particular is substantial, indicating that MNCs are likely to perceive mobile advertising as an effective branding tool to increase brand awareness and im-

age. Also, technological infrastructure and the availability of sophisticated mobile handsets are prerequisites for mobile marketing. As expected, unfavorable mobile Internet pricing negatively affects the MNCs' intention to use mobile advertising. On the other hand, the contributions of location-based services, public regulation, and lifestyle and habits are not only statistically insignificant, but also trivial in terms of the coefficient magnitude. One reason why location-based services were not identified as a significant factor is that the GPS system is not as widespread in Europe as it is in Japan. In addition, many Scandinavian firms, leaders of sophisticated mobile Internet service practitioners, were not included in the study. Admitting the danger of simple generalization, the findings of this study may imply that MNCs are concerned to a lesser extent with regulatory and cultural impediments to adopting mobile advertising.

KEY TERMS

Barcode Mobile Coupon: Mobile barcoding can be used in the form of a picture SMS which is delivered to a mobile phone. Recipients save the image, arrive at the destination, and present their barcode SMS to be scanned.

i-mode: A broad range of Internet services for a monthly fee of approximately three euro, including e-mail, transaction services (e.g., banking, trading, shopping, ticket reservations, etc.), infotainment services (e.g., news, weather, sports, games, music download, karaoke, etc.), and directory services (e.g., telephone directory, restaurant guide, city information, etc.), which offers more than 3,000 official sites accessible through the i-mode menu.

Push Messaging Service: Various forms of messaging services are generally offered in mobile Internet. For example, SMS and WAP Push messaging generally allow users to send 100-160 characters, while mobile e-mail in Japanese i-mode allows up to 1,000 characters.

SPAM: Unsolicited or undesired bulk electronic messages. Because of the development of anti-SPAM programs, they are often deleted without being opened.

SPIM: A variation of SPAM through instant messaging systems.

Shot Boundary Detection Techniques for Video Sequences

INTRODUCTION

The advances in digital video encoding and compression techniques that achieve high compression ratios by exploiting both spatial and temporal redundancy in video sequences have made possible the storage, transmission, and provision of very high-volume video data over communication networks.

Today, a typical end user of a multimedia system is usually overwhelmed with video collections, facing the problem of organizing them in a browsing-friendly way. Thus, in order to allow an efficient exploitation and browsing of these video-anthologies, it is necessary to design techniques and methods for content-based search and access. Therefore, the issue of analyzing and categorizing the video content by retrieving highly representative optical information has been raised in the research community.

Thus, the current trend has led to the development of sophisticated technologies for representing, indexing, and retrieving multimedia data. A common first step towards this is the segmentation of a video sequence into elementary shots, each comprising a sequence of consecutive frames that record a video event or scene continuously in the spatial and temporal domain. Moreover, these elementary shots appear as they have been captured by a single camera action. Two adjacent elementary streams are divided by a *shot boundary* or *shot transition*, also known as scene cut, when the change of video content occurs over a single frame, or *gradual shot boundary*, when the changes occur gradually over a short sequence of frames (e.g., dissolve, fade in/out, etc.) (Lu & Tan, 2005).

In general, gradual transitions are more demanding in detection than abrupt scene cuts, because they must be

distinguished from regular camera operations that cause similar temporal variances and usually trigger false detections. Especially for video content with high spatial and temporal activity level, the detection of gradual scene changes becomes even more challenging (Hampapur, Jain, & Weymouth, 1995).

Hence, the goal of this temporal video segmentation is to divide the video stream into a set of meaningful and manageable segments that are used as basic elements for indexing. Further analysis may be performed, such as representation of the video content and event identification.

In future multimedia systems, the offered video services will be provided in the form of MPEG-21 digital items, which integrate a typical encoded media clip along with its XML-based metadata descriptors, enabling in this way advanced search and retrieve abilities. Also future multimedia implementations will adapt MPEG-21 schema, which means that upcoming media recorders must be able to automatically create video content indexing.

This chapter will outline the various existing methods of boundary shot and scene change detection.

BACKGROUND

A primitive typical approach to indexing video data was the manual creation of textual annotations along with time headers in the metadata of a media file. However, such a human-based method is time consuming and practically not applicable. Moreover, such methods suffer from the subjectivity of the human operator during the textual description.

Therefore, it is necessary to develop an integrated framework for automatic extraction of the most character-

istic frames of a video sequence, which will finally enable the efficient indexing and description of a video sequence. More specifically, by developing methods that enable the automatic build of a scene-access menu for a video clip, the viewer may use this index for quick access at a specific scene or for performing scene searches.

Several approaches have been proposed in the literature for automatic video indexing, which can be basically categorized as methods for temporal segmentation in an uncompressed or compressed video domain (Koprinska & Carrato, 2001; Lienhart, 1999; Dailianas, Allen, & England, 1995).

Thus, the various temporal video segmentation methods for each class (i.e., uncompressed/compressed) will be discussed in the following sections.

SHOT BOUNDARY DETECTION IN UNCOMPRESSED DOMAIN

Video segmentation in an uncompressed domain includes all the boundary shot detection methods that perform using metrics and mathematical models on the uncompressed/spatial video signal. Most existing methods detect shot boundaries of video based on some change of the video content on the visual domain between consecutive frame pairs. If the measured change is above a predetermined threshold, then a shot boundary is assumed and reported.

Based on the metrics nature that is used to detect the differences between successive frames, the algorithms can be generally classified into the following classes: pixel-based, block-based, and histogram-based (Zhang, Low, Gong, & Smoliar, 1994, 1995).

Pixel-Based Methods

Pixel-based methods evaluate the differences in luminance or color domain between pixel values of successive frames (Kikukawa & Kawafuchi, 1992). Hence, a per pixel comparison is performed between frame pairs. Depending on the measured difference from the pixel-based comparison, a scene cut is detected and reported if the calculated difference is above a pre-defined threshold value. Otherwise no scene change is reported. The sensitivity and the efficiency of the pixel-based methods are strongly related to the selection of the reference threshold.

Block-Based Methods

In contrast to the aforementioned pixel-based methods, where the whole frame of a video movie is taken under consideration for the scene change detection and the corresponding measured difference in the pixel values, either in color or

luminance domain, in block-based methods each frame is divided into blocks that in turn are compared to their corresponding blocks in the successive frame (Kasturi & Jain, 1991; Shahraray, 1995). More specifically, in contrast to the aforementioned pixel-based techniques, where the critical unit is the number of pixels whose difference is above a threshold value, these methods report a scene change, when the number of changed blocks is greater than a predefined threshold.

Histograms Comparisons

The aforementioned categories exploit pixel comparison in order to derive a decision. On the contrary, histogram-based methods exploit the fact that a set of frames that belong in the same scene retain, in general unchanged, their luminance- or color-level histograms. A luminance- or color-level histogram of a frame depicts the density of the number of pixels that have specific luminance or color value.

As has been described, the majority of the aforementioned methods are implemented based on metrics of the uncompressed video domain, utilizing a common framework: a similarity measurement between successive frames.

SHOT BOUNDARY DETECTION IN COMPRESSED DOMAIN

Multimedia applications that distribute audiovisual content over communication networks (such as video-on-demand (VOD) and real-time entertainment streaming services) are based on digital encoding techniques (e.g., MPEG-1/2/4 and H.261/2/3 standards) that achieve high compression ratios by exploiting the spatial and temporal redundancy in video sequences. Most of the standards are based on motion estimation and compensation, using the block-based discrete cosine transformation (DCT). The use of transformation facilitates the exploitation in the compression technique of the various psychovisual redundancies by transforming the picture to a domain where different frequency ranges with dissimilar sensitivities at the human visual system (HVS) can be accessed independently.

The DCT operates on a X block of $N \times N$ image samples or residual values after prediction and creates Y , an $N \times N$ block of coefficients. The action of the DCT can be described in terms of a transform matrix A . The forward DCT is given by:

$$Y=AXA^T$$

where X is a matrix of samples, Y is a matrix of coefficients, and A is an $N \times N$ transform matrix. The elements of A are:

$$A_{ij} = C_i \cos \frac{(2j+1)i\pi}{2N}$$

where

$$C_i = \begin{cases} \sqrt{1/N}, & i \neq 0 \\ \sqrt{2/N}, & i = 0 \end{cases} \quad (1)$$

Therefore the DCT can be written as:

$$Y_{xy} = C_x C_y \sum_{i=0}^{N-1} \sum_{j=0}^{N-1} X_{ij} \cos \frac{(2j+1)y\pi}{2N} \cos \frac{(2i+1)x\pi}{2N} \quad (2)$$

Afterwards in the encoding chain, quantization of the aforementioned DCT coefficients is performed, which is the main reason for the quality degradation and the appearance of artifacts, like the ‘blockiness’ effect.

Several methods for shot boundary detection in the compressed domain have been developed. According to Koprinska and Carrato (2001), they can be classified into the following categories, depending on the used metric:

- **DCT Coefficients:** The temporal video segmentation methods based on DCT coefficients apply a comparison technique to the DCT coefficients of the corresponding successive video frames. The difference metric is somewhat similar to the aforementioned pixel-based metric, where a scene change is detected and reported when the measured difference exceeds a specific threshold value (Zhang et al., 1994, 1995). It must be noted that these methods can be applied only on intra-coded frames of a DCT-based coded signal, because only they are fully encoded with DCT coefficients. Thus, the processing requirements may be low, but the temporal accuracy of the detected frame drops dramatically, and it is highly dependent on the intra-frame periodicity.
- **DC Terms:** The DC term is a scaled version of the average value for each block and thus the DC terms are directly related to the pixel domain. So, in a similar way to the uncompressed domain methods, the DC terms-based metrics measure the DC terms differences between successive frames. Again a frame is reported as shot boundary, if the aforementioned measurement is higher than a pre-defined threshold (Yeo & Liu, 1995).
- **DC Terms, Macroblock (MB) Coding Mode:** This is a hybrid method in which, except from the aforementioned DC terms, the type of the macroblock (MB)

coding is taken under consideration as well. When a scene change takes place, then some macroblocks of an inter-coded frame may be intra-coded due to limited reference options, demonstrating where scene change occurs (Meng, Juan, & Chang, 1995).

- **MB Coding Mode and Motion Vectors (MVs):** Similarly to the previously described method, a hybrid model is exploited, where it takes under consideration both the MB coding mode and the MV information of the encoded video sequence.
- **MB Coding Mode and Bit Rate Information:** Finally this method uses both bit rate information and motion-predicted MB types in order to derive accurate estimation of the scene changes. The forced intra-coding of some MBs over a scene change increases the deduced bit rate due to the inefficiency of the intra-coding method.

Similarly to the shot change detection methods of the uncompressed domain, this section has shown that also the methods of the compressed domain exploit analogous frameworks at their implementation, which is based on the comparison of the calculated metric between successive frame pairs.

FUTURE TRENDS

All the aforementioned methods use a threshold parameter in order to distinguish shot boundaries and changes. Thus, a common problem in shot boundary detection lies in the selection of an appropriate threshold for identifying whether a change is sufficiently large to signify a shot boundary or not (Lu & Tan, 2005). If a global threshold is used for the detection of shot boundaries over the whole video, then successful detection rate may vary up to 20% even for the same video content (O’Toole, Smeaton, Murphy, & Marlow, 1999). To improve the efficiency and eliminate this performance variation, some later works propose to use an adaptive threshold which can be dynamically determined based on video content (Lienhart, 1999; Dailianas et al., 1995). But even these methods require a lot of computational power in order to estimate successfully the appropriate threshold parameter, making their implementation a challenging issue, especially for real-time applications.

Thus, the research community faces the challenge of developing new techniques and methods for detecting scene changes over a video signal by eliminating the necessity of threshold parameters in the decision process.

Moreover, in order to allow a more efficient exploitation and browsing of video-anthologies, it is necessary to integrate these boundary shot detection techniques within content-based search and access methods, where the categorization of the video content is occurred by retrieving

highly representative optical and semantic information. In this respect, the combination of frame extraction techniques and semantics will help towards the evolution of the current Web to the Semantic Web, where the browsing and searching of information will be based on semantic information.

CONCLUSION

This article outlines the various methods for detecting and extracting the scene changes from a video sequence. Depending on the metric that is exploited for the detection procedure, the methods that have been proposed are classified into two broad categories: those based on the uncompressed domain and those that exploit the metric of the compressed domain. Both the categories share the common drawback that they use threshold values for their decisions. Thus, the research community faces the challenge to develop new techniques that eliminate the use of threshold values, eliminating in this way the complexity and the computational requirements of the proposed methods.

KEY TERMS

Bit Rate: A data rate expressed in bits per second. In video encoding the bit rate can be *constant*, which means that it retains a specific value for the whole encoding process, or *variable*, which means that it fluctuates around a specific value according to the content of the video signal.

Frame: One of the many still images which as a sequence composes a video signal.

Histogram: A luminance- or color-level histogram of a frame depicts the density of the number of pixels that have specific luminance or color value.

Multimedia: The several different media types (e.g., text, audio, graphics, animation, video).

Pixel: Considered the smallest sample of a digital image or video.

Shot Boundary Detection Techniques for Video Sequences

Shot: An unbroken sequence of frames taken continuously from a single camera.

Video Codec: The device or software that enables the compression/decompression of digital video.

Video Coding: The process of compressing and decompressing a raw digital video sequence.

Smartphone Acceptance among Sales Drivers

Jengchung V. Chen

National Cheng Kung University, Taiwan

INTRODUCTION

The objective of this research is to find out the acceptance of sales drivers in logistic industry to use the smartphone in their work. This research uses two methods to collect data: survey and experiment. This research integrates technology acceptance model (TAM) (Davis, 1989), self-efficacy (Bandura, 1982, 1986), and innovation diffusion theory (IDT) (Rogers, 1962) into the research model to find out the factors of sales drivers in logistic industry accepting the smartphone. This experiment is focused on three user groups: the employees of a business that implements smartphone usage, the employees of businesses that do not use smartphone, and the students that are currently studying at a department of transportation and communication management. The results will help us understand whether this technology should be integrated into the traditional logistics system, and get to know the pros and cons of this idea.

BACKGROUND

Freight businesses in the logistics industry perhaps have few examples of utilizing mobile devices thoroughly in their daily operations. Sales drivers who are responsible for distributing goods on time need to not only interactively exchange information with the headquarters, but also need to use spare time visiting their customers. Because of the needs to better serve their customers and other operational purposes, logistics businesses have their employees equipped with all sorts of devices like hand held terminal (HHT), bar code reader, GPS, and on board unit (OBU) to keep track of the goods. In addition, those drivers who for a long time have been considered as shippers now have another important role—salesperson.

SMARTPHONES

Since the invention of the telephone in 1876, peoples' lifestyles have been changed drastically as time passes. Then, Martin Cooper introduced a whole new level of communication by using the concept of wireless technology, called the cellular phone.

Since then, the cellular phone has been part of many people's lives, and nowadays almost everyone owns a cellular

phone. The cellular technology has evolved so drastically that phones with high-resolution digital cameras, voice recording and digital assistant are very familiar to most people. And to satisfy business users, powerful handheld devices that run the smartphone operating system have been developed. All these gadgets are here so that they can make peoples lives easier. Smartphones support many features that are really helpful in the business sector, for example, this cellular can be associated with OBU (on board unit) to create a more efficient delivery system for logistics companies. This technology has greatly benefited logistics companies since the implication of this technology took place. And more and more functions are being included for example portable bar code scanners and real-time communications systems that can update detailed information amongst the driver and the office at all times. Smartphones not only provide useful business oriented functions; they also provide useful functions such as calendars, task planning and even high-speed mobile Internet over the 3G network (Valletti & Cave, 2002; Ralph, 2002; Funk, 1998).

Different Categories of the Cellular Phones

Cellular phones are separated into three categories; the categories are sorted by the limitations of their functions shown as follows:

- **PDA Phones:** These kinds of phones support all the functions that a PDA can do, it is actually a whole PDA integrated into the phone. PalmOS, Symbian and Windows CE are examples of operating systems that are used in PDA phones. More and more software developers are developing operating systems that are becoming more powerful (e.g., Linux). Most of these PDA phones are even able to read and edit Word, Excel and even PowerPoint files, which is really convenient for business users who don't like to carry their computers around.
- **PIM Phones:** Known as the Personal Information Manager, it could also support features such as Outlook synchronization with a personal computer, but the functions are more limited compared to the PDA phones. PIM phones use a closed operating system; they do not support as many applications like the PDA phones.

Smartphone Acceptance among Sales Drivers

Figure 1. 2000-2007 shipment of smartphones (IDC)

- **Cellular Phones:** This is the most basic form of wireless phones, which usually offer simple address book functions, messaging, GPRS, WAP, MMS, and video calling. Some of these phones might support Java applets, but the functions are still very limited.

Operating System

There are currently many operating systems for mobile phones on the market, namely Linux, Windows Mobile, Symbian and Palm. Microsoft Windows Mobile and Symbian are most commonly used; this is because of the ease of use and the high compatibility of applications. Some of the operating systems' source codes for mobile phones are open for software developers to use, this can allow more software applications to be developed and allow a higher usage of mobile Smartphones (Gruber & Verboven, 2000; Harrison & Holley, 2001).

Differences between the different mobile phone operating systems are shown as follows:

- Windows Mobile is separated into three different categories, namely Pocket PC, Pocket PC Phone edition and Smartphone; these are all developed by Microsoft. All of the three operating systems are very powerful and can support vast amounts of applications just like the PDA and even some PC applications.
- Symbian operating system is very commonly used because of the ease of use of the system. It also has integration of other software-developing companies that are continuously developing new applications and thinking out new ideas to improve it.
- Linux is well-known for being free; this makes no exception for Linux on mobile phones. This operating system's source code is open to the public; it allows any

kind of alteration to the system itself and allows any developer to develop applications, all for free. Linux also turns out to be one of the most stable operating systems on the mobile phone market and the PC market too. But the problem with this operating system is the low support for applications.

- Palm OS has very high usage in the PDA market; they have successfully integrated the PDA technology with mobile phone technology. They are famous for their highly efficient input method by using the touch screen, and the high support of applications. Most applications that can be used on a Palm OS PDA can be used on a mobile phone running Palm OS for mobile phones.

Because of the rapid growth of smartphones' technology, more and more people are switching from a PIM or a normal cellular phone to using a smartphone, because they realize that it really can make a difference in their busy life. Smartphone-based technology has also been integrated into many logistic systems. From the data gathered from the IDC (International Data Collection), it shows that the number of Smartphones shipped is growing annually, and it also has been forecasted that this trend will continue to grow.

LOGISTICS

In the old days the word logistics had to do with the military's operations, it mainly dealt with procurement, distribution, maintenance and replacement of material and personnel. Nowadays it mainly has to do with the flow of material from one place to another, used mainly in the transportation industry. Logistics operation can include many other functions such as warehousing, packaging and other information based functions.

Figure 2. The composition of logistics

Logistics can be separated into four main categories:

- **Manufacturing Logistics:** Logistics activities starting from the manufacturer’s location to the location of the market.
- **Sales Logistics:** Logistics activities from the market to the consumer.
- **Procurement Activities:** Logistics activities based on purchasing of raw materials or other products.
- **Recycling Logistics:** Logistics activities based on returned merchandise.

Examples of motor vehicle logistics:

- Door to door service
- Post office service
- 3rd party logistics service
- Specialized transportation service
- Transportation of dangerous or abnormal goods
- Transportation rental service

As seen from the above, motor vehicles still play an important role in logistics, motor vehicles can access almost any hard to reach area, and it does not need any kind of facility (e.g., railroad, airport, port etc.) to enable the usage. It also can carry a tremendous amount of cargo.

SMARTPHONE AND LOGISTICS

To achieve maximum efficiency in logistics, it is recommended that smartphone technology be integrated. The use of modern technology can be really helpful in logistics service: bar code usage, GPS tracking and GPS navigation facilities have been of great help to the logistics industry in the recent years. These technologies allow customers to use logistics services with more confidence, because they know every detail that they need to know about the parcel. This is achieved by combining bar code technology with real-time GPS tracking. Drivers no longer need to keep calling the

logistics company to track your parcel status. GPS also can navigate the driver to the shortest route available with real-time data; this can save a lot of time because drivers are not always familiar with the area that they are at.

SETTINGS FOR THE EXPERIMENT

This experiment is based on statistical analysis of data that is gathered through a questionnaire. The questionnaire is based on data from logistics companies that have already integrated mobile smartphone technology into their systems. The study is to investigate a case of a logistics company in the freight business; it is one of the major logistics companies in Taiwan that provides overnight delivery service of parcels and mail. They have already integrated smartphone and GPS technology into their delivery system. Bar codes are scanned at every point in the delivery process, and the data scanned is sent through the GSM network to the main control center; therefore a customer’s area allows one to track the status of the objects that are sent. GPS is used to navigate the driver, and to avoid delays caused by heavy traffic zones. GPS can also get the driver to the right location without getting lost.

ANALYSIS OF RESULTS

The study collected 30 samples for this analysis:

- 10 employees from logistics companies that use smartphone
- 9 employees from logistics companies that do not use smartphone
- 11 students from a transportation and communications management major

The entire groups’ ages range between 19 and 50 with an average of 31. Level of education is from high school or higher.

T-Type Analysis

Statistic t-test is used to analyze the data collected and it is found that only two hypotheses had positive results. After the experiment of function comparison, the VOIP function is more important compared to GPS and barcode reading; barcode has been shown to be very important too.

Five hypotheses are proposed, and only one is rejected. The only one that is rejected is the GPS function; they do not think that this is a very important function. But the result shows us that there is a very high level of acceptance of students, and statistics shows that logistics companies might be implementing more modern technology in the future.

FUTURE TRENDS

The demand for smartphone technology will keep increasing in the future as the technology matures. The acceptance of smartphones in the transportation industry is growing, mainly because it can greatly increase the efficiency of delivery and customer relationships. Later models of smartphones bind many functions together so that you don't need to carry a lot of different equipment for different functions; for example handhelds units have GPS, GPRS and some even have barcode reading integrated in just one handheld PDA device. And the prices of these products are dropping gradually making it more affordable and increasing the will for a company to use these products.

CONCLUSION

From the results of the experiment, it shows that:

1. VOIP function shows more acceptance than other functions such as calendar functions.
2. GPS function is more important than the presentation function; navigation can allow drivers to avoid a lot of problems on the road.
3. VOIP is better than the messaging function; voice communication is direct and instantly responsive unlike messages.
4. GPS is more important than the barcode reading function. The barcode reading system has to be integrated with other technology to be able to function, which could sometimes be inconvenient. GPS shows more importance.

It is also identified the different levels of importance between different user groups:

1. GPS is considered useful for logistics companies; with this technology anyone is able to deliver products even if they are unfamiliar with the area.
2. Barcode is very important to companies that are currently using it. A majority of companies that are not using it yet show that they are willing to try it out.
3. VOIP has shown to be important to everyone, because this function can allow companies to save a tremendous amount of money on phone bills.

The utilizing of smartphones can benefit all parties by an increase the efficiency, which is one of the most important factors in the transportation industry. As smartphone technology grows, users outside the industry can also make use of smartphone devices in their daily lives, for example, GPS can be installed in all kinds of vehicles even on some bicycles. One reason for the rapid growth of technology is the high demand for new ideas, there is new technology designed for everyone, and making good use of it can improve our quality of life.

More academic theories should be surveyed to investigate the sales drivers' intention to use such the new technology. Take TAM for example, it excludes Hartwick and Barki's (1994) findings, which says subjective regulation impacts to the new technology acceptance. Other researchers proposed many more factors to be included in the TAM model. Future studies should also take these factors in to account: social influence processes and cognitive instrumental processes (Venkatesh & Davis, 2000), trust (Gefen, 2000), task-technology fit model (Dishaw & Strong, 1999), perceived characteristics of innovation (Plouffe et al., 2001), social influence and behavior control (Taylor & Todd, 1995).

KEY TERMS

Barcode: A series of vertical bars of varying widths, in which each of the digits zero through nine are represented by a different pattern of bars that can be read by a laser scanner.

Global Positioning System (GPS): A system of satellites, computers, and receivers that is able to determine the latitude and longitude of a receiver on Earth by calculating the time difference for signals from different satellites to reach the receiver.

Logistics: Operations that deal with the procurement, distribution, maintenance, and replacement of material and personnel.

On Board Unit (OBU): Portable electronic device similar to a PDA.

Operating System: Software designed to control the hardware of a specific data-processing system in order to allow users and application programs to make use of it.

Smartphones: Mobile phone that had PDA functions integrated into it.

3G: Wireless technology that provides high-speed data transfer and portable video phone call service.

Voiceover Internet Protocol (VoIP): Voice communication that is done through Internet: usually can reduce costs of international calling.

SMS-Based Mobile Learning

Krassie Petrova

Auckland University of Technology, New Zealand

INTRODUCTION

Students today combine study and work and expect significant cost and time savings from the use of information and communication technologies, including mobile communication. A strong interest in implementing mobile technologies in learning has emerged. Experiments with one of the most popular technologies—text messaging—have been reported in the literature (e.g., Stone & Briggs, 2002; Finn, 2004) with some including the development of blended learning models (Stone, Briggs, & Smith, 2002).

An early definition of mobile learning (m-learning) as “learning through mobile computational devices” can be found in Quinn (2000). Later, frameworks and research models were developed, providing guidelines for implementing suitable pedagogical approaches and for building services and applications relevant to a variety of mobile platforms and contextual settings (Garner, Francis, & Wales, 2002; Seng & Lin, 2004; Berth, 2005; Brown, 2005).

SMS (short message service, or text messaging) is an extremely popular and still growing 2G mobile data service, especially with young adults (Finn, 2004; Prensky, 2005; MMA, 2006; Grinter & Eldridge, 2003), which makes it suitable as a learning technology. This short article presents and illustrates the concepts of SMS-enabled m-learning, describing a series of SMS learning scenarios derived from the literature. The defining features of the scenarios are identified and discussed, including future trends.

BACKGROUND

Mobile learning is often referred to as a type of e-learning (Vavoula & Sharples, 2002; Leung & Chan, 2003; Seng & Lin, 2004). For the purposes of this article mobile learning is defined as a form of e-learning, which can take place anytime and anywhere through the use of a wireless and mobile communication device and the related network technology (Brown, 2005; Kukulska-Hulme, Evans, & Traxler, 2005; Wagner, 2005; Petrova, 2007).

An SMS scenario can be defined as a self-contained learning experience focused on a group of participants who act in a specific context and perform specific tasks to achieve knowledge acquisition oriented goals using the SMS mobile technology (Petrova & Sutedjo, 2004; Evans & Taylor, 2004). As text messaging is enabled on all types

Figure 1. An SMS-based learning scenario framework

of 2G and 3G mobile phones, an SMS-learning scenario will be accessible to virtually any mobile phone user.

The framework in Figure 1 captures the main aspects from which researchers have described and evaluated m-learning, including SMS-based learning (Trifonova, 2003; Attewell, 2005; Riordan & Traxler, 2005; Silander & Rytkonen, 2005; Chinnery, 2006).

Architecture

Architecture deals with the specific mobile platform or platforms developed and used within a mobile learning scenario. The basic architecture would include access to the SMS provider network, an SMS-enabled cell phone and an SMS server or gateway (Petrova, 2007; Capuano, Gaeta, Miranda, & Pappacena, 2004). It might also include a number of auxiliary servers, such as a Web site, used to send bulk SMS messages and/or to provide instructions for participants. In some cases, additional infrastructure is needed to support a scenario where SMS is used in conjunction with another mobile technology (e.g., WAP), or a scenario where SMS learning is integrated with another e-learning approach to become part of a blended learning model.

Design and Pedagogy

Design and pedagogy describes the context for which the scenario was designed and developed, including its activities and expected learning outcomes. The framework in Figure 2 presents the general design contexts and the pedagogical aspects of m-learning.

Participants

The *participants* might be learners (university students, adult learners, or the general public) and teachers (faculty,

Figure 2. SMS learning scenarios: Design contexts and pedagogical aspects

| SMS Scenarios: Design Contexts (Roibas, 2002; Bollen, Eimler, & Hoppe, 2004; Kadirire, 2005; Pincas, 2004; Colley & Stead, 2003; McMillan & Keough, 2005) | SMS scenarios: Pedagogical Aspects (Pincas, 2004; Singh, 2003) |
|--|---|
| <ul style="list-style-type: none"> Supporting both independent & collaborative learning Supporting “just-in time learning” Supporting content delivery in a condensed format Supporting multiple learners’ learning styles | <ul style="list-style-type: none"> The urgency of user needs The ownership of initiative The mobility of setting The interactivity of process The situated-ness of needs The integration of content |

administrators). Participants’ background, perceptions, attitudes and priorities play a critical role in the successful adoption of a scenario where they have a stakeholder role (Barker, Krull, & Mallinson, 2005).

TYPES OF SMS-BASED SCENARIOS FOR MOBILE LEARNING

Scenario descriptions were extracted from the literature on mobile learning (2002-2005). These include cases from Europe (UK, Ireland, Greece, Germany, Finland), Asia (Japan, Thailand, Malaysia), Africa (South Africa), Australia and New Zealand. The scenarios were classified based on their context, content, and orientation (Figure 3).

Two major categories were identified, each comprising five scenario types: *learning* (delivery of new content, test and quizzes, learning for revision, simulation-based learning, collaborative learning), and *learning support* (student support, communication, teacher support, blogs, Q&A sessions). Examples that illustrate each type are presented as follows, providing details about the participants, the educational setting, and the required additional technology.

Figure 3. Types of SMS learning scenarios

| Learning | Learning support |
|---------------------------|------------------|
| Delivery of new content | Student support |
| Tests and quizzes | Communication |
| Learning for revision | Teacher support |
| Simulation based learning | Blogs |
| Collaborative learning | Q & A sessions |

Delivery of New Content

All examples in this category refer to learning a foreign language. The participants are learners—there is no interaction with teachers. The SMS server needs to be able to handle registrations and store content.

The InLET project (Pincas, 2004) provided language support for international tourists attending the Olympic games in Athens. Tourists who subscribed to the service received SMS messages with short phrases in Greek. They could also request and receive a translation from or into Greek of a commonly used phrase.

Another example is the structured short course in English delivered to working learners in Hong Kong (Song & Fox, 2005). New words and expressions were sent to learners on a regular basis, following a predefined sequence of learning tasks. The course material was also available on the Web. Similar scenarios were implemented in Japan (Thorton & Houser, 2005) and in Australia (Levy & Kennedy, 2005).

Commercial mobile services for language support are also available (Chinnery, 2006). Munro (2005) describes a commercial application, which delivers a pair of learning objects to a paid customer: a text-based object using SMS, and a sound object via podcast to an MP3 player or a smartphone.

Tests and Quizzes

Tests and quizzes are used for formal learning and for self-assessment. Tests are typically conducted in controlled conditions. Quizzes are used in class or as a supplementary homework activity. Receiving feedback (“the score”) is an important feature of a test or a quiz.

Tretiakov and Kinshuk (2005) describe a scenario where students in class were given a quiz and then had to submit

their answer via SMS. The quiz question could be “multiple choice,” “fill in the blank” or “matching lists.” Students could work individually or share a mobile phone to send the answer as a group. Individual feedback was accessible on a Web site. Very similar is the setting described in Iliescu and Hines (2005), which also expanded the range of question types to include free text questions.

The example found in Capuano et al. (2004) offers functionality similar to the scenarios above. However there is no need for an additional platform (the Web), as all communication is based on SMS: the question text is sent to the student who responds with the answer and receives feedback. In the example the SMS service is part of a larger, multi-channel, integrated platform.

Finally, a formal testing experiment is reported in Whatananarong (2004). Students sent test answers via SMS after being shown or read the questions in the classroom. There is immediate feedback.

Learning for Revision

Mellow (2005) describes the study platform StudyTXT, which was implemented to facilitate a “flash card” scenario at a New Zealand university: students studying sports medicine could download content relevant to a topic of their choice. They could see the list of available topics on a Web site. A similar use of the same platform is proposed in Petrova (2007).

A different approach is adopted in the scenario described in Riordan and Traxler (2003): rather than being given the option to request a revision snippet, students identified as being at risk of failing a test were sent revision tips and directions for further study by their lecturers.

Simulation-Based Learning

Cheung (2004) describes a series of classroom experiments involving simulation gaming in a postgraduate microeconomics class. Students were given the game plan and had to submit responses related to the game via SMS. All responses were transmitted from the mobile network over the Internet to the teacher at their workstation, who then used specialised software to generate individualised return messages. These were broadcast back to students, simulating direct interaction among students.

Another participatory simulation game is described in Lonsdale, Baber, and Sharples (2004). Participants were involved in a role play (as “water droplets”) and were sent “entry” and “exit” messages (commands) directing them to perform certain actions in the physical classroom environment. As the simulation game was run under Java, the text messages were sent from a mobile phone connected to the PC running the game.

Collaborative Learning

Bollen, Eimler, and Hoppe (2004) describe a scenario for a constructive discussion implementing a decision support system (“Cool Modes”) in a literature class. Students were assigned specific roles and sent text messages related to the role from a PDA (mimicking SMS). The messages were delivered via the internal wireless LAN to a MySQL database on the teacher’s PC. The teacher could query the database and display the discussion threads to the class on an electronic whiteboard.

A similar scenario is presented in Kadirire (2005): while listening to a presenter, students used mobile phones to text their comments which were stored in a database and then subsequently organised and formatted to be displayed to the class. The presenter could give feedback based on the comments.

Student Support

In most instances of this scenario (Mohammad & Norhayati, 2003; Stone, 2004a; 2004b; Nonyongo, Mabusela, & Monene, 2005), assistance is offered to a class or a cohort of students informing them about changes in schedules, or reminding them about deadlines and other events. A Web accessible database might be used to register users for the service.

Communication

Seppala and Alamaki (2002) describe an integrated scenario where voice communication, SMS messaging and a WAP gateway were used to create a media-rich environment for communications between instructors and trainee teachers. Text messages were used to transmit general information among all participants.

Teacher Support

Silander and Ryttonen (2005) provide an example for meeting teachers’ pedagogical needs. SMS was used to assist lecturers as part of an intelligent tutoring system (Alykko). Text messages were stored in a Web accessible format and were used to record learning logs (similar to blogs), to send instructions to students and to respond to questions (similar to Q&A sessions).

Blogs

The blog scenario presented in Divitini, Haugalokken, and Morken (2005) included SMS as part of a learning management system (LMS). It enabled students doing their teaching practice to upload entries to a shared community blog and

to individual student blogs. The blogs were accessible for viewing on a Web server.

Questions and Answers (Q&A)

This scenario involves a general tool available to all students on and off-campus, which collects questions and displays them on a Web site (anonymized). Answers from staff are also displayed (Ng'ambi, 2005).

SMS SCENARIOS: SUMMARY

Applying the design contexts framework (Figure 2, left-hand column) it can be concluded that:

- SMS allows for the development of both independent and collaborative learning models. In a significant number of examples a mixed model is implemented—where all participants can benefit from individual experiences
- Multiple learning styles might be supported in cases where SMS is integrated into a larger LMS or VLE (virtual learning environment).
- As a technology, SMS is especially well suited for “just-in-time learning;” however, if integrated with other technologies, technology access issues might interfere with the process (e.g., learners on the move might have access to a mobile phone but not to the Web).
- SMS content always needs to be condensed due to the limitations of the technology (160 characters in one text message).

Analysing the pedagogical aspects of SMS learning (Figure 2, right-hand column) it can be seen that:

- Learner support scenarios are especially well tailored to satisfy urgent needs as most are based on a pull approach (the learner owns the initiative). Some of the learning scenarios are also pull-based (e.g., the flash card scenario) and rely on the learner to realise their need and engage in an m-learning activity.
- While the initiative in some cases belongs entirely to the teacher (e.g., sending tips to “weak” students), a group of scenarios supports both push and pull approaches (e.g., scenarios which augment classroom activities.)
- All scenarios except one use mobile and wireless networks.
- Most scenarios are highly interactive, often using auxiliary infrastructure (e.g., for displaying results, or for providing detailed instructions).

- The enhancement of SMS through adding other technologies to the interactions interferes with the mobility of the learner (e.g., a mobile learner might not have mobile access to all technologies such as the Web, involved in an integrated scenario). The cost of integration needs to be balanced with the benefits derived from the use of other communication channels.
- In most scenarios the level of integration between content and situation is very high (e.g., discussions, Q&A sessions, simulations).

FUTURE TRENDS

SMS has already evolved into enhanced services, which are capable of transferring images and animation (EMS, MMS). Multimedia messaging offers an integrated platform and thus eliminates the need of embedding SMS into environments based on other technologies. MMS and EMS allow the learner to be truly mobile, as users with smartphones can have access to the mobile Internet and to the Web. Some of the SMS scenarios may migrate to MMS (one example is the study of a foreign language). New types of personal learning are expected to evolve around these technologies, and pedagogical models will need to be developed and evaluated alongside with the development of specially organised and formatted content. However, SMS scenarios will continue to be attractive in environments where cost of using more sophisticated or advanced technologies might be prohibitive.

CONCLUSION

This article extensively reviews the literature on mobile learning models using SMS. Based on the results of the review, it classifies SMS-learning scenarios into two major categories and provides examples to illustrate the types identified under each category. A framework of design contexts and pedagogical aspects is used to summarise the findings. Future trends including multimedia and MMS scenarios are also discussed.

KEY TERMS

Blended Learning: A learning paradigm where multiple pedagogical approaches are used.

Blogging: Periodic publishing on the Web in a specially designed space for collaborative writing (Web log).

E-Learning: Learning facilitated by information and communication technologies (“electronic learning”).

EMS: Enhanced message service.

Flash Card Learning: A method of learning by memorising, often used in studying disciplines such as medicine or law. A flash card has two parts—a question part and an answer part.

Just-In-Time Learning: A learning model where learners acquire knowledge as the need arises

LMS: Learning management system

MMS: Multimedia message service

Smartphone: A mobile phone, which can connect to the Web via a browser and support email.

SMS: Short message service

WAP: Wireless application protocol

VLE: Virtual learning environment

Snapshot Assessment of Asia Pacific BWA Business Scenario

INTRODUCTION

The world is moving forward at a soaring rate. Within this change wireless technology is rapidly evolving and is playing an increasing role in the lives of people throughout the world. The people of today demand hassle-free and compact products, which can be used at anytime and anywhere with “always-best-connected” network solutions (Wong, Tan, & Hiew, 2005b). Wireless technology is a possible solution to meeting the immediate needs of society in the case of high-speed data delivery.

This article is devoted to assessing the deployment of wireless networks in the Asia-Pacific region, with special focus on the existing Wi-Fi and the emerging WiMAX solutions. Further, the overviews of wireless technologies as used in different business environments are given. The article is categorized into two sections: logistics, and retail and distribution. Each section discusses an example of a wireless solution adopted in the Asia-Pacific region.

This article offers a compilation of wireless solutions in the Asia-Pacific in order to map possible future scenarios on the use of wireless technologies in this region. The article serves as a foundation for further studies concerning the use of wireless technologies to improve quality of life.

BACKGROUND

The wireless local area network (WLAN) based on the IEEE 802.11 family of standards has demonstrated great efficiency and received positive responses for delivering broadband services. On the other hand, IEEE 802.16 (WiMAX), is a new wireless standard for broadband wireless access (BWA). WiMAX,¹ an acronym that stands for Worldwide Interoperability for Microwave Access, is a certification mark for products that pass conformity and interoperability tests for the IEEE 802.16 standards (Marks, 2006). It further extends

the performance of IEEE 802.11 (Wi-Fi²) in terms of capacity, coverage range, quality of service (QoS), and mobility (with 802.11e-2005).

Technological revolution in communications is taking place in logistics. The industry is advancing significantly, adopting wireless technologies to secure its assets and improve services. The benefits accrued using wireless solutions in logistics include lowered insurance premiums, instant notification of security breach, flexible and secure handling of high-security cargo by authenticated personnel, data access through a wide range of mobile devices, and so forth.

In addition, wireless solutions have the fastest returns on investment in the back office and supply chain functions of retail environments. Wireless applications in retail and distribution make workers more productive, streamline operations, help goods flow faster, and provide access to real-time data and inventory. As a result, productivity increases with the reduction in errors, which ultimately improves the customer's experience. Businesses in other sectors have embraced the information revolution to reduce costs and improve productivity (Frist & Clinton, 2004). They use information technologies not as an end, but as a means to innovate and improve.

Problem Description: Logistics Industry

Today transportation companies are experiencing unprecedented upheaval (Baracoda, 2005). Amid growing customer demands and soaring costs, the logistics industry struggles to develop successful business models that can drive profitable results and achieve customer loyalty. Managing logistics business in the Asia-Pacific is very challenging and highly complex due to multiple countries, currencies, languages, and customs; varying technologies and logistics infrastructure; and multi-modal transportation (The Logistics Institute-Asia Pacific, 2002). Other problems faced by the logistics industry include security breaches, theft, high insurance premiums, and inability to track goods delivery in real time.

Retail and Distribution

The common problems faced in retail and distribution include the time taken in filling out and sending order forms, as well as printing of customers' orders and receipts, failure to provide one-to-one effective marketing due to the inability to access customer and product data at all times, the hassle to retrieve an up-to-date product catalog, and so forth. The increasing general enthusiasm on mobile technologies such as Bluetooth and radio frequency identification (RFID) has a positive effect on the acceptance of new mobile applications and services in retail and distribution (Ondrus & Pigneur, 2004). This would explain the reasons why wireless point of sale (POS) solutions are adopted by retailers. Wireless payments and ticketing are becoming a new trend for quick-service-oriented industries such as toll booths (e.g., Smart Tag in Malaysia).

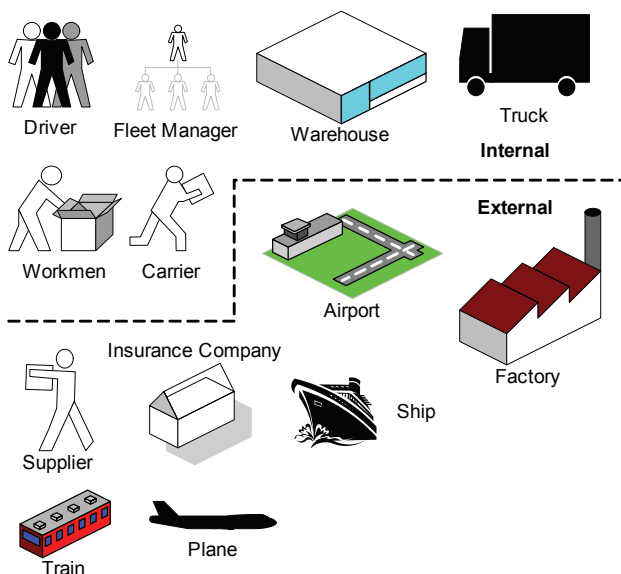

VIEWS OF ENVIRONMENT AND PROCESSES: LOGISTICS INDUSTRY

The cargo transportation industry is advancing significantly adopting wireless technologies to secure its assets and improve services (Nithyasree, 2005). Figure 1 shows the business environment of wireless applications used in the industry.

Uses of Wireless Solutions in Logistics Industry

- **Asset/ Cargo Tracking System:** A satellite-based vehicle tracking system using global positioning system

Figure 1. Business environment for the logistics industry

(GPS) with satellite communications, geofencing³, and cellular communication technologies allows fleet managers to remotely monitor, track, and communicate with their drivers in real time (Nithyasree, 2005).

- **Electronic Seals and RFID:** RFID technology is effectively utilized in the shipping and railroad industries alike. Electronic tracking tags and seals attached to a rail or ship create a WLAN that automatically informs the driver or a central control station of a broken seal (Nithyasree, 2005). These tags can also send vital information about the shipments such as the current status, whether tampered prior to destination, and so forth.

Example of Cargo Tracking System

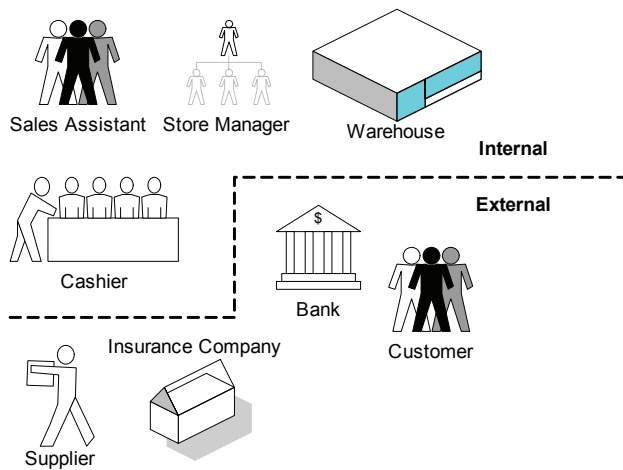

When the workmen pack goods to be delivered onto a truck, the fleet manager checks his personal digital assistant (PDA) for a list of guards on duty. He can see on his PDA the whereabouts of the security guards, and he makes sure that there is no sign of intrusion. Elsewhere, at a seaport, another fleet manager checks his PDA for information on each container, including its physical location based on GPS, parameters such as temperature and humidity, and whether there is any sign of intrusion. The information gathered can be connected to centralized databases. A service-oriented infrastructure allows the staffs to instantly share information. At the same time, a customer checks the location of his goods using his laptop at a hotspot (Wi-Fi). He is pleased that the goods will arrive on time. Once the goods are safely delivered to the customer, the driver enters details into his PDA to notify the fleet managers instantly. An example of a cargo tracking system deployed in the Asia-Pacific region is Kwikfleet (<http://www.kwikfleet.com/>).

Kwikfleet is a Malaysian company offering products and services either fully or jointly developed in Malaysia. With mobile data terminals (MDT), ruggedized portable computers, and wireless modems in their vehicles, fleet managers and their drivers in the field can take advantage of two-way computer-aided dispatching to stay connected while maintaining optimized scheduling and lowest time to destinations through advanced matching and dispatch algorithms. On-the-fly route planning technology will allow dynamic route planning algorithms to be run remotely on the MDT or locally on the intelligent vehicle location system server to serve portable data terminals (Kwikfleet, 2005). By using a geographic information system (GIS) and GPS, fleet managers are able to track a vehicle's location, speed, route traveled, as well as fuel level and so forth.

Business Processes

The logistics industry-related business processes involved in the cargo tracking system example are:

Figure 2. Business environment for retail and distribution

- security monitoring,
- asset/goods management,
- logistics personnel communications, and
- route selection.

Retail and Distribution

Retailers are using employee-activated wireless handheld devices to update inventory processes and increase accuracy and efficiency in all areas of the supply chain. In the process, they are taking significant steps toward reducing human error, returning salespeople to the business of helping customers, and avoiding problems like out-of-stocks and overstocking in order to gain competitive advantage (Schwartz, 2002). Figure 2 shows the business environment of wireless applications used in retail and distribution today.

Uses of Wireless Solutions in Retail and Distribution Industry

- **Wireless POS:** Eliminating cables not only improves user convenience, productivity, and safety, but also cuts down on extra expenses over time. As cables age, they have to be replaced at a rate of two cables per terminal per year. Wireless POS provides better customer service by accommodating fluctuations in customer volumes and providing timely service. This can be achieved using Wi-Fi for WLAN connections, and subsequently using WiMAX or Mobile-Fi (based on IEEE 802.20) for connections between branches at different locations (Wu & Yallapragada, 2006).
- **Inventory Management and Replenishment:** A supplier typically would deliver a certain quantity of

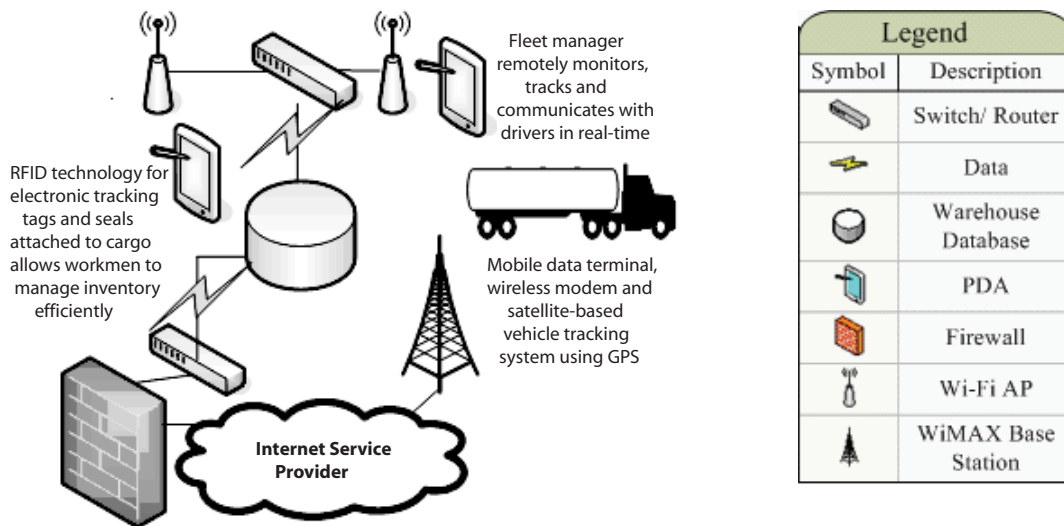

items, scratch out an invoice for the retail store manager to file away, and deliver a copy of that invoice back to the supplier's own accounts department for processing. Retailers frequently dispute bills submitted for payment because of pricing discrepancies, or charged back for unauthorized deliveries. Payments were slow and often incomplete. As a result of this tedious process, retailers suffered from inaccurate inventories. At the same time, suppliers were troubled by lengthy check-in times and high administrative costs, and struggled with remittance. By accessing information from inventory management by means of wireless access technologies, a store manager will be able to retrieve information about goods availability anywhere in real time and plan ahead to schedule purchases by notifying the suppliers. Suppliers will be able to respond almost instantly whether they are able to fulfill the order at a specific time and arrange for delivery.

- **Price Management:** If the retailer has a concern with pricing and price markdowns, a price management application with real-time access (mobile wireless) to the in-store computer has proven to improve item price accuracy (Pillar, 2003).

Example of Wireless Solutions for Retailers

At a corner of a supermarket, a customer scans a number of products at a kiosk while cruising through the store to check for prices and additional information. Elsewhere, a store manager accesses stock details from his portable device. The inventory management system prompts him to make a number of purchase orders to replenish a number of goods. He immediately sends purchase orders to suppliers. One of the suppliers responded that the goods could not be delivered on time. The store manager searches for other suppliers in order to stock up the goods. Customers are queuing up to make payment at the counters. One of the customers who is in a rush makes purchases online via his PDA and is happy that the goods will be delivered to his house within an hour. In the warehouse, a number of workmen place goods into a truck according to the list shown on their portable devices. An example of wireless solutions for retail and distribution industry deployed in the Asia-Pacific region is the SkyWire Wireless Automatic Data Capture Solution (<http://www.skywire.com.au/>). The solution aims at making stocktaking, price checking, and other retail applications more "hassle free." The improved functionality offered by real-time data flow between shop floor and back office systems helped a duty-free retail chain in Australia to deliver even better customer services and enjoy improved operational efficiencies (SkyWire, 2005).

Figure 3. Technical environment for wireless solutions in logistics industry

Business Processes

The retail and distribution business processes involved in the example of wireless solutions for retailers are:

- inventory management and replenishment,
- retailers and distributors negotiation, and
- price management.

FUTURE TRENDS: LOGISTICS INDUSTRY

Figure 3 proposes the devices required to deploy wireless solutions in the logistics industry. In this business scenario, PDAs can be used within the coverage of WLAN. Switches/routers are connected (wired) to a central database where fleet managers and workmen access timesheets, inventory, and so forth.

A firewall is required to protect the system from intrusion to ensure that confidential data is not tampered with. Access to the Internet is likely to be restricted by security policy. Drivers will be accessing the warehouse database using mobile WiMAX (802.16e-2005) or Mobile-Fi (802.20) which supports mobility.

RFID is an automatic identification method, relying on storing and remotely retrieving data using devices called RFID tags or transponders (Want, 2004). An RFID system may consist of several components: tags, tag readers, edge servers, middleware, and application software. The purpose of an RFID system is to enable data to be transmitted by a mobile device, called a tag, which is read by an RFID reader and processed according to the needs of a particular applica-

tion. The data transmitted by the tag may provide identification or location information, or specifications about the product tagged, such as price, color, date of purchase, and so on.

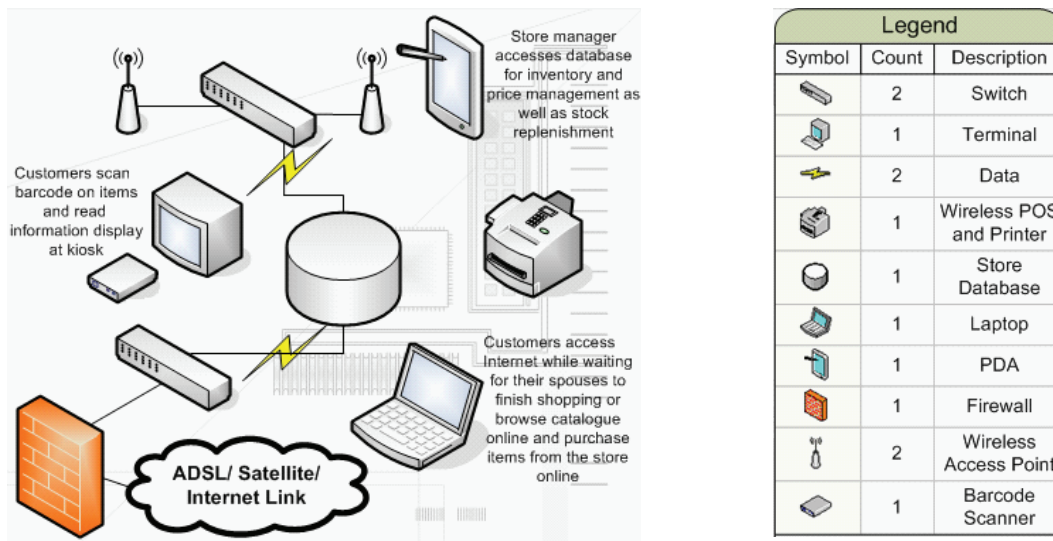

GPS is a satellite navigation system used for determining one's precise location and providing a highly accurate time reference almost anywhere on Earth or in Earth orbit (Beisner, Rudd, & Benner, 1996). The GPS system is divided into three segments: space, control, and user. The space segment comprises the GPS satellite constellation, whereas the control segment comprises ground stations around the world that are responsible for monitoring the flight paths of the GPS satellites, synchronizing the satellites' onboard atomic clocks, and uploading data for transmission by the satellites. The user segment consists of GPS receivers.

Retail and Distribution

Figure 4 depicts the devices required to deploy wireless solutions in retail and distribution. In this business scenario, PDAs and laptops can be used within the coverage area of WLAN. Switches/routers are connected (wired) to a central database where store managers and sales assistants access inventory. A firewall is required to protect the system from intrusion to ensure that confidential data is not tampered with. Access to the Internet is likely to be restricted by in-house security policy.

Customers may also scan barcodes found on items in the store to retrieve more information, for example, the number of items available, date of availability, item description, and so forth. Although wireless networking and computing is widely used in store operations, relatively few retailers have leveraged these investments with complementary wireless printing applications (Retail Biz, 2005).

Figure 4. Technical environment for wireless solutions in retail and distribution

Retailers can take advantage of wireless printing. Various wireless printing applications can lower total in-store printing expenses, provide total cost of ownership benefits compared with traditional printers, improve labor efficiency, reduce store operating expenses, improve safety measures, and increase customer satisfaction (Retail Biz, 2005).

Eliminating cables not only improves user convenience, productivity and safety but also cuts down on extra expenses significantly adding to the printer's cost of ownership over time (Retail Biz, 2005).

CONCLUSION

This article focuses on addressing one of the most widespread issues facing executives: aligning IT with business. The accomplishment of any major IT project is measured by the extent to which it is linked to business requirements, and demonstrably supports and enables the enterprise to reach its business goals (Wong, Tan, & Hiew, 2005a). This article has presented business scenarios in logistics as well as retail and distribution sectors. These analyses shape important techniques that may be exploited at various stages of defining enterprise architecture in order to derive characteristics of the architecture directly from high-level requirements of the business. In this study, this is achieved by examining business and technical environments, as well as related processes to enable successful deployment of wireless solutions in both of these industries. The technique has been used to help identify and understand business requirements, and hence to derive business requirements that the architecture development and ultimately the IT has to address. This

helps to encourage the uptake of wireless technologies in the Asia-Pacific region.

KEY TERMS

Global Information System (GIS): Enables one to envision geographic aspects of a body of data. Basically, it allows query of a database and receives results in the form of map. A GIS can have many uses, for example, weather forecasting, sales analysis, population forecasting, land use planning, and so forth.

Global Positioning System (GPS): A "constellation" of 24 well-spaced satellites that orbit the Earth and make it possible for people with ground receivers to pinpoint their geographic location. The location accuracy is anywhere from 100 to 10 meters for most equipment. Accuracy can be pinpointed to within one meter with special military-approved equipment. GPS equipment is widely used in science and

has now become sufficiently low cost so that almost anyone can own a GPS receiver.

Quality of Service (QoS): On the Internet and in other networks, QoS is the idea that transmission rates, error rates, and other characteristics can be measured, improved, and, to some extent, guaranteed in advance. QoS is of particular concern for the continuous transmission of high-bandwidth video and multimedia information. Transmitting this kind of content dependably is difficult in public networks using ordinary "best effort" protocols.

Radio Frequency Identification (RFID): A technology that incorporates the use of electromagnetic or electrostatic coupling in the radio frequency portion of the electromagnetic spectrum to uniquely identify an object, animal, or person. RFID is coming into increasing use in industry as an alternative to the bar code. The advantage of RFID is that it does not require direct contact or line-of-sight scanning.

Wireless Fidelity (Wi-Fi): A term for certain types of WLAN that use specifications in the 802.11 family. The term Wi-Fi was created by an organization called the Wi-Fi Alliance, which oversees tests that certify product interoperability. Wi-Fi has gained acceptance in many businesses, agencies, schools, and homes as an alternative to a wired LAN. Many airports, hotels, and fast-food facilities offer public access to Wi-Fi networks. These locations are known as hotspots.

Wireless Point of Sale (POS): A component of wireless telemetry, or machine-to-machine correspondence. Specifically, wireless POS is the ability to make a purchase using a credit or debit card in businesses that would use a wireless POS terminal, such as taxicabs, limos, home repair services (e.g., carpet cleaners or refrigerator repair), restaurants, or mobile merchants.

Worldwide Interoperability for Microwave Access (WiMAX): A wireless industry coalition whose members organized to advance IEEE 802.16 standards for BWA networks. WiMAX 802.16 technology is expected to enable multimedia applications with wireless connection and, with a range of up to 30 miles, enable networks to have a wireless last-mile solution.

ENDNOTES

- ¹ For further reading, access the WiMAX Forum at <http://www.wimaxforum.org/>
- ² For further reading, access the Wi-Fi Alliance at <http://www.wi-fi.org/>
- ³ Restrict the movement of a vehicle or other object to within a specified area. The location of the vehicle is monitored by telemetry, and an alarm is raised if it goes outside that area.

Software Platforms for Mobile Programming

Khoo Wei Ju

Malaysia University of Science and Technology, Malaysia

Malaysia University of Science and Technology, Malaysia

INTRODUCTION

Java 2 Micro Edition (J2ME), .NET Compact Framework (.NET CF), and Active Server Pages .NET (ASP.NET) Mobile Controls are commonly used alternatives in mobile programming. They provide an environment for applications to run on mobile devices. However, they are different in many ways, such as supported mobile devices, architecture, and development. Hence, it is important for mobile application developers to understand the differences between them in order to choose the one that meets their requirement. Therefore, in this article we will discuss the general architecture of J2ME, .NET CF and ASP.NET Mobile Controls and compare the three alternatives.

BACKGROUND AND INTRODUCTION

Since the mid-1990s, the growth of wireless communications has led to the mushrooming of mobile devices in the market. Initially, the mobile devices were mainly cell phones with limited programmability. However, many analysts and company executives were worried that mobile phone sales would eventually slow down, prompting research and development into software suitable for cell phones (Grice & Charny, 2001). Hence, now, there is a rise of programmable mobile devices. Furthermore, programmable mobile devices these days include not just cell phones but smartphones, PDAs, and pocket PCs. There are three well-known alternatives in mobile programming for general-purpose applications: J2ME, .NET CF, and ASP.NET Mobile Controls.

J2ME is a version of Java that provides an application environment running on consumer devices and embedded devices. It targets machines with as little as 128KB of RAM (Tauber, 2001). J2ME consists of Java virtual machines (JVMs) and a set of standard Java application program interfaces (APIs) defined through the Java community process (JCP). J2ME can be used with different configurations and profiles, which provide specific information to a group of related devices. Configurations support the Java core APIs. Profiles are built on top of configurations to support device-specific features like networking and user interfaces. The J2ME is available in two main configurations: connected

limited device configuration (CLDC) and connected device configuration (CDC). Figure 1 shows the hierarchical structure of J2ME.

.NET CF is a lightweight version of Microsoft's .NET framework. It provides an environment for executing client-side code and eXtensible Markup Language (XML) Web services to smart devices. It is compatible with C# and Visual Basic.NET (VB.NET), and it supports (.NET Compact Framework Team, 2005):

- Windows mobile (2000, 2002, 2003)-based pocket PC,
- Windows mobile-based smartphones, and
- embedded systems running Windows CE .NET 4.1 and later.

.NET CF consists of two main components: the development environment and the runtime environment. The development environment, known as smart device extensions (SDEs), is a Visual Studio .NET (VS.NET) 2003 project type that allows .NET CF applications to be developed rapidly by simply dragging appropriate controls into the application. The runtime environment is the common language runtime (CLR). The size of the CLR and relevant class libraries is smaller than 2MB, which is suitable for mobile devices. The architecture of .NET CF is shown in Figure 2.

Active server pages (ASPs) is Microsoft's server-side scripting technology. An active server page has an .asp extension, and it mixes HyperText Markup Language (HTML) and scripting code that can be written in VBScript or JavaScript. ASP is distributed with Microsoft's Internet information services (IIS) Web server, so most hosts using IIS will also offer ASP for dynamic Web programming. ASP.NET is the version of ASP that works with Microsoft's .NET Framework.

ASP.NET Mobile Controls was previously known as Microsoft mobile Internet toolkit (MMIT). It was renamed as ASP.NET Mobile Controls to reinforce the concept that it is a collection of ASP.NET controls designed for mobile applications. It extends the ASP.NET server-side technology to allow developers to develop applications for a variety of mobile devices. Executing on the IIS Web server, ASP.NET Mobile Controls allows Web applications to be accessed by

Figure 1. Hierarchical structure of J2ME

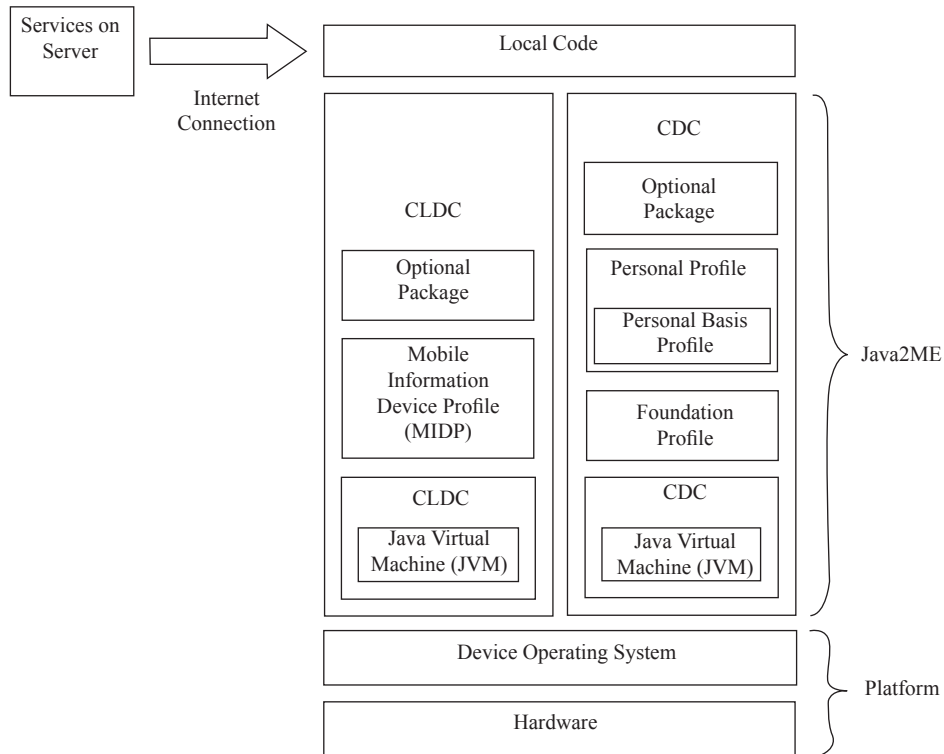

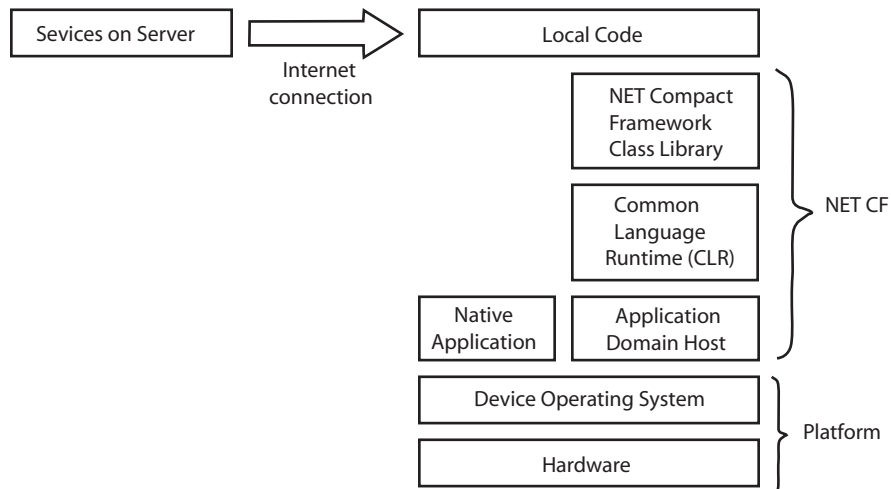

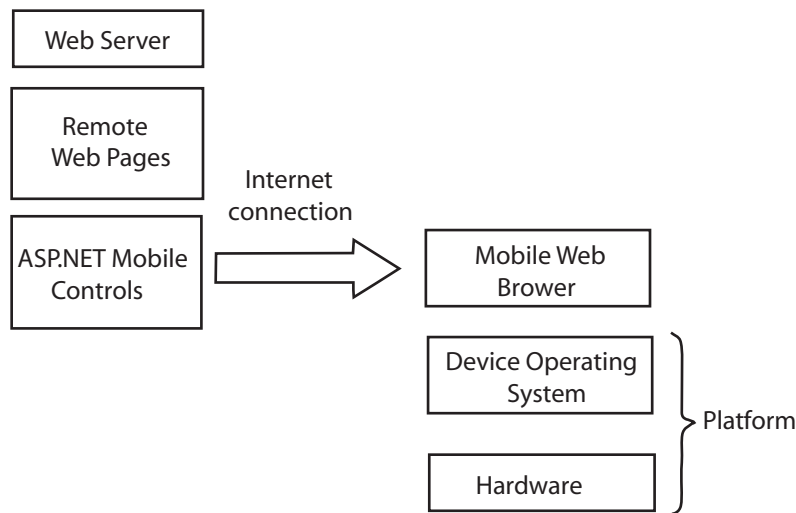

Figure 2. .NET compact framework

almost any Internet-enabled mobile device. During runtime, it will automatically detect the device running the application. The application is then transformed into a form suitable for that device. This frees the developer to concentrate on the application logic and leaves the user interface rendering to the runtime (Lee, 2002a). Furthermore, it allows developers to visually drag and drop controls on forms aimed at mobile

devices using VS.NET. The rest of the work, such as writing the proper markup language (e.g., Wireless Markup Language (WML)), wireless application protocol (WAP)), is handled by the toolkit. The application development environment for ASP.NET Mobile Controls should be familiar to most ASP.NET programmers. Figure 3 shows the architecture of ASP.NET Mobile Controls.

Figure 3. ASP.NET mobile controls

FEATURE COMPARISON

J2ME, .NET CF, and ASP.NET Mobile Controls cannot be easily compared feature-to-feature because the analysis must include non-technology aspects such as market acceptance, development and testing tools, reach, standardization, and platform coherence. Besides, the final releases of J2ME's mobile information device profile (MIDP), personal basis profile, and personal profile are still in production (Sun, 2005). On the other hand, .NET CF is in the final stages of its beta tests. Nevertheless, a feature comparison, although limited, should still be useful.

Flexibility of Machine Control and Scope of Applications

Virtual Machines, Pointers, Native Features

In the .NET Compact Framework, the common language runtime (CLR) environment executes .NET's Microsoft Intermediate Language code. The CLR also offers support services, such as code verification, memory, and code security. The managed code is always translated into native machine code rather than interpreted. CLR supports interfaces and pointers. As for security policy, .NET CF grants full trust to all code (Microsoft, 2005b). The standard frameworks cover only a limited set of commonly used mobile device features. Other features are accessible via native methods. Besides, it is believed that .NET CF has better support for native methods than J2ME because Microsoft controls both .NET CF and the Windows operating system (Yuan, 2002).

With J2ME, Java source code is compiled into machine-independent byte code. The byte code is then interpreted

by the Java virtual machine (JVM) during runtime. J2ME employs different versions of the JVM based on the needs of a particular situation. The configuration specifications define the characteristics of the J2ME virtual machines. In most cases, features of the JVM are removed to accommodate the needs of a configuration. The CDC runs on a C-virtual machine (CVM) that is fully compliant with the Java virtual machine specification. The CDC profile accommodates devices with as little as 512kB of memory, although it is really designed for platforms with about 2 MB of available memory (White & Hemphill, 2002). Sun provides a reference implementation of the CLDC specification that is based on the KVM, a small footprint of JVM that satisfies the CLDC requirements. However, products need not be based on KVM—any virtual machine that has the features required by the specification and can work within the resource restrictions of the CLDC environment can be used (Topley, 2002). Although JVM supports interfaces, it does not support pointers because it can result in unsafe code. The Java native interface (JNI), which allows access to native methods, can be used but only by CDC. For CLDC, the native features must be built into the runtime.

Consumer Applications, Multimedia, Gaming

.NET CF supports direct draw on canvas, double buffering, and device button remapping through its rich Windows Forms User Interface library. It also supports multimedia playback by using the native methods from Windows Media Player on Pocket PC (Yuan, 2002).

In J2ME, the mobile information device profile (MIDP) 2.0 for CLDC includes animation and game controls in the `javax.microedition.lcdui.game` package. Multimedia play-

back is supported via the Java media framework (JMF) on the CDC or the multimedia optional package for the CLDC. Many game developers prefer J2ME, because it is supported by a wider range of mobile platforms.

Development Support

Programming Languages

ASP.NET supports any language supported by the .NET Framework, including C, C++, C#, Visual Basic, and even Java. However, .NET CF currently supports only two major .NET languages: C# and VB.NET (Microsoft, 2005a). C# and VB.NET are standardized by EMCA and ISO/IEC. Hence, Microsoft has long been criticized for tightly controlling its technologies. However, the support of multiple standardized languages allow developers flexibility in programming in .NET CF.

J2ME only supports Java. Anyone can propose a Java specification request (JSR) to the Java community process (JCP) for a new platform extension. Unlike with the tightly controlled development of .NET compact framework and ASP.NET, it may appear that under a more free process like the JCP, developers have to spend much time understanding the features to make use of all extensions in the language. However, J2ME APIs undergo rigorous standardization processes to ensure wide industry support and minimum learning for developers.

Platforms

.NET CF supports high-end PDAs such as Windows pocket PCs, Windows smartphones, and embedded devices running

on the Windows CE .NET platform (Microsoft, 2005a). Windows devices consist of only a small part of today's mobile device population.

With J2ME, most of the cell phone devices (Motorola iDEN, Nokia Symbian OS, and Qualcomm Brew platforms) and low-end PDAs (Palm OS and Real-Time OS platforms) have built-in Java support because Java allows developers to be productive across many mobile platforms.

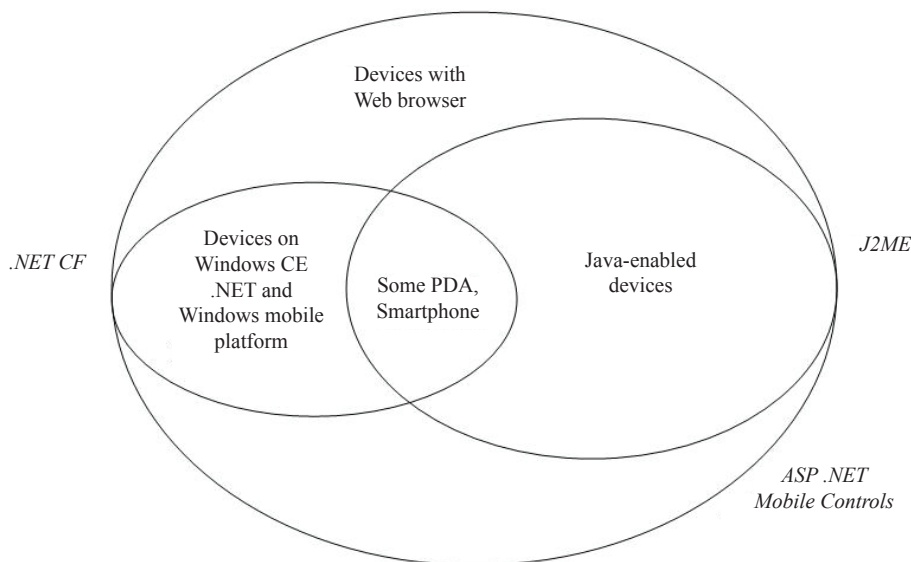

Because it is server-side based, placing minimal requirements on the client, ASP.NET is supported by the widest range of mobile devices, including all devices that support .NET CF, all devices that support J2ME, and more. However, each of these devices may present the output of the ASP.NET controls differently due to their different limitations and capabilities.

Development Tools

Regarding .NET CF and ASP.NET, Visual Studio .NET provides similar design interfaces for both mobile and non-mobile applications. It supports Web services integration and relational database access, and VS.NET is tightly integrated with Visio Enterprise Network Tools edition, which can generate C# or VB.NET code from UML (Unified Modeling Language) diagrams. Furthermore, VS.NET supports debugging on both emulators and real devices. However, VS.NET is not free.

Sun's J2ME Wireless Toolkit is a widely used MIDP development tool. Furthermore, command-line tools and vendor-specific toolkits are readily available. All major Java integrated development environments (IDEs) have J2ME modules or plug-ins. A big challenge for all J2ME IDEs is vendor software development kit (SDK) integration. Every

Figure 4. Devices supported by .NET CF, J2ME, and ASP.NET mobile controls

device vendor provides SDKs for their device emulators and proprietary J2ME extensions. The unified emulator interface (UEI) is designed to standardize the interfaces between IDEs and device SDKs. However, the UEI is available only through a Sun licensing program.

Miscellaneous

Specification Process

When a new technology emerges, Microsoft has the veto power to make decisions and make it available on .NET CF and/or ASP.NET. This saves time and effort. On the other hand, this also means that developers have no say on the specification process.

The Java community process (JCP) decides the new J2ME standard APIs, whereas Sun has veto power on only Java language specifications. The JCP develops all current J2ME configurations, profiles, and optional packages, so the specification process is arguably very lengthy and inefficient. However, some developers like this because more people are allowed to contribute and decide.

Gateways

There are technical difficulties in using .NET CF in mobile gateways because it was not designed to run lightweight application servers required in mobile gateways. Although Microsoft mobile information server (MIS) is a powerful gateway, messaging, and synchronization server, .NET CF lacks built-in APIs to interact with Microsoft MIS (Yuan, 2002).

For J2ME, the primary mobile service gateway product is from IBM. The Oracle9i wireless application server and Oracle J2ME SDKs provide gateway integration points for mobile devices to many other Oracle or third-party application servers (Yuan, 2002).

Additional Comparisons Between .NET CF and ASP.NET Mobile Controls

Server-Client Side

.NET CF uses client-side technology. Code is executed on the mobile device using just-in-time (JIT) compilation and native execution. ASP.NET uses server-side technology. Code is executed on the server, producing markup-language-based output such as HTML to be interpreted by a Web browser.

Web Server

For .NET CF, a Web server is not needed because code is executed directly on the device. For ASP.NET, a Web server (such as Microsoft IIS 5.0 or 6.0) that supports ASP.NET is required. The ASP.NET HTTP runtime is used to handle and process requests via a set of ASP.NET server controls.

Device Support

Only devices that have .NET CF runtime can execute programs written on .NET CF. On the other hand, since ASP.NET is server-side based, less processing is required on the client side compared to .NET CF. However, each of these devices may present the output of the ASP.NET controls differently due to their different limitations and capabilities.

Connectivity

For .NET CF, standalone applications can be created and installed on portable devices such as the pocket PC, pocket PC phone, and smartphone. By having the applications downloaded into such devices, the devices can either be connected or not connected. The XML or SQL Server 2000 Windows CE editions are used for local storage when

Table 1. Comparison summary between .NET CF, J2ME (CDC and CLDC) and ASP.NET Mobile Controls

| | .NET Compact Framework | J2ME Connected Device Configuration | J2ME Connected Limited Device Configuration | ASP.NET Mobile Controls |

working off-line. With ASP.NET Mobile Controls, an HTTP connection is required to request an ASP.NET page that uses the Mobile Controls.

FUTURE TRENDS

In recent years, a strange trend can be seen in the design of mobile devices; they are getting bigger and bigger. They are gradually taking on more of the features of regular computers. We say this is a strange trend because mobile devices were originally meant to be stripped down, barebones devices with only the most useful features for mobile usage. Nevertheless, this trend is getting encouraging responses from users because the mobile devices are able to hold all the files they need to carry around. Due to the encouraging response from the users and the advances in technology, it is predicted that the trend will continue.

Besides, the sales of traditional PDAs have declined in the past few years (ETForecasts, 2003). This is because the PDA market is gradually being taken over by the smartphone, also known as the PDA phone. Users favor phones with computer features, such as storage capacity and clearer display (Kewney, 2005).

Currently, non-Microsoft operating systems like Symbian dominate the smartphone operating system market. As the sales and variety of smartphones are increasing worldwide, assuming Windows mobile platform keeps the same percentage of the market, the usage of Windows mobile platform will grow as well. Besides, given the past success of Microsoft to expand into new related markets, it is quite likely that they could increase their market share over the next few years, and there is much room for them to grow. Since Windows mobile platform will support only .NET CF (Java is not included), the growth of Windows mobile platform will directly lead to the increase in the use of .NET CF in mobile programming.

Furthermore, the current versions of .NET CF grant full trust to all code. However, the upcoming versions of .NET CF will offer a subset of the policy-driven, evidence-based code access security of the full .NET framework (Microsoft, 2005b). This is a good feature from the security point of view; however, it may be less convenient for developers compared to the current version.

Hopefully in the future, both Microsoft and Java applications can coexist in the same mobile device.

CONCLUSION

.NET CF and J2ME are both excellent platforms for developing smart clients for mobile commerce applications. J2ME has already gained a lot of industry support as the most favorable platform for developing mobile applications, and there are over 500,000 skilled Java developers around the world (Wishart, 2002). J2ME implements a modular design and is portable across a variety of devices. The platform provides balanced support for both enterprise and consumer applications. J2ME vendors offer excellent selections of mobile databases and gateway application server products.

On the other hand, .NET has the advantage over J2ME where it provides a single development platform and common coding practices based around Visual Studio. There are more than 1.5 million skilled developers worldwide (Wishart, 2002), and Microsoft has the largest tools and third-party developers program. The .NET CF platform focuses on enterprise applications with rich user interface, database, and XML Web services support. Hence, .NET CF is suitable for cash-rich customers with controlled mobile environments. However, .NET CF runs only on Windows-powered high-end PDAs. As a young platform, it currently lacks support for gateway servers and choices for mobile databases.

For the near future, the choice between .NET CF and J2ME is not so much a question of the desired platform features (both are excellent in this respect) as the targeted devices. In the short run, J2ME is supported by more devices than .NET CF. In the long run, most experts expect both platforms to coexist in all market sectors. Developers must choose the right tools and make them all work in heterogeneous environments. For example, J2ME clients would need to work with .NET backend servers and vice versa. So it would ultimately not come down to a choice between J2ME or .NET CF.

Both .NET CF and J2ME have advantages over ASP.NET Mobile Controls in supporting code that will execute on the device, and that can run in disconnected, connected, or occasionally connected modes. Therefore, for most enterprise mobile solutions, .NET CF and J2ME are more appropriate.

On the other hand, if browser-based applications are required, Microsoft ASP.NET Mobile Controls can be used to develop mobile Web applications that adapt their page rendering for a range of devices, such as micro-browsers on PDAs, smartphones, and WAP phones. ASP.NET Mobile Controls allows the developers to target the users they need to target, without worrying about the device they are using.

KEY TERMS

Active Server Page (ASP): Microsoft's server-side technology that allows scripting language for dynamically generated Web.

Cell Phone (Mobile Phone): Electronic telecommunications device that is able to move over a wide area, connected using wireless radio wave transmission technology.

Personal Digital Assistant (PDA): Mobile device that serves as personal organizer. The basic features of a PDA include phone book, address book, task list, memo pad, clock, and calculator software.

Pocket PC: Operating platform for handheld devices introduced by Microsoft, based on the Windows CE operating system.

Smartphone: Mobile device that integrates the functionality of a mobile phone and PDA by adding telephone functions to a PDA or including the PDA capabilities on a mobile phone.

Web Service: Software system designed to support interoperability among machines over a network using a standardized interface.

Windows CE: A simplified version of the Windows operating system designed to run on handheld-size computers.

Windows Mobile: Operating system that replaced the Windows CE operating system on mobile devices. It includes a suite of basic applications for mobile devices based on the Microsoft Win32 API.

Standard-Based Wireless Mesh Networks

INTRODUCTION

As various wireless networks evolve into the next-generation fixed broadband wireless access (BWA) systems, the wireless mesh network (WMN), expected as a promising technology, is still being standardized in IEEE 802.16 and commercialized in the World interoperability for Microwave Access (WiMAX) forum at present. In fixed BWA systems, the objective of applying mesh-typed topology is to build self-organized networks in the places where wired infrastructure is not pre-existing or not worthy to be deployed. The term “mesh-typed” here can also be described as “relay-based” or “multi-hopping,” which means that the connection from a particular mesh subscriber station (mesh SS) to the mesh base station (mesh BS) is via one or more successive wireless links. Multi-hop wireless networking has traditionally led to significant research in the context of ad hoc or peer-to-peer networks. However, the fundamental goal of relaying augmented networks like WMNs is to provide wide-bandwidth coverage and high-data-rate throughput, while the defining goal of conventional ad hoc networks is to accomplish communications without any pre-existing infrastructure in a short time.

The mesh concept applying in WMAN systems has the relay-based and multi-hopping features. Since communications could take place through relay nodes, link distance could become much shorter, frequency and spatial reuse could become much more efficient, and interference could also become much lower. Thus WMNs could provide non-line-of-sight (NLOS) connectivity with high-data-rate capacity to extend the coverage range of existing point-to-multipoint (PMP) wireless networks, such as cellular mobile networks.

Figure 1 depicts a possible scenario where WMNs can be deployed to provide broadband access to the IPv6 backbone network. In WMNs, each mesh SS operates as not only a host but also a wireless router, which forwards transferring traffic within the network as well as traffic that goes out to other networks. The network is dynamically self-organizing and self-configuring, with both mesh BS and mesh SS

automatically establishing and maintaining routes among themselves. All the nodes can use the distributed scheduling to ensure collision-free transmissions within their two-hop neighborhood, or use the centralized scheduling to complete functions in a more centralized manner through conveying much of the control work to the mesh BS; the combination of these two control mechanisms is termed as hybrid-controlling. Mesh BS is connected with WiMAX PMP BS through first tier wireless backhaul, and then WiMAX PMP BS is connected with the IPv6 backbone network through second tier wireless or wired backhaul.

In the centralized scheduling mode of WMNs, all traffic is restricted to be either in the direction of the mesh BS or away from the mesh BS. However, in the distributed scheduling mode, the transmissions are communicated between arbitrary pairs of nodes. Hence, an ad hoc network, described in Figure 1, could be considered as a type of uncoordinated distributed WMN.

Wireless sensor networks (WSNs) differ from the WMNs in that they contain hundreds or thousands of sensor nodes to allow for sensing over large geographical regions and these sensor nodes have much more limited computation capabilities, sensing capabilities, storage space, battery power, and transmission range. Even so, these sensors have the basic ability to communicate either among themselves or directly with an external BS, making WSN similar to both centralized and distributed WMN.

This article introduces a functional architecture supporting the wireless mesh networks for the IEEE 802.16 standard. Three essential techniques—collision avoiding, packet scheduling, and wireless routing—are intensively presented. Based on the mesh extension of the IEEE 802.16 medium access control (MAC) layer protocol and the relay-based characteristic of WMNs, the algorithms concerning those three essential techniques are briefly reviewed. The suitable algorithms for collision avoiding and packet scheduling mechanisms are analyzed. Meanwhile, the wireless routing algorithm for the proposal architecture is discussed. The future research work is presented and the research problems are focused.

Figure 1. WMN internetworking architecture

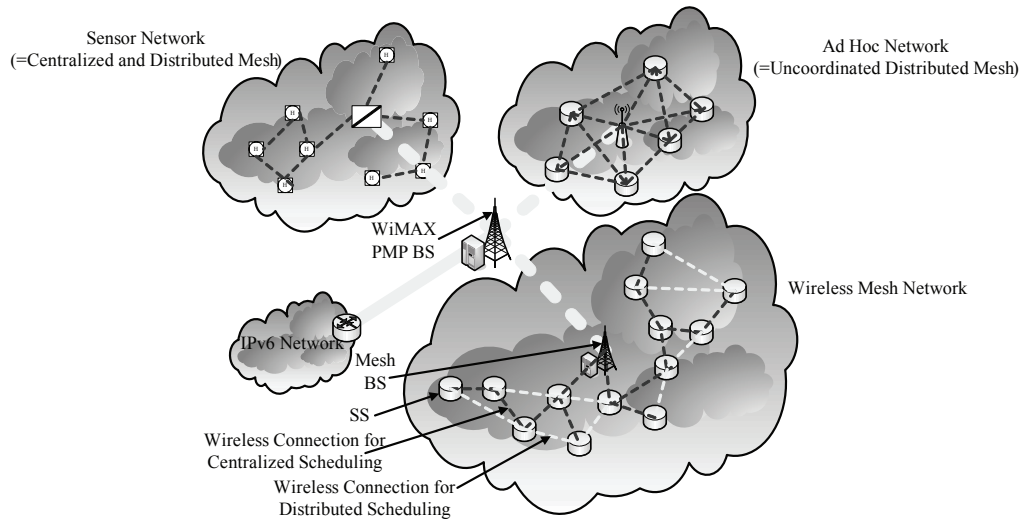

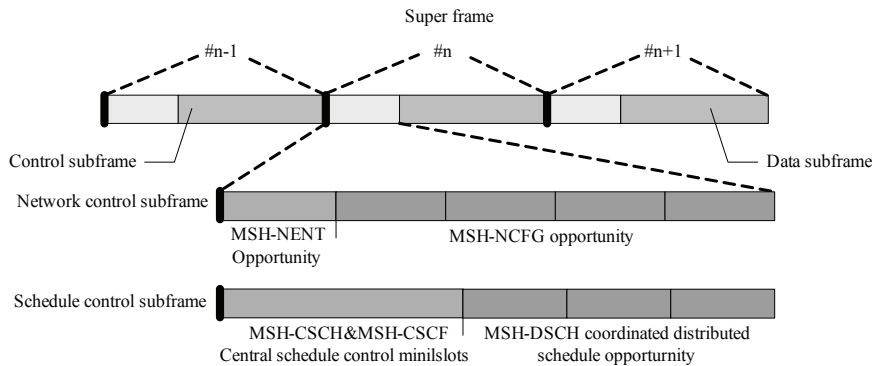

Figure 2. Frame structure for IEEE 802.16 mesh mode

SYSTEM BLOCK

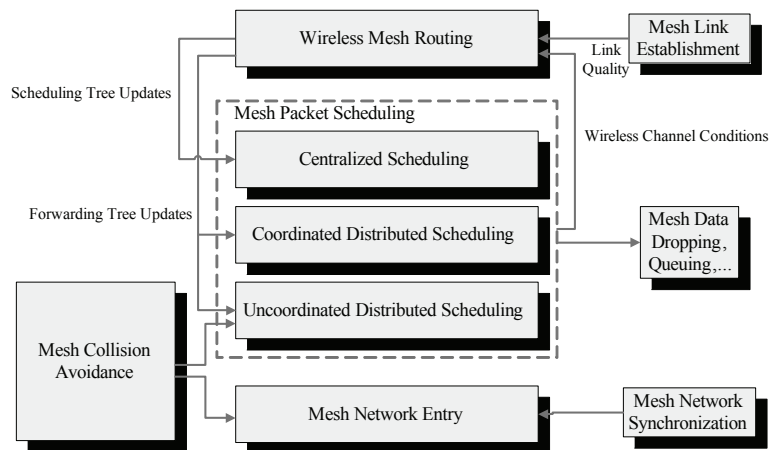

IEEE 802.16 mesh mode is an optional extension of the IEEE 802.16 MAC layer as an alternative or a complement to the conventional PMP architecture in the fixed BWA systems. The physical layer of it supports OFDM modulation, particularly as presented in the IEEE 802.16 standard with both the licensed frequencies and the license-exempt frequencies operating below 11G Hz. In this physical environment with long wavelength, requirements of line-of-sight (LOS) are not necessary and impacts of multi-path may be significant.

IEEE 802.16 mesh mode provides a novel method for new nodes to enter the network with the help of a full functionality member (sponsor node) in the network and has three kinds of scheduling modes including centralized scheduling, coordinated distributed scheduling, and unco-

ordinated distributed scheduling for efficient transmission of the data packets as well as control messages. The mesh frame structure defined in IEEE 802.16 mesh mode, which has no difference between uplink and downlink, is demonstrated in Figure 2.

We refer to the frame containing the network control subframe as the “network frame” and similarly term the frame including the schedule control subframe as the “schedule frame” for short. One network frame and several schedule frames constitute a super frame. In the network control subframe, the first opportunity with seven OFDM symbols is for NENT (network entry) message transmission in which a new node sends an entry request or entry acknowledgement. The symbols remaining are for NCFG (network configuration) message transmission in which the network configurations are advertised. In the schedule subframe every seven symbols

Figure 3. Functional architecture for IEEE 802.16 standard-based WMN

are grouped as a transmission opportunity. The first several transmission opportunities are utilized for central schedule messages, including CSCH (central scheduling) messages and CSCF (central scheduling configuration) messages, while the remains are for coordinated distributed schedule messages: DSCH (distributed scheduling) messages. DSCH messages may also appear in the data subframes during uncoordinated distributed scheduling. Data transmissions scheduled uncoordinatedly should submit to those scheduled coordinately.

FUNCTIONAL ARCHITECTURE AND RESEARCH AREAS

In order to focus on researching the key techniques of WMN, the suitable functional architecture, shown in Figure 3, is presented which is based on the cross-layer design and is to optimize the system performance. The proposed architecture consists of three main models: wireless mesh routing, mesh packet scheduling, and mesh network entry.

There are three sub-parts in the mesh packet scheduling model: centralized scheduling, coordinated distributed scheduling, and uncoordinated distributed scheduling, which are defined to represent these three scheduling mechanisms respectively. Meanwhile, in order to support the mesh routing procedure, the wireless mesh routing model is involved. Since both scheduling and routing algorithms require the wireless channel conditions to improve the throughput and meet the quality of service (QoS) requirement to support the various applications, there is a cross-layer design between wireless mesh routing and mesh packet scheduling models. The wireless mesh routing model will forward the routing message to the mesh packet scheduling and make the scheduling model update its scheduling tree periodically. When

the radio channel condition is bad or there is not enough radio resource, the scheduling model can send a request message to the wireless mesh routing model to change the mesh routing. In order to guarantee the real-time requirement and minimize the delay, the directional and periodical signal exchange are necessary. Furthermore, the link measurement and establishment must be completed in the lower MAC layer, and the model mesh link establishment is added to assist the wireless mesh routing model.

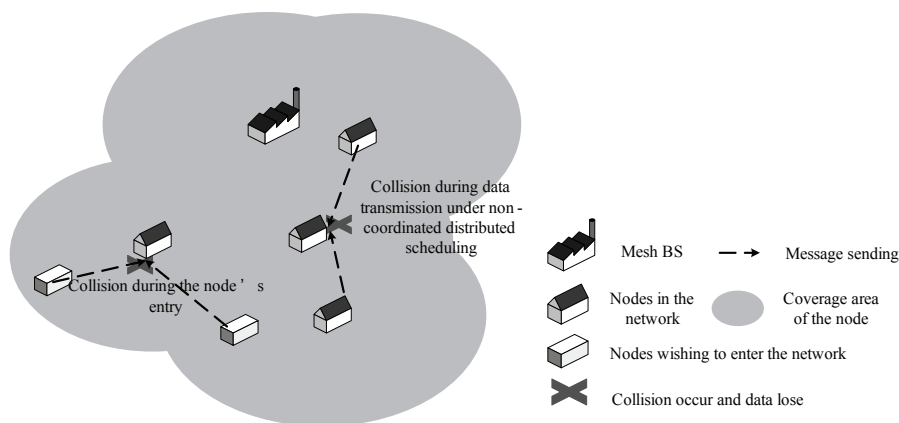

What is more, the mesh collision avoidance model is proposed to avoid collisions that may occur during the mesh network entry process and the uncoordinated distributed scheduling process.

The mesh data dropping, queuing, etc., model is corresponding with the mesh scheduling mechanisms, while the mesh network synchronization model works together with the network entry procedure.

Among functional parts described in Figure 3, collision avoidance mechanisms, scheduling techniques, and routing algorithms are three challenging research areas. Most existing MAC protocols based on conventional collision avoidance mechanisms solve partial collision problems, but raise others. Considering particular features of wireless multi-hop mesh networks, how to improve existing mechanisms to avoid collision that would happen both in network entry procedure and in uncoordinated distributed scheduling is a crucial issue according to the scalability of the entire network. Since resources needed to be scheduled are dependent on transmission techniques applied by PHY layer, scheduling techniques must make adaptations correspondingly, especially when advanced techniques such as MIMO and cognitive radios are introduced. Routing in WMNs is also a tough task due to the delay-sensitive applications, as well as higher throughput and bandwidth requirements which distinguish these networks from other wireless multi-hop

Figure 4. Collisions in IEEE 802.16 mesh mode

networks like ad hoc and sensor networks. Therefore, novel routing algorithms need to be proposed to utilize the potential advantages of the wireless medium.

KEY TECHNIQUES FOR PROTOCOL IMPLEMENTATION

Collision avoiding, scheduling, and routing can play a significant role in the implementation of IEEE 802.16 standard protocol. In this section we briefly review algorithms concerning those three key techniques and propose our new collision avoidance schemes, scheduling phases' division, and routing metrics exploration respectively.

Collision Avoidance Schemes

Although collision avoidance schemes have been presented in IEEE 802.16 mesh mode, collisions may still occur as demonstrated in Figure 4 during a new node entry process as well as during data transmissions controlled by uncoordinated distributed scheduling.

Solutions for alleviating collisions in the above situations could increase the network throughput and reduce the average delay to some extent. Since both the start time and the duration of a transmission are unpredictable, taking into account the low-cost-requirement of normal mesh devices, we focus our attention on random access schemes for WMNs rather than fixed resource allocation schemes or dynamic resource allocations-on-demand schemes.

Wireless Scheduling Mechanisms

IEEE 802.16 mesh mode MAC supports three scheduling mechanisms: coordinated centralized scheduling, coordinated distributed scheduling, and uncoordinated distributed

scheduling. Uncoordinated means performing in a partially, contention-based manner, while coordinated means using scheduling packets transmitted in a collision-free way within scheduling control subframes. Distributed means opportunity-based scheduling between two nodes, while centralized means mesh BS coordinates the radio resource allocation within the mesh network. In the centralized mechanism, every mesh SS sends its resource request to the mesh BS, and the mesh BS determines the resource allocation for each link and broadcasts the grants to SSs. A centralized mechanism is best for scheduling over links supporting persistent traffic streams, while distributed scheme is best for scheduling over links with occasional or brief traffic needs. Figure 5 depicts the scheduling tree for centralized scheduling and other possible connections for distributed scheduling. As shown in Figure 5, the centralized scheduled traffic only occurs on scheduling tree, in which different colors represent different hops from the mesh BS, while the distributed scheduled traffic occurs on both the scheduling tree and other links which are not scheduling tree branches. As most of the packet scheduling algorithms proposed for multi-hop wireless networks are TDMA based and could be further ameliorated for OFDM-based networks, our discussion will focus on the scheduling in a TDMA network.

The scheduling mechanisms discussed as follows are based on the following assumptions: nodes are assumed to use omni-directional antennas and operate in half-duplex mode, which means a node cannot transmit and receive in the same moment. The wireless channel is free of non-collision-related errors.

Wireless Routing Algorithms

In the case of IEEE 802.16 mesh mode, we consider routing in a relay-based network in which communication relations are limited to a few hops only. The choice of routing

Figure 5. Multiple scheduling mechanisms in IEEE 802.16 mesh mode

algorithm becomes challenging when considering multiple possible relays.

When an intermediate node in the proposed WMN architecture receives traffic, its routing function decides the next hop on the path to the destination, and this node forwards traffic along to the next hop node. In this type of relay-based network, traffic at a node waiting for routing decision may be on behalf of other nodes that are not within direct wireless transmission range of a mesh BS. This is the mechanism that is generally used for routing algorithm designing in ad hoc and sensor networks. Compared to ad hoc networks, WMNs applying relaying via fixed nodes do not need complicated distributed routing algorithms, while retaining the flexibility of being able to quickly select another route as a link between relays breaks. Based on the performance of the existing routing algorithms for wireless multi-hop networks and the specific requirements of WMNs, we examine the following issues to design an optimal routing algorithm for WMNs:

- Routing Overhead:** The routing overhead in wireless mobile multi-hop networks may become severe because of substantial memory requirements and wide bandwidth spending for route establishing and maintaining, thus it results in low efficiency in network throughput. Studies of routing algorithms for mobile ad hoc networks (MANETs) by the MANET subgroup of the Internet Engineering Task Force (IETF) have shown high routing overhead and reduced potential efficiency of multi-hop techniques. However, for WMNs, limiting the number of hops in a range ($HR_{\text{threshold}}$, which is a configuration value that need only be known to the mesh BS, as it can be derived by the other nodes from the MSH-CSCF message) would greatly simplify routing complexity. The other factor that would also simplify routing complexity is nodes' minimal mo-

bility. Taking into account these two factors, routing overhead would be reduced greatly. Based on these simplicity results from inherent characters of WMNs, the routing algorithm must minimize routing overhead as much as possible.

- Fault Tolerance:** Some links between neighboring nodes may fail or be blocked due to physical damage or environmental interference. The failure of links should not affect the overall task of the WMNs to ensure robustness as one of the objectives to deploy WMNs. If a link breaks, the routing algorithm should be able to quickly select another route to avoid service disruption.
- Scalability:** Since the number of user nodes in WMNs may be much larger than that in ad hoc networks, and routing in a relatively large wireless network must take convergence time and end-to-end delay into account, scalability is also an important routing design parameter in WMNs.
- Load Balancing:** Relay-based is the most distinguishing characteristic of the WMNs. Thus the potential substantial network resources could be shared among many users through relay-based communications. In this cooperative way, load-sensitivity is an important factor to measure the relative performance of different routing metrics. For example, when a part of a WMN experiences congestion, new traffic flows on behalf of other users should be routed through other routes avoiding this part.
- Routing Metrics:** Many existing routing algorithms for ad hoc networks have traditionally attempted to find routes by using shortest path as a routing metric. It is known that the defining goal of conventional ad hoc networks is to function without any pre-existing infrastructure, while the fundamental goal of mesh-typed multi-hop augmented networks is to provide wide-bandwidth coverage and high-data-rate throughput. Therefore, using shortest path metric for routing in multi-hop wireless networks is not sufficient to construct routes that are able to effectively transport traffic with reasonable delay, reliability, and throughput. In order to satisfy the original goal of WMNs, a routing algorithm must select better routes between given neighboring node pairs by explicitly using link quality measurements to explain the differences in quality of the paths. One obstacle to taking link quality into account is combining route metrics to form a path metric. This problem is not straightforward inherently, since several parameters might be used to give enough indication about the quality and behavior of a wireless link.

In order to exploit the potential advantages that the wireless medium defined by IEEE 802.16 offers, the approach

employing cross-layer design is a good way to explore new routing metrics. The objective is to turn lower layer drawbacks into advantages through use of MAC and PHY information to help routing selection and making the routing layer control some lower layer settings.

SUMMARY AND FUTURE WORK

The emergence of new multimedia and Internet applications for the wireless domain has spurred the study of WMNs for providing larger capacity and wider coverage. In this article, a novel functional architecture of WMNs based on IEEE 802.16 standard is proposed, and three key techniques demonstrated in this architecture, including collision avoiding, scheduling, and routing, are extensively studied.

While discussing the desirable features and suitable techniques, in addition to the basic properties of wireless relay-based networks, the special characteristics of IEEE 802.16 mesh mode, such as fixed and hybrid-controlling, are also taken into account. Since the new node entry process in IEEE 802.16 mesh mode involves no resource allocation or link establishment and there would be rare new nodes required to enter the network simultaneously. Considering the multi-hop topology and multi-service applications in this kind of network, the three-phase scheduling mechanism is presented and analyzed. Finally, we discuss the approach of cross-layer design for integrating the link quality into the routing metrics.

While we are designing the routing and scheduling algorithms, we should consider the physical limitations of each node and the interference between the transmissions of nodes in their neighborhoods. How to reflect the link condition from the physical layer to the network layer in time is a problem related to cross-layer design and needs more research work in the future. Besides that the path of a flow consists of multiple links, how to evaluate the overall performance of the route reasonably to choose the best routes is also an open issue. In addition, we need to consider more about the effective combination of scheduling and routing algorithms. Furthermore, there exist multi-services such as voice, minimum bandwidth required traffic flow, and best effort service. Therefore, QoS differentiation and guarantees must be supported.

Wireless mesh will transmit data packets based on all-IP protocol, and with the emergence of new services, the user of WMAN based on IPv6 will wish not only to access the Internet through wireless links but also to remain online even while they are moving. The WMAN technology based on IPv6 is therefore widely envisioned to have tremendous market potential. With this background, it would be meaningful to investigate the network protocol of IEEE 802.16 mesh mode and its integration with IPv6.

KEY TERMS

CSCF: Central scheduling configuration message.

CSCH: Central scheduling message.

DSCH: Distributed scheduling message.

$HR_{\text{threshold}}$: A configuration value that need only be known to the mesh BS, as it can be derived by the other nodes from the CSCF message.

NCFG: Network configuration message.

NENT: Network entry message.

Network Frame: The frame containing the network control subframe to “network frame.”

Schedule Frame: The frame containing the schedule control subframe to “schedule frame.”

Super Frame: One network frame and several schedule frames constitute a super frame.

Taxonomies, Applications, and Trends of Mobile Games

INTRODUCTION

Wireless communications and the distribution of cell phones have been rapidly extended with the expansion of mobile content services since the early 2000s. With such extension, mobile games have been viewed as a separate branch in game device platforms. While studies on mobile contents have increased for several years, research on mobile games is still in the early stages. Although mobile games have developed and expanded their ranges in game markets, there is little research on the classification and development trend of mobile games. Considering that game devices have been converged into ubiquitous communication/networking features and the range of games has been expanded from entertainment to education, health, and exercise, there is an urgent need to study mobile games' taxonomy, application, and future trends.

In this article, mobile games are classified by several criteria (i.e., contents, platforms, and multi-layer based). Examples of mobile games are summarized, along with taxonomies. Lastly, applications and the macro trend of mobile games will be presented. In addition, some insights in the design and development of mobile games will be discussed.

MOBILE GAME TAXONOMIES

Games are different from other genres such as music, film, and literature in the participation of users. *Interactivity* and *narratives* are two important factors to categorize games. Aarseth, Smedtad, and Sunnana (2003) classified games with a number of basic dimensions such as space, perspective, time, and teleology. Klabbers (2003) suggested social systems such as actors, rules, and resources for the establishment of game taxonomy. Wolf (2005) considered some standards such as the games' goals and objectives, and the nature of the games' play-characters and control devices. The devices have been applicable to traditional games in PC or console games with wide monitors, gorgeous graphic environments, and broad structures of narratives. Nowadays, however, with the development of fusion games and the acceleration of

genre convergence, the clear division of game genres has been difficult because many cross-listed games emerged in two or more genres (Wolf, 2005). Considering such a trend and characteristics of mobile games, this article classifies mobile games into some basic genres.

First, content-based taxonomy is conducted from the basic features of games such as the control range of gamers, the role of characters, and the degree of user participation. Second, platform-based is from mobile device platforms with which games are played. Third, multi-layer-based is from the capability of multi-player network and 3D graphic technology.

Content-Based Taxonomy

The role of gamers is the essential element in game taxonomy. Gamers can take their own individual roles or become omnipresent beings in games. Role-playing games (RPGs) comprise the representative genre of individual role games; strategic simulation games are controlled by omnipresent gamers. These games can be divided by the environments of the role of gamers: gamers should be a shooting gunner in shooting games; gamers should be an adventurer in an unknown world in adventure games. In these games, users usually take on their own roles. Finally, such games could be classified by the degree of user participation: multi-player games are played by the collaboration of individual roles; team games are played by teams (or guilds) with enough members having individual roles.

- **Role Playing Games:** A gamer as a character takes on an individual role in accomplishing missions or quests. The user can upgrade his/her character and take items to complete missions effectively.
- **Simulation Games:** Users complete their missions in simulated environments by controlling resources such as objects, characters, and items with their own strategies. There are some types of simulation games such as construction, management, or war simulation games.
- **Fighting Games:** Gamers take a character and fight with skills of kicking or striking against other char-

acters to win the contests. There are some kinds of fighting games mixed with action marshals such as judo and boxing; they are sometimes referred to as action fighting games.

- **Shooting Games:** Users take on their missions as a shooter or artilleryman in a war or as an infiltrating agent in an operation. In these games, the perspective of a user is a very essential element in attracting the user’s involvement. Therefore, shooting games with the first-person perspective are usually referred to independently as first-person shooting games (FPSs).
- **Adventure Games:** Users take travels to unknown space or environment as travelers or warriors.
- **Sports Games:** Users take on a role or control teams in sports contests such as baseball, basketball, or football. Racing sports such as riding and car racing are usually called racing games.
- **Board Games:** Users compete with opponents in traditional board games such as chess, Tetris, puzzles, oriental chess, baduk, and so forth.
- **Single-User Games:** Only one user can participate with a role or mission.
- **Team (or Guild) Games:** Users should join a team with other users to complete missions or win a contest.
- **Massively Multi-Player Online Games (MMOGs):** A huge number of users can participate simultaneously with their roles or missions.

Platform-Based Taxonomy

Mobile devices are also regarded as independent platforms. Each mobile device has its own features in containing mobile games. Thus, if producers want to transplant a game in a device into another one, they should restart the product processes from the beginning. For this reason, platform-based taxonomy is beneficially used in mobile games. In

terms of mobile devices, mobile games are classified into mobile phone, portable console, and PDA games. In terms of mobile platforms, mobile games are called Java games, Brew games, and WAP games.

- **Mobile Phone Games:** Conducted in cell phones.
- **Portable Console Games:** Played in portable consoles; examples include PSP (Play Station Portable), NDS (Nintendo Dual Screen), and GBA (Game Boy Advance).
- **PDA Games:** Embedded or downloaded in PDAs.

Multi-Layer-Based Taxonomy

Multi-layer-based games are classified with the adaptation of high technology including capability of multi-player network and 3D graphic technology. Mobile games have developed from text-based to 3D multi-user network games. Therefore, in terms of multi-layer-based taxonomy, mobile games can be classified into five types: text-based, 2D graphic, 2D network, 3D half network, and 3D multi-user network games. Table 1 summarizes the taxonomies of mobile games with genre examples by the criteria of division.

MOBILE GAME APPLICATIONS AND INDUSTRY

Application Areas of Mobile Games

The application areas of mobile games can be categorized into four areas: traditional game industry, mobile Internet applications, mobile advertisements, and new applicable areas.

The most applicable area of mobile games concerns the traditional game industry. With the development of handheld

Table 1. Taxonomies of mobile games

| | Criteria of Division | Genre Examples | Examples |
|-------------------|---|---|---|
| Content-Based | Control range of gamers | RPGs Simulations | <i>Doom RPG</i> <i>Real Estate Tycoon</i> |
| | Role of characters | Fighting (Action) Shooting, Sports Adventure, Board | <i>Mortal Kombat</i> <i>Quake Mobile, FIFA06</i> <i>Tomb Raider, Tetris</i> |
| | Degree of user participation | Single-user, Team, Multi-user | <i>Deep Pocket Chess</i> <i>Samgukji, Undercover2</i> |
| Platform-Based | Device platforms | Cell phones, PDAs, Portable consoles, etc. | |
| | Game platforms | WAP, Java, Brew, etc. | |
| Multi-Layer-Based | Adaptation of 3D graphic and network technology | Text-based, 2D graphic, 2D network, 3D half network (3D games with two or several users) 3D multi-user network (3D MMOGs, etc.) | |

mobile services, PC and console games have transplanted popular games into mobile devices: old big hit games have found their new hit area in game markets, so big game companies have expanded their business areas into mobile games. Owing to the advanced technology, some traditional game devices have included mobile capabilities. The boundary between mobile phone games and portable console devices has been revolutionarily converged, and mobile game cartridges or multimedia cards (MMCs) have been sold in game shops with game CDs and DVDs. Mobile games have provided various channels of game services. Internet portals and interactive TV service companies have provided mobile game services, and console game manufacturers have opened mobile portal services for their customers of portable console devices with network capability. In particular, game producers developed new games such as LBS (location-based service) games using the features of mobile devices, and old mobile games have been upgraded to multi-user 3D games with the development of technology. Most of all, mobile games have been used by game companies to provide further services to users. Gamers can use their items and avatars saved in PC or console games by using mobile games, because PC and console network games can be used in mobile devices at any place, and they are linked to original devices without any loss of user information.

Secondly, mobile games have great potential making mobile Internet applications flourish. Mobile game communities could expand mobile communities: the conversion of Internet games into mobile games could drive many Internet game communities to change their main space into mobile communities. Like the online shopping malls connected with Internet game portals, mobile game users could be excellent resources for shopping malls in mobile services; as with Internet chatting rooms in game portals, mobile chatting services could be developed with the connection of mobile games. With the division of mobile game users into heavy and light users, mobile portal sites would be differentiated: mobile game user types could be applied to analyze mobile user types for business, because game users could account for a high ratio of heavy mobile users. For the security of big hit mobile game information, mobile security technology and anti-duplication technology of mobile content sources would be applied into mobile games. Mobile game events such as mobile game exhibition, mobile game contests, and mobile game character shows could expand areas of mobile Internet applications.

Thirdly, as mobile game users are not restricted in terms of age, gender, and social status, advertisements through mobile games could be as effective as public broadcasts. Companies can inform consumers of their logos or specific brands through mobile games. Recently, public relationships using the characters of popular games have been attracting the attention of companies, and information services about new products for target customers have been provided through

SMS (short messaging services), EMS (enhanced messaging services), or MMS (multimedia messaging services).

Finally, mobile games could be applied to new areas such as education, exercise, and therapy in mobile services. Games could be a good way to enhance participation and involvement, while mobile devices could provide both easy accessibility and convenience. So, mobile services in the form of interactive games such as game-applied education, exercise programs with interactive games, and health programs with MMS could be developed.

Mobile Game Industry

Mobile games comprise a rapidly developing industry in the game markets. In the market of mobile phone games, according to Datamonitor (2002) and In-stat/MDR (2004), the market size estimated around \$500 million in 2002 is expected to grow over \$5 billion in 2008. The size of the U.S. market was about \$40 million in 2002, but it is expected to exceed \$1 billion in 2008. Mobile game users are expected to reach over 70 million in 2008, which is about 10 times higher than in 2002. These figures exceed the growth ratio of other game markets such as PC-online and console games. As the economy of developing countries improves, and mobile devices continue to spread, mobile games are increasingly regarded to comprise a most fascinating market. The Asia-Pacific market has captured over 50% of the total mobile phone game market, with Japan and Korea in the lead, but China, India, and South Asian countries have been expanding their market share at a speed parallel to the spread of mobile devices. In portable console games, according to NPD (2006), revenue in 2005 was \$1.4 billion, notwithstanding the stagnation of console game markets in the U.S. Portable console markets have grown rapidly both in Europe and Asia with the development of network games.

Mobile games have been developed with the spread of mobile devices, gradual upgrade of capabilities of mobile devices, development of graphic technology, introduction of the flat sum system, and the spread of mobile cultures. The mobile game market is no longer independent from other game markets, because most traditional games in PCs and consoles are translated into mobile devices, and games are converged without the division of game machines. The advent of game-specialized mobile phones and portable console game devices with network capability has accelerated the convergence of games. World game publishers have merged mobile game aggregators and extended the ratio of mobile game products. Leading game machine manufacturers (platform holders) such as MS, Sony, and Nintendo are competing for dominance of the future market, not only of game devices, but also of home entertainment devices. They are striving to take the world standard of new media with their game machines. Mobile game devices will be the ultimate destination for business triumph, because mobile

devices are the most prevalent tools used by game users, and mobile games would be the most useful and profitable content in the entertainment market using state-of-the-art technology.

FUTURE TRENDS AND CONCLUSION

Several trends in the mobile games industry are expected in the near future: the convergence of game devices, variation in game content, and prevalence of mobile game cultures. The first outstanding change will be the acceleration of device convergences into mobile game devices. As console game machines have been developed into portable devices, mobile phones will be enhanced with high-capability games, and new mobile game devices based on PC capabilities will be created. To conquer preoccupation of future mobile device markets, game publishers will focus on popular game brands and develop new technologies with high multimedia functions. Game producers will create less-expensive 3D network games and more various genre games. User interfaces in mobile devices will be enhanced, and devices will be focused on game functions that can massively run multi-user games. Long-lasting charge cells will be developed for mobile devices, and local area network (LAN) games with Wi-Fi and Bluetooth will be pervaded. High-definition screens will be able to run previous PC or console games with multimedia cards and security digital (SD) cards.

The second trend is variation in game genres. Games will be differentiated for heavy and light users: for heavy users, hit MMORPG or strategic games such as *World of Warcraft*, *Starcraft*, and *Lineage* series will be created as mobile games. Mobile portals will be differentiated in terms of specified services, and their services will include generic mobile services such as shopping, chatting, and transactions. With the diffusion of flat sum services and the stabilization of the mobile network, 3D network games could be used in both mobile devices and PC or console devices simultaneously.

The third trend is the expansion of the mobile game cultures. As game contests and exhibitions are popularized in game markets, mobile game events would gain more space among them. Mobile games will extend their ranges and lead mobile content services, and they will be regarded as one of the best ways to provide mobile interactive services such as education, medical consultation, and exercises. Therefore, new mobile games using such mobile cultures will be created beyond entertainment.

In short, mobile games expand their areas not only with the convergence of game devices, but also with the expansion of their areas of application. With the development of state-of-the-art mobile devices and network technology, mobile games can include all the games played in other

device platforms such as PCs, consoles, and arcade game machines with the same environment. MMOGs in online computer games and high-definition 3D games in consoles can be adapted into mobile games. Furthermore, with the prevalence of mobile cultures, mobile games are thought of as a tool to communicate with others in various ways. As mobile cultures such as mobile communities expand, mobile games have expanded their ranges from entertainment to more applicable services such as education, exercise, and industry advertisements. Mobile games will expand their shares not only in game markets, but also in mobile-applied content markets.

KEY TERMS

Game Genre: One of several classified game types in terms of storylines, role of players, or device platforms.

Game Publisher: Game provider and copyright owner who connects game producers and content providers.

Local Area Network (LAN) Game: A network game played with other users within a short distance using LAN equipment such as Wi-Fi and Bluetooth.

Multi-Layer Game: A multi-user game where high-dimensional graphic and network technologies are adapted, such as a 3D full-network game.

Platform Holder: A company that provides game platforms to developers for development of games. In console games, device manufacturers are the same as platform holders.

WAP Game: Game serviced by wireless application protocol (WAP).

A Technology Intervention Perspective of Mobile Marketing

INTRODUCTION

In the last decade, the explosive growth and adoption of mobile phones has become commonplace in our everyday lives (Haghirian, Madlberger, & Tanuskova, 2005). In 1997, there were only 215 million people worldwide who used mobile phones as communication devices (Bauer, Barnes, Reichardt, & Neumann, 2005). Today, it is estimated that 2 billion people own a mobile phone worldwide and this number makes up a third of the entire human population (Wireless Intelligence, 2005).

Mobile phones are no longer thought of as mere personal communication tools (Cheong & Park, 2005; Ito & Okabe, 2005). They have become a fashion symbol for teenagers and young adults (Katz & Sugiyama, 2005). Personalised ring tones, colours, display logos and accessories are individualised accordingly to suit individuals' preferences (Bauer, Barnes, Reichardt, & Neumann, 2005). Furthermore, mobile phones are no longer just a platform for voice calls and sending and receiving text messages such as short messaging service (SMS). Photos, pictures and video clips can be attached as a multimedia message service (MMS) for communication purposes too (Okazaki, 2005a). With the recent introduction of 3G mobile technology, mobile phone users are able to perform more activities via their 3G enabled phone sets. They are able to browse the Internet fairly quickly, access online banking, play video games wirelessly, watch television programs, check for weather forecasts, allow instant messaging, and perform live video-conferencing (Okazaki, 2005b).

The rapid growth of the mobile industry has created a foundation for mobile commerce (m-commerce). M-commerce facilitates electronic commerce via the use of mobile devices to communicate and conduct transactions through public and private networks (Balasubramanian, Peterson, & Jarvenpaa, 2002). The current emerging set of applications and services that m-commerce offers include mobile financial applications, mobile entertainment and services, product locating and shopping, wireless engineering, mobile auc-

tions, wireless data centres and mobile advertising (Malloy, Varshney, & Snow, 2002). Commercial research has indicated that consumers' interest in m-commerce services and mobile payments have increased from 23% in 2001 to 39% in 2003 (Harris, Rettie, & Cheung, 2005). It is projected that by 2009 the global mobile commerce market will be worth at least US\$40 billion (Juniper Research, 2004).

Considering the projected worth of mobile commerce and the number of mobile subscribers, mobile marketing is increasingly attractive, as companies can now directly convey their marketing efforts to reach their consumers without time or location barriers (Barnes, 2002). The potential of using the mobile medium to market is now more attractive than before (Karjaluo, 2005), as it can assist companies in building stronger relationships with consumers (Barwise & Strong, 2002), and can be used as a promotional channel to reach consumers directly (Barnes, 2002; Kavassalis, Spyropoulou, Drossos, Mitrokostas, Gikas, & Hatzistamatiou, 2003; Okazaki, 2004) anywhere and anytime.

However, many aspects of mobile marketing are still in its infancy (Bauer, Barnes, Reichardt, & Neumann, 2005; Haghirian, Madlberger, & Tanuskova, 2005; Okazaki, 2004, 2005b; Tsang, Ho, & Liang, 2004). Research into mobile marketing is currently lacking, as this is a relatively new phenomenon. Very few studies have been conducted to demonstrate how the mobile phone channel can be successfully integrated into marketing activities of companies (Balasubramanian, Peterson, & Jarvenpaa, 2002; Haghirian, Madlberger, & Tanuskova 2005). Furthermore, no studies to date have compared the effectiveness of this mobile medium in delivering advertising and sales promotion with other more established media such as the print medium.

The fundamental question that remains unresolved is, "What is the difference between mobile marketing and traditional marketing?" Will this new form of marketing be effective? How will consumers respond to this form of marketing? What will be the benefit to marketers when consumers receive this type of advertising? These are just some of the issues that marketers are concerned with in order to

evaluate the mobile channels for marketing purposes and are questions that are core to computer-supported collaborative work (CSCW) and technology intervention research.

MOBILE MARKETING

Mobile marketing via SMS-based advertising and sales promotions is now being carried out by several multinational corporations (MNCs) in Europe and the United States of America. MNCs are very cautious in integrating such a new medium into their marketing mix (Mayor, 2005; Okazaki, 2005a). This is mainly because marketers are not fully convinced of the value of mobile channels as a marketing tool (Haghirian, Madlberger, & Tanuskova, 2005). Marketers are unsure whether their marketing efforts will cause positive or negative impacts on their consumers.

Another issue is the difference in worldwide telecommunication networks and mobile handsets used in the last decade (Leppaniemi & Karjaluo, 2005). The recent introduction of 3G mobile technology as a worldwide standard for telecommunication networks and mobile handsets has brought about a new level of investment safety for companies (Karjaluo, 2005). Companies are beginning to test their marketing efforts via the mobile phone medium (Cheong & Park, 2005). This suggests the need for researchers to develop theories and models to inform how mobile marketing can work effectively in the mobile phone context (Karjaluo, 2005).

According to Tsang, Ho, and Liang (2004), mobile marketing can be classified as either permission-based, incentive-based or location-based. Permission-based marketing requires mobile users' prior approval before specific marketing messages can be sent (Barwise & Strong, 2003). By getting the permission of the mobile users, the factor of irritation may be reduced when users read the advertisement. Incentive-based marketing provides specific rewards to individuals who agree to receive promotions (Tsang, Ho, & Liang, 2004). For instance, mobile phone users may get free connection time from their mobile service providers for retrieving and reading advertisements. Location-based marketing targets mobile users in a certain location. The advantage of location-based marketing is that advertisements are sent to those individuals who are present or near the location (Barnes, 2003).

The incentive-based marketing approach is adopted because most consumers perceive the current mobile marketing as advertising, without making a distinction between sales promotions and advertising messages (Gogus, 2004). In other words, most consumers will generally term any marketing message received on their mobile phones as an advertisement, regardless of content (Gogus 2004). Moreover, the dominant form of mobile "advertising" appears to be in the form of promotion (Kavassalis, Spyropoulou, Drossos,

Mitrokostas, Gikas, & Hatzistamatiou, 2003; Haghirian, Madlberger, & Tanuskova, 2005; Mayor, 2005; Okazaki, 2004; Tsang, Ho, & Liang, 2004).

In the marketing literature, a sales promotion can be defined as a more direct form of persuasion that may offer incentives to stimulate immediate purchase behaviour (Rossiter & Percy, 1998). Examples of sales promotional incentives include coupons, on-pack promotions, bonus packs, samples, premiums, and sweepstakes (Rossiter & Bellman, 2005; Shimp, 2003). Most of these promotional tools are based in print and termed as traditional promotional incentives (Belch & Belch, 2004).

On the other hand, advertising can be defined as a relatively indirect form of persuasion that may cause a favourable mental impression and then create an inducement toward a purchase response (Rossiter & Percy, 1998). Advertising is considered as the placement of a message to either increase product awareness, promote sales of goods and services, or just disseminate information (Leppaniemi & Karjaluo, 2005). Advertisements may also include the element of sales promotion, a common example of which is in the form of coupons.

Coupons are considered to be some types of inducement that provide extra incentives to buy (Belch & Belch, 2004). Thus, in the context of mobile promotion, a mobile coupon is defined as an incentive that is paperless and electronic in nature (Wehmeyer & Müller-Lankenau, 2005). It is the fusion of the traditional print-based coupon with the mobile phone medium. A mobile coupon is delivered to a mobile phone handset as a message and is associated with mobile services and contents (Wehmeyer & Müller-Lankenau, 2005).

INTERACTION DESIGN AND THE LOCALES FRAMEWORK

The Locales Framework is a comprehensive theoretical CSCW and interaction design framework in the field of information and computer science (Fitzpatrick, 2003). According to Fitzpatrick, Kaplan, & Mansfield (1998), this research framework is an approach that allows for the creation of shared abstractions among stakeholders (e.g., companies, individuals, consumers, marketers), and also to narrow the gap between social and computing concerns with a common language. Understanding the social phenomenon and designing a relevant application that can fit the social setting are the two important factors when applying the Locales Framework. It is the aim of Locales Framework analysis that more pragmatic design and systems applications are built to suit the social world (Fitzpatrick, 2003).

The Locales Framework is based on five aspects, each of which are interdependent and overlapping, as they share various concerns with one another and are used to approach the domain to be studied from different perspectives—rather

than separating the domain into distinct subdomains to be studied independently.

The *locale foundation* aspect portrays the social world and the locale it uses for its interaction (Fitzpatrick, 1998, p. 91). The social world can be characterised by a number of issues such as collective goal, memberships, duration, structure, culture and roles. A locale is the primary unit of analysis in the Locales Framework. A locale consists of the site and means that a social world uses in its pursuit of the shared purposes. According to Fitzpatrick (2003), a site is a place the social world uses and means are the objects within this place. The social world needs sites and means to facilitate their shared interactions.

The *civic structure* aspect takes the locale of interest and considers its relationships and interactions with the wider community (Fitzpatrick, 1998, p. 92). In other words, it concerns the facilitation of interaction with the wider community within and beyond a person's known social worlds and locales. The interaction with a wider community can possibly relate to an environment that is physical, spatial, geographical, organizational, informational, professional, legislative, and so on.

The *individual view* aspect describes an individual's single perspectives on one social world as well as on multiple social worlds (Fitzpatrick, 1998, p. 115). A single perspective is how an individual sees one social world, and is dependent on the level of engagement with the centre of that world, whereas multiple view sets incorporate the individual's views of all the social worlds with which he or she is engaged. Individuals personalize their views to suit their tasks according to their current level of engagement.

The *interaction trajectory* aspect identifies the dynamic, temporal aspects of the social world in action (Fitzpatrick, 1998, p. 122). This aspect identifies the actual interactions individuals have over time within the setting and with each other. Moreover, this aspect is not only concerned with the current action, but also with the past and projected futures. Awareness of past actions and outcomes, present situations, and visions for the future are important for creating plans and strategies. An important consideration to understand this aspect is to look at what perspective or point of view is applied to any particular domain.

The *mutuality* aspect is a collaborative activity that draws specific attention to how the locale supports presence, and how awareness of that presence is supported for the achievement of shared activity. The mutuality aspect enables questions on who, what, when, where, why and how to be answered.

When the Locales Framework is used, it involves a two-phase approach. This is iterative in order to better understand the nature of the given (Fitzpatrick, 1998). The first phase is to understand the current locales of interest from the view of the interaction needs. This could involve using qualitative data collected through an ethnographic study or a one-to-one interview. Generally the data collected could

then help to provide some relevant structure to designers when they engage in the design process of an application. It is argued that for designers who do not have any social science background, the Locales Framework could be applied as a sensitizing device to aid in formulating initial questions for the design process (Fitzpatrick, 1998).

The second phase in applying this framework is to evolve new locales. The goal is to discover more possibilities for the existing locale of interest in order to better support the activities that take place there and to explore possible newer locales that can evolve as a result. This phase is to identify the advantages of any available medium, physical or computational, and the synergy among them, so that the needs of the social world are better met. Specific questions that will help to drive this phase include: What interaction needs does the social world need that are lacking in this current locale? How can the existing locale be enhanced to support the aspects of the Locales Framework; namely, mutuality, individual views, civic structure and interaction trajectory? Can new technology be applied to the locale? Can new social worlds evolve if the resources are used in newer locales?

MOBILE MARKETING AS TECHNOLOGY INVENTION

Prior research has identified the importance of coupons in affecting consumers' cognitive, affective and conative behaviour during promotional campaigns (Raghubir, Inman, & Grande, 2004), but relatively little research has been conducted into the use of electronic coupons (Fortin, 2000; Suri & Swaminathan, 2004), particularly the form of mobile coupons (Okazaki, 2004). Most research in coupon studies is based mainly in the traditional medium of print (Coyle & Thorson, 2001; Liu & Shrum, 2002).

Much of the current literature that has been mentioned is adapted purely from a marketing perspective. Since mobile marketing involves people, technology and applications, mobile marketing should also be investigated from a human-computer interaction (HCI) and CSCW perspective. This will perhaps provide a better understanding of how and what is best for mobile marketing.

To better design mobile marketing strategies from a technological viewpoint, the use of the Locales Framework can be applied. The five inter-dependent characteristics of the Locales Framework guide study of the product or service to be marketed. An example may be a coffee shop:

Locale Foundation

The social world will be portrayed by consumers trying to buy beverages or food at the cafes and the locale is the cafe. The means in this case will be the chairs, tables, coffee

machines, coffee counters, and the cashier's machine found within this site. The new technologies, that is, mobile phones and systems to send mobile coupons, are also included. More broadly the café may be situated in a locale such as a shopping centre or University that has its own means.

Civic Structure

The civic structure aspect considers issues such as the physical location of the café in its broader situation, store layout, and any competitors of café.

Individual View

In the case of mobile marketing, the individual that comes into the café will be a consumer and thus his or her task may be to purchase a cup of beverage for enjoyment. When they leave the café, their perspective may change to follow the priority that they may have to engage in. Perhaps the perspective may change to acquire knowledge and thus attend lesson at a lecture theatre or maybe need to catch a ride home by become a passenger when boarding a public transport such as a bus.

Interaction Trajectory

In this case study, the interaction trajectory aspect will determine the objective of the consumer coming to the café and how does the consumer interact with the surrounding environment. Despite receiving a discount coupon for cheaper beverages via the mobile phone, the consumer may come into the café with the purpose of meeting someone and not buy any beverages at all. To this consumer, the café has become a meeting venue and not a place for consumption. The café may become a place for taking a coffee break with fellow colleagues, and therefore the consumer may take advantage to purchase a cup of coffee at the special price for enjoyment.

Mutuality

In this case scenario, the mutuality factor will look into how mobile marketing is supported and how applications can be created to support mobile marketing in the context of a café.

Several advantages of the Locales Framework, as according to Fitzpatrick (1998, pp. 152,153), are listed as follow:

- It provides a common tool for understanding and designing of a social problem.

- It has the potential to analyse issues from group to individual level, local setting to global context, and structure to process;
- It is independent of any one theoretical orientation when investigating into one phenomenon.
- It is a framework that is strong in identifying key elements of a collaborative environment but sufficiently generic, open and incomplete so as not to prescribe nor circumscribe all that is of interest.

Applying the Locales Framework approach to mobile marketing, we are able to build several “locales” (which can be defined as potential social world scenarios) in helping companies to consider before they actually implement their marketing plan. Moreover, companies that implement mobile marketing should consider the aspect of civic structure—the facilitation of interaction among various factors like physical, informative, geographical and technological parties. In the context of mobile marketing, companies should look at who their telecommunication service providers are, where their potential consumers are located, what applications should be used to generate response from consumers and what types of mobile phones should be able to receive mobile marketing. Companies need to understand that their potential consumers have many different perspectives and opinions, another aspect considered in the Locales Framework analysis.

As mentioned earlier, the inducement of using a coupon to induce potential consumers to respond to mobile advertisements is a possible suggestion. Furthermore, companies need to understand that the locale does not stay static, as it is always changing and evolving. Therefore companies need to involve the interaction trajectory aspect that identifies actual interactions individuals have over time within a given context setting and with each other. The last aspect on mutuality involves companies to consider how best mobile marketing can be supported in a given location and how mobile marketing can create awareness for the companies.

The Locales Framework does not attempt to account the findings of one particular phenomenon that is generalisable. It does, however, deliberately aim to characterise its findings that are open in many ways. In fact, one of its aims is to focus on providing an evolvable framework that can be made relevant for both understanding the social situation (in this case mobile marketing) and for improving better technology development to it. This approach, unlike many traditional marketing strategic research approaches, does not assume that the technology introduction has to accept static technologies, or unchanging user attitudes towards technology (rather than the product). A dynamic, multi-dimensional picture of clients and possible interactions allows more dynamic engagement models—supported by dynamic technology, not based on working around systems controlled by other developments.

FUTURE TRENDS

Mobile marketing still lacks research. However, approaching this area from a technological perspective we can suggest several possible outcomes that a marketing and CSCW combined approach indicate:

First, companies are increasingly able to understand potential consumers' attitudes and behaviours in the context of mobile marketing from a more holistic perspective. In particular, the adoption of Locales Framework can provide insights to companies on how to further improve their design and concept for mobile marketing strategies in a particular situation.

Second, there is a need to consider the aspect of interaction design in mobile marketing campaigns. Companies who intend to reach the target market effectively should consider factors like interactivity in their marketing materials, what types of technology (Wifi, Bluetooth, RFID, or global positioning system) can the companies adapt in mobile marketing and how best can the mobile medium fit in a given situation as well as to their potential consumers. The technology perspective of mobile marketing should be considered thoroughly.

Third, situational factors like time and location are important issues that any given companies who decide to use the mobile channel for marketing need to consider. At present, there are no concrete solutions and applications for companies to fully adapt when they design their marketing materials.

Fourth, marketing and technology are both at the fore-fronts of innovation and fashion. Technology introduction-based marketing methods may also drive technology R&D, when the integrated study approach suggests technological improvements.

Lastly, companies may need to consider social factors like culture, values and norms prior to the launch of a mobile marketing campaign. A single set of mobile marketing materials cannot be carried out in different places, as the social factors are often different. Thus, companies operating across many countries may just need to create a general set of guidelines for mobile marketing with the ability to be tailored to specific context situations. The adoption of the Locales Framework is a suitable tool to be considered for such a multi-level guidelines and customisation approach.

CONCLUSION

Using mobile phones as a medium for marketing is a new phenomenon. Companies need to understand the impact of this medium thoroughly before proceeding. Current research into mobile marketing begins with the traditional marketing perspectives and replaces existing media with mobile technol-

ogy. Such an approach is based on a historical perspective that doesn't arise from the capabilities of human-computer interaction. The introduction of a theoretical-based research framework such as the Locales Framework is suitable in the investigation of this new medium for mobile marketing. A holistic perceptive of technology introduction in a business-to-client interaction to understand mobile marketing is described, with guidelines for supporting the development of mobile marketing strategies. Such a hybrid marketing/interaction design approach generates new possibilities for both technology development and client engagement that either approach individually would not.

KEY TERMS

Computer-Supported Collaborative Work (CSCW): Combines the understanding of the way people work in groups with the enabling technologies of computer networking and associated hardware, software, services and techniques (Wilson, 1991). CSCW also addresses how collaborative activities and coordination can be supported by means of computer systems (Carstensen & Schmidt, 2002). Moreover, CSCW involves incommensurate perspectives as well as incongruent strategies and discordant motives (Schmidt & Bannon, 1992) to gain a better understanding of collaborative efforts within organizations so that this understanding can be used to effectively design collaborative technology that can be best deployed within the organizations.

Human-Computer Interaction (HCI): The study of how people interact with computers and to what extent computers are or are not developed for successful interaction with human beings (ACM SIGCHI, 1996). In fact, HCI is a very broad discipline that encompasses different fields with different perspectives regarding computer development. For instance, HCI in psychology is concerned with the cognitive processes of humans and the behaviour of users, while HCI in computer science is concerned with the application design and engineering of the human interfaces. In sociology and anthropology, HCI is concerned with the interactions between technology, work and organization and the way that human systems and technical systems mutually adapt to each other.

Interaction Design (ID): The study of designing interactive products to support people in their everyday and working lives (Sharp, Rogers, & Preece, 2002). One of the objectives in ID is to produce usable products that are easy to learn, effective to use and also provide an enjoyable experience. Generally users are engaged in the design process.

Locales Framework, The: The Locales Framework is a theoretical-based research framework for interaction design, with a key focus on CSCW. It approaches the study of a certain context or domain with the aim to discover findings that are open in many ways. The general set of guidelines derived from a context or domain is known as the five interdependent aspects. They are: locale foundations, civic structure, individual views, interaction trajectory, and mutuality.

Mobile Advertising (M-Advertising): Advertising is a mass-mediated communication tool. Its aim is to communicate with the intended audience to buy into the desired message. In the context of mobile phones, mobile advertising aims to present the desired information to the consumers, hoping that consumers will react. Currently, most “advertising” contents found on mobile phones are considered as sales promotional materials, which aim to persuade consumers to buy the products.

Mobile Marketing (M-Marketing): Marketing a company’s advertised and promotional materials via mobile phones through short message service (SMS) or multimedia messaging service (MMS) is known as mobile marketing. The mobile phone is to the adapted a marketing channel to reach consumers.

Technology Intervention: Technology intervention is the intentional introduction of a technology, or method, into a context to alter that environment. Technology intervention may be targeted at improving information flow, communication, or other types of awareness. In mobile marketing, mobile phones can be seen as a technology intervention in the company-client relationship. Interaction design specifically focuses how to use technology intervention to improve interactions.

INTRODUCTION

Currently, five terrestrial radio interfaces, which can be categorized as frequency division duplex (FDD) and time division duplex (TDD) modes, have been approved as the IMT-2000 radio interfaces. CDMA in TDD (TDD-CDMA) mode will be based on the harmonization between UTRA (UMTS terrestrial radio access) TDD and TD-SCDMA (time division-synchronous CDMA). Compared to UTRA TDD, which is 3.84Mcps in 5MHz bandwidth, TD-SCDMA, is also called low chip rate (LCR) TDD or Narrowband (NB) TDD for its 1.28Mcps in 1.6MHz bandwidth. TDD uses a combined time division and code division multiple access scheme. Hence the signals of different users are separated in both time and code domains (Chen, Fan, & Lu, 2002).

Jointly developed by the China Academy of Telecommunications Technology (CATT) and Siemens, TD-SCDMA is one of the five IMT-2000 standards accepted by the ITU. The main benefits of TD-SCDMA are that it can be implemented less expensively than comparable 3G systems since it is much more spectrum efficient and is compatible with the current deployment of GSM network elements in China, allowing 3G asymmetric services without installation of completely new infrastructure.

Compared with WCDMA and CDMA, TD-SCDMA (Peng et al., 2005) adopts TDD duplex mode, uses the same frequency band for the uplink and downlink, and makes full use of the asymmetrical frequency resource. Meanwhile, the TDD mode has the adjustable switch point between uplink and downlink, which can adapt to the asymmetrical service in uplink and downlink and makes full use of the spectrum. Furthermore, the symmetrical channel feature of TDD systems makes it very flexible and convenient for TD-SCDMA to adopt the advanced technologies such as joint transmission, smart antenna, and so on, which can improve the system capacity and spectrum efficiency. Because the uplink and downlink of TD-SCDMA use the same carrier frequency, the channel propagation features and channel

impulse response in downlink and uplink have strong correlation when the interval between uplink reception and downlink transmit is less than the channel coherent time. So the channel information estimated in uplink can be directly used for downlink transmission, and this provides a good condition for implementation of smart antenna. Therefore, compared with the FDD system, channel estimation, power control, and smart antenna in the TD-SCDMA system become more simple and feasible.

As the CDMA system is a self-interfering system, interference among users is the key factor that limits the system capacity (Klein, Irwin, & Roberto, 1991). Using joint detection (JD), inter-symbol interference (ISI), and multiple access interference (MAI) can be effectively eliminated, and as a result, the system capacity is improved (Peng et al., 2004). With the spatial location information, smart antenna can focus the transmit signal power in the direction of the target user, through which users will receive more useful signal power, and interference is highly compressed. This is another way to increase system capacity. However, what is the difference of the radio network planning between TD-SCDMA and WCDMA/cdma2000? Based on the TDD mode, TD-SCDMA covers all application scenarios: voice and data services, packet and circuit-switched transmissions for symmetric and asymmetric traffic, pico, and micro and macro coverage for pedestrian and high mobility users. However, the adopted key techniques, such as time division duplex, smart antenna, multi-user joint detection (MUD), dynamic channel distribution, uplink synchronization, and baton handover, make the network design in TD-SCDMA have a significant difference from WCDMA and cdma2000 (Peng et al., 2005). Unfortunately, to the best of our knowledge, there are still no papers investigating and proposing network design solutions for TD-SCDMA in which the impacts of key techniques have been considered. In this article, the key techniques impacting on the radio network design of TD-SCDMA are introduced. Meanwhile, some special radio network design issues for TD-SCDMA are presented.

Figure 1. TD-SCDMA frame structure

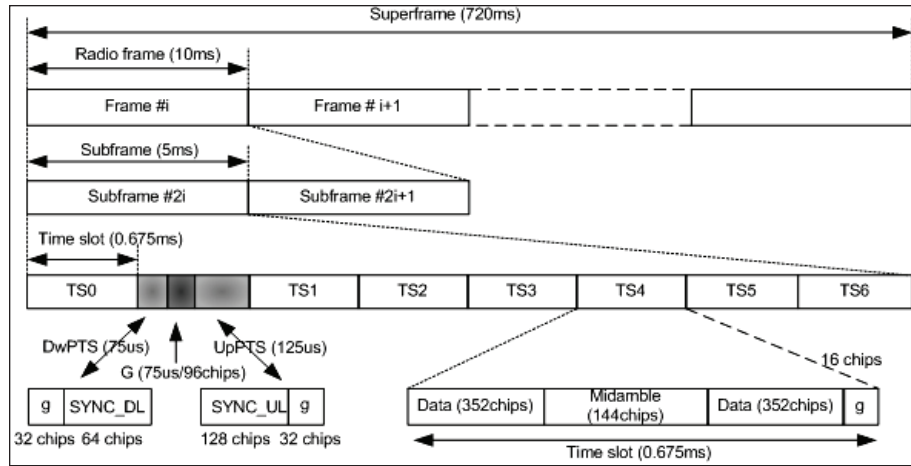

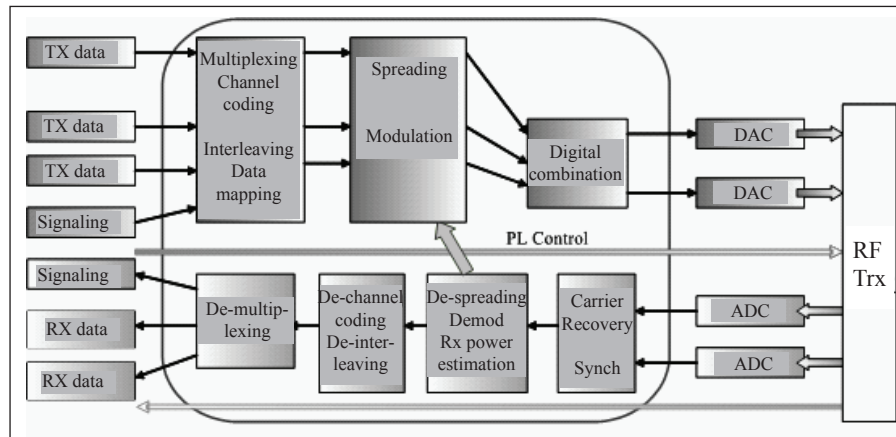

Figure 2. System block of TD-SCDMA base band data processing

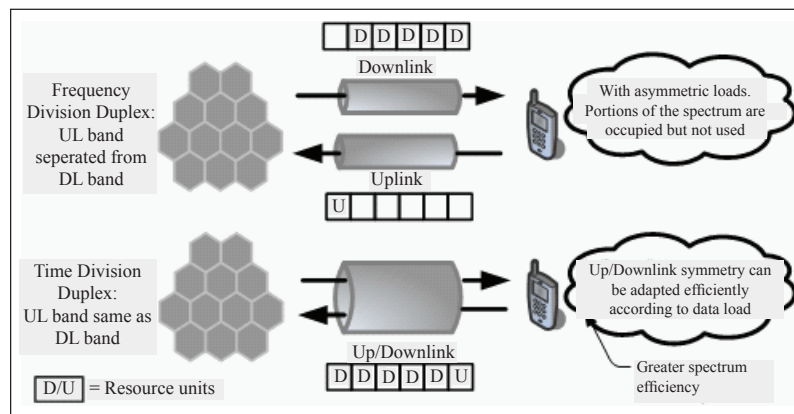

SYSTEM BLOCK

TD-SCDMA makes use of both TDMA and CDMA techniques such that channelization in TD-SCDMA is implemented using both time slots and signature codes to differentiate mobile terminals in a cell. The frame structure of TD-SCDMA is shown in Figure 1, where the hierarchy of four different layers—super-frame, radio frame, sub-frame, and time slot—are depicted.

A sub-frame (5 ms) consists of 7 normal time slots and 3 special time slots, where TS0 is reserved for downlink and TS1 for uplink only, whereas the rest (TS2-TS6) should form two groups, the first (whose size can vary from 1 to 4 slots) for uplink and the second (whose size can vary from 4 to 1 slots) for downlink. The slot number ratio of the two groups can take 1/4, 2/3, 3/2, and 4/1 to suit particular traffic

requirements. The agility in support of asymmetric traffic is a very attractive feature of TD-SCDMA and of particular importance for Internet services with rich multimedia content in 3G applications. The other three special time slots are downlink pilot (DwPTS), guard period (G), and uplink pilot (UpPTS), respectively. DwPTS and UpPTS are used as a synchronization channel (SCH) for downlink and uplink, respectively, which should be encoded by different pseudo-noise (PN) codes to distinguish different base stations and mobiles. Meanwhile, the subscribers use the midamble part of every burst to estimate the channel impulse response. The subscribers in the same cell are assigned the same basic midamble with different time shift. Using the Steiner estimate principle, the base station can estimate the channel impulse response of all the subscribers simultaneously. The base band data processing is described in Figure 2.

Figure 3. Explaining of TDD and FDD

KEY TECHNIQUES IN TD-SCDMA

The wireless access technique of TD-SCDMA is based on the TDMA (time division multiple access)/TDD, while WCDMA and cdma2000 are both based on the FDD. Some advanced techniques, such as smart antenna, MUD, and dynamic channel allocation (DCA), can be utilized more conveniently in TD-SCDMA than WCDMA and cdma2000, which can be categorized as the advantage of TD-SCDMA. Meanwhile, the uplink synchronization and handover have a stricter requirement, which can be regarded as the disadvantage in TD-SCDMA.

CDMA Plus TDMA/TDD

The TDD mode allows uplink and downlink on the same frequency band and does not require the pair frequency bands. In TDD, uplink and downlink are transmitted in the same frequency channel but at different times, and the difference between TDD and FDD is described in Figure 3. It is possible to change the duplex switching point and move capacity from uplink to downlink or vice versa, thus utilizing spectrum optimally. It allows for symmetric and asymmetric data services. TDMA is a digital technique that divides each frequency channel into multiple time-slots and thus allows transmission channels to be used by several subscribers at the same time. CDMA increases the traffic density in each cell by enabling simultaneous multiple-user access on the same radio channel. In order to decrease the interference sourcing from the MAI, smart antenna and MUD are utilized. Since TD-SCDMA is based on TDMA/TDD, the air interface for both uplink and downlink is interoperable, which makes smart antenna efficiency.

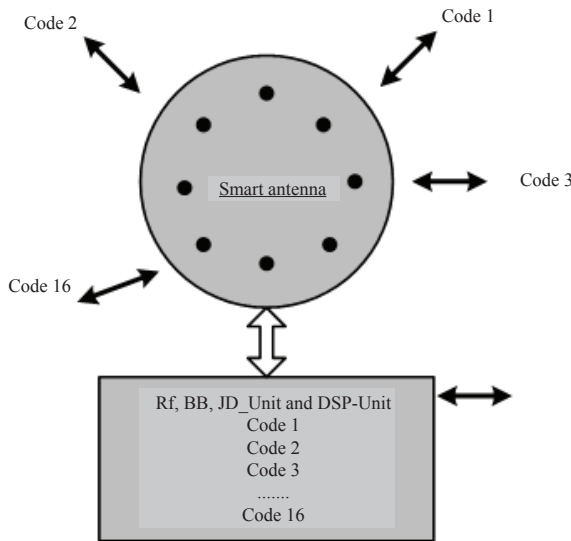

Smart Antenna

A smart antenna system is composed of N antenna elements, N related feed cables, and N coherent radio frequency (RF) transceivers. By using the A/D converters or D/A converters in the analog base-band (ABB), the receiver and transmitter analog signals are interfaced to the digital base-band (DBB) part over the high-speed data bus. The beam-forming which points to a particular user equipment (UE) can be obtained through smart antenna. Due to the inherent robustness of CDMA and the space diversity realized by smart antenna, the interference for multi-path propagation is greatly overcome, and the inter-symbol interface can be greatly reduced. For downlink, beam-forming can also reduce the interference to the other co-channel UEs. These performances can lead to the higher capacity of the TD-SCDMA system.

Smart antennas employed by TD-SCDMA technology are not conventional diversity beam-switching antennas but advanced beam-forming (and beam-steering) bi-directional adaptive antenna arrays. The maximal individual directivity between base stations and mobile terminals is achieved by a concentric array of eight antenna elements with programmable electronic phase and amplitude relations. The terminals tracking is performed by the fast angle of arrival (AOA) measurements in intervals of 5 ms 200 times per second.

The basic idea of the smart antenna is to track the user's mobility, make the interference among different users compressed by spatial filtering, and enhance the desired signal received or focus the energy of the signal on the direction of the desired user location. Thus the system coverage, power efficiency, and system capacity can be improved. The most common antenna array geometry structures are uniform linear array (ULA) and uniform circle array (UCA), which is described in Figure 4.

Figure 4. Basic principle of uniform circle array

The beam pattern of the ULA is symmetrical along the boresight of the antenna array, that is to say ULA cannot distinguish the users that locate at the symmetry location along the boresight of the antenna array. The more the user location deviates the boresight of the antenna array, the wider the beam and the lower the resolution of the antenna array will be.

For UCA, as the distance between the elements increases, the aperture of the antenna array becomes larger, and the resolution of AOA increases; meanwhile the amplitude of the side lobe becomes larger. Compared to the ULA, no phase blur happens. So except the sector scenario, UCA will be adopted.

Three types of beam-forming antennas are introduced in TD-SCDMA: phased array, switch-beam, and Eigen-

beamforming. For the phased array, the weighted combining only do some phase rotation on the received signals. Switch-beam is a simplification of the phased array, in which the whole cell is divided into several sectors and a set of pre-defined beam-forming weights are used to cover these sectors one by one. The rationale of the Eigen-beamforming is that the maximum Eigen value and Eigen vector of the spatial correlation matrix of the user is found by Eigen value decomposition as the power gain and beamforming weight. The performance of the switch-beam is little worse than that of phased array, and the Eigen-beamforming is expected to be the best.

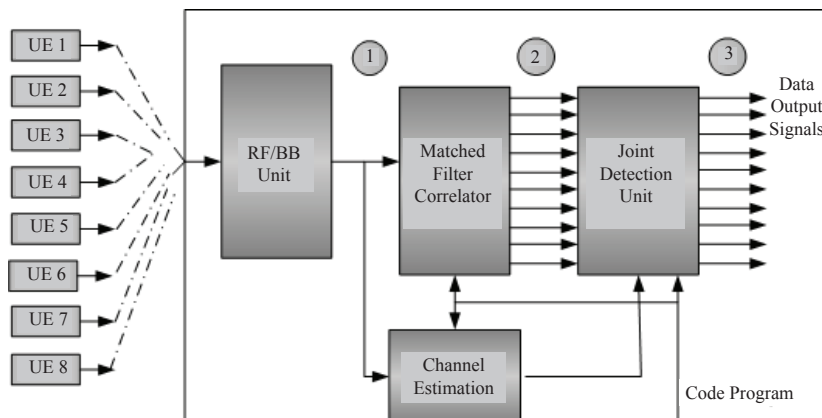

In the current TD-SCDMA system, the phased array smart antenna is utilized to suppress the interference from both the inter-cell and intra-cell. However, if the air condition is too bad and the AOA estimation is incorrect, the smart antenna cannot work efficiently. In this way, the multi-user joint detection technique is adopted to suppress only the intra-cell interference.

Multi-User Joint Detection

Multi-user joint detection (MUD) allows the receiver to estimate the radio channel and works for all signals simultaneously. Through the parallel processing of individual traffic streams, MUD eliminates the MAI and minimizes intra-cell interference, thus increasing the transmission capacity.

Figure 5 describes the basic principle of MUD. The first step is that all signals from the various UEs are received in the node B receiver through the radio frequency (RF)/baseband (BB). The second step is to detect the signals barely emerging from the MAI with a low signal to noise ratio (SNR). In the last step, using a specific algorithm, a DSP thus extracts all CDMA channels in parallel and removes the interference caused by the undesired CDMA channels. The result is a clear signal (high signal to noise ratio) for each CDMA code.

Figure 5. Basic principle of MUD

Note that the efficiency of MUD in TD-SCDMA technology is based on the TDMA/TDD operation and on the limited number of codes employed. The total number of users per radio carrier is distributed over the different time slots of the basic TDMA frame, so that a maximal number of 16 codes per time slot per radio carrier can be easily processed in parallel and detected. However, due to the huge number of spread codes used by WCDMA and cdma2000, the implementation of an optimal multi-user receiver in these systems is difficult, since the implementation complexity is an exponential function of the numbers of codes. In order to combat MAI, both WCDMA and cdma2000 systems employ the suboptimal detection schemes, such as the rake receiver, which do not extract all CDMA codes in parallel.

Dynamic Channel Allocation

A further minimization of inter-cell interference is achieved by dynamic channel allocation (DCA). There are different radio resource dimensions for TD-SCDMA: TDMA, FDMA, CDMA, and SDMA (space division multiple access). Making an optimal use of these degrees of freedom, DCA provides an adaptive allocation of the radio resources according to the interference scenario, minimizing the inter-cell interference (Peng et al., 2003).

In TD-SCDMA, the DCA is divided into two parts: Slow DCA allocates resources to cells, while Fast DCA allocates resources to the bearer services, balances the load in the different slot/frequency, and congregates the radio resource for supporting the high bit rate services. Both UEs and node Bs perform the periodic monitoring and reporting to support DCA. Fast DCA is always terminated at the node B, but slow DCA can be terminated at any network entity above the node-Bs that forms the seamless coverage area. The slow DCA algorithm allocates the radio resource units in a cell-related preference list for Fast DCA to acquire them for different bearers. In the first phase the cell-related preference list is a fixed table that is given as a parameter for each base station. Fast DCA resides in each node B and is responsible for utilizing the slots assigned to the node B in the most efficient manner possible. This involves: (1) assigning each UE to the slot(s) best suited in each particular case at the start of a connection, and (2) reshuffling/reallocation of UEs when traffic and/or environmental conditions have changed or if the requirements of an existing connection have been altered by the UE.

According to the asymmetry of transmission bits, the switched point between uplink and downlink is different in the adjacent cells in which the cross slot interference sourcing from the node B-node B is huge. In order to suppress the cross slot interference, the Fast DCA combines the smart antenna technique to allocate the radio resource in the cross slots to the UEs close to the serving node B. In this way, the

total transmission power in the cross slots decreases and the interference is suppressed.

Uplink Synchronization

Like all TDMA systems (e.g., GSM), TD-SCDMA needs an accurate synchronization between mobile terminal and base station—that is, the UEs' spread signals arriving at the node B at the same time can effectively simplify the demodulator in node B, decrease MAI, and increase the system capacity. This synchronization becomes more complex through the mobility of the subscribers, because they can stay at varying distances from the node B, and their signals present varying propagation times.

An uplink synchronization procedure includes two stages: synchronization establishment and synchronization maintenance. The synchronization establishment is often associated with UE's access procedure, and the synchronization maintenance is often associated with the dedicated communication procedure between UE and network. Due to the multipath and shadow fading, however, the establishment and maintenance of the uplink synchronization between different UEs in a cell are difficult. The simple, effective, and low-cost establishing and maintaining uplink synchronization solution will bring benefits to TD-SCDMA. The UL synchronization is equivalent to a very high precise timing advance according to the physical layer specifications. Therefore, an extended time advanced (TA) option by means of a sub-chip granular operation is utilized in TD-SCDMA. The granularity of TA, in the case of UL synchronization, is $\pm 1/8$ chips.

Baton Handover

The conventional hard handover has some shortages, for example the dropping ratio of the hard handover is high, and the efficiency of the radio resource usage of soft handover is low. With smart antenna and uplink synchronization, the handover strategy will change and the performance will be improved in TD-SCDMA. The UE position information and AOA are provided to predict the handover request, prepare for handover and pre-synchronize for handover, shorten handover time, decrease handover blocking, simplify handover procedure, and improve handover confidence. This is named baton handover in TD-SCDMA (Peng et al., 2003).

The basic principles of baton handover are: (1) the system knows the position of all UE, (2) the system knows and determines the target cell for handover, (3) the system informs mobile the information about the node B in neighboring cells, (4) mobile measurement helps the system to make the final decision, and (5) after the cell search procedure, the mobile UT has already established.

Since UE can synchronize to the node-B in target cell, the baton handover costs a shorter handover time period

for both inside the TD-SCDMA system and between TD-SCDMA and the different systems. In the TD-SCDMA system, the parameters that UE measure are not only the received signal power level, but also their transmission time offset and so on.

TD-SCDMA RADIO NETWORK DESIGN

Since the TD-SCDMA system adopts many advanced techniques, there are some unique issues when doing TD-SCDMA radio network designs (Peng et al., 2005). First, the scramble codes in TD-SCDMA are only 16 chip lengths, and the orthogonality between different scramble codes is easy to lose which will cause difficulty in pilot searching and reception. So, the scramble code planning is especially important in a TD-SCDMA system. Second, as TD-SCDMA is a narrowband system, its bandwidth is one-third of that of WCDMA, and the capacity of single carrier TD-SCDMA is low compared to WCDMA. That means if TD-SCDMA occupies the same bandwidth as WCDMA, the multi-carrier system can be adopted to form a higher capacity (Peng, Chen, & Wang, 2006). Besides, multi-carrier with careful configuration of carrier can make scramble codes planning much easier. Multi-carrier TD-SCDMA layout is proposed to form a network and provide many kinds of mobile services. Third, coverage of a certain system is of great importance. It can be analyzed in a theoretical way by link budget. Link budget of TD-SCDMA differs from that of CDMA2000 and WCDMA, due to its own properties and the advanced techniques that TD-SCDMA employs. Finally, coexistence of TD-SCDMA with other 3G systems is another important issue both for TD-SCDMA and other related system performances (Peng et al., 2004).

CONCLUSION

In TD-SCDMA only 16 codes for each timeslot for each carrier are used. The intra-cell interference is eliminated by MUD, and inter-cell interference is minimized by the joint use of smart antennas and DCA. Meanwhile, since most interference is suppressed under the condition of smart antenna working efficiently, the capacity is radio resource limited, and the cell breathing effect is not an issue anymore. However, some new problems occur due to the key techniques and features of TD-SCDMA, such as the N frequency planning, scrambling code planning, multi-operators coexistence planning, and advanced radio resource management.

In order to successfully deploy the commercial TD-SCDMA network, the key techniques impacting on the network performance and the novel network strategies should be proposed. The special network planning method

and project steps should be configured for TD-SCDMA. This article discussed all these confusing problems in TD-SCDMA network planning and presented the principle solutions. Some special issues should be investigated, such as the handover strategies between TD-SCDMA and other mobile communication systems, indoor network design, and repeater design specified for TD-SCDMA.

KEY TERMS

Code Division Multiple Access (CDMA): A kind of multi-access method. Users are distinguished in code domain. Other well-known multiple access methods are FDMA (frequency division multiple access), in which frequencies are used to distinguish different users; and TDMA (time division multiple access), in which time is used to distinguish different users.

DCA: Another key technique that a TD-SCDMA system holds, by which radio resources are allocated to different traffic bears of different cells.

Multiple Access Interference (MAI): The main kind of interference in a CDMA system. It has a bad impact on CDMA system capacity.

Multi-User joint Detection (MUD): A kind of detection method at receiver. Other common detection methods are rake receiver and matching receiver.

Radio Network Design: Design of network framework, layout, and so on. This is a key for a system to be commercially feasible.

Smart Antenna: A key technique of a TD-SCDMA system which can enlarge received signal power and suppress interference, thus improving received SNR (signal to noise ratio) and enlarging system capacity.

System Capacity: The number of users of certain traffic that the system simultaneously holds. Other definitions are the number of Erlang that a system holds simultaneously.

Time Division Duplex (TDD): A kind of duplex mode. Another well-known duplex is FDD (frequency division duplex) mode. Uplink (from user to network) and downlink (from network to user) in TDD mode are divided by time and in FDD by frequency.

Time Division duplex-Synchronous Code Division Multi-Access (TD-SCDMA): A3G standard proposed by the China Academy of Telecommunications Technology (CATT) and Siemens jointly, and accepted by the ITU in 1999.

Transaction Management in Mobile Databases

INTRODUCTION

Recent advances in wireless communications and computer technology have provided users the opportunity to access information and services regardless of their physical location or movement behavior. In the context of database applications, these mobile users should have the ability to both query and update public, private, and corporate databases. The main goal of mobile software research is to provide as much functionality of network computing as possible within the limits of the mobile computer's capabilities. Consequently, transaction processing and efficient update techniques for mobile and disconnected operations have been very popular. In this article, we present the main architecture of mobile transactions and the characteristics with a database perspective. Some of the extensive transaction models and transaction processing for mobile computing are discussed with their underlying assumptions. A brief comparison of the models is also included.

TRANSACTION MANAGEMENT IN MOBILE DATABASES

A mobile database system is a special multi-database system on a mobile computing environment. It allows mobile hosts to access and manipulate data stored on several pre-existing, autonomous, and heterogeneous local database systems located on different parts of the wired network. Transactions in a mobile database system may access data from several local databases at different sites. Management of these transactions requires different approaches in mobile databases than in a multi-database. This is mainly due to the fact that a mobile host is not suitable to manage a global transaction by itself due to the described nature of the mobile computing environment. Usually this management is done by the mobile host's base station or by coordination of it.

Due to the described nature of the mobile computing environments, transaction management has to be reevaluated for mobile databases. The transactions in mobile computing environments are usually long-living transactions, possibly covering one or more disconnected durations. Supporting disconnected operation (i.e., allowing a mobile host to operate autonomously during disconnection) raises issues in consistency. Providing disconnected operation also requires some pre-caching of data that will be required for the necessary operations to be performed during disconnection. The moving behavior of the transactions in mobile computing environments also requires new mechanisms. As a mobile host moves from a cell to another cell, its transactions might need to migrate from one base station to another. In general, transactions in mobile databases require relaxed ACID properties. There are several works on mobile transactions, each addressing some of the issues in mobile transaction management. We will explain some of them in the following sections.

Kangaroo Transactions

Kangaroo transactions (KTs) are introduced in Dunham and Helal (1997). As the name suggests, this model mostly addresses the moving behavior of the mobile transactions. As the transactions hop from one site to another, the management of the transaction also moves.

In addition to the mobile computing environment we have described, these systems introduce a couple of other terminologies. The term *source system* represents a collection of systems that offer information services to mobile users. These systems could be any type of system that exists in the mobile computing environment. One good example is a distributed database system. The term *data access agent (DAA)* represents an agent that is hosted by each base station. Mobile hosts reach data in source systems by sending their transactions to DAAs. When a handoff occurs, the DAA at

the new base station receives the transaction information from the DAA in the old base station. A *mobile transaction* is defined as the basic unit of computation in the mobile environment. The management of a mobile transaction might hop through different base stations, which are not known until it completes its execution. DAAs at base stations are responsible for management of the mobile transactions. One part of the DAA responsible for the management of the transactions is called the *mobile transaction manager (MTM)*. The main responsibilities of an MTM are maintaining the status of mobile transactions in execution, logging recovery information, and performing needed checkpointing.

In this model it is assumed that a mobile transaction issued by a mobile host to a DAA might include several subtransactions that require access to data at several global database systems (GDBSs) and DBMSs residing at different places of the fixed network. As a result DAAs serve as a mobile transaction manager built on top of GDBSs and DBMSs. DAAs also keep log information about the mobile transaction parts that have executed on them. Remember that a mobile transaction changes its DAA as it moves from one cell to another.

Since mobile transactions are long lived and include possible disconnected durations; the atomicity of a mobile transaction in this model is not always guaranteed. The time between an interruption of a transaction and its resume could be quite long. As a result, it is valuable to commit early on some portions of a mobile transaction, while breaking the atomicity property of the transactions. These early commits enable the release of possible important resources, instead of holding them for a long time.

A mobile transaction in this model, which is called a *kangaroo transaction*, is an extension to global transactions (GTs). Figure 1 shows a global transaction, which consists of subtransactions called local transactions (LTs). Each local transaction is assumed to be issued to a DMBS.

A kangaroo transaction can be composed of both GTs and LTs. The mixture of GTs and LTs are grouped under a transaction type called Joey transactions (JTs) based on the DAA on which they have initiated. Figure 2 shows an example kangaroo transaction.

Each JT represents the unit of execution at one base station. When a mobile host makes a transaction request to

Figure 1.

the DAA on its associated base station, a KT is formed. In addition to that, a JT is formed for managing subtransactions that originate from the mobile host when the KT is under the control of the first DAA. When a mobile host hops from one cell to another, the control of its KTs changes to the new DAA on the new base station. The new DAA creates a new JT for handling the future subtransactions the mobile host might request to this DAA. The old JT is committed independently from the new one. Note that this breaks atomicity. To enable a KT to be completely undone, previously committed transactions should be compensated.

Kangaroo transactions have two different modes of execution. The first mode is called *compensating mode* where a JT fails and all KT is undone. However, this mode of operation requires compensating transactions for undoing operations of the previous JTs, since they are independently committed building compensating transactions requiring input from the user. As a result this mode is rarely used. Note that this mode tries to preserve atomicity of the KT, which breaks the durability of the subtransactions. The second mode, which is the default mode, is called the *split mode*. In this mode of operation, when a JT fails, no new JTs are created, but the previously committed Ms are also not undone. This mode breaks the atomicity. None of the modes ensures serializability.

Clustered Model

In Pitoura and Bhargava (1995), the sites are grouped in clusters if they are connected by strong network links or they are pre-grouped in clusters. In a cluster, full consistency is always enforced, however over the clusters a bounded inconsistency is permitted. A site can be a member of a cluster or leave one dynamically based on the network conditions, for example, a mobile host forms a cluster itself when it is disconnected.

Mobile transactions are grouped into two types: strict and weak transactions. Weak transactions access data in the same cluster, and they have two commit points: cluster and global. Global commit can only be made after clusters merge. Strict transaction can only access data that is ac-

Figure 2.

cessed by a strict transaction or globally committed weak transaction. They are not allowed to access inconsistent data. Applications updating private data—mostly updated by the mobile host on itself—can use weak transactions during disconnections. Applications accessing global data can use weak transactions also if they are tolerant of inconsistent data to some level.

A Pre-Serialization Transaction Management Model

This model (Dircke & Gruenwald, 2000) also assumes a fixed and attached mobile network like the kangaroo model. MUs connect to MSSs. MUs access the mobile multi-database system (MMDBS) via an interface called global transaction manager (GTM). GTM is responsible for providing consistent and reliable units of computing. GTM is a group of global transaction coordinators (GTCs) and site transaction managers (STMs). A GTC runs on every MSS. There exists an STM on each local database. GTC handles disconnections and logging, and delivers the transactions and transaction compensators to the STMs. The STM returns the commit or abort results to the GTC once the transaction submitted to it is completed. In case of a global abort, the compensators on STMs are used to roll-back the transactions. GTC tries to forward the result to the MU or saves it if the MU is disconnected. GTC also tries to conclude if an MU is disconnected for a short time or failed for a prolonged period. Transactions of MUs that are failed are aborted as they become obstacles to other transactions.

A transaction is a group of compensatable, open-nested, vital and non-vital subtransactions. All subtransactions can commit independently. After all the vital subtransactions are committed, a transaction is checked for atomicity and isolation (A/I). After this point if that transaction is not aborted, it can submit only non-vital subtransactions. If any vital subtransaction aborts, then the transaction is aborted.

An algorithm called partial global serialization graph (PGSG) algorithm is used to check the A/I constraints. Each STM maintains a local serialization graph for vital transactions. These graphs are forwarded to GTCs upon request. After merging these graphs if there is no cycle then the transaction is toggled (marked checked), else it is aborted and all subtransactions are compensated.

A toggled transaction is guaranteed to commit if its mobile station is alive or only disconnected for a small amount of time. If a catastrophic failure has occurred, then a toggled transaction can be aborted if it obstructs other transactions.

This model allows subtransactions to commit independently, thus allowing them to release resources as they are not needed. Also a suspended state where transactions can be aborted is introduced. In case of a catastrophic failure, an MU is assumed to be in the suspended state. However,

determining if an MU has failed should be done carefully, so not to abort transactions of a disconnected host.

Deno

In Cetintemel and Kelender (2002), Deno, a replicated object storage system designed for use in mobile and weakly connected environments, is discussed. Deno is designed to support weak connections and limitations of mobile hosts, such as limited processing power and limited coverage area. Thus, it is a lightweight, peer-to-peer, fully decentralized, and asynchronous system.

An MU does not need to know the other hosts, but it needs to be in contact with at least one other node. Pair-wise anti-entropy sessions are used to spread information—votes in this case; update transactions are always voted to commit after they are committed locally on a node. This scheme works as follows: if two nodes x and y can communicate with each other, x can ask y if it knows any globally committed transactions it does not know, if so it copies this information. If y does not know anything, it just sends commit candidates it voted for to x and casts its own vote. Any voter keeps track of a number of votes for an object k and the number of unknown votes. Since currencies (weights) are distributed such that the total is 1.0, any node can keep track of unknown votes. If on any MU the votes for k are more than the votes for j and unknown, then it can commit k . This method ensures that all updates are committed in the same order globally.

In the case of planned disconnections (e.g., sleep mode), a node can appoint a proxy for itself and transfers its currency to that proxy. After returning to the network, the formerly disconnected node can claim its currency back.

In case of an unplanned disconnection, a proxy for the disconnected node is selected using the voting scheme described above. If the proxy election is globally committed, the currency (weight) of the disconnected node is transferred to the elected proxy. In the case of network partitioning, only proxies for the partition that has the smaller total currency can be selected because the proxy election is done using the voting scheme described above. As in the planned case, any re-connected MU can claim its currency.

Weight assignment is crucial to designing a good working scheme; basically, assigning more weights to strongly connected hosts (e.g., stable and more powerful hosts) is a good strategy. Currency distribution is discussed in detail in Cetintemel and Kelender (2002).

Pro-Motion Model

The pro-motion model (Walborn & Chrysanthis, 1996) is designed to support disconnected transaction processing. The motivation is that disconnected MUs can execute transactions if they have the data and methods required.

The fundamental building block is the compact, which is the basic unit of data replication for caching and hoarding. A compact is not only a piece of data, but it is an object that includes restrictions (allowable operations), obligations (such as an expiration time), and methods. In other words compact is a mini database that is moved to the local hosts upon request. A database server delegates an MU as the controller of a compact for local transaction processing. The MU should agree on all obligations and restrictions that the database server sets by the database.

Pro-motion uses open-nested split transactions. When an MU is connected to the network, it identifies a group of compacts that are updated by locally committed subtransactions. Those transactions are split from the uncommitted ones and sent to the owner of the compact. Those transactions are then committed on the database, making the updates visible to all other transactions.

An MU first caches the compacts it needs, then disconnects and processes the transactions. When reconnected it resynchronizes with the fixed database. Transactions can be of two types—local and traditional. Local transaction results are made visible when they commit to the other transactions on the same MU. A transaction can also be traditional, which means its results are invisible until resynchronization.

To allow the resources to be released in a timely manner, each compact is assigned a deadline. An MU can request an extension if the deadline has passed. If the compact is free, then a new deadline is negotiated; if not, this compact is marked invalid and all transactions accessed are aborted. Also the other compacts written by these transactions are marked unavailable, and transactions read from unavailable compacts are aborted.

The valid compacts are resynchronized with the databases. The operations made on the compact are sent to the database servers. These operations are executed as a single transaction. If this transaction can complete, then a commit message is returned to the MU, else the MU receives an abort message and executes compensating procedures for the committed local transactions' owners.

A 10-level scale of correctness is defined in pro-motion from serial to no-guarantee. Each method in a compact is assigned a level. Each transaction is also assigned a minimal level for READ and WRITE operations, and it can only perform operations at that level and READ operations on a higher level than WRITE operations.

TCOT Protocol

Kumar, Prabhu, Dunham, and Seydim (2002) present a timeout-based commitment protocol, TCOT. Like Deno, it is designed for weakly connected, less powerful MUs. TCOT tries to minimize the communication, since bandwidth is scarce and is non-blocking since MUs can disconnect un-

predictably. It assumes that MU has a cache and transaction processing power.

A coordinator (CO) is responsible for a transaction submitted by an MU. COs are either base stations (BSs) or a node on the fixed network. The MU extracts the subtransaction t_{rj} ; it will run from transaction $T_i = \{t_{rj} | l \leq n \leq n_j\}$ and sends $T_i - t_{rj}$ to the CO. MU sends extra information such as how long it will take to process the subtransaction and to ship the updates to the CO. The CO distributes the subtransaction to the fixed nodes on the network and starts its timer according to the values it received from the MU.

Any node executing a subtransaction can request a time extension. But if the CO does not receive a message from the MU or the other participating nodes, then it aborts the transaction and sends an abort message to all of the nodes. Else, if it receives commit messages from all nodes and updates from MU, it does not send any further messages.

Since some nodes commit without a global commit, compensating transactions are necessary to undo the globally aborted but locally committed subtransactions.

Choosing or calculating timeout values is important through this scheme; extension messages are minimized and the transaction restart MUs should be able to choose values for initial timeout values based on the network conditions. Moreover they can request extensions from those incremented with each request. The CO should be able to reject an extension request if the system throughput falls under-desired value.

MANET Model

A mobile ad-hoc network (MANET) has restrictions, which make models like TCOT and kangaroo transactions infeasible to use. MANETs lack nodes which are on fixed networks and BSs which can act as CO or DAA. Moreover, since all nodes route traffic, if they fail the network starts to weaken, partitions can occur, and usable bandwidth between the nodes starts to drop.

Gruenwald and Banik (2001) propose a model to tackle these problems. It is assumed that there are two types of nodes, large mobile hosts (LMHs) and small mobile hosts (SMHs). LMHs have more processing power, storage capacity, and power source than SMHs. An SMH sends its transaction to an LMH depending on the transaction type. If the transaction is a firm transaction, it should be finished before its deadline or it has no value. If the transaction is soft, then it has two deadlines. The earlier deadline can be violated, but the value of the transaction starts to decrease to zero towards its second deadline.

A fixed transaction is always processed by the nearest LMH, whereas a soft transaction is processed by the LMH with the highest remaining energy level. LMH distributes the subtransactions to other LMHs upon submission. The

subtransactions are also grouped into two sets: *vitals* and *non-vitals*. After all vital subtransactions finish, the transaction is verified against atomicity and isolation using PGSG (Dircke & Gruenwald, 2000), as described earlier. If the transaction does not violate these conditions, it would be marked as ready and toggled to commit, and it starts to wait for the non-vital subtransactions.

A toggled transaction is guaranteed to commit unless it blocks another global transaction while it is in the suspended state. A transaction is in suspended state if its MU disconnects.

The LMH tries to send the result to the originating the SMH, but if it fails while sending the result of a firm transaction, it aborts the transaction. However, if it fails while trying to send a soft transaction, it retries until the second deadline is reached.

While a transaction is executing, the SMH can be in doze mode or sleep mode to conserve energy. If it is waiting for a result of fixed transaction, it should not go into the sleep mode for a long time, otherwise the transaction would be aborted. If it is waiting for a soft transaction, it can sleep until the end of the second deadline, saving energy.

Planned Disconnection Modes

Planned disconnection modes (Datta et al., 1999; Demers et al., 1994) involve informing the distributed system of the intention to disconnect and may include the appointing of a proxy. The purpose of a planned disconnection procedure is to enable the remaining connected sites to continue processing with minimal disruption. There are a number of different ways that a disconnection can affect the database. In this section, we explore the possible kinds of planned disconnection and provide appropriate terminology.

In *basic sign-off* mode (Datta et al., 1999), an MH decides to disconnect and informs the system, consisting of the currently connected sites, of its intention. The database of the disconnected MH becomes read-only while the access capabilities of the remaining connected sites are unaffected.

In *check-out* mode (Demers et al., 1994), the MH wants to disconnect and be able to update a set of data items X . There are three variations to this mode that determine what type of access to non-checked-out items is allowed.

The first variation is *DB partition*. In DB partition mode, the database is partitioned into X and $DB-X$. The disconnected site has complete and unlimited access to X and nothing else, while the remaining system has complete access to $DB-X$ and nothing else. The second variation is *check-out with mobile read*. This mode allows the disconnected site to have read access to all database items in addition to the read/write access to the checked-out items X . The remaining connected sites in the system have complete (read/write) access to $DB-X$ and no access to X .

The third variation is *check-out with system read*. This mode allows the connected sites in the system to have read access to all database items in addition to the read/write access to the non-checked-out items $DB-X$. In check-out mode, when the MH checks out an object, either the MH or the remaining connected sites are prevented from accessing to read some of the objects in the database. Although this is necessary to preserve serializability, many database systems operate on lesser degrees of isolation (Chrysanthis et al., 1994). Therefore, we define a *relaxed check-out* mode in which the remaining sites can read the items that other sites have checked out, while disconnected sites can read items they have not checked out.

COMPARISON OF MODELS

Kangaroo, pre-serialization, TCOT, and pro-motion models are designed for multi-tiered networks. It is assumed that there is a fixed and reliable wired network that can support mobile hosts. Moreover, all local databases are assumed to be located in the fixed network, which makes replication management and deadlock detection algorithms easier to implement.

These models mentioned above are all making use of a similar notion called DAAs. DAAs execute the transaction for mobile units, and since they reside on the fixed network, they are never disconnected.

Pro-motion is different from the other terms in that mobile units can execute transactions by themselves, which is an advantage if they are working on small units of data and they need user interaction. In other systems user interaction is not considered. If a transaction needs user input, it should wait for the originating mobile node to be disconnected. A drawback of pro-motion is that it assumes that wireless bandwidth is not a scarce resource, since it moves data back and forth.

Kangaroo is the only modal that addresses the mobility issue. Although in the other models mobility can be handled similarly to kangaroo, it is not explicitly addressed.

In the models mentioned the problem of failed hosts is handled differently. TCOT uses time-outs to abort transactions that can hold the resources for a long time. In pre-serialization, transaction of unresponsive nodes are not aborted immediately, rather they are aborted as new transactions need the resources held by those suspended. In pro-motion the data sent to mobile hosts are attached an expiration time so it is guaranteed that they will be released without blocking the other transactions. While using time-outs can be a problem because of the unpredictable transaction durations and messages exchanged for extension, it would be easier to predict if a node is dead for a long time or not.

None of these models tries to minimize the power used by mobile nodes. Moreover, in pro-motion mobile nodes

execute transactions and exchange large amounts of data compared to the other ones. The other models try to minimize the messages passed on the wireless network, which in turn means mobile nodes will use less messages and power.

Models like Deno, clustered, and MANET are different from the models mentioned above in that they do not assume that there is a fixed network.

Deno is the most interesting model among all the models. It does not make any assumptions about the network topology, node capacities, and connection characteristics. It is a fully distributed model and it can handle network partitions seamlessly. However, it does not take advantage of the more powerful nodes if there are any in the network.

The MANET model assumes that there are more powerful nodes in the network. This is not an unreasonable assumption for the mobile networks. MANET can be used to take advantage of the wired network if there is any. It also tries to distribute the energy usage homogeneously, which is unique for all the models. Since this model assumes more powerful and always-connected nodes, disconnections can be handled similarly to the models mentioned above.

The clustered model is similar to Deno for that: it does not make assumptions about network topology. It also defines two types of transactions: weak and strong. Weak transaction can proceed when the network is partitioned.

The planned disconnected model supports transaction management in a disconnection mobile database, and increases flexibility and allows the distributed database to take advantage of mobility and use new ways.

The planned disconnected protocol produces executions that are one-copy serializable. Briefly, it can be argued that, since all of the transactions of the disconnected site are read-only, the values of the data that are read are those of a snapshot taken at the time of disconnection. All of the read-only transactions of the disconnected site can be serialized at the time of disconnection.

The check-out mode in a planned disconnected model with system reads produces executions that are one-copy serializable. The locked data items are modified by the transactions at the disconnected site, and these transactions are serialized with respect to each other because of local two-phase locking. They are serialized with respect to the transactions of the rest of the system at the point in time of reconnection (rather than the point of disconnection, as for check-out with mobile read).

SUMMARY AND CONCLUSION

The aim of this article was to present a comparison between a few of the transaction management models in distributed mobile databases. The study suggests that a few improvements still need to be accomplished in this context. Limitations such as low and inconsistent connections, low storage

space, processing speed, and the fact that the computing is distributed made mobile databases subtle and prone to more difficulties.

The ACID model suggests that, in some situations, a client requests a sequence of separate requests to a server to be atomic, provided that they are free from interference by operations being performed on behalf of other concurrent clients; and either all of the operations must be completed successfully or have no effect at all in case of server crash.

Many of the transaction management models start from these concepts that ACID suggests. They normally use relaxing ACID as an architectural model. The kangaroo model, however, suggests that a new mobile transaction definition is needed, specific to the mobile computing proposed.

Each of the transaction management models makes its own assumptions about the infrastructure needed to support the respective model. For example the pre-serialization transaction management model and kangaroo model both give a very general architecture by which mobile computing can be performed in a heterogeneous multi-database environment.

The constantly decreasing price of mobile devices is leading to a revolution in the field of mobile computing. The set of enhanced services currently provided to the owners of PDAs is expected to reach the users of the next generation of mobile phones and other mobile devices. A set of very powerful applications is expected to support this revolution, ranging from simply text transfer up to even multimedia transfer.

Université de Technologie de Belfort-Montbéliard, France

INTRODUCTION

The recent evolution of network connectivity from wired connection to wireless to mobile access together with their crossing has engendered their widespread use with new network-computing challenges. More precisely, network infrastructures are not only continuously growing, but their usage is also changing and they are now considered to be the foundation of other new technologies. A related research area concerns ubiquitous and pervasive computing systems and their applications. The design and development of ubiquitous and pervasive applications require new operational models that will permit an efficient use of resources and services, and a reduction of the need for the administration effort typical in client-server networks (Gaber, 2000, 2006). More precisely, in ubiquitous and pervasive computing, to be able to develop and implement applications, new ways and techniques for resource and service discovery and composition need to be developed. Service discovery is the process of locating which services are available to take part in a service composition. The service composition process so far concentrates on combining different available existing services as a result of the service discovery process. Most research to date in service discovery and composition is based on the traditional client/server interaction paradigm (CSP). This paradigm is impracticable in ubiquitous and pervasive environments and does not meet their related needs and requirements. Gaber (2000, 2006) has proposed two alternative paradigms to the traditional client/server interaction paradigm to design and implement ubiquitous and pervasive computing applications: the adaptive services/client paradigm (SCP) and the spontaneous service emergence paradigm (SEP).

Bio-inspired approaches are adequate to carry out these new paradigms for designing and implementing ubiquitous and pervasive applications (Gaber, 2000). Indeed, the adaptive servers/client paradigm, considered as the opposite of CSP, could be implemented via a self-adaptive and reactive middleware inspired by a biological system like the natural immune system. The service emergence paradigm could also be implemented by a natural system that involves self-organizing and emergence behaviors (Gaber, 2000).

Recently, agent-based approaches, with self-adapting and self-organizing capabilities, have been proposed in Bakhouya

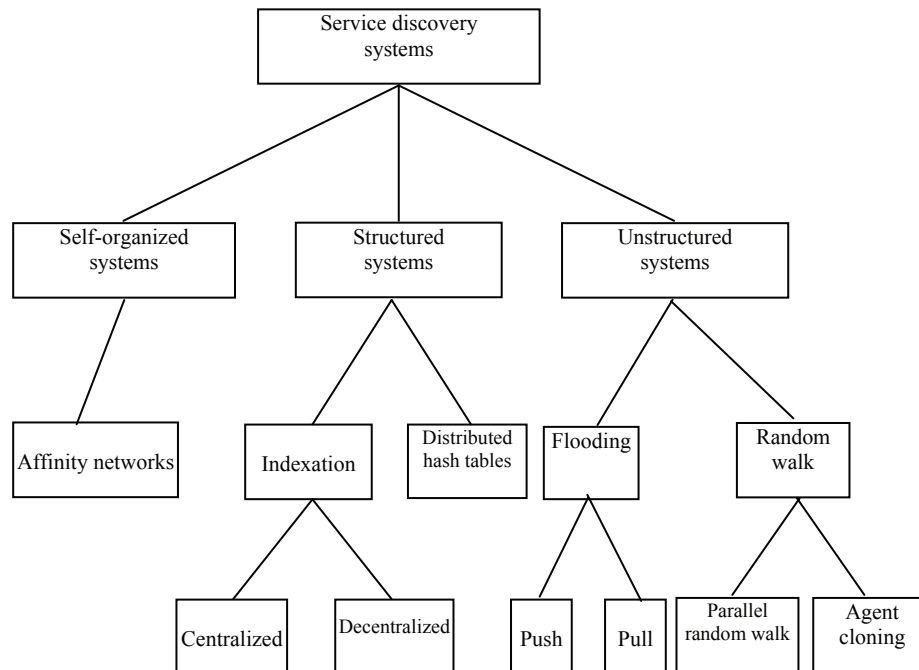

(2005) and Bakhouya and Gaber (2001, 2006a, 2006b) to implement SCP and SEP respectively. More precisely, these approaches, inspired by the human immune system, provide scalable and adaptive service discovery and composition systems for ubiquitous and pervasive environments.

UBIQUITOUS COMPUTING

In ubiquitous computing (UC), the objective is to provide users the ability to access services and resources all the time and irrespective to their locations (Weiser, 1993). Service discovery and access systems can be classified into three categories as depicted in Figure 1: structured systems, unstructured systems, and self-organized systems. Structured systems can be classified also in indexation-based architectures and hashing-based architectures. In indexation-based architectures, there are two categories: centralized and decentralized systems. In centralized indexation-based systems, typical resource discovery architectures (Bettstetter & Renner, 2000), such as Jini (2001), consist of three entities: service providers that create and publish services, a broker that maintains a repository of published services to support their discovery, and services requesters that search the service broker's repository. Centralized approaches scale poorly and have a single point of failure. To overcome the scalability problem, decentralized approaches, such as m-SLP (Zhao, Schulzrinne, & Guttman, 2000) or Secure Service Discovery Service (Xu, Nahrstedt, & Wichadakul, 2001), traditionally have a hierarchical architecture consisting of multiple repositories that synchronize periodically. In hashing-based architectures (Wang & Li, 2003), proposed primarily to file-sharing, distributed hash tables (DHTs) are used to assign files to specific nodes. This technique allows the implementation of direct search algorithm to efficiently locate files. However, hashing-based architectures require overlay networks between nodes that are generally hard to maintain.

In unstructured systems, the most typical localization mechanisms are flooding and random walk. There are two main flooding techniques: the push and the pull technique. In the first technique, the server advertises periodically its services across the network. The clients receive the service

Figure 1. Classification of service discovery systems according to their architectures and their operating modes

advertisement and cache the information. This information must have a time period associated with it, and must be flushed out from the cache when this time period expires. Hence, the user has a complete knowledge of the available services, and no request resolution process is required. In the pull technique, the client has no knowledge of services present in the network. In this case, a service request is broadcast to all neighbors within a certain radius with a TTL (time to live) tag (Wang & Li, 2003). A random walk is a stochastic process that evolves in the following manner (Gaber & Bakhouya, 2006b). A client sends its query message (i.e., a walker) to a randomly chosen neighbor. At each step, the query message is forwarded to a neighbor of its current location, and the process continues this way by taking random steps that are independent of all the previous ones until meeting the required service. Consequently, the random walk technique avoids message duplication inherent to the flooding mechanism (Wang & Li, 2003). More precisely, by using one walker, it cuts down the message overhead significantly. Nevertheless, the delay for a successful request resolution could be high. To decrease this delay, a requester could send k parallel query messages, and each query message takes its own random walk. However, it is difficult to determine a priori a suitable value for k . In other words, if this number k is big enough, the message traffic could increase considerably. An alternative approach to avoid this problem uses both random walks together with an adaptive cloning agent-based technique for service discovery (Gaber & Bakhouya, 2006b).

It should be noted that the fundamental aspect of these systems is the process of service discovery based on the traditional client to server paradigm. More precisely, it is the user who should initiate a request, should know a priori that the required service exists, and should be able to provide the location of a server holding that service. This is why the use of repositories is essential in these discovery systems. However, ubiquitous environments have the potential ability to integrate a continuously increasing number of services and resources that can be nomadic mobiles and partially connected. A user can be mobile or partially connected, and its ability to use and access services will no longer be limited to those that she/he currently has at hand or those statically located on a set of hosts known a priori. Therefore, the ability to maintain, allocate, and access a variety of continuously increasing numbers of heterogeneous resources and services distributed over a mixed network (i.e., wired, wireless, and mobile network) is difficult to achieve with the traditional client/server approaches (Gaber, 2000, 2006). More precisely, these architectures cannot meet the requirements of scalability and adaptability simultaneously. The way in which they have typically been constructed is often very inflexible due to the risk of bottlenecks, the difficulty of repositories updating, or the network loading problem. This is particularly true for the cases where some services could be disconnected from the network and new ones may join it at any time.

An appropriate model was proposed originally by Gaber in Gaber (2000) as an alternative to the traditional client/

server paradigm. This model can be viewed as opposed to the client/server model and is denoted *adaptive servers/client paradigm*. In this model, it is the service that comes to the user. In other words, in this paradigm, a decentralized and self-organizing middleware should be able to provide services to users according to their availability and the network status. As pointed out in Gaber (2000), such a middleware can be inspired from biological systems like the natural immune system. The immune system has a set of organizing principles such as scalability, adaptability, and availability that are useful for developing a distributed networking model in a highly dynamic and instable setting. In Gaber (2000, 2006), the immune-based approach operates as follows: unlike the classical client/server approach, each user request is considered as an attack launched against the global network. The immune networking middleware reacts like an immune system against pathogens that have entered the body. It detects the infection (i.e., user request) and delivers a response to eliminate it (i.e., satisfy the user request).

Recently, an immune approach using mobile agents with cloning capabilities was proposed in Bakhouya (2005) and Bakhouya and Gaber (2006a, 2006b) to implement SCP. A mobile agent is a software program that may move from location to location to meet other agents or to access resources provided at each location. Using a mobile agent that can clone itself in order to increase system robustness and performance is an attractive idea. The clone operation creates multiple instances of an agent that runs on different machines. For example, an initial mobile agent starts on the requesting machine and, after a local step, creates replications (i.e., clones) that initiate parallel walks to further machines. This would allow agents to cover a much wider area of machine space in a reasonable amount of time (Gaber & Bakhouya, 2006b). However, it should be noted that increasing agent population with cloning operation will increase resource demands in the network, which would indirectly affect network performance. Since mobile agents operate in a dynamic and distributed environment, it is difficult, even impossible, to estimate a priori an appropriate number of agents in the network (Bakhouya, 2005). Also, changing the population dynamically in response to its environment is a complex issue in the absence of a central controller. A distributed approach for the regulation of mobile agent population and inspired by the immune system is proposed in Bakhouya (2005) and Bakhouya and Gaber (2002, 2006b).

The immune system consists primarily of lymphocytes that circulate through the body in the blood and lymph system. There are two categories of lymphocytes, the B-cells and T-cells. The B-cells are developed in the bone marrow and the T-cells are developed in the thymus. The principle function of T-cells is to potentiate the immune response by the secretion of specialized factors that activate other cells to fight off infection. The major function of the B-cell is the production of antibodies in response to foreign antigens.

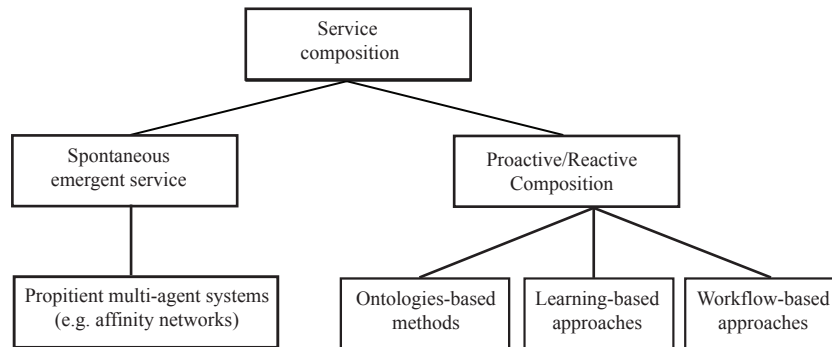

According to Jerne, B-cells are interconnected by affinity relationship against foreign antigens and form idiotypic networks (Jerne, 1974).

The mapping between the immune system entities and the middleware agents is done in the following manner. T-cells represent servers while B-cells represent services and resources. Antigens correspond to client requests while antibodies correspond to delivered responses. Servers are organized into communities by the creation of affinity relationships in order to represent services in the network. The establishment of relationship affinities between servers allows the solving, by collaboration, of user requests. A reinforcement learning mechanism is used to adjust and reinforce dynamical relationship affinity values according to delivered responses (Bakhouya, 2005). This reinforcement mechanism permits coping with dynamic changes in the network, the services availability, and the user requests. Similar to the natural immune system, new communities may be created or modified according to a dynamically changing environment. In other words, servers may acquire new or drop current servers through establishing or deleting the affinity relationship.

PERVASIVE COMPUTING

Pervasive computing (PC), often considered the same as ubiquitous computing in the literature, is a related concept that can be distinguished from ubiquitous computing in terms of environment conditions. We can consider that the aim in UC is to provide any mobile device access to available services in an existing network all the time and everywhere, while the main objective in PC is to provide spontaneous services created on the fly by mobiles that interact by ad hoc connections (Gaber, 2000, 2006). Service composition systems can be classified into three categories as depicted in Figure 2: proactive composition systems, reactive composition systems, and spontaneous emergent service systems. The first category refers to off-line composition of available services to form new ones. Services that may be used for proactive service composition can be considered stable, widely and always available (Chakraborty & Joshi, 2001). The second category refers to the process of creating a composite service on demand. In other words, a composite service is created only when a user requests the execution of that service. Most known reactive and proactive service composition systems, such as the eFlow system (Casati, Ilnicki, Jin, Krishnamoorthy, & Shan, 2000), are based on a centralized broker which manages the service composition process (Chakraborty & Joshi, 2001). The drawback is that if a huge number of users attempt to access a variety and increasing number of services distributed over the network, the broker quickly becomes a bottleneck. It should be noted also that these systems are based on the client/server paradigm; it is the user who should

Figure 2. Classification of service composition systems according to their architectures and their operating modes

initiate a request, and moreover, services and future demands are known in advance.

Gaber (2000, 2006) has proposed a second alternative paradigm to the client/server one for service composition that suits pervasive environments. This paradigm involves the concept of spontaneous emergence and is called the *spontaneous service emergence paradigm*. This paradigm can also be carried out by an inspired natural immune middleware that allows the emergence of ad hoc services on the fly according to dynamically changing context environments such as computing context and user context (Gaber, 2000). More precisely, in this model, ad hoc or composite services are represented by an organization or group of autonomous agents. Agents correspond to the immune system B-cells. Agents establish relationships based on affinities to form groups or communities of agents in order to provide composite services. A community of agents corresponds to the idiotypic network in the human immune system (Gaber, 2000).

More generally, agents together with their affinity relationships as a whole form a *propitient multi-agent system* (Bakhouya & Gaber, 2006c). A propitient system is a system with the ability to self-organize in order to adapt towards the most appropriate agent organization structures according to unpredictable changes in the environment. This emergent behavior is delivered as a result of agent-to-agent and agent-to-environment interactions that adapt until the system hits a most suitable affinity network. Therefore, a propitient multi-agent system implements the SEP.

A self-organizing approach assumes that individual agents are autonomous agents, while multi-agent organizations are emerged structures that are not represented explicitly, but they exist through the affinity relationships between agents. In other words, agents cooperate equally rather than being assigned subordinate and supervisory relationships. It is worth noting that this multi-organization based on dynamic affinities supported by relationships provides a highly decentralized system while remaining adaptive in dynamic and open environments. More precisely, this decentralized organizational structure offers a high degree of resilience against an agent

leaving the organization. For example, when an agent leaves an organization, all the peer affinity relationships with other agents are removed without additional messages since it does not rely on any overlay control structure. An affinity-driven clustering learning mechanism could be used to adjust the affinity relationships between nodes to cope with the user context and provoke or produce an emergent service (Gaber, 2000; Gaber & Bakhouya, 2006a). More precisely, an ad hoc emergent service is created spontaneously on the fly for a user or between a group of users in an unpredictable manner (i.e., without a priori intention).

CONCLUSION

The design and development of ubiquitous and pervasive applications require alternative operational models to the traditional client/server paradigm. The adaptive servers/client paradigm and spontaneous service emergence paradigm are more adequate to ubiquitous and pervasive computing respectively. Service discovery and composition systems based on these three paradigms and proposed in the literature are presented with emphasis on self-organizing and self-adapting approaches inspired by the immune system to implement SCP and SEP. Self-adaptation and self-organization are crucial issues in systems that operate in an open and dynamic environment.

KEY TERMS

Adaptive Services/Client Interaction Paradigm (SCP): Adaptive Services to Client interaction paradigm is the opposed model to the traditional Client/Server interaction paradigm in which it is the most appropriate service that comes to the user in response to a request. This most suitable service can be computed by the network itself via an intelligent middleware.

Mobile Agents: A mobile agent is a software entity which may move with its own code and execution context from node to node to meet other agents or to access resources provided at each location.

Pervasive Computing: The main objective of pervasive computing is to provide spontaneous emergent services created on the fly by mobiles that interact by ad hoc connections

Propitient System: An agent-based system with the ability to self-organize in order to adapt towards the most appropriate organization that copes with the unpredictable changes in the environment.

Reinforcement Learning: A mechanism used to adjust and reinforce dynamically relationship affinity values according to delivered responses and in order to cope with dynamic changes in the network, the service's availability and user requests.

Service Composition: Service composition process concentrates on combining different available and selected

services via the service discovery process to deliver new ones.

Service Discovery: Service discovery is the process of locating which services are available to take place in a service composition.

Spontaneous Service Emergence Paradigm (SEP): Allows the emergence of ad hoc services on the fly for a user or group of users without a priori planning or intention

Traditional Client/Server Interaction Paradigm (CSP): The traditional Client to Server paradigm is based on the following fundamental aspect: it is the user who should initiate a request, should know a priori that the required service exists and should be able to provide the location of a server holding that service. It should be noted that push, pull and P2P systems are still based on the Client/Server interaction paradigm.

Ubiquitous Computing: the main objective of ubiquitous computing is to provide users with the ability to access services and resources all the time and irrespective to their location.

The “Umbrella” Distributed Hash Table Protocol for Content Distribution

Athanasios-Dimitrios Sotiriou

National Technical University of Athens, Greece

INTRODUCTION

During the past few decades, the Internet has blossomed due to the immense growth of the telecommunication backbone, making it one of the key players in a wide area of fields. Even traditional players such as television or radio are now being challenged by the new entertainment media, the home computer. The increase of share communities such as Weblogs (Drezner & Farrell, 2004) or MySpace (www.myspace.com) and content-sharing software proves that people want to share their content with their global Web community. The need for such content-sharing software is therefore undisputable. Such attempts have been introduced in many ways during the past, with perhaps the most common example being Napster (www.napster.com) and Gnutella (<http://gnutella.wego.com>).

The technical and ethical issues of these systems proved to be their weak point. Systems that have no central point of control and distribute functions among all users seem better fit for sharing and distributing content. A solution has been proposed in the form of *distributed hash-tables (DHTs)*. This article proposes an alternative architecture for content distribution based on a new DHT routing scheme. The proposed architecture is well structured and self-organized in such a way as to be fault-tolerant and highly efficient. It provides users with content distribution and discovery capabilities on top of an overlay network. The novelty of our proposed architecture lies in its routing table which is maintained by each node and is of constant size, as opposed to other algorithms that are proportional to the network's size (usually $O(\log N)$). All operations in our architecture are of $O(\log_b N)$ steps (entry, publishing, and lookups) and degrade gracefully as up-to-date information of the routing table decreases due to numerous node failures.

BACKGROUND

The firsts to introduce routing algorithms that could be applied to DHT systems were Plaxton, Rajaraman, and Richa (1997). The algorithm was not developed for P2P systems,

and thus every node had a neighborhood of $O(\log N)$ and inquires resulted in $O(\log N)$ steps. It was based on the ground rule of comparing one byte at a time until all bytes of the identifier (or best compromise) were met. Our scheme meets the logarithmic growth of inquiries introduced by Plaxton et al. (1997), even though nodes are not placed within constant distance from each other.

A variation of the Plaxton algorithm was developed by Tapestry (Zhao et al., 2004), properly adjusted for P2P systems (where overall state is not available). The algorithm once again tackles one digit at a time, and through a routing table of $\beta \cdot \log_b N$ neighbors routes to the appropriate node, resulting in a search of $\log_b N$ maximum steps.

Pastry (Rowstron, 2001) is similar to Tapestry, but added a leaf set of neighbors that the node first checks before referring to the routing table. Also a different neighbor set is maintained for tolerability issues. Each node maintains a neighborhood of $\log_2 bN$ rows with $(2^b - 1)$ elements in each row and requires a maximum of $O(\log_2 bN)$ steps for enquires. Proper routing is maintained as long as $(L/2)$ nodes are available in the neighborhood of each node. Once again, the variable size of each node's table (which must be maintained up-to-date) limits the algorithm's scalability.

In Chord (Stoica, Karger, Kaashoek, & Balakrishnan, 2001) a different approach was applied, placing nodes in a circular space and maintaining information only for a number of successor and predecessor nodes through a finger table. Routing is established through forwarding queries to the correct successor based on the identifier. Even though the basic Chord mechanism only requires the knowledge of one successor, modifications were needed in order for the system to be applicable to a robust environment, introducing a finger table of $O(\log N)$ size.

Finally, Kademlia (Maymounkov & Mazieres, 2002) bases nodes in a binary-tree through identifiers. Each node of the tree retains information concerning one node from each leaf, other than the one in which it resides. It also differentiates by applying an XOR comparison on identifiers instead of the casual comparison of each bit, adopted by all other algorithms.

SYSTEM ARCHITECTURE

In this section we will give an overview of the Umbrella architecture. The main functions consist of the insertion of nodes, the assignment of keys to corresponding nodes, and the routing mechanisms for three principle operations, namely the insertion of nodes, publication of content, and lookup of keys. Our architecture is based on an overlay network, and thus we assume that node connectivity is both symmetric and transitive.

Hashing Function

The proposed architecture is based on the creation of an overlay network, where all inserting nodes are identified by a unique code, asserted by applying the SHA-1 (NIST, 1995) hash-function on the combination of IP and computer name, which returns a 160-bit identifier. This hash-function has been proven to distribute keys uniformly in the 160-bit space and thus provides the desired load balancing for both the user space and the content space, as the same function is applied to each content destined for distribution in the system.

Structure Overview

The main objective of the architecture is to insert and retain nodes in a simple and well-structured manner, thus querying and fetching of content is both efficient and fault-tolerant. In addition, each node will need only to retain up-to-date information of a limited, constant number of neighboring nodes, allowing the system to escalate in population of both users and content. Each node is inserted into the system through an existing node, which announces the new entrance. When this procedure has ended successfully, the new node can, having acquired and informed all neighboring nodes, continue to publish all of its content. The publishing procedure is similar to the insertion mechanism, as content is characterized by a number of keys, which after being hashed can be forwarded in the same manner. All keys are published in an existing node whose identifier is the closest match to the key identifier. In a similar fashion, querying is performed by routing the request to the node with the identifier closest to the desired key. If no such node exists, it is assumed that the desired content is not available.

The overlay network is constructed in the form of a loose B-Tree, where each node is placed in a hierarchy tree with a parent node and b child nodes, which in our initial architecture is of the value 16 (in order to classify the 160-bit identifiers to a maximum B-Tree of height ≤ 40). All nodes are placed along the tree structure, without being required to fulfill pre-defined ranges as in a proper B-tree structure, and are responsible for updating their connections with

Figure 1. The Umbrella architecture

neighboring nodes that reside on either the parent, sibling, or child level. Along with obvious connections (parent, child, and sibling level of each node), further links to a limited number of nodes in the near vicinity are kept in record for fault-tolerant operations. Figure 1 illustrates the structure of this loose B-Tree. Routing in the umbrella protocol is simple and constitutes the forwarding of messages to either a parent or child node until the appropriate node is reached. In the rest of the article, with the term-appropriate node we will refer to either the exact or closest match alike.

Key Mapping

Each level n of the structure is capable of withholding b^{n+1} nodes. Each node has a unique parent node, which is always one level higher, and a maximum of b children at a lower level. The Umbrella overlay network is configured with the following simple rule. The relation between a parent node at level n and a child node (which must by default reside on level $n+1$) is defined as such and only such that:

- The $n+1$ first (from left to right) digits of the parent's identifier are equal to the corresponding digits of the child's identifier.
- The $n+2$ digit of the child's identifier determines the child's position in the parent's child list. Thus all children of the same parent share the first $n+1$ digits and all differ in the $n+2$ digit.

The above simple rule is obeyed by all nodes entering the Umbrella overlay network, with only the exception of the first node that actually initiates the network and is considered to be positioned at level -1. As already stated, the SHA-1 hash

Table 1. Fields of the neighborhood table

| Field | Set | Description |
|-----------|-------|---|
| Level | Basic | The level it resides |
| Right | Basic | The non-empty node to the right |
| Left | Basic | The non-empty node to the left |
| Up | Basic | The parent node |
| Right2 | Upper | The node residing to the right of the parent node |
| Left2 | Upper | The node residing to the left of the parent node |
| Up2 | Upper | The parent’s parent node |
| Right3 | Lower | One (random) child of the node to the right |
| Left3 | Lower | One (random) child of the node to the left |
| Umbrella | Basic | All child nodes |
| Umbrella2 | Lower | A (random) child node from each child |

function is used to assign identifiers to both nodes and content, offering a uniform distribution in the 160-bit space along with non-voluntary placement anonymity (Milojicic et al., 2002) of the published content. In order to apply the routing algorithms, we define a comparing function for identifiers as *comp*, which compares two identifiers and calculates their difference as a long integer, with importance given to digits from left to right. The consistent hash function balances key distribution among nodes, as stated in Karger et al. (1997) in the form of the following theorem:

Theorem 1. Given a set of nodes N and keys K , then with high probability each node is responsible for an average of K/N keys, with a maximum of $(1+\alpha)K/N$, whereas α is a parameter with bound of $O(\log N)$.

Routing Table

As in most DHT systems, a routing table is maintained by each node in order to route incoming messages. Each node is responsible for keeping the table up-to-date by issuing messages to all nodes in its table at different intervals. The routing table in our architecture consists of three different sets—a basic, an upper, and a lower set. The basic set stores nodes and information needed for basic routing operations under fault-free conditions. The upper and lower sets store additional indexes to nodes in the upper and lower levels, correspondingly, which are utilized when nodes in the basic set become unreachable. These three sets constitute the node’s neighborhood table and are presented in Table 1.

The above elements are sufficient to maintain proper routing in our architecture even in the case of sudden failure of nodes. The upper set allows routing to nodes of higher level (when the parent node is unreachable) and the lower set to nodes of lower level (when child nodes fail). Each node is responsible to modify or fix its routing table when nodes enter/leave the network or a failure to communicate with another node is detected, respectively. Our architecture’s structure and routing table described so far ensure that a published key can be located by an appropriate query within

logarithmic overlay steps to the total size of the network. This is stated and proved within the following two theorems:

Theorem 2. Given an Umbrella network of N nodes with identifiers of base b acquired by a consistent hash function, the maximum height of the loose B-tree structure is of logarithmic scale.

Proof: Let b denote the base of our identifiers, N the total number of nodes, and k a particular level in the Umbrella structure. Then according to the Umbrella protocol, in each level a maximum of b^k nodes can reside, with $b^0=1$ as stated for the first node that creates the network. Thus, if m denotes the number of levels required for the above population of nodes, we acquire the following relation, in respect to Theorem 1 that provides, with high probability, a uniform distribution of identifiers to our space:

$$N = \sum_{k=0}^m b^k = \frac{b^0 - b^{m+1}}{1 - b} = \frac{1 - b^{m+1}}{1 - b} \Leftrightarrow$$

$$\Leftrightarrow m = \{\log_b [N(b-1) + 1]\} - 1$$

Thus the maximum height m of our structure is of $O(\log_b N)$.

Theorem 3. A successful lookup in an Umbrella network requires, with high probability, $O(\log_b N)$ steps.

Proof: Suppose that a node p that resides at level l_p is seeking a specific key k that resides within our network in another node f at level l_f . If m denotes the number of levels of the current network, N the nodes, and b the base of identifiers, then we could argue that the worst-case scenario would require both nodes to reside at level m and with maximum distance between them (thus node p is an m -depth child of the first child at level 0 and on-forth, and node f is the m -depth child of the b child at level 0 and on-forth). In this case, the lookup must first ascend all the way to the top of our structure (thus m steps) and then descend to the bottom (m steps again). In total, a maximum of $2m$ steps are required. Hence, from Theorem 2, the required maximum steps for a successful lookup is, with high probability, of $O(\log_b N)$ steps.

ALGORITHMS AND IMPROVEMENTS

Main Algorithms

During the creation of the overlay network, the first node to enter creates the new network by placing itself on the top of the system. As new nodes arrive, they are placed according to their identifier, as described in the previous section. A node only needs to contact an existing node in the system

in order to be inserted (special mechanisms for fetching existing nodes by outside contacts are not of the scope of this article, as our architecture can embody any of numerous such techniques already proposed (Francis, 1999)). Only the first node is automatically inserted regardless of its identifier; all subsequent nodes are placed within the system based on the insertion algorithm. The insertion mechanism is quite simple, intentionally, as with all of the system’s mechanisms, and consists of the following steps:

- Contact an already connected node and issue a request for insertion.
- The established node checks if the n+1 first digits of the identifier match its own, where n is the level the node resides.
- If not, the insertion message is forwarded to the node’s parent.
- If yes, the message is forwarded to the child with the n+2 digit common with that of the new node.
- If such a child does not exist, then the new node is placed as a child to the current node and is informed of its new neighbors and via versa.

The publish procedure is similar to insertion and is therefore suppressed. Conversely, the search mechanism is executed as follows:

- The node first checks for the keyword in its list of published keywords.
- If it exists then the search terminates.
- If not, then it checks whether the first n+1 digits are identical to its own identifier.
- If not, the message is forwarded to its parent.
- If yes, then it is forwarded to the child with the corresponding n+2 digit matching.
- If no such child exists, then the search fails.

The pseudo code of the above algorithm is given in Figure 2.

The final mechanism provided by our protocol is that of node departure from the system. When a node issues a departure, the following steps are followed:

- If the node has no children, then all of its keywords are forwarded to its parent and it informs all its neighbors of its departure.
- If it has any child, then it randomly picks one and copies all of its neighborhood and keyword information to it before departing. The chosen child moves up a level and substitutes the departing node.
- If the chosen child has any child, then the previous step is repeated recursively until a node with no children is reached and the first step is then executed ending the algorithm.

```

Enhanced Algorithms

The algorithms presented in the previous section embody the main mechanisms of our architecture and are capable of maintaining the system stable and fully functional under normal conditions, as will be validated by our simulation results in the following article. The system is however liable to node departures, either intentional or due to network disconnections. In the next set of mechanisms, we will concentrate on sudden departures of nodes, which we will call “node failures.” These are due to either voluntary departure without calling the appropriate mechanism, sudden departures due to client errors, or nodes becoming unavailable due to network disconnections. We will treat all of the above cases in the same manner, and through changes in the algorithms already presented, we will allow the system to bypass node failures. Most changes are based on using the upper and lower set of our neighborhood table to bypass nodes that are not responding. The upper set is utilized to forward messages to nodes of a higher level, while the lower set is for nodes on a lower level.

In the first case, when a node is unable to contact its parent node, it attempts to forward requests consequently to:

- the parent’s parent node (field Up2 on the upper set),
- the node to the right of the parent node (field Right2 on the upper set), and
- the node to the left of the parent node (field Left2 on the upper set).

Whichever of the above succeeds first will terminate the mechanism. The only exception to the above algorithm is that of the node on level -1, which triggers a variation since it has no parent or sibling nodes, and attempts are made toward nodes on either the left or the right of the child node.

In the latter case of a child node failure, the corresponding nodes are contacted in the following order:

Table 2. Corresponding forwarding of repair messages in order to reach a parent node

| Failing Node | Action Taken |
|-----------------|------------------------------------|
| Up | Contact Up2 |
| Node2 | Contact Node |
| Left3 or Right3 | Contact Left or Right respectively |
| Left2 or Right2 | Contact Up2 |
| Left or Right | Contact Up |
| Up2 | Contact Up |

- one of the child’s child (field Umbrella2 on the lower set),
- the node on the right of the child (field Umbrella on the basic set),
- the node on the left of the child (field Umbrella on the basic set),
- a child of the node right of the issuing node (field Right3), and
- a child of the node left of the issuing node (field Left3).

Repair Mechanism

In order to address the problem of node failures even further, we have designed a repair mechanism, which is invoked whenever such a failure is detected. The algorithm utilizes the delete algorithm presented in our main mechanisms section in order to repair a failure to a child node. It can be proven that all other failures can be transformed into a child failure through contacting nodes in the neighboring table and forwarding a repair message to higher or lower levels until the parent node of the failing node is reached. More details of the actions involved in order to resolve the appropriate node are given in Table 2.

Once the appropriate node is reached and informed of the child failure, a variation of the delete algorithm is evoked in order to repair the failure by substituting the failed node with one of its children or by deleting it if none is available. Each node is responsible for checking its neighborhood table periodically by issuing ping messages to all node entries and invoking the repair mechanism whenever a failure is detected.

SYSTEM EXTENSIONS

Having presented the core structure and logic behind our routing protocol, we will continue with a number of extensions that improve the system’s performance. The first extension introduces the use of replication schemas, which have been shown to increase the robustness of content distribution systems (Ghodsi, Alima, & Haridi., 2005). In this article we have implemented three additional replication schemas.

Table 3. Singular identifier assignment functions

| Name | Details | Instance |
|------|---|-----------------|
| OI | This is the base fuction | a b c d e f g h |
| II | This function inverses the identifier | h g f e d c b a |
| IP | The identifier’s digits are inversed by pair | b a d c f e h g |
| IPW | All digits are inversed by pair as in the case of IP and the result is inversed as a whole as in II | g h e f c d a b |
| IH | The II function is applied to the first and second half of the indentifier independently | d c b a h g f e |
| SH | The first and second halves are switched without being inversed | e f g h a b c d |
| RR | A random reordering of the identifier’s digits | d a e c g h b f |
| SRR | Same as the case of RR but with different random generator | c f b a h g d e |

Our core routing protocol publishes a keyword in a single node, the one with the closest identifier to that of the keyword. All three replications schemas retain this quality and enhance it by also publishing the keyword to a number of additional nodes, from which one can recall a successful lookup. Our three variations follow:

1. **Local Spread Replication (LSR):** The keyword is also published in all nodes residing in its neighboring table.
2. **Inverse Replication (IR):** This mechanism publishes keywords to the closest match and to the inverse closest match.
3. **Local Spread Inverse Replication (LSIR):** It implements a local spread in both the closest and the inverse closest match.

The second extension implemented allows nodes to participate in a number of virtual networks, with a different identifier in each one. This allows each node to have a different set of neighbors and thus increase its tolerability substantially. In order to achieve this, we have defined a number of singular identifier assignment functions that transform the original identifiers into a new set of identifiers. This new set is then used to allocate nodes and route requests in the virtual networks. We have defined seven different such functions, which are given in Table 3.

CONCLUSION

Through the course of this article, we presented the Umbrella protocol, a novel protocol based on a distributed hash table that supports key publishing and retrieval on top of an overlay network for content distribution. We have analyzed our protocol and its algorithms through theoretical means, and provided a number of algorithms and extensions. Its main novelty lies in its fixed-size routing table sustained by each node, which is able to provide efficient routing even under contrary conditions. The protocol is also highly scalable due to its low traffic load demands.

KEY TERMS

DHT: Distributed hash table.

Hashing: Producing hash values for accessing data or for security. A hash value (or simply hash), also called a message digest, is a number generated from a string of text. The hash is substantially smaller than the text itself, and is generated by a formula in such a way that it is extremely unlikely that some other text will produce the same hash value.

Overlay Network: A network built on top of one or more existing networks. This network adds an additional layer of indirection/virtualization and also changes properties in one or more areas of underlying network.

P2P: Peer-to-peer.

Replication: A duplicate copy of similar data on the same or a different platform.

Routing: The process of moving a packet of data from source to destination. Routing in P2P networks refers to finding a path to the desired node.

SHA-1: Secure hash standard.

Understanding Multi-Layer Mobility

Sasu Tarkoma

Helsinki Institute for Information Technology, Finland

Jouni Korhonen

TeliaSonera Corporation, Finland

INTRODUCTION

Mobility is an important requirement for many application domains, where entities change their physical or logical location. Physical location denotes the real-world location of a device, whereas logical location is not necessarily dependent on the physical environment. Mobility support may be divided into several technical layers and also categories depending on the nature of mobility. In this article, we consider mobility protocols starting from the network layer (layer 3 in the OSI stack) and ending at the application layer (layer 7), and focus on physical mobility.

The most fundamental network-level protocols for supporting mobile hosts are the Mobile-IP protocols standardized by the IETF (Perkins, 2002; Johnson, Perkins, & Arkko, 2004). Another related network-level solution is *network mobility* (NEMO) (Devarapalli et al., 2004), in which complete sub-networks may change location as well as single hosts. Mobility can also be handled on the transport layer. *Transport layer seamless handover* (TraSH) (Fu et al., 2004), *datagram congestion control protocol* (DCCP) (Kohler, 2006), and mSCTP (Xing, Karl, Wolisz, & Müller, 2002) are recent examples of such solutions. Yet another way of managing host mobility is with mobility-aware *virtual private networks* (VPNs) such as MOBIKE-based IPsec VPNs (Kivinen, 2006). Protocols such as wireless CORBA (WCORBA) (OMG, 2004) and the *session initiation protocol* (SIP) (Schulzrinne & Wedlund, 2000) provide more fine-grained mobility than host based, and they do not assume underlying transport- or network-level mobility support.

Middleware support for mobility is required in order to provide location transparency for objects, agents, and other components; support efficient and reliable communication in wireless environments; and buffer messages and other data for disconnected operation. In addition, the middleware may support scalability and availability of resources and services.

Mobility is inherently tied with the way nodes are addressed in a distributed network. In this article, we examine three different ways to address mobile nodes and components: addresses with *location and identity*, *locator/identity split*, and *content-based addressing*. The first addressing model is used by the IP protocol. The second model is an extension of

the first and used, for example, in the *host identity protocol* (HIP) and the *i3 overlay* (Stoica, Adkins, Zhuang, Shenker, & Surana, 2002). The third model has been proposed for expressive communication in ubiquitous environments.

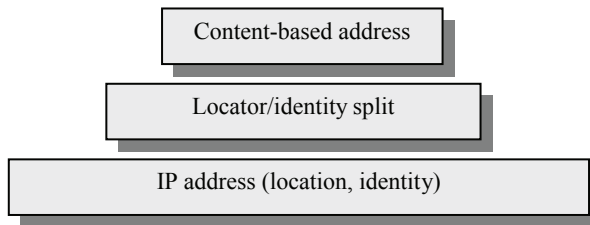

The aim of this article is to examine the addressing models and investigate cross-layer interactions of different mobility protocols. One of the interesting questions is how mobility should be handled and coordinated when there are multiple layers offering support for mobility. We also consider the case of the hop-by-hop routed layer-7 environment, implemented typically using SOAP (W3C, 2003), CORBA, or SIP in the telecommunications sector. These three technologies are the most frequently used, have differing characteristics and product bases, and contain the essence of middleware/application layer communication. SOAP is an abstract and generic messaging framework with extendable header system, allowing rich facilities for hop-by-hop propagation of messages.

ADDRESSING MODELS

The way mobile and stationary nodes are addressed is crucial in how mobility is supported in a distributed system. We define three different addressing models for mobile systems (see Figure 1):

1. **Address with Both Location and Identity:** This form of addressing couples the communicating end-points to specific locations in a network. For example the IP address is used in both identifying a node and routing packets to it. This form of addressing typically uses a mediating stationary node to handle the mobility management and location updates for the mobile nodes.
2. **Address with Locator/Identity Split:** This way of addressing separates the identity of a node and the location of the node. This allows more flexible mobility support since the identity may be used to lookup the physical location of a node. For example the Internet Indirection Architecture (i3) and the HIP are based on this form of addressing.
3. **Content-Based Addressing:** This goes beyond locator/identity split, because it decouples the destination

Figure 1. Three addressing models

from both identity and location. The destination is no longer defined by a single identity, such as the IP address or a cryptographic public key, but rather it is defined by logical rules set by applications running on the destination host. The rules are applied on messages or packets in order to make forwarding decisions. This means that using content-based addressing, we have decoupled many-to-many communication. On the other hand, the realization of content-based communication is more complex and costly. The cost of mobility in content-based routing is high when compared with the other forms of addressing. Research systems such as Siena (Carzaniga, Rosenblum, & Wolf, 2000) and Rebeca (Mühl, Ulbrich, Herrmann, & Weis, 2004) use content-based addressing.

These addressing models are not orthogonal and may be applied on different layers of the communications stack. Since the current Internet is based on the IP protocol, it provides the baseline addressing with location and identity contained in the IP address. Above that, we may implement the locator/identity split using HIP or an overlay network such as i3. Content-based addressing is also implemented above IP using application-level routers.

Identity-based mechanisms may be extended to support anonymous communication and multicast. For example, i3 supports multicast using triggers and anonymity by chaining private and public triggers. Content-based routing may, on the other hand, be extended to support identity-based communication by subscribing public keys, for example.

The addressing models have differing notions of the addressing space, in which addresses are defined. These differences can be used to characterize the difference between identity-based addressing and content-based addressing. The identity vector (public key) is a point in the flat one-dimensional addressing space of an overlay system. The content-based address, which is defined using a logical rule, is a subspace of a multi-dimensional addressing space. This illustrates the main difference, which is the expressiveness of the communication. In essence, for IP mobility there is a single, fixed indirection point; for locator/identity split there is a single indirection point; and with content-based there are multiple indirection points.

MOBILITY-ENABLING PROTOCOLS

A Taxonomy

Host mobility happens when a host relocates to a new location in the network, thereby possibly causing a change of the underlying IP address. Since IP addressing is tied to the location, this may cause a fundamental change in routing for the relocated host. This host relocation is commonly referred to as a *handover*. Handovers are usually divided into two main categories: *horizontal handovers* and *vertical handovers*. A horizontal handover is commonly understood as a handover that takes place within the same access network technology. A vertical handover is handover that takes place across different access network technologies (and from the host's point of view, between different networking interfaces).

There are also two ways of doing the handover: *break-before-make* or *make-before-break*. The difference of these two approaches is whether the mobility-enabling protocol or the terminal implementation (in hardware, point of view) allows creating connectivity to the new access network or router before leaving the old access network or router.

The host may also have several active IP addresses, which is called *multi-addressing*. Multi-addressing may also be used to realize *multi-homing*, which generally means that the client is connected to two independent networks for increased reliability. Multi-homing is also needed when several different access network technologies are used simultaneously. Server-side resiliency is commonly realized by connecting services to multiple network providers. This is called site multi-homing.

User *mobility* happens when a user changes the host device or access host, which causes a change in the underlying physical address of the user. The device characteristics may also change, for example when the user changes from a PDA (personal digital assistant) to a laptop. An important subcategory of user mobility is *session mobility*, which allows the relocation of user sessions from one host to another. Session mobility is an important requirement for current and future mobile applications, in which instant messaging (IM), multimedia, and voice sessions, for example, are moved from one device to another.

Service or *application mobility* happens when a service relocates or resides on a mobile host that moves. Service mobility may be triggered by factors not related with a user, for example load balancing.

Network Layer Solutions

The current solutions being standardized by IETF for network-layer mobility support are the Mobile IPv6 (MIPv6) and Mobile IPv4 (MIPv4) protocols. MIP is a layer-3 mobility protocol for supporting clients that roam between IP net-

works. Upper-layer protocols and applications are unaware of possible changes in network location and thus can operate uninterrupted while the host moves.

MIP6 mobility support consists of the triangle of the *home agent* (HA), *correspondent host* (CH), and the *mobile node* (MN). MIP4 has an additional optional networking node called *foreign agent* (FA) that has been left out from the MIP6 specifications. In both MIP versions the HA serves as an anchor point for MNs, and any CN may communicate and initially reach the MNs through the HA.

The basic MIP routing is triangular. A CN sends packets to an MN via an HA, and then the HA tunnels packets to MN's current location. Finally the MN sends packets directly to the CN. In practice, triangular routing is inefficient and generally also impossible due to widely used *ingress filtering*. Practical MIP deployments either route all packets via HA (reverse tunneling) or the MN and CN communicate directly (route optimization, which can be negotiated with the help of HA). The distance between the MN and the HA may also be long both topologically and geographically. Thus routing packets between the MN and the HA may cause considerable delay. However, to improve the situation, an HA may also be allocated from the network (Calhoun, Johansson, Perkins, Hiller, & McCann, 2004) the MN is currently visiting. A similar way of optimizing IP mobility is utilizing some form of localized or hierarchical mobility management.

The *hierarchical mobile IPv6 mobility* (HMIPv6) (Soliman, Castelluccia, Malki, & Bellier, 2005) management solution introduces local *mobility anchor points* (MAPs) that are essentially Home Agents. MAPs can be located at any level in a hierarchical network of routers, including the access routers. The aim of the HMIPv6 is to minimize the signaling latency and reduce the number of required signaling messages. As long as the MN stays inside one MAP domain, it only needs to update its location with the MAP. The localized mobility management can also be completely handled on the network side without MN's involvement at the IP mobility protocol level. In these cases the network side needs to employ some kind of tunneling or local routing solution that is transparent to the MN.

Another network-layer mobility solution being standardized by IETF is the NEMO. The technical solution of NEMO is close to that of MIP6. NEMO allows complete sub-networks to change their location in a network instead of single hosts. This is realized with a mobile router that manages the mobile network. Hosts behind the mobile router do not need to be aware of mobility in any way. All packets destined to hosts behind the mobile router get routed towards the virtual home network. Then an HA managing the virtual home network tunnels all packets to the mobile router managing the mobile network.

One practical application of IPsec-based VPNs is to extend the user's home network environment to be accessible from any location. In a tunneled mode, VPNs tunnel

all packets between the mobile host and a *security gateway* (that is usually located at the edge of user's home network). Until recently IPsec VPNs have not survived the change of underlying IP addresses that are also used as the outer IP addresses of the VPN tunnel. Both IKE (Kaufman, 2004) and IPsec SAs (*security associations*) had to be rekeyed after IP addresses of either end of the tunnel changed. This practically caused all existing connections to drop. Recent developments in standardization have addressed this issue. For example, MOBIKE aims to support a way to update the IKE SA and IPsec SA endpoint addresses without rekeying the SAs. This would allow keeping the existing IKE and IPsec SAs in place even when the IP address changes.

Transport Layer Solutions

The recent need for multi-homing support for transport protocols has made it possible to provide limited mobility support at the transport level. Examples of recent such transport protocols are DCCP with multi-homing and mobility extension to the base protocol (Kohler, 2006), TraSH, and mSCTP. The latter two are based on mobile SCTP, which is defined as SCTP with the *ADDIP extension* (Stewart et al., 2004).

The basic idea of transport layer mobility is to maintain the end-to-end connectivity at the transport layer, and solve the mobility problem without additional infrastructure and functionality at the network layer. When a host's point of attachment to the network changes—that is, the underlying IP address changes—the transport-layer mobility protocol needs to refresh the association between the MN and the CN using some protocol-dependent mechanism. This approach is very appealing because it requires no additional tunneling and does not interfere the natural routing of IP packets. It has also been shown that transport-layer protocols are capable of smooth handovers (Fu et al., 2004).

The biggest downside of current transport-layer mobility solutions is the lack of proper mobility management. As long as everything is MN initiated, the proposed solutions work. If a CN needs to locate an MN or both communicating ends are mobile (so called *double jump problem*), current transport-layer mobility solutions most probably fail to work properly. Proposals to solve the mobility management are still open research issues.

MIP suffers from a number of limitations, such as packet loss, high handover latency, packet encapsulation overhead, and conflict with network-level security solutions (Fu et al., 2004; Schulzrinne & Wedlund, 2000). MIP requires that location management resides on the HA. TraSH decouples location management from data traffic forwarding (Fu et al., 2004), and thus a lookup server, such as DNS, may be used for location management. TraSH leverages the multi-homing capabilities of SCTP. The difference between TraSH and MIP is that TraSH sends packets directly to the MN without using the HA.

Between Network- and Transport-Layer: HIP

Above the network level, we have various requirements for mobility in the transport and application layers. Transport-level mobility support needs to cope with changing subnets and prevent, for example, socket errors during mobility. HIP is located between the network and transport layers, and provides this kind of functionality by associating each socket to a public cryptographic key instead of an IP address. The fundamental idea behind HIP is to separate the address of a network-addressable node to two parts: the identity and locator parts. The identity part uniquely identifies the host using a cryptographic namespace, and the locator part uniquely defines the location of the node. The former part is assumed to be a long-living identifier. The latter is typically the IP address of the mobile node. Additional benefits of HIP are authentication and support for denial of service (DoS) attacks through cryptographic puzzles in the initiation phase of the protocol (Moskowitz, Nikander, Jokela, & Henderson, 2006).

Application Layer

SIP mobility support is similar in nature to the HA mechanism used in MIP. SIP mobility support is based on the *home registrar*, which is a rendezvous point for information for a particular user. SIP mobility is simplest for pre-call mobility that only requires updating of the home registrar. In addition, SIP supports midcall mobility, which requires the mobile host to send an INVITE request with the new IP address to the correspondent host (Schulzrinne & Wedlund, 2000). SIP supports session mobility, in which a media session can be maintained while changing hosts. Moreover, the end point of an active session may be changed to another device.

The Wireless CORBA specification was designed to provide a minimal useful functionality for CORBA applications. The specification defines extensions and protocols for applications in which clients and servers are executed on hosts that can move. The specification introduces the *mobile IOR* (interoperable object reference), which is a relocatable object reference that identifies the *access bridge* and the terminal on which the target object resides (OMG, 2004).

An entity called the *home location agent* (HLA) keeps track of the access bridge to which the terminal is currently connected. The mobile IOR provides mobility transparency and contains either the home location agent's address or the last known access bridge of the mobile host. In the former case the HLA will provide the new address of the mobile host. In the latter case, the last known access bridge provides the current address or forwards the invocation. Each terminal is identified using a unique terminal identifier.

The access bridges may support handoff and the specification defines two different cases of handoff: the *backward* and *forward handoff*. The former is the normal case and the latter is used to re-establish connectivity after a sudden disconnection. The backward handoff (or simply handoff) may be network initiated or terminal initiated, whereas the forward handoff is always terminal initiated.

The Internet Indirection Infrastructure (i3) (Stoica et al., 2002) is an overlay network that aims to provide a more flexible communication model than the current IP addressing (Stoica et al., 2002). In i3 each packet is sent to an identifier. Packets are routed using the identifier to a single server in the distributed system. The server, an i3 node, maintains triggers that are installed by receivers that are associated with identifiers. When a matching trigger is found, the packet is forwarded to the associated receiver. An i3 identifier may be bound to a host, object, or a session, unlike the IP address, which is always bound to a specific host.

The *robust overlay architecture for mobility* (ROAM) builds on i3 and allows end-hosts to control the placement of rendezvous points (indirection points) for efficient routing and handovers (Zhuang, Lai, Stoica, Katz, & Shenker, 2002). ROAM uses trigger server caching and trigger sampling, and supports fast handovers and multicast-based handovers for make-before-break. ROAM supports legacy applications using a user-level proxy that encapsulates IP packets within i3 packets and manages trigger-related operations.

Application mobility may require special mobility protocols, for example for applications that use or participate in overlay networks. Content-based routing and publish/subscribe (pub/sub) networks (Eugster, Felber, Guerraoui, & Kermarrec, 2003; Tarkoma et al., 2003) are examples of this kind of behavior. These systems build large-scale multicast event distribution trees over point-to-point communication links. When an application providing or subscribing certain events moves, a part of the routing topology needs to be updated to reflect this change (Burcea, Jacobsen, de Lara, Muthusamy, & Petrovic, 2004).

Pub/sub systems require their own mobility protocols in order to update the event routing topology and optimize event flow. In content-based routing of information, event brokers forward notifications based on a routing configuration established by advertisement and subscription messages. The main motivation for a pub/sub mobility protocol is the avoidance of triangle routing through a designated home broker, which may be inefficient. Experimental results shows that home-broker-based approaches do not perform well (Tarkoma, Kangasharju, & Raatikainen, 2003; Burcea et al., 2004). Mobility protocols are also needed for load balancing subscribers and advertisers between brokers. Efficient mobility protocols for pub/sub are currently an active research topic.

Table 1. Differences in mobility-aware systems and protocols I

| | MIP | HIP | SIP |
|------------------|------------------------|-------------|----------------------|
| Target | MN | MN | Session |
| Mechanism | HA | DNS/Overlay | Home registrar |
| Buffering | No | No | Yes (stateful proxy) |
| Update Point | 1 Fixed | 1 | 1 Fixed |
| Location Privacy | Yes (not /w route opt) | No | No |
| Authentication | Yes | Yes | Yes |

Table 2. Differences in mobility-aware systems and protocols II

| | WCORBA | i3 | Pub/Sub |
|------------------|-------------|------------------|------------|
| Target | Object | Any | Subs/Advs |
| Mechanism | Home bridge | Rendezvous point | Hop-by-hop |
| Buffering | Yes | No | Yes |
| Update Point | 1 Fixed | 1 | >1 |
| Location Privacy | Yes | Yes | Yes |
| Authentication | - | - | - |

DISCUSSION

Tables 1 and 2 illustrate the differences between different mobility-aware systems and protocols discussed in this article. The target denotes the nature of the mobile entity. The target is the mobile node for MIP and HIP. Higher-level mobility protocols allow more fine-grained mobility, SIP supports session mobility, WCORBA object mobility, i3 leaves the entity unspecified, and mobile pub/sub systems support the mobility of subscriptions and advertisements to various degrees.

The *mechanism* term denotes the type of handover protocol, for example the HA- based scheme of MIP or DNS/Overlay update of HIP. SIP uses the home registrar for location updates, WCORBA has the home bridge. The i3 overlay uses a rendezvous point that manages the triggers, and mobile pub/sub systems typically have to update the whole routing path between the source and destination of mobility. The update point denotes the number of indirection points and whether or not they are fixed. MIP, WCORBA, and SIP have a single, fixed indirection point: the HA, home bridge, or the home registrar. HIP—with overlay-based address resolution—and i3 have a single, non-fixed indirection point. Finally, pub/sub systems have typically multiple indirection points.

Buffering of packets and messages is a useful functionality for supporting disconnected operation. MIP and HIP do

not support this feature. SIP supports disconnected operation through stateful proxies and buffering messages for delivery. SIP also copes with network partitions using retransmission (Schulzrinne & Wedlund, 2000). WCORBA access bridges maintain a list of pending invocations, and pub/sub systems buffer notifications for disconnected clients. The i3 overlay, on the other hand, does not buffer packets.

Location privacy hides the current IP address of the mobile entity. MIP supports location privacy with the exception of the route-optimization option. HIP and SIP do not support location privacy. A HIP host has access to the IP address corresponding to the public key (host identity) of a mobile node. SIP does not hide the IP address; it is disclosed in the session description. WCORBA provides support for location privacy. Terminals are addressed using the terminal identifier, and the access bridge hides the transport address of the terminal. On the other hand, the location of an access bridge is revealed. The i3 overlay supports the hiding of source addresses with private triggers. Typically mobile pub/sub systems, such as Siena and Rebeca, provide anonymous communication, and only the edge brokers know the transport addresses.

Authentication of terminals and users is also an important functionality for mobile systems. MIP provides authentication of signaling messages using various authorization extensions. IPSec and Internet Key Exchange (IKE) can be used to protect the integrity and authenticity of MIP signaling. On the other hand, IPSec and IKE were not initially

designed for multi-homed operation, and currently, multi-homed operation has overhead due to additional database entries and key negotiations for each pair of source/destination address. HIP supports authentication through the host identity, which is essentially a public key. SIP supports three authentication styles: HTTP-style basic authentication, digest authentication, and S/MIME. WCORBA may be used with the CORBA security specification (OMG, 2002), and i3 and pub/sub systems may be extended to support various forms of authentication.

CROSS-LAYER INTERACTIONS

Mobility support is currently available on many layers. Assuming that the base network-level routing technology is the Internet protocol (IP), mobility solutions are also needed on many layers. First, the lower layers need to be able to detect mobility and activate higher-level protocols. These mechanisms are outside the scope of this article. Second, after physical mobility the IP address will change, and after user mobility it may change; both instances require solutions for informing others that the address of the host has changed. This may be accomplished by pure network-level solutions (mobile IP), a hybrid approach (HIP), or through purely application-level solutions (overlay, DNS update). The mobility of sessions and objects is more subtle than the mobility of hosts, and we need mechanisms above L3 to cope with session and object mobility due to reconfiguration and, for example, load balancing decisions.

Lower-level mobility protocols are in some cases complementary to higher-level protocols. Both MIP and HIP are complementary, as is the case for MIP and middleware mobility protocols—for example, WCORBA and multi-hop application-level overlays such as i3 and Siena. If SIP or WCORBA provides mobility support, a higher-level mobility solution is not required. In general, a higher-level handover protocol is required for more fine-grained mobility support and optimizations. If only host mobility support is required, higher-level protocols are not needed. MIP may still be useful in scenarios where application-level mobility protocols are used and the client needs to be contacted using the home IP address. For example, pub/sub and many overlay systems hide the IP addresses of the communicating entities. In these systems the IP address of the terminal (care-off address) is not used for end-to-end communication, but only for the last-hop at the edge of the network. If MIP is not used, clients cannot address the mobile node directly since its IP address changes with the access location.

If MIP or HIP are not used, higher-level protocols need to provide mobility support. In this scenario there are no interactions between network-level mobility protocols and higher-level protocols. The transport, middleware, or overlay layer handles the locator/identity split and indirection. There

are many possibilities for supporting mobile applications, for example SCTP, mSCTP, TraSH, and the middleware protocols.

HIP provides useful features for the higher layers, such as persistent transport-layer connections, multi-homing, and authentication. On the other hand, the timeliness and efficiency of the HIP key/address distribution mechanism is still open and requires interaction with an application-level lookup service, such as DNS or i3. The use of HIP with SCTP, SIP, and other protocols are currently open issues.

Each networking layer operates mostly on its own. Due to the lack of cross-layer interactions, similar tasks may be repeated multiple times on each layer. We can consider access authentication and service authorization as an example of this. Several networking layers, including the final application-level service, may initiate similar authentication and authorization transactions that all end up at the same AAA (*authentication, authorization, accounting*) backend system located in the user's home network or the service provider's premises.

CONCLUSION

We presented taxonomy of mobility-enabling protocols on different layers of the networking stack starting from the network layer. Three useful addressing models were identified that are inherently related with mobility: addresses with both location and identity, locator/identity split, and content-based addressing. The first is currently used in the IP network architecture, and mobility solutions typically use triangle routing with optimizations. The second model has been proposed, because of its mobility-friendly characteristics—mainly a non-fixed point of indirection. The last model has also been proposed for expressive communication and is believed to be a good candidate for supporting mobile and distributed applications.

The distinguishing feature of the models is the number of indirection points and whether or not they are fixed. Content-based addressing is most flexible, but may also require the update of several indirection points, which is more costly than updating a single point. We identified several useful cross-layer interactions, but noted that some protocols are complementary. Especially if middleware mobility support is used, the benefit of using lower-level mobility protocols is uncertain. Middleware mobility support is needed for object, session, and pub/sub mobility.

KEY TERMS

Break-Before-Make: A mobility solution feature where the connection to the old point of attachment must be torn down before establishing a connection to the new point of attachment to the network during handover.

Content-Based Routing: The process of forwarding messages based on their content.

Horizontal Handover: A handover within the same access technology.

Locator/Identity Split: Form of addressing, in which the identity and location of a node have been separated.

Make-Before-Break: A mobility solution feature that allows establishing connectivity to the new point of attachment in the network prior to tearing down the connection to the old point of attachment during handover.

Mobile IP: A classical layer-3 mobility solution based on tunneling and a stable anchor point representing the mobile node.

Service or Application Mobility: The mobility of an application or service from one physical location to another.

Understanding Multi-Layer Mobility

Session Mobility: The seamless transfer of an ongoing communication session from one device to another.

User Mobility: The ability of an end user to send and receive information regardless of mobile terminal and current location.

Vertical Handover: A handover between different access technologies.

Using Mobile Devices for Electronic Commerce

INTRODUCTION

Electronic commerce is becoming the most used mechanism for non-traditional commerce. However, several popular delivery services are still accessed via telephone, which enables commerce anytime, anywhere. Such telephony-based services have several problems: they do not offer a more detailed description of available products; users may ask the attendant to repeat the description of a certain product, directly affecting the time of product selling; the number of concurrently attended clients is limited to the number of attendants; and the product list must also be continuously updated, by adding or removing products, but the user cannot be automatically informed about that.

Mobile devices offer a sophisticated interface that allows better user interaction by means of lists, menus, multimedia features such as images, and much more. A user can indefinitely explore product categories very fast. It is possible to offer a more detailed description of products, with visual elements such as pictures or even videos. Besides, the number of concurrent accesses depends only on the number of connections supported by the server.

In this article, we describe an architecture for mobile commerce which allows the use of mobile devices for electronic commerce. The architecture enables the development of applications to be executed on a mobile device, which lists selling products having their own textual descriptions and pictures. We discuss architectural modules and the implementation of an application for selling fast food called Mobile Menu. We begin with the main background concepts related to our proposed architecture.

BACKGROUND

Electronic commerce has attracted significant attention in the last few years (Varsghney & Vetter, 2002). The continuously increasing number of users of mobile devices, such

as mobile phones and personal digital assistants (PDAs), and advances in wireless network technology provide an ideal scenario for offering personalized services to mobile users and give place to the rapid development of mobile electronic commerce (MEC) (Tsalgaidou, Veijalainen, & Pitoura, 2000).

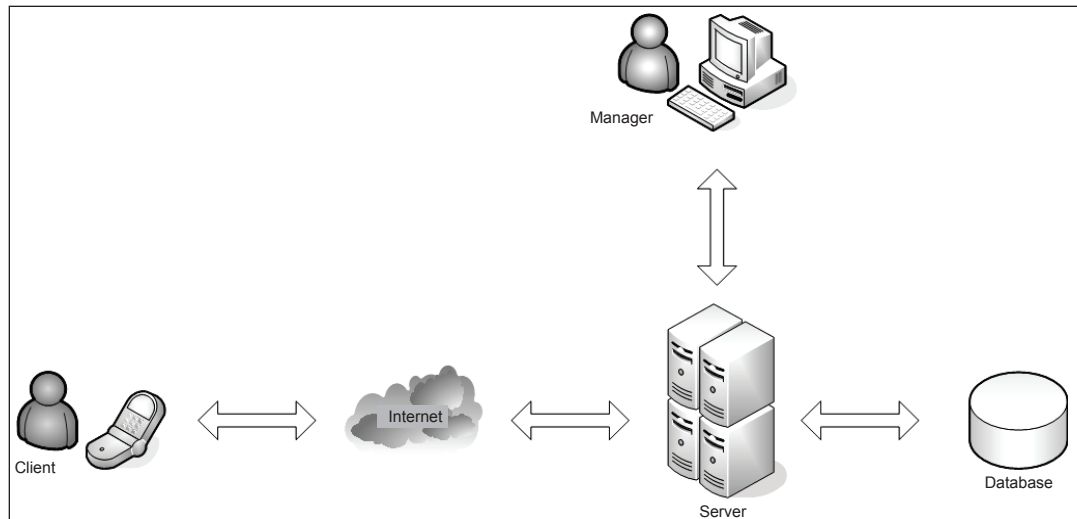

The way MEC operates is partially different from Internet e-commerce due to special characteristics and constraints of mobile terminals and wireless networks. The context, situation, and circumstances under which people use their mobile devices are also different (Tsalgaidou et al., 2000).

Wireless and mobile networks are increasing in exponential rate in terms of capabilities of mobile devices and user acceptance (Varsghney & Vetter, 2002). Today, more than 1 billion cell phones and other mobile devices are in use worldwide. MEC also has more advantages than traditional e-commerce applications: location-awareness, adaptivity, ubiquity, personalization, and broadcasting (Tsalgaidou et al., 2000). Applications for mobile devices are also easier to use, because the user interface of such devices is very intuitive.

Mobile devices have less resources than desktop and mainframes computers: limited memory, disk capacity, and computational power. The user interface of such devices also has some constraints: for example, small screens and small multi-functional keypads (Tsalgaidou et al., 2000). These constraints restrict the variety of applications for mobile devices and must be taken into account when designing new systems for such platforms.

Applications that demand a considerable quantity of system resources are harder to develop for mobile devices. For example, applications that need a large database to constantly perform queries and update the data are very difficult to develop for mobile devices, because the limited memory of devices does not support a database management system (DMS). Distributed architecture shares tasks among the elements of it, so that harder activities which demand memory and computational power can be allocated to those which have more resources.

Figure 1. Mobile menu architecture

Client-server architecture is largely used as a distributed design; it shares the tasks of the elements and provides a certain level of decoupling. It has two elements that establish communication with each other: the front-end or client, and the back-end or server. The client makes a service request to the server whereas the server provides service to the request. The client-server architecture allows an efficient way to interconnect programs that are distributed at different places (Jorwekar, 2005). However, client-server architecture is more than just a separation of a user from a server computer (Fastie, 1999). Each portion also has its own modules: presentation, which handles inputs from devices and outputs to screen display, application, and data; application, which has the rules of the business; and data, which provides services for storing the data of the application (Fastie, 1999).

AN ARCHITECTURE FOR MOBILE COMMERCE

We propose an architecture that enables mobile commerce for mobile devices. The architecture is illustrated in Figure 1. The application has three elements: the *client*, which requests the information about selling products; the *manager*, which updates information on the products; and the *server*, which receives requests and sends responses.

To start with, the user accesses the service anytime and establishes a connection with the server. Then, a list with pre-defined categories of products is sent to the user. These categories help the user to browse through the list of products. After selecting the product, the user can obtain more specific information about it or purchase the item, if more detailed information about the product is requested. At the other side, the server receives the request of purchasing or

obtaining more information about the product, such as name, description, and price. Other more elaborate elements that describe the products, such as pictures and videos, can be attached. The application can be accessed anytime.

The client application can run on a mobile device and establishes a connection with the server. It requests services to the server and receives the data. The server has two modules: the network layer, which manages the network connection of the mobile devices; and the database layer, which establishes connection with the database and manages data.

Another important element of the application is the manager side. It is a desktop application which interacts with the system by modifying the database: it inserts or removes products and also modifies information about them, like price, name, and description.

This architecture provides an interesting solution by delegating tasks for members of the system: client, server, and manager. The tasks performed by each one does not demand a considerable amount of resources from each system. For example, a mobile device cannot store a large amount of data. Thus, the architecture delegates the storing/processing tasks to the server that is supposed to have more resources. The layered architecture decouples the modules, so each one can be modified interchangeably, and also provides reuse of code.

Mobile Menu

Food delivery is a frequently used service usually accessed via telephone. It has some problems that affect the business, for example: detailed descriptions about the products are not easy available; for each client, an attendant is allocated; and a request can be mistakenly made.

Based on the architecture described, we developed Mobile Menu, which is an application for fast food mobile commerce.

Figure 2. Client-server protocol

It was implemented using Java™ Platform–J2SE for desktop applications and J2ME for mobile applications.

The functioning of Mobile Menu is represented in Figure 2. The client connects to the server and requests the menu, which is sent by the server (1, 2). The first part of the menu has only categories and subcategories of the products (pastas, salads, drinks, beverage, etc.) (3). If the client wants to see the products of a specific subcategory, it sends a request to the server and the latter sends a list of all products (3). This list contains the name of each product and its ID. If the user wants to know a detailed description of the product, the client sends a request to the server and receives additional information (4).

The menu can be updated anytime through the manager side of the application. Mobile Menu adds considerable business value in food delivery services, usually accessed via telephone. The user can indefinitely explore the categories very quickly. It is possible to offer a more detailed description of products, with visual elements like pictures or even videos on them. The number of accesses depends only on the quantity of connections supported by the server.

FUTURE TRENDS

Mobile e-commerce has several classes of applications (Timmers, 1999) with different characteristics. For example, Internet banking is a very different kind of mobile commerce which is not explored here. As for future works, we propose enhancing the architecture so more classes of mobile applications can use it.

For example, the architecture does not solve problems like selling multimedia products such as video to mobile devices.

These devices have limited memory/processing. Thus, storing and playing large videos with high quality, for example, is not viable. Another aspect that was not explored is data security: the messages are not encrypted and the channel is not secure. The architecture can be adapted by adding other modules to solve some security problems.

CONCLUSION

Mobile e-commerce is an area that creates opportunities for many players in the field. Mobile devices have some constraints that must be taken into account when designing the application for such platforms. However, these devices also have important characteristics that make them an interesting channel of commerce.

The number of services available through mobile devices is increasing: banking, purchasing of images and music, and much more. These applications make services easily accessible to the client, providing consumption of a large variety of products and services in a convenient way.

In this article we proposed an architecture for mobile devices that enables the use of mobile devices for electronic commerce. We applied the proposed architecture to develop Mobile Menu, an application for food delivery based on mobile commerce. Although this application is specific for such a domain, the architecture is generic and could be adapted to any mobile commerce application.

Using Mobile Devices for Electronic Commerce

Wesel, E. K. (19998). *Wireless multimedia communications, networking video, voice and data*. San Francisco: Addison-Wesley.

KEY TERMS

Client-Server Architecture: A basic concept used in computer networking, wherein servers retrieve information requested by clients and clients display that information to the user.

Distributed Network: A system where resources are spread among many computers, instead of being stored in a single location

Electronic Commerce (E-Commerce): The buying and selling of information, products, and services electronically over the Internet.

Mobile Devices: Any portable device used to access a network (Internet, for example).

Multimedia Application: Applications that support the interactive use of text, audio, still images, video, and graphics.

Protocol: A set of rules and procedures governing communication between entities connected by the network.

User Interface: The means by which an individual communicates with a computer through a software application. The common methods for such communication are, commands, menus, and icons.

Wireless Network: Networks without connecting cables, that rely on radio waves for transmission of data.

Using Mobile Devices to Manage Traffic Infractions

INTRODUCTION

Mobile computing is one of the recent technologies with the most impact on people's lives. Several research and industrial applications are benefiting from mobile computing, supporting various human daily activities. Transit law enforcement officials can benefit from the availability of powerful mobile devices, such as smart phones and PDAs, to help them to execute their daily tasks. In such a scenario, an official can verify a driver's data record and issue tickets online.

In this article we describe the SM-FIT system that makes it possible for transit law enforcement officials to perform online queries about potential infractions of a driver of a vehicle by using a mobile device. Queries are performed based on a unique identifier: the driver's license number.

The system is implemented based on a client-server paradigm, where mobile devices are clients and servers are base stations. Clients must have a local database to store each result of a query, when needed. Each registry stored has the following attributes: a unique identifier, the number of the vehicle's plate, the date and time that the officer registered the infraction, and the status of the infraction. Besides, photographs can be stored, digitally signed, and transmitted to a database for future prosecution.

The remainder of this article is organized as follows. We first outline some background concepts related to the system's development. We then present the proposed system architecture and functioning, and discuss some trends related to future research in this area. We close with some final remarks.

BACKGROUND

This section describes briefly some concepts related to J2ME and, more specifically, MIDlets. Such technologies have been used for developing the proposed system.

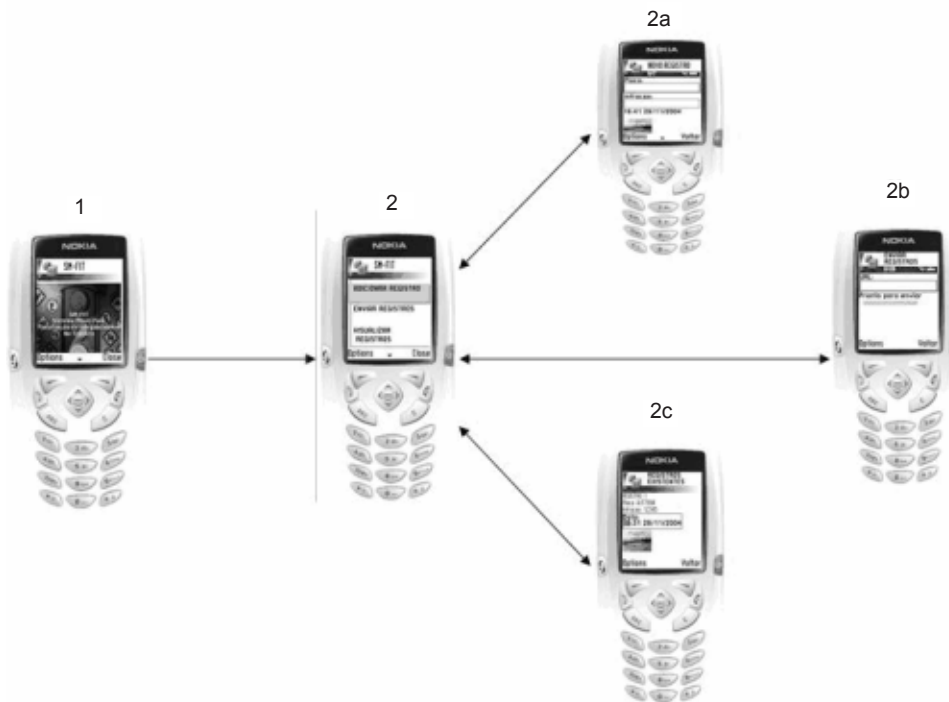

J2ME

J2ME is a development platform based on Java Technology for developing mobile and embedded applications. It focuses on two types of devices:

- **High-End Consumer Devices:**
 - CDC (connected device configuration);
 - interactive TVs, videophones, wireless devices;
 - a large variety of user interfaces;
 - typical memory of 2 to 4 Mb; and
 - persistent connection, generally TCP/IP.
- **Low-End Consumer Devices:**
 - CLDC (connected limited device configuration);
 - cell phones, bidirectional pagers, PDAs, and so forth;
 - limited processors (8 to 32 MHz);
 - limited memory;
 - lazy connection, intermittent (9600bps) and generally not based on TCP/IP; and
 - powered by batteries.

The J2ME platform includes flexible user interfaces, a robust security model, a broad range of built-in network

Figure 1.

protocols, and extensive support for networked and off-line applications. Besides this, applications based on J2ME specifications are written once for a wide range of devices.

MIDlets

Java applications running on MIDP devices are known as MIDlets, which consist of at least one Java class and have to be derived from the abstract class `javax.microedition.midlet.MIDlet`. These MIDlets use an execution environment within the Java Virtual Machine to control the application's lifecycle through a set of methods implemented by this MIDlet.

MIDlets can also use methods to obtain services from the environment. A group of related MIDlets can be put together in a MIDlet suite, which is packaged and installed in (or removed from) a device as a unique entity. MIDlets in a suite share all static and dynamic resources in their environment:

- Execution data can be shared by MIDlets, and the usual Java conventions of synchronization can be used to control data access.
- Persistent data can also be accessed by all MIDlets in a suite.

All files in a MIDlet suite must be within a JAR package. These packages contain the classes of the MIDlet and other

resources, like images, and a manifest file. This manifest file contains a list of attributes and definitions to be used by application managers to install the JAR files in the device.

Security in MIDlets

The JAVA security model in its standard edition (J2SE) is too expensive in terms of costs for memory allocation, and it requires configuration knowledge that is not present in users of mobile devices. Thus, neither CLDC nor MIDP include these functionalities.

Cryptography of public key and certifiers are not available as default, so it is necessary to pay attention when installing MIDlets and, preferentially, only accept software from trustable fonts. MIDP 2.0 included the https protocol that helps to diminish these problems.

SYSTEM DESCRIPTION

The SM-FIT is a system that makes it possible for transit law enforcement officials to register transit irregularities in a local database. Each record of this database consists of the number of the vehicle's plate, a code of the infraction, date and time that the infraction occurred, and the photography of the vehicle involved in the corresponding infraction.

The system is implemented based on a client-server paradigm, where mobile devices are clients and servers are base stations. At the end of the day, transit law enforcement officials send the registers of their mobile devices to the server in order to make available more space in their devices for local databases.

Consider Figure 1 to understand the system functioning. Through the starting screen of the system (1), it is possible to access the system main menu (2). This menu of options includes: *Add a record*, *Send records*, and *View records*.

If the user chooses the first option (2a), to add a record, it is shown a screen with the following data to be filled: the vehicle's plate involved in the infraction, the code of the infraction, date and time of the infraction (this information is taken automatically from the mobile device), and the photography of the vehicle involved in the infraction.

If the user wants to send all the records stored in the mobile device to the server (2b), it is shown a screen that requests the IP address of the server. Then, the process of sending the information to the database is initiated.

Finally, if the user chooses to visualize the records of the mobile device (2c), it is shown a screen with a list of records contained in the local database. This visualization is taken in a way that each record is shown individually on the screen.

FUTURE TRENDS

Future research and development of new technologies may make possible the transferring of streams from mobile devices to the server. In this way, the system described here could store videos of infractions or even the voice of the transit law enforcement official describing how the infraction occurred. For this kind of improvement, it would be necessary to consider efficient lower battery consumption mechanisms.

Another point to be considered is cryptography in mobile devices, which would increase security during the transference of records from the mobile devices to the server. Considering that it is an industrial application, security is an essential requirement.

In the context of the driver, a module for drivers to consult the situation of their licenses or cars could be made available. This module would make available all the information contained in the server database.

CONCLUSION

The usage of mobile devices to manage traffic infractions can bring some benefits, such as saving time on queries made to check if drivers have any previous infractions. Another benefit is that using a mobile device that can take pictures, when the

transit law enforcement official registers a new infraction, he/she can also take a picture of the vehicle involved in the infraction to prove in the future that it really occurred.

Regardless of application domain, there is a widespread use of mobile devices and an increasing need for real-time answers wherever a person is. This makes it necessary to use a technology like the SM-FIT system. It allows for transit law enforcement officials to get real-time answers for their queries about the drivers' situations, and also about their vehicles. But this system can also be adapted to be used in many other application scenarios, such as to make restaurant reservations, access credit card accounts, and make payments.

KEY TERMS

Base Station: A centralized repository for the storage and management of information, organized for a particular area.

CDC: Connected device configuration.

CLDC: Connected limited device configuration.

IP Address: An Internet protocol address attributed to a client or a server in the client-server paradigm.

J2ME: Java Second Micro Edition.

MIDP: Mobile information device profile.

Personal Digital Assistant (PDA): A handheld device that combines computing, telephone, Internet, and networking features.

Using Service Proxies for Content Provisioning

INTRODUCTION

In modern broadband mesh networks, communication between two end nodes is carried out not directly, but through a number of intermediate nodes. While these nodes' only function may be to relay information from one point to another, they may also host computational elements which perform some service on behalf of other applications. We deal with the problem of optimally mapping multimedia content transcoding service elements onto network resources. There may be several places in the network where the required compression and decompression services could be performed. We would like to select the best locations that meet the application's requirements. We propose a new approximation algorithm for constrained path optimization, which provides better scalability and simplicity than previous approaches. This is accomplished basically by partitioning the overall problem into smaller ones.

RELATED WORK

The majority of the proposed schemes are focused on solving the similar multi-constrained optimal-path problem (MCOP). This problem aims to find in a network an optimal path that satisfies multiple additive path constraints and has been proven to be of NP-complete complexity, therefore unsolvable in polynomial time. Several algorithms have been proposed for the above problem. For the MCOP problem with two parameters, Jaffe (1984) proposed to use a linear weight combination of the two constraint parameters. Other proposed algorithms include Iwata et al. (1996), SAMCRA (Van Mieghem, De Neve, & Kuipers, 2001), and the Chen-Nahrstedt algorithm (Chen & Nahrstedt, 1998). All of the above algorithms require a global state to be maintained at every node. Most algorithms transform the routing problem to a shortest path problem and then solve it by Dijkstra's or the Bellman-Ford algorithm.

The concept of service path has been proposed in smaller numbers. In TranSquid (Maheshwari, Sharma, Ramamritham, & Shenoy, 2002), a transcoding and caching proxy for heterogeneous clients is proposed. In the Ninja Project (Gribble et al., 2001), service path is defined as a sequence

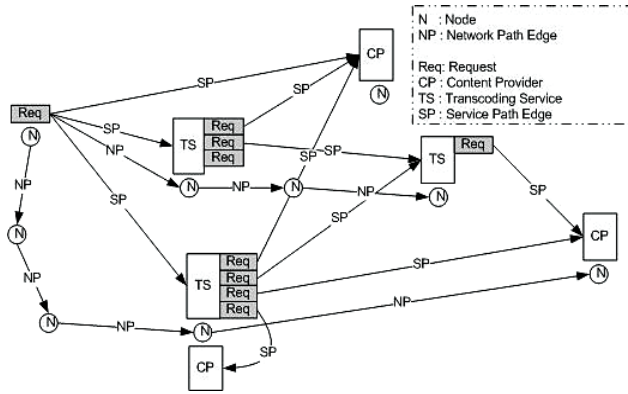

of application-level service operators and connectors. In Lienhart, Holliman, Chen, and Yeung (2002), the authors propose the addition of a media support module (MAPS) on top of an existing peer-to-peer service layer, in order to improve multimedia services across heterogeneous computing platforms. This module is responsible for transcoding and route path selection based on the single-pair shortest-path problem and utilizes Dijkstra's algorithm to provide a solution. Our system is a combination of the above two research areas. It uses the service paths concept and also fully implements the MCOP, rather than the simpler path-finding solutions.

NETWORK AND SERVICE MODELING

We assume that our network topology matches that of a partial mesh network. A mesh network is reliable and offers redundancy. If one node can no longer operate, all the rest can still communicate with each other, directly or through one or more intermediate nodes. Mesh networks work well when nodes are located at scattered points that do not lie near a common line.

As a service, we denote any network resource which may include computational elements and performs some online activity on behalf of other applications. A service is an online facility that is always available to all requestors, at a predefined cost and delay. The services may be available on more than one node, either serially or concurrently. Although services in communication networks delivering multimedia content may include conversion processes like media data adaptation, merging of multiple media sources, copyright protection, metadata extraction, enhancements, and recovery, in our modeling we focus mainly on transcoding. Possible forms of transcoding include: lowering the bit rate of a media stream by reducing the image/video resolution, size, and/or frame rate; converting a media stream from one encoding format to another; or a combination of the above. The expected benefits from these adaptations are on one hand to move computation (data transformation) from the client site to the proxy, and on the other hand to reduce the volume of data transferred to the client. In any case, a service in our modeling accepts a media stream which is

Figure 1. Network and service paths

characterized from an input data rate, performs application-level processing on the media data, and forwards the stream at a new output data rate.

The connection requests are initiated by clients that wish to acquire specific content from content providers. The procedure that the clients follow to detect content providers with desirable content is out of the scope of this article. The notion of clients, content providers (CP), and service providers (SP) is used here to state the dynamic nature of the network connections. The scope of multimedia service provision is to provide clients with customized and satisfactory QoS, under the constraint of end-to-end resource availability observed by each client. Several requests are initiated, targeting various service entities.

The main pattern for the proposed solution is to split the problem into smaller ones, as shown in Figure 1. Each request forms two bids. The first bid concerns the path from the request to the service that has the desired output. This bid includes the network and service paths, and the delay and cost for the path and the usage of the service. The second bid is required if the chosen service does not own the content, and acquisition is needed from somewhere else. In this case, a new request is formed and its result is returned to the initial request. The results from the second bid contain everything after the service, including any subsequent services that may be used.

PROBLEM FORMULATION AND HEURISTICS

Let directed, connected graph $G(V, E)$ denote the network topology, where V is the set of vertices of the graph (representing network components (e.g., switches, routers, hosts, aggregated subgraphs) and E the edges (representing communication links). There are four basic entities used in our problem formulation, shown in Table I. Edges and vertices

are part of the actual network and services, and requests are part of the overlay network.

PROBLEM ENTITIES

| Edge e | Vertex v | Service s | Request req |
|-----------------------------|---------------|--------------------------------------|-----------------------------|
| B_e : available bandwidth | d_v : delay | v_s : host vertex | v_{req} : host vertex |
| d_e : delay | | r_{in}/r_{out} : input/output rate | D_{req}^{max} : max delay |
| c_e : cost per rate | | c_s : cost | R_{req} : requested rate |
| | | d_s : delay | |

For every request, ensure the end-to-end delay constraint is met:

$$\sum_{v \in P} d_v + \sum_{e \in P} d_e + \sum_{s \in SP} d_s \leq D_{req}^{max} \quad (1)$$

while the available bandwidth for all edges in the path is at least the required rate at that point:

$$R_{req} \leq B_e, \forall e \in P \quad (2)$$

and minimize cost:

$$C_{tot} = \sum_{e \in P} C_e * r_e + \sum_{s \in SP} c_s \quad (3)$$

where P is the network path and SP the service path.

The problem, as described above, is more accurately described as unicast link-constrained path-constrained path-optimization routing. The link constraint refers to the available bandwidth, the path constraint to the total delay, and the desirable path optimization to the minimization of the total cost.

The Heuristics Solution

The main steps for estimating the optimal paths are the following:

- **Step 1. Topology Filtering:** For every request req initiated at host vertex t and inquiring an object with optimal rate R_{req} and maximum delay D_{req}^{max} , filter all links (and possibly disconnected nodes) that do not satisfy the requested minimum linear QoS constraints, in our case, minimum available bandwidth B_e as in equation (2).
- **Step 2. Finding Available Services:** Let $S_R \in S$ be the sum of services that have an output rate R_{req} —that is,

the services that either own or can produce the object are chosen.

- **Step 3. Bid 1:** For every service $s \in S_R$ hosted at vertex t_s , solve the partial MCOP problem of (1) and (3) from t_{req} to t_s . In our implementation, we use an extended version of Jaffe's algorithm, combining: $w(P) = a * c(P) + b * d(P)$, in order to obtain the results. The main difference from the original algorithm is the usage of non-static variables a and b , which change according to the pseudocode below:

```
double alpha=1, b=0, step=0.1;
while (delay1 > D_req1 || b!=1) {
    alpha=alpha-step;
    b=b+step;
    P=new Dijkstra(alpha,b);
    delay1=getDelay(P); }
```

The logic is simple. First seek to optimize path with respect to cost only and check if the delay constraint is met. If not, increase the delay factor by a step and try again until a solution is found.

- **Step 4. Bid 2:** For every node $v \in V$ that hosts a service $s \in S_R$, if s has an input rate $R_{in} \neq 0$, form a new request for object with optimal rate R_{in} and maximum delay $D_{req2} < D_{req}^{max}$. Go to step 1. Results are path2, spath2, cost2, and delay2.
- **Step 5. Negotiation of Bids:** The negotiation process deals with the sharing of partial delay constraints D_{req1} and D_{req2} between bids 1 and 2 respectively, so that $delay1 + delay2 < D_{req}^{max}$ and the overall cost is kept minimal. The negotiation is done according to the pseudocode as follows:

```
PROCEDURE bid()
    D_req1 = D_req^max - delay2
    delay = tryBid1(D_req1)
    D_req2 = D_req^max - delay1
    delay2 = tryBid2 (D_req2)
    do
        if (delay1 < 0 && delay2 < 0)
            No feasible solution for bid1 and bid2, bid fails
        if (delay1 < 0 && delay2 > 0)
            ask trybid2 () for a better delay, try bids again
            D_req2 = delay2 - 1
        if (delay1 > 0 && delay2 > 0)
            valid delays for both bid1, bid2, bid succeeds
        if (delay1 > 0 && delay2 < 0)
            ask trybid () for a better delay, try bids again
            D_req1 = delay1 - 1
    while bid succeeds or bid fails
END PROCEDURE
```

The worst case overall complexity of the algorithm is analogue to the complexity of the Jaffe Algorithm:

$O(N \log N + 2E)$. Also, for a total number of S services, the algorithm can be run $S!$ times, that is S times for the first time and $S-k$, for the k -th iteration, when s services will have been added to the service path. However, the algorithm is bounded by the maximum delay D_{req} , so given that each service s adds a mean delay \tilde{d}_s (service delay + path delay), the iteration happens $k = D_{req} / \tilde{d}_s$ times and the MCOP algorithm of bid1 is executed $S! / (S-k)! < S^k$ times. So, the overall complexity of our heuristics is $O(S! / (S-k)! (N \log N + 2E))$.

SIMULATION RESULTS

The algorithm described above was implemented in Java, using the JUNG (<http://jung.sourceforge.net/>) software package. The simulations were conducted using three different network topologies:

- **Grid 16:** This network is composed of 16 vertices that form a grid network. Each vertex is connected to its two neighbors to the east and south, for a total of 32 edges. The east-most and south-most nodes at the edges of the square grid also have links that wrap around to the corresponding node at the opposite side, which results in a grid topology.
- **Grid 64:** This network has the same structure as the Grid 16 network described above, but has 64 vertices and a total of 128 edges.
- **Random:** The network is composed of 40 vertices and 86 edges.

For each of the above topologies, two major sets of simulations were contacted:

- With CPs but without TSSs, simulating the classic QOSR MCOP problem.
- With a variable number of service proxies. The optimal route selection heuristics described above was used in this case.

The following configuration parameters affect the simulation results:

- **Density and Location of Services:** The density of servers is defined by the ratio of the number of services to the total number of nodes. The host nodes for the services were randomly selected for Grid64 and Random, while for Grid16, all nodes hosted services.
- **Bandwidth Reserved per Request:** The bandwidth that an individual request reserves at each link is set approximately to 4% of the available link bandwidth.
- The values for the delays in edges and nodes are of the same order and 70% less than the delay caused by

Figure 2. The Grid 16 network

services, while the cost of transcoding is generally less than the cost of content provider.

Finding the Optimal Position for the Transcoding Services

The algorithm that was described previously was used in order to find the most suitable host nodes for positioning transcoding services. The Grid 16 network, shown in Figure 2, is used as an example.

The following parameters hold for nodes, edges, services, and requests:

- Every node causes a delay=1.
- Every edge has cost/rate=1, delay=4 and bandwidth=1500.
- Two services at V0 are content providers:
 - S0→10@V0 with delay=10 cost=130.
 - S0→20@V0 with delay=10 cost=20.

Figure 3. Importance of services

We wanted to find out where to put a number of TS with S10→20 and S20→10 with delay=4 cost=10 that would serve as many requests as possible. Every other node (V1-V15) was a potential host for services, so we put TSs in all of them. Next, we placed two requests for the two rates (10, 20) that were supported in our network on each node other than V0 which hosted the CPs. Their delay constraint was loose and equal to 50. In total, there were 30 requests.

As expected, from Figure 3 we see that the most useful services for implementation in our test network are the S20→10@V1 and S20→10@V4. These services compensate for the high cost of S0→10@V0. They are preferred by all 15 requests that demand rate=10, while the S0→10@V0 serves zero clients and is actually ignored.

The S20→10@V1 and S20→10@V4 services are also used for five requests that demand rate=20, despite the fact that there is already a CP (S0→20@V0) that produces it. These requests come from nodes that are far away from node V0, and it is more convenient for them to choose a service path that would reduce the cost spent at the edges of the network. For example, for node V7, the service path is SP=S0→20@V0 S20→10@V1 S10→20@V7.

From Figure 4, we confirm the fact that most network paths contain the nodes that host the most preferred services, particularly E0(V0,V1), E1(V0,V4), and E3(V1, V5).

The results from the simulations that we conducted can lead us to certain useful considerations.

Using transcoding services is necessary when there is no content provider that can satisfy a client request or its costs are unacceptable. When transcoding results to higher bit rate, the transcoder should be placed as close to the destination as possible. Accordingly, when transcoding results to lower bit rate, the transcoder should be placed as close to the content provider as possible.

Transcoding resulting in lower bit rate may be necessary even when it leads to worse performance (i.e., excess delay)

Figure 4. Importance of edges

Using Service Proxies for Content Provisioning

Figure 5. Cost-delay diagram for (a) Grid 16 and (b) Grid 64 networks

(a)

(b)

when the available bandwidth is low and many requests need to be served. Transcoding has better results when the cost and delay of the transcoding service is relatively low, and also when the host node of the service is included in the optimal path between the content provider and the receiver. In other words, the deviation of the flow for using a service must be minimal. The rate reduction is important and the request has not very tight delay constraints.

Figure 6. Cost-delay diagram for random network

Overall Network Statistics

In the cost-delay diagrams shown in Figures 5 and 6, we show the improvements on performance by using service proxies. In all cases, only the minimum required content providers were used in the network.

In Figure 7(a) for total number of 200 requests, and in Figures 7(b) and 8 for 500 requests, the ratio of served requests is shown for each network with and without transcoding services. For the Grid 16 and Grid 64 networks, the percentages are about 90% and 80% respectively with the usage of services. Again, the benefits of using services are more evident when the network tends to reach congestion. As the optimized network resource usage increases, so does the admission control rate.

The random network has an even better comparative performance admission control rate, which is evident from the beginning due to the fact that certain client requests are unfulfilled due to the limited number of content providers.

(b)

Figure 8. Admission control diagram for random network

CONCLUSION

In this article we have presented a distributed approach for finding the best feasible paths in networks with respect to QoS requirements. We focused on the usage of transcoding services and especially services that alter the bit rate. This approach is applied in the unicast distribution of multimedia streams. Our heuristics involved transformation of the original problem to a series of conventional shortest path QoS problems that are solved using a new MCOP algorithm. Through our extensive simulations we proved that transcoding proxies can induce positive results in reducing costs, improving load balancing/network congestion, and consequently increasing admission control rates.

KEY TERMS

Content Provider: A service that provides multimedia content.

Mobile Computing: Ability to use technology untethered, that is not physically connected, or in remote or mobile (nonstatic) environments.

Multimedia: Media that uses multiple forms of information content and information processing (e.g., text, audio, graphics, animation, video, interactivity) to inform or entertain the (user) audience.

Network: A network of telecommunications links arranged so that data may be passed from one part of the network to another over multiple links.

Network Topology: The pattern of links connecting pairs of nodes of a network.

Path Optimization: Finding a path between two vertices such that the sum of the weights of its constituent edges is minimized.

QOS Routing: Process of finding a loop-less path between nodes in a network, satisfying a given set of constraints on parameters like bandwidth, delay, etc.

Service: Any network resource that performs some online activity on behalf of other applications.

Verifying Mobile Agent Design Patterns with RPOO

INTRODUCTION

The act of modeling concurrent distributed systems is not a trivial task. Besides, when mobility is added to the scenario, things get worse because of new problems like variations in the communication conditions and remote execution. An important thing to be considered is how to analyze these mobile agent-based systems in order to validate and improve them.

An interesting tool to verify such systems is named Petri net. Petri net, or simply PN, is a powerful formal, graphical, and executable tool commonly used for verifying communication protocols and concurrent systems. A variant of Petri net, named RPOO (Guerrero, 2002)—Object Oriented Petri net, brings all the advantages of Petri nets and object-oriented semantics and puts them together. This union produces a new tool, with the formal semantics of Petri net models and the object-oriented semantics of some programming languages, like C++ and Java. This makes the semantics of formal behavior models closer to the semantics of those programming languages. With this, formal models of programs are built easier than with classical Petri nets. Besides, a closer model, speaking about semantics, is used to verify and analyze mobile agent design patterns which gives a more trusted verification.

This article presents the formalization and analysis of three migration design patterns—itinerary, star-shaped, and branching—done by using of RPOO. A brief comparison between RPOO models and classical Colored Petri net (Jensen, 1992, 1997) models is also briefly presented.

BACKGROUND

Mobile Agent Migration Design Patterns

In this article we consider three migration design patterns proposed in Tahara, Ohsuga, and Honiden (1999): itinerary,

star-shaped, and branching patterns. In the sequence we detail each pattern. We used a message sequence diagram to show an overall picture of the design patterns.

Itinerary

This pattern provides a way to execute the migration of an agent, which will be responsible for executing a given job in remote hosts. The agent receives an itinerary on the source agency, indicating the sequence of agencies it should visit. Once in an agency, the agent executes its job locally and then continues on its itinerary. After visiting the last agency, the agent returns to its source agency. This pattern is a good solution to agents that need to execute sequential jobs. In Guedes, Machado, and Medeiros (2003) and Medcraft (2003), case studies that apply this pattern are shown.

In Figure 1, we present a possible execution sequence for this pattern. We use a notation that is equivalent to the one presented in Klein, Rausch, Sihling, and Wen (2001). In this notation, an object is used to represent an entity that controls agents' execution in a given agency (creation, destruction, migration) and indicates their location. Migrations are represented by message passing from one agency entity to the other. The message is labeled as MIGRATING AGENT. Before migration, agent execution is interrupted (arrow labeled as destroy()). Execution is continued in the target agency (arrow labeled as initialize()).

As we can see, there are three agencies: a SourceAgency and two search agencies (DestinationAgency1 and DestinationAgency2). Following the diagram, we see that there is an agent (ItineraryAgent) that sets its itinerary, moves to the first search agency where it executes its job, then it moves to the second one, executes the job, and returns to the source agency.

Star-Shaped

On the star-shaped pattern, the agent receives a list of agencies that it has to migrate to. Initially, the agent migrates to

Figure 1. Message sequence chart for Itinerary

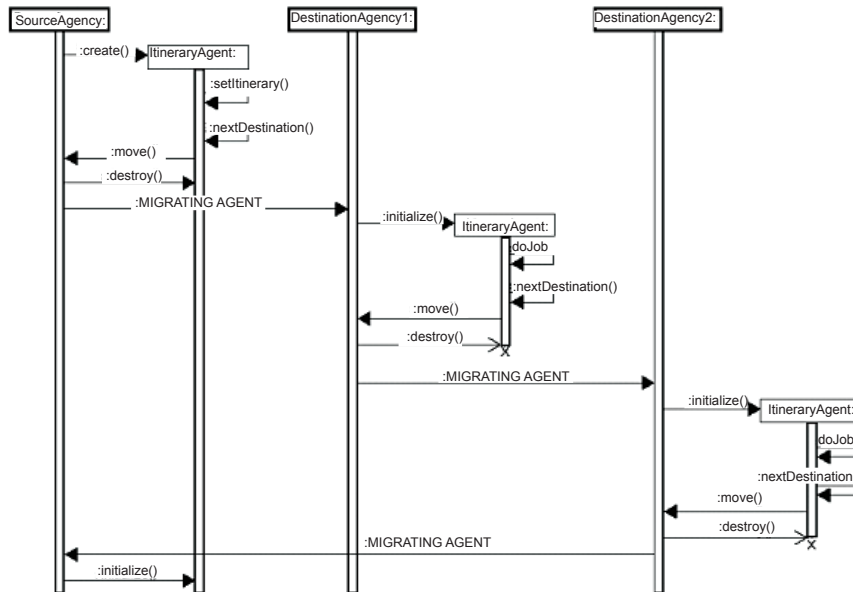

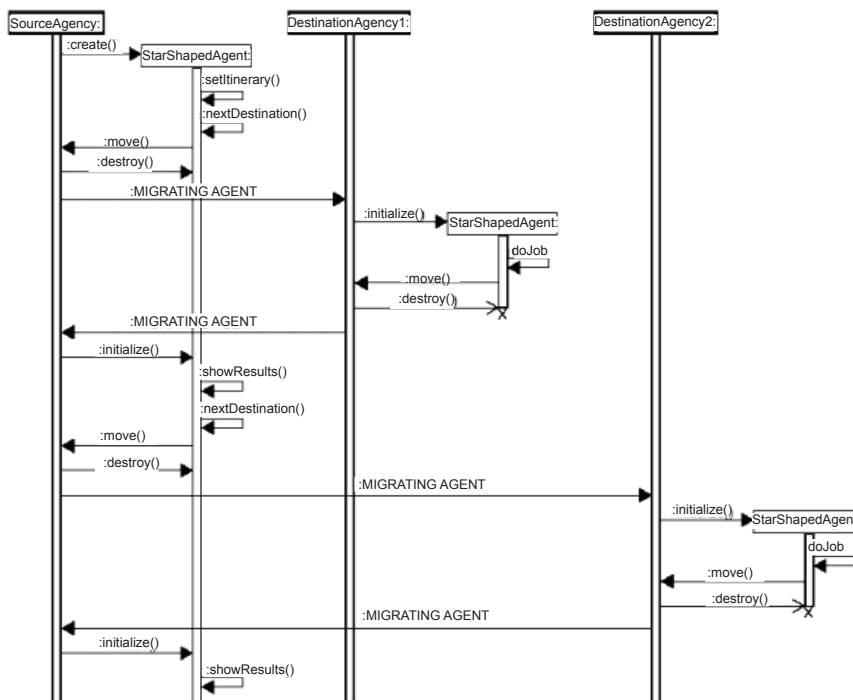

Figure 2. Message sequence chart for Star-Shaped

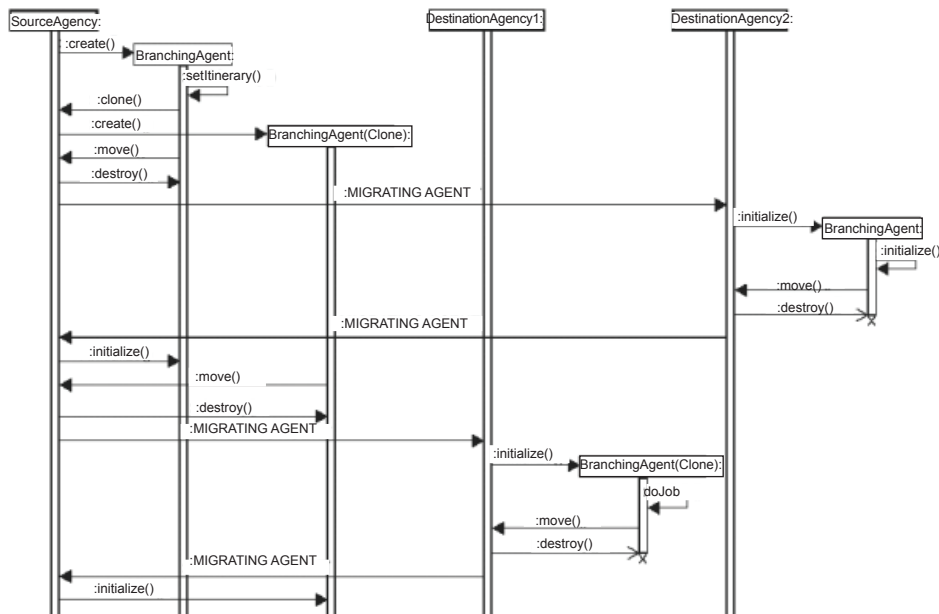

the first destination agency in the list. After migration is completed, it executes the relevant job and resumes migration going back to the source agency. The agent repeats this cycle until the last agency on its list is visited. The advantage of this pattern is that the agent stores the results of its job in the source agency and does not need to migrate to the others' agency with them. Depending on the application, the results can be shown to the user as soon as the agent stores them in the source agency. In this way, the user can

already know the partial results before the agent finishes its migration through all search agencies.

In Figure 2, we can see an execution sequence for the Star-Shaped pattern. In this diagram, we have the same configuration of the sequence diagram shown for the itinerary pattern: three agencies and one agent. Following the diagram, we observe that the agent sets its itinerary and then travels to the first search agency. After executing its job, the agent returns to the source agency, where it stores the job's result.

Figure 3. Message sequence chart for branching

After that, the agent travels to the second search agency, executes its jobs, and returns to the source agency, storing the results obtained.

Branching

In the branching pattern, the agent receives a list of agencies to visit and clones itself according to the numbers of agencies in the defined itinerary. Each clone is assigned an agency from the received list. Each clone has to migrate to its corresponding agency, execute its job, and notify the source agency when the job is completed. The importance of this pattern is that it splits the tasks that can be executed in parallel. The treatment of the final results is an issue not covered by this pattern. For instance, the clones can put the result of the task in a user interface or send it to another agent.

Figure 3 shows an execution sequence for this pattern, in a scenario where there are three agencies and one agent. Following this figure, we can see that the agent sets its itinerary and then clones itself. After that, each agent (the original and the clone) migrates to a search agency, where they execute the job and then return to the source agency.

Petri Nets

A colored Petri net (Jensen, 1992, 1997), or simply CPN, is a formal method with a mathematical base and a graphical notation for the specification and analysis of systems with characteristics such as concurrent, parallel, distributed, asynchronous, timed, among others. For the mathematical definition, the reader can refer to Jensen (1992, 1997). The graphical notation is a bipartite graph with places, repre-

sented as ellipses, and transitions, represented as rectangles. Transitions represent actions, and the marking of the places represents the state of the model. A marking of a place at a given moment is the token present at that place. A token can be a complex data type in CPN/ML language (Christensen & Haagh, 1996). Each place has an associated color set that represents the kind of tokens the place can have. The transitions can have guards and code associated to it. Guard is a Boolean expression that must be true for the transition to fire. Code can be a function that is executed every time the transition fires. Arcs go from places to transitions and from transitions to places, and never from transition to transition or place to place; they can have complicated expressions and function calls associated to them.

For a transition to fire, it is necessary that all input places, that is, places that have arcs that go from the place to the transition, have the number of tokens greater than or equal to the weight of the arc, $w(p,t)$, and the guard of the transition must be true. When these characteristics hold the transition is said to be enabled to fire. An enabled transition can fire at any time and not necessarily immediately. Once a transition fires it removes $w(p_i,t)$ from each input place p_i , and the output places, that is, the places that have arcs from the transition to the place, receive tokens according to the arc expression from the transition to the place: $w(t,p)$.

For a detailed explanation of colored Petri nets, consult Jensen (1992, 1997).

Object-oriented Petri net (RPOO) models consist of a set of classes and their corresponding Petri nets. Classes are described and can be related to each other like UML classes. The Petri nets describe the internal behavior of objects. For each object, there is one Petri net that models it. A variety

of RPOO actions (instantiate objects, call methods, destroy objects, etc.) that can be performed by the objects and actions are depicted by transition inscriptions in the colored Petri nets. An inscription may describe several actions, and all the actions in an inscription are executed atomically. A set of atomically executed actions is called an event.

In RPOO, each object is a thread, and interaction between two objects may be asynchronous. This means that when an object *a* calls a method of (sends a message to) object *b* in asynchronous mode, the system moves to a state where the data passed as parameter will be pending and may be consumed in a further action by object *b*. RPOO actions also include synchronous calls, where messages are sent and consumed atomically.

A set of interconnected objects and its pending messages form a structure of an object system. Besides this structure, an object system also knows what is called imminent actions, that is, actions that may be executed in the current structure. Briefly, an action will be executed, in case of concurrency.

In RPOO, synchronously sent messages are presented by inscriptions like `obj.set(data)`. In other words, the current object is sending a message to `obj` object. To send a synchronous message, the exclamation point `obj!set(data)` is used. To fire a transition when a message has been waiting, there must be an inscription like `obj?set(data)`, denoting that a message is waiting.

For a more detailed explanation of RPOO, consult Guerrero (2002).

FORMAL MODELS AND ANALYSIS OF PATTERNS

Before modeling the patterns, it is necessary to identify all the entities that will be part of the whole model. And it is also necessary to build a diagram class containing these entities and their relationships to each other.

Figure 4 shows the class diagram for this system. There are three types of agents, one for each one of the migration patterns presented in this article: `ItineraryAgent`, `StarShapedAgent`, and `BranchingAgent`. An agent has a list of agencies that represents its destination. At the beginning of the model, the current agent belongs to an agency, the source one. All the relationships change during the execution of the model. The class diagram represents the initial state of the scenario.

RPOO Models

There is no tool for editing RPOO models, so the famous tool set Design/CPN (CPN Group, 1999) is used to edit and analyze such models. Each class is declared using the CPN/ML inscriptions (Christensen & Haagh, 1996).

Figure 4. Class diagram of design patterns

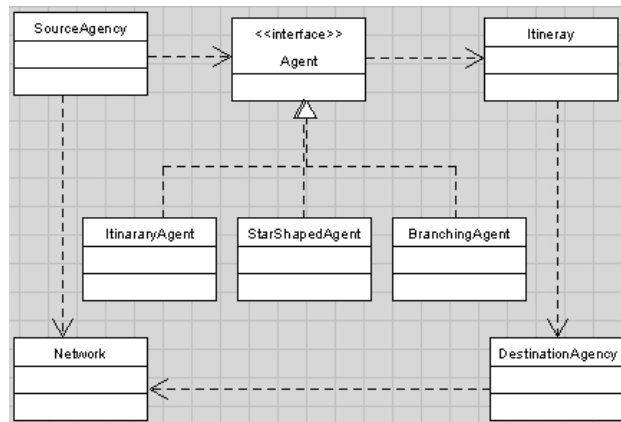

Figure 5 shows the model for the `Itinerary` class. In this model, we see the behavior of the class and its relationship with agent classes that implement agent interface and with `SourceAgency` class.

Figure 6 shows the modeling of the `DestinationAgency` class. There is no complex behavior here; just the initialization of the agent is modeled. This initialization also represents the jobs to be executed locally.

In Figure 7, the `SourceAgency` class is modeled. Its actions, based on its relationships with `itinerary`, `network`, and `BranchingAgent`, are presented.

Figure 8 shows an abstraction of the network (e.g., Internet). It models the network class. Agents and agencies are transmitted through the network. Each agency receives its corresponding agent.

Figure 9 shows the RPOO model for the `ItineraryAgent` class. It models the `Itinerary` migration pattern. The agent goes to every destination agency, it does its local job, and it returns to the source agency.

The `StarShapedAgent` class is modeled by the RPOO net presented in the Figure 10. This model interleaves each destination agency with the source agency. With this, the agent always visits its source agency after it makes a job remotely.

And Figure 11 presents the RPOO model for the `BranchingAgent` class. For each different destination agency, the model shown in Figure 7 makes a clone of this agent. Each one of these clones receives a list of destination agencies containing just one agency. Each one of the clone agents goes to the remote agency, does its job locally, and then returns with the results to the source agency.

Analysis

For each one of the mobile migration patterns presented here, simulations were done using the classical CPN simulator

Figure 5. RPOO model for Itinerary class

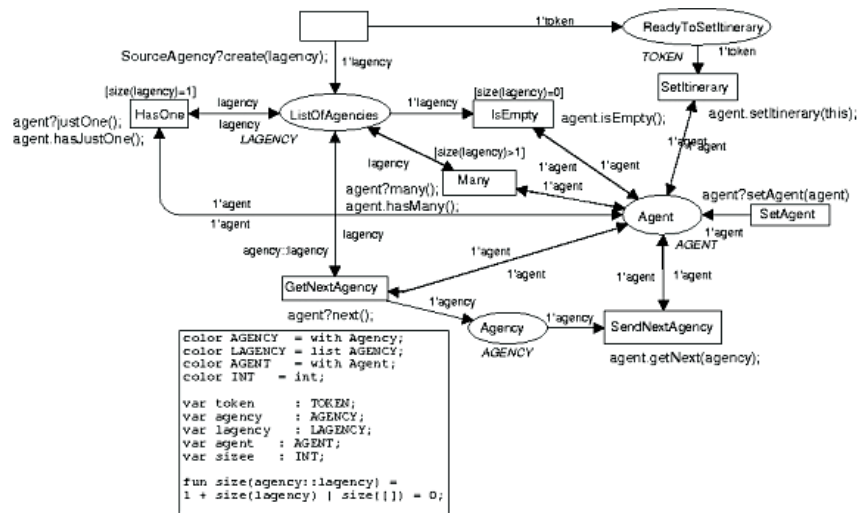

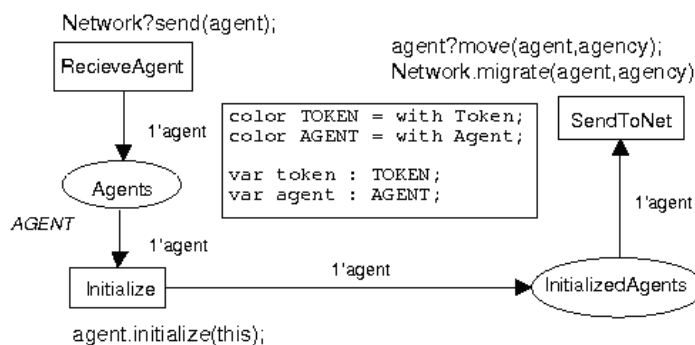

Figure 6. RPOO model for DestinationAgency class

Design/CPN. All the models behaved as expected. However, not all the possible behaviors were analyzed because of restrictions of existent tools. However, the RPOO models presented in this article showed how objected-oriented and mobile systems can be formally modeled and analyzed. To analyze all possible behavior, it is necessary to generate the state space of the formal model, also known as occurrence graph. With this graph and a model checker that supports RPOO model format, it will be possible to reason about some interesting properties described using some temporal logic.

BRIEF COMPARISON WITH CLASSICAL CPN MODELS

The models presented in this article have an object-oriented feature. This feature makes the modeling task easier because the formalism used is semantically closer to the modeled

system. The classical colored Petri nets presented in Lima (2004) and in Lima, Figueiredo, and Guerrero (2004) do not have this feature, which makes the mapping between the Petri net world and the programming language work more difficult.

Due to this object-oriented feature, models can express the system behavior in a separate way. As it was said, each class in the class diagram is modeled in a unique RPOO model. This aspect makes all the modeled systems more organized and easier to be analyzed and studied.

FUTURE TRENDS

One future trend is to use RPOOt (Guerra, 2005; Guerra, Figueiredo, & Guerrero, 2005), or timed RPOO, to analyze the performance of each pattern presented here in some different contexts. With this, it will be possible to say more about them.

Figure 7. RPOO model for SourceAgency class

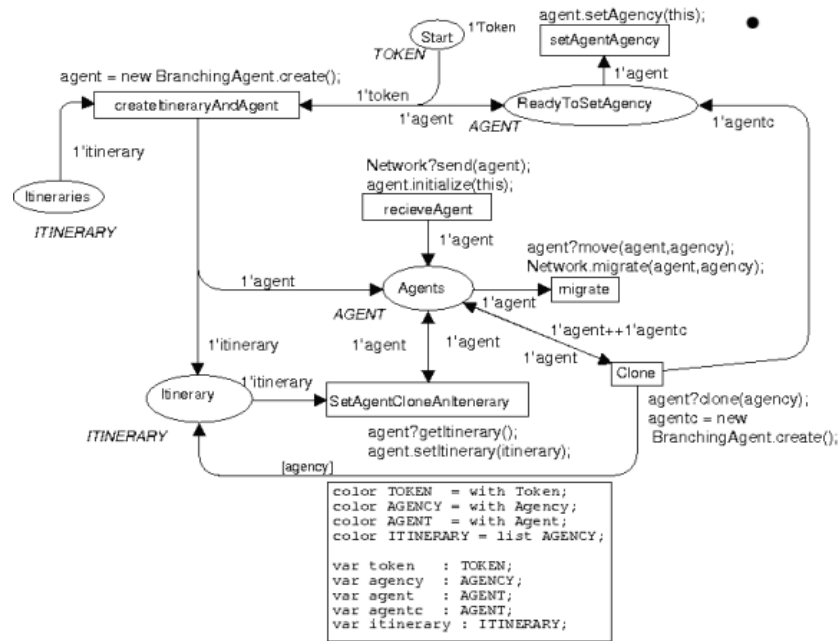

Figure 8. RPOO model for Network class

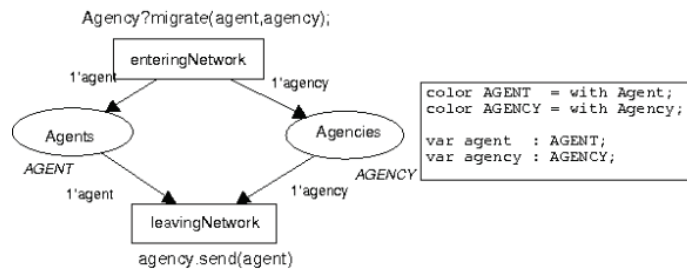

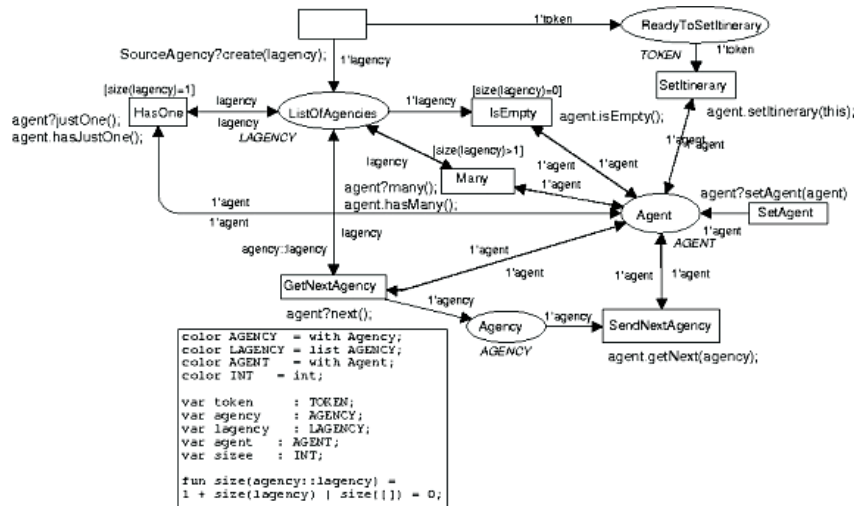

Figure 9. RPOO model for ItineraryAgent class

CONCLUSION

As it can be seen, modeling a system with an object-oriented Petri net is not a trivial task. However, the benefits it brings to the development process is worth the effort. RPOO has an advantage over classical colored Petri nets: their semantics are closer to the programming language paradigm. But it is clear that the absence of a specific tool for editing RPOO models represents a large disadvantage for its usage for verifying and analyzing tasks.

It is clear that RPOO is a good formalism to model mobile systems. Due to its object-oriented feature, the whole model is kept organized. Based on this experiment, RPOO showed to be more interesting in modeling such a mobile system than the classical colored Petri nets. But, a larger experiment is needed to show if this feature is general or if it was just in this specific context.

KEY TERMS

Agent Migration Pattern: A solution for a given problem inside the context of mobile agents.

Computation Tree Logic (CTL): A type of temporal logic in which different futures are considered.

Mobile Agent: A piece of computer software that is able to migrate (move) from one computer to another autonomously and continue its execution on the destination computer.

Object-Oriented Petri Net: A formalism that puts together the Petri net formalism and the object-oriented paradigm. In Portuguese: Redes de Petri Orientadas a Objetos (RPOO).

Verifying Mobile Agent Design Patterns with RPOO

Occurrence Graph: A graph in which each node represents a single possible state of the model.

RPOO (Redes de Petri Orientadas a Objetos): See *Object-Oriented Petri Net*.

RPOOt (Redes de Petri Orientadas a Objetos temporizadas): A timed *Object-Oriented Petri Net*.

Temporal Logic: Term used to describe any system of rules and symbolism for representing, and reasoning about, propositions qualified in terms of time.

V

Virtualization and Mobility in Client and Server Environments

Eduardo Correia

Christchurch Polytechnic Institute of Technology, New Zealand

INTRODUCTION

A great deal of popular software is not designed for mobility (Griffiths, 2004). This is peculiar because many mobile users expect to have easy access to an information infrastructure that links up their mobile phone, laptop, personal digital assistant (PDA), and other devices, while the backend systems of organizations need to be agile, especially as the number, range, and diversity of services and associated technologies grow. Enter virtualization, a technology that has been part of computing for many years, but only fairly recently become mainstream (Intel, 2006; Singh, 2004). It makes use of a virtual machine monitor (VMM), a mechanism that frees up systems from many of the physical constraints of hardware, by adding a software layer that abstracts hardware, so that an entire machine, operating system, applications, and even data can be stored as a set of standard folders and files. While it is well established that this architecture enhances security and reliability (Rosenblum & Garfinkel, 2004), it also enables both users and systems, as this article shows, to be mobile and responsive to change, both in client and server environments.

VMware Workstation, Microsoft Virtual PC, and other virtualization software takes the form of a standard application that can be installed on physical computers. As Figure 1 shows, these applications provide a VMM, which

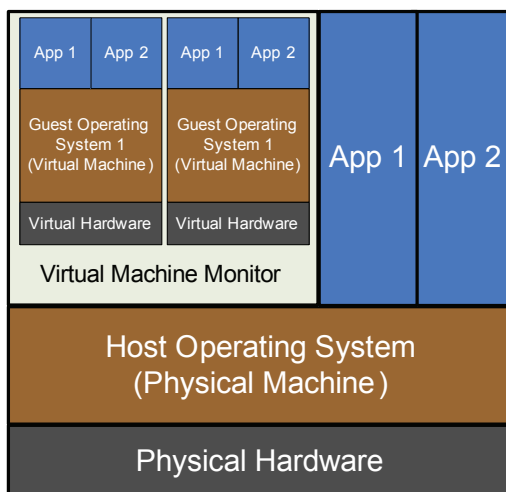

enables one system (the guest) to run within the context of another system (the host). The VMM presents a complete set of virtual hardware to each guest virtual machine (VM) running within this environment. Just as ordinary computers access physical resources, such as memory, processors, hard disks, and network adapters, so too do each of the virtual or guest systems, only their hardware is an instance of a generic abstraction that the VMM generates for each of them. The VMM then mediates various calls made by VMs to access the physical hardware of the host machine. Whereas the standard computer has a single operating system with applications installed to it, a computer with virtualization software runs, in addition, within the VMM one or more operating systems, each with their own applications installed.

MOBILE VIRTUAL MACHINES

While virtual private networks enable users to work from remote locations, as if they are sitting at a machine on the local network to some extent, this approach has certain drawbacks. Users may wish to connect with machines that do not belong to the organization and therefore do not adhere to its policies and standards. Antivirus software may be out of date or updates not installed, for example. One solution is to provide a quarantine area that will allow a machine into the network, but restrict its access to resources until certain criteria have been met. Cisco Systems' Network Admission Control (NAC) and Microsoft's Network Access Protection (NAP) are examples of this kind of solution (Conry-Murray, 2005). Alternatively, network administrators can make use of the VMware Assured Computing Environment (ACE) to produce and deploy secure, fully built virtual machines that apply custom policies and adhere to certain specified standards (Burt, 2004).

The fact that it is in effect the VM that forms part of the network and not the physical machine means that it does not matter to the network administrators that these particular hosts may not have the latest antivirus signature files or applied recent updates, as this underlying (physical) system does not interact with the network and cannot influence it in any way. Naturally, the user's physical machine could fail causing the VM itself to fail, but this will still not affect the network, and restoring the client machine is simply a matter

Figure 1. Virtualization architecture

of copying the ACE VM from removable media, such as DVD or a pen drive (VMware, 2006a). In this way anyone needing temporary access to the network can be given it because perhaps the only way of accessing it using their own machine is through a VM compliant with the standards set by the organization, including exactly which resources can be accessed and the length of time the VM can be used.

SYSTEM AND SESSION MIGRATIONS

When conventional systems need to be moved from one set of hardware to another, the operating system and server applications first need to be installed and then the data, assuming it is on the same system, moved, either by simply copying it or restoring it from a backup. It is not just that this is a time-consuming exercise, but also it often entails having to navigate the complexities of making a system work with significantly different hardware, and its associated drivers and other software. This can cause lengthy outages and make system migrations complex and arduous. Virtual systems, by contrast, always access the same set of physical resources the VMM presents to it, whatever the differences in the actual underlying physical hardware, making them much more mobile than conventional systems. In fact, moving the entire system is simply a matter of copying data from one (physical) machine to another, making VMs highly portable (Wolf & Halter, 2005, p. 481). With Vmotion, systems administrators can even move virtual machines without interrupting service availability (VMware, 2006b), something that has been used with success in live production environments (Rosenkoetter, 2006). This makes it feasible to apply many changes during business hours that would otherwise have been scheduled for weekends or at least when the network is quiet (Cline, 2006).

In such cases virtualization enables easier migration of systems from one set of hardware to another, and significantly reduces the risk associated with such change. This risk is reduced further by the ease with which it is possible to store multiple older versions of virtual systems. Where for instance poor software or problematic devices are installed, virtualization enables administrators to return the machine easily to a selected previous state. This concept can be taken a step further by capturing and virtualizing a client's entire session with an existing server, then migrating to another system that is the same or different, such as from a desktop machine to a PDA (Baratto, Potter, Su, & Nieh, 2004). In fact virtualization can even be used by mobile users to "decouple" a computer into a "body (display, CPU, RAM, I/O) and a soul (session state, software, data, preferences)" so that a user with a portable device can walk up to any computer and resume a session started on another machine (Cáceres, Carter, Narayanaswami, & Raghunath, 2005, p. 65).

CONCLUSION

Virtualization has expanded dramatically in recent years because it is a flexible, scalable technology. It allows powerful hardware to be used more efficiently by distributing the processing, storage, and movement of data among several virtual systems that can still make use of clustering and other conventional forms of load balancing and redundancy. VMware ESX Server and Microsoft Virtual Server for instance make it cost effective to host a single major application per server, so reducing software conflicts and increasing reliability by isolating each of the guest systems, as well as the host from one another while enabling systems administrators to fine tune systems to resident applications. It also makes it easy to retain (copies of) entire systems either for the purposes of disaster recovery or to test future development, perhaps with a view to implementing such changes on production systems.

Virtualization can be utilized in a range of situations in both client and server environments, be it as part of a mission-critical system users connect to; a disaster-recovery infrastructure; a gateway for connecting securely to the network; a deployment of secure, fully built clients that comply with specified standards; or a portable learning environment comprising an entire network of virtual machines that may or may not be connected to virtual and even physical switches, but which can be easily moved from one physical machine to another. It is true that virtualization often demands powerful hardware in order for it to cope with the demands of hosting numerous systems; but with the reduction in the cost of hardware, the use of virtual systems becomes a viable proposition for organizations, especially as they are easier to manage and more agile than conventional systems. It is no wonder then that manufacturers are beginning to produce hardware that is designed with virtualization in mind (Intel, 2006), and that VMware and Virtual PC have become such well-known brands in recent times. According to one survey, respondents expected 45% of new servers deployed this year to make use of virtual machines (IDC, 2005), a trend, it appears, that is set to continue.

KEY TERMS

Application: A program that performs a specific task or related group of tasks and which requires an operating system to run successfully.

Guest: A virtual machine that runs in the context of a virtual machine monitor, which provides for it an abstracted hardware environment. See *Virtual Machine*.

Host: A node on a network that requires an IP address to communicate with other hosts, but in this article refers specifically to a physical computer that runs a virtual machine monitor capable of running one or more virtual machines.

Migration: The movement of operating systems, applications, and data from one computer to another; it can now also include the transfer of a session from one device to another.

Operating System: A general-purpose program that performs many basic tasks such as accepting input from the keyboard or printing output to a screen, as well as mediating access to software and hardware resources.

Virtualization: Partitioning a physical machine into a number of virtual machines, each of which effectively functions the same as a physical machine and can replace a physical machine on a network.

Virtual Machine: A machine much like a physical machine, in that it requires an operating system, can have applications installed, can present itself in exactly the same way as a physical machine on the network, but which functions within the specific abstracted hardware environment of a virtual machine monitor.

Virtual Machine Monitor: An environment created by an application, such as VMware or Virtual PC, with the purpose of enabling one or more virtual machines to run.

Voice Recognition Intelligent Agents Technology

Călin Gurău

Montpellier Business School, France

INTRODUCTION

Mobile computing technology is evolving at a rapid pace. Under the pressure of market demands, the format of mobile devices evolves towards a contradictory situation: on one hand, the handset tends to become smaller, but on the other hand, the users demand increased data search, transmission, and saving capabilities. In order to achieve this, the model of interaction between humans and mobile devices has to evolve from the presently prevalent keyboard-screen system for data input and output towards *voice-recognition intelligent agents* technology.

This article attempts to present the rationale and the advantages of this development, and to analyze the possible problems raised by the introduction of this technology.

The article starts with a presentation of the existing mobile phone technology, outlining its main limitations in terms of functionality, which are logically determined by the way and the context in which mobile phones are normally used. Based on the analysis of the contradictions between the present model of interaction with mobile phones and the requirements of users, the article presents possible solutions to this problem. The study argues that the introduction of voice recognition intelligent agents can enhance significantly the functionality of mobile phones, representing a true revolution in mobile computing. Various practical applications of this technology are briefly presented, as well as the main problems related with its development and implementation.

The article ends with a summary of the arguments discussed and with definitions of the main terms and concepts presented.

BACKGROUND

Mobile phone technology was developed with the aim to provide users with a telephone connection anyplace, anytime. The main innovation that allowed the mass adoption and use of mobile phones was the cellular approach in transmitting a radio signal. Traditionally, people that required frequent communications could install in their car a radio telephone, but the small number of radio channels available in one area limited drastically the number of possible users of this technology. By dividing a large area into small cells,

and each of these cells having a low-power transmitter, the number of communication channels increases significantly, since people that are not located in neighboring cells can use the same frequency to communicate (Layton, Brain, & Tyson, 2005).

The introduction of digital technology (2G) has increased even further the number of communication channels. Finally, 3G technology represents the latest trend in mobile phones standards, offering increased bandwidth and information transfer rates to accommodate Web-based applications and phone-based audio and video files.

However, the use of mobile phones to access Internet applications presents a number of limitations, some of which are related with the specific interface of mobile phones, and others with the existing Web protocols adapted for mobile networks. The screens of mobile phones are small and have a lower resolution in comparison with PC or laptop screens/monitors. On the other hand, the wireless application protocol (WAP) works badly on wireless devices with small screens, and it is dependent on mobile technology's bandwidth (such as GSM or CDMA) for access to information and services (Yeo, & Huang, 2003). Other problems are connected with the Web navigation and site structure, or with the input methods available for mobile phone users (Buchanan et al., 2001).

The future development of mobile services requires a revolution in the technological model applied, which is based on transforming the Web architecture, as well as the usage of mobile devices.

WIRELESS WEB APPLICATIONS FOR MOBILE PHONES

At the moment, the Internet is a network of databases supported by applications that allow users to search, retrieve, and use information contained in computers' memory. However, the rapid increase of online available data makes it more and more difficult for users to find the specific information they need. A trivial search on the Google search engine usually displays a list of a few million more or less relevant Web documents. In this case, the use of a search engine is only the beginning and not the end of searching for particular data,

and this process can indeed be very time consuming, without providing any guarantees for a successful result.

An alternative is to use customized intelligent agents, which can search the Web for clearly defined data. These intelligent agents are usually adapted for a specific type of Web search—for example, they can provide a list of companies that offer online a specific type of product. Strictly speaking, they are not very intelligent, because traditionally, these applications were not able to learn and improve in time their searching capabilities. However, this can be changed. Using neural network technology, and registering a history of operations realized or a particular user, the advanced intelligent agents can progressively learn the preferences of their customers and provide improved results.

Wireless devices such as mobile phones have a number of limitations determined by their specific circumstances of usage. The main advantage of a mobile phone is obviously its mobility, which implies a small size and weight, combined with good usability, in various environment and circumstances. These characteristics limit the size and the resolution of the screen, the size, and the functionality of keypads; the power and memory capacity; as well as the bandwidth. Because of these problems, the mobile phones cannot be used like a PC device, which incorporates autonomous computing capabilities. However, the model of distributed networks and resources can be effectively applied to a mobile phone (Mattern, 2000). In a traditional sense, mobile phones are simple communicating devices, more like interface terminals than personal computers. The solution for their effective use is to create easily accessible networks with distributed resources, and to develop advanced software

applications in order to improve the mobile communication capability (Alesso, & Smith, 2001).

Some of these applications that can significantly improve the interface between the user and the distributed network are based on voice-recognition technology. On the other hand, the nature of mobile devices is adapted to a model of discontinuous, time-limited use; therefore, the user does not have the time himself/herself to browse the Internet in search of relevant information. Even given the required time and stability, the user might prefer the use of an Internet-connected PC or terminal, which offers better interaction and visualization capabilities. This problem can be solved by developing intelligent applications that can work automatically and independently of any human supervision, using the instructions given by the user.

The solution of improved Web services using mobile devices is the combination of voice-recognition technology with the use of intelligent agents (Lai, Mitchell, Viveros, Wood, & Lee, 2002). The mobile phone user will initiate a command by directly speaking with one or more intelligent agents, which then can search for specific information on the Web and announce the results through an SMS message. This type of interaction is presented in Figure 1.

The intelligent agents pass through a succession of phases in order to fulfill their tasks (Rodríguez, Favela, & Muñoz, 2003):

- **Activated:** This represents the main state of the agent, which includes a number of specific sub-states:
 - **Learning:** Represents the initial sub-state of an agent, in which the agent acquires knowledge

Figure 1. The use of voice recognition intelligent agents in mobile phones services

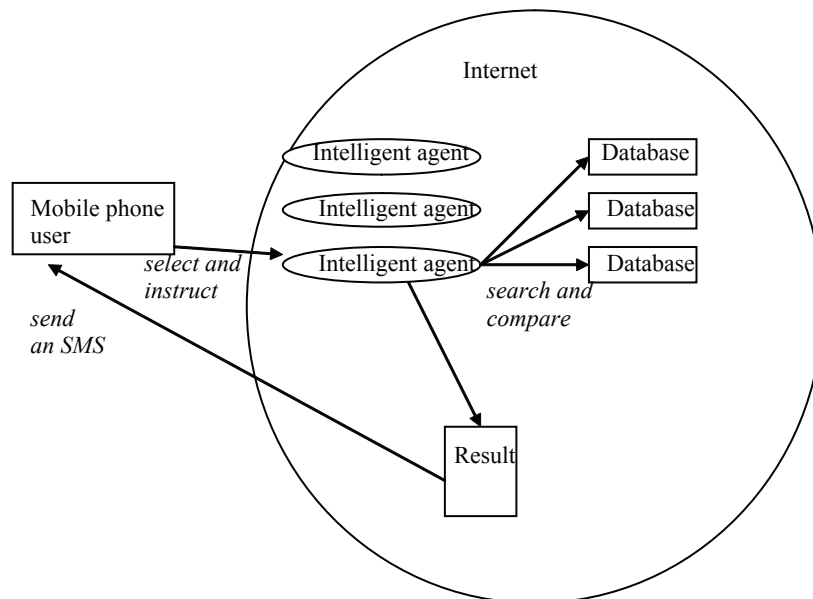

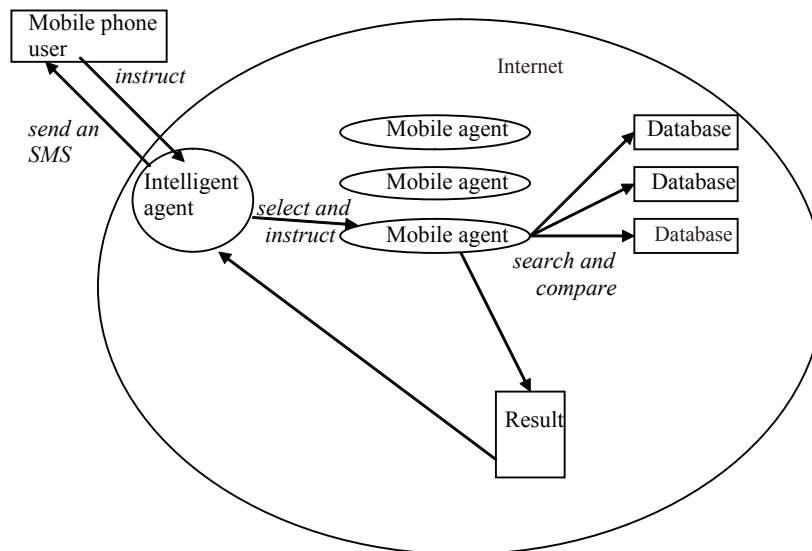

Figure 2. The use of voice recognition intelligent agents and mobile agents in mobile phones services

about its environment in various ways (through direct instructions from the user, a service, or other agents; from a sensor connected with the working environment; or through autonomous learning).

- **Analyzing:** On the basis of the data obtained in the previous sub-state, the agent establishes its goal and the method of fulfilling it.
- **Executing:** The agent performs the action plan established in the previous sub-state.
- **Communicating:** The agent can communicate with the user or with other agents, in order to collect additional information or to presents the results of its task.
- **Suspended:** While it waits for information, the agent can suspend its activity.

However, this model has two major problems:

- For the moment, the intelligent agents active on the Web are strictly specialized for specific tasks. The search for a specific agent can be cumbersome for the mobile phone user in terms of time and interface. In fact, in this case, the search for online information is replaced by the search for the best intelligent agent that can perform the automatic search.
- The size of software applications that correspond to Web intelligent agents is quite significant. If for the classical online navigation this is not a problem, the use of these applications in a mobile phone network—where bandwidth is still limited—can reduce the speed of the entire operation.

A model developed by Kowalczyk et al. (2003) provides a possible solution to these problems. The model includes the use of two different types of agents (see Figure 2):

- **Intelligent Agents:** These are personalized software applications that manage the information search needs of a particular mobile phone user; they are stationary agents that are not able to migrate to other platforms.
- **Mobile Agents:** These are of a smaller size, specialized in specific tasks, active on the Web, and have low demands on network connection, quality, and online time, because after their migration to a new platform or device, the online connection must not be maintained while they are working locally.

This solution is particularly adapted to a distributed network architecture, which represents the most suitable infrastructure for mobile devices; for example, the personalized intelligent agent can be located on the home or office-based PC of the user, the mobile phone representing just a communication device between various elements of this process (Lino, Tate, Siebra, & Chen-Burger, 2003).

Despite its advantages, the large-scale use of voice-recognition agents for mobile phones is likely to develop a number of problems (Wong & Starner, 2001):

1. **Unreliable Voice Recognition:** The voice recognition techniques that are adequate for an office environment might not be feasible in mobile environments, where the voice power is likely to vary and the ambient noises

might deteriorate the quality of sounds (D'Agostino, 2005).

2. **Privacy:** The use of voice-recognition agents on mobile devices raises the problem of privacy of the user, since s/he is transmitting the instructions to the intelligent agent with a loud, clear voice.
3. **Cognitive Load and Attention:** The capacity of the human brain to coordinate multiple tasks is limited, which has to be taken into account considering that often, the users of mobile devices are also engaged in other activities.
4. **Security of Mobile Intelligent Agents:** This is noted by van Eijk, Hamers, Klos, and Bargh (2002) and can be found in various environments.

The possible applications of intelligent agents in mobile and pervasive computing have determined the development of various platforms for developing agent and multi-agent systems. On the other hand, the problems raised by platform compatibility have encouraged the standardization of different systems. The result of these efforts was concretized in two internationally recognized standards (van Eijk et al., 2002): the Foundation for Intelligent Physical Agents (FIPA) and the Object Management Group (OMG). One of the best agent platforms for mobile devices is the JADE/LEAP platform, which was the result of the integration between a project funded by an EU grant for the development of an agent platform implemented in the JAVA software language (JADE), and a project called the Lightweight and Extensible Agent Platform, initiated by a consortium consisting of Motorola, ADAC, BT, Broadcom Eireann Research, Telecom Italia Lab, University of Parma, and Siemens.

FUTURE TRENDS

These models of mobile phone Web services are still in the development stage. However, the missing elements of the process are gradually developed and integrated in systems with multiple applications. At the basis of this model is the concept of the Semantic Web. The Semantic Web is an extension of the current Web in which information is given well-defined meaning, better enabling computers and people to work in cooperation. It is based on the idea of having data on the Web defined and linked such that it can be used for more effective discovery, automation, integration, and reuse across various applications (Hendler, Berners-Lee, & Miller, 2002).

Semantic Web services can be used, among others, for intelligent mobile construction collaborations (Aziz, Anumba, Ruikar, Carrillo, & Bouchlaghem, 2004), participation in Web site auctions (Kowalczyk et al., 2003), and banking services or real estate transactions (Clareity, 2004).

CONCLUSION

This article has attempted to provide a general overview of the main problems in mobile communication and computing, and has presented a possible solution through the application of voice-recognition intelligent agents to small mobile devices.

The future of mobile intelligent agents based on voice-recognition technology is full of opportunities. Various public and private organizations are already developing the various elements of this system. However, the successful implementation of these applications has to take into account the following issues:

1. The use of mobile intelligent agents requires a completely restructured Internet system, which defines and links various information and databases using the semantic model.
2. The applicability of intelligent agents to small mobile devices depends on the implementation of pervasive computing environments, with networks of distributed resources in terms of memory, databases, services, and applications.
3. The capacity of mobile intelligent agents to migrate among various platform raises issues of compatibility and security.
4. The use of voice-recognition technology also creates challenges at social, ethical, and moral levels (e.g., the use of voice-recognition systems in social environments or personal privacy issues).

These problems require an answer that can integrate the informational, technological, social, and personal levels before the mobile intelligent agents and voice-recognition technology will become widespread commercial applications.

KEY TERMS

Bandwidth: The amount of data that can be transmitted in a fixed amount of time. For digital devices, the bandwidth is usually expressed in bits per second or bytes per second. For analog devices, the bandwidth is expressed in cycles per second, or Hertz (Hz).

Code-Division Multiple Access (CDMA): A digital cellular technology that uses spread-spectrum techniques. Unlike competing systems, such as GSM, CDMA does not assign a specific frequency to each user; instead, every channel uses the full available spectrum.

Distributed Network: A network structure in which the network resources, such as switching equipment and processors, are distributed throughout the geographical area being served.

Global System for Mobile Communications (GSM): One of the leading digital cellular systems. GSM uses narrowband Time Division Multiple Access technology, which allows eight simultaneous calls on the same radio frequency.

Neural Network: An interconnected collection of simple processing elements, units, or nodes whose functionality is loosely based on the animal brain. The processing ability of the network is stored in the inter-unit connection strengths, or weights, obtained by a process of adaptation to, or learning from, a set of training patterns. Neural nets are used in bioinformatics to map data and make predictions.

3G: Third generation of mobile communications technology. 3G provides increased bandwidth up to 384 Kbps when a device is stationary or moving at pedestrian speed, 128 Kbps in a car, and 2 Mbps in fixed applications. 3G works over wireless air interfaces such as GSM or CDMA.

2G: Second-generation wireless service, also known as personal communications services. Refers to digital voice cell phone systems deployed in the 1990s. Delivers both voice and data transmissions using switched technology where each call requires its own cell channel.

Wireless Application Protocol (WAP): A standard protocol for providing cellular phones, pagers, and other handheld devices with secure access to e-mail and text-based Web pages. WAP provides a complete environment for wireless applications that includes a wireless counterpart of TCP/IP and a framework for telephony integration such as call control and phonebook access.

The Wi-INET Model for Achieving M-Health Success

Nilmini Wickramasinghe

Illinois Institute of Technology, USA

Steve Goldberg

INET International Inc., Canada

INTRODUCTION

Medical science has made revolutionary changes in the past decades. Contemporaneously however, healthcare has made incremental changes at best. The growing discrepancy between the revolutionary changes in medicine and the minimal changes in healthcare processes is leading to inefficient and ineffective healthcare delivery—one, if not *the*, significant contributor to the exponentially increasing costs plaguing healthcare globally. Healthcare organizations can respond to these challenges by focusing on three key solution strategies: access, quality, and value. These three components are interconnected such that they continually impact on the other, and all are necessary to meet the key challenges facing healthcare organizations today.

The application of mobile commerce to healthcare—namely, m-health—appears to offer a way for healthcare delivery to revolutionize itself and simultaneously address the critical areas of access, quality, and value. Integral to such an approach is the need for a robust wireless model. We propose the Wi-INET (wireless Internet, intranet, extranet) model as the way to deliver m-health excellence.

BACKGROUND

Currently the healthcare industry in the United States as well as globally is contending with relentless pressures to lower costs while maintaining and increasing the quality of service in a challenging environment. It is useful to think of the major challenges facing today's healthcare organizations in terms of the categories of demographics, technology, and finance. Demographic challenges are reflected by longer life expectancy and an aging population; technology challenges include incorporating advances that keep people younger and healthier; and finance challenges are exacerbated by the escalating costs of treating everyone with the latest technologies. Healthcare organizations can respond to these challenges by focusing on three key solution strategies: (1) *access*—caring for anyone, anytime, anywhere; (2) *quality*—offering world-class care and establishing integrated

information repositories; and (3) *value*—providing effective and efficient healthcare delivery. These three components are interconnected such that they continually impact on the other and all are necessary to meet the key challenges facing healthcare organizations today. In short then, the healthcare industry is finding itself in a state of turbulence and flux (National Coalition on Healthcare, 2004; Pallarito, 1996; European Institute of Medicine, 2003; WHO, 2000, 2004; Wickramasinghe & Silvers, 2003). Such an environment, is definitely well suited for a paradigm shift with respect to healthcare delivery (von Lubitz & Wickramasinghe, 2005). Many experts within the healthcare field area agree that m-health appears to offer solutions for healthcare delivery and management that serve to maximize the value proposition for healthcare. However, to date, little if anything has been written regarding how to achieve excellence in m-health, nor does there exist any useful model for framing m-health delivery.

MAIN THRUST: INTEGRATIVE MODEL FOR M-HEALTH

Successful m-health projects require a consideration of many components. Figure 1 provides an integrative model for all key factors that we have identified through our research that are necessary in order to achieve m-health excellence (Wickramasinghe et al., 2005; Goldberg et al., 2002a, 2002b, 2002c, 2002d, 2002e; Wickramasinghe & Goldberg, 2004). What makes this model unique and most beneficial is its focus on enabling and supporting all areas necessary for the actualization of information and communication technology initiatives in healthcare. By design, the model identifies the inputs necessary to bring an innovative chronic disease management solution to market. These solutions are developed and implemented through a physician-led mobile e-health project. This project is the heart of the model to bridge the needs and requirements of many different players into a final (output) deliverable, a “Wireless Healthcare Program.” To accomplish this, the model is continually updated to identify, select, and prioritize the ICT project inputs that will:

The Wi-INET Model for Achieving M-Health Success

- Accelerate healthcare system enhancements and achieve rapid healthcare benefits. The model identifies the key healthcare system inputs with the four Ps: **people** that deliver healthcare, **process** to define the current healthcare delivery tasks, **platform** used in the healthcare technology infrastructure, and **protection** of patient data.
- Close the timing gaps between information research studies and its application in healthcare operational settings.
- Shorten the time cycle to fund an ICT project and receiving a return on the investment.

IT Architecture and Standard Mobile Environment

By adopting a mobile/wireless healthcare delivery solution, it is possible to achieve rapid healthcare delivery improvements, which impact both the costs and the quality of healthcare delivery. This is achieved by using an e-business acceleration project which provides hospitals a way to achieve desired results within a standardized mobile Internet (wireless) environment. Integral to such an accelerated project is the ability to build on the existing infrastructure of the hospital. This then leads to what we call the three-tier Web-based architecture (see Figure 2).

In such an environment, Tier-1 is essentially the presentation layer; which contains the Web browser, but no patient

data is stored within this layer, thereby ensuring compliance with international security standards/policies like HIPAA. Tier-2, shown as the HTTP Server, provides the business logic including but not limited to lab, radiology, and clinical transcription applications; messaging of HL7, XML, DICOM, and other data protocols; and interface engines to a hospital information system (HIS), lab information systems (LIS), radiology information systems (RIS), as well as external messaging systems such as Smart Systems for Health (an Ontario healthcare IT infrastructure project). This latter messaging feature may also be included in the third tier, which consists of the back-end database servers like Oracle, MySQL, or Sybase.

Mapping Case Study to Model

During the past six years, INET has used an e-business acceleration project to increase information and communication technology (ICT) project successes (Goldberg et al., 2002a, 2002b, 2002c, 2002d, 2002e). Today INET is repurposing the e-business acceleration project into a mobile e-health project to apply, enhance, and validate the mobile e-health project delivery model. Such a model provides a robust structure, and in turn serves to ensure excellence in the m-health initiative. INET's data provides the perfect opportunity to examine the components of our model (Figure 1), as it is both rich and longitudinal in nature. In mapping the data and specific business case, we have drawn upon many well-recognized

Figure 1. Wi-INET business model

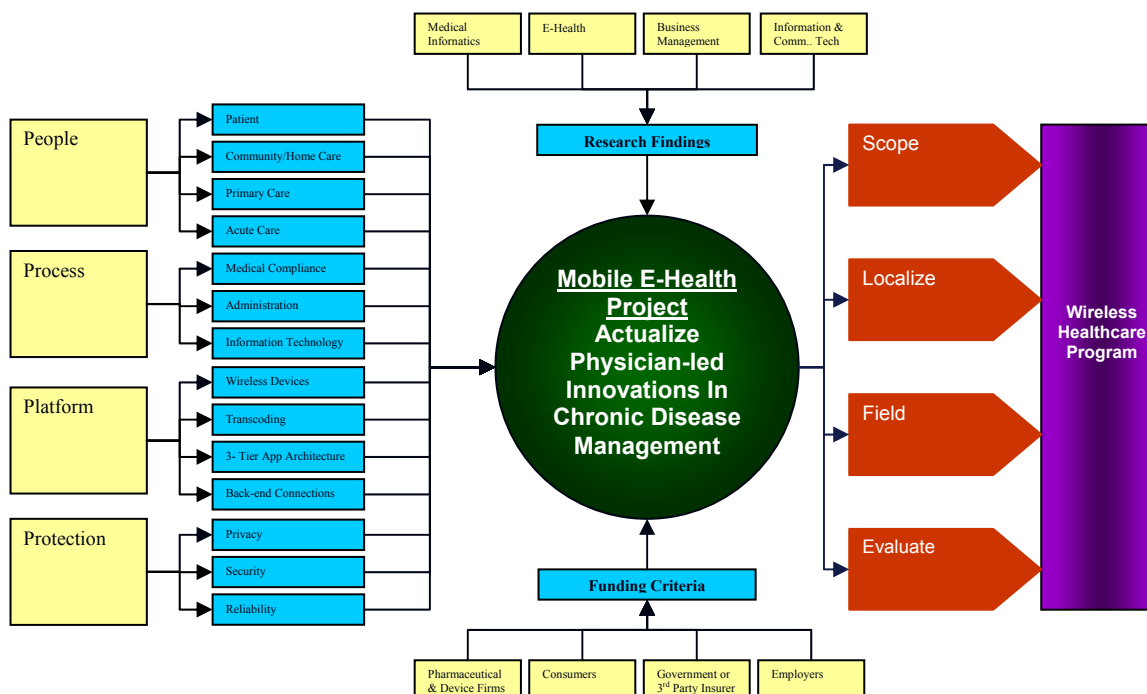

Figure 2. Three-tier Web-based architecture

qualitative techniques, including conducting both structured and unstructured interviews, in-depth archival analysis, and numerous site visits.

Goldberg et al. (2002a, 2002b, 2002c, 2002d, 2002e) capture and substantiate the findings discussed, while Kavale (1996), Boyatzis (1998), and Einhardt (1989) detail the importance and richness of the methodologies we have adopted in presenting the following findings. Key criteria were established from the Standish Group International (1994) and the Institute of Medicine in America (2001).

The INET Mobile E-Health project objectives include:

1. Accelerate consensus building with an e-health solution that is focused on a disease state and driven by the medical model, with the primary objective to streamline communications and information exchange between patients, and providers of community/home care, primary care, and acute care.
2. Acquire commercial funding early with a compelling business case. For instance, enhancing therapeutic compliance can improve patient quality of life with significant healthcare cost savings. It is well documented that in diabetes, this will have immediate and high impact-benefits for healthcare consumers, pharmaceutical firms, governments, insurers, and employers.
3. Avoid risk by reengineering large-scale healthcare delivery processes in small manageable pieces. Today, organizations can harness a rigorous method to incrementally enhance a process one step at a time. This is a way to achieve quick wins early and frequently.
4. Rapid development of simple-to-use, low-cost, and private/secure information and communication technology solutions. Achieve these benefits through a wireless application service provider (ASP). In addition to rapid development, a wireless ASP can easily connect and bring together many independent healthcare information systems and technology projects.

To actualize the mobile e-health project, INET is looking to the Wi-INET model as a framework. For INET, this will

support an INET Mobile E-Health Project Management Office (PMO) to manage the costs and quality, deliver many small projects, and replicate projects for local and international distribution. As a first case scenario for the model, INET is proposing an INET Wireless Diabetes Program, with leadership from a family physician. The INET PMO is provisioning a project manager to support this physician-led project to meet both research and commercial sponsors' interests and objectives in diabetes. A detailed description of the key attributes of the INET Wireless Diabetes Program includes:

Problem Statement

There are many communication and information exchange bottlenecks between patients and their family physicians that prevent the effective treatment of diabetes. As background, a fundamental problem today is the ability to have a private and secure way to manage, search, and retrieve information at the point-of-care. In diabetes, physicians cannot quickly and easily respond to patients with high glucose levels. They need to wait for people to come to the office, respond to phone calls, reply using traditional mail delivery, or never receive the patient information.

Solution Mandate

Implement a diabetes monitoring program to enhance therapeutic compliance, such as release a program to enhance the usage of oral hypoglycemic agents (drugs) and/or the usage of blood sugar monitoring devices.

As background, everyone wins when enhancing patients' ability to follow instructions in taking prescribed medication. The patient's health, safety, and quality of life improve with significant healthcare cost savings. However, it is well documented that many patients do not stay on treatments prescribed by physicians.¹ This is where wireless technology may have the greatest impact to enhance compliance.

One solution may be as simple as using a cell phone and installing a secure wireless application for patients to

Table 1. INET wireless diabetes program results

| INET Wireless Diabetes Program | | | |
|--------------------------------|-----------------------|------------|---------------------|
| Patient | Change in HA1C Levels | | % reduction in HA1C |
| | Pre-Pilot | Post-Pilot | |
| 1 | 0.082 | 0.069 | -16% |
| 2 | 0.090 | 0.071 | -21% |
| 3 | 0.108 | 0.050 | -54% |
| 4 | 0.113 | 0.084 | -26% |

monitor glucose levels, and provisioning a physician to use a PDA (connected to a wireless network) to confidentially access, evaluate, and act on the patient’s data.

Business Case

In Ontario the cost savings may represent almost \$1 billion over three years. INET uses a simple calculation to determine the \$1 billion savings. This can be found at www.inet-international.com; please select the INET mobile e-health project section to review the calculations.

The business case can be backed with additional data on how the cost of prevention (drugs) is far less than the cost savings associated with reducing the risk of complications associated with diabetes. For instance, the impact of a 1% decrease in A1C is significant. More data is available to support the business case for the prevention of type 2 diabetes such as lowering the incidence of End Stage Renal Disease (ESRD).

In summary, there is plenty of data today to quickly build consensus, fund, and implement a national and international wireless diabetes program to enhance patients’ quality of life with significant healthcare cost reductions—that is, meet the objectives of access, quality, and value.

Systems Development Lifecycle Project Delivery

Use an INET mobile e-health project to scope, localize, field, and evaluate an INET wireless diabetes program led by a physician. Each project can easily and simply customize a program to quickly meet the unique needs of a rural and urban healthcare delivery setting, age, ethnicity, income, language, and culture. These are small manageable projects. Each project collects data on patient/healthcare provider relationships, wireless medical informatics, therapeutic compliance business case, and ICT usability to accelerate acceptance of a wireless diabetes program using wireless technology. The program may include cellular network and application usage, support, healthcare provider PDA, and

consulting fees for a family physician and other healthcare providers. However, it is expected that the costs may not include items such as consumer cell phone, medication, or blood sugar monitoring devices/supplies. It is recommended that commercial and/or research sponsors pay for an INET project and help subsidize the user costs.

In June 2005, INET applied the Wi-INET model to pilot a wireless diabetes program with the objective to decrease diabetes-related complications with better control of glycemic levels, measured by HA1C.

The core component of the program is the relationship between family physicians and patients supported by a wireless diabetes management protocol.² This protocol describes how a patient can enter his or her glucose readings into a cell phone and transmit the results to his or her family physician. The protocol further details how the physician, in turn, is able to monitor any number of patients on his or her PDA, such as a Palm Treo or RIM Blackberry device. A physician, if required, can take immediate action with a message electronically sent to the patient’s cell phone. The program was tested through a pilot project with four patients and led by Dr. Sheldon Silver, and was completed in July 2005. The pilot project lasted approximately three months. The preliminary results are significant as shown in Table 1.

In summary, INETs research data indicates that using the Wi-INET model will increase ICT project success in healthcare. To realize and test this, INET continues to map the player’s from an INET wireless diabetes program (use case scenario) to the model. To show how this works, please review the mapping exercise below. The bold text in black is a project player and the color text in [] parenthesis relates to the sections of the model presented in Figure 1.

Physician Mobile E-Health Project Lead: [“Mobile E-Health Project” in Figure 1]. Physicians provide the linkage to the medical model to enhance disease management programs to enhance patient care and safety, improve research and education, increase healthcare quality, and reduce healthcare costs. For INET’s use case scenario, the final outcome is a Wireless Diabetes Program [“Wireless Healthcare Program” in Figure 1]. And the mobile e-health projects are led by Dr. Sheldon Silver, MD, Staff Physician, Credit Valley Hospital.

Commercial Sponsor(s) [“Funding Criteria” in Figure 1]. The project delivers information and communication solutions for:

- Consumers wishing to improve their quality of life with an enhanced relationship with their healthcare provider’s—that is, family physicians.
- Pharmaceutical firms looking to increase revenues with e-compliance programs.
- Government/insurers investigating ways to significantly reduce administration and healthcare costs, and shorten healthcare delivery time cycles (wait times.)

- Employers wanting to increase productivity and avoid absenteeism with a healthier workforce.

Research Sponsor(s) [“Research Findings” in Figure 1]: The project develops intellectual property for researchers in the fields of:

- Patient and Healthcare Provider Relationships
- Wireless Medical Informatics
- Therapeutic Compliance Business Case
- Wireless Information Technology Usability

An INET Mobile E-Health Project Delivery Team:

Healthcare Delivery Team [“People” in Figure 1]: For a wireless diabetes program the players may include:

- Healthcare Consumer: People with Diabetes
- Community Care: Nurse Specializing in Diabetes
- Primary Care: Family Physician
- Acute Care: Endocrinologist and Diabetes Education/Management Centers

Business Process Analyst [“Process” in Figure 1]

Privacy and Security Consultant [“Protection” in Figure 1]:

Programmer using a wireless ASP [“Platform” in Figure 1]:

- Wireless Network and Devices
- Device and Application Transcoding
- Application Service Provider
- Back-End Connection

In conclusion, INET is looking forward to further advancements in the mobile e-health project delivery model to:

- achieve rapid advancements in healthcare delivery,
- improve diabetes management,
- enhance therapeutic compliance, and
- realize significant healthcare care cost savings.³

INET is planning to continue its role as a source of use case scenarios for the model with the delivery of mobile e-health projects.

FUTURE TRENDS AND CRITICAL SUCCESS FACTORS

INET’s experience and preliminary findings are pointing to one critical success factor—the commercialization of physi-

cians’ innovations in chronic disease management. INET is expecting significant growth in this healthcare trend, with wireless technology as the fundamental enabler. With antidotal comments from patients that participated in the INET pilot project are testimonials to this new era in healthcare delivery. A few of their comments (*Canadian Healthcare Technology*, 2005) include:

“All I had to do was pick up my phone and dial, punch in my ID, put in the number for my blood sugar level, and hit enter. That was it. Did it twice a day,” said patient Jim Pott at the INET conference. “It gave me the feeling of constantly being looked after because, if I forgot to do it, Dr. Silver would be on my case, sending a text message to remind me.” For patient Dave Rowan: “I’m in the computer industry, so using an input device like my Treo phone is something I am very used to. Even so, to have it confirmed that my information was received and have subsequent interaction with Dr. Silver was terrific. And I could do it from all over North America.” For Joy Merritt, the trial has been life transforming. “Dr. Silver saved my life with this system. I felt totally out of control before. But now I feel I can control my life. And because I see my levels every day, and I know the doctor does too, that’s motivated me to exercise more and try to bring them down.”

The preceding has served to outline all the critical aspects that must be considered when trying to actualize a mobile health initiative. Clearly, mobile e-health or m-health projects are complex and require much planning and coordination within and between the web of healthcare players. Success is never guaranteed in any large initiative, however in order to realize the four major healthcare deliverables depicted in Figure 1 (enhance patient care and safety, improve research and education, increase healthcare quality, and reduce healthcare costs), it is vital that any m-health initiative focus on the key success factors of people process and technology. Specifically, the technology must be correct and functioning as desired. Further, it must integrate seamlessly with existing ICT infrastructure and enable the processes. The processes must be well defined and at all times ensure that they are of a high quality and error free.

The Institute of Medicine in America (2001) identified medical errors as the fourth leading cause of many deaths. In trying to prevent such errors, it has identified six key quality aims:

1. **Healthcare Should be Safe:** Avoiding injuries to patients from the care that is intended to help them.
2. **Healthcare Should be Effective:** Providing services based on scientific knowledge to all who could benefit, and refraining from providing services to those who will not benefit (i.e., avoiding under use and overuse).
3. **Healthcare Should be Patient-Centered:** Providing care that is respectful of and responsive to individual

- patient preferences, needs, and values, and ensuring that patient values guide all clinical decisions.
4. **Healthcare Should be Timely:** Reducing waiting and sometimes harmful delays for both those receiving care and those who give care.
 5. **Healthcare Should be Efficient:** Avoiding waste.
 6. **Healthcare Should be Equitable:** Providing care that does not vary in quality based on personal characteristics.

Finally, and arguably the most critical key success factor, is the web of healthcare players. Any m-health project must consider the impact and role on each of these players, the interactions of such an initiative both within one group of the web of players as well as between groups of players. As discussed, and based on the findings from INETs longitudinal studies, it is critical to the ultimate success of these projects and the ability to in fact realize the healthcare deliverables that they are indeed physician led.

DISCUSSION AND CONCLUSION

Healthcare in the United States and globally is at the crossroads. It is facing numerous challenges in terms of demographics, technology, and finance. The healthcare industry is responding by trying to address the key areas of access, quality, and value. M-health, or mobile e-health, provides a tremendous opportunity for healthcare to make the necessary evolutionary steps in order to realize its goals and truly achieve its value proposition. What is important is to ensure m-health excellence. This requires not only detailed theoretically studies, but ultimately the need to turn theory into practice. By an in-depth analysis of the rich and longitudinal data of INET, we have developed the Wi-INET model to facilitate the achievement of m-health excellence. Systematic and detailed analysis and integration of all the key drivers and implication of healthcare delivery have enabled the development of the Wi-INET model. Moreover its structure facilitates rapid development and actualization of m-health solutions. To the best of our knowledge, it is the first such model, and while it is certainly not a panacea, it does help to set the stage and outline the key issues that must be addressed for a successful m-health initiative, and it enables healthcare to reap the benefits of wireless. We are confident that through the adoption of the Wi-INET model, healthcare delivery too can make revolutionary changes and we can all enjoy superior healthcare delivery.

KEY TERMS

Healthcare Challenge: One of the challenges that can be thought of in terms of demographic issues such as the aging population, technology issues such as the need to embrace technologies into healthcare, and finance issues such as escalating healthcare costs.

Key Healthcare System Input: Includes people, process, platform, and protection.

M-Health: The application of wireless technology to healthcare delivery.

Mobile Healthcare Business Model: A model to identify all the key drivers and actors for a mobile healthcare initiative.

Mobile Healthcare Delivery Model: A model that outlines the process and procedures to realize the outlined business model.

Superior Healthcare Delivery: A patient-centric healthcare delivery system that tries to maximize access, quality, and value.

Three-Tier Web-Based Architecture: ICT backbone of the wireless m-health initiative.

Wireless Healthcare Program: The incorporation of wireless technology into a specific healthcare program, for example, the use of wireless technology in a diabetes program.

ENDNOTES

¹ Fourteen percent to 21% of patients never fill their original prescription, and 10% to 50% of patients ignore or otherwise compromise their medication instructions (<http://www.managedhealthcareexecutive.com/mhe/article/articleDetail.jsp?id=105388>).

INTRODUCTION

Security is one of the world's main challenges. Research and industrial applications related to security include several areas such as personal security, organizational security, and computer security, among others. This article is concerned with secure environments, which is related to the control of people entering an environment, building, rooms, laboratories, and so forth. In this context, access control systems are the main security mechanisms to control the access of authorized people to environments.

Nowadays, locks and keys are not enough to keep an environment secure against unwanted or uncontrolled visitors. To have access, mechanical security systems are widely used, however, such systems—purely mechanical—can be easily defrauded. To construct high-security access systems, the embedded electronics have associated to the mechanical security, with the objective of increasing the level of reliability of such systems. Besides, with the increasing use of mobile devices, users are more and more interested in mobile solutions to support several activities, including security-related ones.

This article presents an access control system that uses Bluetooth technology (Ericsson Bluetooth, 2006) to allow control of the entrance to environments. By using the proposed system, a person with a smart phone can use it to get access to environments, such as buildings, labs, rooms, and so forth.

The remainder of this article is organized as follows. First we present the architectural components of the proposed system and detail their functioning. We then discuss future trends and offer concluding remarks.

BACKGROUND

Bluetooth

The Bluetooth specification was developed by Ericsson (now Sony Ericsson) and later formalized by the Bluetooth Special Interest Group (SIG). The SIG was formally announced on May 20, 1999, and originally founded by Ericsson, IBM, Intel, Nokia, and Toshiba.

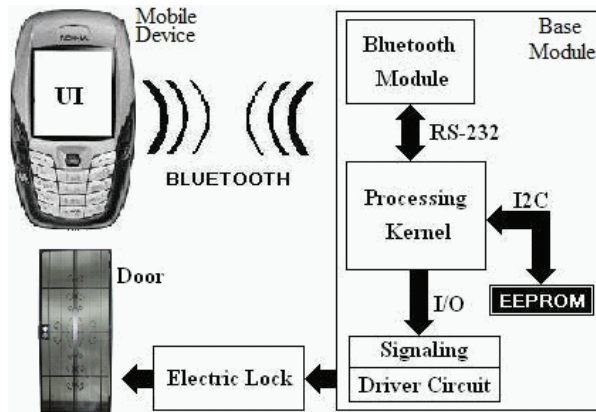

Bluetooth is an industrial standard for wireless personal area networks (PANs), also known as IEEE 802.15.1 (Bluetooth SIG, 2004). It provides a secure, low-cost way to connect and exchange information between devices, such as personal digital assistants (PDAs), mobile phones, laptops, PCs, printers, and digital cameras, in a globally available short-range radio frequency. This technology eliminates cables and wires between devices, facilitates both data and voice communication, and enables ad-hoc networks between multiple Bluetooth devices (Cardei, 2002).

Bluetooth is a radio standard primarily designed for low power consumption, with a short range (power class dependent: 1 meter, 10 meters, 100 meters) and with a low-cost transceiver microchip in each device. It lets these devices communicate with each other when they come in range, even if they are not in the same room, as long as they are within up to 100 meters of each other, depending on the power class of the product (Kardach, 1998).

Microcontrollers

A microcontroller (MCU) is a computer-on-a-chip used to control electronic devices. It is a microprocessor emphasis-

Figure 1. Wireless access control system architecture

ing self-sufficiency and cost-effectiveness, in contrast to a general-purpose microprocessor used in a PC. It can be defined as a single integrated circuit with a central processing unit, usually small and simple; input/output interfaces, such as serial ports; peripherals, such as timers and watchdog circuits; RAM for data storage; ROM for program storage; and a clock generator, often an oscillator for a quartz timing crystal, resonator, or RC circuit (Stewart, 1993).

In addition to the key features, most microcontrollers today take further advantage of not needing external pins for memory buses. They can afford to use the Harvard architecture: separate memory buses for instructions and data, allowing multiple access to occur concurrently (Cady, 1997).

A typical microcontroller contains all memory and interfaces needed for a simple application, whereas a general purpose microprocessor requires additional chips to provide these functions. Microcontrollers also usually have a variety of input/output interfaces. Serial I/O (UART) is very common, and many include analog-to-digital converters, timers, or specialized serial communications interfaces like I²C, serial peripheral interface (SPI), and controller area network (CAN).

A microcontroller is also a programmable device that can be destined for several purposes. The firmware recorded in its memory is responsible for the characteristic of its application. Microcontrollers are versatile tools and with low cost for embedded systems design.

Originally, microcontrollers were only programmed in assembly language, or later in C code. Recent microcontrollers, integrated with on-chip debug circuitry accessed by in-circuit emulator via JTAG, enable a programmer to debug the software of an embedded system with a debugger (Cady, 1997).

Microcontrollers trade speed and flexibility against ease of equipment design and low cost. This integration drastically

reduces the number of chips and the amount of wiring and space that would be needed to produce equivalent systems using separate chips. Manufacturers and designers have to balance the need to minimize the chip size against additional functionality.

SYSTEM ARCHITECTURE

The access control system architecture depicted in Figure 1 consists of two modules: mobile and base. A smart phone contains the software responsible for beginning the authentication process, acting as mobile module. The base module is responsible to receive a valid authentication code and to allow the access to the environment by unlocking an electric lock embedded in the environment entrance door.

The base module is composed of a Bluetooth module (Wintec BT Module, 2005); a processing kernel, represented by a microcontroller (Microchip PIC18FXX2, 2002); an external data storage unit, represented by an EEPROM memory (Microchip 24LC256, 2002); and an electric lock interface, represented by a driver circuit to unlock the electric lock.

In general, the user authentication process consists of sending the user authentication key from the application running in a mobile device to the Bluetooth module, through Bluetooth connection. The Bluetooth module sends such information to the processing kernel, which performs the authentication through comparison of the user key sent with that stored in the external data storage unit. Next, the processing kernel sends the search authentication result to the mobile device and to the electric lock interface. If the user key is valid, the electric lock interface unlocks the environment entrance door. Each architectural component is detailed in what follows.

Mobile Module and Bluetooth Module

Mobile module is the application embedded in a mobile device that performs the communication with the Bluetooth module. It has been developed in J2ME language (J2ME, 2006). Such an application is based on the Bluelet open source software (Bluelet, 2006). The entire connection negotiation process has been implemented using protocols of the Bluetooth protocol stack to perform connections via Serial Port Profile (Wintec Bluetooth, 2004).

The basic process to connection negotiation consists of three steps:

1. Search for the Bluetooth module (discovery function), through the name “Wintec Serial Port” or the Bluetooth module address.
2. Authentication, or pairing, using the code sent by the mobile device to the Bluetooth module (bond function).

3. Connection establishment (connect function) based on serial port profile. A wireless communication is emulated by a connection via serial port with UART protocol (Wintec Bluetooth, 2004).

Regarding the application functioning, first of all an initial connection attempt is performed to connect to the Bluetooth Module directly, through the Bluetooth module address. Such an address is discovered by localization of Bluetooth devices and stored in the device. If the Bluetooth module is inaccessible—distant or turned off—or if it is not found in the direct connection attempt, the software automatically performs two more attempts, notifying the user visually. If no attempt works, then the software will be finished.

After the Bluetooth connection establishment, the access control system awaits the sending of the user key. In this case, a string containing the user authentication key is transmitted from the smart phone to the Bluetooth module. This key needs to be registered in the application by the user and then stored in the mobile device. If the operation is successful, the electric lock is unlocked and the user is informed visually that the door has been opened. Afterwards, the connection is closed and the application is finished.

Processing Kernel

During the connection establishment process between the smart phone and the Bluetooth module, messages (in ASCII format) are sent from the Bluetooth module to the microcontroller host, which represents the Processing Kernel. The firmware contained in the microcontroller host monitors these messages awaiting the final message of connection closing. Meanwhile, it continues awaiting the user authentication key that must be sent by the mobile device. When it receives such a key, it analyzes it, and if the key is registered in the system database, the host will unlock the electric lock. After the data exchange between the mobile device and the Bluetooth module, the microcontroller sends to the Bluetooth module the escape sequence to close the Bluetooth connection.

External Data Storage Unit

The external memory EEPROM is used as a persistent data storage device in this wireless access control system. It is very important due to the reduced capacity of internal memory available in the microcontroller.

The user information is stored in the external memory as a *login/password* table. A pointer to free memory positions is used to indicate which memory spaces are available to register new users.

The recording operation of user authentication keys begins when the processing kernel receives a *write command*.

The user information, *login* and *password*, contained in this command are then stored in the external memory unit.

The search operation for user authentication keys begins when the processing kernel receives an *access command*. The user information, *login* and *password*, contained in this command are acquired and stored in vectors, for search and comparison with stored data in the memory unit. If user information is valid, the operation will be successful. Otherwise, the operation has failed and the electric lock will not be unlocked.

Electric Lock Interface

The electric lock interface is represented by a driver circuit of the electric lock and by a panel composed by LEDs that indicates the current operations during the authentication process. It is responsible for informing of the status of the driver circuit. There are four LEDs. One of them indicates that the circuit is energized and active. Another indicates that a recording operation is currently being performed. Yet another LED indicates that the search operation for user key has been performed successfully and the electric lock was unlocked, allowing access to the environment. The last LED indicates that the search operation has failed (invalid code) and the electric lock has not been unlocked, not allowing the user access to the environment.

FUTURE TRENDS

In the context of the proposed system, in order to improve the reliability of the data exchange between the remote device and the access control system, revisions in the firmware contained in the processing kernel are necessary. Some suggestions to increase the reliability are: addition of an administrator user, development of new functions for this administrator to control and supervise the system, and better sub-routines to search for registered users.

Regarding future efforts in mobile-related access control technologies, the main trends are concerned with pervasive environments. For example, current access control technology works by keeping the entrance door closed and opening it for authorized persons. But there is another way: the door could be left open and only closes when an unauthorized person tries to enter. In this case, the access control system must be monitoring the environment, and when an unauthorized person comes close, the door is blocked. This example has a pervasive characteristic in which the system is “invisible” for the user. Several access control researches are moving in that direction, to conceive environments that manage and control their security without needing a direct user intervention.

CONCLUSION

Security is a growing need throughout the world, and lack of security can result in great damage. Many solutions are available for all levels of access control—from highly restricted areas such as laboratories or computer rooms to less restricted areas such as storage rooms.

Access control solutions include electronic keys, magnetic stripe cards, proximity cards, and smart cards or biometric devices, including hand and fingerprint readers. More sophisticated access control capabilities, such as auto-unlock/auto-lock functionalities, allow programming an electronic locking system to lock and unlock any door at any time.

With the increasing personal use of mobile devices and growing industry investments in this area, it is a trend to use mobility capabilities to support user activities, mainly security-related ones. The proposed access control system using Bluetooth is a good example of how to join mobility and reliability to support user activities in a practical and secure way.

KEY TERMS

American Standard Code for Information Interchange (ASCII): A standard for coding text files. Every character has an associated number, and any text can be represented by a sequence of numbers.

Electrically Erasable Programmable Read-Only Memory (EEPROM): A non-volatile storage chip used in computers and other devices (such as USB flash drives, in its flash memory version); also called E2PROM.

I²C (Inter-IC) Bus: A bi-directional two-wire serial bus that provides a communication link between integrated circuits (ICs).

J2ME: Collection of Java APIs for the development of software for resource-constrained devices such as PDAs, cell phones, and other consumer appliances.

Serial Port Profile (SPP): Defines how to configure and connect the virtual serial port between two wireless devices supporting Bluetooth technology.

Smart Phone: Any electronic handheld device that integrates the functionality of a mobile phone, personal digital assistant (PDA), or other information appliance. This is often achieved by adding telephone functions to an existing PDA or putting “smart” capabilities, such as PDA functions, into a mobile phone. A key feature of a smart phone is that additional applications can be installed on the device. The applications can be developed by the manufacturer of the handheld device, by the operator, or by any other third-party software developer.

Symbian OS: An operating system designed for mobile devices, with associated libraries, user interface frameworks, and reference implementations of common tools, produced by Symbian Ltd.

UART: Universal asynchronous receiver/transmitter protocol.

Wireless Client Server Application Model Using Limited Key Generation Technique

Rohit Singh

Phu Dung Le

Monash University, Australia

INTRODUCTION

The introduction of personal digital assistants (PDAs) and laptops has brought in mobility for carrying out computing jobs (Pasquale, Hung, Newhouse, Steinberg, & Ramabhadran, 2002; Varshney & Vetter, 2000). Wireless networks in working areas cater the need for installation flexibility, reduced cost-of-ownership, mobility and scalability. Mobile computing is distinguished from classical, fixed-connection computing due to the mobility of nomadic users and their devices (Jing, Helal, & Elmagarmid, 1999) and mobile environment is defined as low bandwidth and high latency networks with devices supporting limited input methods and containing low power processors, small display size and short battery life (Buszko, Lee, & Helal, 2001). Mobile working environments attract the users, employees and students, but presents hardships to the security programmer because the settings and the environment of mobile devices vary significantly from that of wired devices.

The ease of network access should be combined with reliable security services. Wireless networks are exposed to the security compromises because it provides hacker easy access to transport media. An attacker can sniff the packets by setting up equipment monitoring at 2.4GHz frequencies and capable of interpreting the packets of 802.11 standard (Borisov, Goldberg, & Wagner, 2001; IEEE Standard 802.11b, 1999; Josang & Sanderud, 2003). This unauthorized access to the network is a matter of great concern for any network security administrator. Cryptography, that is encryption of the data, is one of the best ways to provide security to wireless communication. Even the strongest of the encryption procedures can become vulnerable to possible attacks when the keys of the parties get compromised. Thus the lack of security is predominantly due to poor management of keys rather than the weakness in the encryption algorithm (Josang & Sanderud, 2003).

In this article we implement a client server model using limited-used key generation scheme (Kungpisdan, Le,

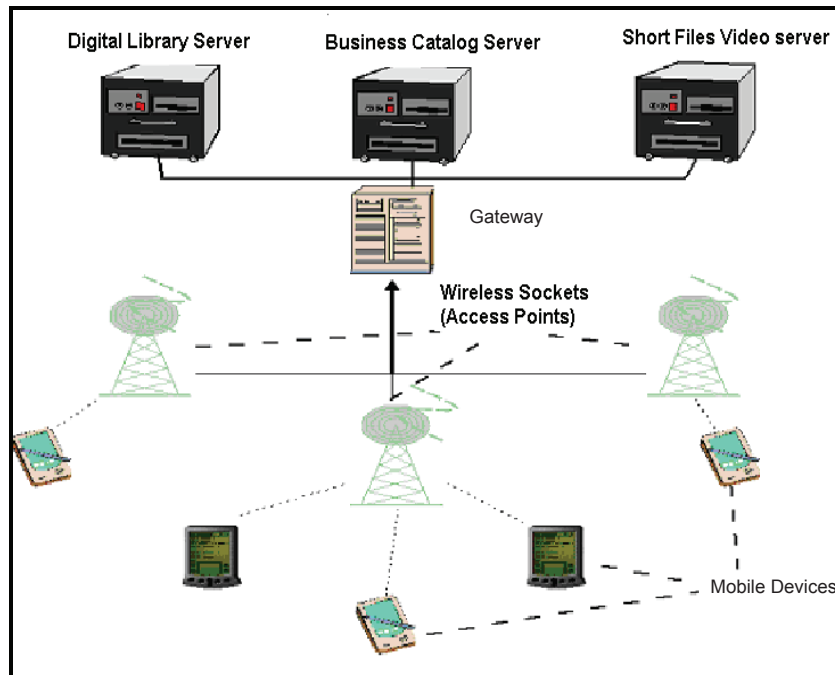

& Srinivasan, 2004) to generate a set of session keys that are never transmitted, which means that there is no chance for the attacker to sniff the packets and retrieve keys while they are being transmitted. These session keys are used for encrypting and hashing the data to be transmitted from mobile client device to the servers in wired network and vice versa. The updating of the session keys used in this technique does not rely on any long-term shared key, instead the process is based upon the last session key used. This technique of elevating the frequency of the key update to the next possible level makes the system much more secure than the other present techniques. In addition to providing better security, this technique also enhances the performance of a limited resource device by avoiding the repeated generation of keys on it.

The rest of the article is organized as follows. The second section gives an overview of the communication between mobile devices and the various servers running in the wired network. The third section describes the proposed technique. The fourth section discusses the technique in applied state. Next, the fifth section discusses about other key management and security issues of the technique. The last section concludes the article.

CLIENT SERVER MODEL

The client server model in a wireless environment is depicted in Figure 1. Mobile clients in wireless networks first connect to an access point, which is connected with wired media to the main network infrastructure. After a successful connection with the access point, mobile clients can start communicating with the gateway and servers that are present within the main network. The model described in this article proposes to set up a gateway program which authenticates every mobile client before it connects to any server inside the main network. The authentication is carried on the basis of the technique discussed in the fourth section. The gateway program can be executed at the gateway server of organization.

Figure 1. Remote access model

The course of action that is carried out in the proposed protocol is as follows:

- $C \rightarrow G$: Server Connection (Request), Command Execution (Request)
- $G \rightarrow S$: Command-Execution (Request)
- $S \rightarrow G$: Command-Execution (Response)
- $G \rightarrow C$: Server Connection (Response), Command-Execution (Response)

- $\{M\}_{K_x^{-1}}$: the message M signed with the private key of the party X .
- $h(M)$: the one-way hash function (FIPS, 1995) of the message M .
- $MAC(M, K)$: the message authentication code (MAC) of the message M with the key K .

PROPOSED TECHNIQUE

Notations

- $\{C, G, S\}$: the set of clients, gateway and server, respectively.
- $\{K_A, K_A^{-1}\}$: the set of public/ private key for party A .
- $\{ID_C, ID_S, ID_G\}$: the set of identities of client, the server and the gateway respectively.
- $ID_G Req$: request for ID_G
- CI : Command execution information.
- $CRes$: Command response
- $\{M\}_X$: the message M symmetrically encrypted with the shared key X .
- $\{M\}_{K_x}$: the message M encrypted with the public key of the party X .

Initial Assumption and Settings

Initial assumptions and settings for the proposed technique are as follows:

1. Client is considered to be a person with the wireless device and has access to the organization's network.
2. Client's employment record (CER), containing employee code and other information about the client, is the long-time shared secret between the server and Client. CER is assumed to be a key that never expires.
3. The distributed key DK is another shared key between client and server. This key is distributed by performing authenticated key exchange (AKE) (Boyd & Park, 1998; Horn & Preneel, 1998; Kungpisdan, Le, & Srinivasan, 2003; Toh, Kungpisdan, & Le, 2004; Wong & Chan, 2001; Zhu, Wong, Chan, & Ye, 2002) protocol between client and server.

$$C \rightarrow S: \{ID_C, DK, n\}_k$$

$$S \rightarrow C: \{n\}_k$$

This key is then further used to generate session key Y_i using the technique explained in the third section.

- There is another distributed key X that is a shared secret between client and gateway. This key is transferred to the gateway by performing AKE protocol.

$$C \rightarrow G: \{ID_C, X, n\}_k$$

$$G \rightarrow C: \{n\}_k$$

This key X is then further used to generate session key X_i using the technique explained in 3.3.2.

- $h(M, K)$ stands for the key hashed function for the message M and key K . For higher security reason HMAC is preferred.

Key Generation Technique

Generating Y_i : Figure 2 shows the procedure to generate Y_i . The steps to generate keys on the communicating terminals are as follows:

- Client generates the distributed key and transfers the same to the server through a secure channel. Client and server generate a set of preference keys K_i , where $i=1,2,3, \dots, m$:

$$K_1 = h(DK, CER), K_2 = h(DK, K_1) \dots \dots, \\ K_m = h(DK, K_{m-1})$$

CER is then removed from the system. This type of recursive hashing is represented by $DK * CER$ in remaining part of paper.

- Client generates a random number r , which is sent to the server at the start of every session.

$$C \rightarrow S: r$$

- Client selects two preference keys K_{mid1} and K_{mid2} . K_{mid1} is the middle key among $\{K_1, K_2, K_3 \dots \dots, K_w\}$, where $w = r \text{ mod } m$ and K_{mid2} is the middle key among $\{K_1, K_2 \dots \dots K_{mid1}\}$. Using these keys session initialization key (SIK) is calculated.

$$SIK = h(K_{mid1}, K_{mid2})$$

After generating SIK , K_{mid1} and K_{mid2} are removed from the terminals. As the value of r was transmitted over to the server, the same SIK is generated at the server's terminal as well.

- Server and client generate a set of session keys Y_i , where $i=1, 2, \dots, n$.

$$Y_1 = h(SIK, DK), Y_2 = h(SIK, Y_1) \dots Y_n = h(SIK, Y_{n-1})$$

These session keys are then used by server and client to encrypt, decrypt and hash the data passed between them.

Figure 2. Generation of Y_i

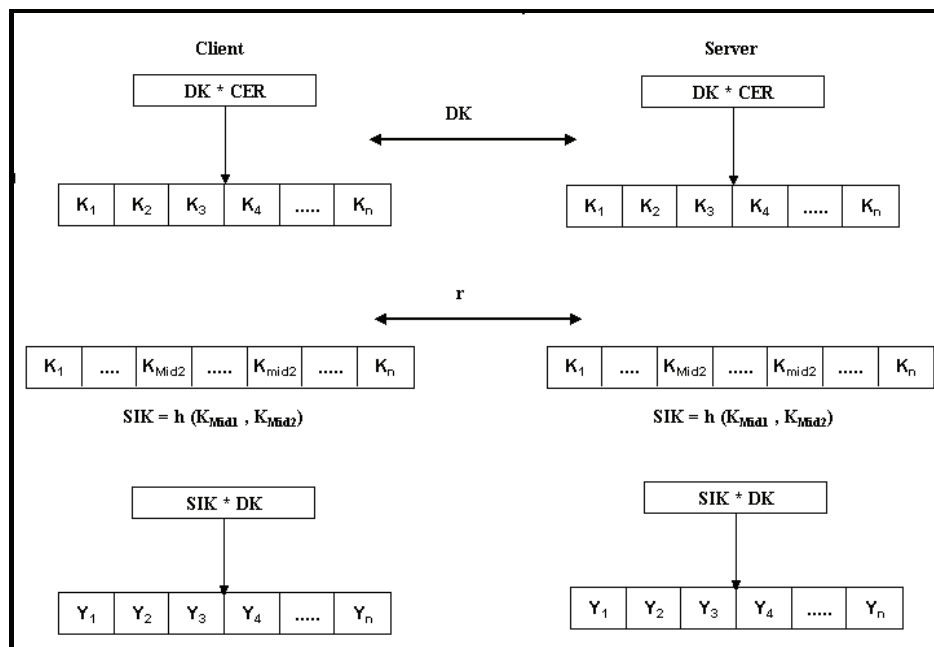

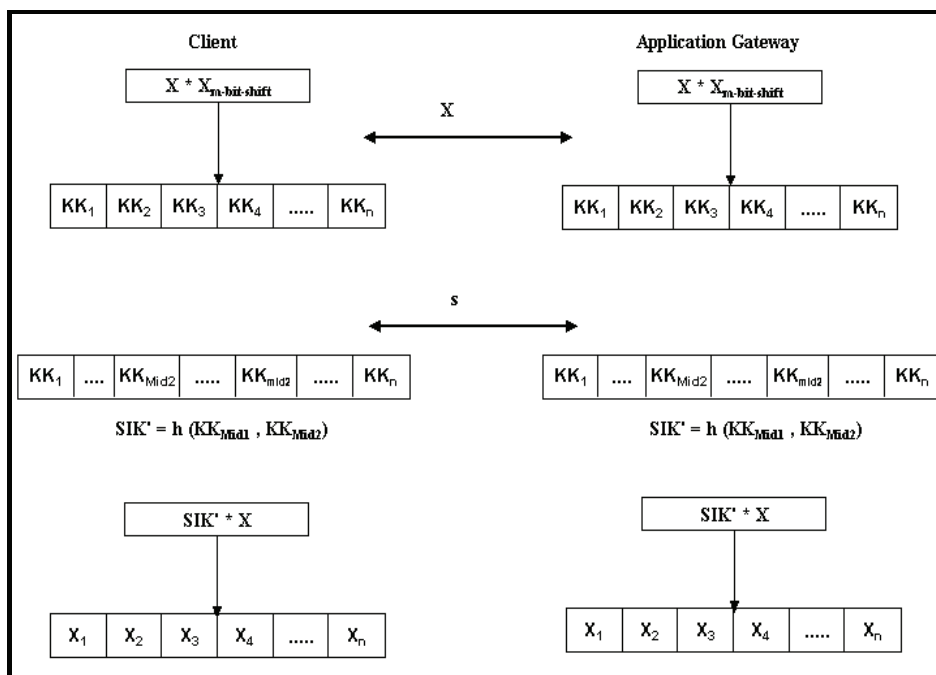

Figure 3. Generation of X_i

The application of the session keys in proposed technique is discussed in the fourth section.

Generating X_i : Figure 3 shows the procedure to generate X_i . The steps to generate keys on communicating terminals are as follows:

1. Client generates the key and distributes to the gateway through a secure channel. Client and gateway generate a set of preference keys KK_i , where $i=1, 2, 3, \dots, m$.

$$KK_1 = h(X, X_{m\text{-bit-shift}}), KK_2 = h(X, KK_1), \dots, KK_m = h(X, KK_{m-1})$$

2. Client generates a random number s , which is later on send to gateway.

$C \rightarrow G: s$

3. Client selects two preference keys KK_{mid1} , and KK_{mid2} . KK_{mid1} is the middle key among $\{KK_1, KK_2, KK_3, \dots, KK_x\}$, where $x = s \bmod rm$ and rm stands for remaining number of keys in the set of KK_i . The second key KK_{mid2} is the middle key among $\{KK_1, KK_2, \dots, KK_{mid1}\}$. After this, session initialization key (SIK') is calculated.

$$SIK' = h(KK_{mid1}, KK_{mid2})$$

After generating SIK' , KK_{mid1} and KK_{mid2} are removed from the terminals.

4. Gateway and client generate a set of session keys X_i , where $i=1, 2, \dots, n$.

$$X_1 = h(SIK', X), X_2 = h(SIK', X_1) \dots X_n = h(SIK', X_{n-1})$$

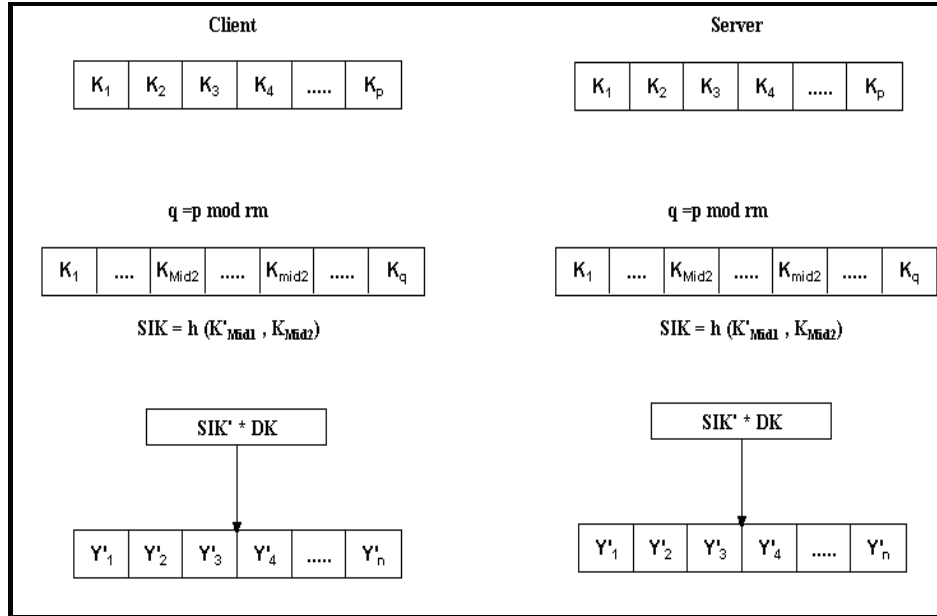

These session keys are then used by gateway and client to encrypt, decrypt and verify the messages sent amongst them.

Updating Session Keys

Figure 4 shows the procedure to update session keys. The technique proposed for updating session keys Y_i and X_i is similar, so for this section Y_i will be used for representing both. The session key update is performed as follows:

- **Step 1:** Client and the server have used Y_i up to Y_p , where $1 \leq p \leq n$. Then two preference keys are chosen from remaining K_i ; the first key selected is K'_{Mid1} , where K'_{Mid1} is the middle key among $\{K_1, \dots, K_q\}$, $q = p \bmod rm$, rm is the number of preference keys in the set of K_i . The second preference key chosen is K'_{Mid2} , where K'_{Mid2} is the middle key among $\{K_1, \dots, K'_{Mid1}\}$. Then, a new session initialization key (SIK') is generated as follows:

Figure 4. Updating session keys

$$SIK' = h(K'_{Mid1}, K'_{Mid2})$$

After generating SIK' , K'_{Mid1} and K'_{Mid2} are removed from both the systems.

- **Step 2:** After SIK' is generated, A new set of session key Y'_i is generated where $i = 1, 2, 3 \dots n$, using the following method.

$$Y'_1 = h(SIK, DK), Y'_2 = h(SIK, Y'_1) \dots Y'_n = h(SIK, Y'_{n-1})$$

This results in the generation of a set of new session keys (Y'_i) without redistributing or updating the distributed key DK . DK can be used repeatedly until all the preference keys in set of K_i gets used up.

Updating Distributed Key

Updating the distributed key leads to generation a new set preference keys K'_i . After new DK has been generated and distributed, K'_i is generated as follows: It should be noted that CER , which was used with DK for the first time to generate K_p , is no more stored on the client terminal. Thus a preference key K'_v is selected from remaining K_r , where $v = s \text{ mod } rm$ and s is the index of most recently used session key Y'_s .

$$K'_1 = h(DK', K'_v), K'_2 = h(DK', K'_v) \dots \dots, K'_m = h(DK', K'_{m-1})$$

After having the new set of K'_i the same procedure, as described in the third section, can be used to generate the new set of session keys.

Applying the Proposed Technique

After generating the session keys X_i and Y_i and the random numbers s and r on the client terminal, the client side protocol proceeds in the following way to connect to remote server and to get its command executed.

- **Step 1:** $C \rightarrow G: ID_C, s, r, ID_GReq$
 $G \rightarrow C: \{ID_G\}_{X_i}$
- **Step 2:** $C \rightarrow G: \{ID_G, CI, MAC [(ID_C, ID_G, CI), Y_i]\}_{X_i}, MAC [(ID_C, ID_G), X_{i+1}]$
- **Step 3:** $G \rightarrow S: \{\{MAC [(ID_C, ID_G, CI), Y_i], ID_G, CI, r, ID_G\}_{K'_s} K'_s^{-1}\}$
- **Step 4:** $S \rightarrow G: \{\{CRes\}_{Y'_i} ID_G\}_{K'_s} K'_s^{-1}$
- **Step 5:** $G \rightarrow C: \{\{CRes\}_{Y'_i}\}_{X_{i+1}}$

Command information (CI) and command response ($CRes$) can vary according to the server to which the client wants to connect. The technique discussed above has been implemented in a lab environment using HP iPAQ Pocket PC as client device, D-link wireless bridge as access point,

and Redhat Linux machine with the gateway program and server applications accessing databases on Windows and Linux machines.

DISCUSSION

Key Management

For the remaining part of the article we will be discussing about the keys on the server side, but any discussed feature on keys will also apply on the keys with the gateway. The proposed technique requires two set of keys, K_i and Y_i , to carry out the secure communication. Both of the keys are generated on the terminals of each party but only K_i is stored on the terminals. The stored set of keys reduces the overhead of generating K_i for every new session thus enhancing the performance of client device.

Security of the Proposed Technique Against Possible Attacks

The long-time shared secret (CER) is never stored on the terminal. It is removed as soon as the first K_i is generated from it and never used again. The set of preference keys, which were used to generate SIK , is also removed from the terminal to eliminate any chance of regenerating a previously used SIK . Non-deployment of CER in the proposed technique offers flexibility in making changes to the records without giving much consideration about the network connectivity. The remainder of the section points out the other attacks and security schemes that need to be employed to keep track of the attacks and how to recover from them.

Given a situation that the session key Y_i gets compromised, even then the value of SIK still remains secure due to the fact that it is totally infeasible to perform the reverse computation on the values generated by one way hash functions. In another situation where an attacker has collected a number of session keys and tries to guess the next session key, the server can keep track of the total number of incorrectly hashed or encrypted messages and can even suspend the client's account in case the number of incorrect messages goes beyond the precise limit.

Taking into account the worst scenario, where an attacker has guessed all the right values of session keys and the server has failed to track the fake messages, the short life span of session keys can embark upon this threat in a comprehensively better way. So the compromise of session keys does not concern the participating parties in a longer run.

As session keys are a result of hash function ($SIK*DK$), there is a possibility that the session keys can be generated if these values are compromised. If an attacker has captured all the session keys and has generated the same set of session

keys, the deceit can still be traced out by the system when it finds two MAC s (one from a valid client and one from a fake client) hashed with same session keys. A simple solution to this situation is to update the session keys. The participating parties—who ever discovers the deceit—requests the other party to update their session keys. Thus both the parties generate new set of session keys Y_i' (as described in the third section) by generating SIK' which makes the compromised Y_i and SIK as invalid.

A successful attack on this technique means that the attacker should succeed in capturing the entire set of K_i from the device of any of the participating parties and hack the values of r, p and DK during distribution. Given a scenario as mentioned the deceit will still be detected by the system when it receives a MAC with a previously used session key.

The proposed technique inherits these security features because of the property that it never re-uses a session key and, moreover, the generation of these session keys are not based on any long term shared key. These keys are generated from randomly chosen set of preference keys K_p , which are deleted after they are used. Thus, more and more usage of the technique for conducting sessions keeps on enhancing the security of the system.

CONCLUSION

In this article we presented the wireless client model for remote access to servers by mobile clients based on a simple but secure key generation protocol. We modified and implemented the technique that was originally proposed by Kungpisdan, Le, and Srinivasan (2003) in our protocol to generate session keys for encrypting and hashing the data ought to be transmitted. Then we applied the protocol in our model to demonstrate the security provided to the wireless communications between mobile clients and servers. Our work considerably enhances the systems capability to alleviate attacks based on key compromise.

KEY TERMS

Authenticated Key Exchange (AKE): AKE is block of operation in which two parties generate shared keys secretly. Many information exchanges are authenticated and secured on the basis of these shared keys.

Hash Function: Hash functions are algorithms that accept messages of any length and compute a fixed length string termed as a digital fingerprint or message digest or hash value.

Long-Term Shared Key: Long-term shared keys are keys that are shared for a longer period of time. This key forms the basis of authentication and security of information exchange between two parties.

Message Authentication Code: MAC is defined as checksum for the data transferred through unreliable media like the Internet. This check sum is also computed at the receiving ends and then the similarity of the checksum computed and received proves the authenticity of the data.

Mobile Environment: Is a generic term used to describe the environment where portable and computing devices connect wirelessly to utilize the central repository of data or applications.

Session Initialization Key (SIK): SIK can be considered as the mother of all session keys. SIK is hashed recursively with long-time shared key to generate session keys. One SIK expires after it has generated a predefined number of session keys.

Session Keys: Session keys are short lifespan encryption keys, which are used for encrypting one message or group of messages for a session.

Wireless Network Security

INTRODUCTION

Wireless networks have a number of security issues. Signal leakage means that network communications can be picked up outside the physical boundaries of the building in which they are being operated, meaning a hacker can operate from the street outside or discretely from blocks away. In addition to signal leakage, the wired equivalent privacy protocol is inherently weak, and in addition to WEP's weaknesses, there are various other attacks that can be initiated against WLANs, all with detrimental effects. On the surface WLANs act the same as their wired counterparts, transporting data between network devices. However, there is one fundamental, and quite significant, difference: WLANs are based on radio communications technology as an alternative to structured wiring and cables. Data is transmitted between devices through the air by utilizing the radio waves. Devices that participate in a WLAN must have a network interface card (NIC) with wireless capabilities. This essentially means that the card contains a small radio device that allows it to communicate with other wireless devices within the defined range for that card, for example, the 2.4-2.4853 GHz range. For a device to participate in a wireless network, it must firstly be permitted to communicate with the devices in that network, and secondly it must be within the transmission range of the devices in that network. To communicate, radio-based devices take advantage of electromagnetic waves and their ability to be altered in such a manner that they can carry information, known as modulation (Sundaralingham, 2004). Here we discuss wireless security mechanisms.

BACKGROUND

Wired networks have always presented their own security issues, but wireless networks introduce a whole new set of rules with their own unique security vulnerabilities. Most wired security measures are just not appropriate for application within a WLAN environment; this is mostly due to the complete change in transmission medium. However, some of the security implementations developed specifically for WLANs are also not terribly strong. Indeed, this aspect could be viewed as a *work-in-progress*; new vulnerabilities

are being discovered just as quickly as security measures are being released. Perhaps the issue that has received the most publicity is the major weaknesses in WEP, and more particularly the use of the RC4 algorithm and relatively short initialization vectors (IVs). WLANs suffer from all the security risks associated with their wired counterparts; however, they also introduce some unique risks of their own. The main issue with radio-based wireless networks is signal leakage. Due to the properties of radio transmissions, it is impossible to contain signals within one clearly defined area. In addition, because data is not enclosed within cable, it makes it very easy to intercept without being physically connected to the network (Hardjono & Lakshminath, 2005). This puts it outside the limits of what a user can physically control; signals can be received outside the building and even from streets away. Signal leakage may not be a huge priority when organizations are implementing their WLAN, but it can present a significant security issue, as demonstrated below. The signals that are transmitting data around an organization's office are the same signals that can also be picked up from streets away by an unknown third party. This is what makes WLANs so vulnerable. Before WLANs became common, someone wishing to gain unauthorized access to a wired network had to physically attach themselves to a cable within the building. This is why wiring closets should be kept locked and secured. Any potential hacker had to take great risks to penetrate a wired network. Today potential hackers do not have to use extreme measures, there's no need to smuggle equipment on site when it can be done from two streets away. It is not difficult for someone to obtain the necessary equipment; access can be gained in a very discrete manner from a distance.

WIRELESS SECURITY MECHANISMS

To go some way towards providing the same level of security the cable provides in wired networks, the wired equivalent protocol (WEP) was developed. WEP was designed to provide the security of a wired LAN by encryption through use of the RC4 (Rivest Code 4) algorithm. Its primary function is to safeguard against eavesdropping (sniffing), by making the data that is transmitted unreadable by a third party who does

not have the correct WEP key to decrypt the data. RC4 is not specific to WEP, it is a random generator, also known as a key stream generator or a stream cipher, and was developed in RSA Laboratories by Ron Rivest in 1987 (hence the name Rivest Code). It takes a relatively short input and produces a somewhat longer output, called a pseudo-random key stream. This key stream is simply added modulo two that is exclusive ORed (XOR), with the data to be transmitted, to generate what is known as ciphertext (Briere, 2005).

WEP is applied to all data above the 802.11b WLAN layers (physical and data link layers, the first two layers of the OSI reference model) to protect traffic such as transmission control protocol/Internet protocol (TCP/IP), Internet packet exchange (IPX), and hyper text transfer protocol (HTTP). It should be noted that only the frame body of data frames are encrypted, and the entire frame of other frame types are transmitted in the clear, unencrypted (Karygiannis & Owens, 2003). To add an additional integrity check, an initialization vector (IV) is used in conjunction with the secret encryption key. The IV is used to avoid encrypting multiple consecutive ciphertexts with the same key, and is usually 24 bits long. The shared key and the IV are fed into the RC4 algorithm to produce the key stream. This is XORed with the data to produce the ciphertext; the IV is then appended to the message. The IV of the incoming message is used to generate the key sequence necessary to decrypt the incoming message. The ciphertext, combined with the proper key sequence, yields the original plaintext and integrity check value (ICV) (Hardjono & Lakshminath, 2005). The decryption is verified by performing the integrity check algorithm on the recovered plaintext and comparing the output ICV to the ICV transmitted with the message. If it is in error, an indication is sent back to the sending station. The IV increases the key size, for example, a 104-bit WEP key with a 24-bit IV becomes a 128-bit RC4 key. In general, increasing the key size increases the security of a cryptographic technique. Research has shown that key sizes of greater than 80 bits make brute force¹ code breaking extremely difficult. For an 80-bit key, the number of possible keys— 10^{24} , which puts computing power to the test; but this type of computing power is not beyond the reach of most hackers. The standard key in use today is 64 bit. However, research has shown that the WEP approach to privacy is vulnerable to certain attacks regardless of key size (Karygiannes & Owens, 2003). Although the application of WEP may stop casual sniffers, determined hackers can crack WEP keys in a busy network within a relatively short period of time.

WEP's Weaknesses

When WEP is enabled in accordance with the 802.11b standard, the network administrator must personally visit each wireless device in use and manually enter the appropriate WEP key. This may be acceptable at the installation stage of

a WLAN or when a new client joins the network, but if the key becomes compromised and there is a loss of security, the key must be changed. This may not be a huge issue in a small organization with only a few users, but it can be impractical in large corporations, which typically have hundreds of users (Gavrilenko, 2004). As a consequence, potentially hundreds of users and devices could be using the same, identical key for long periods of time. All wireless network traffic from all users will be encrypted using the same key; this makes it a lot easier for someone listening to traffic to crack the key, as there are so many packets being transmitted using the same key. Unfortunately, there were no key management provisions in the original WEP protocol.

A 24-bit initialization vector WEP is also appended to the shared key. WEP uses this combined key and IV to generate the RC4 key schedule; it selects a new IV for each packet, so each packet can have a different key (Walker, 2002). Mathematically there are only 16,777,216 possible values for the IV. This may seem like a huge number, but given that it takes so many packets to transmit useful data, 16 million packets can easily go by in hours on a heavily used network. Eventually the RC4 algorithm starts using the same IVs over and over. Thus, someone passively *listening* to encrypted traffic and picking out the repeating IVs can begin to deduce what the WEP key is. Made easier by the fact that there is a static variable (the shared key), an attacker can eventually crack the WEP key (Nakhjiri, 2005). For example, a busy AP, which constantly sends 1,500 byte packets at 11Mbps, will exhaust the space of IVs after $1,500 \times 8 / (11 \times 10^6) \times 2^{24} = 18,000$ seconds, or 5 hours. (The amount of time may actually be smaller since many packets are less than 1,500 bytes). This allows an attacker to collect two ciphertexts that are encrypted with the same key stream. This reveals information about both messages. By XORing, two ciphertexts that use the same key stream would cause the key stream to be cancelled out and the result would be the XOR of the two plaintexts (Vines, 2002).

War-Driving

So called *war-driving* is a term used to describe a hacker who—armed with a laptop, a wireless NIC, an antenna, and sometimes a GPS device—travels, usually by car, scanning or sniffing for WLAN devices, or more specifically unprotected or *open* and easily accessed networks. The name is thought to have come from another hacking technique called war-dialing, where a hacker programs a system to call hundreds of phone numbers in search of a poorly protected computer dial-up (Nakhjiri, 2005). Due to the increased use of WLANs in recent years, it is quite possible that the number of unsecured devices has also risen in tandem, thus providing potential hackers with more choice. After all that has been written about the insecurities of WLAN, some users/organizations still insist on implementing them with their

default settings and no encryption (Ulanoff, 2003). There is a plethora of hacking tools widely available to download from the Internet for any potential war-driver to use. There has been a lot of press globally, and many articles and papers written about wireless networks and their security vulnerabilities. However, despite all the literature, some enterprises still make the mistake of believing that they do not have to worry about wireless security if they are running non-critical systems with non-sensitive information across their WLANs. All information is sensitive information, and what an enterprise may class as being non-sensitive to them may be very useful to a hacker. In addition, most WLANs will connect with the wired enterprise backbone at some point, thus providing hackers with a launch pad to the entire network. The havoc an unwelcome third party could cause from here would be unlimited and very difficult to trace. Aside from the various attacks they could instigate (DoS and viruses), the loss of confidentiality, privacy, and integrity that would occur if someone were able to steal, alter, or delete information on your customer database is damaging enough. Access to sensitive information would be made relatively easy, perhaps even customers' credit card details. This could have an un-quantifiable effect on business, perhaps resulting in the loss of customers/clients and future revenue (AirDefense, 2003).

Wireless Attack Methods

A passive attack is an attack on a system that does not result in a change to the system in any way; the attack is purely to monitor or record data. Passive attacks affect confidentiality, but not necessarily authentication or integrity. *Eavesdropping* and *traffic analysis* fall under this category. When an attacker eavesdrops, he or she simply monitors transmissions for message content. It usually takes the form of someone listening into the transmissions on a LAN between stations/devices.

Eavesdropping is also known as sniffing or wireless footprinting. There are various tools available for download online which allow the monitoring of networks and their traffic; these are developed by hackers, for hackers. Netstumbler, Kismet, Aircrack-ng, WEPCrack, and Ethereal are all well-known names in wireless hacking circles, and all are designed specifically for use on wireless networks, with the exception of Ethereal, which is a packet analyzer and can also be used on a wired LAN. NetStumbler and Kismet can be used purely for passive eavesdropping; they have no additional active functions, except perhaps their ability to work in conjunction with global positioning systems (GPSs) to map the exact locations of identified wireless LANs. NetStumbler is a Windows-based sniffer, where Kismet is primarily a Linux-based tool. NetStumbler uses an 802.11 Probe Request sent to the broadcast destination address, which causes all APs in the area to issue an 802.11 Probe Response

containing network configuration information, such as their SSID, WEP status, the MAC address of the device, name (if applicable), the channel the device is transmitting on, the vendor and the type, either peer or AP, along with a few other pieces of information. Using the network information and GPS data collected, it is then possible to create maps with tools such as StumbVerter and MS Mappoint.

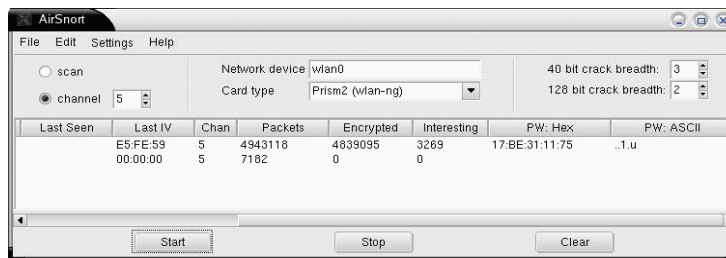

Kismet, although not as graphical or user friendly as NetStumbler, is similar to its Windows counterpart, but it provides superior functionality. While scanning for APs, packets can also be logged for later analysis. Logging features allow for captured packets to be stored in separate categories, depending upon the type of traffic captured. Kismet can even store encrypted packets that use weak keys separately to run them through a WEP key cracker after capture, such as Aircrack-ng or WEPCrack (Sundaralingham, 2005). Wireless network GPS information can be uploaded to a site called Wigle (<http://www.wigle.net>). Therefore, if Wigle data exists for a particular area, there is no need to drive around that area probing for wireless devices; this information can be obtained in advance from the Wigle Web site. All that remains is to drive to a location where known networks exist to observe traffic. Wigle currently has a few hundred thousand networks on its database.

Traffic analysis gains intelligence in a more subtle way by monitoring transmissions for patterns of communication. A considerable amount of information is contained in the flow of messages between communicating parties. Airopeek NX, a commercial 802.11 monitoring and analysis tool for Windows, analyzes transmissions and provides a useful node view, which groups detected stations and devices by their MAC address and will also show IP addresses and protocols observed for each. The Peer Map view, within Airopeek NX, presents a matrix of all hosts discovered on the network by their connections to each other. This can make it very easy to visualize AP and client relationships, which could be useful to hackers in deciding where to try and gain access or target for an attack (McClure, Scambray, & Jurtz, 2003). Some attacks may begin as passive, but then crossover to active as they progress. For example, tools such as Aircrack-ng or WEPCrack may passively monitor transmissions, but their intent is to crack the WEP key used to encrypt data being transmitted. Figure 1 shows a screen shot of Aircrack-ng showing the number of packets gathered and the WEP key—17BE311175.

Ultimately the reasons for wanting to crack the key are so that an unauthorized individual can access a protected network and then launch an active attack of some form or another. These types of attacks are classed as passive decryption attacks.

An active attack, also referred to as a malicious attack, occurs when an unauthorized third party gains access to a network and proceeds to perform denial of service (DoS) attack, to disrupt the proper operation of a network, to intercept network traffic and either modify or delete it, or

Figure 1. Screen shot from Airsnort showing 64-bit key crack

inject extra traffic onto the network. There are many active attacks that can be launched against wireless networks; the following few paragraphs outline almost all of these attacks, how they work, and what effect they have (Karygiannis & Owens, 2003). DoS attacks are easily the most prevalent type of attack against 802.11 networks and can be waged against a single client or an entire WLAN. In this type of attack, the hacker usually does not steal information; he or she simply prevents users from accessing network services, or causes services to be interrupted or delayed. Consequences can range from a measurable reduction in performance to the complete failure of the system. Some common DoS attacks are outlined below.

A man-in-the-middle attack is carried out by inserting a malicious station between the victim station and the AP, thus the attacker becomes the man in the middle; the station is tricked into believing that the attacker is the AP, and the AP into believing that the attacker is the legitimate station. To begin the attack, the perpetrator passively monitors the frames sent back and forth between the station and the AP during the initial association process with an 802.11 analyzer. As a result, information is obtained about both the station and the AP, such as the MAC and IP address of both devices, association ID for the station, and SSID of the network. With this information a rogue station/AP can be set up between the two unsuspecting devices. Because the original 802.11 does not provide mutual authentication, a station will happily re-associate with the rogue AP. The rogue AP will then capture traffic from unsuspecting users; this of course can expose information such as user names and passwords (Gavrilenko, 2004).

An Association flood is a resource starvation attack. When a station associates with an AP, the AP issues an associate identification (AID) number to the station in the range of 1-2007. This value is used for communicating power management information to a station that has been in a power-save state. This attack works by sending multiple authentication and association requests to the AP, each with a unique source MAC address. The AP is unable to differentiate the authentication requests generated by an attacker and those created by legitimate clients, so it is forced

to process each request. Eventually, the AP will run out of AIDs to allocate and will be forced to de-associate stations to reuse previously allocated AIDs. In practice, many APs will restart after a few minutes of authentication flooding, however this attack is effective in bringing down entire networks or network segments; if repeatedly carried out, it can cause a noticeable decrease in network up time (Wright, 2003). The final issue is a threat posed by the simple network management protocol (SNMP).

Attacks that Alter Transmissions

The following attacks describe how it is possible for an attacker to modify messages in transit, without detection. Message modification attacks are made relatively trivial if no message encryption exists; however, even if it does, the hacker can still get around it by first cracking the encryption and then carrying out the attack.

- Injecting Traffic:** If an attacker knows the exact plaintext for one encrypted message, he or she can then use this knowledge to construct more correctly encrypted packets. This procedure involves constructing a new message, calculating the CRC-32 checksum, and performing bit-flips² on the original encrypted message to change the plaintext to the new message. This packet can now be sent to the AP, and it will be accepted as a valid packet. Because RC4 encrypts data a byte at a time, an attacker can modify one byte of ciphertext and the recipient would not know the data has been changed. RC4 does not detect errors (Borisov, Goldberg, & Wagner, 2003).
- IP Redirection:** By intercepting and modifying the IP address of the destination in a packet, an attacker can effectively re-route messages. This attack can be used where an AP acts as an IP router with Internet connectivity, which is fairly common. The idea is to take an encrypted packet that has been transmitted and modify it so it has a new destination address—one the attacker controls. The AP will then decrypt the packet and send it off to its new destination, where the attacker

can read the packet, now in the clear (Borisov et al., 2003).

- **SNMP Attack:** The final issue is a threat posed by the simple network management protocol (SNMP). Some APs can be managed via wireless link, usually with a proprietary application, replying on SNMP. Executing these operations can represent a frightening vulnerability for the whole LAN; because eavesdroppers can decipher the password to access read/write mode on the AP using a packet analyzer, this means that they share the same administration privileges with the WLAN administrator and can manage the WLAN in a malicious manner (Me, 2003). The sheer number of attacks, and their effects, would seem to put WLANs at a severe disadvantage over their wired counterparts. However, there are just as many, if not more, security measures that users can utilize to counteract most of the above attacks. Layering one security measure on top of another, to strengthen the overall system to deter any potential attackers or make their task more difficult, is not impossible. However, not all organizations, or indeed individuals, take the time to implement any form of security, or they implement it weakly. The next article discusses, firstly, what route the primary research will take, and secondly, the findings resulting from the primary research.

FUTURE TRENDS

IEEE specifies basically two categories of WLAN standards—those that specify the fundamental protocols for the complete wireless system and those that address specific weaknesses or provide additional functionality (3COM, 2006). Here we mention just three of the latter standards which may have a significant influence in the coming days.

802.11i is a major extension because it was intended to improve WLAN security on 802.11a and 802.11b networks, which was in tatters. It adds two main blocks of improvements: improved security for data in transit, and better control of who can use a network. It covers key management and distribution, encryption, and authentication, the three main components of security (Briere, 2005). The 802.11i specification can be viewed as consisting of three main sections, organized into two layers. On the lower level are improved encryption algorithms in the form of the temporal key integrity protocol (TKIP) and the counter mode with cipher block chaining-message authentication code, CBC-MAC protocol (CCMP). Both of these provide enhanced data integrity over WEP, with TKIP being targeted at legacy equipment and CCMP being targeted at future WLAN equipment (Nakhjiri, 2005).

The goal of the 802.11k standard is to make measurements from layers one and two of the OSI protocol stack—physical

and data link layers—available to the upper layers. It is expected that the upper layers will then be able to make decisions about the radio environment. It is called radio resource management. One feature is better traffic distribution. Normally a wireless device will connect to whatever AP gives it the strongest signal. However, this can lead to an overload on some APs and under-load on others, resulting in an overall lowered service level. The 802.11k standard will allow network management software to detect this situation and redirect some of the users to under-utilized APs. 802.11n is a high-performance standard that would boost both 802.11b and 802.11a 11Mbps and 54Mbps, respectively. Proposals say it could go to 108Mbps or beyond, to as much as 320Mbps. This standard is not expected to be complete until early 2007.

Community 802.11b networks will continue to grow as people realize they can share their high-speed, high-cost Internet connections, turning them into high-speed, low- or no-cost connections for a larger group of people (Imai, 2005).

CONCLUSION

Wireless networks have a number of security issues. Signal leakage means that network communications can be picked up outside the physical boundaries of the building in which they are being operated, meaning a hacker can operate from the street outside or discretely from blocks away. In addition to signal leakage, wireless networks have various other weaknesses. WEP, the protocol used within WLANs to provide the equivalent security of wired networks, is inherently weak. The use of the RC4 algorithm and weak IVs makes WEP a vulnerable security measure. In addition to WEP's weaknesses, there are various other attacks that can be initiated against WLANs, all with detrimental effects.

KEY TERMS

Denial of Service: An incident in which a user or organization is deprived of the services of a resource they would normally expect to have. Typically, the loss of service is the inability of a particular network service to be available or the temporary loss of all network connectivity and services.

Direct Sequence Spread Spectrum (DSSS): Combines a data signal with a higher data rate bit sequence, referred to as a chipping code. The data is exclusive ORed (XOR) with a PRS that results in a higher bit rate, This increases the signal's resistance to interference.

Frequency Hopping Spread Spectrum (FHSS): Here the signal hops from frequency to frequency over a wide band of frequencies. The transmitter and receiver change the frequency they operate on in accordance with a pseudo-random sequence (PRS) of numbers. To properly communicate, both devices must be set to the same hopping code.

IEEE 802.11 Standard: IEEE has developed several specifications for WLAN technology, the names of which resemble the alphabet. There are basically two categories of standards: those that specify the fundamental protocols for the complete wireless system—these are called 802.11a, 802.11b, and 802.11g; and those that address specific weaknesses or provide additional functionality—these are 802.11d, e, f, h, I, j, k, m, and n.

Initialization Vector (IV): Used in conjunction with the secret encryption key in WEP (see *Wired Equivalent Privacy*). The IV is used to avoid encrypting multiple consecutive ciphertexts with the same key, and is usually 24 bits long.

War Driving: A term used to describe a hacker who—armed with a laptop, a wireless NIC, an antenna, and sometimes a GPS device—travels, usually by car, scanning or sniffing for WLAN devices, or more specifically unprotected or open and easily accessed networks.

Wired Equivalent Privacy (WEP): Designed to provide the security of a wired LAN by encryption through use of the RC4 (Rivest Code 4) algorithm. Its primary function is to safeguard against eavesdropping (sniffing), by making the data that is transmitted unreadable by a third party who does not have the correct WEP key to decrypt the data.

ENDNOTES

- ¹ A method that relies on sheer computing power to try all possibilities until the solution to a problem is found; usually refers to cracking passwords by trying every possible combination of a particular key space.
- ² Bit-flipping—changing one or more bits within a message. For example, change a 0 to a 1, or vice versa.

INTRODUCTION

The fast growth of wireless technology has exponentially increased the abilities and possibilities of computing equipment. Corporate users can now move around enterprise buildings with their laptops, PDAs, and WiFi; enable VoIP handsets; and retain communications with their offices. Business users can work from almost anywhere by attaching their laptops to WiFi hotspots and connecting to their corporate network. However, not many enterprises know and understand the potential security vulnerabilities that are introduced by the use of WiFi technologies. Wireless technologies are insecure by their nature. Anyone with the appropriate hardware can steal information transmitted using the airwaves. This article discusses the security vulnerabilities that are inherited in wireless networks. Also, it provides a description of the current security trends and protocols used to secure such WiFi networks along with the problems from their application.

BACKGROUND

Currently, several enterprises consider information security as a monolithic architecture, in which simply they install a firewall or an intrusion detection system. Unfortunately security is not a single device or software:

In the real world, security involves processes. It involves preventive technologies, but also detection and reaction processes, and an entire forensics system to hunt down and prosecute the guilty. Security is not a product; it itself is a process. (Schneier, 2000)

The above definition represents the fact that total protection of corporate networks goes beyond a firewall engine. Each appliance that is added and/or changed into a system should incorporate the re-designing of a system's overall

security policy and infrastructure. The same principle exists when incorporating wireless devices to extend the overall enterprise architecture. Deploying a wireless network has as a consequence the change of the security risks and needs of the entire network infrastructure. Nowadays, the techniques that are used for the realization of attacks in wireless connected networks resemble those used to target common LANs. In the next paragraphs, we present the major categories of attacks, including techniques that have been successfully used for attacking corporate wireless networks.

Denial of Service. In their simplest form, an adversary can continuously transmit *association request* packets. Such action could render an access point unavailable to authorized users. Adversaries can use a powerful RF transceiver to transmit amplified signals in all frequency band frequencies (channels), creating an interjection that prevents the communication of terminals with the corporate access points (RF Jamming). Such an attack could be easily deployed from the outside premises of an enterprise (e.g., parking). An example appliance that can be used for the concretization of this attack is the Power Signal Generator (PSG -1) by the YDI.

Man-in-the-Middle Attacks. Combining an RF Jamming attack with the use of a portable computer and necessary software, an attacker can easily steal or alter corporate information (Akin, 2003). The adversary will use a denial-of-service attack to force authorized terminals connected to a corporate access point to identify and roam to an access point with better signal than the one already connected to. Using this predetermined behavior the attacker can masquerade his/her laptop as an access point and force all wireless clients to connect to it. By using this technique an adversary can intercept all wireless communications links and read or alter information on them.

Fresnel Zone Sniffing. Stealing information from point-to-point wireless links is difficult. The attacker needs to calculate the link path and identify ways to attach its laptop to the link's Fresnel Zone.

Rogue Wireless Gateways. A rogue wireless gateway is a security vulnerability that is detected in many of today's

enterprise networks. A rogue wireless gateway is an unauthorized access point that is installed on an enterprise network. Such access points are usually installed by corporate users, to assist them in the everyday work (i.e., transfer files/e-mails from a desktop to a laptop computer). Unfortunately enterprise users do not know and understand the security implications of installing a wireless device on a system. Leaving such devices connected to the corporate network provides an opportunity to adversaries to connect and steal corporate information.

Ad Hoc Networks. The 802.11 protocol specification allows wireless terminals to interconnect without the use of an access point. This mode of operation is called ad hoc. Unfortunately many of today's corporate users enable the ad hoc facility on their laptops and PDAs either accidentally or deliberately in order to exchange files with other users. Enabling the ad hoc mode without deploying the necessary security procedures (i.e., encryption and authentication) could seriously damage corporate security. Adversaries can search for such unprotected ad hoc networks and connect to those. From there adversaries can either read the locally stored corporate information, or if the user's device is connected to the corporate networks (i.e., LAN, dialup, and VPN), access the corporate resources (Papadimitratos & Haas, 2002).

The previous example attacks emphasize the need for security that results from the use of wireless technology. The problem of security becomes more apparent when the technology of wireless networking is applied in government-owned systems. The need for security in those systems is extensive due to the legislation on personal data protection and the human lives factors involved.

MAIN THRUST OF THE ARTICLE

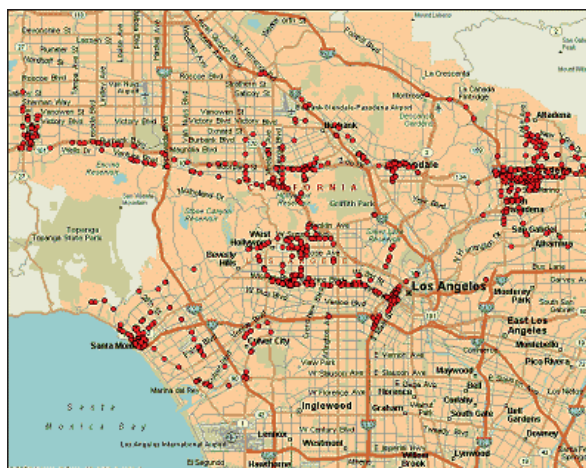

In the last few years, the computing and telecommunications community has realized the necessity of deploying security controls on wireless networks. Unfortunately most of today's wireless security controls have been proven unsafe or managerial infeasible to maintain. The next few paragraphs describe the most common security protocols and techniques, as well as their vulnerabilities.

Discovering Wireless Networks

Many enterprises support their notion of using insecure WiFi networks based on the idea that their *small wireless networks* are hidden from hackers and adversaries. This notion is called Security through Obscurity, and is something that the IT security community analyzed and abolished long before the appearance of wireless networks.

Modern hackers have invented a number of new techniques, collectively known as *War Driving* or *War Chalking*, which aim at discovering unprotected wireless networks. An

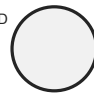

Figure 1. A War Driving result in Los Angeles

adversary uses a laptop computer, along with appropriate discovery software (i.e., NetStumbler) and a GPS received, to pinpoint the exact location of access points on a map. Today such maps are distributed among the War Driving community. It is not unusual for enterprises to discover their company access points on maps found on War Driving Web sites (see Figure 1).

Many enterprise administrators try to hide their wireless networks by activating the *close system* option found on access point hardware equipment. This option prohibits the access point from transmitting the network's beacon information that incorporates the network's service set identifier (SSID). Unfortunately the SSID is incorporated into almost all network management frames. Software packages like

Table 1. War Chalking symbols

| node | symbol |
|-------------|--|
| open node | SSID  bandwidth |
| closed node | SSID  |
| WEP node | SSID  access contact bandwidth |

NetStumbler will force the access points in transmitting the SSID by issuing such management frames (i.e., *Reassociation Request*).

The techniques of War Driving and War Chalking has been used today to an extended degree, and adversaries have developed their own marking symbols (see Table 1) in order to denote the buildings where wireless networks are discovered. Writing these symbols in various buildings of the city, adversaries mark their potential targets.

MAC Access Control Lists

To enhance security, many corporations develop media access control (MAC) *control lists* declaring the MAC addresses of wireless terminals that are authorized to access the wired segment of a corporate network. Unfortunately the deployment of MAC access control lists increases management time and difficulty without offering real protection from experienced hackers. Having discovered a wireless network, an adversary can eavesdrop on the network and detect authorized MAC addresses that connect to an access point. Having a list of such authorized MAC addresses, the adversary can use MAC spoofing attacks and masquerade his laptop as an authorized client (e.g., using the SMAC software, a snapshot of which is depicted in Figure 2).

Wired Equivalent Privacy (WEP)

The first security protocol developed for wireless networks is *wired equivalent privacy* (WEP). WEP uses RC4 PRNG algorithm (LAN MAN, 1999) for the coding of information. The WEP key, with a 24-bit *initializing vector* (IV), is used for the encryption/decryption of wireless data. The protocol works with keys of 64 or with 128 bit (the actual key lengths are 40 and 104 bit, but are concatenated with the IV during

the encryption phase). In a WEP environment the encryption keys are installed by the administrator of the system in each terminal and access point, and thus the management of the network becomes more complicated.

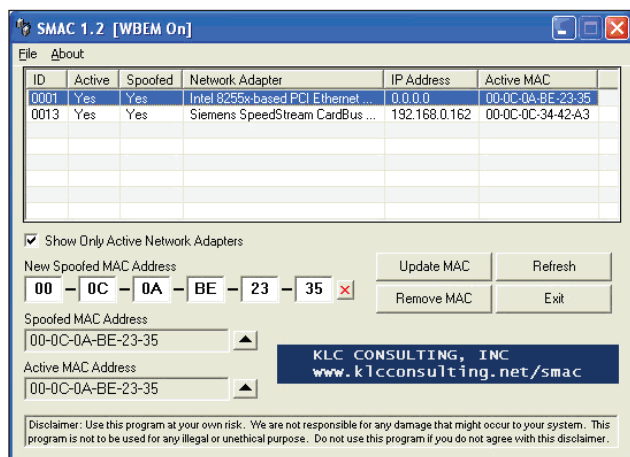

The WEP does not offer user authentication; therefore, discovering the WEP key allows access to a corporate network (Borisov, Goldberg, & Wagner, 2001). The two authentication models provided by WEP are open system and the shared-key authentication (Lambrinouidakis & Gritzalis, 2005). The open system model uses the MAC access control lists discussed in the previous paragraphs. In the shared key authentication, WEP uses the encryption key to implement a Challenge-Response authentication scheme.

At the same time WEP uses a 32-bit *cycle redundancy check* algorithm as integrity check value (ICV) in order to ensure the integrity of data. Currently, the CRC algorithm has already been broken by researchers from the University of Berkley (Tyrrell, 2003).

The key recovery process in a system that uses WEP can be actually realized in a few hours. This is due to a vulnerability found in the way WEP uses the RC4 algorithm. The weakness of WEP is based on the fact that the IV is only 24 bit, and thus, in a busy network, the same IV key is used to encrypt different network packets. Having eavesdropped two or more packets encrypted with the same IV, an adversary can apply cryptanalysis techniques and recover the WEP key. Today, a number of freeware software packages that can perform a successful WEP attack are available on the Internet. Examples of such software artifacts include WEPCrack and AIRSnort (see Figure 3).

Due to the fact that WEP encryption keys are static, the time between discovering a compromised key and updating the whole wireless network infrastructure with a new key is extended. This leaves even more time for adversaries to access and copy confidential corporate information.

Figure 2. SMAC software screenshot

WiFi-Protected Access (WPA)

Understanding the problems of WEP, the international community has moved forward in developing a more secure protocol, namely 802.11i (Edney & William, 2003). Due to the delay in the development of the final 802.11i standard, the international community released a pre-802.11i security

Figure 3. AirSnort software screenshot

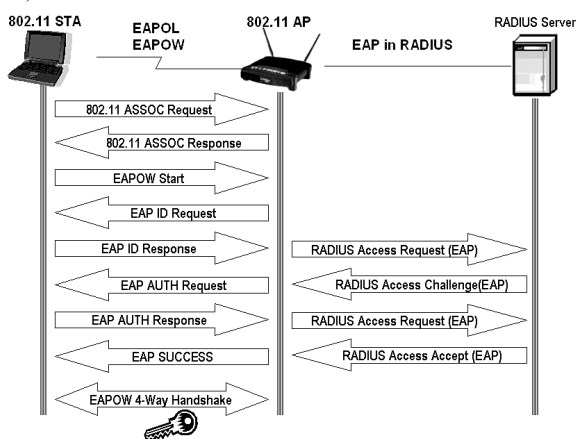

Figure 4. 802.1x EAP authentication (EAP Authentication, 2005)

protocol under the name *WiFi-protected access* (Edney & William, 2003).

The WPA uses algorithm RC 4 (Fluhrer, Mantin, & Shamir, 2001) for the encryption of air data incorporating the *temporal key integrity protocol* (TKIP), in order to use dynamic encryption keys. In order to avoid the security vulnerabilities of CRC-32, WPA utilizes a novel integrity protection algorithm, the Michael Message Integrity Check (MIC) (Cam-Winget, Housley, Wagner, & Walker, 2003), which uses a 64-bit key and partitions data into 32-bit blocks.

TKIP uses an IV of 48 bit, offering better security than the 24-bit IV used by WEP. It combines a 128-bit temporary key, which is preinstalled in all wireless terminals with the MAC address of each terminal, and the 48-bit IV in order to create a new encryption key for each terminal. The protocol changes the encryption key every 10,000 packets that are transmitted.

Moreover, WPA employs the 802.1x protocol (port-based access control) to deliver authenticated connections. This protocol allows the usage of a number of authentication methods to be used such as passwords and digital certificates.

The user or terminal authentication process is performed by the *extensible authentication protocol* (EAP), which is usually associated with a radius server in order to securely authenticate users or devices on a network. Figure 4 displays an example EAP authentication process.

Currently, there exist several EAP implementations:

- **EAP-MD 5** (Funk, 2003): This was the first protocol to use user authentication based on the 802.1x scheme. It provides only one-way authentication, ensuring the authenticity of users but not the servers. The protocol is based on the algorithm MD5. However, research has already proven that this protocol is subject to diction-

ary and man-in-the-middle attacks (Asokan, Niemi, & Nyberg, 2002).

- **CISCO-LEAP:** The lightweight EAP (LEAP), created by CISCO, offers bidirectional authentication. The bidirectional authentication makes the protocol immune to man-in-the-middle attacks, but its challenge handshake authentication protocol (MSCHAP version 2) is subject to dictionary attacks. Currently, there exist several tools on the Internet, like the *asleep*, that can perform successful attacks on LEAP. CISCO tries to tackle this disadvantage, and at this time, the company is developing a new protocol called EAP-FAST.
- **EAP-FAST** (Ghosh & Gupta, 2005): EAP-FAST, developed and marketed by CISCO, is thought to be as secure as EAP-PEAP and as easy to deploy as EAP-LEAP. The protocol operates similarly to EAP-PEAP. It uses two distinct phases. In phase 1 a secure tunnel is established using a Protected Access Credential (PAC) shared key. PAC is used in order to avoid deploying digital certificates. After the establishment of the secure tunnel, authentication is performed on phase 2 using the MSCHAP v2 protocol. The PAC secret can either be manually shared to all nodes or automated through an optional Diffie-Hellman process. Unfortunately, using the manual shared key distribution process will make the management of the network extremely difficult. On the other hand the anonymous Diffie-Hellman process can make the protocol suspect to man-in-the-middle attacks. Along with this, during the anonymous Diffie-Hellman, the protocol transmits the user name in cleartext (unencrypted), and thus possession of a user name could further lead an attacker to perform social engineering attacks. It is going to be a while before the protocol is thoroughly tested and used by the international community (Lambrinoudakis & Gritzalis, 2005).
- **EAP-TLS** (Aboba & Simon, 1999): The EAP-transport layer security (EAP-TLS), developed by Microsoft Corporation, uses the Transport Layer Security (TLS) protocol with digital certificates for both clients and servers in order to provide bidirectional authentication. The protocol transmits the user name in cleartext. A possible information leakage in this form could provide the basis for further attacks (i.e., social engineering). Along with this, the use of both client and server certificates makes the management of this protocol a hassle for large corporate networks.
- **EAP-TTLS** (Funk & Blake-Wilson, 2003): The EAP-tunneled TLS (EAP-TTLS) protocol, created by the companies Funk and Certicom, is based on the idea of EAP-TLS, but in order to minimize the management process, it uses their digital certificates only for the servers and not for the clients. Clients authenticate servers by using digital certificates; thus, the proto-

col builds an *encrypted tunnel*. The encrypted tunnel provides a secure medium on which clients can be authenticated using a challenge response mechanism. Although, currently, there are no known attacks, the protocol is suspected to be vulnerable to man-in-the-middle attacks (Asokan et al., 2002).

- **EAP-PEAP** (Palekar et al., 2003): The protected EAP (PEAP) protocol is the result of a common effort from different IT companies. PEAP uses digital certificates for servers. Also, clients authenticate servers. After a successful server authentication, the protocol creates an encrypted tunnel between the client and the server. Inside this secure tunnel, the system can use any of the previously described EAP authentication methods in order to enable client authentication. The chosen combination today is to use the EAP-TLS inside the encrypted tunnel in order to provide client authentication (EAP-PEAP/EAP-TLS). Similar to the TTLS protocol, no known attack exists today, but PEAP is suspected to be vulnerable to man-in-the-middle attacks.

802.11i

Having discovered the vulnerabilities in WEP, IEEE started producing the specification of a new protocol, IEEE 802.11i. It follows principles similar to WPA, and uses 802.1x and EAP protocols for authentication and key management. 802.11i uses the *counter-mode/CBC-MAC protocol* (CCMP) protocol with the *advance encryption standard* (AES) (NIST, 2001) algorithm to provide data encryption and integrity protection.

In addition, 802.11i provides the robust security network (RSN) feature. RSN allows the two ends of a communication link to negotiate the encryption algorithms and protocols to be used. This facility enables updating a wireless network with new algorithms and protocols in order to protect it from future vulnerabilities.

Still, the 802.11i protocol requires special encryption hardware to run the AES algorithm; due to this fact, additional time is needed for the vendors to change their existing hardware to support the 802.11i protocol. To enable the migration of WEP and WPA systems to 802.11i, the WiFi Alliance has proposed a new security protocol—the WPA2. The new protocol incorporates all 802.11i functionality, but also enables the use of the TKIP protocol to support devices that do not have the necessary hardware to run the AES algorithm.

VPNs

To provide a solution to the problem of security, many companies are extending/developing *virtual private networks* (VPNs) (Karygiannis & Owens, 2002). Maintaining a VPN requires the engagement of specialized personnel or the training of existing personnel; in both cases, the costs associated with deploying a wireless infrastructure are highly increased. Along with the cost associated with the deployment of a VPN, VPNs incorporate a number of operational problems on a system.

In networks where the users roam contentiously, a Layer-3 VPN solution will disrupt a user's connection and may even force the user to re-authenticate. Along with this, applications that run on client terminals and access data stored on the corporate servers may be seriously disrupted from a Layer-3 disconnection. Such disconnections can seriously damage the integrity and availability of corporate information.

CONCLUSION

In this article, we have discussed the critical issue of wireless security. We have presented the security vulnerabilities that are frequently inherited in wireless networks. Also, we have described the most common security protocols and techniques used. Moreover, we have provided a description of the current security trends and protocols used to secure such WiFi networks, along with the problems from their application.

KEY TERMS

Encrypted Tunnel: An encrypted logical (virtual) connection between two ends. Data traveling inside the tunnel are encrypted with an agreed encryption algorithm.

Fresnel Zone: The area around the visual line of sight of a wireless link on which the RF waves are spread. This area must be clear from obstacles, otherwise the RF signal is weakened.

Man-in-the-Middle Attack: An attack where the adversary succeeds in locating himself in an established connection between two or more authorized nodes. Data traveling between the nodes are always passing from the adversary.

Reassociation Request Frame: A data packet transmitted in a wireless network. The packet enables a client to reconnect to an access point. The packet is transmitted after a client disconnection or when a client roams from one access point to another.

Virtual Private Network (VPN): A set of technologies and protocols used to establish encrypted tunnels between one or more network nodes.

WiFi Alliance: A nonprofit organization, with more than 200 members, devoted to promoting the use and operation of wireless networks. Products associated by the WiFi Alliance are able to interoperate.

Wireless Computer Network: Any computer network that uses wireless technologies based on the IEEE 802.11x standards to transmit and receive data.

Wireless Sensor Networks

INTRODUCTION

The origins of networks of sensors can be traced back to the 1980s when DARPA initiated the distributed sensor networks program. However, recent advances in microprocessor fabrication have led to a dramatic reduction in both the physical size and power consumption of such devices. Battery and sensing technology, as well as communications hardware, have also followed a similar miniaturization trend. The aggregation of these advances has led to the development of networked, millimeter-scale sensing devices capable of complex processing tasks. Collectively these form a wireless sensor network (WSN), thus heralding a new era of ubiquitous sensing technology and applications. Large-scale deployments of these networks have been used in many diverse fields such as wildlife habitat monitoring (Mainwaring, Polastre, Szewczyk, Culler, & Anderson, 2003), traffic monitoring (Coleri, Cheung, & Varaiya, 2004), and lighting control (Sandhu, Agogino, & Agogino, 2004).

A number of commercial WSN platforms have been launched in recent years. Examples include the Mica family (Hill, 2003), Smart-Mesh (<http://www.dust-inc.com>), Ember (<http://www.ember.com>), iBeans (Rhee, Seetharam, Liu, & Wang, 2003), Soapbox from VTT (<http://www.vtt.fi/ele/research/tel/projects/soapbox.html>), Smart-Its (<http://www.smart-its.org>), and the Cube sensor platform (O'Flynn et al., 2005). As the miniaturization of the constituent components of a WSN continues unabated, power consumption likewise diminishes, thus the current generation of sensors can function perfectly for years using standard AA batteries (Polastre, Hill, & Culler, 2004). Alternative solutions may not require any batteries; for example iBeans (Rhee et al., 2003) coupled with an energy harvester can operate by scavenging energy from tiny vibrations that occur naturally. Miniaturized solar panels are another possible solution for outdoor operation. Production costs of single nodes are estimated to be less than a dollar, a significant cost reduction

over the price of older sensor models, thus paving the way for large-scale WSN deployments, possibly consisting of a number of nodes several orders of magnitude greater than that in ad-hoc networks (Akyildiz, Su, Sankarasubramaniam, & Cayirci, 2002).

BACKGROUND

The main components of a WSN are gateways and sensor nodes. The sensor nodes can relay their sensed data either directly to the gateway or through each other depending on the scale of the network. In turn the gateway can send commands down to the nodes to, for example, increase their sampling frequency. In some networks, when the gateway is tethered to an adequate power supply, a greater transmission range can be achieved. This gives rise to an asymmetry in the data acquisition and control protocols, where control commands are sent directly to the node but the data sent from the node to the gateway is multi-hopped. Of course multi hopping of the control commands from the gateway can be used also.

Multi-hopping, while useful in extending the reach or scale of a WSN and reducing the overall transmission cost with respect to direct communication, does have its limitations. The cost of transmitting a packet can be greatly increased depending on the distance a node is from its gateway. Secondly, since nodes nearest the base station, that is, one hop away, will not only have to send their data but also that of all other nodes greater than a single hop, there will be a greater demand placed on the power supply of these nodes. This means that, in general, a node lifespan is inversely proportional to the number of hops it is away from the base station. To alleviate this problem, multiple gateways can be used, with the nodes only transmitting data to their local station. A second solution creates a hierarchy of nodes with varying power and transmission capabilities. Higher power

nodes can act as gateways to the gateways for the lower powered sensors.

DEPLOYMENT CONSIDERATIONS

There are a number of issues to consider when deploying a WSN. The first and perhaps most significant is the number of nodes required in the deployment. The quantity of nodes required will primarily be governed by the size of the area to be monitored and the frequency of the sampling required. In general, the more nodes there are in a given WSN, the better the quality of data; however there is a corresponding increase in the time required for processing. Given that the choice on node density has been made, another factor still remains—the node sampling frequency. The choice of this value will depend on what aspect of the environment is being monitored and the power resources available on each node. If the sampling frequency is too high, more power will be consumed than is necessary. However, if it is too low, important events could be missed. A useful strategy might be to alter this value opportunistically so as to deliver optimum performance.

Getting the sensed data from the node requires the wireless transmission of a data packet, a process that can consume a significant portion of the available power resources. One transmission can occur per sensed value when a real-time picture of the environment is required. Or multiple readings can be bundled into a single message. Alternatively the node may intelligently decide not to transmit a packet if, for example, no change in the sensed value had occurred. This can dramatically increase the longevity of the node, and if this is a universal policy adopted by all nodes in the WSN, the lifespan of the WSN can be extended.

Due to the battery operation of the nodes, power management is critically important to the health of a WSN. Another approach to performing power conservation is to enable redundant sensors to hibernate. The rationale behind this is that a sensor consumes little or no power while asleep, and so the more nodes that are hibernating, the less power is being consumed collectively by the network. A hibernating node cannot forward any sensed data, effectively reducing the spatial sampling frequency. Therefore, caution must be exercised when selecting which nodes to hibernate.

Two broad approaches exist for selecting nodes for hibernation. The first is based on defining a sensing radius for each individual sensor. An area is covered if all points within the sensed area lie within the sensing range of at least one sensor. When there are points covered by more than one sensor, it may be possible to hibernate redundant sensors without breaking the coverage constraint.

An alternative approach uses the data being received by nodes. It is based on interpolation and assumes that the

required node density exists. Given a collection of nodes, it is possible for them to interpolate the sensed medium at a required point, assuming an interpolation function exists. By interpolating at the point of an individual node, an interpolated value can be obtained. By comparing this to the actual sensed value, an interpolation error can be derived. If this error is less than a particular threshold, then this node is deemed redundant and will hibernate for a predefined period of time before rechecking its redundancy.

Another fundamental issue for practical WSNs is that of sensor calibration (Whitehouse & Culler, 2003). When two nodes observe different values in their sensed data, is it because they are seeing different events or because one or both of the sensors has malfunctioned? Of course calibration can be done prior to deployment, but if the malfunction causes its accuracy to degrade over time, then a recalibration must occur on the fly after deployment. This is a significant problem, since the environment in which the nodes are sensing usually cannot be controlled for the calibration to occur. When sampling the environment, it may be a requirement for all the sensors to sample at the same point in time. This requires a clock synchronization technique that will work over the entire network, and this is quite a difficult task to perform on such computationally challenged devices.

Multi-hop routing can introduce a considerable lag between the time a message is sent from the node and the time it is received at its destination. When the destination is a gateway, it will in turn send control commands to the network based on the data it receives. These control commands may also be multi-hopped to their destination. The aggregate delay can be unacceptable and is usually symptomatic of an overburdened gateway. The introduction of an additional gateway that efficiently partitions the network would alleviate this issue.

A final issue with a practical deployment of a WSN is that of programming and debugging the nodes themselves. A node considered to have one of the richest user interfaces consists of three LEDs, allowing eight program execution states to be displayed at any given point in time. To alleviate this, a methodology has been developed to allow the development of applications off the nodes so that accuracy of the approach can be verified (Tynan, Ruzzelli, & O'Hare, 2005).

APPLICATION CONSIDERATIONS

The autonomous nature of the wireless sensor networks makes the technology versatile with respect to applications. Sensors can be effectively deployed for monitoring and detecting of malfunctioning industrial machinery during normal production activity. Moreover, as no infrastructure is needed, their deployment is immediate and highly adaptive to the environment in which they operate. By means of

distributed sampling, sensor networks are able to provide a more accurate and in-depth evaluation of the state of the environment at any moment in time.

Sensors can also be programmed to make decisions at a local stage or through a centralized approach. In the first case, nodes are organized in clusters in which a sensor head is elected. Collected data is sent to the sensor head, where it is evaluated before an appropriate decision is made. For instance it can actuate supplementary machinery in cases where production overloading is occurring. In cases where a sensor is not endowed with a decision-making capability, or in particular circumstances where it does not have enough information to make an immediate decision, collected data is sent to the closest gateway for further processing, and the resulting decision is returned to the sensor. In an energy-saving maneuver, data is sent to neighboring nodes that forward it, via a routing procedure, towards the gateway. Such a scenario is an illustration of a centralized approach of decision making.

For more effective management of the production activity, sensors can interact, possibly using either fixed networked or wireless technology, with personal digital assistants (PDAs) or mobile phones. In this way, wireless sensor networks can improve the supervision of an activity and communicate with a user in a more effective and efficient manner. For example, in the case of industrial machine monitoring, should the sensor head sense that a particular machine has excessive vibration or that a temperature exceeds a certain threshold, it may decide to raise an alarm and call a technician for assistance. However, the approach it takes to this may vary. Flagging an alarm in a centralized control system can be implemented quite easily. However, technicians and maintenance staff are generally mobile, as their duties call them to various places in the factory floor. Thus, the sensor head must be able to route a message to them. As technicians are likely to be equipped with PDAs or mobile phones, instant messaging and SMS are two obvious methods of contacting them.

Applications of m-commerce through the use of collaborative wireless sensor networks and PDAs or mobile phones are numerous. In the case of sensors deployed in a shopping center, a shopper with a PDA or smart phone can request a particular product with certain requirements, for example, model, price, and so on. By means of sensor collaboration, products in the shopping center that match the user requirements can be identified. The shopper can then decide whether to buy remotely or go and view the items in question before buying them. Alternatively, a reverse auction could be initiated with the shops in the mall all vying for the shopper's business. While such a scenario illustrates the potential synergic interaction of WSNs and standard mobile devices, a number of issues must be resolved before such a vision can become a reality.

FUTURE TRENDS

Though significant research in WSNs and mobile computing continues, issues concerning the enablement of seamless and transparent interaction between each domain need to be resolved. A number of issues are now identified.

Communication Protocol Issues

In order for a PDA to communicate with a sensor network, it is necessary that both PDAs and WSNs use the same communication protocol. At present, off-the-shelf PDAs have the Bluetooth protocol for short-range communication provided. Unfortunately, studies of the Bluetooth architecture (Leopold, Dydensborg, & Bonnet, 2003) showed the unsuitability of such a protocol for wireless sensor networks. On the other hand, although recent advances propose a vast number of protocols tailored to WSNs, the communication compatibility between the two technologies is still an open issue.

Ontology Issues

Such kinds of issues arise after PDAs and sensors agree which communication protocol to use. In the context of knowledge sharing between PDAs and sensors at the application layer, they should agree with the specification of a conceptualization, also known as an ontology. Although some research proposes the study of semantic techniques for wireless sensor networks (Whitehouse, Liu, & Zhao, 2006), a comprehensive methodology of PDA/sensor interaction is still an open issue to be addressed.

Trust Management Issues

Requests of m-commerce-related information from sensors to PDAs and vice versa raise issues of trust management. In fact, sensors should trust the quality of service offered by the PDA protocol. On the other side, PDAs should trust sensors when, for example, product availability or machinery conditions are sent to a PDA. While the latter case can be considered as an instance of Internet trust management, the former case needs to consider the issue of memory capacity constraints of sensors. Procedures for realizing trust management on individual sensors, for example, through intelligent agent technologies, need further research.

The big "umbrella" of trust management also includes more specific issues of security. In fact, the multi-hop routing of WSNs together with the relatively simple architecture of sensors pose an inherent risk, as an attacker may only need to compromise one device to compromise the security of the entire network. This concern is amplified in applications like m-commerce where private credentials must be fully safely encoded.

CONCLUSION

Significant advances have been made in WSNs over the last decade. Nevertheless, power consumption remains a significant barrier to their widespread deployment. However, significant strides are being made in this area. Though a mature research discipline in its own right, the issues of interaction and interoperability with conventional computing systems, and mobile computing devices in particular, is becoming increasingly important. In extending the reach of computing technologies into what are frequently remote and hostile environments, WSNs will enable an array of new and innovative applications and services for mobile users.

KEY TERMS

Gateway: In general, considered a more powerful node that is used to collect information from the networks and for some architecture to synchronize them. A WSN can have few gateways deployed in the network. Sometimes, they are assumed to be interconnected through alternative wireless technology like WLAN and WiMAX. Gateways are often referred to as sinks or inappropriately called base stations.

MAS: Multi-agent system.

Node Lifespan: Also known as node lifetime, it represents the operational life expectancy of a sensor. Usually, it is calculated for certain network parameters (e.g., network topology, network density) and certain node parameters (e.g., node data rate, duty cycle of a sensor equipped with two AA standard batteries).

Personal Digital Assistant (PDA): Also known as a palmtop.

WSN: Wireless sensor network.

Wireless Technologies for Mobile Computing and Commerce

David Wright

University of Ottawa, Canada

INTRODUCTION

At the time of writing (1Q06) most countries have a small number (2-6) of major cellular operators offering competing 2.5G and 3G cellular services. In addition, there is a much larger number of operators of WiFi networks. In some cases, a major cellular operator, for example, Deutsche Telekom and British Telecom, also offers a WiFi service. In other cases, WiFi services are provided by a proliferation of smaller network operators, such as restaurants, laundromats, airports, railways, community associations and municipal governments. Many organizations offer WiFi free of charge as a hospitality service, for example, restaurants. Cellular services offer ubiquitous, low data rate communications for mobile computing and commerce, whereas WiFi offers higher data rates, but less ubiquitous coverage, with limitations on mobility due to business as opposed to technology reasons.

Emerging networks for mobile computing and commerce include WiMAX and WiMobile (Wright, 2006), which offer higher data rates, lower costs and city-wide coverage with handoff of calls among multiple base stations. These new technologies may be deployed by the organizations that currently deploy cellular and WiFi networks, and also may give rise to a new group of competitive wireless network operators.

This article identifies the capabilities needed for mobile computing and commerce and assesses their technology and business implications. It identifies developments in the wireless networks that can be used for mobile computing and commerce, together with the services that can be provided over such networks. It provides a business analysis indicating which network operators can profitably deploy new networks, and which network operators need to establish business and technology links with each other so as to better serve their customers. The resulting range of next generation service, technologies and network operators available for mobile computing and commerce is identified.

WIRELESS NETWORK ARCHITECTURES

Figure 1 illustrates the network architectures for WiFi, Cellular, WiMAX and WiMobile, including the radio access network on the left and the wired core network on the right.

The cellular architecture is the most sophisticated in that the core network includes a circuit network (for legacy circuit switched voice calls), a packet network (for data calls) and an IP Multimedia Subsystem, IMS (for migration of all traffic onto the Internet).

These three networks essentially allow the cellular operator to maintain control over all calls to and from the mobile device, and hence derive revenue from them. In particular the IMS network contains servers for establishing voice and video calls over IP, authenticating users, maintaining records of the current location of a mobile user, accounting, and security. Cellular operators are migrating traffic from their circuit and packet networks onto the IMS.

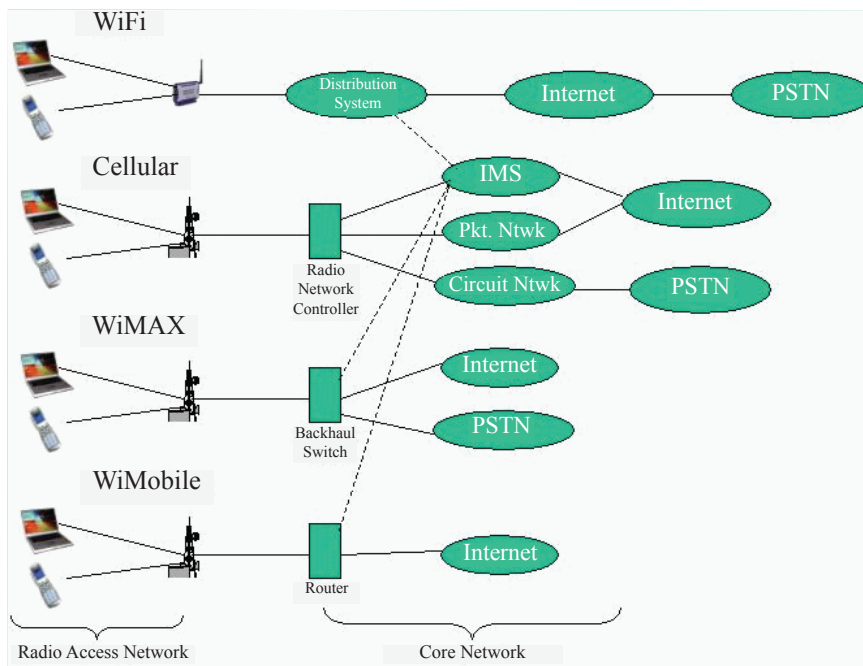

By contrast, WiFi (IEEE, 1999a, 1999b, 1999c, 2003), WiMAX (IEEE, 2006; Ghosh et al., 2005), and WiMobile (IEEE, 2006; Lawton, 2005) are simply radio access technologies and do not specify a core network. They therefore allow more direct access from a mobile device to the Internet. In particular, the WiMobile specification, which is under development at the time of writing, emphasizes that its design is being optimized for operation with IP. This more open access to the Internet allows a mobile user to set up, for instance, a VoIP call using a third party service without the involvement of the wireless network operator. As the user moves from one access point to another, the call can be maintained using Mobile IP, involving servers maintained by the user's ISP, not by the wireless network operator. Mobile IP can operate over diverse wireless access technologies as described by Benzaid et al. (2004).

If the operator of a WiFi, WiMAX or WiMobile network wishes to maintain more control over the traffic passing through their network and hence participate more in the revenue generated by that traffic, they can build an IMS network. Alternatively if they already operate a cellular network, they can provide access to their existing IMS network, as shown by the dashed lines in Figure 1.

REQUIREMENTS FOR MOBILE COMPUTING AND COMMERCE

Any wireless transmitter/receiver has a limited range in order to comply with government regulations regarding maximum power output. A mobile user therefore may move out of the

Figure 1. Wireless network architectures

range of its current wireless access point, and it is necessary to handoff the communication to another access point using either the same or a different wireless technology. Handing off the communication means that the current IP session is maintained, for example, the user continues to browse a Web site as a registered user, a VoIP call is not interrupted, and an enterprise user with a laptop-based secure VPN to an enterprise network continues to use the same VPN. There are four requirements in order to achieve handoff suited to mobile computing and commerce:

1. It must be possible to switch the call from one access point to another
2. If the user is receiving quality of service, QoS, for example, a guaranteed low latency, that QoS is maintained after the handoff, and an acceptable number of packets are lost during handoff.
3. If the access points are operated by different network operators, there must be a business arrangement between them regarding mediation of the billing for the call.
4. The organization deploying the wireless access network must be able to make a profit or to have a business model that focuses on hospitality service.

Requirements 1 and 2 are technology related and are discussed next, followed by the business requirements 3 and 4.

TECHNOLOGY ISSUES

A mobile device that is capable of using multiple wireless access technologies, such as those described above, can continuously scan its radio environment to search for access points that it could potentially use. Some of them may not be available, if, for instance, they are operated by companies with which the user does not have a subscription. In order to choose among the available access points within range the mobile device can apply criteria including: data rate, cost, ability to handoff seamlessly, and QoS; delay (important for voice) and packet loss rate (important for data). For instance, a mobile device with an interactive voice/video call in progress could choose the lowest cost network that provides acceptable delay. A device downloading a large data file could choose the network with the highest data rate given limitations on cost and packet loss rate. Once the network is selected, handoff is initiated.

Handoff among WiFi, WiMAX and WiMobile is handled by IEEE (2006). Handoff between cellular and one of these three technologies is complicated by the need to interwork with the cellular circuit, packet and IMS networks.

- In the case of WiFi, this interworking is provided by a specification from the industry consortium UMA, Unlicensed Mobile Access (2006), which is incorporated as part of the GSM cellular network specifications, release 6.

Table 1. Wireless access network operators revenue sources

| Revenue Source | Service provided by: (N) Network Operator (C) Content Provider | Revenue accrues to: (W) Wireless Network Operator (3) Third Party Service Provider (S) Shared with Content Provider |
|---|--|--|
| Voice/video calls | N | W 3 |
| Audio content | C | S |
| Video content | C | S |
| Gateway to PSTN | N | W 3 |
| Geographic info (e.g., travel directions, highway safety) | N C | W S |
| Location enabled advertising | N C | W S |
| Location enabled buddy lists | N | W |
| Multimedia Messaging Service | C | W 3 S |
| Gaming | C | S |
| QoS | N | W |
| VPN | N | W 3 |

- In the case of WiMAX, similar issues are involved and are being resolved by the WiMAX Forum (2006).
- WiMobile is at an early stage of development and interworking with cellular is not a priority at this stage. A specification may be developed later, or alternatively, WiMobile may differentiate itself from the other technologies by becoming a “native-IP” access mechanism, similar to DSL and cable modem in which customers have direct access to the Internet.

This discussion addresses requirements 1, 2 above. We now move on to requirements 3, 4.

BUSINESS ISSUES

This section presents business strategies for wireless access network operators that take into account sources of revenue related to mobile computing and commerce, plus the need to compete with other technologies and network operators. Earlier work in this area (du Preez & Pistorius, 2003) dates from a time when 3G and wireless data services were emerging technologies. The present section incorporates developments in technology and services to date.

The sources of revenue are given in Table 1 and are classified in two ways:

1. Whether the service is provided by a content provider or a network operator, which may be the wireless access network operator or another network operator. For instance, a VoIP service could be provided by the

wireless operator or by a third party such as Vonage. Either way it is provided by a network operator.

2. Who receives the revenue for the service: the wireless access network operator, a third party or a sharing arrangement with a content provider.

It can be seen from Table 1 that there is a large number of mobile computing and commerce services that can be provided by a mix of wireless network operators, content providers and third parties. In addition there are non-revenue generating services such as e-mail and Web browsing. A clear business strategy is needed to operate successfully in competition with the other players. Strategies suited to the different types of wireless network operators are given in Table 2.

Table 2 divides wireless access network operators into three groups: incumbent cellular operators, hospitality providers such as restaurants and municipalities, and new competitors, who are starting operations based on the availability of new technology. The incumbent cellular operators have complex core networks as shown in Figure 1 and incur costs of operating legacy technologies. They seek to deploy all possible wireless technologies in order to accommodate the needs of all customers. By contrast the new competitors seek to reduce their costs by only operating the most recent technologies. Both these groups are operating commercial services and therefore use licensed spectrum so that their customers do not experience interference from other users. The hospitality providers, however, are providing a free service. Their customers accept that the performance may vary according to the demands of other users and therefore the operators reduce their costs by using unlicensed spectrum.

Table 2. Strategy for wireless access network operators

| | Cellular Operators | Hospitality providers | Competitive Wireless Network Operators |
|----------------------|--|---|---|
| Technologies | 2.5G, 3G, WiFi, WiMax, WiMobile | WiFi, unlicensed WiMAX | WiMAX, WiMobile |
| Revenue sources | Generate revenue from the full range of services | Provide Internet access for the full range of services. | Generate revenue from the full range of services |
| IMS strategy | Lock customers into IMS-based services. | Establish partnerships and interfaces to the IMS of other operators | Build IMS. Establish partnerships and interfaces to the IMS of other operators |
| Competitive strategy | Buy up competitors. | Avoid competing with other operators by a competitive bid process. | Differentiate from incumbents by offering low cost services, focusing on IP, developing next generation services, for example, presence, location, QoS. |

Both the incumbents and the new competitors aim to deliver the full range of services listed in Table 1 to their customers, typically from the IMS, so as to maintain control over the revenue. The hospitality providers, however, are typically providing access only, allowing their customers to get services from any third party they wish, since they do not seek to generate revenue from their networks. For location-based services, the hospitality provider can provide the third party with information about the customer’s current location.

The cellular incumbents typically already have an IMS in place and aim to lock customers into service provided by that IMS. The new competitors need to build an IMS and then establish partnerships with other wireless operators so that calls originating on one IMS can be handed off to another operator. These partnerships are also important to the hospitality providers since they typically have no interest in developing their own IMS.

The competitive strategy of incumbent cellular operators towards WiFi operators historically has been to buy them up, and this strategy is also appropriate for WiMAX and WiMobile operators. The strategy of hospitality operators is to avoid competition, and this is particularly important for municipalities, who should not be seen to use tax dollars to compete against private industry. In order to avoid this perception, they can use a competitive bid process allowing any operator the opportunity to bid on the contract to build and operate their network. The strategy of the new competitors is to compete on three fronts. First, they can offer low cost services, since they do not have the cost of operating legacy networks. Second, they can offer a full range of next generation services, such as presence and location-based services, thus positioning themselves as state-of-the-art suppliers. Third, they can sell QoS guarantees to their customers, since new technologies such as WiMAX and WiMobile are particularly suited to providing such guarantees.

CONCLUSION

The enabling technologies for mobile computing and commerce are developing rapidly. New wireless technologies such as WiMAX and WiMobile offer extended coverage and improved QoS compared to WiFi; and higher data rates and lower costs compared to 2.5G and 3G cellular. A wide range of services is available over these technologies including services that generate revenue (a) for the wireless operator, such as location-based services, (b) for a third party, such as VoIP and (c) for a content provider, such as entertainment. Wireless network operators, including incumbent cellular operators, hospitality providers and new competitive wireless network operators, need to develop strategies that allow handoff of calls among the different technologies and operators. Strategies include locking customers into an IMS, interworking with other operators’ IMSs, buying out competitors and developing a broad range of state-of-the-art services such as location and presence services.

The mobile computing and commerce user can therefore expect a proliferation of services (Table 1), a number of different network operators (Table 2), an array of different wireless technologies, WiFi, 3G, WiMAX and WiMobile, and a mobile device that can make the best choice among these alternatives at any point in time and space.

KEY TERMS

IMS, IP Multimedia Subsystem: Part of the wired core network containing servers for establishing voice and video calls over IP, authenticating users, maintaining records of the current location of a mobile user, accounting, and security.

Location-Based Services: Services that take into account the users current geographical location, for example, advertising locally available products and services, providing directions and alerting drivers to traffic congestion and road accidents.

Mobile IP: An Internet standard that allows a mobile user to move from one point of attachment of the network to another while maintaining an existing TCP/IP session. Incoming packets to the user are forwarded to a server in the user's new access IP subnetwork.

Presence: The ability of a user device to specify characteristics, such as whether the user is online, whether the user is willing to receive calls, whether the user is willing to receive calls of a given type (e.g., voice, video, data, MMS) from specified other users and what is the user's current location to a specified degree of accuracy.

Quality of Service (QoS): Features related to a communication, such as delay, variability of delay, bit error rate and packet loss rate. Additional parameters may also be included, for example, peak data rate, average data rate, percentage of time that the service is available, mean time to repair faults and how the customer is compensated if QoS guarantees are not met by a service provider.

WiFi: A commercial implementation of the IEEE 802.11 standard in which the equipment has been certified by the WiFi Alliance, an industry consortium.

WiMAX: A commercial implementation of the IEEE 802.16 standard in which the equipment has been certified by the WiMAX Forum, an industry consortium.

WiMobile: Another name for the IEEE 802.20 standard, which is in course of development at the time of writing (1Q06).

INTRODUCTION

The widespread availability of network-enabled handheld devices (e.g., PDAs with WiFi) has made *pervasive computing* environment development an emerging reality. Mobile (or multi-hop) Ad-hoc NETWORKS (MANETs—Agrawal & Zeng, 2003) are mobile device networks communicating via wireless links without relying on an underlying infrastructure. Each device in a MANET acts as an endpoint and as a router forwarding messages to devices within radio range. MANETs are a sound alternative to infrastructure-based networks whenever the infrastructure is lacking or unusable, for example, military applications, disaster/relief, emergency situations, and communication between vehicles.

Generally, the use of a MANET requires a strong collaboration among users/devices constituting the network; more often, that collaboration is translated into a list of activities executed in sequence or concurrently by applications running on mobile devices, thus resulting in *cooperative works*. Therefore, in such situations, MANET users would benefit from software supporting their collaboration. Such a *coordination software* would enable them to execute their *activities* through specific applications—for example, computer-supported cooperative work tools (Grudin, 1994), *workflow management* applications (Leymann & Roller, 2000), and so forth—running on handheld devices, thus enabling cooperative processes to be run. All such applications typically require continuous inter-device connections (e.g., for data/information sharing, activity scheduling and coordination, etc.), but these are not generally guaranteed in MANETs, due to the high mobility of the nodes in the network.

Collaborative Scenarios

Consider a scenario of emergency situations, for example, the case of an aftermath of an archeological disaster. A team is equipped with mobile devices (laptops and PDAs) and sent to the affected area to evaluate the condition of archeological sites and buildings, with the goal of drawing a situation

map to schedule rebuilding activities. A typical cooperative process to be enacted by the team would be as shown in Figure 1 (depicted as a UML Activity Diagram—De Rosa, Malizia, & Mecella, 2005):

1. The team leader has previously stored all area details (not included in the process), including a site map, a list of the most important objects located in the site, and previous reports/materials.
2. The team is considered as an overall MANET, in which the team leader's device (requiring the most computing power, therefore usually a laptop) coordinates the other team members' devices, by providing suitable information (e.g., maps, sensitive objects, etc.) and assigning activities/tasks.
3. Team members are equipped with handheld devices (PDAs), which allow them to run some operations but do not have much computing power. Such operations, possibly involving various hardware items (e.g., digital cameras, GPRS connections, computing power for image processing, main storage, etc.) are provided as software services to be coordinated. Team member 1 might fill in some specific questionnaires (after a visual analysis of a building), to be analyzed by the team leader using specific software in order to schedule subsequent activities; team member 3 might take pictures of the damaged buildings, while team member 2 may be responsible for specific processing of previous and recent pictures (e.g., for initial identification of architectural anomalies).

In this case, it might be useful to match new pictures with previously stored images. The device holding the high-resolution camera must therefore be connected to the one containing the stored pictures. But in a situation such as the one shown in Figure 2, the movement of the operator/device equipped with the camera may result in its disconnection from the others.

A pervasive architecture should be able to predict such a situation, alert the coordination layer, and possibly have a

Figure 1. Cooperative process

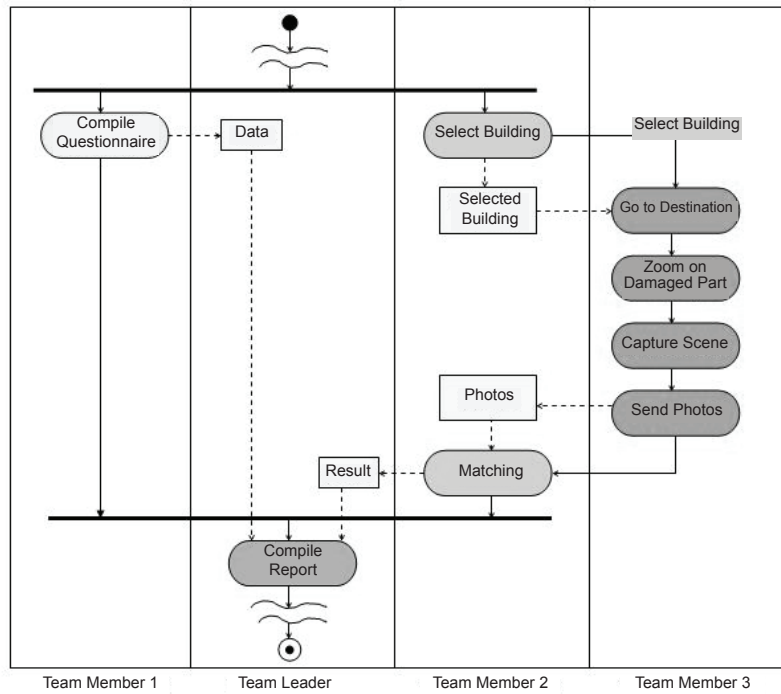

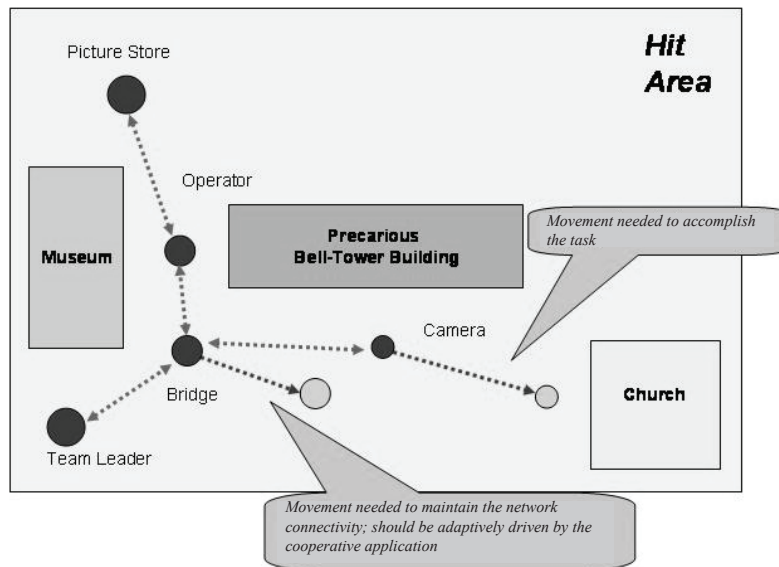

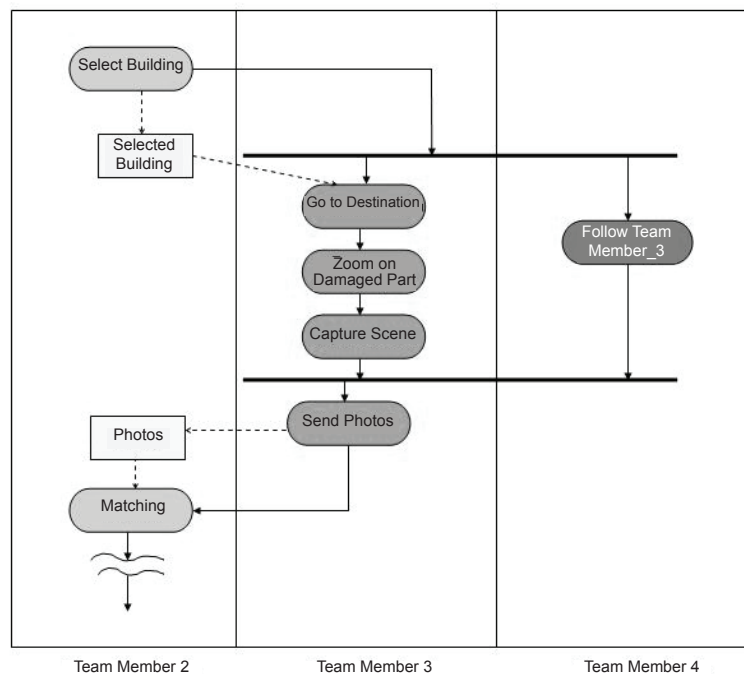

Figure 2. Critical situation and adaptive management

“bridging” device (team member 4’s device) to follow the operator/device moving out of range, maintaining the connection, and ensuring a path between devices. In this way the coordination layer schedules the execution of new activities based on the prediction of a disconnection, as shown in Figure 3 (note the new activity for team member 4).

The process’s adaptive change is centrally managed by the coordination layer, which has “global” knowledge of the status of all operators/devices and takes into account idle devices, operations that can be safely delayed, and so forth.

Figure 3. Modified process (details)

Some Considerations

Cooperative work may be performed by Workflow Management Systems (WfMSs) (Hollingsworth, 1995; van der Aalst & Van Hee, 2002), a software layer for defining, handling, and carrying out computerized processes (referred to as *workflows*), through programs whose performing order is led by a process logic representation.

A workflow is made up of a set of tasks to be performed, a set of state variables handled by tasks, and a set of conditions on such variables which can cause a selection in performing between two or more tasks. Occasionally, some tasks have to be carried out strictly in sequence; other times in a parallel or arbitrary order because there is no causal relationship between them. Actors performing workflow tasks exchange much information needed for their collaboration and coordination. Such an exchange can occur, of course, only if devices/actors are continuously linked to each other.

In a MANET scenario, the “bridging” actions can be seen as supporting activities needed for primary ones which, otherwise, could not be carried out, prejudicing the whole process execution. These support activities are added, when needed, concurrently with other ones. Therefore, a WfMS for MANET has to support dynamic adaptation of processes where the definition of process instances changes on altering of execution context. In MANETs, the altering is caused by disconnection of devices.

The critical issue of current WfMSs is the lack of support of adaptiveness; most WfMSs (both commercial products and academic prototypes) handling adaptiveness assume the presence of an expert who decides which changes have to be applied. In MANETs, the assumption of an expert whose only purpose is disconnection handling is not acceptable, therefore we must investigate how automatically to decide, first, the inadequacy of process instance, and, then which changes on workflow definition must be applied to handle disconnections.

Related and Background Works

In recent years, research in the MANET area has mainly focused on the development of appropriate routing protocols, security and reliability of the communications, methods for energy preservation, and other issues on the lower four ISO/OSI layers (Arbaugh, 2004; Vaidya, 2004). Effective routing in ad-hoc networks is still an actively addressed open problem (Beraldi & Baldoni, 2002; Vaidya, 2004), with some interesting proposals presented in the literature (e.g., dynamic source routing—DSR, ad-hoc on-demand distance vector—AODV routing, zone routing protocol—Z-RP, etc.). Researchers in this area assert that a sound technical basis for MANETs exists and it is thus time to start thinking about how to support applications based on MANETs. In order to enable the development of application layer software (and

thus of any information system for MANETs), abstractions on the specific characteristics of the routing algorithms, and more generally, on the services and data provided by the lower network layers, are required. (De Rosa, Di Martino, Paglione, & Mecella, 2003) proposes a network service interface to be used as the basic layer on which to build application software, starting from the analysis and abstraction of current routing protocols.

As far as the issue of adaptive workflow management (Baresi, Casati, Castano, Mirbel, & Pernici, 1999; Voorhoeve & van der Aalst, 1997), this is still an open issue. Relevant work includes the e-Flow system (Casati & Shan, 2001), in which the issue of manually modifying workflow schemas and then automatically migrating active process instances to the new schema is addressed, and AGENTWORK (Müller, Greiner, & Rahm, 2004), which is one of the few examples of a workflow system in which adaptation is not manual, but automatic, on the basis of a rule-based approach. But in MANETs the adaptation should be carried out in a very frequently changing environment, whereas the previous approaches are targeted to Web-based workflows (indeed workflows composed of different Web services), in which modifications of the schemas are less frequent, but the number of running instances is very high.

THE MOBIDIS PERVASIVE WfMS

Our approach, named MOBIDIS¹, is based on the following specific assumptions:

- Each device includes hardware that lets it know its *communication distance* from the surrounding devices that are within radio range. This is not a very strong assumption, because specific techniques and methods are easily available—for example, TDOA (time difference of arrival), SNR (signal-to-noise ratio), and the Cricket compass (Priyantha et al., 2001).
- No device in the MANET has GPS hardware.
- At start-up, all devices are connected (that is, each device has a path—possibly multi-hop—to any other device). Each device does not have to be within range of any other device; that is, it does not require a *tight* (one-hop) connection. It requires only a *loose* connection, guaranteed by appropriate routing protocols.
- A specific device in the MANET, called the *coordinator*, centrally predicts disconnections and manages them by rewriting the workflow schema and (if it is required) by reassigning the process tasks among the participants.

The proposed approach combines local connection management among devices with global management of both network topology and task assignment. Local connection

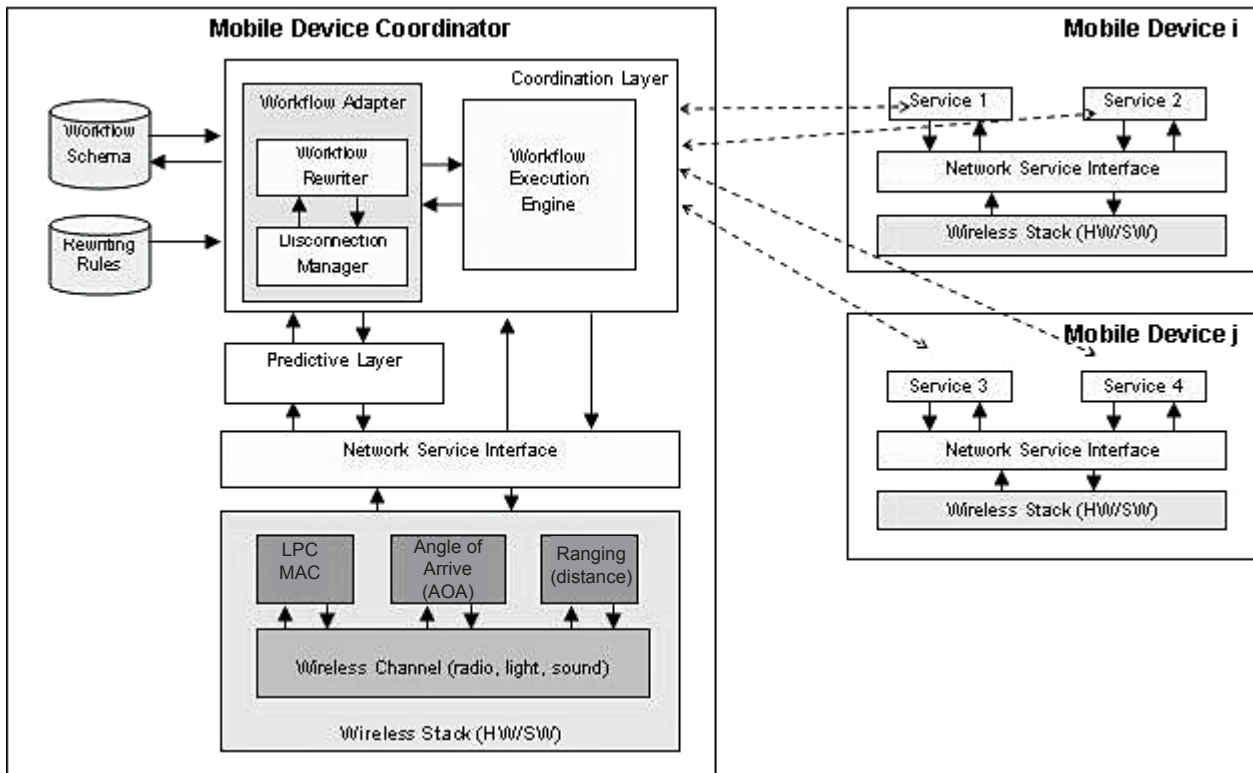

management consists of monitoring and checking one-hop communications between a device and its neighbors. It is realized as special services running on handheld devices that implement techniques for estimating and calculating distances and relative positions (angle and direction of arrival) between a specific device and its direct neighbors. Global management maintains a consistent state of the network and of each peer in the network. It manages the network topology (and its predicted next states) and the tasks each peer is in charge of, as well as services that peers offer (that is, it provides a service registry). On the basis of that information, the coordinator applies algorithms for choosing a bridge and/or executes workflow task reassignment when needed.

Figure 4 shows the proposed architecture to support disconnections and to enact cooperative work in MANETs: each device has a *wireless stack* consisting of a wireless network interface (the *wireless channel* and *LPC MAC* modules) and the hardware for calculating distances from neighbors (*angle of arrive* and *ranging* modules).

On top, a *network service interface* offers to upper layers the basic services for sending and receiving messages (through multi-hop paths) to and from other devices, by abstracting over the specific routing protocols. Offered services (i.e., specific applications supporting tasks of the devices' human users) are accessible to other devices and can be coordinated and composed cooperatively. Some of these services are applications that do not require human intervention (for example, an image-processing utility). Others act as proxies for humans (for example, the service for instructing human users to follow a peer is a simple GUI that alerts the user by displaying a pop-up window on his or her device and emitting a signal).

In contrast, the coordinator device presents the *predictive layer* on top of the network service interface, signaling any probable disconnection to the upper *coordination layer*. The *predictive layer* implements a probabilistic technique (De Rosa et al., 2005) which can predict if all devices will still be connected in the next instant. At a given time instant t_i in which all devices are connected, the coordinator device collects all device distance information and builds a next-connection-graph—that is, the most likely graph at the next time instant t_{i+1} , in which the predicted connected and disconnected devices are highlighted. In the interval $[t_i, t_{i+1}]$, the coordinator layer enacts the appropriate actions to enable all devices to be still connected at t_{i+1} . In predicting at t_i the next-connection-graph, the technique considers not only the current situation, but also recent situations and predictions (i.e., at t_{i-1} , t_{i-2} , etc.), specifically considering distances calculated in the recent past. Thus, although the pervasive architecture guarantees the connection of all devices, MANET's evolution is considered as it would be in a “free” scenario (i.e., without remedial actions by the coordination layer) when predicting the future situation. The reasonable assumption is that if two devices have the

Figure 4. MOBIDIS architecture

tendency to go out of radio range if left “free,” and are thus connected through the coordinator’s remedial actions, then this influences the subsequent connection probability.

The coordination layer manages situations when a peer is going to disconnect, by applying algorithms for choosing a *bridge*, and by executing workflow schema restructuring and workflow task reassignment when needed (e.g., it assigns the activity “follow peer *x*” to the selected bridge). The algorithm for choosing a bridge selects the best one by using the following criteria:

1. The algorithm chooses as bridge the neighbors without performing tasks. Indeed, if the selected one was a neighbor carrying out a task, its performing activity should be rolled-back with a decrease of productivity.
2. If each neighbor is carrying out a task, then the lowest priority task is chosen. By rolling-back task with the lowest priority, inefficiency should be bounded.
3. If two or more actors perform a task with the same lowest priority, the one with the smallest number of neighbors is preferred. The bridge role likely leads to movement of the node and this might cause new disconnections. By selecting a node with the lowest

number of neighbors, the probability of new disconnection is minimized.

4. In the end, the nearest neighbor is preferred.

When the bridge node is selected, the process instance is modified by adding the supporting activity “follow *x*” concurrently with the activity of node *x* going to disconnect. Thus the supporting activities have the same priority of supported ones. This is the situation depicted in Figure 5a in which the bridge node is blue colored. In some cases, the node going to disconnect can produce more than two components (Figure 5b) in the network. In this situation, a bridge is needed for each partition the disconnection is going to create. For each partition, the bridge is selected by applying an algorithm instance over the subset of node belonging to such a partition.

An important issue of the bridge algorithm is the priority among activities. The priority must reflect the process structure (causal dependency): the purpose is to assign higher priority to those tasks whose executions generate the achievement of *enabled* state for a greater number of tasks. An *enabled* task is a not yet *running* task that is ready to be assigned to an actor, as all the preceding tasks have been terminated.

Figure 5. Creation of two (a) or more (b) partitions

The algorithm for computing priorities is based on an n -ary tree that can be built iteratively. A well-structured process can be shown as a composition of many sub-processes decomposable in other smaller sub-processes and so on up to elementary processes—that is, activities. Each node of the tree is a process (elementary or not) whose children are nodes representing the sub-processes it can be decomposed in. The weight of leaves is initially posed to 1; the weight of internal nodes is obtained by combination of weights of children nodes, according to the way the process is decomposed.

Therefore the restructuring of the process is reduced to a transformation of such an n -ary tree.

FUTURE TRENDS

In the context of some Italian and international research projects, we are going to validate our approach in real scenarios. Preliminary experiments on synthetic data shows the feasibility of the approach (De Rosa et al., 2005), but an extensive real validation is needed.

Moreover, we will also address the issue of the approach's fault tolerance. Our approach currently does not cope with sudden downs of devices, which might be frequent in emergency scenarios and are critical if they affect the coordinator node. We also plan to evolve the coordination layer from a centralized to a distributed one (i.e., having a subset of devices act as coordinators). At the moment, the centralized architecture might be a bottleneck, but the current dimensions of a typical MANET for the considered scenarios (tens of devices) do not pose critical scalability issues.

In the future, due to the wide diffusion of mobile devices, applications on MANETs will become more and more interesting. As we have shown, such applications should take into account disconnection anomalies. To date, we have investi-

gated how classical WfMS concepts should be evolved and adapted in order to cope with MANET scenarios, but surely similar issues will also be raised for many other classical technologies, when applied to MANETs.

KEY TERMS

Adaptive WfMS: A system that provides process support like normal WfMS, but in such a way that it is able to deal with certain changes in execution context (like node disconnections).

Bridge: A MANET device in a cooperative group following another one d in order to avoid d going out from the network, by preserving a multi-hop path from every other node to d .

Computer-Supported Cooperative Work (CSCW): A collective name for the methods and techniques of a system that support the cooperative performance of work.

MANET (Mobile (or Multi-hop) Ad-hoc NETWORK): Mobile network where devices communicate one with another via wireless links without relying on an underlying infrastructure, like an access point.

Signal-to-Noise Ratio (SNR): Difference in decibels between the strength of a signal emitted/received from/to a device and the noise emitted/received from/to the same device. In a radio link, the strength of a signal received decays and the noise grows exponentially with the distance from transmitter (so SNR decays). It is possible to deduce distance between a pair of devices by analyzing SNR of receiving signals.

Workflow Management System (WfMS): A system that completely defines, manages, and executes processes through the execution of software whose order of execution is driven by a computer representation of the business process logic.

INTRODUCTION

The development of multimodal tools and mobile devices in particular is producing great interest, especially for accessing Web information, performing transactions, and use of services in general. This article considers the different markup languages proposed by the working groups of W3C (World Wide Web Consortium) to manage multimodal interaction and perspectives of multimodal applications and services.

The trend toward the convergence of various methodologies and technologies has developed new devices providing complex services, contributing to the sharing of experiences, and promoting the inclusion of people as community members (Paternò, 2004). This trend is based on the development of mobile devices and their usability, accessibility, portability, and versatility (Kvale, Warakagoda, & Knudsen, 2003).

The usefulness and usability of services, and the ability to access them and information, are the basic elements in the diffusion of Web systems and development of Web multimodal languages. The diffusion and implementation of multimodal services is supported by the activities of the World Wide Web Consortium, aimed at extending interaction modes for different devices and particularly devoted to solving various problems connected with: (1) multimodal Web interaction through the different devices, and (2) practice Web navigation from different devices.

Some W3C working groups focus their activities on issues such as independence from devices, multimodal Web access, and types of contents for multimodal messaging. These specifications allow rich multimodal contents to be transmitted, and are based on the power and extensibility of XML (eXtensible Markup Language) (Bray, Paoli, Sperberg-McQueen, Maler, & Yergeau, 2004).

XML is highly important in a mobile application environment, as many applications have to manage multimedia

contents and need dedicated tools for this. SMIL (Synchronized Multimedia Integration Language) (Solon, McKeivitt, & Curran, 2004) was proposed to achieve this goal.

In the early years W3C-MMI (W3C—MultiModal Interaction) focused on multimodal interaction modes such as speech and pen interaction, and providing users with W3C technologies.

W3C develops these technologies by orienting individual interaction modes in order to create mixed-namespace XML documents, such as SVG (scalable vector graphics) (Chatty, Lemort, Sire, & Vinot, 2005) and XHTML (eXtensible HyperText Markup Language) (Musciano & Kennedy, 2003) for visual interaction, and VoiceXML (Voice Extensible Markup Language) (Lucas, 2000) for voice interaction.

However, many other XML-derived languages have helped in the development of mobile services.

The next target is the consideration of the mobile network as an extension of the global Internet network. This article explains the importance of XML and its dialects in a mobile application environment to enable their use by the “various applications/services” (today available on the Web). In fact, different dialects may be needed for different mobile devices depending on their characteristics (such as memory, CPU speed, integrated software engine, etc.). For example, two SVG profiles are defined for cellular phones and PDAs (personal digital assistants): SVG Tiny (SVGT) is suitable for the next generation of cellular phones especially, while SVG Basic (SVGB) is aimed at high-tech devices such as PDAs or smart phones (Andersson et al., 2003).

The pervasive use of mobile devices will be the target for the near future (Branco, 2001), given the trend towards considering the mobile network as an extension of the Internet global network. This scenario promotes the development of new dialects for multimodal interaction through mobile devices. The dialects developed for speech, sketch, and visual

interaction are discussed next. An area for future development might focus on interaction through gestures.

XML (eXtensible Markup Language) is a simple, flexible, and powerful markup language, based on text format that allows the development of a potentially unlimited number of innovative multimodal services and applications. It was derived from the more complex, complete SGML (Standard Generalized Markup Language, ISO 8879) (Chamberlin & Goldfarb, 1987), designed for more general purposes. However, XML language is easier to manage, and is genuinely Web oriented and mobile oriented. In other words, XML language is an optimal subset of SGML, constructed in consideration of the possible Web services and applications.

XML can be used to develop several languages taking the specific working context into account. It also plays an important role in the exchange of a wide variety of data, making them available and accessible by Web using computers and mobile devices.

BACKGROUND

The World Wide Web is undergoing continuous development. This has enabled a great expansion in a wide variety of applications and services, covering every human activity. In addition, advanced technology mobile systems are becoming ever more complete, complex devices, which can offer a broad range of Web applications and services originally conceived for personal computers. These two factors explain the need to introduce various multimodal systems (services and applications oriented) to interact with the Web using mobile devices.

In this context, the use of XML-based technology to create powerful, multi-purpose system interfaces is a winning choice. Meta-language XML allows ad hoc language solutions to be developed according to the specific argument.

A multitude of XML “dialects” for multimodal solutions have already been developed, while any others are under current or future development. An exhaustive point of view on XML-based languages is thus not a simple matter. This section provides a panorama of the XML-based languages, considering the different interaction modes, multimediality, and multimodality features.

SMIL (Solon et al., 2004) is a basic, developing technology that allows several multimodal environments to be implemented. It is not an “out and out” multimodal language. As in many multimodal environments, it is necessary to interact with several kinds of multimedia content; SMIL works in the background with many different multimodal applications and services.

SMIL enables interactive audiovisual presentations to be easily produced. It is typically used to choreograph complex multimedia presentations, where audio and video streaming, images, text, graphics, and other media types

are combined in real time. In other words, SMIL makes it possible to manage the temporal and spatial constraints of multimedia presentations. The current SMIL conception offers modules for animation, content control, layout, linking, media objects, meta information, timing and synchronization, and transition effects. This modular approach allows reuse of SMIL syntax and semantics in other XML-based languages, especially those used for timing and synchronization. These fundamental features play a leading role in multimodal user interaction. SMIL is an easy-to-learn, HTML-like language and the World Wide Web Consortium (W3C) recommendation to achieve synchronized multimedia. In this context, it simplifies the creation of time-based multimodal interfaces with a high portability factor. SMIL is also exploited to aid the construction of powerful mobile-oriented multimodal applications and services.

A classic example of SMIL use is to enable authors to specify and control the precise time a sentence is spoken and make it coincide with the display of a given image. This simple “technical pattern” is at the base of several multimodal general systems.

To consider the different languages and problems connected with multimodality, we must take into account the different interaction approaches (visual, voice, etc.). For a visual approach, we must consider SVG. The SVG language (Chatty et al., 2005) is another important basic technology that works in background mode to resolve different types of problems in the multimodal interfaces. It describes two-dimensional graphics and graphical applications in XML, providing facilities for document structuring, shape definition, painting, clipping and masking, compositing, text manipulation, styling, linking, scripting, animation, interactivity, integration of multimedia content, alpha masks, filter effects, and template objects. It supports object zooming, interaction and manipulation, and scene annotation, among others. SVG element features can be static or dynamic, and each complex element can be used in interactive mode. A strong point of this language is the ability to interact with script languages (such as JavaScript, ECMAScript, JScript, etc.), which provide complete access to all elements, attributes, and properties necessary to develop powerful, complete 2D graphical representations. However, this latter point is not a binding factor. In fact, for example, an animation can be defined and triggered either declaratively (i.e., by embedding SVG animation elements in SVG content) or via scripting.

Because of SVG’s ability to produce high-quality rich graphical displays, enable the development of highly interactive user interfaces, and manipulate the contents and structure of an SVG document, it is very well suited for the development of interactive multimodal applications and services.

In fact, it is Web accessible by both personal computer and innovative mobile-oriented systems, and needs sophisticated multimodal environments to satisfy the user’s

requests. SVG recently became a standard on the Web and is now also becoming a standard for mobile devices. However, different technologies need different hardware supports, as each mobile device has its own characteristics (memory, CPU speed, integrated software engine, etc.). Two different profiles are defined for different device families. The first, low-level profile, SVG Tiny (SVGT), is especially suitable for next-generation cell phones, while the second, SVG Basic (SVGB), is aimed at high-tech devices (such as PDAs or smart phones).

Another markup language, which always works in background mode, is XForms (Extendible Forms) (Bals, 2005). This represents the next generation of forms for the Web and is used for mobile systems. It permits describing general user interfaces, such as Web forms, interactive GUI (Graphical User Interface), special windows, and so forth. It is well structured and can also be used in a standalone manner to describe more complex user interfaces.

The real innovation lies in splitting traditional XHTML forms into three parts: model, instance data, and user interface presentation. The construction of a graphical user interface is the most classic example of a multimodal expression.

MPML (Multimodal Presentation Markup Language) (Zong, Dohi, & Ishizuka, 2000) is another important language developed to enable the description of complex multimodal presentations based on character agents.

This markup language allows a new style of effective presentation of information and a new approach to the production of multimodal information content. These different multimodal scenarios use interactive lifelike agents with expressive capability (e.g., verbal conversations, facial expressions, body gesture explanations, behavioral model applications, etc.) that guide users through the multimedia informative content.

MPML language is structured on several defined features, which enhance the capability and potentiality of the multimodal applications and services created with it. Most importantly:

- **It is Independent of the Character Agent System:** It is designed such that authors can write multimodal presentation content independent of specific character agents.
- **It is Easy to Describe:** It is a simple and suitably designed XML-based elaboration designed for multimodal complete presentation only, providing a minimal set of tags to control the presentation and also allowing complete graphical representations.
- **It Supports Interactive Presentation:** It supports a set of mechanisms to guide the presentation interactively.
- **It has Character Control:** Character agents can guide the presentation.

- **It Supports Media Synchronization:** It is in accordance with SMIL, thus enabling the combination and synchronization of various types of multimedia elements such as images, text, animations, audio/video streams, and so forth.

The huge advantage of this language is that authors can provide various features on a single character agent to enable it to adapt to new situations and interactions.

MPML is easy to extend, enabling the expansion of normal application fields and design of multimodal functionality to more complex contexts. For example MPML-VR (Multimodal Presentation Markup Language for Virtual Reality) (Okazaki, Aya, Saeyor, & Ishizuka, 2002), which facilitates multimodal presentation in a 3D virtual space supported from an agent system in VRML (Virtual Reality Modeling Language), was designed by extending MPML. Another versatile extension is MPML-FLASH (Multimodal Presentation Markup Language with Character Agent Control in Flash Medium). Several attempts are ongoing to further widen fields for application of MPML technology.

Another important multimodal XML-based language is EMMA (Extensible MultiModal Annotation Markup Language) (Marrin, Myers, & Aktihanoglu, 2005). Its creators (W3C Multimodal Interaction Working Group) aimed to develop specifications to enable access to the Web (or mobile environment) through multimodal interaction. EMMA is intended for use in systems that provide semantic interpretations for a variety of inputs, including but not necessarily limited to speech, natural language text, GUI, and ink input. Classic examples include prearranged keystroke sequence, speech recognition commands, touch-screen recognition commands, handwriting recognition, semantic vocal streaming understanding, semantic gesture streaming understanding, natural language understanding, interactive ink pens, pointing input tools, and so forth. There is a potentially unlimited possibility to induce numerous input signals from different input devices.

EMMA is used primarily as a standard format for data interchange among the components of a multimodal system. It is automatically generated by interpretation components to represent the semantics of user inputs, not directly authored by developers.

EMMA turns out to be useful in several contexts. It is independent from the specific application field and can be adapted to heterogeneous input types. Different complex devices have their own interaction methods, which can be separately managed to best interact with the user input, and the language provides a set of elements and attributes that focus on accurately representing annotations on the input interpretations. In other words the language focuses on multimodal semantic interpretation of the events that drive user interaction during the composition of one or more inputs.

In general an EMMA document can be considered as consisting of three parts: instance data, data model, and metadata. Instance data is an application-specific markup corresponding to input information meaningful to the consumer of an EMMA document. Instances are built by input processors at runtime. Given that utterances may be ambiguous with respect to input values, an EMMA document may hold more than one instance. The data model imposes constraints on the structure and content of an instance. Metadata represent annotations associated with the data contained in the instance. Annotation values are added by input processors at runtime.

EMMA has a large potential for integrating different devices in several environments. Furthermore, it will be able to make the Web fully accessible for future applications. There should be no difference in interacting with a user via phone DTMF (dual tone multiple frequency) tones, PDA ink pens, or even voice browsers for users with disabilities. This is an impressive goal, and the MIF (multimodal interaction framework, a complex system to support multimodal development of applications and services) is a next step in achieving it.

Another multimodal markup XML-based language is InkML (Ink Markup Language) (Mohamed, Belenkaia, & Ottmann, 2004). It is utilized to build the data format used to represent ink entered with an electronic pen or stylus in a multimodal system. Its main purpose is to transfer digital ink data between devices and software components, and store hand-input traces for handwriting recognition, signature verification, and gesture interpretation.

An increasing number of electronic devices with pen interfaces are now available. These are widely used for various applications and services, such as information, interactive services, semantic interpretation of gestures, multimodal “touched” interaction, and so on. It is also necessary to take into account that handwriting is a very familiar input mode for most users (with or without disabilities), who will thus tend to use it for input and control when available.

Digital ink information is a delicate, complex, and difficult format to manage. Several studies have attempted its comprehensive and productive format standardization. These elements have caused a restricted growth of key technical factors such as digital ink capture, processing, and transmission of digital ink data across heterogeneous devices; communications among different ink management software programs; interactions between ink software applications and hardware devices; and so forth. InkML is also designed to resolve these problems. In fact, its important feature is to provide a simple, platform-independent data format to promote the interchange of digital ink among different kinds of software and hardware applications and services.

An interesting peculiarity of this technology relates to its ability to capture and express the user’s dynamic behavior and relative semantics—that is, the dynamics of the user’s

behavior during the interaction with, for example, the electronic pen on the tablet (to interpret hand-speed, break point, acceleration paths, etc.). To date, only a low information level has been used to interact with the user. It is to be hoped that future studies will examine this scenario. Clearly, this markup language is also useful in both a Web environment and mobile devices. It is becoming a useful standard (W3C recommendation) to tackle entire problematic situations on ink contexts.

The VoiceXML (Lucas, 2000) language provides speech recognition and speech synthesis capabilities for the scripting of voice dialogs and enables integration with other processes through events and IP connectivity. In voice processing, it offers control of voice recognition capabilities through grammars, speech synthesis control, and some basic telephony control. It provides several voice response systems, such as recognition of spoken input and DTMF input. It also allows registration of spoken input and controlling dialogue flow, and can be used to transfer and disconnect telephone calls. VoiceXML also supports the output of synthesized speech and audio files.

This language supports audio file formats, speech grammar formats, and URI schemas.

In order to permit speech applications, VoiceXML is based on a grammar format, called speech recognition grammar specification (SRGS) (Hunt & McGlashan, 2003). SRGS is used by speech recognizers and allows developers to specify the words and word patterns to be listened for by the speech recognizer.

VoiceXML provides semantic interpretations from grammars and makes this information available to the application. It also permits a separation of service logic from interaction behavior.

In IP connectivity VoiceXML allows precise identification of which data to submit to the server, and which HTTP method, GET or POST, to use in the submission.

SSML (Speech Synthesis Markup Language) (Burnett, Walker, & Hunt, 2004) is an XML-based language that presents elements for controlling the pronunciation, tone, inflection, and other characteristics of spoken words. It captures text speed, volume, inflection, and prosody in order to convert it to acoustic speech through a text-to-speech (TTS) synthesis engine. SSML’s main features are interoperability—or interaction with other markup languages—and consistency; in fact, it provides control of voice input across platforms and across speech synthesis implementations.

SALT (speech application language tags) (Cisco Systems, Comverse, Intel Corporation, Microsoft Corporation, & Philips Electronics, 2002) is an extension of HTML and other markup languages, integrating speech and telephony interfaces with Web applications and services. In multimodal applications it supports speech input and output in visual pages. It is used where a speech interface is available in addition to the visual interface.

MAIN FOCUS OF THE ARTICLE

The increasing diffusion and utility of the global network has enabled the spread of applications and services supporting every human activity. These involve both scientific domains, such as online technical services, and typical entertainment domains.

The widespread use of mobile devices has improved the diffusion of multifunctional complex tools satisfying sophisticated user applications and increases the spread of innovative services.

In mobile applications, the “audio/video Multilanguage dictionary” enables the user to immediately discover the meaning of idiomatic expressions and difficult words. The multimedia stream allows the meaning of “sentences” in real contexts to be understood, with practical examples and situations.

In this section we discuss some of the most well-known and useful XML-derived languages used to develop mobile services, and give a table that describes these languages according to their modes, functions, and applications/services.

SMIL is the W3C recommendation to synchronize multimedia on the Web. This XML-based language is used to write interactive multimedia presentations, enabling management of their temporal and spatial constraints. In mobile phones, it enables lightweight multimedia functionality and integrates timing into profiles such as WAP forum’s WML language and XHTML Basic, while MMS is a subset of SMIL for mobile telephone multimedia messaging.

The W3C group’s Voice Browser and Multimodal Interaction are working to standardize XML languages. VoiceXML is used to create voice user interfaces with automatic speech recognition (ASR) and text-to-speech synthesis, audio dialogues that feature synthesized speech; digitized audio; recognition of spoken and DTMF key input; recording of spoken input, telephony, and mixed-initiative conversations; interactive voice response (IVR); and so forth. Many applications and mobile services exploit the potential of VoiceXML,

and there are numerous consolidated contributions in this field. In fact, VoiceXML and SALT are valid instruments to support the integration of visual representation enriched systems and visual browsers, with instruments such as XHTML, cascading style sheet (CSS), SMIL, and SVG.

Similar areas are handled by SALT. This language is being designed to “extend existing markup languages such as HTML, XHTML, and XML.” An important difference between SALT and VoiceXML is the overall approach used to develop applications. Whereas VoiceXML is essentially declarative, using its extensive set of tags, SALT is very procedural and script oriented, with a very small set of core tags. The factor connecting them is that multimodal access enables users to interact with an application in a variety of different ways. Obviously in this case too, there are a number of practical demonstrations.

New trends are developing to allow intermodal interaction by instruments such as InkML, which captures pen movements and enables data exchange by “digital ink.” This mark-up language has an XML data format to describe digital ink data from the pen or stylus in a multimodal system.

A pen-based interface captures digital ink and pen movements by a transducer. The digital ink can be analyzed by recognition software to convert pen input into defined computer actions. Alternatively, it can be stored in ink documents, messages, or notes for later retrieval or exchange through telecommunications.

EMMA is used to implement semantic interpretations of a great variety of inputs, such as voice, text languages, and digital ink. The Speech Services Control (SpeechSC) working group of the Internet Engineering Task Force (IETF) develops protocols to support distributed speech recognition and synthesis and speaker verification services, and expects to take advantage of W3C’s work on speech recognition grammar specification (SRGS), SSML, and semantic interpretation (SI).

Table 1 summarizes the main features of each multimodal XML-based language. The table includes modalities that

Table 1. Main features of multimodal XML-based languages

| XML-Based Dialects | Modalities | Functions | Application and Services |
|--|--|--|---|
| SMIL | Audio, Video, Images, Text, Graphics | Synchronization, Real-time combining, Managing temporal and spatial constraints, Streaming, Timing | Animation, Content control, Layout, Linking, Media objects, Meta information, Transition effects, Web-oriented multimodal application |
| SVG (<i>SVG Tiny—SVGT—for next-generation cell phones, SVG Basic—SVGB—for high-tech devices</i>) | Graphics | Interactivity, Integration of multimedia content, Two-dimensional graphics, Graphics applications in XML | Document structuring, Definition of shape, Painting, Clipping, Masking, Compositing, Text manipulation, Styling, Linking, Animation, Alpha mask, Filter effects, Zooming, Scene annotation, Object manipulation and interaction |
| MPML (<i>MPML-VR, MPML-FLASH</i>) | Integration complex multimedia, Streaming management | Description of complex multimodal presentations based on character agents, Media synchronization | Web and mobile environment applications, Writing multimodal presentation content independent of specific character agents, Providing a minimal set of tags to control presentation, Interactive presentation guidance |

Table 1. continued

| | | | |
|-----------------|--|--|--|
| EMMA | Speech, Natural language, Text, GUI, Ink input | Semantic interpretations for a variety of inputs | Prearranged keystroke sequence, Speech recognition commands, Touch-screen recognition commands, Semantic vocal streaming comprehension, Semantic gesture streaming comprehension, Natural language streaming comprehension, interactive ink pens |
| X-Form | Interactive complex form | Performing several kind of data manipulation tasks, | Web forms, Interactive GUI, Special windows |
| InkML | Graphics | Building data formats used to represent digital ink entered with an electronic pen or stylus; Transferring digital ink data among devices and software components; Storing hand-input traces for handwriting recognition, signature verification, and gesture interpretation | Providing a simple and platform-neutral data format to promote the interchange of digital ink among different kinds of software and hardware applications and services, Information entry and manipulation, Use of applications, Use of interactive services, Semantic interpretation of gestures, Multi-touch interaction |
| VOICEXML | Voice | Speech recognition, Speech synthesis, Control of voice recognition capabilities through grammars, Speech synthesis control | Recognition of spoken input and DTMF input, recording spoken input, and controlling dialogue flow; Transferring and disconnecting telephone calls; Synthesizing speech and audio files; Identifying exactly which data to submit to the server in IP connectivity |
| SSML | Voice | Multimedia streaming management | Controlling the pronunciation, tone, inflection, and other characteristics of spoken words; Capturing text speed, volume, inflection, and prosody |
| SALT | Voice | Integration of speech and video | Integrating speech and telephone interfaces with Web applications and services, Supporting speech input and output in visual pages |

deal with each XML-based dialect, the specific supported functions, and applications and services in Web and mobile environments.

FUTURE TRENDS

Control and interaction with the environment providing different services, and the new need of different devices such as personal computers, mobile phones, PDAs, TVs, and so on, will improve development of standard solutions and languages. In particular a greater development of a new generation of mobile devices, with different interaction modes according to their pervasive use and services, will produce an increasing interest about the development of the XML-based languages about different interaction mode and integration modes.

CONCLUSION

The emergence of new devices for human-computer interaction and communication characterized by various sizes of displays, voice-based interaction, new devices for handwriting, and character input are all elements that require the user

interface to be portable and to support multimodal interaction. That is, XML portability and adaptation to the different devices provide a solution with the different languages that were developed.

This article provides an overview of the evolution of the multimodal XML-based languages used for mobile applications and services. The main focus is on specific applications of each language that are available on the Web environment and mobile devices.

The use of XML and XML-based languages allows solving multimodal problems in several application fields.

Special attention has to be considered for the activity of the World Wide Web Consortium, which is devoted to developing innovative XML technologies (that are standard de facto) in order to make the Web the focal element for data interchange, interoperability, and accessibility to the information according to the different interaction modes and with the different devices.

KEY TERMS

Extendible Form (XForm): A W3C markup language representing the next generation of forms for the Web and mobile systems, used to describe general user interfaces.

Extensible Multimodal Annotation Markup Language (EMMA): An XML-based W3C recommendation used for information automatically extracted from the user's input. It focuses on annotating the interpretation of input information.

Multimodal Presentation Markup Language (MPML): A W3C markup language for use in systems that provide semantic interpretations for a variety of inputs.

Ink Markup Language (InkML): A W3C language to describe ink data acquired with an electronic pen or similar device.

Scalable Vector Graphics (SVG): A W3C markup language describing a two-dimensional vector graphic. It enables shapes, raster graphics images/digital images, and text.

Speech Application Language Tag (SALT): A W3C markup language used for adding voice recognition to HTML and XHTML files.

Speech Synthesis Markup Language (SSML): An XML-based W3C recommendation for speech synthesis.

Synchronized Multimedia Integration Language (SMIL): A W3C-recommended XML-based markup language for multimedia presentations.

VoiceXML: The W3C standard XML format for specifying voice dialogues between a human and a computer.
