Schematic representation of the neuromuscular junction. ACh, acetylcholine; AChE, acetylcholinesterase; JF, junctional folds; M, mitochondrion; V, transmitter vesicle.

(Reproduced, with permission, from Drachman DB: Myasthenia gravis. *N Engl J Med* 1978;298:135.)

At least two additional types of acetylcholine receptors are found within the neuromuscular apparatus. One type is located on the presynaptic motor axon terminal, and activation of these receptors mobilizes additional transmitter for subsequent release by moving more acetylcholine vesicles toward the synaptic membrane. The second type of receptor is found on perijunctional cells and is not normally involved in neuromuscular transmission. However, under certain conditions (eg, prolonged immobilization, thermal burns), these receptors may proliferate sufficiently to affect subsequent neuromuscular transmission.

Skeletal muscle relaxation and paralysis can occur from interruption of function at several sites along the pathway from the central nervous system (CNS) to myelinated somatic nerves, unmyelinated motor nerve terminals, nicotinic acetylcholine

receptors, the motor end plate, the muscle membrane, and the intracellular muscular contractile apparatus itself.

Blockade of end plate function can be accomplished by two basic mechanisms. Pharmacologic blockade of the physiologic agonist acetylcholine is characteristic of the antagonist neuromuscular blocking drugs (ie, nondepolarizing neuromuscular blocking drugs). These drugs prevent access of the transmitter to its receptor and thereby prevent depolarization. The prototype of this nondepolarizing subgroup is **d-tubocurarine**. The second type of blockade can be produced by an excess of a depolarizing agonist, such as acetylcholine. This seemingly paradoxical effect of acetylcholine also occurs at the ganglionic nicotinic acetylcholine receptor. The prototypical depolarizing blocking drug is **succinylcholine**. A similar depolarizing block can be produced by acetylcholine itself when high local concentrations are achieved in the synaptic cleft (eg, by cholinesterase inhibitor intoxication) and by nicotine and other nicotinic agonists. However, the neuromuscular block produced by depolarizing drugs other than succinylcholine cannot be precisely controlled and is of no clinical value.

## BASIC PHARMACOLOGY OF NEUROMUSCULAR BLOCKING DRUGS

### Chemistry

All of the available neuromuscular blocking drugs bear a structural resemblance to acetylcholine. For example, succinylcholine is two acetylcholine molecules linked end-to-end (Figure 27â€³3). In contrast to the single linear structure of succinylcholine and other depolarizing agents (eg, pancuronium) conceal the "double-acetylcholine" structure in one of two types of bulky, semi-rigid ring systems (Figure 27â€³3). The two major families of nondepolarizing blocking drugsâ€”the isoquinoline and steroid derivativesâ€”are shown in Figures 27â€³4 and 27â€³5. Another feature common to all currently used neuromuscular blockers is the presence of one or two quaternary nitrogens, which makes them poorly lipid-soluble and limits entry into the CNS.

Structural relationship of succinylcholine, a depolarizing agent, and pancuronium, a nondepolarizing agent, to acetylcholine, the neuromuscular transmitter. Succinylcholine, originally called diacetylcholine, is simply two molecules of acetylcholine linked through the acetate methyl groups. Pancuronium may be viewed as two acetylcholine-like fragments (outlined in color) oriented on a steroid nucleus.

### Pharmacokinetics of Neuromuscular Blocking Drugs

All of the neuromuscular blocking drugs are highly polar compounds and inactive orally; they must be administered parenterally.

#### NONDEPOLARIZING RELAXANT DRUGS

The rate of disappearance of a nondepolarizing neuromuscular blocking drug from the blood is characterized by a rapid initial distribution phase followed by a slower elimination phase. Neuromuscular blocking drugs are highly ionized, do not readily cross cell membranes, and are not strongly bound in peripheral tissues. Therefore, their volume of distribution is only slightly larger than the blood volume (80–140 mL/kg).

The duration of neuromuscular blockade produced by nondepolarizing relaxants is strongly correlated with the elimination half-life. Drugs that are excreted by the kidney typically have longer half-lives, leading to longer durations of action (> 60 minutes). Drugs eliminated by the liver tend to have shorter half-lives and durations of action (Table 27-1). All steroidal muscle relaxants

are metabolized to their 3-hydroxy, 17-hydroxy, or 3,17-dihydroxy products in the liver. The 3-hydroxy metabolites are usually 40–80% as potent as the parent drug. Under normal circumstances, metabolites are not formed in sufficient quantities to produce a significant degree of neuromuscular blockade during or after anesthesia. However, if the parent compound is administered for several days in the ICU setting, the 3-hydroxy metabolite may accumulate and cause prolonged paralysis because it has a longer half-life than the parent compound. The remaining metabolites possess minimal neuromuscular blocking properties.

**Table 27–1. Some Properties of Neuromuscular Blocking Drugs.**

Drug	Elimination	Clearance (mL/kg/min)	Approximate Duration of Action (minutes)	Approximate Potency Relative to Tubocurarine
<b>Isoquinoline derivatives</b>				
Atracurium	Spontaneous <sup>1</sup>	6.6	20–35	1.5
Cisatracurium	Mostly spontaneous	5–6	25–44	1.5
Doxacurium	Kidney	2.7	> 35	6
Metocurine	Kidney (40%)	1.2	> 35	4
Mivacurium	Plasma ChE <sup>2</sup>	70–95	10–20	4
Tubocurarine	Kidney (40%)	2.3–2.4	> 50	1
<b>Steroid derivatives</b>

<sup>1</sup>Nonenzymatic and enzymatic hydrolysis of ester bonds.

<sup>2</sup>Butyrylcholinesterase (pseudocholinesterase).

The intermediate-acting steroid muscle relaxants (eg, vecuronium and rocuronium) tend to be more dependent on biliary excretion or hepatic metabolism for their elimination. These muscle relaxants are more commonly used clinically than the long-acting steroid-based drugs (eg, pancuronium, pipecuronium).

A very short-acting steroidal nondepolarizing agent (rapacuronium) was briefly introduced in the 1990s for rapid-sequence intubation and induction of anesthesia. It was withdrawn by the manufacturer because of concerns about life-threatening airway complications.

Atracurium (Figure 27–4) is an intermediate-acting isoquinoline nondepolarizing muscle relaxant. In addition to hepatic metabolism, atracurium is inactivated by a form of spontaneous breakdown known as Hofmann elimination. The main breakdown products are laudanosine and a related quaternary acid, neither of which possesses neuromuscular blocking properties. Laudanosine is slowly metabolized by the liver and has a longer elimination half-life (ie, 150 minutes). It readily crosses the blood-brain barrier, and high blood concentrations may cause seizures and an increase in the volatile anesthetic requirement. During surgical anesthesia, blood levels of laudanosine typically range from 0.2 to 1 mcg/mL; however, with prolonged infusions of atracurium in the ICU, laudanosine blood levels may exceed 5 mcg/mL.

Atracurium has several stereoisomers, and the potent isomer **cisatracurium** has become one of the most commonly used muscle relaxants in clinical practice. Although cisatracurium resembles atracurium, it has less dependence on hepatic inactivation, produces less laudanosine, and is less likely to release histamine. From the clinical perspective, cisatracurium has all the advantages of atracurium with fewer side effects. Therefore, cisatracurium has largely replaced atracurium in clinical practice.

Mivacurium, another isoquinoline compound, has the shortest duration of action of all nondepolarizing muscle relaxants (Table 27–1). However, its onset of action is significantly slower than that of succinylcholine. In addition, the use of a larger dose to speed the onset can be associated with profound histamine release leading to hypotension, flushing, and bronchospasm. Clearance of mivacurium by plasma cholinesterase is rapid and independent of the liver or kidney (Table 27–1). However,

because patients with renal failure often have decreased levels of plasma cholinesterase, the short duration of action of mivacurium may be prolonged in patients with impaired renal function. Although mivacurium is no longer in widespread clinical use, an investigational ultra-short-acting isoquinoline nondepolarizing muscle relaxant, gantacurium, is currently in phase III clinical testing. This novel compound has a very rapid onset and short duration of action.

#### DEPOLARIZING RELAXANT DRUGS

The extremely short duration of action of succinylcholine (5–10 minutes) is due to its rapid hydrolysis by butyrylcholinesterase and pseudocholinesterase in the liver and plasma, respectively. Plasma cholinesterase metabolism is the predominant pathway for succinylcholine elimination. Since succinylcholine is more rapidly metabolized than mivacurium, its duration of action is shorter than that of mivacurium (Table 27-1). The primary metabolite of succinylcholine, succinylmonocholine, is rapidly broken down to succinic acid and choline. Because plasma cholinesterase has an enormous capacity to hydrolyze succinylcholine, only a small percentage of the original intravenous dose ever reaches the neuromuscular junction. In addition, as there is little if any plasma cholinesterase at the motor end plate, a succinylcholine-induced blockade is terminated by its diffusion away from the end plate into extracellular fluid. Therefore, the circulating levels of plasma cholinesterase influence the duration of action of succinylcholine by determining the amount of the drug that reaches the motor end plate.

Neuromuscular blockade produced by succinylcholine and mivacurium can be prolonged in patients with a genetically abnormal variant of plasma cholinesterase. The *dibucaine number* is a measure of the ability of a patient to metabolize succinylcholine and can be used to identify at-risk patients. Under standardized test conditions, dibucaine inhibits the normal enzyme by 80% and the abnormal enzyme by only 20%. Many genetic variants of plasma cholinesterase have been identified, although the dibucaine-related variants are the most important. Given the rarity of these genetic variants, plasma cholinesterase testing is not a routine clinical procedure.

#### Mechanism of Action

The interactions of drugs with the acetylcholine receptor-end plate channel have been described at the molecular level. Several modes of action of drugs on the receptor are illustrated in Figure 27-6.

**Figure 27-6**

Schematic diagram of the interactions of drugs with the acetylcholine receptor on the end plate channel (structures are purely symbolic).

**Top:** The action of the normal agonist, acetylcholine, in opening the channel. **Bottom, left:** A nondepolarizing blocker, eg, rocuronium, is shown as preventing the opening of the channel when it binds to the receptor. **Bottom, right:** A depolarizing blocker, eg, succinylcholine, both occupying the receptor and blocking the channel. Normal closure of the channel gate is prevented and the blocker may move rapidly in and out of the pore. Depolarizing blockers may desensitize the end plate by occupying the receptor and causing persistent depolarization. An additional effect of drugs on the end plate channel may occur through changes in the lipid environment surrounding the channel (not shown). General anesthetics and alcohols may impair neuromuscular transmission by this mechanism.

#### NONDEPOLARIZING RELAXANT DRUGS

All the neuromuscular blocking drugs in current use in the USA except succinylcholine are classified as nondepolarizing agents. Although it is no longer in widespread clinical use, *d*-tubocurarine is considered the prototype neuromuscular blocker. When small doses of nondepolarizing muscle relaxants are administered, they act predominantly at the nicotinic receptor site by

competing with acetylcholine. The least potent nondepolarizing relaxants (eg, rocuronium) have the fastest onset and the shortest duration of action. In larger doses, nondepolarizing drugs can enter the pore of the ion channel (Figure 27â€"1) to produce a more intense motor blockade. This action further weakens neuromuscular transmission and diminishes the ability of the acetylcholinesterase inhibitors (eg, neostigmine, edrophonium, pyridostigmine) to antagonize the effect of nondepolarizing muscle relaxants.

Nondepolarizing relaxants can also block prejunctional sodium channels. As a result of this action, muscle relaxants interfere with the mobilization of acetylcholine at the nerve ending. One consequence of the surmountable nature of the postsynaptic blockade produced by nondepolarizing muscle relaxants is the fact that tetanic stimulation, by releasing a large quantity of acetylcholine, is followed by transient posttetanic facilitation of the twitch strength (ie, relief of blockade). An important clinical consequence of this principle is the reversal of residual blockade by cholinesterase inhibitors. The characteristics of a nondepolarizing neuromuscular blockade are summarized in Table 27â€"2 and Figure 27â€"7).

**Table 27â€"2 Comparison of a Typical Nondepolarizing Muscle Relaxant (Rocuronium) and a Depolarizing Muscle Relaxant (Succinylcholine).**

	<b>Rocuronium</b>	<b>Succinylcholine</b>	
		<b>Phase I</b>	<b>Phase II</b>
Administration of tubocurarine	Additive	Antagonistic	Augmented <sup>1</sup>
Administration of succinylcholine	Antagonistic	Additive	Augmented <sup>1</sup>
Effect of neostigmine	Antagonistic	Augmented <sup>1</sup>	Antagonistic
Initial excitatory effect on skeletal muscle	None	Fasciculations	None
Response to a tetanic stimulus	Unsustained (fade)	Sustained <sup>2</sup> (no fade)	Unsustained (fade)
Posttetanic facilitation	Yes	No	Yes
Rate of recovery	30â€"60 min <sup>3</sup>	4â€"8 min	> 20 min <sup>3</sup>

<sup>1</sup>It is not known whether this interaction is additive or synergistic (superadditive).

<sup>2</sup>The amplitude is decreased, but the response is sustained.

<sup>3</sup>The rate depends on the dose and on the completeness of neuromuscular blockade.

**Figure 27â€"7**

No Drug	Nondepolarizing Block	Depolarizing Block	
		Phase I	Phase II
Train-of-four  TOF-R = 1.0	Fade  TOF-R = 0.4	Constant but diminished  TOF-R = 1.0	Fade  TOF-R = 0.4
Double burst	Fade	No fade	Fade

Muscle contraction responses to different patterns of nerve stimulation used in monitoring skeletal muscle relaxation. The alterations produced by a nondepolarizing blocker and depolarizing and desensitizing blockade by succinylcholine are shown. In the train of four (TOF) pattern, four stimuli are applied at 2 Hz. The TOF ratio (TOF-R) is calculated from the strength of the fourth contraction divided by that of the first. In the double burst pattern, three stimuli are applied at 50 Hz, followed by a 700 ms rest period and then repeated. In the posttetanic potentiation pattern, several seconds of 50 Hz stimulation are applied, followed by several seconds of rest and then by single stimuli at a slow rate (eg, 0.5 Hz). The number of detectable posttetanic twitches is the posttetanic count (PTC). \*, first posttetanic contraction.

#### DEPOLARIZING RELAXANT DRUGS

##### Phase I Block (Depolarizing)

Succinylcholine is the only clinically useful depolarizing blocking drug. Its neuromuscular effects are like those of acetylcholine except that succinylcholine produces a longer effect at the myoneural junction. Succinylcholine reacts with the nicotinic receptor to open the channel and cause depolarization of the motor end plate, and this in turn spreads to the adjacent membranes, causing contractions of muscle motor units. Data from single-channel recordings indicate that depolarizing blockers can enter the channel to produce a prolonged "flickering" of the ion conductance (Figure 27â€¸8). Because succinylcholine is not metabolized effectively at the synapse, the depolarized membranes remain depolarized and unresponsive to subsequent impulses (ie, a state of depolarizing blockade). Furthermore, because excitation-contraction coupling requires end plate repolarization ("repriming") and repetitive firing to maintain muscle tension, a flaccid paralysis results. In contrast to the nondepolarizing drugs, this so-called phase I (depolarizing) block is augmented, not reversed, by cholinesterase inhibitors.

Action of succinylcholine on single-channel end plate receptor currents in frog muscle. Currents through a single AChR channel were recorded using the patch clamp technique. The upper trace was recorded in the presence of a low concentration of succinylcholine; the downward deflections represent openings of the channel and passage of inward (depolarizing) current. The lower trace was recorded in the presence of a much higher concentration of succinylcholine and shows prolonged "flickering" of the channel as it repetitively opens and closes or is "plugged" by the drug.

(Reproduced, with permission, from Marshall CG, Ogden DC, Colquhoun D: The actions of suxamethonium (succinylcholine) as an agonist and channel blocker at the nicotinic receptor of frog muscle. *J Physiol [Lond]* 1990;428:155.)

The characteristics of a depolarizing neuromuscular blockade are summarized in Table 27-2 and Figure 27-7.

#### Phase II Block (Desensitizing)

With prolonged exposure to succinylcholine, the initial end plate depolarization decreases and the membrane becomes repolarized. Despite this repolarization, the membrane cannot easily be depolarized again because it is *desensitized*. The mechanism for this desensitizing phase is unclear, but some evidence indicates that channel block may become more important than agonist action at the receptor in phase II of succinylcholine's neuromuscular blocking action. Regardless of the mechanism, the channels behave as if they are in a prolonged closed state (Figure 27-7). Later in phase II, the characteristics of the blockade are nearly identical to those of a nondepolarizing block (ie, a nonsustained twitch response to a tetanic stimulus) (Figure 27-7), with possible reversal by acetylcholinesterase inhibitors.

## CLINICAL PHARMACOLOGY OF NEUROMUSCULAR BLOCKING DRUGS

### Skeletal Muscle Paralysis

Before the introduction of neuromuscular blocking drugs, profound skeletal muscle relaxation for intracavitary operations could be achieved only by producing levels of volatile (inhaled) anesthesia deep enough to produce profound depressant effects on the cardiovascular and respiratory systems. The adjunctive use of neuromuscular blocking drugs makes it possible to achieve adequate muscle relaxation for all types of surgical procedures without the cardiorespiratory depressant effects produced by deep anesthesia.

### Assessment of Neuromuscular Transmission

Monitoring the effect of muscle relaxants during surgery (and recovery following the administration of cholinesterase inhibitors) typically involves the use of a device that produces transdermal electrical stimulation of one of the peripheral nerves to the hand or facial muscles and recording of the evoked contractions (ie, twitch responses). The motor responses to different patterns of peripheral nerve stimulation can be recorded in the operating room during the procedure (Figure 27-7). The three most commonly used patterns include (1) single-twitch stimulation, (2) train-of-four (TOF) stimulation, and (3) tetanic stimulation. Two newer modalities are also available to monitor neuromuscular transmission: double-burst stimulation and posttetanic count.

With single-twitch stimulation, a single supramaximal electrical stimulus is applied to a peripheral nerve at frequencies from 0.1 Hz to 1.0 Hz. The higher frequency is often used during induction and reversal to more accurately determine the peak (maximal) drug effect. TOF stimulation involves four successive supramaximal stimuli given at intervals of 0.5 second (2 Hz). Each stimulus in the TOF causes the muscle to contract, and the relative magnitude of the response of the fourth twitch compared with the first twitch is the TOF ratio. With a depolarizing block, all four twitches are reduced in a dose-related fashion. With a nondepolarizing block, the TOF ratio decreases ("fades") and is inversely proportional to the degree of blockade. During recovery from nondepolarizing block, the amount of fade decreases and the TOF ratio approaches 1.0. Recovery to a TOF ratio greater than 0.7 is typically necessary for resumption of spontaneous ventilation. However, complete clinical recovery from a nondepolarizing block is considered to require a TOF greater than 0.9. Fade in the TOF response after administration of succinylcholine signifies the development of a phase II block.

Tetanic stimulation consists of a very rapid (30–100 Hz) delivery of electrical stimuli for several seconds. During a nondepolarizing neuromuscular block (and a phase II block after succinylcholine), the response is not sustained and fade of the twitch responses is observed. Fade in response to tetanic stimulation is normally considered a presynaptic event. However, the degree of fade depends primarily on the degree of neuromuscular blockade. During a partial nondepolarizing blockade, tetanic nerve stimulation is followed by an increase in the posttetanic twitch response, so-called posttetanic facilitation of neuromuscular transmission. During intense neuromuscular blockade, there is no response to either tetanic or posttetanic stimulation. As the intensity of the block diminishes, the response to posttetanic twitch stimulation reappears. The time to reappearance of the first response to TOF stimulation is related to the posttetanic count and reflects the duration of profound (clinical) neuromuscular blockade.

The double-burst stimulation pattern is a newer mode of electrical nerve stimulation developed with the goal of allowing for manual detection of residual neuromuscular blockade when it is not possible to record the responses to single-twitch, TOF, or tetanic stimulation. In this pattern, three nerve stimuli are delivered at 50 Hz followed by a 700 ms rest period and then, by two or three additional stimuli at 50 Hz. It is easier to detect fade in the responses to double-burst stimulation than to TOF stimulation. The absence of fade in response to double-burst stimulation implies that clinically significant residual neuromuscular blockade does not exist.

The standard approach used for monitoring the clinical effects of muscle relaxants during surgery is to use a peripheral nerve stimulating device to elicit motor responses, which are visually observed by the anesthesiologist. A more quantitative approach to neuromuscular monitoring involves the use of acceleromyography or force-transduction for measuring the evoked response (ie, movement) of the thumb to TOF stimulation over the ulnar nerve at the wrist.

#### NONDEPOLARIZING RELAXANT DRUGS

During anesthesia, administration of tubocurarine, 0.1–0.4 mg/kg IV, initially causes motor weakness, followed by the skeletal muscles becoming flaccid and inexcitable to electrical stimulation (Figure 27–9). In general, larger muscles (eg, abdominal, trunk, paraspinal, diaphragm) are more resistant to neuromuscular blockade and recover more rapidly than smaller muscles (eg, facial, foot, hand). The diaphragm is usually the last muscle to be paralyzed. Assuming that ventilation is adequately maintained, no adverse effects occur. When administration of muscle relaxants is discontinued, recovery of muscles usually occurs in reverse order, with the diaphragm regaining function first. The pharmacologic effect of tubocurarine, 0.3 mg/kg IV, usually lasts 45–60 minutes. However, subtle evidence of residual muscle paralysis detected using a neuromuscular monitor may last for another hour.

**Figure 27–9**

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 11th Edition: <http://www.accessmedicine.com>

Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

Neuromuscular blockade from tubocurarine during equivalent levels of isoflurane and halothane anesthesia in patients. Note that isoflurane augments the block far more than does halothane.

Potency and duration of action of the other nondepolarizing drugs are shown in Table 27–1. In addition to the duration of action, the most important property distinguishing the nondepolarizing relaxants is the time to onset of the blocking effect, which determines how rapidly the patient's trachea can be intubated. Of the currently available nondepolarizing drugs, rocuronium (60–120 seconds) has the most rapid onset time.

#### DEPOLARIZING RELAXANT DRUGS

Following the administration of succinylcholine, 0.75–1.5 mg/kg IV, transient muscle fasciculations occur over the chest and

abdomen within 30 seconds, although general anesthesia and the prior administration of a small dose of a nondepolarizing muscle relaxant tends to attenuate them. As paralysis develops rapidly (< 90 seconds), the arm, neck, and leg muscles are initially relaxed followed by the respiratory muscles. As a result of succinylcholine's rapid hydrolysis by cholinesterase in the plasma (and liver), the duration of neuromuscular block typically lasts less than 10 minutes (Table 27â€1).

### Cardiovascular Effects

Vecuronium, pipecuronium, doxacurium, cisatracurium, and rocuronium all have minimal, if any, cardiovascular effects. The other nondepolarizing muscle relaxants (ie, pancuronium, atracurium, mivacurium) produce cardiovascular effects that are mediated by either autonomic or histamine receptors (Table 27â€3). Tubocurarine and, to a lesser extent, metocurine, mivacurium, and atracurium can produce hypotension as a result of systemic histamine release, and with larger doses, ganglionic blockade may occur with tubocurarine and metocurine. Premedication with an antihistaminic compound attenuates tubocurarine- and mivacurium-induced hypotension. Pancuronium causes a moderate increase in heart rate and a smaller increase in cardiac output, with little or no change in systemic vascular resistance. Although pancuronium-induced tachycardia is primarily due to a vagolytic action, release of norepinephrine from adrenergic nerve endings and blockade of neuronal uptake of norepinephrine may be secondary mechanisms. Although bronchospasm may be produced by neuromuscular blockers that release histamine (eg, mivacurium), insertion of a tracheal tube is the most common reason for bronchospasm after induction of general anesthesia.

**Table 27â€3 Effects of Neuromuscular Blocking Drugs on Other Tissues.**

Drug	Effect on Autonomic Ganglia	Effect on Cardiac Muscarinic Receptors	Tendency to Cause Histamine Release
<b>Isoquinoline derivatives</b>			
Atracurium	None	None	Slight

Vecuronium	None	None	None
<b>Other agents</b>			
Gallamine	None	Strong block	None
Succinylcholine	Stimulation	Stimulation	Slight

<sup>1</sup>Allergic reactions have been reported.

Succinylcholine can cause cardiac arrhythmias when administered during halothane anesthesia. The drug stimulates autonomic cholinergic receptors, including the nicotinic receptors at both sympathetic and parasympathetic ganglia and muscarinic receptors in the heart (eg, sinus node). The negative inotropic and chronotropic responses to succinylcholine can be attenuated by administration of an anticholinergic drug (eg, glycopyrrolate, atropine). With large doses of succinylcholine, positive inotropic and chronotropic effects may be observed. On the other hand, bradycardia has been repeatedly observed when a second dose of succinylcholine is given less than 5 minutes after the initial dose. This transient bradycardia can be prevented by thiopental, atropine, ganglionic-blocking drugs, and by pretreating with a small dose of a nondepolarizing muscle relaxant (eg, pancuronium). Direct myocardial effects, increased muscarinic stimulation, and ganglionic stimulation contribute to this bradycardic response.

### Other Adverse Effects of Depolarizing Blockade

#### HYPERKALEMIA

Patients with burns, nerve damage or neuromuscular disease, closed head injury, and other trauma can respond to succinylcholine by releasing potassium into the blood, which, on rare occasions, results in cardiac arrest.

#### INCREASED INTRAOCULAR PRESSURE

Administration of succinylcholine may be associated with the rapid onset of an increase in intraocular pressure (< 60 seconds), peaking at 2â€4 minutes, and declining after 5 minutes. The mechanism may involve tonic contraction of myofibrils or transient dilation of ocular choroidal blood vessels. Despite the increase in intraocular pressure, the use of succinylcholine for ophthalmologic operations is not contraindicated unless the anterior chamber is open ("open globe") due to trauma.

#### INCREASED INTRAGASTRIC PRESSURE

In heavily muscled patients, the fasciculations associated with succinylcholine may cause an increase in intragastric pressure ranging from 5 to 40 cm H<sub>2</sub>O, increasing the risk for regurgitation and aspiration of gastric contents. This complication is more likely to occur in patients with delayed gastric emptying (eg, those with diabetes), traumatic injury (eg, an emergency case), esophageal dysfunction, and morbid obesity.

#### **MUSCLE PAIN**

Myalgias are a common postoperative complaint of heavily muscled patients and those who receive large doses (> 1.5 mg/kg) of succinylcholine. The true incidence of myalgias related to muscle fasciculations is difficult to establish because of confounding factors, including the anesthetic technique, type of surgery, and positioning during the operation. However, the incidence of myalgias has been reported to vary from less than 1% to 20%. It occurs more frequently in ambulatory than in bedridden patients. The pain is thought to be secondary to the unsynchronized contractions of adjacent muscle fibers just before the onset of paralysis. However, there is controversy over whether the incidence of muscle pain following succinylcholine is actually higher than with nondepolarizing muscle relaxants when other potentially confounding factors are taken into consideration.

#### **Interactions with Other Drugs**

##### **ANESTHETICS**

Inhaled (volatile) anesthetics potentiate the neuromuscular blockade produced by nondepolarizing muscle relaxants in a dose-dependent fashion. Of the general anesthetics that have been studied, inhaled anesthetics augment the effects of muscle relaxants in the following order: isoflurane (most); sevoflurane, desflurane, enflurane, and halothane; and nitrous oxide (least) (Figure 27â€9). The most important factors involved in this interaction are the following: (1) nervous system depression at sites proximal to the neuromuscular junction (ie, central nervous system); (2) increased muscle blood flow (ie, due to peripheral vasodilation produced by volatile anesthetics), which allows a larger fraction of the injected muscle relaxant to reach the neuromuscular junction; and (3) decreased sensitivity of the postjunctional membrane to depolarization.

A rare interaction of succinylcholine with volatile anesthetics results in malignant hyperthermia, a condition caused by abnormal release of calcium from stores in skeletal muscle. This condition is treated with dantrolene and is discussed below under Spasmolytic Drugs and in Chapter 16.

##### **ANTIBIOTICS**

Numerous reports have described enhancement of neuromuscular blockade by antibiotics (eg, aminoglycosides). Many of the antibiotics have been shown to cause a depression of evoked release of acetylcholine similar to that caused by administering magnesium. The mechanism of this prejunctional effect appears to be blockade of specific P-type calcium channels in the motor nerve terminal.

##### **LOCAL ANESTHETICS AND ANTIARRHYTHMIC DRUGS**

In small doses, local anesthetics can depress posttetanic potentiation via a prejunctional neural effect. In large doses, local anesthetics can block neuromuscular transmission. With higher doses, local anesthetics block acetylcholine-induced muscle contractions as a result of blockade of the nicotinic receptor ion channels. Experimentally, similar effects can be demonstrated with sodium channel-blocking antiarrhythmic drugs such as quinidine. However, at the doses used for cardiac arrhythmias, this interaction is of little or no clinical significance. Higher concentrations of bupivacaine (0.75%) have been associated with cardiac arrhythmias independent of the muscle relaxant used.

##### **OTHER NEUROMUSCULAR BLOCKING DRUGS**

The end plate-depolarizing effect of succinylcholine can be antagonized by administering a small dose of a nondepolarizing blocker. To prevent the fasciculations associated with succinylcholine administration, a small nonparalyzing dose of a nondepolarizing drug can be given before succinylcholine (eg, *d*-tubocurarine, 2 mg IV, or pancuronium, 0.5 mg IV). Although this dose usually reduces fasciculations and postoperative myalgias, it can increase the amount of succinylcholine required for relaxation by 50â€90% and can produce a feeling of weakness in awake patients. Therefore, "pre-curarization" before succinylcholine is no longer widely practiced.

#### **Effects of Diseases & Aging on the Neuromuscular Response**

Several diseases can diminish or augment the neuromuscular blockade produced by nondepolarizing muscle relaxants. Myasthenia gravis enhances the neuromuscular blockade produced by these drugs. Advanced age is associated with a prolonged duration of action from nondepolarizing relaxants as a result of decreased clearance of the drugs by the liver and kidneys. As a result, the dosage of neuromuscular blocking drugs should be reduced in older patients (> 70 years).

Conversely, patients with severe burns and those with upper motor neuron disease are resistant to nondepolarizing muscle relaxants. This desensitization is probably caused by proliferation of extrajunctional receptors, which results in an increased dose requirement for the nondepolarizing relaxant to block a sufficient number of receptors.

#### **Reversal of Nondepolarizing Neuromuscular Blockade**

The cholinesterase inhibitors effectively antagonize the neuromuscular blockade caused by nondepolarizing drugs. Their general pharmacology is discussed in Chapter 7. **Neostigmine** and **pyridostigmine** antagonize nondepolarizing neuromuscular blockade by increasing the availability of acetylcholine at the motor end plate, mainly by inhibition of acetylcholinesterase. To a lesser extent, these cholinesterase inhibitors also increase the release of this transmitter from the motor nerve terminal. In contrast, edrophonium antagonizes neuromuscular blockade purely by inhibiting acetylcholinesterase activity. Edrophonium has a more rapid onset of action but may be less effective than neostigmine in reversing the effects of nondepolarizing blockers in the

presence of a profound degree of neuromuscular blockade. These differences are important in determining recovery from *residual block*, the neuromuscular blockade remaining after completion of surgery and movement of the patient to the recovery room. Unsuspected residual block may result in hypoventilation, leading to hypoxia and even apnea, especially if patients have received central depressant medications in the early recovery period.

Since mivacurium is metabolized by plasma cholinesterase, the interaction with the anticholinesterase reversal drugs is less predictable. On the one hand, the neuromuscular blockade is antagonized because of increased acetylcholine concentrations in the synapse. On the other hand, mivacurium concentration may be higher because of decreased plasma cholinesterase breakdown of the muscle relaxant itself.

A novel cyclodextrin reversal drug, **sugammadex**, has been submitted for FDA approval. It can rapidly inactivate steroidal neuromuscular blocking drugs by forming an inactive complex, which is excreted in the urine. This process allows the practitioner to rapidly reverse even profound degrees of neuromuscular blockade produced by rocuronium and vecuronium at the end of the surgical procedure.

## Uses of Neuromuscular Blocking Drugs

### SURGICAL RELAXATION

One of the most important applications of the neuromuscular blockers is in facilitating intracavitary surgery. This is especially important in intra-abdominal and intrathoracic procedures.

### TRACHEAL INTUBATION

By relaxing the pharyngeal and laryngeal muscles, neuromuscular blocking drugs facilitate laryngoscopy and placement of the tracheal tube. Placement of a tracheal tube ensures an adequate airway and minimizes the risk of pulmonary aspiration during general anesthesia.

### CONTROL OF VENTILATION

In critically ill patients who have ventilatory failure from various causes (eg, severe bronchospasm, pneumonia, chronic obstructive airway disease), it may be necessary to control ventilation to provide adequate gas exchange and to prevent atelectasis. In the ICU, neuromuscular blocking drugs are frequently administered to reduce chest wall resistance (ie, improve thoracic compliance) and ineffective spontaneous ventilation in intubated patients.

### TREATMENT OF CONVULSIONS

Neuromuscular blocking drugs (ie, succinylcholine) are occasionally used to attenuate the peripheral (motor) manifestations of convulsions associated with status epilepticus or local anesthetic toxicity. Although this approach is effective in eliminating the muscular manifestations of the seizures, it has no effect on the central processes because neuromuscular blocking drugs do not cross the blood-brain barrier.

## Spasmolytic Drugs

Spasticity is characterized by an increase in tonic stretch reflexes and flexor muscle spasms (ie, increased basal muscle tone) together with muscle weakness. It is often associated with spinal injury, cerebral palsy, multiple sclerosis, and stroke. These conditions often involve abnormal function of the bowel and bladder as well as skeletal muscle. The mechanisms underlying clinical spasticity appear to involve not only the stretch reflex arc itself but also higher centers in the CNS (ie, upper motor neuron lesion), with damage to descending pathways in the spinal cord resulting in hyperexcitability of the alpha motoneurons in the cord. Pharmacologic therapy may ameliorate some of the symptoms of spasticity by modifying the stretch reflex arc or by interfering directly with skeletal muscle (ie, excitation-contraction coupling). The important components involved in these processes are shown in Figure 27-10.

### Figure 27-10

Diagram of the structures involved in the stretch reflex arc. *I* is an inhibitory interneuron; *E* indicates an excitatory presynaptic terminal; *Ia* is a primary intrafusal afferent fiber;  $Ca^{2+}$  denotes activator calcium stored in the sarcoplasmic reticulum of skeletal muscle; *RyR channels* indicates the  $Ca^{2+}$  release channels.

(Reproduced, with permission, from Young RR, Delwaide PJ: Drug therapy: Spasticity. *N Engl J Med* 1981;304:28.)

Drugs that modify this reflex arc may modulate excitatory or inhibitory synapses (see Chapter 21). Thus, to reduce the hyperactive stretch reflex, it is desirable to reduce the activity of the Ia fibers that excite the primary motoneuron or to enhance the activity of the inhibitory interneuronal neurons. These structures are shown in greater detail in Figure 27â€11.

**Figure 27â€11**

Postulated sites of spasmolytic action of tizanidine ( $\alpha_2$ ), benzodiazepines ( $GABA_A$ ), and baclofen ( $GABA_B$ ) in the spinal cord. Tizanidine may also have a postsynaptic inhibitory effect. Dantrolene acts on the sarcoplasmic reticulum in skeletal muscle. Glu, glutamatergic neuron.

A variety of pharmacologic agents described as depressants of the spinal "polysynaptic" reflex arc (eg, barbiturates [phenobarbital] and glycerol ethers [mephenesin]) have been used to treat these conditions of excess skeletal muscle tone. However, as illustrated in Figure 27â€11, nonspecific depression of synapses involved in the stretch reflex could reduce the desired GABAergic inhibitory activity, as well as the excitatory glutamatergic transmission. Currently available drugs can provide significant relief from painful muscle spasms, but they are less effective in improving meaningful function (eg, mobility and return to work).

## DIAZEPAM

As described in Chapter 22, benzodiazepines facilitate the action of  $\gamma$ -aminobutyric acid (GABA) in the central nervous system. Diazepam acts at  $GABA_A$  synapses, and its action in reducing spasticity is at least partly mediated in the spinal cord because it is somewhat effective in patients with cord transection. Although diazepam can be used in patients with muscle spasm of almost any origin (including local muscle trauma), it also produces sedation at the doses required to reduce muscle tone. The initial dosage is 4 mg/d, and it is gradually increased to a maximum of 60 mg/d. Other benzodiazepines have been used as spasmolytics (eg, midazolam), but clinical experience with them is limited.

## BACLOFEN

Baclofen (*p*-chlorophenyl-GABA) was designed to be an orally active GABA-mimetic agent and is an agonist at  $GABA_B$  receptors.

Activation of these receptors by baclofen results in hyperpolarization, probably by increased  $K^+$  conductance (see Figure 24â€2). It has been suggested that hyperpolarization causes presynaptic inhibition by reducing calcium influx (Figure 27â€11) and reduces the release of excitatory transmitters in both the brain and the spinal cord. Baclofen may also reduce pain in patients with spasticity, perhaps by inhibiting the release of substance P (neurokinin-1) in the spinal cord.

**Baclofen**

Baclofen is at least as effective as diazepam in reducing spasticity and causes less sedation. In addition, baclofen does not reduce overall muscle strength as much as dantrolene. It is rapidly and completely absorbed after oral administration and has a plasma half-life of 3–4 hours. Dosage is started at 15 mg twice daily, increasing as tolerated to 100 mg daily. Adverse effects of this drug include drowsiness; however, patients become tolerant to the sedative effect with chronic administration. Increased seizure activity has been reported in epileptic patients. Therefore, withdrawal from baclofen must be done very slowly.

Studies have confirmed that intrathecal administration of baclofen can control severe spasticity and muscle pain that is not responsive to medication by other routes of administration. Owing to the poor egress of baclofen from the spinal cord, peripheral symptoms are rare. Therefore, higher central concentrations of the drug may be tolerated. Partial tolerance to the effect of the drug may occur after several months of therapy, but can be overcome by upward dosage adjustments to maintain the beneficial effect. Excessive somnolence, respiratory depression, and even coma have been described. Although a major disadvantage of this therapeutic approach is the difficulty of maintaining the drug delivery catheter in the subarachnoid space, long-term intrathecal baclofen therapy can improve the quality of life for patients with severe spastic disorders.

Oral baclofen has been studied in several other medical conditions, including patients with intractable low back pain. Preliminary studies suggest that it may also be effective in reducing craving in recovering alcoholics (see Chapter 32). Finally, it has been alleged to be effective in preventing migraine headaches in some patients.

### TIZANIDINE

As noted in Chapter 11,  $\alpha_2$  agonists such as clonidine and other imidazoline compounds have a variety of effects on the CNS that are not fully understood. Among these effects is the ability to reduce muscle spasm. Tizanidine is a congener of clonidine that has been studied for its spasmolytic actions. Tizanidine has significant  $\alpha_2$ -adrenoceptor agonist effects, but it reduces spasticity in experimental models at doses that cause fewer cardiovascular effects than clonidine (an  $\alpha_2$ -agonist-antagonist) or dexmedetomidine (a pure  $\alpha_2$  agonist). Neurophysiologic studies in animals and humans suggest that tizanidine reinforces both presynaptic and postsynaptic inhibition in the cord. It also inhibits nociceptive transmission in the spinal dorsal horn.

Clinical trials with oral tizanidine report comparable efficacy in relieving muscle spasm to diazepam, baclofen, and dantrolene. However, tizanidine produces a different spectrum of adverse effects, including drowsiness, hypotension, dry mouth, and asthenia. The dosage requirements vary markedly among patients, and individual dosage titration is necessary to achieve an optimal clinical effect.

### OTHER CENTRALLY ACTING SPASMOLYTIC DRUGS

**Gabapentin** is an antiepileptic drug (see Chapter 24) that has shown considerable promise as a spasmolytic agent in several studies involving patients with multiple sclerosis. Pregabalin is a newer analog of gabapentin that may also prove useful in relieving painful disorders that involve a muscle spasm component. **Progabide** and **glycine** have also been found in preliminary studies to reduce spasticity. Progabide is a GABA<sub>A</sub> and GABA<sub>B</sub> agonist and has active metabolites, including GABA itself. **Glycine** is another inhibitory amino acid neurotransmitter (see Chapter 21) that appears to possess pharmacologic activity when given orally and readily passes the blood-brain barrier. **Idrocilamide** and **riluzole** are newer drugs for the treatment of amyotrophic lateral sclerosis (ALS) that appear to have spasm-reducing effects, possibly through inhibition of glutamatergic transmission in the central nervous system.

### DANTROLENE

Dantrolene is a hydantoin derivative related to phenytoin that has a unique mechanism of spasmolytic activity. In contrast to the centrally acting drugs, dantrolene reduces skeletal muscle strength by interfering with excitation-contraction coupling in the muscle fibers. The normal contractile response involves release of calcium from its stores in the sarcoplasmic reticulum (see Figures 13–2 and 27–10). This activator calcium brings about the tension-generating interaction of actin with myosin. Calcium is released from the sarcoplasmic reticulum via a calcium channel, called the **ryanodine receptor (RyR) channel** because the plant alkaloid ryanodine combines with a receptor on the channel protein. In the case of the skeletal muscle RyR1 channel, ryanodine facilitates the open configuration.

**Dantrolene**

Dantrolene interferes with the release of activator calcium through this sarcoplasmic reticulum calcium channel by binding to the RyR1 and blocking the opening of the channel. Motor units that contract rapidly are more sensitive to the drug's effects than are

slower-responding units. Cardiac muscle and smooth muscle are minimally depressed because the release of calcium from their sarcoplasmic reticulum involves a different RyR channel (RyR2).

Treatment with dantrolene is usually initiated with 25 mg daily as a single dose, increasing to a maximum of 100 mg four times daily as tolerated. Only about one third of an oral dose of dantrolene is absorbed, and the elimination half-life of the drug is approximately 8 hours. Major adverse effects are generalized muscle weakness, sedation, and occasionally hepatitis.

A special application of dantrolene is in the treatment of **malignant hyperthermia**, a rare heritable disorder that can be triggered by a variety of stimuli, including general anesthetics (eg, volatile anesthetics) and neuromuscular blocking drugs (eg, succinylcholine; see also Chapter 16). Patients at risk for this condition have a hereditary alteration in Ca<sup>2+</sup>-induced Ca<sup>2+</sup> release via the RyR1 channel or an impairment in the ability of the sarcoplasmic reticulum to sequester calcium via the Ca<sup>2+</sup> transporter (Figure 27-10). Several mutations associated with this risk have been identified. After administration of one of the triggering agents, there is a sudden and prolonged release of calcium, with massive muscle contraction, lactic acid production, and increased body temperature. Prompt treatment is essential to control acidosis and body temperature and to reduce calcium release. The latter is accomplished by administering intravenous dantrolene, starting with a dose of 1 mg/kg IV, and repeating as necessary to a maximum dose of 10 mg/kg.

## BOTULINUM TOXIN

The therapeutic use of botulinum toxin for ophthalmic purposes and for local muscle spasm was mentioned in Chapter 6. Local facial injections of botulinum toxin are widely used for the short-term treatment (1-3 months per treatment) of wrinkles associated with aging around the eyes and mouth. Local injection of botulinum toxin has also become a useful treatment for generalized spastic disorders (eg, cerebral palsy). Most clinical studies to date have involved administration in one or two limbs, and the benefits appear to persist for weeks to several months after a single treatment. Most studies have used type A botulinum toxin, but type B is also available.

## DRUGS USED TO TREAT ACUTE LOCAL MUSCLE SPASM

A large number of less well-studied, centrally active drugs (eg, **carisoprodol**, **chlorphenesin**, **chlorzoxazone**, **cyclobenzaprine**, **metaxalone**, **methocarbamol**, and **orphenadrine**) are promoted for the relief of acute muscle spasm caused by local tissue trauma or muscle strains. It has been suggested that these drugs act primarily at the level of the brainstem. Cyclobenzaprine may be regarded as the prototype of the group. Cyclobenzaprine is structurally related to the tricyclic antidepressants and produces antimuscarinic side effects. It is ineffective in treating muscle spasm due to cerebral palsy or spinal cord injury. As a result of its strong antimuscarinic actions, cyclobenzaprine may cause significant sedation, as well as confusion and transient visual hallucinations. The dosage of cyclobenzaprine for acute injury-related muscle spasm is 20-40 mg/d orally in divided doses.

## SUMMARY: DRUGS USED

### Drugs Used

Subclass	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>Depolarizing neuromuscular blocking agent</b>				
Succinylcholine	Agonist at nicotinic acetylcholine (ACh) receptors, especially at neuromuscular junctions • depolarizes • may stimulate ganglionic nicotinic ACh and cardiac muscarinic ACh receptors	Initial depolarization causes transient contractions, followed by prolonged flaccid paralysis • depolarization is then followed by repolarization that is also accompanied by paralysis	Placement of tracheal tube at start of anesthetic procedure • rarely, control of muscle contractions in status epilepticus	Rapid metabolism by plasma cholinesterase • normal duration, ~5 min • <b>Toxicities:</b> Arrhythmias • hyperkalemia • transient increased intra-abdominal, intraocular pressure • postoperative muscle pain
<b>Nondepolarizing neuromuscular blocking agents</b>				
<i>d</i> -Tubocurarine	Competitive antagonist at nACh receptors, especially at neuromuscular junctions	Prevents depolarization by ACh, causes flaccid paralysis • can cause histamine release with hypotension • weak block of cardiac muscarinic ACh receptors	Prolonged relaxation for surgical procedures • superseded by newer nondepolarizing agents	Renal excretion • duration, ~40-60 min • <b>Toxicities:</b> Histamine release • hypotension • prolonged apnea
Cisatracurium	Similar to tubocurarine	Like tubocurarine but lacks histamine release and antimuscarinic effects	Prolonged relaxation of surgical procedures • relaxation of respiratory muscles to facilitate mechanical	Not dependent on renal or hepatic function • duration, ~25-45 min • <b>Toxicities:</b> Prolonged apnea but less toxic than atracurium

Rocuronium	Similar to cisatracurium	Like cisatracurium but slight antimuscarinic effect	Like cisatracurium • useful in patients with renal impairment	ventilation in intensive care unit Hepatic metabolism • duration, ~20â€³35 min • <i>Toxicities:</i> Like cisatracurium
------------	--------------------------	---	---	---

*Mivacurium: Rapid onset, short duration (10â€³20 min); metabolized by plasma cholinesterase*

*Vecuronium: Intermediate duration; metabolized in liver*

#### Centrally acting spasmolytic drugs

Baclofen	GABA <sub>B</sub> agonist, facilitates spinal inhibition of motor neurons	Pre- and postsynaptic inhibition of motor output	Severe spasticity due to cerebral palsy, multiple sclerosis, stroke	Oral, intrathecal • <i>Toxicities:</i> Sedation, weakness
Cyclobenzaprine	Poorly understood inhibition of muscle stretch reflex in spinal cord	Reduction in hyperactive muscle reflexes • antimuscarinic effects	Acute spasm due to muscle injury • inflammation	Hepatic metabolism • duration, ~4â€³6 h • <i>Toxicities:</i> Strong antimuscarinic effects
<i>Chlorphenesin, methocarbamol, orphenadrine, others: Like cyclobenzaprine with varying degrees of antimuscarinic effect</i>				
Diazepam	Facilitates GABAergic transmission in central nervous system (see Chapter 22)	Increases interneuron inhibition of primary motor afferents in spinal cord • central sedation	Chronic spasm due to cerebral palsy, stroke, spinal cord injury • acute spasm due to muscle injury	Hepatic metabolism • duration, ~12â€³24 h • <i>Toxicities:</i> See Chapter 22
Tizanidine	α <sub>2</sub> -Adrenoceptor agonist in the spinal cord	Presynaptic and postsynaptic inhibition of reflex motor output	Spasm due to multiple sclerosis, stroke, amyotrophic lateral sclerosis	Renal and hepatic elimination • duration, 3â€³6 h • <i>Toxicities:</i> Weakness, sedation • hypotension

#### Direct-acting muscle relaxants

Dantrolene	Blocks RyR1 Ca <sup>2+</sup> -release channels in the sarcoplasmic reticulum of skeletal muscle	Reduces actin-myosin interaction • weakens skeletal muscle contraction	IV: Malignant hyperthermia • Oral: Spasm due to cerebral palsy, spinal cord injury, multiple sclerosis	IV, oral • duration, 4â€³6 h • <i>Toxicities:</i> Muscle weakness
------------	---	--	--	---

## PREPARATIONS AVAILABLE

### NEUROMUSCULAR BLOCKING DRUGS

#### **Atracurium** (generic, Tracrium)

Parenteral: 10 mg/mL for injection

#### **Cisatracurium** (Nimbex)

Parenteral: 2, 10 mg/mL for IV injection

#### **Doxacurium** (Nuromax)

Parenteral: 1 mg/mL for IV injection

#### **Metocurine** (generic, Metubine Iodide)

Parenteral: 2 mg/mL for injection

#### **Mivacurium** (Mivacron)

Parenteral: 0.5, 2 mg/mL for injection

#### **Pancuronium** (generic)

Parenteral: 1, 2 mg/mL for injection

#### **Pipecuronium** (Arduan)

Parenteral: powder for 1 mg/mL for IV injection

**Rocuronium** (generic, Zemuron)

Parenteral: 10 mg/mL for IV injection

**Succinylcholine** (generic, Anectine)

Parenteral: 20, 50, 100 mg/mL for injection; 500, 1000 mg per vial powders to reconstitute for injection

**Tubocurarine** (generic)

Parenteral: 3 mg (20 units)/mL for injection

**Vecuronium** (generic, Norcuron)

Parenteral: 10, 20 mg powder to reconstitute for injection

## **MUSCLE RELAXANTS (SPASMOLYTICS)**

**Baclofen** (generic, Lioresal)

Oral: 10, 20 mg tablets

Intrathecal: 0.05, 0.5, 2 mg/mL

**Botulinum toxin type A** (Botox)

Parenteral: Powder for solution, 100 units/vial

**Botulinum toxin type B** (Myobloc)

Parenteral: 5000 units/mL for injection

**Carisoprodol** (generic, Soma)

Oral: 350 mg tablets

**Chlorzoxazone** (generic, Paraflex)

Oral: 250, 500 mg tablets, caplets

**Cyclobenzaprine** (generic, Flexeril)

Oral: 5, 7.5, 10 mg tablets; 15, 30 mg capsules

**Dantrolene** (Dantrium)

Oral: 25, 50, 100 mg capsules

Parenteral: 20 mg per vial powder to reconstitute for injection

**Diazepam** (generic, Valium)

Oral: 2, 5, 10 mg tablets; 5 mg/5 mL, 5 mg/mL solutions

Parenteral: 5 mg/mL for injection

**Gabapentin** (Neurontin)

Oral: 100, 300, 400 mg capsules; 600, 800 mg tablets; 50 mg/mL oral solution

*Note:* This drug is labeled for use only in epilepsy and postherpetic neuralgia.

**Metaxalone** (Skelaxin)

Oral: 800 mg tablets

**Methocarbamol** (generic, Robaxin)

Oral: 500, 750 mg tablets

Parenteral: 100 mg/mL for IM, IV injection

**Orphenadrine** (generic, Norflex)

Oral: 100 mg tablets; 100 mg sustained-release tablets

Parenteral: 30 mg/mL for IM, IV injection

**Riluzole** (Rilutek)

Oral: 50 mg tablets

*Note:* This drug is labeled only for use in amyotrophic lateral sclerosis.

**Tizanidine** (Zanaflex)

Oral: 2, 4 mg tablets, capsules; 6 mg capsules

**Basic and Clinical Pharmacology** > Chapter 28. Pharmacologic Management of Parkinsonism & Other Movement Disorders >

## CASE STUDY

A 64-year-old architect complains of right-hand tremor at rest, which interferes with his writing and drawing. He also notes a stooped posture, a tendency to drag his left leg when walking, and slight unsteadiness on turning. He remains independent in all activities of daily living. Examination reveals hypomimia (flat facies), hypophonia, a rest tremor of the left arm and leg, mild rigidity in all limbs, and impaired rapid alternating movements in the left limbs. Neurologic and general examinations are otherwise normal. What is the likely diagnosis and prognosis, and how should his condition be managed?

## PHARMACOLOGIC MANAGEMENT OF PARKINSONISM & OTHER MOVEMENT DISORDERS: INTRODUCTION

Several types of abnormal movement are recognized. **Tremor** consists of a rhythmic oscillatory movement around a joint and is best characterized by its relation to activity. Tremor at rest is characteristic of parkinsonism, when it is often associated with rigidity and an impairment of voluntary activity. Tremor may occur during maintenance of sustained posture (postural tremor) or during movement (intention tremor). A conspicuous postural tremor is the cardinal feature of benign essential or familial tremor. Intention tremor occurs in patients with a lesion of the brain stem or cerebellum, especially when the superior cerebellar peduncle is involved; it may also occur as a manifestation of toxicity from alcohol or certain other drugs.

**Chorea** consists of irregular, unpredictable, involuntary muscle jerks that occur in different parts of the body and impair voluntary activity. In some instances, the proximal muscles of the limbs are most severely affected, and because the abnormal movements are then particularly violent, the term *ballismus* has been used to describe them. Chorea may be hereditary or may occur as a complication of a number of general medical disorders and of therapy with certain drugs.

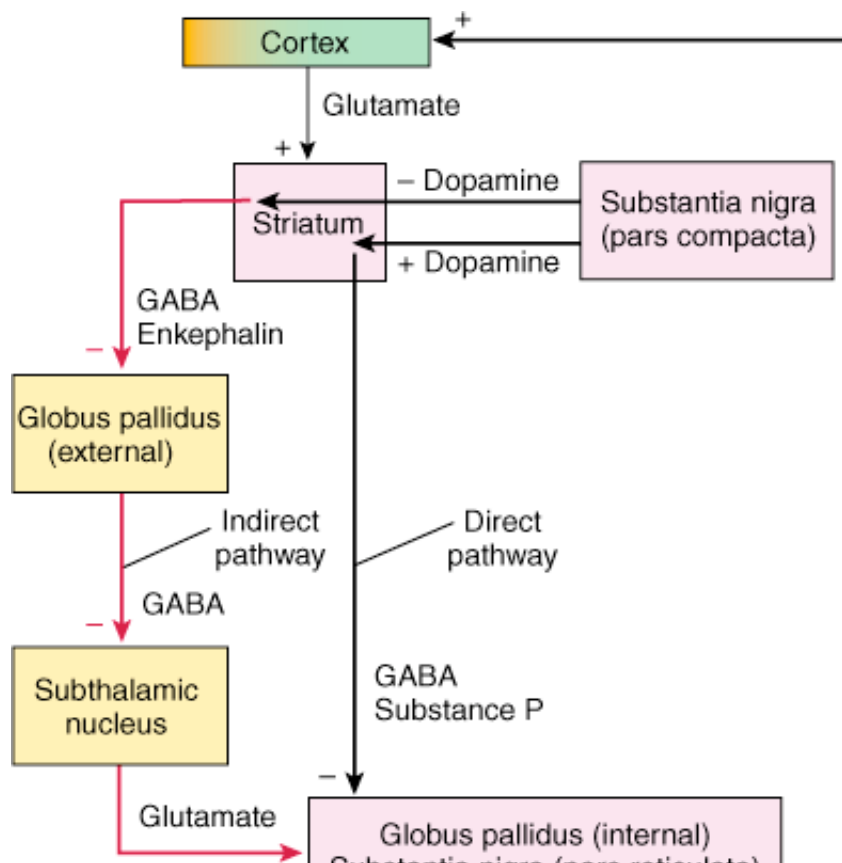

Abnormal movements may be slow and writhing in character (**athetosis**) and in some instances are so sustained that they are more properly regarded as abnormal postures (**dystonia**). Athetosis or dystonia may occur with perinatal brain damage, with focal or

generalized cerebral lesions, as an acute complication of certain drugs, as an accompaniment of diverse neurologic disorders, or as an isolated inherited phenomenon of uncertain cause known as idiopathic torsion dystonia or dystonia musculorum deformans. Various genetic loci have been reported (eg, 9q34, 8p21-q22, 18p, 1p36.32-p36.13, 14q22.1-q22.2, 14q13) depending on the age of onset, mode of inheritance, and response to dopaminergic therapy. Its physiologic basis is uncertain, and treatment is unsatisfactory.

**Tics** are sudden coordinated abnormal movements that tend to occur repetitively, particularly about the face and head, especially in children, and can be suppressed voluntarily for short periods of time. Common tics include repetitive sniffing or shoulder shrugging. Tics may be single or multiple and transient or chronic. Gilles de la Tourette's syndrome is characterized by chronic multiple tics; its pharmacologic management is discussed at the end of this chapter.

Many of the movement disorders have been attributed to disturbances of the basal ganglia. The basic circuitry of the basal ganglia involves three interacting neuronal loops that include the cortex and thalamus as well as the basal ganglia themselves (Figure 28-1). However, the precise function of these anatomic structures is not yet fully understood, and it is not possible to relate individual symptoms to involvement at specific sites.

### **Figure 28-1**

Functional circuitry between the cortex, basal ganglia, and thalamus. The major neurotransmitters are indicated. In Parkinson's disease, there is degeneration of the pars compacta of the substantia nigra, leading to overactivity in the indirect pathway (red) and increased glutamatergic activity by the subthalamic nucleus.

## PARKINSONISM

Parkinsonism is characterized by a combination of rigidity, bradykinesia, tremor, and postural instability that can occur for a variety of reasons but is usually idiopathic (Parkinson's disease or paralysis agitans). Cognitive decline occurs in many patients as

the disease advances. The pathophysiologic basis of the idiopathic disorder may relate to exposure to some unrecognized neurotoxin or to oxidation reactions with the generation of free radicals. Studies in twins suggest that genetic factors may also be important, especially when the disease occurs in patients under age 50. Mutations of the  $\alpha$ -synuclein gene at 4q21, the leucine-rich repeat kinase 2 (*LRRK2*) gene at 12cen, and the *UCHL1* gene may cause autosomal dominant parkinsonism. Mutations in the *parkin* gene (6q25.2–q27) may cause early-onset, autosomal-recessive, familial parkinsonism, or sporadic juvenile-onset parkinsonism. Several other genes or chromosomal regions have been associated with other familial forms of the disease. Parkinson's disease is generally progressive, leading to increasing disability unless effective treatment is provided.

The normally high concentration of dopamine in the basal ganglia of the brain is reduced in parkinsonism, and pharmacologic attempts to restore dopaminergic activity with levodopa and dopamine agonists alleviate many of the motor features of the disorder. An alternative but complementary approach has been to restore the normal balance of cholinergic and dopaminergic influences on the basal ganglia with antimuscarinic drugs. The pathophysiologic basis for these therapies is that in idiopathic parkinsonism, dopaminergic neurons in the substantia nigra that normally inhibit the output of GABAergic cells in the corpus striatum are lost (Figure 28–2). Drugs that induce parkinsonian syndromes either are dopamine receptor antagonists (eg, antipsychotic agents; see Chapter 29) or lead to the destruction of the dopaminergic nigrostriatal neurons (eg, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine [MPTP]; see below). Various other neurotransmitters, such as norepinephrine, are also depleted in the brain in parkinsonism, but these deficiencies are of uncertain clinical relevance.

Schematic representation of the sequence of neurons involved in parkinsonism. **Top:** Dopaminergic neurons (red) originating in the substantia nigra normally inhibit the GABAergic output from the striatum, whereas cholinergic neurons (orange) exert an excitatory effect. **Bottom:** In parkinsonism, there is a selective loss of dopaminergic neurons (dashed, red).

## LEVODOPA

Dopamine does not cross the blood-brain barrier and if given into the peripheral circulation has no therapeutic effect in parkinsonism. However, (â€œ)-3-(3,4-dihydroxyphenyl)-L-alanine (levodopa), the immediate metabolic precursor of dopamine, does enter the brain (via an L-amino acid transporter, LAT), where it is decarboxylated to dopamine (see Figure 6â€œ5). Several noncatecholamine dopamine receptor agonists have also been developed and may lead to clinical benefit, as discussed in the text that follows.

Dopamine receptors are discussed in detail in Chapters 21 and 29. Dopamine receptors of the D<sub>1</sub> type are located in the pars compacta of the substantia nigra and presynaptically on striatal axons coming from cortical neurons and from dopaminergic cells in the substantia nigra. The D<sub>2</sub> receptors are located postsynaptically on striatal neurons and presynaptically on axons in the substantia nigra belonging to neurons in the basal ganglia. The benefits of dopaminergic antiparkinsonism drugs appear to depend mostly on stimulation of the D<sub>2</sub> receptors. However, D<sub>1</sub>-receptor stimulation may also be required for maximal benefit and one of the newer drugs is D<sub>3</sub>-selective. Dopamine

agonist or partial agonist ergot derivatives such as lergotrile and bromocriptine that are powerful stimulators of the D<sub>2</sub> receptors have antiparkinsonism properties, whereas certain dopamine blockers that are selective D<sub>2</sub> antagonists can induce parkinsonism.

### **Chemistry**

Dopa is the amino acid precursor of dopamine and norepinephrine (discussed in Chapter 6). Its structure is shown in Figure 28-3. Levodopa is the levorotatory stereoisomer of dopa.

Some drugs used in the treatment of parkinsonism.

## Pharmacokinetics

Levodopa is rapidly absorbed from the small intestine, but its absorption depends on the rate of gastric emptying and the pH of the gastric contents. Ingestion of food delays the appearance of levodopa in the plasma. Moreover, certain amino acids from ingested food can compete with the drug for absorption from the gut and for transport from the blood to the brain. Plasma concentrations usually peak between 1 and 2 hours after an oral dose, and the plasma half-life is usually between 1 and 3 hours, although it varies considerably among individuals. About two thirds of the dose appears in the urine as metabolites within 8 hours of an oral dose, the main metabolic products being 3-methoxy-4-hydroxyphenyl acetic acid (homovanillic acid, HVA) and dihydroxyphenylacetic acid (DOPAC). Unfortunately, only about 1% of administered levodopa actually enters the brain unaltered; the remainder is metabolized extracerebrally, predominantly by decarboxylation to dopamine, which does not penetrate the blood-brain barrier. Accordingly, levodopa must be given in large amounts when used alone. However, when given in combination with a dopa decarboxylase inhibitor that does not penetrate the blood-brain barrier, the peripheral metabolism of levodopa is reduced, plasma levels of levodopa are higher, plasma half-life is longer, and more dopa is available for entry into the brain (Figure 28-4). Indeed, concomitant administration of a peripheral dopa decarboxylase inhibitor such as carbidopa may reduce the daily requirements of levodopa by approximately 75%.

Fate of orally administered levodopa and the effect of carbidopa, estimated from animal data. The width of each pathway indicates the absolute amount of the drug at each site, whereas

the percentages shown denote the relative proportion of the administered dose. The benefits of coadministration of carbidopa include reduction of the amount of levodopa required for benefit and of the absolute amount diverted to peripheral tissues and an increase in the fraction of the dose that reaches the brain. GI, gastrointestinal.

(Data from Nutt JG, Fellman JH: Pharmacokinetics of levodopa. Clin Neuropharmacol 1984;7:35.)

## Clinical Use

The best results of levodopa treatment are obtained in the first few years of treatment. This is sometimes because the daily dose of levodopa must be reduced over time to avoid adverse effects at doses that were well tolerated initially. Some patients become less responsive to levodopa, perhaps because of loss of dopaminergic nigrostriatal nerve terminals or some pathologic process directly involving striatal dopamine receptors. For such reasons, the benefits of levodopa treatment often begin to diminish after about 3 or 4 years of therapy, regardless of the initial therapeutic response. Although levodopa therapy does not stop the progression of parkinsonism, its early initiation lowers the mortality rate. However, long-term therapy may lead to a number of problems in management such as the on-off phenomenon discussed below. The most appropriate time to introduce levodopa therapy must therefore be determined individually.

When levodopa is used, it is generally given in combination with carbidopa (Figure 28â€³), a peripheral dopa decarboxylase inhibitor, which reduces peripheral conversion to dopamine. **Combination** treatment (**Sinemet**) is started with a small dose, eg, Sinemet-25/100 (carbidopa 25 mg, levodopa 100 mg) three times daily, and gradually increased. It should be taken 30â€“60 minutes before meals. Most patients ultimately require Sinemet-25/250 (carbidopa 25 mg, levodopa 250 mg) three or four times daily. It is generally preferable to keep treatment with this agent at a low level (eg, Sinemet-25/100 three times daily) when possible, and to use a dopamine agonist instead, to reduce the risk of development of response fluctuations. A controlled-release formulation of Sinemet is available and may be helpful in patients with established response fluctuations or as a means of reducing dosing frequency. A formulation of carbidopa-levodopa (10/100, 25/100, 25/250) that disintegrates in the mouth and is swallowed with the saliva (**Parcopa**) is now available commercially and is best taken about 1 hour before meals. The combination (**Stalevo**) of levodopa, carbidopa, and a catechol-O-methyltransferase (COMT) inhibitor (entacapone) is discussed in a later section. Finally, monotherapy by *intraduodenal infusion* of levodopa-carbidopa appears to be safe and is superior to a number of oral combination therapies in patients with response fluctuations. This approach has been used to a greater extent in Europe than the USA, but interest is growing.

Levodopa can ameliorate all the clinical features of parkinsonism, but it is particularly effective in relieving bradykinesia and any disabilities resulting from it. When it is first

introduced, about one third of patients respond very well and one third less well. Most of the remainder either are unable to tolerate the medication or simply do not respond at all, especially if they do not have classic Parkinson's disease.

## **Adverse Effects**

### **GASTROINTESTINAL EFFECTS**

When levodopa is given without a peripheral decarboxylase inhibitor, anorexia and nausea and vomiting occur in about 80% of patients. These adverse effects can be minimized by taking the drug in divided doses, with or immediately after meals, and by increasing the total daily dose very slowly; antacids taken 30–60 minutes before levodopa may also be beneficial. The vomiting has been attributed to stimulation of the chemoreceptor trigger zone located in the brain stem but outside the blood-brain barrier. Fortunately, tolerance to this emetic effect develops in many patients. Antiemetics such as phenothiazines should be avoided because they reduce the antiparkinsonism effects of levodopa and may exacerbate the disease.

When levodopa is given in combination with carbidopa, adverse gastrointestinal effects are much less frequent and troublesome, occurring in less than 20% of cases, so that patients can tolerate proportionately higher doses.

### **CARDIOVASCULAR EFFECTS**

A variety of cardiac arrhythmias have been described in patients receiving levodopa, including tachycardia, ventricular extrasystoles and, rarely, atrial fibrillation. This effect has been attributed to increased catecholamine formation peripherally. The incidence of such arrhythmias is low, even in the presence of established cardiac disease, and may be reduced still further if the levodopa is taken in combination with a peripheral decarboxylase inhibitor.

Postural hypotension is common, but often asymptomatic, and tends to diminish with continuing treatment. Hypertension may also occur, especially in the presence of nonselective monoamine oxidase inhibitors or sympathomimetics or when massive doses of levodopa are being taken.

### **DYSKINESIAS**

Dyskinesias occur in up to 80% of patients receiving levodopa therapy for long periods. The form and nature of dopa dyskinesias vary widely among patients but tend to remain constant in character in individual patients. Choreoathetosis of the face and distal extremities is the most common presentation. The development of dyskinesias is dose-related, but there is considerable individual variation in the dose required to produce them.

### **BEHAVIORAL EFFECTS**

A wide variety of adverse mental effects have been reported, including depression,

anxiety, agitation, insomnia, somnolence, confusion, delusions, hallucinations, nightmares, euphoria, and other changes in mood or personality. Such adverse effects are more common in patients taking levodopa in combination with a decarboxylase inhibitor rather than levodopa alone, presumably because higher levels are reached in the brain. They may be precipitated by intercurrent illness or operation. It may be necessary to reduce or withdraw the medication. Several atypical antipsychotic agents that have low affinity for dopamine D<sub>2</sub> receptors (clozapine, olanzapine, quetiapine, and risperidone; see Chapter 29) are now available and may be particularly helpful in counteracting such behavioral complications.

### **FLUCTUATIONS IN RESPONSE**

Certain fluctuations in clinical response to levodopa occur with increasing frequency as treatment continues. In some patients, these fluctuations relate to the timing of levodopa intake, and they are then referred to as wearing-off reactions or end-of-dose akinesia. In other instances, fluctuations in clinical state are unrelated to the timing of doses (**on-off phenomenon**). In the on-off phenomenon, off-periods of marked akinesia alternate over the course of a few hours with on-periods of improved mobility but often marked dyskinesia. The phenomenon is most likely to occur in patients who responded well to treatment initially. The exact mechanism is unknown. For patients with severe off-periods who are unresponsive to other measures, subcutaneously injected apomorphine may provide temporary benefit.

### **MISCELLANEOUS ADVERSE EFFECTS**

Mydriasis may occur and may precipitate an attack of acute glaucoma in some patients. Other reported but rare adverse effects include various blood dyscrasias; a positive Coombs' test with evidence of hemolysis; hot flushes; aggravation or precipitation of gout; abnormalities of smell or taste; brownish discoloration of saliva, urine, or vaginal secretions; priapism; and mild—usually transient—elevations of blood urea nitrogen and of serum transaminases, alkaline phosphatase, and bilirubin.

### **Drug Holidays**

A drug holiday (discontinuance of the drug for 3–21 days) may temporarily improve responsiveness to levodopa and alleviate some of its adverse effects but is usually of little help in the management of the on-off phenomenon. Furthermore, a drug holiday carries the risks of aspiration pneumonia, venous thrombosis, pulmonary embolism, and depression resulting from the immobility accompanying severe parkinsonism. For these reasons and because of the temporary nature of any benefit, drug holidays are not recommended.

### **Drug Interactions**

Pharmacologic doses of pyridoxine (vitamin B<sub>6</sub>) enhance the extracerebral metabolism of levodopa and may therefore prevent its therapeutic effect unless a peripheral

decarboxylase inhibitor is also taken. Levodopa should not be given to patients taking monoamine oxidase A inhibitors or within 2 weeks of their discontinuance because such a combination can lead to hypertensive crises.

### **Contraindications**

Levodopa should not be given to psychotic patients because it may exacerbate the mental disturbance. It is also contraindicated in patients with angle-closure glaucoma, but those with chronic open-angle glaucoma may be given levodopa if intraocular pressure is well controlled and can be monitored. It is best given combined with carbidopa to patients with cardiac disease; even so, the risk of cardiac dysrhythmia is slight. Patients with active peptic ulcer must also be managed carefully, since gastrointestinal bleeding has occasionally occurred with levodopa. Because levodopa is a precursor of skin melanin and conceivably may activate malignant melanoma, it should be used with particular care in patients with a history of melanoma or with suspicious undiagnosed skin lesions; such patients should be monitored by a dermatologist regularly.

### **DOPAMINE RECEPTOR AGONISTS**

Drugs acting directly on dopamine receptors may have a beneficial effect in addition to that of levodopa (Figure 28â€”5). Unlike levodopa, they do not require enzymatic conversion to an active metabolite, have no potentially toxic metabolites, and do not compete with other substances for active transport into the blood and across the blood-brain barrier. Moreover, drugs selectively affecting certain (but not all) dopamine receptors may have more limited adverse effects than levodopa. A number of dopamine agonists have antiparkinsonism activity. The older dopamine agonists (bromocriptine and pergolide) are ergot (ergoline) derivatives (see Chapter 16), and their side effects are of more concern than those of the newer agents (pramipexole and ropinirole).

### **Figure 28â€”5**

Pharmacologic strategies for dopaminergic therapy of Parkinson's disease. Drugs and their effects are highlighted (see text). MAO, monoamine oxidase; COMT, catechol-*O*-methyltransferase; DOPAC, dihydroxyphenylacetic acid; L-DOPA, levodopa; 3-OMD, 3-*O*-methyl dopa.

There is no evidence that one agonist is superior to another; individual patients, however, may respond to one but not another of these agents. Apomorphine is a potent

dopamine agonist but is discussed separately in a later section in this chapter because it is used primarily as a rescue drug for patients with disabling response fluctuations to levodopa.

Dopamine agonists have an important role as first-line therapy for Parkinson's disease, and their use is associated with a lower incidence of the response fluctuations and dyskinesias that occur with long-term levodopa therapy. In consequence, dopaminergic therapy may best be initiated with a dopamine agonist. Alternatively, a low dose of carbidopa plus levodopa (eg, Sinemet-25/100 three times daily) is introduced, and a dopamine agonist is then added. In either case, the dose of the dopamine agonist is built up gradually depending on response and tolerance. Dopamine agonists may also be given to patients with parkinsonism who are taking levodopa and who have end-of-dose akinesia or on-off phenomenon or are becoming resistant to treatment with levodopa. In such circumstances, it is generally necessary to lower the dose of levodopa to prevent intolerable adverse effects. The response to a dopamine agonist is generally disappointing in patients who have never responded to levodopa.

### **Bromocriptine**

Bromocriptine is a D<sub>2</sub> agonist; its structure is shown in Table 16-6. This drug has been widely used to treat Parkinson's disease in the past, but is now rarely used for this purpose, having been superseded by the newer dopamine agonists. Bromocriptine is absorbed to a variable extent from the gastrointestinal tract; peak plasma levels are reached within 1-2 hours after an oral dose. It is excreted in the bile and feces. The usual daily dose of bromocriptine for parkinsonism varies between 7.5 and 30 mg. To minimize adverse effects, the dose is built up slowly over 2 or 3 months from a starting level of 1.25 mg twice daily after meals; the daily dose is then increased by 2.5 mg every 2 weeks, depending on the response or the development of adverse reactions.

### **Pergolide**

Pergolide, another ergot derivative, directly stimulates both D<sub>1</sub> and D<sub>2</sub> receptors. It too has been widely used for parkinsonism, and comparative studies suggest that it is more effective than bromocriptine in relieving the symptoms and signs of the disease, increasing on-time among response fluctuators, and permitting the levodopa dose to be reduced. The drug is no longer available because its use has been associated with the development of valvular heart disease.

### **Pramipexole**

Pramipexole is not an ergot derivative, but it has preferential affinity for the D<sub>3</sub> family of receptors. It is effective as monotherapy for mild parkinsonism and is also helpful in patients with advanced disease, permitting the dose of levodopa to be reduced and smoothing out response fluctuations. Pramipexole may ameliorate affective symptoms. A

possible neuroprotective effect has been suggested by its ability to scavenge hydrogen peroxide and enhance neurotrophic activity in mesencephalic dopaminergic cell cultures.

### **Pramipexole**

Pramipexole is rapidly absorbed after oral administration, reaching peak plasma concentrations in approximately 2 hours, and is excreted largely unchanged in the urine. It is started at a dosage of 0.125 mg three times daily, doubled after 1 week, and again after another week. Further increments in the daily dose are by 0.75 mg at weekly intervals, depending on response and tolerance. Most patients require between 0.5 and 1.5 mg three times daily. Renal insufficiency may necessitate dosage adjustment.

### **Ropinirole**

Another nonergoline derivative, ropinirole (now available in a generic preparation) is a relatively pure D<sub>2</sub> receptor agonist that is effective as monotherapy in patients with mild disease and as a means of smoothing the response to levodopa in patients with more advanced disease and response fluctuations. It is introduced at 0.25 mg three times daily, and the total daily dose is then increased by 0.75 mg at weekly intervals until the fourth week and by 1.5 mg thereafter. In most instances, a dosage between 2 and 8 mg three times daily is necessary. Ropinirole is metabolized by CYP1A2; other drugs metabolized by this isoform may significantly reduce its clearance. A prolonged-release preparation (Ropinirole XL) taken once daily is now available.

### **Ropinirole**

### **Rotigotine**

The dopamine agonist rotigotine, delivered daily through a skin patch, was approved in 2007 by the FDA for treatment of early Parkinson's disease. It supposedly provides more continuous dopaminergic stimulation than oral medication in early disease; its efficacy in

more advanced disease is less clear. Benefits and side effects are similar to those of other dopamine agonists but reactions may also occur at the application site and are sometimes serious. The product was recalled in 2008 because of crystal formation on the patches, affecting the availability and efficacy of the agonist.

## **Adverse Effects of Dopamine Agonists**

### **GASTROINTESTINAL EFFECTS**

Anorexia and nausea and vomiting may occur when a dopamine agonist is introduced and can be minimized by taking the medication with meals. Constipation, dyspepsia, and symptoms of reflux esophagitis may also occur. Bleeding from peptic ulceration has been reported.

### **CARDIOVASCULAR EFFECTS**

Postural hypotension may occur, particularly at the initiation of therapy. Painless digital vasospasm is a dose-related complication of long-term treatment with the ergot derivatives (bromocriptine or pergolide). When cardiac arrhythmias occur, they are an indication for discontinuing treatment. Peripheral edema is sometimes problematic. Cardiac valvulopathy may occur with pergolide.

### **DYSKINESIAS**

Abnormal movements similar to those introduced by levodopa may occur and are reversed by reducing the total dose of dopaminergic drugs being taken.

### **MENTAL DISTURBANCES**

Confusion, hallucinations, delusions, and other psychiatric reactions are potential complications of dopaminergic treatment and are more common and severe with dopamine receptor agonists than with levodopa. Disorders of impulse control may lead to compulsive gambling, shopping, betting, sexual activity, and other behaviors. They clear on withdrawal of the offending medication.

### **MISCELLANEOUS**

Headache, nasal congestion, increased arousal, pulmonary infiltrates, pleural and retroperitoneal fibrosis, and erythromelalgia are other reported adverse effects of the ergot-derived dopamine agonists. Cardiac valvulopathies may occur with pergolide. Erythromelalgia consists of red, tender, painful, swollen feet and, occasionally, hands, at times associated with arthralgia; symptoms and signs clear within a few days of withdrawal of the causal drug. In rare instances, an uncontrollable tendency to fall asleep at inappropriate times has occurred, particularly in patients receiving pramipexole or ropinirole; this requires discontinuation of the medication.

## **Contraindications**

Dopamine agonists are contraindicated in patients with a history of psychotic illness or recent myocardial infarction, or with active peptic ulceration. The ergot-derived agonists

are best avoided in patients with peripheral vascular disease.

## **MONOAMINE OXIDASE INHIBITORS**

Two types of monoamine oxidase have been distinguished in the nervous system. Monoamine oxidase A metabolizes norepinephrine, serotonin, and dopamine; monoamine oxidase B metabolizes dopamine selectively. **Selegiline** (deprenyl) (Figure 28â€³), a selective irreversible inhibitor of monoamine oxidase B at normal doses (at higher doses it inhibits MAO-A as well), retards the breakdown of dopamine (Figure 28â€µ); in consequence, it enhances and prolongs the antiparkinsonism effect of levodopa (thereby allowing the dose of levodopa to be reduced) and may reduce mild on-off or wearing-off phenomena. It is therefore used as adjunctive therapy for patients with a declining or fluctuating response to levodopa. The standard dose of selegiline is 5 mg with breakfast and 5 mg with lunch. Selegiline may cause insomnia when taken later during the day.

Selegiline has only a minor therapeutic effect on parkinsonism when given alone. Studies in animals suggest that it may reduce disease progression, but trials to test the effect of selegiline on the progression of parkinsonism in humans have yielded ambiguous results. The findings in a large multicenter study were taken to suggest a beneficial effect in slowing disease progression but may simply have reflected a symptomatic response.

**Rasagiline**, another monoamine oxidase B inhibitor, is more potent than selegiline in preventing MPTP-induced parkinsonism and is being used for early symptomatic treatment. The standard dosage is 1 mg/d. Rasagiline is also used as adjunctive therapy at a dosage of 0.5 or 1 mg/d to prolong the effects of levodopa-carbidopa in patients with advanced disease. A large trial has recently shown that it provides neuroprotective benefit (ie, slows the disease course), but a full report has yet to be published.

Neither selegiline nor rasagiline should be taken by patients receiving meperidine. They should be used with care in patients receiving tricyclic antidepressants or serotonin reuptake inhibitors because of the theoretical risk of acute toxic interactions of the serotonin syndrome type (see Chapter 16), but this is rarely encountered in practice. The adverse effects of levodopa may be increased by these drugs.

The combined administration of levodopa and an inhibitor of both forms of monoamine oxidase (ie, a nonselective inhibitor) must be avoided, because it may lead to hypertensive crises, probably because of the peripheral accumulation of norepinephrine.

## **CATECHOL-O-METHYLTRANSFERASE INHIBITORS**

Inhibition of dopa decarboxylase is associated with compensatory activation of other pathways of levodopa metabolism, especially catechol-O -methyltransferase (COMT), and this increases plasma levels of 3-O -methyldopa (3-OMD). Elevated levels of 3-OMD have been associated with a poor therapeutic response to levodopa, perhaps in part because 3-OMD competes with levodopa for an active carrier mechanism that governs its

transport across the intestinal mucosa and the blood-brain barrier. Selective COMT inhibitors such as **tolcapone** and **entacapone** also prolong the action of levodopa by diminishing its peripheral metabolism (Figure 28â€5). Levodopa clearance is decreased, and relative bioavailability of levodopa is thus increased. Neither the time to reach peak concentration nor the maximal concentration of levodopa is increased. These agents may be helpful in patients receiving levodopa who have developed response fluctuationsâ€ leading to a smoother response, more prolonged on-time, and the option of reducing total daily levodopa dose. Tolcapone and entacapone are both widely available, but entacapone is generally preferred because it has not been associated with hepatotoxicity.

The pharmacologic effects of tolcapone and entacapone are similar, and both are rapidly absorbed, bound to plasma proteins, and metabolized before excretion. However, tolcapone has both central and peripheral effects, whereas the effect of entacapone is peripheral. The half-life of both drugs is approximately 2 hours, but tolcapone is slightly more potent and has a longer duration of action. Tolcapone is taken in a standard dosage of 100 mg three times daily; some patients require a daily dose of twice that amount. By contrast, entacapone (200 mg) needs to be taken with each dose of levodopa, up to five times daily.

Adverse effects of the COMT inhibitors relate in part to increased levodopa exposure and include dyskinesias, nausea, and confusion. It is often necessary to lower the daily dose of levodopa by about 30% in the first 48 hours to avoid or reverse such complications. Other adverse effects include diarrhea, abdominal pain, orthostatic hypotension, sleep disturbances, and an orange discoloration of the urine. Tolcapone may cause an increase in liver enzyme levels and has been associated rarely with death from acute hepatic failure; accordingly, its use in the USA requires signed patient consent (as provided in the product labeling) plus monitoring of liver function tests every 2 weeks during the first year and less frequently thereafter. No such toxicity has been reported with entacapone.

A commercial preparation named **Stalevo** consists of a combination of levodopa with both carbidopa and entacapone. It is available in three strengths: Stalevo 50 (50 mg levodopa plus 12.5 mg carbidopa and 200 mg entacapone), Stalevo 100 (100 mg, 25 mg, and 200 mg, respectively), and Stalevo 150 (150 mg, 37.5 mg, and 200 mg). Use of this preparation simplifies the drug regimen and requires the consumption of a lesser number of tablets than otherwise. Stalevo is priced at or below the price of its individual components.

## **APOMORPHINE**

Subcutaneous injection of apomorphine hydrochloride (**Apokyn**), a potent dopamine agonist, is effective for the temporary relief ("rescue") of off-periods of akinesia in patients on optimized dopaminergic therapy. It is rapidly taken up in the blood and then

the brain, leading to clinical benefit that begins within about 10 minutes of injection and persists for up to 2 hours. The optimal dose is identified by administering increasing test doses until adequate benefit is achieved or a maximum of 10 mg is reached. Most patients require a dose of 3–6 mg, and this should be given no more than about three times daily.

Nausea is often troublesome, especially at the initiation of apomorphine treatment; accordingly, pretreatment with the antiemetic trimethobenzamide (300 mg three times daily) for 3 days is recommended before apomorphine is introduced and is then continued for at least 1 month, if not indefinitely. Other adverse effects include dyskinesias, drowsiness, chest pain, sweating, hypotension, and bruising at the injection site. Apomorphine should be prescribed only by physicians familiar with its potential complications and interactions.

## **AMANTADINE**

Amantadine, an antiviral agent, was by chance found to have antiparkinsonism properties. Its mode of action in parkinsonism is unclear, but it may potentiate dopaminergic function by influencing the synthesis, release, or reuptake of dopamine. It has been reported to antagonize the effects of adenosine at adenosine A<sub>2A</sub> receptors, which are receptors that may inhibit D<sub>2</sub> receptor function. Release of catecholamines from peripheral stores has also been documented.

### **Pharmacokinetics**

Peak plasma concentrations of amantadine are reached 1–4 hours after an oral dose. The plasma half-life is between 2 and 4 hours, most of the drug being excreted unchanged in the urine.

### **Clinical Use**

Amantadine is less efficacious than levodopa, and its benefits may be short-lived, often disappearing after only a few weeks of treatment. Nevertheless, during that time it may favorably influence the bradykinesia, rigidity, and tremor of parkinsonism. The standard dosage is 100 mg orally two or three times daily. Amantadine may also help in reducing iatrogenic dyskinesias in patients with advanced disease.

### **Adverse Effects**

Amantadine has a number of undesirable central nervous system effects, all of which can be reversed by stopping the drug. These include restlessness, depression, irritability, insomnia, agitation, excitement, hallucinations, and confusion. Overdosage may produce an acute toxic psychosis. With doses several times higher than recommended, convulsions have occurred.

Livedo reticularis sometimes occurs in patients taking amantadine and usually clears

within 1 month after the drug is withdrawn. Other dermatologic reactions have also been described. Peripheral edema, another well-recognized complication, is not accompanied by signs of cardiac, hepatic, or renal disease and responds to diuretics. Other adverse reactions to amantadine include headache, heart failure, postural hypotension, urinary retention, and gastrointestinal disturbances (eg, anorexia, nausea, constipation, and dry mouth).

Amantadine should be used with caution in patients with a history of seizures or heart failure.

## **ACETYLCHOLINE-BLOCKING DRUGS**

A number of centrally acting antimuscarinic preparations are available that differ in their potency and in their efficacy in different patients. Some of these drugs were discussed in Chapter 8. These agents may improve the tremor and rigidity of parkinsonism but have little effect on bradykinesia. Some of the more commonly used drugs are listed in Table 28-1.

**Table 28-1 Some Drugs with Antimuscarinic Properties Used in Parkinsonism.**

<b>Drug</b>	<b>Usual Daily Dose (mg)</b>
Benzotropine mesylate	1-6
Biperiden	2-12
Orphenadrine	150-400
Procyclidine	7.5-30
Trihexyphenidyl	6-20

### **Clinical Use**

Treatment is started with a low dose of one of the drugs in this category, the dosage gradually being increased until benefit occurs or until adverse effects limit further increments. If patients do not respond to one drug, a trial with another member of the drug class is warranted and may be successful.

### **Adverse Effects**

Antimuscarinic drugs have a number of undesirable central nervous system and peripheral effects (see Chapter 8) and are poorly tolerated by the elderly. Dyskinesias occur in rare cases. Acute suppurative parotitis sometimes occurs as a complication of dryness of the mouth.

If medication is to be withdrawn, this should be accomplished gradually rather than

abruptly to prevent acute exacerbation of parkinsonism. For contraindications to the use of antimuscarinic drugs, see Chapter 8.

## **SURGICAL PROCEDURES**

In patients with advanced disease that is poorly responsive to pharmacotherapy, worthwhile benefit may follow thalamotomy (for conspicuous tremor) or posteroventral pallidotomy. Ablative surgical procedures, however, have generally been replaced by functional, reversible lesions induced by high-frequency deep brain stimulation, which has a lower morbidity.

Stimulation of the subthalamic nucleus or globus pallidus by an implanted electrode and stimulator has yielded good results for the management of the clinical fluctuations occurring in advanced parkinsonism. The anatomic substrate for such therapy is indicated in Figure 28â€1. Such procedures are contraindicated in patients with secondary or atypical parkinsonism, dementia, or failure to respond to dopaminergic medication.

Transplantation of dopaminergic tissue (fetal substantia nigra tissue) has been reported to confer benefit in some parkinsonism patients, but the results are conflicting. In one controlled trial, symptomatic benefit occurred in younger (less than 60 years old) but not older patients. In another trial, benefits were inconsequential. Furthermore, uncontrollable dyskinesias occurred in some patients in both studies. This was attributed to a relative excess of dopamine from continued fiber outgrowth from the transplant. Further basic studies are required before other trials of cellular therapies are undertaken, and such approaches therefore remain investigational.

## **NEUROPROTECTIVE THERAPY**

A number of compounds are under investigation as potential neuroprotective agents that may slow disease progression. These compounds include antioxidants, antiapoptotic agents, glutamate antagonists, intraparenchymally administered glial-derived neurotrophic factor, coenzyme Q10, creatine, and anti-inflammatory drugs. The role of these agents remains to be established, however, and their use for therapeutic purposes is not indicated at this time. The possibility that rasagiline has a protective effect was discussed earlier.

## **GENE THERAPY**

Three phase I (safety) trials of gene therapy for Parkinson's disease have now been completed in the USA. All trials involved infusion into the striatum of adeno-associated virus type 2 as the vector for the gene. The genes were for glutamic acid decarboxylase (the precursor of GABA, an inhibitory neurotransmitter), infused into the subthalamic nucleus to cause inhibition; for aromatic acid decarboxylase infused into the putamen to increase metabolism of levodopa to dopamine; and for neurturin (a growth factor that

may enhance the survival of dopaminergic neurons), infused into the putamen. All agents were deemed safe, and the data suggested efficacy. Phase II trials are now planned or in progress.

## **THERAPY FOR NONMOTOR MANIFESTATIONS**

Persons with cognitive decline may respond to rivastigmine (1.5–6 mg twice daily), memantine (5–10 mg daily), or donepezil (5–10 mg daily) (see Chapter 60); affective disorders to antidepressants or anxiolytic agents (see Chapter 30); excessive daytime sleepiness to modafinil (100–400 mg in the morning) (see Chapter 9), and bladder and bowel disorders to appropriate symptomatic therapy (see Chapter 8).

## **GENERAL COMMENTS ON DRUG MANAGEMENT OF PATIENTS WITH PARKINSONISM**

Parkinson's disease generally follows a progressive course. Moreover, the benefits of levodopa therapy often diminish with time, and serious adverse effects may complicate long-term levodopa treatment. Nevertheless, dopaminergic therapy at a relatively early stage may be most effective in alleviating symptoms of parkinsonism and may also favorably affect the mortality rate due to the disease. Therefore, several strategies have evolved for optimizing dopaminergic therapy, as summarized in Figure 28–5.

Symptomatic treatment of mild parkinsonism is probably best avoided until there is some degree of disability or until symptoms begin to have a significant impact on the patient's lifestyle. When symptomatic treatment becomes necessary, a trial of rasagiline, amantadine, or an antimuscarinic drug may be worthwhile. With disease progression, dopaminergic therapy becomes necessary. This can conveniently be initiated with a dopamine agonist, either alone or in combination with low-dose Sinemet therapy. Physical therapy is helpful in improving mobility. In patients with severe parkinsonism and long-term complications of levodopa therapy such as the on-off phenomenon, a trial of treatment with a COMT inhibitor or rasagiline may be helpful. Regulation of dietary protein intake may also improve response fluctuations. Deep brain stimulation is often helpful in patients who fail to respond adequately to these measures. Treating patients who are young or have mild parkinsonism with rasagiline may delay disease progression and merits consideration.

## **DRUG-INDUCED PARKINSONISM**

Reserpine and the related drug tetrabenazine deplete biogenic monoamines from their storage sites, whereas haloperidol, metoclopramide, and the phenothiazines block dopamine receptors. These drugs may therefore produce a parkinsonian syndrome, usually within 3 months after introduction. The disorder tends to be symmetric, with inconspicuous tremor, but this is not always the case. The syndrome is related to high dosage and clears over several weeks or months after withdrawal. If treatment is necessary, antimuscarinic agents are preferred. Levodopa is of no help if neuroleptic

drugs are continued and may in fact aggravate the mental disorder for which antipsychotic drugs were prescribed originally.

In 1983, a drug-induced form of parkinsonism was discovered in individuals who attempted to synthesize and use a narcotic drug related to meperidine but actually synthesized and self-administered MPTP, as discussed in MPTP & Parkinsonism.

### **MPTP & Parkinsonism**

Reports in the early 1980s of a rapidly progressive form of parkinsonism in young persons opened a new area of research in the etiology and treatment of parkinsonism. The initial report described apparently healthy young people who attempted to support their opioid habit with a meperidine analog synthesized by an amateur chemist. They unwittingly self-administered 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and subsequently developed a very severe form of parkinsonism.

MPTP is a protoxin that is converted by monoamine oxidase B to *N*-methyl-4-phenylpyridinium (MPP<sup>+</sup>). MPP<sup>+</sup> is selectively taken up by cells in the substantia nigra through an active mechanism normally responsible for dopamine reuptake. MPP<sup>+</sup> inhibits mitochondrial complex I, thereby inhibiting oxidative phosphorylation. The interaction of MPP<sup>+</sup> with complex I probably leads to cell death and thus to striatal dopamine depletion and parkinsonism.

Recognition of the effects of MPTP suggested that spontaneously occurring Parkinson's disease may result from exposure to an environmental toxin that is similarly selective in its target. However, no such toxin has yet been identified. It also suggested a successful means of producing an experimental model of Parkinson's disease in animals, especially nonhuman primates. This model is assisting in the development of new antiparkinsonism drugs. Pretreatment of exposed animals with a monoamine oxidase B inhibitor such as selegiline prevents the conversion of MPTP to MPP<sup>+</sup> and thus protects against the occurrence of parkinsonism. This observation has provided one reason to believe that selegiline or rasagiline may retard the progression of Parkinson's disease in humans.

## **OTHER MOVEMENT DISORDERS**

### **Tremor**

Tremor consists of rhythmic oscillatory movements. Physiologic postural tremor, which is a normal phenomenon, is enhanced in amplitude by anxiety, fatigue, thyrotoxicosis, and intravenous epinephrine or isoproterenol. Propranolol reduces its amplitude and, if administered intra-arterially, prevents the response to isoproterenol in the perfused limb, presumably through some peripheral action. Certain drugs—especially the

bronchodilators, valproate, tricyclic antidepressants, and lithium may produce a dose-dependent exaggeration of the normal physiologic tremor that is reversed by discontinuing the drug. Although the tremor produced by sympathomimetics such as terbutaline (a bronchodilator) is blocked by propranolol, which antagonizes both  $\beta_1$  and  $\beta_2$  receptors, it is not blocked by metoprolol, a  $\beta_1$ -selective antagonist; this suggests that such tremor is mediated mainly by the  $\beta_2$  receptors.

Essential tremor is a postural tremor, sometimes familial with autosomal dominant inheritance, which is clinically similar to physiologic tremor. At least three gene loci (*ETM1* on 3q13, *ETM2* on 2p24.1, and a locus on 6p23) have been described. Dysfunction of  $\beta_1$  receptors has been implicated in some instances, since the tremor may respond dramatically to standard doses of metoprolol as well as to propranolol. The most useful approach is with propranolol, but whether the response depends on a central or peripheral action is unclear. The pharmacokinetics, pharmacologic effects, and adverse reactions of propranolol are discussed in Chapter 10. Daily doses of propranolol on the order of 120 mg (range, 60–240 mg) are usually required, prescribed as 40–120 mg orally twice daily, and reported adverse effects have been few. Propranolol should be used with caution in patients with heart failure, heart block, asthma, and hypoglycemia. Patients can be instructed to take their own pulse and call the physician if significant bradycardia develops. Metoprolol is sometimes useful in treating tremor when patients have concomitant pulmonary disease that contraindicates use of propranolol. Primidone (an antiepileptic drug; see Chapter 24), in gradually increasing doses up to 250 mg three times daily, is also effective in providing symptomatic control in some cases. Patients with tremor are very sensitive to primidone and often cannot tolerate the doses used to treat seizures; they should be started on 50 mg once daily and the daily dose increased by 50 mg every 2 weeks depending on response.

Topiramate, another antiepileptic drug, may also be helpful in a dose of 400 mg daily, built up gradually. Small quantities of alcohol may suppress essential tremor but only for a short time. Alprazolam (in doses up to 3 mg daily) or gabapentin (100–2400 mg/d) is helpful in some patients. Others are helped by intramuscular injections of botulinum toxin. Thalamic stimulation by an implanted electrode and stimulator is often worthwhile in advanced cases refractory to pharmacotherapy. Diazepam, chlordiazepoxide, mephenesin, and antiparkinsonism agents have been advocated in the past but are generally worthless. Anecdotal reports of benefit from mirtazapine were not confirmed in a double-blind study, which found no effect on the tremor in most patients.

**Intention tremor** is present during movement but not at rest; sometimes it occurs as a toxic manifestation of alcohol or drugs such as phenytoin. Withdrawal or reduction in dosage provides dramatic relief. There is no satisfactory pharmacologic treatment for intention tremor due to other neurologic disorders.

**Rest tremor** is usually due to parkinsonism.

## **Huntington's Disease**

Huntington's disease is an autosomal dominant inherited disorder caused by an abnormality (expansion of a CAG trinucleotide repeat that codes for a polyglutamine tract) of the *huntingtin* gene on chromosome 4. An autosomal recessive form may also occur. Huntington disease-like (HDL) disorders are not associated with an abnormal CAG trinucleotide repeat number of the *huntingtin* gene. Autosomal dominant (*HDL1*, 20pter-p12; *HDL2*, 16q24.3) and recessive forms (*HDL3*, 4p15.3) occur.

Huntington's disease is characterized by progressive chorea and dementia that usually begin in adulthood. The development of chorea seems to be related to an imbalance of dopamine, acetylcholine, GABA, and perhaps other neurotransmitters in the basal ganglia (Figure 28-6). Pharmacologic studies indicate that chorea results from functional overactivity in dopaminergic nigrostriatal pathways, perhaps because of increased responsiveness of postsynaptic dopamine receptors or deficiency of a neurotransmitter that normally antagonizes dopamine. Drugs that impair dopaminergic neurotransmission, either by depleting central monoamines (eg, reserpine, tetrabenazine) or by blocking dopamine receptors (eg, phenothiazines, butyrophenones), often alleviate chorea, whereas dopamine-like drugs such as levodopa tend to exacerbate it.

### **Figure 28-6**

Schematic representation of the sequence of neurons involved in Huntington's chorea. **Top:** Dopaminergic neurons (red) originating in the substantia nigra normally inhibit the GABAergic output from the striatum, whereas cholinergic neurons (gray) exert an excitatory effect. **Bottom:** In Huntington's chorea, some cholinergic neurons may be lost (gray), but even more GABAergic neurons (black) degenerate.

Both GABA and the enzyme (glutamic acid decarboxylase) concerned with its synthesis are markedly reduced in the basal ganglia of patients with Huntington's disease, and GABA receptors are usually implicated in inhibitory pathways. There is also a significant decline in concentration of choline acetyltransferase, the enzyme responsible for synthesizing acetylcholine, in the basal ganglia of these patients. These findings may be of pathophysiologic significance and have led to attempts to alleviate chorea by enhancing central GABA or acetylcholine activity, but with disappointing results. As a consequence, the most commonly used drugs for controlling dyskinesia in patients with Huntington's disease are still those that interfere with dopamine activity. With all the latter drugs, however, reduction of abnormal movements may be associated with iatrogenic parkinsonism.

**Reserpine** depletes cerebral dopamine by preventing intraneuronal storage (see Chapter 6); it is introduced in low doses (eg, 0.25 mg daily), and the daily dose is then built up gradually (eg, by 0.25 mg every week) until benefit occurs or adverse effects become troublesome. A daily dose of 2–5 mg is often effective in suppressing abnormal movements, but adverse effects may include hypotension, depression, sedation,

diarrhea, and nasal congestion. **Tetrabenazine** (12.5–50 mg orally three times daily) resembles reserpine in depleting cerebral dopamine and has less troublesome adverse effects; it is now available in the USA. Treatment with postsynaptic dopamine receptor blockers such as phenothiazines and butyrophenones may also be helpful. Haloperidol is started in a small dose, eg, 1 mg twice daily, and increased every 4 days depending on the response. If haloperidol is not helpful, treatment with increasing doses of perphenazine up to a total of about 20 mg daily sometimes helps. Several recent reports suggest that olanzapine may also be useful; the dose varies with the patient, but 10 mg daily is often sufficient although doses as high as 30 mg daily are sometimes required. The pharmacokinetics and clinical properties of these drugs are considered in greater detail elsewhere in this book. Selective serotonin reuptake inhibitors may reduce depression, aggression, and agitation.

### **Other Forms of Chorea**

Benign hereditary chorea is inherited (usually autosomal dominant; possibly also autosomal recessive) or arises spontaneously. Chorea develops in early childhood and does not progress during adult life; dementia does not occur. In patients with *TITF-1* gene mutations, thyroid and pulmonary abnormalities may also be present (brain-thyroid-lung syndrome). Familial chorea may also occur as part of the chorea-acanthocytosis syndrome, together with orolingual tics, vocalizations, cognitive changes, seizures, peripheral neuropathy, and muscle atrophy; serum  $\beta$ -lipoproteins are normal. Treatment of these hereditary disorders is symptomatic.

Treatment is directed at the underlying cause when chorea occurs as a complication of general medical disorders such as thyrotoxicosis, polycythemia vera rubra, systemic lupus erythematosus, hypocalcemia, and hepatic cirrhosis. Drug-induced chorea is managed by withdrawal of the offending substance, which may be levodopa, an antimuscarinic drug, amphetamine, lithium, phenytoin, or an oral contraceptive. Neuroleptic drugs may also produce an acute or tardivedyskinesia (discussed below). Sydenham's chorea is temporary and usually so mild that pharmacologic management of the dyskinesia is unnecessary, but dopamine-blocking drugs are effective in suppressing it.

### **Ballismus**

The biochemical basis of ballismus is unknown, but the pharmacologic approach to management is the same as for chorea. Treatment with haloperidol, perphenazine, or other dopamine-blocking drugs may be helpful.

### **Athetosis & Dystonia**

The pharmacologic basis of these disorders is unknown, and there is no satisfactory medical treatment for them. A subset of patients respond well to levodopa medication (dopa-responsive dystonia), which is therefore worthy of trial. Occasional patients with

dystonia may respond to diazepam, amantadine, antimuscarinic drugs (in high dosage), carbamazepine, baclofen, haloperidol, or phenothiazines. A trial of these pharmacologic approaches is worthwhile, though often not successful. Patients with focal dystonias such as blepharospasm or torticollis often benefit from injection of botulinum toxin into the overactive muscles. The role of deep brain stimulation for the treatment of these conditions is being explored.

## Tics

The pathophysiologic basis of tics is unknown. Chronic multiple tics (**Gilles de la Tourette's syndrome**) may require symptomatic treatment if the disorder is severe or is having a significant impact on the patient's life. Education of patients, family, and teachers is important.

The most effective pharmacologic approach is with **haloperidol**, and patients are better able to tolerate this drug if treatment is started with a small dosage (eg, 0.25 or 0.5 mg daily) and then increased gradually (eg, by 0.25 mg every 4 or 5 days) over the following weeks depending on response and tolerance. Most patients ultimately require a total daily dose of 3–8 mg. Adverse effects include extrapyramidal movement disorders, sedation, dryness of the mouth, blurred vision, and gastrointestinal disturbances. Pimozide, another dopamine receptor antagonist, may be helpful in patients who are either unresponsive to or intolerant of haloperidol. Treatment is started at 1 mg/d, and the dosage is increased by 1 mg every 5 days; most patients require 7–16 mg/d.

If these measures fail, clonidine, fluphenazine, clonazepam, or carbamazepine should be tried. The pharmacologic properties of these drugs are discussed elsewhere in this book. Clonidine reduces motor or vocal tics in about 50% of children so treated. It may act by reducing activity in noradrenergic neurons in the locus coeruleus. It is introduced at a dose of 2–3 mcg/kg/d, increasing after 2 weeks to 4 mcg/kg/d and then, if required, to 5 mcg/kg/d. It may cause an initial transient fall in blood pressure. The most common adverse effect is sedation; other adverse effects include reduced or excessive salivation and diarrhea. Phenothiazines such as fluphenazine sometimes help the tics, as do dopamine agonists. The role of the newer atypical antipsychotic agents, such as risperidone, is unclear.

Injection of botulinum toxin A at the site of problematic tics is sometimes helpful. Treatment of any associated attention deficit disorder (eg, with clonidine patch, guanfacine, pemoline, methylphenidate, or dextroamphetamine) or obsessive-compulsive disorder (selective serotonin reuptake inhibitors or clomipramine) may be required. Bilateral thalamic stimulation is sometimes worthwhile in otherwise intractable cases.

## Drug-Induced Dyskinesias

Levodopa or dopamine agonists produce diverse dyskinesias as a dose-related phenomenon in patients with Parkinson's disease; dose reduction reverses them. Chorea may also develop in patients receiving phenytoin, carbamazepine, amphetamines, lithium, and oral contraceptives, and it resolves with discontinuance of the offending medication. Dystonia has resulted from administration of dopaminergic agents, lithium, serotonin reuptake inhibitors, carbamazepine, and metoclopramide; and postural tremor from theophylline, caffeine, lithium, valproic acid, thyroid hormone, tricyclic antidepressants, and isoproterenol.

The pharmacologic basis of the acute dyskinesia or dystonia sometimes precipitated by the first few doses of a phenothiazine is not clear. In most instances, parenteral administration of an antimuscarinic drug such as benztropine (2 mg intravenously), diphenhydramine (50 mg intravenously), or biperiden (2–5 mg intravenously or intramuscularly) is helpful, whereas in other instances diazepam (10 mg intravenously) alleviates the abnormal movements.

**Tardive dyskinesia**, a disorder characterized by a variety of abnormal movements, is a common complication of long-term neuroleptic or metoclopramide drug treatment (see Chapter 29). Its precise pharmacologic basis is unclear. A reduction in dose of the offending medication, a dopamine receptor blocker, commonly worsens the dyskinesia, whereas an increase in dose may suppress it. The drugs most likely to provide immediate symptomatic benefit are those interfering with dopaminergic function, either by depletion (eg, reserpine, tetrabenazine) or receptor blockade (eg, phenothiazines, butyrophenones). Paradoxically, the receptor-blocking drugs are the very ones that also cause the dyskinesia.

**Tardive dystonia** is usually segmental or focal; generalized dystonia is less common and occurs in younger patients. Treatment is the same as for tardive dyskinesia, but anticholinergic drugs may also be helpful; focal dystonias may also respond to local injection of botulinum A toxin. **Tardive akathisia** is treated similarly to drug-induced parkinsonism. **Rabbit syndrome**, another neuroleptic-induced disorder, is manifested by rhythmic vertical movements about the mouth; it may respond to anticholinergic drugs.

Because the tardive syndromes that develop in adults are often irreversible and have no satisfactory treatment, care must be taken to reduce the likelihood of their occurrence. Antipsychotic medication should be prescribed only when necessary and should be withheld periodically to assess the need for continued treatment and to unmask incipient dyskinesia. Thioridazine, a phenothiazine with a piperidine side chain, is an effective antipsychotic agent that seems less likely than most to cause extrapyramidal reactions, perhaps because it has little effect on dopamine receptors in the striatal system. Finally, antimuscarinic drugs should not be prescribed routinely in patients receiving

neuroleptics, because the combination may increase the likelihood of dyskinesia.

**Neuroleptic malignant syndrome**, a rare complication of treatment with neuroleptics, is characterized by rigidity, fever, changes in mental status, and autonomic dysfunction. Symptoms typically develop over 1–3 days (rather than minutes to hours as in malignant hyperthermia) and may occur at any time during treatment. Treatment includes withdrawal of antipsychotic drugs, lithium, and anticholinergics; reduction of body temperature; and rehydration. Dantrolene, dopamine agonists, levodopa, or amantadine may be helpful, but there is a high mortality rate (up to 20%) with neuroleptic malignant syndrome.

### **Restless Legs Syndrome**

Restless legs syndrome is characterized by an unpleasant creeping discomfort that seems to arise deep within the legs and occasionally the arms. Symptoms occur particularly when patients are relaxed, especially when they are lying down or sitting, and they lead to an urge to move about. Such symptoms may delay the onset of sleep. A sleep disorder associated with periodic movements during sleep may also occur. The cause is unknown, but the disorder is especially common among pregnant women and also among uremic or diabetic patients with neuropathy. In most patients, no obvious predisposing cause is found, but several genetic loci have been associated with it (12q12-q21, 14q13-q31, 9p24-p22, 2q33, and 20p13).

Symptoms may resolve with correction of coexisting iron-deficiency anemia and often respond to dopamine agonists, levodopa, diazepam, clonazepam, gabapentin, or opiates. Dopaminergic therapy is the preferred treatment for restless legs syndrome and should be initiated with long-acting dopamine agonists (eg, **pramipexole** 0.125–0.75 mg or **ropinirole** 0.25–4.0 mg once daily) to avoid the augmentation that may be associated with levodopa-carbidopa (100/25 or 200/50 taken about 1 hour before bedtime). Augmentation refers to the earlier onset or enhancement of symptoms; earlier onset of symptoms at rest; and a briefer response to medication. When augmentation occurs with levodopa, the daily dose should be reduced or a dopamine agonist substituted. If it occurs in patients receiving an agonist, the daily dose should be lowered or divided, or opioids substituted. When opiates are required, those with long half-lives or low addictive potential should be used. Oxycodone is often effective; the dose is individualized. Gabapentin is an alternative to opioids and is taken once or twice daily (in the evening and before sleep); the starting dose is 300 mg daily, building up depending on response and tolerance (to approximately 1800 mg daily).

### **Wilson's Disease**

A recessively inherited (13q14.3–q21.1) disorder of copper metabolism, Wilson's disease is characterized biochemically by reduced serum copper and ceruloplasmin concentrations, pathologically by markedly increased concentration of copper in the brain

and viscera, and clinically by signs of hepatic and neurologic dysfunction. Neurologic signs include tremor, choreiform movements, rigidity, hypokinesia, and dysarthria and dysphagia. Siblings of affected patients should be screened for asymptomatic Wilson's disease.

Treatment involves the removal of excess copper, followed by maintenance of copper balance. A commonly used agent for this purpose is **penicillamine** (dimethylcysteine), a chelating agent that forms a ring complex with copper. It is readily absorbed from the gastrointestinal tract and rapidly excreted in the urine. A common starting dose in adults is 500 mg three or four times daily. After remission occurs, it may be possible to lower the maintenance dose, generally to not less than 1 g daily, which must thereafter be continued indefinitely. Adverse effects include nausea and vomiting, nephrotic syndrome, a lupus-like syndrome, pemphigus, myasthenia, arthropathy, optic neuropathy, and various blood dyscrasias. In some instances, worsening occurs with penicillamine. Treatment should be monitored by frequent urinalysis and complete blood counts. Dietary copper should also be kept below 2 mg daily. **Potassium disulfide**, 20 mg three times daily with meals, reduces the intestinal absorption of copper and should also be prescribed.

For patients who are unable to tolerate penicillamine, **trientine**, another chelating agent, may be used in a daily dose of 1–1.5 g. Trientine appears to have few adverse effects other than mild anemia due to iron deficiency in a few patients. Zinc acetate administered orally increases the fecal excretion of copper and is sometimes used for maintenance therapy. The dose is 50 mg three times a day. Zinc sulfate (200 mg/d orally) has also been used to decrease copper absorption. Zinc blocks copper absorption from the gastrointestinal tract by induction of intestinal cell metallothionein. Its main advantage is its low toxicity compared with that of other anticopper agents, although it may cause gastric irritation when introduced.

## SUMMARY: DRUGS USED FOR MOVEMENT DISORDERS

### Drugs Used for Movement Disorders

Subclass	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>Levodopa and combinations</b>				
Levodopa	Transported into the central nervous	Ameliorates all symptoms of Parkinson's disease and	Parkinson's disease: Most efficacious	Oral • ~ 6–8 h effect • <i>Toxicity:</i> Gastrointestinal upset, arrhythmias,

system (CNS) and converted to dopamine (which does not enter the CNS); also converted to dopamine in the periphery	causes significant peripheral dopaminergic effects (see text)	therapy but not always used as the first drug due to development of disabling response fluctuations over time	dyskinesias, on-off and wearing-off phenomena, behavioral disturbances • <i>Interactions:</i> Use with carbidopa greatly diminishes required dosage • use with COMT or MAO-B inhibitors prolongs duration of effect.
--	---	---	--

*Levodopa + carbidopa (Sinemet): Carbidopa inhibits peripheral metabolism of levodopa to dopamine and reduces required dosage and toxicity. Carbidopa does not enter CNS.*

*Levodopa + carbidopa + entacapone (Stalevo): Entacapone is a catechol-O-methyltransferase (COMT) inhibitor (see below)*

### **Dopamine agonists**

Pramipexole	Direct agonist at D <sub>3</sub> receptors, nonergot	Reduces symptoms of parkinsonism • smooths out fluctuations in levodopa response	Parkinson's disease: Can be used as initial therapy • also effective in on-off phenomenon	Oral • ~ 8 h effect • <i>Toxicity:</i> Nausea and vomiting, postural hypotension, dyskinesias
-------------	--	--	---	---

*Ropinirole: Similar to pramipexole; nonergot; relatively pure D<sub>2</sub> agonist*

*Bromocriptine: Ergot derivative; potent agonist at D<sub>2</sub> receptors; more toxic than pramipexole or ropinirole*

*Apomorphine: Nonergot; subcutaneous route useful for rescue treatment in levodopa-induced dyskinesia; high incidence of nausea and vomiting*

### **Monoamine oxidase (MAO) inhibitors**

Rasagiline	Inhibits MAO-B selectively, higher doses also inhibit MAO-A	Increases dopamine stores in neurons; may have neuroprotective	Parkinson's disease; adjunctive to levodopa; smooths levodopa	Oral • <i>Toxicity &amp; interactions:</i> may cause serotonin syndrome with meperidine, and theoretically also with
------------	---	--	---	--

effects	response	selective serotonin reuptake inhibitors, tricyclic antidepressants
---------	----------	--

*Selegiline: Like rasagiline, adjunctive use with levodopa; may be less potent than rasagiline in MPTP-induced parkinsonism*

**COMT inhibitors**

Entacapone	Inhibits COMT in periphery • does not enter CNS	Reduces metabolism of levodopa and prolongs its action	Parkinson's disease	Oral • <i>Toxicity:</i> Increased levodopa toxicity • nausea, dyskinesias, confusion
------------	---	--	---------------------	--

*Tolcapone: Like entacapone but enters CNS. Some evidence of hepatotoxicity, elevation of liver enzymes.*

**Antimuscarinic agents**

Benztropine	Antagonist at M receptors in basal ganglia	Reduces tremor and rigidity • little effect on bradykinesia	Parkinson's disease	Oral • <i>Toxicity:</i> Typical antimuscarinic effects: sedation, mydriasis, urinary retention, dry mouth
-------------	--	---	---------------------	---

*Biperiden, orphenadrine, procyclidine, trihexyphenidyl: Similar antimuscarinic agents with CNS effects*

**Drugs used in Huntington's disease**

Tetrabenazine, reserpine	Deplete amine transmitters, especially dopamine, from nerve endings	Reduce chorea severity	Huntington's disease • other applications, see Chapter 11	Oral • <i>Toxicity:</i> Hypotension, sedation, depression, diarrhea • tetrabenazine somewhat less toxic
--------------------------	---	------------------------	---	---

*Haloperidol, other neuroleptics: Sometimes helpful*

**Drugs used in Tourette's syndrome**

Haloperidol	Blocks central D <sub>2</sub> receptors	Reduces vocal and motor tic frequency, severity	Tourette's syndrome • other applications, see Chapter 29	Oral • <i>Toxicity:</i> Parkinsonism, other dyskinesias • sedation
-------------	---	---	--	--

*Clonidine: Effective in ~ 50% of patients; see Chapter 11 for basic pharmacology*

*Phenothiazines, benzodiazepines, carbamazepine: Sometimes of value*

## PREPARATIONS AVAILABLE

### **Amantadine** (Symmetrel, others)

Oral: 100 mg capsules; 10 mg/mL syrup

### **Apomorphine** (Apokyn)

Subcutaneous injection titration kit: 10 mg/mL

### **Benzotropine** (Cogentin, others)

Oral: 0.5, 1, 2 mg tablets

Parenteral: 1 mg/mL for injection

### **Biperiden** (Akineton)

Oral: 2 mg tablets

Parenteral: 5 mg/mL for injection

### **Bromocriptine** (Parlodel)

Oral: 2.5 mg tablets; 5 mg capsules

### **Carbidopa** (Lodosyn)

Oral: 25 mg tablets

### **Carbidopa/levodopa** (Sinemet, others)

Oral: 10 mg carbidopa and 100 mg levodopa, 25 mg carbidopa and 100 mg levodopa, 25 mg carbidopa and 250 mg levodopa tablets

Oral sustained-release (Sinemet CR): 25 mg carbidopa and 100 mg levodopa; 50 mg carbidopa and 200 mg levodopa

### **Carbidopa/levodopa/entacapone** (Stalevo)

Oral: 12.5 mg carbidopa, 200 mg entacapone and 50 mg levodopa; 25 mg carbidopa, 200 mg entacapone, and 100 mg levodopa; 37.5 mg carbidopa, 200 mg entacapone, and 150 mg levodopa

**Entacapone** (Comtan)

Oral: 200 mg tablets

**Levodopa** (Dopar, Larodopa)

Oral: 100, 250, 500 mg tablets, capsules

**Orphenadrine** (various)

Oral: 100 mg tablets

Oral sustained-release: 100 mg tablets

Parenteral: 30 mg/mL for injection

**Penicillamine** (Cuprimine, Depen)

Oral: 125, 250 mg capsules; 250 mg tablets

**Pergolide** (Permax, other)<sup>1</sup>

Oral: 0.05, 0.25, 1 mg tablets

**Pramipexole** (Mirapex)

Oral: 0.125, 0.25, 1, 1.5 mg tablets

**Procyclidine** (Kemadrin)

Oral: 5 mg tablets

**Rasagiline** (Azilect)

Oral: 0.5, 1 mg tablets

**Ropinirole** (Requip, Requip XL)

Oral: 0.25, 0.5, 1, 2, 5 mg tablets; 2, 4, 8 mg extended release tablets

**Selegiline** (deprenyl) (generic, Eldepryl)

Oral: 5 mg tablets, capsules

**Tetrabenazine** (Xenazine)

Oral: 12.5, 25 mg tablets

**Tolcapone** (Tasmar)

Oral: 100, 200 mg tablets

**Trientine** (Syprine)

Oral: 250 mg capsules

**Trihexyphenidyl** (Artane, others)

Oral: 2, 5 mg tablets; 2 mg/5 mL elixir

Oral sustained-release (Artane Sequels): 5 mg capsules

Basic and Clinical Pharmacology > Chapter 29. Antipsychotic Agents & Lithium >

## CASE STUDY

A 17-year-old male high school student is referred to the psychiatry clinic for evaluation of suspected schizophrenia. After a diagnosis is made, haloperidol is prescribed at a gradually increasing dose on an outpatient basis. The drug improves the patient's positive symptoms but ultimately causes intolerable side effects. Although more costly, risperidone is then prescribed, which, over the course of several weeks of treatment, improves his symptoms and is tolerated by the patient. What signs and symptoms would support an initial diagnosis of schizophrenia? In the treatment of schizophrenia, what benefits do the atypical antipsychotic drugs offer over the traditional agents such as haloperidol? In addition to the management of schizophrenia, what other clinical indications warrant consideration of the use of drugs nominally classified as antipsychotics?

\*The author acknowledges the contributions of the previous author of this chapter, William Z. Potter, MD, PhD.

## ANTIPSYCHOTIC AGENTS

Antipsychotic drugs are able to reduce psychotic symptoms in a wide variety of conditions, including schizophrenia, bipolar disorder, psychotic depression, senile psychoses, various organic psychoses, and drug-induced psychoses. They are also able to improve mood and reduce anxiety and sleep disturbances, but they are not the treatment of choice when these symptoms are the primary disturbance in nonpsychotic patients. A **neuroleptic** is a subtype of antipsychotic drug that produces a high incidence of extrapyramidal side effects (EPS) at clinically effective doses or catalepsy in laboratory animals. The **"atypical" antipsychotic drugs**, now the most widely used type of antipsychotic drug, dissociate antipsychotic action and EPS.

### History

Reserpine and chlorpromazine were the first drugs found to be useful to reduce psychotic symptoms in schizophrenia. Reserpine was used only briefly for this purpose and is no longer of interest as an antipsychotic agent. Chlorpromazine is a neuroleptic agent; that is, it produces catalepsy in rodents and EPS in man. The discovery that its antipsychotic action was related to dopamine (D or DA)-receptor blockade led to the identification of other compounds as antipsychotics between the 1950 and 1970. The discovery of clozapine in 1959 led to the realization that antipsychotic drugs need not cause EPS in humans. Clozapine was called an atypical antipsychotic drug because of this dissociation; since its discovery, interest in antipsychotic drugs has shifted to the atypical group. The use of typical and atypical antipsychotic drugs led to massive changes in disease management, including brief instead of life-long hospitalizations. These drugs have also proved to be of great value in studying the pathophysiology of schizophrenia and other psychoses. Thus, schizophrenia and bipolar disorder are no longer believed by many to be separate disorders but rather to be part of a continuum of brain disorders with psychotic features.

### Nature of Psychosis & Schizophrenia

The term "psychosis" denotes a variety of mental disorders: the presence of delusions (false beliefs), various types of hallucinations, usually auditory or visual, but sometimes tactile or olfactory, and grossly disorganized thinking in a clear sensorium. Schizophrenia is a particular kind of psychosis characterized mainly by a clear sensorium but a marked thinking disturbance. Psychosis is not unique to schizophrenia and is not present in all patients with schizophrenia at all times.

Schizophrenia is considered to be a neurodevelopmental disorder. This implies that structural and functional changes in the brain are present even in utero in some patients, or that they develop during childhood and adolescence, or both. Twin, adoption, and family studies have established that schizophrenia is a genetic disorder with high heritability. No single gene is involved. Current theories involve multiple genes with common and rare mutations combining to produce a very variegated clinical presentation and course.

## THE SEROTONIN HYPOTHESIS OF SCHIZOPHRENIA

The discovery that indole hallucinogens such as LSD (lysergic acid diethylamide) and mescaline are serotonin (5-HT) agonists led to the search for endogenous hallucinogens in the urine, blood, and brains of patients with schizophrenia. This proved fruitless, but the identification of many 5-HT-receptor subtypes led to the pivotal discovery that 5-HT<sub>2A</sub>-receptor stimulation was the basis for the hallucinatory effects of these agents.

It has been found that 5-HT<sub>2A</sub>-receptor blockade is a key factor in the mechanism of action of the main class of atypical antipsychotic drugs such as clozapine and quetiapine. These drugs are *inverse agonists* of the 5-HT<sub>2A</sub> receptor; that is, they block the constitutive activity of these receptors. These receptors modulate the release of dopamine in the cortex, limbic region, and striatum. Stimulation of 5-HT<sub>2A</sub> receptors leads to depolarization of glutamate neurons, but also stabilizes NMDA receptors on postsynaptic NMDA receptors. Recently, it has been found that hallucinogens can modulate the stability of a complex consisting of 5-HT<sub>2A</sub> and NMDA receptors.

5-HT<sub>2C</sub>-receptor stimulation provides a further means of modulating cortical and limbic dopaminergic activity. 5-HT<sub>2C</sub> agonists are currently being studied as antipsychotic agents.

## THE DOPAMINE HYPOTHESIS OF SCHIZOPHRENIA

The dopamine hypothesis for schizophrenia was the first neurotransmitter-based concept to be developed but is no longer considered adequate to explain all aspects of schizophrenia. Nevertheless, it is still highly relevant to understanding the major dimensions of schizophrenia, such as positive and negative (emotional blunting, social withdrawal, lack of motivation) symptoms, cognitive impairment, and possibly depression. It is also essential to

understanding the mechanism of the action of most and probably all antipsychotic drugs.

Several lines of evidence suggest that excessive limbic dopaminergic activity plays a role in psychosis: (1) many antipsychotic drugs strongly block postsynaptic D<sub>2</sub> receptors in the central nervous system, especially in the mesolimbic and striatal-frontal system; this includes partial dopamine agonists, such as aripiprazole and bifeprunox. (2) Drugs that increase dopaminergic activity, such as levodopa, amphetamines, and bromocriptine and apomorphine, either aggravate schizophrenia psychosis or produce psychosis de novo in some patients. (3) Dopamine-receptor density has been found postmortem to be increased in the brains of schizophrenics who have not been treated with antipsychotic drugs. (4) Some but not all postmortem studies of schizophrenic subjects have reported increased dopamine levels and D<sub>2</sub>-receptor density in the nucleus accumbens, caudate, and putamen. (5) Imaging studies have shown increased amphetamine-induced striatal dopamine release, increased baseline occupancy of striatal D<sub>2</sub> receptors by extracellular dopamine, and other measures consistent with increased striatal dopamine synthesis and release.

However, the dopamine hypothesis is far from a complete explanation of all aspects of schizophrenia. *Diminished* cortical or hippocampal dopaminergic activity has been suggested to underlie the cognitive impairment and negative symptoms of schizophrenia. Postmortem and in vivo imaging studies of cortical, limbic, nigral and striatal dopaminergic neurotransmission in schizophrenic subjects have reported findings consistent with diminished dopaminergic activity in these regions. Decreased dopaminergic innervation in medial temporal cortex, dorsolateral prefrontal cortex, and hippocampus, and decreased levels of DOPAC, another metabolite of dopamine, in the anterior cingulate have been reported in postmortem studies. Imaging studies have found increased prefrontal dopamine D<sub>1</sub>-receptor levels that correlated with working memory impairments.

The fact that several of the atypical antipsychotic drugs have much less effect on D<sub>2</sub> receptors and yet are effective in schizophrenia has redirected attention to the role of other dopamine receptors and to nondopamine receptors. Serotonin receptors—particularly the 5-HT<sub>2A</sub>-receptor subtype—may mediate synergistic effects or protect against the extrapyramidal consequences of D<sub>2</sub> antagonism. As a result of these considerations, the direction of research has changed to a greater focus on compounds that may act on several transmitter-receptor systems, eg, serotonin and glutamate. The atypical antipsychotic drugs share the property of weak D<sub>2</sub>-receptor antagonism and more potent 5-HT<sub>2A</sub>-receptor blockade.

## THE GLUTAMATE HYPOTHESIS OF SCHIZOPHRENIA

Glutamate is the major excitatory neurotransmitter in the brain (see Chapter 21). Phencyclidine and ketamine are noncompetitive inhibitors of the NMDA receptor that exacerbate both cognitive impairment and psychosis in patients with schizophrenia. This was the starting point for the hypothesis that hypofunction of NMDA receptors, located on GABAergic interneurons, leading to diminished inhibitory influences on neuronal function, contributed to schizophrenia. The diminished GABAergic activity can induce disinhibition of downstream glutamatergic activity, which can lead to hyperstimulation of cortical neurons through non-NMDA receptors. Preliminary evidence suggests that LY2140023, a drug that acts as an agonist of the metabotropic 2/3 glutamate receptor (mGluR2/3), may be effective in schizophrenia.

The NMDA receptor, an ion channel, requires glycine for full activation. It has been suggested that in patients with schizophrenia, the glycine site of the NMDA receptor is not fully saturated. There have been several trials of high doses of glycine to promote glutamatergic activity, but the results are far from convincing. Currently, glycine transport inhibitors are in development as possible antipsychotic agents.

Ampakines are drugs that potentiate currents mediated by AMPA-type glutamate receptors. In behavioral tests, ampakines are effective in correcting behaviors in various animal models of schizophrenia and depression. They protect neurons against neurotoxic insults, in part by mobilizing growth factors such as brain-derived neurotrophic factor (BDNF).

## Basic Pharmacology of Antipsychotic Agents

### Chemical Types

A number of chemical structures have been associated with antipsychotic properties. The drugs can be classified into several groups as shown in Figures 29-1 and 29-2.

#### Figure 29-1

**Phenothiazine derivatives**

**Thioxanthene derivative**

**Chlorpromazine** (2)-Cl (10)-CH<sub>2</sub>-CH<sub>2</sub>-CH<sub>2</sub>-N-(CH<sub>3</sub>)<sub>2</sub>

**Thiothixene** (2)-SO<sub>2</sub>N(CH<sub>3</sub>)<sub>2</sub>

**Piperazine side chain**

**Trifluoperazine** (2)-CF<sub>3</sub> (10)-CH<sub>2</sub>-CH<sub>2</sub>-CH<sub>2</sub>-

**Perphenazine** (2)-Cl (10)-CH<sub>2</sub>-CH<sub>2</sub>-CH<sub>2</sub>-

**Fluphenazine** (2)-CF<sub>3</sub> (10)-CH<sub>2</sub>-CH<sub>2</sub>-CH<sub>2</sub>-

**Butyrophenone**

Structural formulas of some older antipsychotic drugs: phenothiazines, thioxanthenes, and butyrophenones. Only representative members of each type are shown.

**Figure 29â€²2**

Structural formulas of some newer antipsychotic drugs.

### PHENOTHIAZINE DERIVATIVES

Three subfamilies of phenothiazines, based primarily on the side chain of the molecule, were once the most widely used of the antipsychotic agents. Aliphatic derivatives (eg, **chlorpromazine**) and piperidine derivatives (eg, **thioridazine**) are the least potent. These drugs produce more sedation and weight gain. Piperazine derivatives are more potent (effective in lower doses) but not necessarily more efficacious. Perphenazine, a piperazine derivative, was the typical antipsychotic drug used in the CATIE study described in the following text. The piperazine derivatives are also more selective in their pharmacologic effects (Table 29â€1).

**Table 29â€1 Antipsychotic Drugs: Relation of Chemical Structure to Potency and Toxicities.**

Chemical Class	Drug	D <sub>2</sub> /5-HT <sub>2A</sub> Ratio <sup>1</sup>	Clinical Potency	Extrapyramidal Toxicity	Sedative Action	Hypotensive Actions
Phenothiazines						
Aliphatic	Chlorpromazine	High	Low	Medium	High	High

Piperazine	Fluphenazine	High	High	High	Low	Very low
Thioxanthene	Thiothixene	Very high	High	Medium	Medium	Medium
Butyrophenone	Haloperidol	Medium	High	Very high	Low	Very low
Dibenzodiazepine	Clozapine	Very low	Medium	Very low	Low	Medium
Benzisoxazole	Risperidone	Very low	High	Low <sup>2</sup>	Low	Low
Thienobenzodiazepine	Olanzapine	Low	High	Very Low	Medium	Low
Dibenzothiazepine	Quetiapine	Low	Low	Very Low	Medium	Low to Medium
Dihydroindolone	Ziprasidone	Low	Medium	Very Low	Low	Very Low
Dihydrocarbostyryl	Aripiprazole	Medium	High	Very Low	Very Low	Low

<sup>1</sup>Ratio of affinity for D<sub>2</sub> receptors to affinity for 5-HT<sub>2A</sub> receptors.

<sup>2</sup>At dosages below 8 mg/d.

Recently, a large study in the USA (CATIE) reported that perphenazine was as effective as atypical antipsychotic drugs, with the modest exception of olanzapine, and concluded that typical antipsychotic drugs are the treatment of choice for schizophrenia based on their lower cost. However, this study did not adequately consider the risk of tardivedyskinesia or the treatment history of patients in the design of this study.

#### THIOXANTHENE DERIVATIVES

This group of drugs is exemplified primarily by thiothixene.

#### BUTYROPHENONE DERIVATIVES

This group, of which **haloperidol** is the most widely used, has a very different structure from those of the two preceding groups. Haloperidol, a butyrophenone, is the most widely used typical antipsychotic drug, despite its high level of EPS relative to typical antipsychotic drugs. Diphenylbutylpiperidines are closely related compounds. The butyrophenones and congeners tend to be more potent and to have fewer autonomic effects but greater extrapyramidal effects than phenothiazines (Table 29â€¹1).

#### MISCELLANEOUS STRUCTURES

Pimozide and molindone are typical antipsychotic drugs. There is no significant difference in efficacy between these newer typical and the older typical antipsychotic drugs.

#### ATYPICAL ANTIPSYCHOTIC DRUGS

**Loxapine, clozapine, asenapine, olanzapine, quetiapine, paliperidone, risperidone, sertindole, ziprasidone, zotepine, and aripiprazole** are atypical antipsychotic drugs (Figure 29â€²2). Clozapine is the prototype. Paliperidone is 9-hydroxyrisperidone, the active metabolite of risperidone. Risperidone is rapidly converted to 9-hydroxyrisperidone in vivo in most patients, except for about 10% of patients who are poor metabolizers. Asenapine and sertindole are likely to be approved for use in the USA in 2009. Sertindole is approved in some European countries.

These drugs have complex pharmacology but they share a greater ability to alter 5-HT<sub>2A</sub>-receptor activity than to interfere with D<sub>2</sub>-receptor action. In most cases, this is accomplished through a partial agonist mechanism.

Sulpride and sulpiride constitute another class of atypical agents. They have equivalent potency for D<sub>2</sub> and D<sub>3</sub> receptors, but they are also 5-HT<sub>7</sub> antagonists. They dissociate EPS and antipsychotic efficacy. However, they also produce marked increases in serum prolactin levels and are not as free of the risk of tardive dyskinesia as are drugs such as clozapine and quetiapine.

#### Pharmacokinetics

##### ABSORPTION AND DISTRIBUTION

Most antipsychotic drugs are readily but incompletely absorbed. Furthermore, many undergo significant first-pass metabolism. Thus, oral doses of chlorpromazine and thioridazine have systemic availability of 25â€³35%, whereas haloperidol, which has less first-pass metabolism, has an average systemic availability of about 65%.

Most antipsychotic drugs are highly lipid-soluble and protein-bound (92â€³99%). They tend to have large volumes of distribution (usually more than 7 L/kg). They generally have a much longer clinical duration of action than would be estimated from their plasma half-lives. This is paralleled by prolonged occupancy of D<sub>2</sub> dopamine receptors in the brain by the typical antipsychotic drugs.

Metabolites of chlorpromazine may be excreted in the urine weeks after the last dose of chronically administered drug. Long-acting injectable formulations may still cause some blockade of D<sub>2</sub> receptors 3â€³6 months after the last injection. Time to recurrence of psychotic symptoms is highly variable after discontinuation of antipsychotic drugs. The average time for relapse in stable patients with schizophrenia who discontinue their medication is 6 months. Clozapine is an exception in that relapse after discontinuation is usually rapid and severe. Thus, clozapine should never be discontinued abruptly unless clinically needed because of adverse effects such as myocarditis or agranulocytosis, which are true medical emergencies.

##### METABOLISM

Most antipsychotic drugs are almost completely metabolized by oxidation or demethylation, catalyzed by liver microsomal cytochrome P450 enzymes. CYP2D6, CYP1A2 and CYP3A4 are the major isoforms involved (see Chapter 4). Drug-drug interactions should be considered when combining antipsychotic drugs with various other psychotropic drugs or drugsâ€³such as ketoconazoleâ€³that inhibit various cytochrome P450 enzymes. At the typical clinical doses, antipsychotic drugs do not usually interfere with the metabolism of other drugs.

#### Pharmacodynamics

The first phenothiazine antipsychotic drugs, with chlorpromazine as the prototype, proved to have a wide variety of central nervous system, autonomic, and endocrine effects. Although efficacy of these drugs is primarily driven by D<sub>2</sub>-receptor blockade, their adverse actions were traced to blocking effects at a wide range of receptors including  $\alpha$  adrenoceptors and muscarinic, H<sub>1</sub> histaminic, and 5-HT<sub>2</sub> receptors.

#### **DOPAMINERGIC SYSTEMS**

Five important dopaminergic systems or pathways are important for understanding schizophrenia and the mechanism of action of antipsychotic drugs. The first pathway—the one most closely related to behavior and psychosis—is the **mesolimbic-mesocortical** pathway, which projects from cell bodies near the substantia nigra to the limbic system and neocortex. The second system—the **nigrostriatal** pathway—consists of neurons that project from the substantia nigra to the dorsal striatum, which includes the caudate and putamen; it is involved in the coordination of voluntary movement. Blockade of the D<sub>2</sub> receptors in the nigrostriatal pathway is responsible for EPS. The third pathway—the **tuberoinfundibular** system—arises in the arcuate nuclei and periventricular neurons and releases dopamine into the pituitary portal circulation. Dopamine released by these neurons physiologically inhibits prolactin secretion from the anterior pituitary. The fourth dopaminergic system—the **medullary-periventricular** pathway—consists of neurons in the motor nucleus of the vagus whose projections are not well defined. This system may be involved in eating behavior. The fifth pathway—the **incertohypothalamic** pathway—forms connections from the medial zona incerta to the hypothalamus and the amygdala. It appears to regulate the anticipatory motivational phase of copulatory behavior in rats.

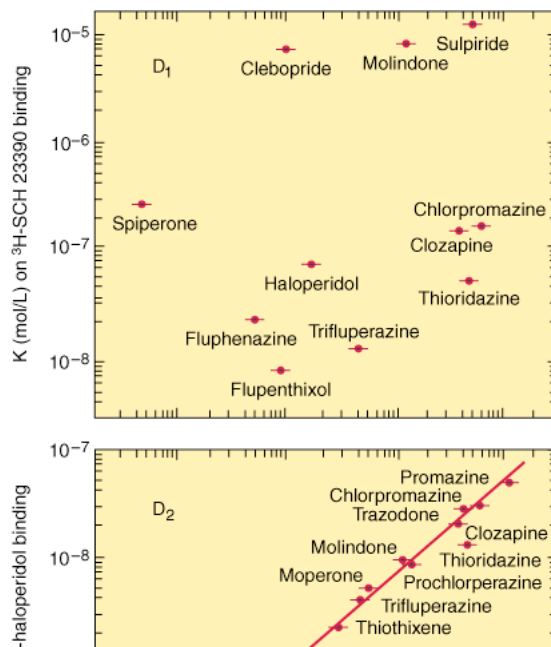

After dopamine was identified as a neurotransmitter in 1959, it was shown that its effects on electrical activity in central synapses and on production of the second messenger cAMP by adenylyl cyclase could be blocked by antipsychotic drugs such as chlorpromazine, haloperidol, and thiothixene. This evidence led to the conclusion in the early 1960s that these drugs should be considered **dopamine-receptor antagonists** and was responsible for the dopamine hypothesis of schizophrenia described earlier in this chapter. The antipsychotic action is now thought to be produced (at least in part) by their ability to block dopamine in the mesolimbic and mesocortical systems.

#### **DOPAMINE RECEPTORS AND THEIR EFFECTS**

At present, five dopamine receptors have been described, consisting of two separate families, the D<sub>1</sub>-like and D<sub>2</sub>-like receptor groups. The D<sub>1</sub> receptor is coded by a gene on chromosome 5, increases cAMP by G<sub>s</sub>-coupled activation of adenylyl cyclase, and is located mainly in the putamen, nucleus accumbens, and olfactory tubercle and cortex. The other member of this family, D<sub>5</sub>, is coded by a gene on chromosome 4, also increases cAMP, and is found in the hippocampus and hypothalamus. The therapeutic potency of antipsychotic drugs does not correlate with their affinity for binding to the D<sub>1</sub> receptor (Figure 29â€³3, top) nor did a selective D<sub>1</sub> antagonist prove to be an effective antipsychotic in patients with schizophrenia. The clinical dose of the typical agents, a crude measure of efficacy, correlates strongly with D<sub>2</sub> affinity. The D<sub>2</sub> receptor is coded on chromosome 11, decreases cAMP (by G<sub>i</sub>-coupled inhibition of adenylyl cyclase), and inhibits calcium channels but opens potassium channels. It is found both pre- and postsynaptically on neurons in the caudate-putamen, nucleus accumbens, and olfactory tubercle. A second member of this family, the D<sub>3</sub> receptor, also coded by a gene on chromosome 11, is thought to also decrease cAMP and is located in the frontal cortex, medulla, and midbrain. D<sub>4</sub> receptors also decrease cAMP and are concentrated in the cortex.

**Figure 29â€³3**

Correlations between the therapeutic potency of antipsychotic drugs and their affinity for binding to dopamine D<sub>1</sub> (top) or D<sub>2</sub> receptors (bottom). Potency is indicated on the horizontal axes; it decreases to the right. Binding affinity for D<sub>1</sub> receptors was measured by displacing the selective D<sub>1</sub> ligand SCH 23390; affinity for D<sub>2</sub> receptors was similarly measured by displacing the selective D<sub>2</sub> ligand haloperidol. Binding affinity decreases upward.

(Modified and reproduced, with permission, from Seeman P: Dopamine receptors and the dopamine hypothesis of schizophrenia. *Synapse* 1987;1:133.)

The typical antipsychotic agents block D<sub>2</sub> receptors stereoselectively for the most part, and their binding affinity is very strongly correlated with clinical antipsychotic and extrapyramidal potency (Figure 29â€³, bottom). In vivo imaging studies of D<sub>2</sub>-receptor occupancy indicate that for antipsychotic efficacy, the typical antipsychotic drugs must be given in sufficient doses to achieve 60% occupancy of striatal D<sub>2</sub> receptors. This is not required for the atypical antipsychotic drugs such as clozapine and olanzapine, which are effective at lower occupancy levels of 30â€³50%, most likely because of their concurrent high occupancy of 5-HT<sub>2A</sub> receptors. The typical antipsychotic drugs produce EPS when the occupancy of striatal D<sub>2</sub> receptors reaches 80% or higher.

Positron emission tomography (PET) studies with aripiprazole show very high occupancy of D<sub>2</sub> receptors, but this drug does not cause EPS because it is a partial D<sub>2</sub>-receptor agonist. Aripiprazole also gains therapeutic efficacy through its 5-HT<sub>2A</sub> antagonism and possibly 5-HT<sub>1A</sub> partial agonism.

These findings have been incorporated into the dopamine hypothesis of schizophrenia. However, additional factors complicate interpretation of dopamine receptor data. For example, dopamine receptors exist in both high- and low-affinity forms, and it is not known whether schizophrenia or the antipsychotic drugs alter the proportions of receptors in these two forms. The fact that aripiprazole shows partial agonism at D<sub>2</sub> and 5-HT<sub>1A</sub> receptors in preclinical studies suggests that the proportions of several receptors in their various affinity states may prove clinically important.

Of most importance, newer drugsâ€“clozapine, olanzapine, quetiapine, and aripiprazoleâ€“do not have very high affinity for the D<sub>2</sub> receptor, which suggests that additional actions are critical to their antipsychotic effects. Nevertheless, it has not been convincingly demonstrated that antagonism of any dopamine receptor other than the D<sub>2</sub> receptor plays a role in the action of antipsychotic drugs. Selective and relatively specific D<sub>3</sub>- and D<sub>4</sub>-receptor antagonists have been tested repeatedly with no evidence of antipsychotic action. Most of the newer atypical antipsychotic agents and some of the traditional ones have a higher affinity for the 5-HT<sub>2A</sub>-receptor than for the D<sub>2</sub> receptor (Table 29â€³1), suggesting an important role for the

serotonin 5-HT system in the etiology of schizophrenia and the action of these drugs.

### DIFFERENCES AMONG ANTIPSYCHOTIC DRUGS

Although all effective antipsychotic drugs block D<sub>2</sub> receptors, the degree of this blockade in relation to other actions on receptors varies considerably among drugs. Vast numbers of ligand-receptor binding experiments have been performed in an effort to discover a single receptor action that would best predict antipsychotic efficacy. A summary of the relative receptor-binding affinities of several key agents in such comparisons illustrates the difficulty in drawing simple conclusions from such experiments:

Chlorpromazine:  $\alpha_1 = 5\text{-HT}_{2A} > D_2 > D_1$

Haloperidol:  $D_2 > \alpha_1 > D_4 > 5\text{-HT}_{2A} > D_1 > H_1$

Clozapine:  $D_4 = \alpha_1 > 5\text{-HT}_{2A} > D_2 = D_1$

Olanzapine:  $5\text{-HT}_{2A} > H_1 > D_4 > D_2 > \alpha_1 > D_1$

Aripiprazole:  $D_2 = 5\text{-HT}_{2A} > D_4 > \alpha_1 = H_1 >> D_1$

Quetiapine:  $H_1 > \alpha_1 > M_{1,3} > D_2 > 5\text{-HT}_{2A}$

Thus, most of the atypical and some typical antipsychotic agents are at least as potent in inhibiting 5-HT<sub>2</sub> receptors as they are in inhibiting D<sub>2</sub> receptors. The newest, aripiprazole, appears to be a partial agonist of D<sub>2</sub> receptors. Varying degrees of antagonism of  $\alpha_2$  adrenoceptors are also seen with risperidone, clozapine, olanzapine, quetiapine, and aripiprazole. The clinical relevance of these actions remains to be ascertained.

Current research is directed toward discovering atypical antipsychotic compounds that are either more selective for the mesolimbic system (to reduce their effects on the extrapyramidal system) or have effects on central neurotransmitter receptors—such as those for acetylcholine and excitatory amino acids—that have been proposed as new targets for antipsychotic action.

In contrast to the difficult search for receptors responsible for antipsychotic *efficacy*, the differences in receptor effects of various antipsychotics do explain many of their *toxicities* (Tables 29â€”1 and 29â€”2). In particular, extrapyramidal toxicity appears to be consistently associated with high D<sub>2</sub> potency.

**Table 29â€”2 Adverse Pharmacologic Effects of Antipsychotic Drugs.**

Type	Manifestations	Mechanism
Autonomic nervous system	Loss of accommodation, dry mouth, difficulty urinating, constipation	Muscarinic cholinergic blockade
	Orthostatic hypotension, impotence, failure to ejaculate	$\alpha$ -Adrenoceptor blockade
Central nervous system	Parkinson's syndrome, akathisia, dystonias	Dopamine-receptor blockade
	Tardivedyskinesia	Supersensitivity of dopamine receptors
	Toxic-confusional state	Muscarinic blockade
Endocrine system	Amenorrhea-galactorrhea, infertility, impotence	Dopamine-receptor blockade resulting in hyperprolactinemia
Other	Weight gain	Possibly combined H <sub>1</sub> and 5-HT <sub>2</sub> blockade

### PSYCHOLOGICAL EFFECTS

Most antipsychotic drugs cause unpleasant subjective effects in nonpsychotic individuals. The mild to severe EPS, including akathisia, sleepiness, restlessness, and autonomic effects are unlike any associated with more familiar sedatives or hypnotics. Nevertheless, low doses of some of these drugs, particularly quetiapine, are used to promote sleep onset and maintenance, although there is no approved indication for such usage.

Nonpsychotic persons also experience impaired performance as judged by a number of psychomotor and psychometric tests. Psychotic individuals, however, may actually show improvement in their performance as the psychosis is alleviated. The ability of the atypical antipsychotic drugs to improve some domains of cognition in patients with schizophrenia and bipolar disorder is controversial. Some individuals experience marked improvement and for that reason, cognition should be assessed in all patients with schizophrenia and a trial of an atypical agent considered, even if positive symptoms are well controlled by typical agents.

### ELECTROENCEPHALOGRAPHIC EFFECTS

Antipsychotic drugs produce shifts in the pattern of electroencephalographic (EEG) frequencies, usually slowing them and increasing their synchronization. The slowing (hypersynchrony) is sometimes focal or unilateral, which may lead to erroneous diagnostic interpretations. Both the frequency and the amplitude changes induced by psychotropic drugs are readily apparent and can be quantitated by sophisticated electrophysiologic techniques. Some of the neuroleptic agents lower the seizure threshold and induce EEG patterns typical of seizure disorders; however, with careful dosage titration, most can be used safely in epileptic patients.

### ENDOCRINE EFFECTS

Older typical antipsychotic drugs, as well as risperidone and paliperidone, produce adverse effects marked by elevations of prolactin, see Adverse Effects, below. Newer antipsychotics such as olanzapine, quetiapine, and aripiprazole cause no or minimal increases of prolactin and reduced risks of extrapyramidal system dysfunction and tardive dyskinesia, reflecting their *diminished* D<sub>2</sub> antagonism.

## CARDIOVASCULAR EFFECTS

The low-potency phenothiazines frequently cause orthostatic hypotension and tachycardia. Mean arterial pressure, peripheral resistance, and stroke volume are decreased. These effects are predictable from the autonomic actions of these agents (Table 29â€"2). Abnormal ECGs have been recorded, especially with thioridazine. Changes include prolongation of QT interval and abnormal configurations of the ST segment and T waves. These changes are readily reversed by withdrawing the drug. Thioridazine, however, is *not* associated with increased risk of torsade more than other typical antipsychotics, whereas haloperidol, which does not increase QT<sub>c</sub>, is.

Among the newest atypical antipsychotics, prolongation of the QT or QT<sub>c</sub> interval has received much attention. Because this was believed to indicate an increased risk of dangerous arrhythmias, sertindole has been delayed and ziprasidone and quetiapine are accompanied by warnings. There is, however, no evidence that this has actually translated into increased incidence of arrhythmias.

## ANIMAL SCREENING TESTS

Inhibition of conditioned (but not unconditioned) avoidance behavior is one of the most predictive tests of antipsychotic action. Another is the inhibition of amphetamine- or apomorphine-induced stereotyped behavior. Other tests that may predict antipsychotic action are reduction of exploratory behavior without undue sedation, induction of a cataleptic state, inhibition of intracranial self-stimulation of reward areas, and prevention of apomorphine-induced vomiting. Most of these tests are difficult to relate to any model of clinical psychosis.

The psychosis produced by phencyclidine (PCP) has been used as a model for schizophrenia. Because this drug is an antagonist of the NMDA glutamate receptor, attempts have been made to develop antipsychotic drugs that work as NMDA agonists. Sigma receptor and cholecystokinin type b (CCK<sub>b</sub>) antagonism have also been suggested as potential targets. Thus far, NMDA receptor-based models have pointed to agents that modulate glutamate release as potential antipsychotics. 5-HT<sub>2A</sub> inverse agonists such as pimavanserin, ritanserin, and M100907 are potent inhibitors of PCP-induced locomotor activity, whereas D<sub>2</sub> antagonists are relatively weak in comparison. Thus, atypical antipsychotic drugs that act as 5-HT<sub>2A</sub> antagonists appear much more potent than typical antipsychotic drugs in PCP models.

## Clinical Pharmacology of Antipsychotic Agents

### Indications

#### PSYCHIATRIC INDICATIONS

**Schizophrenia** is the primary indication for antipsychotic agents. Antipsychotic drugs are also used very extensively in patients with psychotic bipolar disorder (BP1), psychotic depression, and treatment resistant depression.

**Catatonic** forms of schizophrenia are best managed by intravenous benzodiazepines. After catatonia has ended, antipsychotic drugs may be needed to treat psychotic components of that form of the illness, and remain the mainstay of treatment for this condition. Unfortunately, many patients show little response, and virtually none show a complete response.

Antipsychotic drugs are also indicated for **schizoaffective disorders**, which share characteristics of both schizophrenia and affective disorders. No fundamental difference between these two diagnoses has been reliably demonstrated. They are part of a continuum with bipolar psychotic disorder. The psychotic aspects of the illness require treatment with antipsychotic drugs, which may be used with other drugs such as antidepressants, lithium, or valproic acid. The manic phase in **bipolar affective disorder** often requires treatment with antipsychotic agents, although lithium or valproic acid supplemented with high-potency benzodiazepines (eg, lorazepam or clonazepam) may suffice in milder cases. Recent controlled trials support the efficacy of monotherapy with atypical antipsychotics in the acute phase (up to 4 weeks) of mania, and olanzapine and quetiapine has been approved for this indication.

As mania subsides, the antipsychotic drug may be withdrawn, although maintenance treatment with atypical antipsychotic agents has become more common. Nonmanic excited states may also be managed by antipsychotics, often in combination with benzodiazepines.

Other indications for the use of antipsychotics include **Tourette's syndrome**, disturbed behavior in patients with **Alzheimer's disease**, and, with antidepressants, **psychotic depression**. Antipsychotics are not indicated for the treatment of various withdrawal syndromes, eg, opioid withdrawal. In small doses, antipsychotic drugs have been promoted (wrongly) for the relief of anxiety associated with minor emotional disorders. The antianxiety sedatives (see Chapter 22) are preferred in terms of both safety and acceptability to patients.

#### NONPSYCHIATRIC INDICATIONS

Most older typical antipsychotic drugs, with the exception of thioridazine, have a strong **antiemetic** effect. This action is due to dopamine-receptor blockade, both centrally (in the chemoreceptor trigger zone of the medulla) and peripherally (on receptors in the stomach). Some drugs, such as prochlorperazine and benzquinamide, are promoted solely as antiemetics.

Phenothiazines with shorter side chains have considerable **H<sub>1</sub>-receptor-blocking** action and have been used for relief of pruritus or, in the case of promethazine, as preoperative sedatives. The butyrophenone droperidol is used in combination with an opioid, fentanyl, in **neuroleptanesthesia**. The use of these drugs in anesthesia practice is described in Chapter 25.

### Drug Choice

Choice among antipsychotic drugs is based mainly on differences in adverse effects and possible differences in efficacy. Since use of the older drugs is still widespread, especially for patients treated in the public sector, knowledge of such agents as chlorpromazine and haloperidol remains relevant. Thus, one should be familiar with one member of each of the three subfamilies of phenothiazines, a member of the thioxanthene and butyrophenone group, and all of the newer compounds—clozapine, risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole. Each may have special benefits for selected patients. A representative group of antipsychotic drugs is presented in Table 29â€"3.

### Table 29â€"3 Some Representative Antipsychotic Drugs.

Drug Class	Drug	Advantages	Disadvantages
Phenothiazines			
Aliphatic	Chlorpromazine <sup>1</sup>	Generic, inexpensive	Many adverse effects, especially autonomic
Piperidine	Thioridazine <sup>2</sup>	Slight extrapyramidal syndrome; generic	800 mg/d limit; no parenteral form; cardiotoxicity
Piperazine	Fluphenazine <sup>3</sup>	Depot form also available (enanthate, decanoate)	(?) Increased tardivedyskinesia
Thioxanthene	Thiothixene	Parenteral form also available; (?) decreased tardive dyskinesia	Uncertain
Butyrophenone	Haloperidol	Parenteral form also available; generic	Severe extrapyramidal syndrome
Dibenzoxazepine	Loxapine	(?) No weight gain	Uncertain
Dibenzodiazepine	Clozapine	May benefit treatment-resistant patients; little extrapyramidal toxicity	May cause agranulocytosis in up to 2% of patients; dose-related lowering of seizure threshold
Benzisoxazole	Risperidone	Broad efficacy; little or no extrapyramidal system dysfunction at low doses	Extrapyramidal system dysfunction and hypotension with higher doses
Thienobenzodiazepine	Olanzapine	Effective against negative as well as positive symptoms; little or no extrapyramidal system dysfunction	Weight gain; dose-related lowering of seizure threshold
Dibenzothiazepine	Quetiapine	Similar to olanzapine; perhaps less weight gain	May require high doses if there is associated hypotension; short $t_{1/2}$ and twice-daily dosing
Dihydroindolone	Ziprasidone	Perhaps less weight gain than clozapine, parenteral form available	QT <sub>c</sub> prolongation
Dihydrocarbostyryl	Aripiprazole	Lower weight gain liability, long half-life, novel mechanism potential	Uncertain, novel toxicities possible

<sup>1</sup>Other aliphatic phenothiazines: promazine, trifluorpromazine.

<sup>2</sup>Other piperidine phenothiazines: piperacetazine, mesoridazine.

<sup>3</sup>Other piperazine phenothiazines: acetophenazine, perphenazine, carphenazine, prochlorperazine, trifluoperazine.

For approximately 70% of patients with schizophrenia, and probably for a similar proportion of patients with bipolar disorder with psychotic features, typical and atypical antipsychotic drugs are of equal efficacy for treating positive symptoms. However, the evidence favors atypical drugs for benefit for negative symptoms and cognition, for diminished risk of tardivedyskinesia and other forms of EPS, and for lesser increases in prolactin levels.

Some of the atypical antipsychotic drugs produce more weight gain and increases in lipids than some typical antipsychotic drugs. A small percentage of patients develop diabetes mellitus, most often seen with clozapine and olanzapine. Ziprasidone is the atypical drug causing the least weight gain. Risperidone, paliperidone, and aripiprazole usually produce small increases in weight and lipids. Asenapine and quetiapine have an intermediate effect. Clozapine and olanzapine frequently result in large increases in weight and lipids. Thus, these drugs should be considered as second-line drugs unless there is a specific indication. That is the case with clozapine, which at high doses (300–900 mg/d) is effective in the majority of patients with schizophrenia refractory to other drugs, provided that treatment is continued for up to 6 months. Case reports and several clinical trials suggest that high-dose olanzapine, ie, doses of 30–45 mg/d, may also be efficacious in refractory schizophrenia when given over a 6-month period. Clozapine is the only atypical antipsychotic drug indicated to reduce the risk of suicide. All patients with schizophrenia who have made life-threatening suicide attempts should be seriously evaluated for switching to clozapine.

New antipsychotic drugs have been shown in some trials to be more effective than older ones for treating negative symptoms. The floridly psychotic form of the illness accompanied by uncontrollable behavior probably responds equally well to all potent antipsychotics but is still frequently treated with older drugs that offer intramuscular formulations for acute and chronic treatment. Moreover, the low cost of the older drugs contributes to their widespread use despite their risk of adverse EPS effects. Several of the newer antipsychotics, including clozapine, risperidone, and olanzapine, show superiority over haloperidol in terms of overall response in some controlled trials. More comparative studies with aripiprazole are needed to evaluate its relative efficacy. Moreover, the superior adverse-effect profile of the newer agents and low to absent risk of tardivedyskinesia suggest that these should provide the first line of treatment.

The best guide for selecting a drug for an individual patient is the patient's past responses to drugs. Within the older group, the trend has been away from low-potency agents such as chlorpromazine and thioridazine and toward the high-potency drugs such as haloperidol. At present, clozapine is limited to those patients who have failed to respond to substantial doses of conventional antipsychotic drugs. The agranulocytosis and seizures associated with this drug prevent more widespread use. Risperidone's superior side-effect profile (compared with that of haloperidol) at dosages of 6 mg/d or less and the lower risk of tardivedyskinesia have contributed to its widespread use. Olanzapine and quetiapine may have even lower risk and have also achieved widespread use. Whether any of the other recently introduced antipsychotic drugs can substitute for clozapine remains to be established.

## Dosage

The range of effective dosages among various antipsychotic agents is broad. Therapeutic margins are substantial. At appropriate dosages, antipsychotics—with the exception of clozapine and perhaps olanzapine—are of equal efficacy in broadly selected groups of patients. However, some

patients who fail to respond to one drug may respond to another; for this reason, several drugs may have to be tried to find the one most effective for an individual patient. Patients who have become refractory to two or three antipsychotic agents given in substantial doses become candidates for treatment with clozapine or high-dose olanzapine. These drugs salvage 30%–50% of patients previously refractory to standard doses of other antipsychotic drugs. In such cases, the increased risk of clozapine can well be justified. Risperidone does not appear to substitute for clozapine, although reports are mixed. Whether other antipsychotics will show efficacy similar to that of clozapine remains to be determined.

Some dosage relationships between various antipsychotic drugs, as well as possible therapeutic ranges, are shown in Table 29-4.

**Table 29-4 Dose Relationships of Antipsychotics.**

	<b>Minimum Effective Therapeutic Dose (mg)</b>	<b>Usual Range of Daily Doses (mg)</b>
Chlorpromazine	100	100–1000
Thioridazine	100	100–800
Trifluoperazine	5	5–60
Perphenazine	10	8–64
Fluphenazine	2	2–60
Thiothixene	2	2–120
Haloperidol	2	2–60
Loxapine	10	20–160
Molindone	10	20–200
Clozapine	50	300–600
Olanzapine	5	10–30
Quetiapine	150	150–800
Risperidone	4	4–16
Ziprasidone	40	80–160
Aripiprazole	10	10–30

### Parenteral Preparations

Well-tolerated parenteral forms of the high-potency older drugs haloperidol and fluphenazine are available for rapid initiation of treatment as well as for maintenance treatment in noncompliant patients. Since the parenterally administered drugs may have much greater bioavailability than the oral forms, doses should be only a fraction of what might be given orally, and the manufacturer's literature should be consulted. Fluphenazine decanoate and haloperidol decanoate are suitable for long-term parenteral maintenance therapy in patients who cannot or will not take oral medication.

### Dosage Schedules

Antipsychotic drugs are often given in divided daily doses, titrating to an effective dosage. The low end of the dosage range in Table 29-4 should be tried for at least several weeks. After an effective daily dosage has been defined for an individual patient, doses can be given less frequently. Once-daily doses, usually given at night, are feasible for many patients during chronic maintenance treatment. Simplification of dosage schedules leads to better compliance.

### Maintenance Treatment

A very small minority of schizophrenic patients may recover from an acute episode and require no further drug therapy for prolonged periods. In most cases, the choice is between "as needed" increased doses or the addition of other drugs for exacerbations versus continual maintenance treatment with full therapeutic dosage. The choice depends on social factors such as the availability of family or friends familiar with the symptoms of early relapse and ready access to care.

### Drug Combinations

Combining antipsychotic drugs confounds evaluation of the efficacy of the drugs being used. Use of combinations, however, is widespread, with more emerging experimental data supporting such practices. Tricyclic antidepressants or, more often, selective serotonin reuptake inhibitors (SSRIs) are often used with antipsychotic agents for symptoms of depression complicating schizophrenia. The evidence for the usefulness of this polypharmacy is minimal. Electroconvulsive therapy (ECT) is a useful adjunct for antipsychotic drugs, not only for treating mood symptoms, but for positive symptom control as well. Electroconvulsive therapy can augment clozapine when maximum doses of clozapine are ineffective. In contrast, adding risperidone to clozapine is not beneficial. Lithium or valproic acid is sometimes added to antipsychotic agents with benefit to patients who do not respond to the latter drugs alone. There is some evidence that lamotrigine is more effective than any of the other mood stabilizers for this indication (see below). It is uncertain whether instances of successful combination therapy represent misdiagnosed cases of mania or schizoaffective disorder. Benzodiazepines may be useful for patients with anxiety symptoms or insomnia not controlled by antipsychotics.

### Adverse Reactions

Most of the unwanted effects of antipsychotic drugs are extensions of their known pharmacologic actions (Tables 29-1 and 29-2), but a few effects are allergic in nature and some are idiosyncratic.

### BEHAVIORAL EFFECTS

The older typical antipsychotic drugs are unpleasant to take. Many patients stop taking these drugs because of the adverse effects, which may be

mitigated by giving small doses during the day and the major portion at bedtime. A "pseudodepression" that may be due to drug-induced akinesia usually responds to treatment with antiparkinsonism drugs. Other pseudodepressions may be due to higher doses than needed in a partially remitted patient, in which case decreasing the dose may relieve the symptoms. Toxic-confusional states may occur with very high doses of drugs that have prominent antimuscarinic actions.

#### NEUROLOGIC EFFECTS

Extrapyramidal reactions occurring early during treatment with older agents include typical **Parkinson's syndrome, akathisia** (uncontrollable restlessness), and **acute dystonic reactions** (spastic retrocollis or torticollis). Parkinsonism can be treated, when necessary, with conventional antiparkinsonism drugs of the antimuscarinic type or, in rare cases, with amantadine. (Levodopa should never be used in these patients.) Parkinsonism may be self-limiting, so that an attempt to withdraw antiparkinsonism drugs should be made every 3-4 months. Akathisia and dystonic reactions also respond to such treatment, but many prefer to use a sedative antihistamine with anticholinergic properties, eg, diphenhydramine, which can be given either parenterally or orally.

**Tardive dyskinesia**, as the name implies, is a late-occurring syndrome of abnormal choreoathetoid movements. It is the most important unwanted effect of antipsychotic drugs. It has been proposed that it is caused by a relative cholinergic deficiency secondary to supersensitivity of dopamine receptors in the caudate-putamen. The prevalence varies enormously, but tardive dyskinesia is estimated to have occurred in 20-40% of chronically treated patients before the introduction of the newer atypical antipsychotics. Early recognition is important, since advanced cases may be difficult to reverse. Any patient with tardive dyskinesia treated with a typical antipsychotic drug or possibly risperidone or paliperidone should be switched to quetiapine or clozapine, the atypicals with the least likelihood of causing tardive dyskinesia. Many treatments have been proposed, but their evaluation is confounded by the fact that the course of the disorder is variable and sometimes self-limited. Reduction in dosage may also be considered. Most authorities agree that the first step should be to discontinue or reduce the dose of the current antipsychotic agent or switch to one of the newer atypical agents. A logical second step would be to eliminate all drugs with central anticholinergic action, particularly antiparkinsonism drugs and tricyclic antidepressants. These two steps are often enough to bring about improvement. If they fail, the addition of diazepam in doses as high as 30-40 mg/d may add to the improvement by enhancing GABAergic activity.

**Seizures**, though recognized as a complication of chlorpromazine treatment, were so rare with the high-potency older drugs as to merit little consideration. However, de novo seizures may occur in 2-5% of patients treated with clozapine. Use of an anticonvulsant is able to control seizures in most cases.

#### AUTONOMIC NERVOUS SYSTEM EFFECTS

Most patients are able to tolerate the antimuscarinic adverse effects of antipsychotic drugs. Those who are made too uncomfortable or who develop urinary retention or other severe symptoms can be switched to an agent without significant antimuscarinic action. Orthostatic hypotension or impaired ejaculation—common complications of therapy with chlorpromazine or mesoridazine—should be managed by switching to drugs with less marked adrenoceptor-blocking actions.

#### METABOLIC AND ENDOCRINE EFFECTS

Weight gain is very common, especially with clozapine and olanzapine, and requires monitoring of food intake, especially carbohydrates. Hyperglycemia may develop, but whether secondary to weight gain-associated insulin resistance or to other potential mechanisms remains to be clarified. Hyperlipidemia may occur. The management of weight gain, insulin resistance, and increased lipids should include monitoring of weight at each visit and measurement of fasting blood sugar and lipids at 3-6 month intervals. Measurement of hemoglobin A<sub>1c</sub> may be useful when it is impossible to be sure of obtaining a fasting blood sugar. Diabetic ketoacidosis has been reported in a few cases. The triglyceride:HDL ratio should be less than 3.5 in fasting samples. Levels higher than that indicate increased risk of atherosclerotic cardiovascular disease.

Hyperprolactinemia in women results in the amenorrhea-galactorrhea syndrome and infertility; in men, loss of libido, impotence, and infertility may result. Hyperprolactinemia may cause osteoporosis, particularly in women. If dose reduction is not indicated, or ineffective in controlling this pattern, switching to one of the atypicals that do not raise prolactin levels, eg, aripiprazole, may be indicated.

#### TOXIC OR ALLERGIC REACTIONS

Agranulocytosis, cholestatic jaundice, and skin eruptions occur rarely with the high-potency antipsychotic drugs currently used.

In contrast to other antipsychotic agents, clozapine causes agranulocytosis in a small but significant number of patients—approximately 1-2% of those treated. This serious, potentially fatal effect can develop rapidly, usually between the 6th and 18th weeks of therapy. It is not known whether it represents an immune reaction, but it appears to be reversible upon discontinuance of the drug. *Because of the risk of agranulocytosis, patients receiving clozapine must have weekly blood counts for the first 6 months of treatment and every 3 weeks thereafter.*

#### OCULAR COMPLICATIONS

Deposits in the anterior portions of the eye (cornea and lens) are a common complication of chlorpromazine therapy. They may accentuate the normal processes of aging of the lens. Thioridazine is the only antipsychotic drug that causes retinal deposits, which in advanced cases may resemble retinitis pigmentosa. The deposits are usually associated with "browning" of vision. The maximum daily dose of thioridazine has been limited to 800 mg/d to reduce the possibility of this complication.

#### CARDIAC TOXICITY

Thioridazine in doses exceeding 300 mg daily is almost always associated with minor abnormalities of T waves that are easily reversible. Overdoses of thioridazine are associated with major ventricular arrhythmias, eg, torsade de pointes, cardiac conduction block, and sudden death; it is not certain whether thioridazine can cause these same disorders when used in therapeutic doses. In view of possible additive antimuscarinic and quinidine-like actions with various tricyclic antidepressants, thioridazine should be combined with the latter drugs only with great care. Among the atypical agents, ziprasidone carries the greatest risk of QT prolongation and therefore should not be combined with other drugs that prolong the QT interval, including thioridazine, pimozide, and group IA or III antiarrhythmic drugs. Clozapine is sometimes associated with myocarditis and must be discontinued if myocarditis manifests. Sudden death due to arrhythmias is common in schizophrenia. It is not always drug-related and there are no studies that definitively show increased risk with particular drugs. Monitoring of QT<sub>c</sub> prolongation has proved to be of little use unless the values increase to more

than 500 ms and this is manifested in multiple rhythm strips or a Holter monitor study. A 20,000 patient study of ziprasidone versus olanzapine showed minimal or no increased risk of torsade de pointes or sudden death in patients who were randomized to ziprasidone.

#### **USE IN PREGNANCY; DYSMORPHOGENESIS**

Although antipsychotic drugs appear to be relatively safe in pregnancy, a small increase in teratogenic risk could be missed. Questions about whether to use these drugs during pregnancy and whether to abort a pregnancy in which the fetus has already been exposed must be decided individually. If a pregnant woman could manage to be free of antipsychotic drugs during pregnancy, this would be desirable because of their effects on the neurotransmitters involved in neurodevelopment.

#### **NEUROLEPTIC MALIGNANT SYNDROME**

This life-threatening disorder occurs in patients who are extremely sensitive to the extrapyramidal effects of antipsychotic agents (see also Chapter 16). The initial symptom is marked muscle rigidity. If sweating is impaired, as it often is during treatment with anticholinergic drugs, fever may ensue, often reaching dangerous levels. The stress leukocytosis and high fever associated with this syndrome may erroneously suggest an infectious process. Autonomic instability, with altered blood pressure and pulse rate, is often present.

Muscle-type creatine kinase levels are usually elevated, reflecting muscle damage. This syndrome is believed to result from an excessively rapid blockade of postsynaptic dopamine receptors. A severe form of extrapyramidal syndrome follows. Early in the course, vigorous treatment of the extrapyramidal syndrome with antiparkinsonism drugs is worthwhile. Muscle relaxants, particularly diazepam, are often useful. Other muscle relaxants, such as dantrolene, or dopamine agonists, such as bromocriptine, have been reported to be helpful. If fever is present, cooling by physical measures should be tried. Various minor forms of this syndrome are now recognized. Switching to an atypical drug after recovery is indicated.

#### **Drug Interactions**

Antipsychotics produce more important pharmacodynamic than pharmacokinetic interactions because of their multiple effects. Additive effects may occur when these drugs are combined with others that have sedative effects,  $\alpha$ -adrenoceptor-blocking action, anticholinergic effects, and "for thioridazine and ziprasidone" quinidine-like action.

A variety of pharmacokinetic interactions have been reported, but none are of major clinical significance.

#### **Overdoses**

Poisonings with antipsychotic agents (unlike tricyclic antidepressants) are rarely fatal, with the exception of those due to mesoridazine and thioridazine. In general, drowsiness proceeds to coma, with an intervening period of agitation. Neuromuscular excitability may be increased and proceed to convulsions. Pupils are miotic, and deep tendon reflexes are decreased. Hypotension and hypothermia are the rule, although fever may be present later in the course. The lethal effects of mesoridazine and thioridazine are related to induction of ventricular tachyarrhythmias. Patients should be given the usual "ABCD" treatment for poisonings (see Chapter 58) and treated supportively. Management of overdoses of thioridazine and mesoridazine, which are complicated by cardiac arrhythmias, is similar to that for tricyclic antidepressants (see Chapter 30).

#### **Psychosocial Treatment and Cognitive Remediation**

Patients with schizophrenia need psychosocial support based around activities of daily living, including housing, social activities, returning to school, obtaining the optimal level of work they may be capable of and restoring social interactions. Unfortunately, funding for this crucial component of treatment has been minimized in recent years. Case management and therapy services are a vital part of the treatment program that should be provided to patients with schizophrenia. First-episode patients are particularly needful of this support because they often deny their illness and are noncompliant with medication.

#### **Benefits & Limitations of Drug Treatment**

As noted at the beginning of this chapter, antipsychotic drugs have had a major impact on psychiatric treatment. First, they have shifted the vast majority of patients from long-term hospitalization to the community. For many patients, this shift has provided a better life under more humane circumstances and in many cases has made possible life without frequent use of physical restraints. For others, the tragedy of an aimless existence is now being played out in the streets of our communities rather than in mental institutions.

Second, these antipsychotic drugs have markedly shifted psychiatric thinking to a more biologic orientation. Partly because of research stimulated by the effects of these drugs on schizophrenia, we now know much more about central nervous system physiology and pharmacology than was known before the introduction of these agents. However, despite much research, schizophrenia remains a scientific mystery and a personal disaster for the patient. Although most schizophrenic patients obtain some degree of benefit from these drugs "in some cases substantial benefit" none are made well by them.

#### **LITHIUM, MOOD-STABILIZING DRUGS, AND OTHER TREATMENT FOR BIPOLAR DISORDER**

Bipolar disorder, once known as manic-depressive illness, was conceived of as a psychotic disorder distinct from schizophrenia at the end of the 19th century. Before that both of these disorders were considered part of a continuum. It is ironic that the weight of the evidence today is that there is profound overlap in these disorders. This is not to say that there are no pathophysiologically important differences or that some drug treatments are differentially effective in these disorders. According to *DSM-IV*, they are separate disease entities while research continues to define the dimensions of these illnesses and their genetic and other biological markers.

Lithium was the first agent shown to be useful in the treatment of the manic phase of bipolar disorder that was not also an antipsychotic drug. Lithium has no known use in schizophrenia. Lithium continues to be used for acute-phase illness as well as for prevention of recurrent manic and depressive episodes.

Another group of mood-stabilizing drugs that are also anticonvulsant agents have become more widely used than lithium. These include **carbamazepine** and **valproic acid** for the treatment of acute mania and for prevention of its recurrence. **Lamotrigine** is approved for prevention of recurrence. **Gabapentin**, **oxcarbazepine**, and **topiramate** are sometimes used to treat bipolar disorder but are not approved by FDA for this

indication. **Aripiprazole, chlorpromazine, olanzapine, quetiapine, risperidone, and ziprasidone** are approved by FDA for the treatment of manic phase of bipolar disorder. Olanzapine plus fluoxetine in combination and quetiapine are approved for the treatment of bipolar depression.

### Nature of Bipolar Affective Disorder

Bipolar affective (manic-depressive) disorder occurs in 1-3% of the adult population. It may begin in childhood, but most cases are first diagnosed in the third and fourth decades of life. The key symptoms of bipolar disorder in the manic phase are excitement, hyperactivity, impulsivity, disinhibition, aggression, diminished need for sleep, psychotic symptoms in some (but not all) patients, and cognitive impairment. Depression in bipolar patients is phenomenologically similar to that of major depression, with the key features being depressed mood, diurnal variation, sleep disturbance, anxiety, and sometimes, psychotic symptoms. Mixed manic and depressive symptoms are also seen. Patients with bipolar disorder are at high risk for suicide.

The sequence, number, and intensity of manic and depressive episodes are highly variable. The cause of the mood swings characteristic of bipolar affective disorder is unknown, although a preponderance of catecholamine-related activity may be present. Drugs that increase this activity tend to exacerbate mania, whereas those that reduce activity of dopamine or norepinephrine relieve mania. Acetylcholine or glutamate may also be involved. The nature of the abrupt switch from mania to depression experienced by some patients is uncertain. Bipolar disorder has a strong familial component, and there is abundant evidence that bipolar disorder is genetically determined.

Many of the genes that increase vulnerability to bipolar disorder are common to schizophrenia but some genes appear to be unique to each disorder. Genome-wide association studies of psychotic bipolar disorder have shown replicated linkage to chromosomes 8p and 13q. Several candidate genes have shown association with bipolar disorder with psychotic features and with schizophrenia. These include genes for dysbindin, *DAOA/G30*, disrupted-in-schizophrenia-1 (*DISC-1*), and neuregulin 1.

### Basic Pharmacology of Lithium

The first use of lithium for therapeutic purposes began in the mid-19th century to treat gout. Lithium had a relatively brief period of use as a substitute for sodium chloride in hypertensive patients in the 1940s, but it proved too toxic when available without monitoring and was banned. In 1949, Cade discovered that lithium was an effective treatment for bipolar disorder, engendering a series of controlled trials which confirmed its efficacy as monotherapy for the manic phase of bipolar disorder.

### Pharmacokinetics

Lithium is a small monovalent cation. Its pharmacokinetics are summarized in Table 29-5.

**Table 29-5 Pharmacokinetics of Lithium.**

Absorption	Virtually complete within 6-8 hours; peak plasma levels in 30 minutes to 2 hours
Distribution	In total body water; slow entry into intracellular compartment. Initial volume of distribution is 0.5 L/kg, rising to 0.7-0.9 L/kg; some sequestration in bone. No protein binding.
Metabolism	None
Excretion	Virtually entirely in urine. Lithium clearance about 20% of creatinine. Plasma half-life about 20 hours.
Target plasma concentration	0.6-1.4 mEq/L
Dosage	0.5 mEq/kg/d in divided doses

### Pharmacodynamics

Despite considerable investigation, the biochemical basis for mood stabilizer therapies including lithium and anticonvulsant mood stabilizers is not clearly understood. Lithium directly inhibits two signal transduction pathways. It both suppresses inositol signaling through depletion of intracellular inositol and inhibits glycogen synthase kinase-3 (GSK-3), a multifunctional protein kinase. GSK-3 is a component of diverse intracellular signaling pathways. These include insulin/insulin-like growth factor signaling, brain-derived neurotrophic factor (BDNF) signaling, and the Wnt signaling pathway. All of these lead to inhibition of GSK-3. GSK-3 phosphorylates  $\beta$ -catenin, resulting in interaction with transcription factors. The pathways that are facilitated in this manner modulate energy metabolism, provide neuroprotection, and increase neuroplasticity.

Studies on the enzyme prolyl oligopeptidase and the sodium myo-inositol transporter support an inositol depletion mechanism for mood-stabilizer action. Valproic acid may indirectly reduce GSK-3 activity and can up-regulate gene expression through inhibition of histone deacetylase. Valproic acid also inhibits inositol signaling through an inositol depletion mechanism. There is no evidence of GSK-3 inhibition by carbamazepine, a second antiepileptic mood stabilizer. In contrast, this drug alters neuronal morphology through an inositol depletion mechanism, as seen with lithium and valproic acid. The mood stabilizers may also have indirect effects on neurotransmitters and their release.

### EFFECTS ON ELECTROLYTES AND ION TRANSPORT

Lithium is closely related to sodium in its properties. It can substitute for sodium in generating action potentials and in  $\text{Na}^+$ - $\text{Na}^+$  exchange across the membrane. It inhibits the latter process; that is,  $\text{Li}^+$ - $\text{Na}^+$  exchange is gradually slowed after lithium is introduced into the body. At therapeutic concentrations (around 1 mmol/L), it does not significantly affect the  $\text{Na}^+$ - $\text{Ca}^{2+}$  exchanger or the  $\text{Na}^+$ , $\text{K}^+$  ATPase pump.

### EFFECTS ON SECOND MESSENGERS

Some of the enzymes affected by lithium are listed in Table 29-6. One of the best-defined effects of lithium is its action on inositol phosphates. Early studies of lithium demonstrated changes in brain inositol phosphate levels, but the significance of these changes was not appreciated until the second-messenger roles of inositol-1,4,5-trisphosphate ( $\text{IP}_3$ ) and diacylglycerol (DAG) were discovered. As described in Chapter 2, inositol trisphosphate and diacylglycerol are important second messengers for both  $\alpha$ -adrenergic and muscarinic transmission. Lithium inhibits inositol monophosphatase (IMPase)

and other important enzymes in the normal recycling of membrane phosphoinositides, including conversion of IP<sub>2</sub> (inositol diphosphate) to IP<sub>1</sub> (inositol monophosphate) and the conversion of IP<sub>1</sub> to inositol (Figure 29â€4). This block leads to a depletion of free inositol and ultimately of phosphatidylinositol-4,5-bisphosphate (PIP<sub>2</sub>), the membrane precursor of IP<sub>3</sub> and DAG. Over time, the effects of transmitters on the cell diminish in proportion to the amount of activity in the PIP<sub>2</sub>-dependent pathways. The activity of these pathways is postulated to be markedly increased during a manic episode. Treatment with lithium would be expected to diminish the activity in these circuits.

**Table 29â€6 Enzymes Affected by Lithium at Therapeutic Concentrations.**

Enzyme	Enzyme Function; Action of Lithium
Inositol monophosphatase	The rate-limiting enzyme in inositol recycling; inhibited by lithium, resulting in depletion of substrate for IP <sub>3</sub> production (Figure 29â€4)
Inositol polyphosphate 1-phosphatase	Another enzyme in inositol recycling; inhibited by lithium, resulting in depletion of substrate for IP <sub>3</sub> production (Figure 29â€4)
Bisphosphate nucleotidase	Involved in AMP production; inhibited by lithium; may be target that results in lithium-induced nephrogenic diabetes insipidus
Fructose 1,6-bisphosphatase	Involved in gluconeogenesis; inhibition by lithium of unknown relevance
Phosphoglucomutase	Involved in glycogenolysis; inhibition by lithium of unknown relevance
Glycogen synthase kinase-3	Constitutively active enzyme that appears to limit neurotrophic and neuroprotective processes; lithium inhibits

AMP, adenosine monophosphate; IP<sub>3</sub>, inositol 1,4,5-trisphosphate.

Effect of lithium on the IP<sub>3</sub> (inositol trisphosphate) and DAG (diacylglycerol) second-messenger system. The schematic diagram shows the synaptic membrane of a neuron. (PIP<sub>2</sub>, phosphatidylinositol-4,5-bisphosphate; PLC, phospholipase-C; G, coupling protein; Effects, activation of protein kinase C, mobilization of intracellular Ca<sup>2+</sup>, etc.) Lithium, by inhibiting the recycling of inositol substrates, may cause depletion of the second-messenger source PIP<sub>2</sub> and therefore reduce the release of IP<sub>3</sub> and DAG. Lithium may also act by other mechanisms.

Studies of noradrenergic effects in isolated brain tissue indicate that lithium can inhibit norepinephrine-sensitive adenylyl cyclase. Such an effect could relate to both its antidepressant and its antimanic effects. The relationship of these effects to lithium's actions on IP<sub>3</sub> mechanisms is currently unknown.

Because lithium affects second-messenger systems involving both activation of adenylyl cyclase and phosphoinositol turnover, it is not surprising that G proteins are also found to be affected. Several studies suggest that lithium may uncouple receptors from their G proteins; indeed, two of lithium's most common side effects, polyuria and subclinical hypothyroidism, may be due to uncoupling of the vasopressin and thyroid-stimulating hormone (TSH) receptors from their G proteins.

The major current working hypothesis for lithium's therapeutic mechanism of action supposes that its effects on phosphoinositol turnover, leading to an early relative reduction of myoinositol in human brain, are part of an initiating cascade of intracellular changes. Effects on specific isoforms of protein kinase C may be most relevant. Alterations of protein kinase C-mediated signaling alter gene expression and the production of proteins implicated in long-term neuroplastic events that could underlie long-term mood stabilization.

## Clinical Pharmacology of Lithium

### Bipolar Affective Disorder

Until recently, lithium carbonate was the universally preferred treatment for bipolar disorder, especially in the manic phase. With the approval of valproate, aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone for this indication, a smaller percentage of bipolar patients now receive lithium. This trend is reinforced by the slow onset of action of lithium, which has often been supplemented with concurrent use of antipsychotic drugs or

potent benzodiazepines in severely manic patients. The overall success rate for achieving remission from the manic phase of bipolar disorder can be as high as 80% but lower among patients who require hospitalization. A similar situation applies to maintenance treatment, which is about 60% effective overall but less in severely ill patients. These considerations have led to increased use of combined treatment in severe cases. After mania is controlled, the antipsychotic drug may be stopped and benzodiazepines and lithium continued as maintenance therapy.

The depressive phase of manic-depressive disorder often requires concurrent use of an antidepressant drug (see Chapter 30). Tricyclic antidepressant agents have been linked to precipitation of mania, with more rapid cycling of mood swings, although most patients do not show this effect. Selective serotonin reuptake inhibitors are less likely to induce mania but may have limited efficacy. Bupropion has shown some promise but "like tricyclic antidepressants" may induce mania at higher doses. As shown in recent controlled trials, the anticonvulsant lamotrigine is effective for many patients with bipolar depression. For some patients, however, one of the older monoamine oxidase inhibitors may be the antidepressant of choice. Quetiapine and the combination of olanzapine and fluoxetine has been approved for use in bipolar depression.

Unlike antipsychotic or antidepressant drugs, which exert several actions on the central or autonomic nervous system, lithium ion at therapeutic concentrations is devoid of autonomic blocking effects and of activating or sedating effects, although it can produce nausea and tremor. Most important is that the prophylactic use of lithium can prevent both mania and depression. Many experts believe that the aggressive marketing of newer drugs has inappropriately produced a shift to drugs that are less effective than lithium for substantial numbers of patients.

### Other Applications

**Recurrent endogenous depression** with a cyclic pattern is controlled by either lithium or imipramine, both of which are superior to placebo.

**Schizoaffective disorder**, another condition with an affective component characterized by a mixture of schizophrenic symptoms and depression or excitement, is treated with antipsychotic drugs alone or combined with lithium. Various antidepressants are added if depression is present.

Lithium alone is rarely successful in treating **schizophrenia**, but adding it to an antipsychotic may salvage an otherwise treatment-resistant patient. Carbamazepine may work equally well when added to an antipsychotic drug.

An interesting application of lithium that is relatively well supported by controlled studies is as an adjunct to tricyclic antidepressants and selective serotonin reuptake inhibitors in patients with **unipolar depression** who do not respond fully to monotherapy with the antidepressant. For this application, concentrations of lithium at the lower end of the recommended range for manic-depressive illness appear to be adequate.

### Monitoring Treatment

Clinicians rely on measurements of serum lithium concentrations for assessing both the dosage required for treatment of acute mania and for prophylactic maintenance. These measurements are customarily taken 10–12 hours after the last dose, so all data in the literature pertaining to these concentrations reflect this interval.

An initial determination of serum lithium concentration should be obtained about 5 days after the start of treatment, at which time steady-state conditions should have been attained. If the clinical response suggests a change in dosage, simple arithmetic (new dose equals present dose times desired blood level divided by present blood level) should produce the desired level. The serum concentration attained with the adjusted dosage can be checked after another 5 days. Once the desired concentration has been achieved, levels can be measured at increasing intervals unless the schedule is influenced by intercurrent illness or the introduction of a new drug into the treatment program.

### Maintenance Treatment

The decision to use lithium as *prophylactic* treatment depends on many factors: the frequency and severity of previous episodes, a crescendo pattern of appearance, and the degree to which the patient is willing to follow a program of indefinite maintenance therapy. If the present attack was the patient's first or if the patient is unreliable, one might prefer to terminate treatment after the episode has subsided. Patients who have one or more episodes of illness per year are candidates for maintenance treatment. Although some patients can be maintained with serum levels as low as 0.6 mEq/L, the best results have been obtained with higher levels, such as 0.9 mEq/L.

### Drug Interactions

Renal clearance of lithium is reduced about 25% by diuretics (eg, thiazides), and doses may need to be reduced by a similar amount. A similar reduction in lithium clearance has been noted with several of the newer nonsteroidal anti-inflammatory drugs that block synthesis of prostaglandins. This interaction has not been reported for either aspirin or acetaminophen. All neuroleptics tested to date, with the possible exception of clozapine and the newer atypical antipsychotics, may produce more severe extrapyramidal syndromes when combined with lithium.

### Adverse Effects & Complications

Many adverse effects associated with lithium treatment occur at varying times after treatment is started. Some are harmless, but it is important to be alert to adverse effects that may signify impending serious toxic reactions.

#### NEUROLOGIC AND PSYCHIATRIC ADVERSE EFFECTS

**Tremor** is one of the most common adverse effects of lithium treatment, and it occurs with therapeutic doses. Propranolol and atenolol, which have been reported to be effective in essential tremor, also alleviate lithium-induced tremor. Other reported neurologic abnormalities include choreoathetosis, motor hyperactivity, ataxia, dysarthria, and aphasia. Psychiatric disturbances at toxic concentrations are generally marked by mental confusion and withdrawal. Appearance of any new neurologic or psychiatric symptoms or signs is a clear indication for temporarily stopping treatment with lithium and for close monitoring of serum levels.

#### DECREASED THYROID FUNCTION

Lithium probably decreases thyroid function in most patients exposed to the drug, but the effect is reversible or nonprogressive. Few patients develop frank thyroid enlargement, and fewer still show symptoms of hypothyroidism. Although initial thyroid testing followed by regular monitoring of thyroid function has been proposed, such procedures are not cost-effective. Obtaining a serum TSH concentration every 6–12 months, however, is prudent.

#### NEPHROGENIC DIABETES INSIPIDUS AND OTHER RENAL ADVERSE EFFECTS

Polydipsia and polyuria are common but reversible concomitants of lithium treatment, occurring at therapeutic serum concentrations. The principal physiologic lesion involved is loss of responsiveness to antidiuretic hormone (nephrogenic diabetes insipidus). Lithium-induced diabetes insipidus is resistant to vasopressin but responds to amiloride.

Extensive literature has accumulated concerning other forms of renal dysfunction during long-term lithium therapy, including chronic interstitial nephritis and minimal-change glomerulopathy with nephrotic syndrome. Some instances of decreased glomerular filtration rate have been encountered but no instances of marked azotemia or renal failure.

Patients receiving lithium should avoid dehydration and the associated increased concentration of lithium in urine. Periodic tests of renal concentrating ability should be performed to detect changes.

#### **EDEMA**

Edema is a common adverse effect of lithium treatment and may be related to some effect of lithium on sodium retention. Although weight gain may be expected in patients who become edematous, water retention does not account for the weight gain observed in up to 30% of patients taking lithium.

#### **CARDIAC ADVERSE EFFECTS**

The bradycardia-tachycardia ("sick sinus") syndrome is a definite contraindication to the use of lithium because the ion further depresses the sinus node. T-wave flattening is often observed on the ECG but is of questionable significance.

#### **USE DURING PREGNANCY**

Renal clearance of lithium increases during pregnancy and reverts to lower levels immediately after delivery. A patient whose serum lithium concentration is in a good therapeutic range during pregnancy may develop toxic levels after delivery. Special care in monitoring lithium levels is needed at these times. Lithium is transferred to nursing infants through breast milk, in which it has a concentration about one-third to one-half that of serum. Lithium toxicity in newborns is manifested by lethargy, cyanosis, poor suck and Moro reflexes, and perhaps hepatomegaly.

The issue of lithium-induced dysmorphogenesis is not settled. An earlier report suggested an increase in cardiac anomalies—especially Ebstein's anomaly—in lithium babies, and it is listed as such in Table 59â€”1 in this book. However, more recent data suggest that lithium carries a relatively low risk of teratogenic effects. Further research is needed in this important area.

#### **MISCELLANEOUS ADVERSE EFFECTS**

Transient acneiform eruptions have been noted early in lithium treatment. Some of them subside with temporary discontinuance of treatment and do not recur with its resumption. Folliculitis is less dramatic and probably occurs more frequently. Leukocytosis is always present during lithium treatment, probably reflecting a direct effect on leukopoiesis rather than mobilization from the marginal pool. This adverse effect has now become a therapeutic effect in patients with low leukocyte counts.

#### **Overdoses**

Therapeutic overdoses of lithium are more common than those due to deliberate or accidental ingestion of the drug. Therapeutic overdoses are usually due to accumulation of lithium resulting from some change in the patient's status, such as diminished serum sodium, use of diuretics, or fluctuating renal function. Since the tissues will have already equilibrated with the blood, the plasma concentrations of lithium may not be excessively high in proportion to the degree of toxicity; any value over 2 mEq/L must be considered as indicating likely toxicity. Because lithium is a small ion, it is dialyzed readily. Both peritoneal dialysis and hemodialysis are effective, although the latter is preferred.

#### **VALPROIC ACID**

Valproic acid (valproate), discussed in detail in Chapter 24 as an antiepileptic, has been demonstrated to have antimanic effects and is now being widely used for this indication in the USA. (Gabapentin is not effective, leaving the mechanism of action of valproate unclear.) Overall, valproic acid shows efficacy equivalent to that of lithium during the early weeks of treatment. It is significant that valproic acid has been effective in some patients who have failed to respond to lithium. Moreover, its side-effect profile is such that one can rapidly increase the dosage over a few days to produce blood levels in the apparent therapeutic range, with nausea being the only limiting factor in some patients. The starting dosage is 750 mg/d, increasing rapidly to the 1500â€”2000 mg range with a recommended maximum dosage of 60 mg/kg/d.

Combinations of valproic acid with other psychotropic medications likely to be used in the management of either phase of bipolar illness are generally well tolerated. Valproic acid is an appropriate first-line treatment for mania, although it is not clear that it will be as effective as lithium as a maintenance treatment in all subsets of patients. Many clinicians advocate combining valproic acid and lithium in patients who do not fully respond to either agent alone.

#### **CARBAMAZEPINE**

Carbamazepine has been considered to be a reasonable alternative to lithium when the latter is less than optimally efficacious. The mode of action of carbamazepine is unclear, and oxcarbazepine is not effective. Carbamazepine may be used to treat acute mania and also for prophylactic therapy. Adverse effects (discussed in Chapter 24) are generally no greater and sometimes less than those associated with lithium. Carbamazepine may be used alone or, in refractory patients, in combination with lithium or, rarely, valproate.

The use of carbamazepine as a mood stabilizer is similar to its use as an anticonvulsant (see Chapter 24). Dosage usually begins with 200 mg twice daily, with increases as needed. Maintenance dosage is similar to that used for treating epilepsy, ie, 800â€”1200 mg/d. Plasma concentrations between 3 and 14 mg/L are considered desirable, although no therapeutic range has been established. Blood dyscrasias have figured prominently in the adverse effects of carbamazepine when it is used as an anticonvulsant, but they have not been a major problem with its use as a mood stabilizer. Overdoses of carbamazepine are a major emergency and should generally be managed like overdoses of tricyclic antidepressants (see Chapter 58).

#### **OTHER DRUGS**

Lamotrigine has been reported to be useful in preventing the depression that often follows the manic phase of bipolar disorder. A number of novel agents are under investigation for bipolar depression, including riluzole, a neuroprotective agent that is approved for use in amyotrophic lateral sclerosis; ketamine, a noncompetitive NMDA antagonist previously discussed as a drug believed to model schizophrenia but thought to act by producing relative

enhancement of AMPA receptor activity; and AMPA receptor potentiators.

## SUMMARY: ANTIPSYCHOTIC DRUGS & LITHIUM

### Antipsychotic Drugs & Lithium

Subclass	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>Phenothiazines</b>				
Chlorpromazine Fluphenazine Thioridazine	Blockade of D <sub>2</sub> receptors >> 5HT <sub>2A</sub> receptors	α-Receptor blockade (fluphenazine least) • muscarinic (M)-receptor blockade (especially chlorpromazine and thioridazine) • H <sub>1</sub> -receptor blockade (chlorpromazine, thiothixene)	Psychiatric: schizophrenia (alleviate positive symptoms), bipolar disorder (manic phase) • nonpsychiatric: antiemesis, preoperative sedation (promethazine) • pruritus	Oral and parenteral forms, long half-lives with metabolism-dependent elimination • <i>Toxicity:</i> Extensions of effects on α- and M- receptors • blockade of dopamine receptors may result in akathisia, dystonia, parkinsonian symptoms, tardivedyskinesia, and hyperprolactinemia
<b>Thioxanthene</b>				
Thiothixene		• central nervous system (CNS) depression (sedation) • decreased seizure threshold • QT prolongation (thioridazine)		
<b>Butyrophenone</b>				
Haloperidol	Blockade of D <sub>2</sub> receptors >> 5HT <sub>2A</sub> receptors	Some α blockade, but minimal M receptor blockade and much less sedation than the phenothiazines	Schizophrenia (alleviates positive symptoms), bipolar disorder (manic phase), Huntington's chorea, Tourette's syndrome	Oral and parenteral forms with metabolism-dependent elimination • <i>Toxicity:</i> Extrapyramidal dysfunction is major adverse effect
<b>Atypical antipsychotics</b>				
Aripiprazole Clozapine Olanzapine Quetiapine Risperidone Ziprasidone	Blockade of 5HT <sub>2A</sub> receptors > blockade of D <sub>2</sub> receptors	Some α blockade (clozapine, risperidone, ziprasidone) and M-receptor blockade (clozapine, olanzapine) • variable H <sub>1</sub> -receptor blockade (all)	Schizophrenia • improve both positive and negative symptoms • bipolar disorder (olanzapine or risperidone adjunctive with lithium) • agitation in Alzheimer's and Parkinson's (low doses) • major depression (aripiprazole)	<i>Toxicity:</i> Agranulocytosis (clozapine), diabetes (clozapine, olanzapine), hypercholesterolemia (clozapine, olanzapine), hyperprolactinemia (risperidone), QT prolongation (ziprasidone), weight gain (clozapine, olanzapine)
<b>Lithium</b>				
	Mechanism of action uncertain • suppresses inositol signaling and inhibits glycogen synthase kinase-3 (GSK-3), a multifunctional protein kinase	No significant antagonistic actions on autonomic nervous system receptors or specific CNS receptors • no sedative effects	Bipolar affective disorder • prophylactic use can prevent mood swings between mania and depression	Oral absorption, renal elimination • half-life 20 h • narrow therapeutic window (monitor blood levels) • <i>Toxicity:</i> Tremor, edema, hypothyroidism, renal dysfunction, dysrhythmias • pregnancy category D • <i>Interactions:</i> Clearance decreased by thiazides and some NSAIDs
<b>Newer agents for bipolar disorder</b>				
Carbamazepine Lamotrigine Valproic acid	Mechanism of action in bipolar disorder unclear (see Chapter 24 for putative actions in seizure disorders)	Carbamazepine causes dose-related diplopia and ataxia • lamotrigine causes nausea, dizziness, and headache • valproic acid causes gastrointestinal distress, possible weight gain, alopecia	Valproic acid is increasingly used as first choice in acute illness • carbamazepine and lamotrigine are also used both in acute mania and for prophylaxis in depressive phase	Oral absorption • once-daily dosing • carbamazepine forms active metabolite • lamotrigine and valproic acid form conjugates • <i>Toxicity:</i> Hematotoxicity and induction of P450 drug metabolism (carbamazepine), rash (lamotrigine), tremor, liver dysfunction, weight gain, inhibition of drug metabolism (valproic acid)

## PREPARATIONS AVAILABLE

### ANTIPSYCHOTIC AGENTS

#### Aripiprazole (Abilify)

Oral: 2, 5, 10, 15, 20, 30 mg tablets; 1 mg/mL solution

Parenteral: 7.5 mg/mL for IM injection

#### Chlorpromazine (generic, Thorazine)

Oral: 10, 25, 50, 100, 200 mg tablets; 100 mg/mL concentrate

Rectal: 100 mg suppositories

Parenteral: 25 mg/mL for IM injection

**Clozapine** (generic, Clozaril)

Oral: 12.5, 25, 50, 100, 200 mg tablets; 25, 100 mg orally disintegrating tablets

**Fluphenazine** (generic, Prolixin)

Oral: 1, 2.5, 5, 10 mg tablets; 2.5 mg/5 mL elixir

Parenteral: (fluphenazine HCl): 2.5 mg/mL for IM injection

**Fluphenazine decanoate** (generic, Prolixin)

Parenteral: 25 mg/mL for IM or SC injection

**Haloperidol** (generic, Haldol)

Oral: 0.5, 1, 2, 5, 10, 20 mg tablets; 2 mg/mL concentrate

Parenteral: 5 mg/mL for IM injection

**Haloperidol ester** (Haldol Decanoate)

Parenteral: 50, 100 mg/mL for IM injection

**Loxapine** (generic, Loxitane)

Oral: 5, 10, 25, 50 mg capsules

**Molindone** (Moban)

Oral: 5, 10, 25, 50 mg tablets

**Olanzapine** (Zyprexa)

Oral: 2.5, 5, 7.5, 10, 15, 20 mg tablets; 5, 10, 15, 20 mg orally disintegrating tablets

Parenteral: 10 mg powder for injection

**Paliperidone** (Invega)

Oral: 3, 6, 9 mg extended-release tablets

**Perphenazine** (generic)

Oral: 2, 4, 8, 16 mg tablets; 16 mg/5 mL concentrate

**Pimozide** (Orap)

Oral: 1, 2 mg tablets

**Prochlorperazine** (generic, Compazine)

Oral: 5, 10 mg tablets; 5 mg/5 mL syrup

Oral sustained-release: 10, 15 mg capsules

Rectal: 2.5, 5, 25 mg suppositories

Parenteral: 5 mg/mL for IM injection

**Quetiapine** (Seroquel)

Oral: 25, 50, 100, 200, 300, 400 mg tablets; 200, 300, 400 mg extended release tablets

**Risperidone** (Risperdal)

Oral: 0.25, 0.5, 1, 2, 3, 4 mg tablets; 0.5, 1, 2, 3, 4 mg orally disintegrating tablets; 1 mg/mL oral solution

Parenteral: 12.5, 25, 37.5, 50 mg powder for injection; long-acting injectable 25, 37.5, 50 mg

**Thioridazine** (generic, Mellaril)

Oral: 10, 15, 25, 50, 100, 150, 200 mg tablets; 30 mg/mL concentrate

**Thiothixene** (generic, Navane)

Oral: 1, 2, 5, 10, 20 mg capsules

**Trifluoperazine** (generic)

Oral: 1, 2, 5, 10 mg tablets

**Ziprasidone** (Geodon)

Oral: 20, 40, 60, 80 mg capsules

Parenteral: 20 mg powder for IM injection

## MOOD STABILIZERS

**Carbamazepine** (generic, Tegretol)

Oral: 200 mg tablets, 100 mg chewable tablets; 100 mg/5 mL oral suspension

Oral extended-release: 100, 200, 400 mg tablets; 100, 200, 300 mg capsules

**Divalproex** (Depakote)

Oral: 125, 250, 500 mg delayed-release tablets

**Lamotrigine** (Lamictal)

Oral: 2, 5, 25, 100, 150, 200 mg tablets

**Lithium carbonate** (generic, Eskalith) (Note: 300 mg lithium carbonate = 8.12 mEq Li<sup>+</sup>.)

Oral: 150, 300, 600 mg capsules; 300 mg tablets; 8 mEq/5 mL syrup

Oral sustained-release: 300, 450 mg tablets

**Topiramate** (Topamax)

Oral: 25, 50, 100, 200 mg tablets

**Valproic acid** (generic, Depakene)

Oral: 250 mg capsules; 250 mg/5 mL syrup

Basic and Clinical Pharmacology > Chapter 30. Antidepressant Agents >

## CASE STUDY

A 47-year-old woman presents to her primary care physician with a chief complaint of fatigue. She indicates that she was promoted to senior manager in her company approximately 11 months earlier. Although her promotion was welcome and came with a sizable raise in pay, it resulted in her having to move away from an office and group of colleagues she very much enjoyed. In addition, her level of responsibility increased dramatically. The patient reports that for the last 7 weeks, she has been waking up at 3 AM every night and being unable to go back to sleep. She dreads the day and the stresses of the workplace. As a consequence, she is not eating as well as she might and has dropped 7% of her body weight in the last 3 months. She also reports being so stressed that she breaks down crying in the office occasionally and has been calling in sick frequently. When she comes home, she finds she is less motivated to attend to chores around the house and has no motivation, interest, or energy to pursue recreational activities that she once enjoyed such as hiking. She describes herself as "chronically miserable and worried all the time." Her medical history is notable for chronic neck pain from a motor vehicle accident for which she is being treated with tramadol and meperidine. In addition, she is on hydrochlorothiazide and propranolol for hypertension. The patient has a history of one depressive episode after a divorce that was treated successfully with fluoxetine. Medical workup including complete blood cell count, thyroid function tests, and a chemistry panel reveals no abnormalities. She is started on fluoxetine for a presumed major depressive episode and referred for cognitive behavioral psychotherapy. What CYP450 and pharmacodynamic interactions might be associated with fluoxetine use in this patient? Which class of antidepressants would be contraindicated in this patient?

## ANTIDEPRESSANT AGENTS: INTRODUCTION

The diagnosis of depression still rests primarily on the clinical interview. Major depressive disorder (MDD) is characterized by depressed mood most of the time for at least 2 weeks and/or loss of interest or pleasure in most activities. In addition, depression is characterized by disturbances in sleep and appetite as well as deficits in cognition and energy. Thoughts of guilt, worthlessness, and suicide are common. Coronary artery disease, diabetes, and stroke appear to be more common in depressed patients, and depression may considerably worsen the prognosis for patients with a variety of comorbid medical conditions.

According to a 2007 report by the Centers for Disease Control and Prevention, antidepressant drugs were the most commonly prescribed medications in the USA at the time of the survey. The wisdom of such widespread use of antidepressants is debated. However, it is clear that American physicians have been increasingly inclined to use antidepressants to treat a host of conditions and that patients have been increasingly receptive to their use.

The primary indication for antidepressant agents is the treatment of MDD. Major depression, with a lifetime prevalence of around 17% in the USA and a point prevalence of 5%, is associated with substantial morbidity and mortality. MDD represents one of the most common causes of disability in the developed world. In addition, major depression is commonly associated with a variety of medical conditions—from chronic pain to coronary artery disease. When depression coexists with other medical conditions, the patient's disease burden increases, and the quality of life—and often the prognosis for effective

treatmentâ€”decreases significantly.

Some of the growth in antidepressant use may be related to the broad application of these agents for conditions other than major depression. For example, antidepressants have received FDA approvals for the treatment of panic disorder, generalized anxiety disorder (GAD), post-traumatic stress disorder (PTSD), and obsessive-compulsive disorder (OCD). In addition, antidepressants are commonly used to treat pain disorders such as neuropathic pain and the pain associated with fibromyalgia. Some antidepressants are used for treating premenstrual dysphoric disorder (PMDD), mitigating the vasomotor symptoms of menopause, and treating stress urinary incontinence. Thus, antidepressants have a broad spectrum of use in medical practice. However, their primary use remains the treatment for MDD.

### **Pathophysiology of Major Depression**

There has been a marked shift in the last decade in our understanding of the pathophysiology of major depression. In addition to the older idea that a deficit in function or amount of monoamines (the **monoamine hypothesis**) is central to the biology of depression, there is evidence that neurotrophic and endocrine factors play a major role (the **neurotrophic hypothesis**). Histologic studies, structural and functional brain imaging research, genetic findings, and steroid research all suggest a complex pathophysiology for MDD with important implications for drug treatment.

### **Neurotrophic Hypothesis**

There is substantial evidence that nerve growth factors such as **brain-derived neurotrophic factor (BDNF)** are critical in the regulation of neural plasticity, resilience, and neurogenesis. The evidence suggests that depression is associated with the loss of neurotrophic support and that effective antidepressant therapies increase neurogenesis and synaptic connectivity in cortical areas such as the hippocampus. BDNF is thought to exert its influence on neuronal survival and growth effects by activating the tyrosine kinase receptor B in both neurons and glia (Figure 30â€”1).

### **Figure 30â€”1**

The neurotrophic hypothesis of major depression. Changes in trophic factors (especially brain-derived neurotrophic factor, BDNF) and hormones appear to play a major role in the development of major depression (A). Successful treatment results in changes in these factors (B). CREB, cAMP response element-binding (protein). BDNF, brain-derived neurotrophic factor.

(Redrawn, with permission, from Nestler EJ: *Neurobiology of depression*. *Neuron* 2002;34[1]:13-25.)

Several lines of evidence support the neurotrophic hypothesis. Animal and human studies indicate that stress and pain are associated with a drop in BDNF levels and that this loss of neurotrophic support contributes to atrophic structural changes in the hippocampus and perhaps other areas such as the medial frontal cortex and anterior cingulate. The hippocampus is known to be important both in contextual memory and regulation of the hypothalamic-pituitary-adrenal (HPA) axis. Likewise, the anterior cingulate plays a role in the integration of emotional stimuli and attention functions, whereas the medial orbital frontal cortex is also thought to play a role in memory, learning, and emotion.

Over 30 structural imaging studies suggest that major depression is associated with a 5-10% loss of volume in the hippocampus, although some studies have not replicated this finding. Depression and chronic

stress states have also been associated with a substantial loss of volume in the anterior cingulate and medial orbital frontal cortex. Loss of volume in structures such as the hippocampus also appears to increase as a function of the duration of illness and the amount of time that the depression remains untreated.

Another source of evidence supporting the neurotrophic hypothesis of depression comes from studies of the direct effects of BDNF on emotional regulation. Direct infusion of BDNF into the midbrain, hippocampus, and lateral ventricles of rodents has an antidepressant-like effect in animal models. Moreover, all known classes of antidepressants are associated with an increase in BDNF levels in animal models with chronic (but not acute) administration. This increase in BDNF levels is consistently associated with increased neurogenesis in the hippocampus in these animal models. Other interventions thought to be effective in the treatment of major depression, including electroconvulsive therapy, also appear to robustly stimulate BDNF levels and hippocampus neurogenesis in animal models.

Human studies seem to support the animal data on the role of neurotrophic factors in stress states. Depression appears to be associated with a drop in BDNF levels in the cerebrospinal fluid and serum as well as with a decrease in tyrosine kinase receptor B activity. Conversely, administration of antidepressants increases BDNF levels in clinical trials and may be associated with an increase in hippocampus volume in some patients.

Much evidence supports the neurotrophic hypothesis of depression, but not all evidence is consistent with this concept. Animal studies in BDNF knockout mice have not always suggested an increase in depressive or anxious behaviors that would be expected with a deficiency of BDNF. In addition, some animal studies have found an increase in BDNF levels after some types of social stress and an increase rather than a decrease in depressive behaviors with lateral ventricle injections of BDNF.

A proposed explanation for the discrepant findings on the role of neurotrophic factors in depression is that there are polymorphisms for BDNF that may yield very different effects. Mutations in the *BDNF* gene have been found to be associated with altered anxiety and depressive behavior in both animal and human studies.

Thus, the neurotrophic hypothesis continues to be intensely investigated and has yielded new insights and potential targets in the treatment of MDD.

### **Monoamines and Other Neurotransmitters**

The monoamine hypothesis of depression (Figure 30â€²) suggests that depression is related to a deficiency in the amount or function of cortical and limbic serotonin (5-HT), norepinephrine (NE), and dopamine (DA).

**Figure 30â€²**

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 11th Edition: <http://www.accessmedicine.com>

Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

The amine hypothesis of major depression. Depression appears to be associated with changes in serotonin or norepinephrine signaling in the brain (or both) with significant downstream effects. Most antidepressants cause changes in amine signaling. AC, adenylyl cyclase; 5-HT, serotonin; CREB, cAMP response element-binding (protein); DAG, diacyl glycerol; IP<sub>3</sub>, inositol trisphosphate; MAO, monoamine oxidase; NET, norepinephrine transporter; PKC, protein kinase C; PLC, phospholipase C; SERT, serotonin transporter.

(Redrawn, with permission, from Belmaker R, Agam G: Major depressive disorder. *N Engl J Med* 2008;358:59.)

Evidence to support the monoamine hypothesis comes from several sources. It has been known for many years that reserpine treatment, which is known to deplete monoamines, is associated with depression in a

subset of patients. Similarly, depressed patients who respond to serotonergic antidepressants such as fluoxetine often rapidly suffer relapse when given diets free of tryptophan, a precursor of serotonin synthesis. Patients who respond to noradrenergic antidepressants such as desipramine are less likely to relapse on a tryptophan-free diet. However, depleting catecholamines in depressed patients who have previously responded to noradrenergic agents likewise tends to be associated with relapse. Administration of an inhibitor of norepinephrine synthesis is also associated with a rapid return of depressive symptoms in patients who respond to noradrenergic but not necessarily in patients who had responded to serotonergic antidepressants.

Another line of evidence supporting the monoamine hypothesis comes from genetic studies. A functional polymorphism exists for the promoter region of the serotonin transporter gene, which regulates how much of the transporter protein is available. Subjects who are homozygous for the s (short) allele may be more vulnerable to developing major depression and suicidal behavior in response to stress. In addition, homozygotes for the s allele may also be less likely to respond to and tolerate serotonergic antidepressants. Conversely, subjects with the l (long) allele tend to be more resistant to stress and may be more likely to respond to serotonergic antidepressants.

Studies of depressed patients have sometimes shown an alteration in monoamine function. For example, some studies have found evidence of alteration in serotonin receptor numbers (5-HT<sub>1A</sub> and 5-HT<sub>2C</sub>) or norepinephrine ( $\alpha_2$ ) receptors in depressed and suicidal patients, but these findings have not been consistent. A reduction in the primary serotonin metabolite 5-hydroxyindoleacetic acid in the cerebrospinal fluid is associated with violent and impulsive behavior, including violent suicide attempts. However, this finding is not specific to major depression and is associated more generally with violent and impulsive behavior.

Finally, perhaps the most convincing line of evidence supporting the monoamine hypothesis is the fact that (at the time of this writing) all available antidepressants appear to have significant effects on the monoamine system. All classes of antidepressants appear to enhance the synaptic availability of 5-HT, norepinephrine, or dopamine. Attempts to develop antidepressants that work on other neurotransmitter systems have not been effective to date.

The monoamine hypothesis, like the neurotrophic hypothesis, is at best incomplete. Many studies have not found an alteration in function or levels of monoamines in depressed patients. In addition, some candidate antidepressant agents under study do not act directly on the monoamine system. These include glutamate antagonists, melatonin agonists, and glucocorticoid-specific agents. Thus, monoamine function appears to be an important but not exclusive factor in the pathophysiology of depression.

### **Neuroendocrine Factors in the Pathophysiology of Depression**

Depression is known to be associated with a number of hormonal abnormalities. Among the most replicated of these findings are abnormalities in the HPA axis in patients with MDD. Moreover, MDD is associated with elevated cortisol levels (Figure 30-1), nonsuppression of adrenocorticotrophic hormone (ACTH) release in the dexamethasone suppression test, and chronically elevated levels of corticotropin-releasing hormone. The significance of these HPA abnormalities is unclear, but they are thought to indicate a dysregulation of the stress hormone axis. More severe types of depression, such as psychotic depression, tend to be associated with HPA abnormalities more commonly than milder forms of major depression. It is well known that both exogenous glucocorticoids and endogenous elevation of cortisol are associated with mood symptoms and cognitive deficits similar to those seen in MDD.

Thyroid dysregulation has also been reported in depressed patients. Up to 25% of depressed patients are reported to have abnormal thyroid function. These include a blunting of response of thyrotropin to

thyrotropin-releasing hormone, and elevations in circulating thyroxine during depressed states. Clinical hypothyroidism often presents with depressive symptoms, which resolve with thyroid hormone supplementation. Thyroid hormones are also commonly used in conjunction with standard antidepressants to augment therapeutic effects of the latter.

Finally, sex steroids are also implicated in the pathophysiology of depression. Estrogen deficiency states, which occur in the postpartum and postmenopausal periods, are thought to play a role in the etiology of depression in some women. Likewise, severe testosterone deficiency in men is sometimes associated with depressive symptoms. Hormone replacement therapy in hypogonadal men and women may be associated with an improvement in mood and depressive symptoms.

### **Integration of Hypotheses Regarding the Pathophysiology of Depression**

The several pathophysiologic hypotheses just described are not mutually exclusive. It is evident that the monoamine, neuroendocrine, and neurotrophic systems are interrelated in important ways. For example, HPA and steroid abnormalities may contribute to suppression of transcription of the *BDNF* gene. Glucocorticoid receptors are found in high density in the hippocampus. Binding of these hippocampal glucocorticoid receptors by cortisol during chronic stress states such as major depression may decrease BDNF synthesis and may result in volume loss in stress-sensitive regions such as the hippocampus. The chronic activation of monoamine receptors by antidepressants appears to have the opposite effect of stress and results in an increase in BDNF transcription. In addition, activation of monoamine receptors appears to down-regulate the HPA axis and may normalize HPA function.

One of the weaknesses of the monoamine hypothesis is the fact that amine levels increase immediately with antidepressant use, but maximum beneficial effects of antidepressants are not seen for many weeks. The time required to synthesize neurotrophic factors has been proposed as an explanation for this delay of antidepressant effects. Appreciable protein synthesis of products such as BDNF typically takes 2 weeks or longer and coincides with the clinical course of antidepressant treatment.

## **BASIC PHARMACOLOGY OF ANTIDEPRESSANTS**

### **Chemistry and Subgroups**

The currently available antidepressants make up a remarkable variety of chemical types. These differences and the differences in their molecular targets provide the basis for distinguishing several subgroups.

#### **SELECTIVE SEROTONIN REUPTAKE INHIBITORS**

The selective serotonin reuptake inhibitors (SSRIs) represent a chemically diverse class of agents that have as their primary action the inhibition of the serotonin transporter (SERT) (Figure 30-3). Fluoxetine was introduced in the United States in 1988 and quickly became one of the most commonly prescribed medications in medical practice. The development of fluoxetine emerged out of the search for chemicals that had high affinity for monoamine receptors but lacked the affinity for histamine, acetylcholine, and  $\alpha$  adrenoceptors that is seen with the tricyclic antidepressants (TCAs). There are currently six available SSRIs, and they are the most common antidepressants in clinical use. In addition to their use in major depression, SSRIs have indications in GAD, PTSD, OCD, panic disorder, PMDD, and bulimia. **Fluoxetine**, **sertraline**, and **citalopram** exist as isomers and are formulated in the racemic forms, whereas **paroxetine** and **fluvoxamine** are not optically active. **Escitalopram** is the *S* enantiomer of citalopram. As with all antidepressants, SSRIs are highly lipophilic. The popularity of SSRIs stems largely from their ease of use, safety in overdose, relative tolerability, cost (all except escitalopram are generically available), and broad spectrum of uses.

### **Figure 30-3**

Structures of several selective serotonin reuptake inhibitors.

### SEROTONIN-NOREPINEPHRINE REUPTAKE INHIBITORS

Two classes of antidepressants act as combined serotonin and norepinephrine reuptake inhibitors: selective **serotonin-norepinephrine reuptake inhibitors (SNRIs)** and **tricyclic antidepressants (TCAs)**.

#### Selective Serotonin-Norepinephrine Reuptake Inhibitors

The SNRIs include **venlafaxine**, its metabolite **desvenlafaxine**, and **duloxetine**. Another SNRI, **milnacipran**, is in late clinical trials in the USA but has been available in Europe for several years. In addition to their use in major depression, other applications of the SNRIs include the treatment of pain disorders including neuropathies and fibromyalgia. SNRIs are also used in the treatment of generalized anxiety, stress urinary incontinence, and vasomotor symptoms of menopause.

SNRIs are chemically unrelated to each other. Venlafaxine was discovered in the process of evaluating chemicals that inhibit binding of imipramine. Venlafaxine's in vivo effects are similar to those of imipramine but with a more favorable adverse-effect profile. All SNRIs bind the serotonin (SERT) and norepinephrine (NET) transporters, as do the TCAs. However, unlike the TCAs, the SNRIs do not have much affinity for other receptors. Venlafaxine and desvenlafaxine are bicyclic compounds, whereas duloxetine is a three-ring structure unrelated to the TCAs. Milnacipran contains a cyclopropane ring and is provided as a racemic mixture.

**Duloxetine**

R = CH<sub>3</sub> : **Venlafaxine**  
 R = H : **Desvenlafaxine**

#### Tricyclic Antidepressants

The TCAs were the dominant class of antidepressants until the introduction of SSRIs in the 1980s and 1990s. Nine TCAs are available in the USA, and they all have an iminodibenzyl (tricyclic) core (Figure 30â€4). The chemical differences between the TCAs are relatively subtle. For example, the prototype TCA **imipramine** and its metabolite, **desipramine**, differ by only a methyl group in the propylamine side chain. However, this minor difference results in a substantial change in their pharmacologic profiles. Imipramine is highly anticholinergic and is a relatively strong serotonin as well as norepinephrine reuptake inhibitor. In contrast, desipramine is much less anticholinergic and is a more potent and somewhat more selective norepinephrine reuptake inhibitor than is imipramine.

**Figure 30â€4**

Structures of the tricyclic antidepressants (TCAs).

At the present time, the TCAs are used primarily in depression that is unresponsive to more commonly used antidepressants such as the SSRIs or SNRIs. Their loss of popularity stems in large part from relatively poorer tolerability compared with newer agents, to difficulty of use, and to lethality in overdose. Other uses for TCAs include the treatment of pain conditions, enuresis, and insomnia.

### 5-HT<sub>2</sub> ANTAGONISTS

Two antidepressants are thought to act primarily as antagonists at the 5-HT<sub>2</sub> receptor: **trazodone** and **nefazodone**. Trazodone's structure includes a triazolo moiety that is thought to impart antidepressant effects. Its primary metabolite, m-chlorphenylpiperazine (m-cpp), is a potent 5-HT<sub>2</sub> antagonist. Trazodone was among the most commonly prescribed antidepressants until it was supplanted by the SSRIs in the late 1980s. The most common use of trazodone in current practice is as an unlabeled hypnotic, since it is highly sedating and not associated with tolerance or dependence.

Nefazodone is chemically related to trazodone. Its primary metabolites, hydroxynefazodone and m-cpp are both inhibitors of the 5-HT<sub>2</sub> receptor. Nefazodone received an FDA black box warning in 2001 implicating it in hepatotoxicity, including lethal cases of hepatic failure. Though still available generically, nefazodone is no longer commonly prescribed. The primary indications for both nefazodone and trazodone are major

depression, although both have also been used in the treatment of anxiety disorders.

#### TETRACYCLIC AND UNICYCLIC ANTIDEPRESSANTS

A number of antidepressants do not fit neatly into the other classes. Among these are **bupropion**, **mirtazapine**, **amoxapine**, and **maprotiline** (Figure 30â€5). Bupropion has a unicyclic aminoketone structure. Its unique structure results in a different side-effect profile than most antidepressants (described below). Bupropion somewhat resembles amphetamine in chemical structure and like the stimulant, has central nervous system (CNS) activating properties.

**Figure 30â€5**

Structures of the tetracyclics, amoxapine, maprotiline, and mirtazapine and the unicyclic, bupropion.

Mirtazapine was introduced in 1994 and, like bupropion, is one of the few antidepressants not commonly associated with sexual side effects. It has a tetracyclic chemical structure and belongs to the piperazinoazepine group of compounds.

Mirtazapine, amoxapine, and maprotiline have tetracyclic structures. Amoxapine is the *N*-methylated metabolite of loxapine, an older antipsychotic drug. Amoxapine and maprotiline share structural similarities and side effects comparable to the TCAs. As a result, these tetracyclics are not commonly prescribed in current practice. Their primary use is in MDD that is unresponsive to other agents.

### MONOAMINE OXIDASE INHIBITORS

Arguably the first modern class of antidepressants, monoamine oxidase inhibitors (MAOIs) were introduced in the 1950s but are now rarely used in clinical practice because of toxicity and potentially lethal food and drug interactions. Their primary use now is in the treatment of depression unresponsive to other antidepressants. However, MAOIs have also been used historically to treat anxiety states, including social anxiety and panic disorder. In addition, selegiline is used for the treatment of Parkinson's disease (see Chapter 28).

Current MAOIs include the hydrazine derivatives **phenelzine** and **isocarboxazid** and the non-hydrazines **tranylcypromine**, **selegiline**, and **moclobemide** (the latter is not available in the USA). The hydrazines and tranylcypromine bind irreversibly and nonselectively with MAO-A and -B, whereas other MAOIs may have more selective or reversible properties. Some of the MAOIs such as tranylcypromine resemble amphetamine in chemical structure, whereas other MAOIs such as selegiline have amphetamine-like metabolites. As a result, these MAOIs tend to have substantial CNS-stimulating effects.

**Phenzelzine**

**Tranylcypromine**

### Pharmacokinetics

The antidepressants share several pharmacokinetic features (Table 30â€"1). Most have fairly rapid oral absorption, achieve peak plasma levels within 2â€"3 hours, are tightly bound to plasma proteins, undergo hepatic metabolism, and are renally cleared. However, even within classes, the pharmacokinetics of individual antidepressants vary considerably.

**Table 30â€"1 Pharmacokinetic Profiles of Selected Antidepressants.**

Class, Drug	Bioavailability (%)	Plasma $t_{1/2}$ (hours)	Active Metabolite $t_{1/2}$ (hours)	Volume of Distribution (L/kg)	Protein Binding (%)

<sup>1</sup>Desvenlafaxine has similar properties but is less completely metabolized.

MAOIs, monoamine oxidase inhibitors; ND, no data found; SNRIs, serotonin-norepinephrine reuptake inhibitors; SSRIs, selective serotonin reuptake inhibitors.

**SELECTIVE SEROTONIN REUPTAKE INHIBITORS**

The prototype SSRI, fluoxetine, differs from other SSRIs in some important respects (Table 30â€"1). Fluoxetine is metabolized to an active product, norfluoxetine, which may have plasma concentrations greater than those of fluoxetine. The elimination half-life of norfluoxetine is about three times longer than fluoxetine and contributes to the longest half-life of all the SSRIs. As a result, fluoxetine has to be discontinued 4 weeks or longer before an MAOI can be administered to mitigate the risk of serotonin syndrome.

Fluoxetine and paroxetine are potent inhibitors of the CYP2D6 isoenzyme, and this contributes to potential drug interactions (see drug interactions). In contrast, fluvoxamine is an inhibitor of CYP3A4, whereas citalopram, escitalopram, and sertraline have more modest CYP interactions.

**SEROTONIN-NOREPINEPHRINE REUPTAKE INHIBITORS****Selective Serotonin-Norepinephrine Reuptake Inhibitors**

Venlafaxine is extensively metabolized in the liver via the CYP2D6 isoenzyme to *O*-desmethylvenlafaxine (desvenlafaxine). Both have similar half-lives of about 11 hours. Despite the relatively short half-lives, both drugs are available in formulations that allow once-daily dosing. Venlafaxine and desvenlafaxine have the lowest protein binding of all antidepressants (27â€"30%). Unlike most antidepressants, desvenlafaxine is conjugated and does not undergo extensive oxidative metabolism. At least 45% of desvenlafaxine is excreted unchanged in the urine compared with 4â€"8% of venlafaxine.

Duloxetine is well absorbed and has a half-life of about 12 hours but is dosed once daily. It is tightly bound to protein (97%) and undergoes extensive oxidative metabolism via CYP2D6 and CYP1A2. Hepatic impairment significantly alters duloxetine levels unlike desvenlafaxine.

**Tricyclic Antidepressants**

The TCAs tend to be well absorbed and have long half-lives (Table 30â€"1). As a result, most are dosed once daily at night because of their sedating effects. TCAs undergo extensive metabolism via demethylation, aromatic hydroxylation, and glucuronide conjugation. Only about 5% of TCAs are excreted unchanged in the urine. The TCAs are substrates of the CYP2D6 system, and the serum levels of these agents tend to be substantially influenced by concurrent administration of drugs such as fluoxetine. In addition, genetic polymorphism for CYP2D6 may result in low or extensive metabolism of the TCAs.

The secondary amine TCAs, including desipramine and nortriptyline, lack active metabolites and have fairly linear kinetics. These TCAs have a wide therapeutic window, and serum levels are reliable in predicting

response and toxicity.

### **5-HT<sub>2</sub> ANTAGONISTS**

Trazodone and nefazodone are rapidly absorbed and undergo extensive hepatic metabolism. Both drugs are extensively bound to protein and have limited bioavailability because of extensive metabolism. Their short half-lives generally require split dosing when used as antidepressants. However, trazodone is often prescribed as a single dose at night as a hypnotic in lower doses than are used in the treatment of depression. Both trazodone and nefazodone have active metabolites that also exhibit 5-HT<sub>2</sub> antagonism.

Nefazodone is a potent inhibitor of the CYP3A4 system and may interact with drugs metabolized by this enzyme (see Drug Interactions).

### **TETRACYCLIC AND UNICYCLIC AGENTS**

Bupropion is rapidly absorbed and has a mean protein binding of 85%. It undergoes extensive hepatic metabolism and has a substantial first-pass effect. It has three active metabolites including hydroxybupropion; the latter is being developed as an antidepressant. Bupropion has a biphasic elimination with the first phase lasting about 1 hour and the second phase lasting 14 hours.

Amoxapine is also rapidly absorbed with protein binding of about 85%. The half-life is variable, and the drug is often given in divided doses. Amoxapine undergoes extensive hepatic metabolism. One of the active metabolites, 7-hydroxyamoxapine, is a potent D<sub>2</sub> blocker and is associated with antipsychotic effects.

Maprotiline is similarly well absorbed orally and 88% bound to protein. It undergoes extensive hepatic metabolism.

Mirtazapine is demethylated followed by hydroxylation and glucuronide conjugation. Several CYP isozymes are involved in the metabolism of mirtazapine, including 2D6, 3A4, and 1A2. The half-life of mirtazapine is 20–40 hours, and it is usually dosed once in the evening because of its sedating effects.

### **MONOAMINE OXIDASE INHIBITORS**

The different MAOIs are metabolized via different pathways but tend to have extensive first-pass effects that may substantially decrease bioavailability. Tranylcypromine is ring hydroxylated and *N*-acetylated, whereas acetylation appears to be a minor pathway for phenelzine. Selegiline is *N*-demethylated and then hydroxylated. The MAOIs are well absorbed from the gastrointestinal tract.

Because of the prominent first-pass effects and their tendency to inhibit MAO in the gut (resulting in tyramine pressor effects), alternative routes of administration are being developed. For example, selegiline is available in both transdermal and sublingual forms that bypass both gut and liver. These routes decrease the risk of food interactions and provide substantially increased bioavailability.

### **Pharmacodynamics**

As previously noted, all currently available antidepressants enhance monoamine neurotransmission by one of several mechanisms. The most common mechanism is inhibition of the activity of SERT, NET, or both monoamine transporters (Table 30–2). Antidepressants that inhibit SERT, NET, or both include the SSRIs and SNRIs (by definition), and the TCAs. Another mechanism for increasing the availability of monoamines is inhibition of their enzymatic degradation (the MAOIs). Additional strategies for enhancing monoamine tone include binding presynaptic autoreceptors (mirtazapine) or specific postsynaptic receptors (5-HT<sub>2</sub> antagonists and mirtazapine). Ultimately, the increased availability of monoamines for binding in the synaptic cleft results in a cascade of events that enhance the transcription of some proteins and the inhibition of others. It is the net production of these proteins, including BDNF, glucocorticoid receptors, β-adrenoceptors, and other proteins that appears to determine the benefits as well as the toxicity of a given agent.

**Table 30-2 Antidepressant Effects on Several Receptors and Transporters.**

Antidepressant	ACh M	$\alpha_1$	H <sub>1</sub>	5-HT <sub>2</sub>	NET	SERT

ACh M, acetylcholine muscarinic receptor;  $\alpha_1$ ,  $\alpha_1$ -adrenoceptor; H<sub>1</sub>, histamine<sub>1</sub> receptor; 5-HT<sub>2</sub>, serotonin 5-HT<sub>2</sub> receptor; NET, norepinephrine transporter; SERT, serotonin transporter. 0/+, minimal affinity; +, mild affinity; ++, moderate affinity; +++, high affinity.

#### SELECTIVE SEROTONIN REUPTAKE INHIBITORS

The serotonin transporter (SERT) is a glycoprotein with 12 transmembrane regions embedded in the axon terminal and cell body membranes of serotonergic neurons. When extracellular serotonin binds to receptors on the transporter, conformational changes occur in the transporter and serotonin, Na<sup>+</sup>, and Cl<sup>-</sup> are moved into the cell. Binding of intracellular K<sup>+</sup> then results in return of the transporter to its original conformation and the release of serotonin inside the cell. SSRIs allosterically inhibit the transporter by binding the receptor at a site other than active binding site for serotonin. At therapeutic doses, about 80% of the activity of the transporter is inhibited. Functional polymorphisms exist for SERT that determine the activity of the transporter.

SSRIs have modest effects on other neurotransmitters. Unlike TCAs and SNRIs, there is little evidence that SSRIs have prominent effects on  $\beta$  adrenoceptors or the norepinephrine transporter, NET. Binding to the

serotonin transporter is associated with tonic inhibition of the dopamine system, although there is substantial interindividual variability in this effect. The SSRIs do not bind aggressively to histamine, muscarinic, or other receptors.

### **DRUGS THAT BLOCK BOTH SEROTONIN AND NOREPINEPHRINE TRANSPORTERS**

A large number of antidepressants have mixed inhibitory effects on both serotonin and norepinephrine transporters. The newer agents in this class (venlafaxine and duloxetine) are denoted by the acronym SNRIs, whereas the older group (tricyclic antidepressants) are termed TCAs.

#### **Serotonin-Norepinephrine Reuptake Inhibitors**

SNRIs bind both the serotonin and the norepinephrine transporters. The NET is structurally very similar to the 5-HT transporter. Like the serotonin transporter, it is a 12-transmembrane domain complex that allosterically binds norepinephrine. The NET also has a moderate affinity for dopamine.

Venlafaxine is a weak inhibitor of NET, whereas desvenlafaxine, duloxetine, and milnacipran are more balanced inhibitors of both SERT and NET. Nonetheless, the affinity of most SNRIs tends to be much greater for SERT than for NET. The SNRIs differ from the TCAs in that they lack the potent antihistamine,  $\alpha$ -adrenergic blocking, and anticholinergic effects of the TCAs. As a result, the SNRIs tend to be favored over the TCAs in the treatment of MDD and pain syndromes because of their better tolerability.

#### **Tricyclic Antidepressants**

The TCAs resemble the SNRIs in function, and their antidepressant activity is thought to relate primarily to their inhibition of 5-HT and norepinephrine reuptake. Within the TCAs, there is considerable variability in affinity for SERT versus NET. For example, clomipramine has relatively very little affinity for NET but potently binds SERT. This selectivity for the serotonin transporter contributes to clomipramine's known benefits in the treatment of OCD. On the other hand, the secondary amine TCAs, desipramine and nortriptyline, are relatively more selective for NET. Although the tertiary amine TCA imipramine has more serotonin effects initially, its metabolite, desipramine, then balances this effect with more NET inhibition.

Common adverse effects of the TCAs, including dry mouth and constipation, are attributable to the potent antimuscarinic effects of many of these drugs. The TCAs also tend to be potent antagonists of the histamine  $H_1$  receptor. TCAs such as doxepin are sometimes prescribed as hypnotics and used in treatments for pruritus because of their antihistamine properties. The blockade of  $\alpha$  adrenoceptors can result in substantial orthostatic effects, particularly in older patients.

### **5-HT<sub>2</sub> ANTAGONISTS**

The principle action of both nefazodone and trazodone appears to be blockade of the 5-HT<sub>2A</sub> receptor. Inhibition of this receptor in both animal and human studies is associated with substantial antianxiety, antipsychotic, and antidepressant effects. Conversely, agonists of the 5-HT<sub>2A</sub> receptor, eg, lysergic acid (LSD) and mescaline, are often hallucinogenic and anxiogenic. The 5-HT<sub>2A</sub> receptor is a G protein-coupled receptor and is distributed throughout the neocortex.

Nefazodone is a weak inhibitor of both SERT and NET but is a potent antagonist of the postsynaptic 5-HT<sub>2A</sub> receptor, as are its metabolites. Trazodone is also a weak but selective inhibitor of SERT with little effect on NET. Its primary metabolite, m-cpp, is a potent 5-HT<sub>2</sub> antagonist, and much of trazodone's benefits as an antidepressant might be attributed to this effect. Trazodone also has weak-to-moderate presynaptic  $\alpha$ -adrenergic blocking properties and is a modest antagonist of the  $H_1$  receptor.

### **TETRACYCLIC AND UNICYCLIC ANTIDEPRESSANTS**

The actions of bupropion remain poorly understood. Bupropion and its major metabolite hydroxybupropion are modest-to-moderate inhibitors of norepinephrine and dopamine reuptake in animal studies. However,

these effects seem less than are typically associated with antidepressant benefit. A more significant effect of bupropion is presynaptic release of catecholamines. In animal studies, bupropion appears to substantially increase the presynaptic availability of norepinephrine and dopamine to a lesser extent. Bupropion has virtually no direct effects on the serotonin system.

Mirtazapine has a complex pharmacology. It is an antagonist of the presynaptic  $\alpha_2$  autoreceptor and enhances the release of both norepinephrine and 5-HT. In addition, mirtazapine is an antagonist of 5-HT<sub>2</sub> and 5-HT<sub>3</sub> receptors. Finally, mirtazapine is a potent H<sub>1</sub> antagonist, which is associated with the drug's sedative effects.

The actions of amoxapine and maprotiline resemble those of TCAs such as desipramine. Both are potent NET inhibitors and less potent SERT inhibitors. In addition, both possess anticholinergic properties. Unlike the TCAs or other antidepressants, amoxapine is a moderate inhibitor of the postsynaptic D<sub>2</sub> receptor. As such, amoxapine possesses some antipsychotic properties.

### **MONOAMINE OXIDASE INHIBITORS**

MAOIs act by mitigating the actions of monoamine oxidase in the neuron and increasing monoamine content. There are two forms of monoamine oxidase. MAO-A is present in both dopamine and norepinephrine neurons and is found primarily in the brain, gut, placenta, and liver; its primary substrates are norepinephrine, epinephrine, and serotonin. MAO-B is found primarily in serotonergic and histaminergic neurons and is distributed in the brain, liver, and platelets. MAO-B acts primarily on tyramine, phenylethylamine, and benzylamine. Both MAO-A and -B metabolize tryptamine and dopamine.

MAOIs are classified by their specificity for MAO-A or -B and whether their effects are reversible or irreversible. Phenelzine and tranylcypromine are examples of irreversible, nonselective MAOIs. Moclobemide is a reversible and selective inhibitor of MAO-A but is not available in the USA. Moclobemide can be displaced from MAO-A by tyramine, and this mitigates the risk of food interactions. In contrast, selegiline is an irreversible MAO-B-specific agent at low doses. Selegiline is useful in the treatment of Parkinson's disease at these low doses, but at higher doses it becomes a nonselective MAOI similar to other agents.

## **CLINICAL PHARMACOLOGY OF ANTIDEPRESSANTS**

### **Clinical Indications**

#### **DEPRESSION**

The FDA indication for the use of the antidepressants in the treatment of major depression is fairly broad. Most antidepressants are approved for both acute and long-term treatment of major depression. Acute episodes of MDD tend to last about 6–14 months untreated but at least 20% of episodes last 2 years or longer.

The goal of acute treatment of MDD is remission of all symptoms. Since antidepressants may not achieve their maximum benefit for 1–2 months or longer, it is not unusual for a trial of therapy to last 8–12 weeks at therapeutic doses. The antidepressants are successful in achieving remission in about 30–40% of patients within a single trial of 8–12 weeks. If an inadequate response is obtained, therapy is often switched to another agent or augmented by addition of another drug. For example, bupropion, an atypical antipsychotic, or mirtazapine might be added to an SSRI or SNRI to augment antidepressant benefit if monotherapy is unsuccessful. Seventy to eighty percent of patients are able to achieve remission with sequenced augmentation or switching strategies. Once an adequate response is achieved, continuation therapy is recommended for a minimum of 6–12 months to reduce the substantial risk of relapse.

Approximately 85% of patients who have a single episode of MDD will have at least one recurrence in a lifetime. Many patients have multiple recurrences, and these recurrences may progress to more serious,

chronic, and treatment-resistant episodes. Thus, it is not unusual for patients to require maintenance treatment to prevent recurrences. Although maintenance treatment studies of more than 5 years are uncommon, long-term studies with TCAs, SNRIs, and SSRIs suggest a significant protective benefit when given chronically. Thus, it is commonly recommended that patients be considered for long-term maintenance treatment if they have had two or more serious MDD episodes in the previous 5 years or three or more serious episodes in a lifetime.

It is not clear whether antidepressants are useful for all subtypes of depression. For example, patients with bipolar depression may not benefit much from antidepressants even when added to mood stabilizers. In fact, the antidepressants are sometimes associated with switches into mania or more rapid cycling. There has also been some debate about the overall efficacy of antidepressants in unipolar depression, with some meta-analyses showing large effects and others showing more modest effects. Although this debate is not likely to be settled immediately, there is little debate that antidepressants have important benefits for most patients.

Psychotherapeutic interventions such as cognitive behavior therapy appear to be as effective as antidepressant treatment for mild to moderate forms of depression. However, cognitive behavior therapy tends to take longer to be effective and is generally more expensive than antidepressant treatment. Psychotherapy is often combined with antidepressant treatment, and the combination appears more effective than either strategy alone.

### **ANXIETY DISORDERS**

After major depression, anxiety disorders represent the most common application of antidepressants. A number of SSRIs and SNRIs have been approved for all the major anxiety disorders, including PTSD, OCD, social anxiety disorder, GAD, and panic disorder. Panic disorder is characterized by recurrent episodes of brief overwhelming anxiety, which often occur without precipitant. Patients may begin to fear having an attack, or they avoid situations in which they might have an attack. In contrast, GAD is characterized by a chronic, free-floating anxiety and undue worry that tends to be chronic in nature. Although older antidepressants and drugs of the sedative-hypnotic class are still occasionally used for the treatment of anxiety disorders, SSRIs and SNRIs have largely replaced them.

The benzodiazepines (see Chapter 22) provide much more rapid relief of both generalized anxiety and panic than do any of the antidepressants. However, the antidepressants appear to be at least as effective and perhaps more effective than benzodiazepines in the long-term treatment of these anxiety disorders. Furthermore, antidepressants do not carry the risks of dependence and tolerance that may occur with the benzodiazepines.

OCD is known to respond to serotonergic antidepressants. It is characterized by repetitive anxiety-provoking thoughts (obsessions) or repetitive behaviors aimed at reducing anxiety (compulsions). Clomipramine and several of the SSRIs are approved for the treatment of OCD, and they are moderately effective. Behavior therapy is usually combined with the antidepressant for additional benefits.

Social anxiety disorder is an uncommonly diagnosed but a fairly common condition in which the patient experiences severe anxiety in social interactions. This anxiety may limit their ability to function adequately in their jobs or interpersonal relationships. Several SSRIs and venlafaxine are approved for the treatment of social anxiety. The efficacy of the SSRIs in the treatment of social anxiety is greater in some studies than their efficacy in the treatment of MDD.

PTSD is manifested when a traumatic or life-threatening event results in intrusive anxiety-provoking thoughts or imagery, hypervigilance, nightmares, and avoidance of situations that remind the patient of the trauma. SSRIs are considered first-line treatment for PTSD and can benefit a number of symptoms including anxious thoughts and hypervigilance. Other treatments, including psychotherapeutic

interventions, are usually required in addition to antidepressants.

### **PAIN DISORDERS**

It has been known for over 40 years that antidepressants possess analgesic properties independent of their mood effects. TCAs have been used in the treatment of neuropathic and other pain conditions since the 1960s. Medications that possess both norepinephrine and 5-HT reuptake blocking properties are often useful in treating pain disorders. Ascending corticospinal monoamine pathways appear to be important in the endogenous analgesic system. In addition, chronic pain conditions are commonly associated with major depression. TCAs continue to be commonly used for some of these conditions, and SNRIs are increasingly used. The SNRI duloxetine was the first antidepressant to secure FDA approval for the treatment of pain associated with diabetic neuropathy and fibromyalgia. Other SNRIs, eg, desvenlafaxine and milnacipran, are being investigated for a variety of pain conditions from postherpetic neuralgia to chronic back pain.

### **PREMENSTRUAL DYSPHORIC DISORDER**

Approximately 5% of women in the child-bearing years will have prominent mood and physical symptoms during the late luteal phase of almost every cycle; these may include anxiety, depressed mood, irritability, insomnia, fatigue, and a variety of other physical symptoms. These symptoms are more severe than those typically seen in premenstrual syndrome (PMS) and can be quite disruptive to vocational and interpersonal activities. The SSRIs are known to be beneficial to many women with PMDD, and fluoxetine and sertraline have been approved for this indication. Treating for 2 weeks out of the month in the luteal phase may be as effective as continuous treatment. The rapid effects of SSRIs in PMDD may be associated with rapid increases in pregnenolone levels.

### **SMOKING CESSATION**

Bupropion was approved in 1997 as a treatment for smoking cessation. Approximately twice as many people treated with bupropion as with placebo have a reduced urge to smoke. In addition, patients taking bupropion appear to experience fewer mood symptoms and possibly less weight gain while withdrawing from nicotine dependence. Bupropion appears to be about as effective as nicotine patches in smoking cessation. The mechanism by which bupropion is helpful in this application is unknown, but the drug may mimic nicotine's effects on dopamine and norepinephrine and may antagonize nicotinic receptors. Nicotine is also known to have antidepressant effects in some people, and bupropion may substitute for this effect.

Other antidepressants may also have a role in the treatment of smoking cessation. Nortriptyline has been shown to be helpful in smoking cessation, but the effects have not been as consistent as those seen with bupropion.

### **EATING DISORDERS**

Bulimia nervosa and anorexia nervosa are potentially devastating disorders. Bulimia is characterized by episodic intake of large amounts of food (binges) followed by ritualistic purging through emesis, the use of laxatives, or other methods. Medical complications of the purging, such as hypokalemia, are common and dangerous. Anorexia is a disorder in which reduced food intake results in a loss of weight of 15% or more of ideal body weight, and the person has a morbid fear of gaining weight and a highly distorted body image. Anorexia is often chronic and may be fatal in 10% or more cases.

Antidepressants appear to be helpful in the treatment of bulimia but not anorexia. Fluoxetine was approved for the treatment of bulimia in 1996, and other antidepressants have shown benefit in reducing the binge-purge cycle. The primary treatment for anorexia at this time is refeeding, family therapy, and cognitive behavioral therapy.

Bupropion may have some benefits in treating obesity. Nondepressed, obese patients treated with bupropion were able to lose somewhat more weight and maintain the loss relative to a similar population treated with placebo. However, the weight loss was not robust, and there appear to be more effective

options for weight loss.

### **OTHER USES FOR ANTIDEPRESSANTS**

Antidepressants are used for many other on- and off-label applications. Enuresis in children is an older labeled use for some TCAs, but they are less commonly used now because of their side effects. The SNRI duloxetine is approved in Europe for the treatment of urinary stress incontinence. Many of the serotonergic antidepressants appear to be helpful for treating vasomotor symptoms in perimenopause. Desvenlafaxine is under consideration for FDA approval for the treatment of these vasomotor symptoms, and studies have suggested that SSRIs, venlafaxine, and nefazodone may also provide benefit. Although serotonergic antidepressants are commonly associated with inducing sexual adverse effects, some of these effects might prove useful for some sexual disorders. For example, SSRIs are known to delay orgasm in some patients. For this reason, SSRIs are sometimes used to treat premature ejaculation. In addition, bupropion has been used to treat sexual adverse effects associated with SSRI use, although its efficacy for this use has not been consistently demonstrated in controlled trials.

### **Choosing an Antidepressant**

The choice of an antidepressant depends first on the indication. Not all conditions are equally responsive to all antidepressants. However, in the treatment of MDD, it is difficult to demonstrate that one antidepressant is consistently more effective than another. Thus, the choice of an antidepressant for the treatment of depression rests primarily on practical considerations such as cost, availability, adverse effects, potential drug interactions, the patient's history of response or lack thereof, and patient preference. Other factors such as the patient's age, gender, and medical status may also guide antidepressant selection. For example, older patients are particularly sensitive to the anticholinergic effects of the TCAs. On the other hand, the CYP3A4-inhibiting effects of the SSRI fluvoxamine may make this a problematic choice in some older patients because fluvoxamine may interact with many other medications that an older patient may require. There is some suggestion that female patients may respond to and tolerate serotonergic better than noradrenergic or TCA antidepressants, but the data supporting this gender difference have not been consistent. Patients with narrow-angle glaucoma may have an exacerbation with noradrenergic antidepressants, whereas bupropion and other antidepressants are known to lower the seizure threshold in epilepsy patients.

At present, SSRIs are the most commonly prescribed first-line agents in the treatment of both MDD and anxiety disorders. Their popularity comes from their ease of use, tolerability, and safety in overdose. The starting dose of the SSRIs is usually the same as the therapeutic dose for most patients, and so titration may not be required. In addition, most SSRIs are now generically available and inexpensive. Other agents, including the SNRIs, bupropion, and mirtazapine, are also reasonable first-line agents for the treatment of MDD. Bupropion, mirtazapine, and nefazodone are the antidepressants with the least association with sexual side effects and are often prescribed for this reason. However, bupropion is not thought to be effective in the treatment of the anxiety disorders and may be poorly tolerated in anxious patients. The primary indication for bupropion is in the treatment of major depression, including seasonal (winter) depression. Off-label uses of bupropion include the treatment of attention deficit hyperkinetic disorder (ADHD), and bupropion is commonly combined with other antidepressants to augment therapeutic response. The primary indication for mirtazapine is in the treatment of major depression. However, its strong antihistamine properties have contributed to its occasional use as a hypnotic and as an adjunctive treatment to more activating antidepressants.

The TCAs and MAOIs are now relegated to second- or third-line treatments for MDD. Both the TCAs and MAOIs are potentially lethal in overdose, require titration to achieve a therapeutic dose, have serious drug interactions, and have many troublesome adverse effects. As a consequence, their use in the treatment of MDD or anxiety is now reserved for patients who have been unresponsive to other agents. Clearly, there

are patients whose depression responds only to MAOIs or TCAs. Thus, TCAs and MAOIs are probably underused in treatment-resistant depressed patients.

The use of antidepressants outside the treatment of MDD tends to require specific agents. For example, the TCAs and SNRIs appear to be useful in the treatment of pain conditions, but other antidepressant classes appear to be far less effective. SSRIs and the highly serotonergic TCA, clomipramine, are effective in the treatment of OCD, but noradrenergic antidepressants have not proved to be as helpful for this condition. Bupropion and nortriptyline have usefulness in the treatment of smoking cessation, but SSRIs have not been proven useful. Thus, outside the treatment of depression, the choice of antidepressant is primarily dependent on the known benefit of a particular antidepressant or class for a particular indication.

## Dosing

The optimal dose of an antidepressant depends on the indication and on the patient. For SSRIs, SNRIs, and a number of newer agents, the starting dose for the treatment of depression is usually a therapeutic dose (Table 30-3). Patients who show little or no benefit after at least 4 weeks of treatment may benefit from a higher dose even though it has been difficult to show a clear advantage for higher doses with SSRIs, SNRIs, and other newer antidepressants. The dose is generally titrated to the maximum dosage recommended or to the highest dosage tolerated if the patient is not responsive to lower doses. Some patients may benefit from doses lower than the usual minimum recommended therapeutic dose. TCAs and MAOIs typically require titration to a therapeutic dosage over several weeks. Dosing of the TCAs may be guided by monitoring TCA serum levels.

**Table 30-3 Antidepressant Dose Ranges.**

<b>Drug</b>	<b>Usual Therapeutic Dosage (mg/d)</b>
<b>SSRIs</b>	
Citalopram	20-60
Escitalopram	10-30
Fluoxetine	20-60
Fluvoxamine	100-300
Paroxetine	20-60
Sertraline	50-200
<b>SNRIs</b>	
Venlafaxine	75-375
Desvenlafaxine	50-200
Duloxetine	40-120
<b>Tricyclics</b>	
Amitriptyline	150-300
Clomipramine	100-250
Desipramine	150-300
Doxepin	150-300
Imipramine	150-300
Nortriptyline	50-150
Protriptyline	15-60

Trimipramine maleate	150â€”300
----------------------	-----------

### **5-HT<sub>2</sub> antagonists**

Nefazodone	300â€”500
------------	-----------

Trazodone	150â€”300
-----------	-----------

### **Tetracyclics and unicyclics**

Amoxapine	150â€”400
-----------	-----------

Bupropion	200â€”450
-----------	-----------

Maprotiline	150â€”225
-------------	-----------

Mirtazapine	15â€”45
-------------	---------

### **MAOIs**

Isocarboxazid	30â€”60
---------------	---------

Phenelzine	45â€”90
------------	---------

Selegiline	20â€”50
------------	---------

Tranylcypromine	30â€”60
-----------------	---------

MAOIs, monoamine oxidase inhibitors; SNRIs, serotonin-norepinephrine reuptake inhibitors; SSRIs, selective serotonin reuptake inhibitors.

Some anxiety disorders may require higher doses of antidepressants than are used in the treatment of major depression. For example, patients treated for OCD often require maximum or somewhat higher than maximum recommended MDD doses to achieve optimal benefits. Likewise, the minimum dose of paroxetine for the effective treatment of panic disorder is higher than the minimum dose required for the effective treatment of depression.

In the treatment of pain disorders, modest doses of TCAs are often sufficient. For example, 25â€”50 mg/d of imipramine might be beneficial in the treatment of pain associated with a neuropathy but this would be a subtherapeutic dose in the treatment of MDD. In contrast, SNRIs are usually prescribed in pain disorders at the same doses used in the treatment of depression.

### **Adverse Effects**

Although some potential adverse effects are common to all antidepressants, most of their adverse effects are specific to a subclass of agents and to their pharmacodynamic effects. An FDA warning applied to all antidepressants is the risk of increased suicidality in patients under the age 25. The warning suggests that use of antidepressants is associated with suicidal ideation and gestures, but not completed suicides, in up to 4% of patients under 25 years who were prescribed antidepressant in clinical trials. This rate is about twice the rate seen with placebo treatment. For those over 25, there is either no increased risk, or a reduced risk of suicidal thoughts and gestures on antidepressants, particularly after age 65. Although a small minority of patients may experience a treatment-emergent increase in suicidal ideation with antidepressants, the absence of treatment of a major depressive episode in all age groups is a particularly important risk factor in completed suicides.

### **SELECTIVE SEROTONIN REUPTAKE INHIBITORS**

The adverse effects of the most commonly prescribed antidepressantsâ€”the SSRIsâ€”can be predicted from their potent inhibition of SERT. SSRIs enhance serotonergic tone, not just in the brain but throughout

the body. Increased serotonergic activity in the gut is commonly associated with nausea, gastrointestinal upset, diarrhea, and other gastrointestinal symptoms. Gastrointestinal adverse effects usually emerge early in the course of treatment and tend to improve after the first week. Increasing serotonergic tone at the level of the spinal cord and above is associated with diminished sexual function and interest. As a result, at least 30%–40% of patients treated with SSRIs report loss of libido, delayed orgasm, or diminished arousal. The sexual effects often persist as long as the patient remains on the antidepressant but may diminish with time.

Other adverse effects related to the serotonergic effects of SSRIs include an increase in headaches and insomnia or hypersomnia. Some patients gain weight while taking SSRIs, particularly paroxetine. Sudden discontinuation of short half-life SSRIs such as paroxetine and sertraline is associated with a discontinuation syndrome in some patients characterized by dizziness, paresthesias, and other symptoms beginning 1 or 2 days after stopping the drug and persisting for 1 week or longer.

#### **SEROTONIN-NOREPINEPHRINE REUPTAKE INHIBITORS AND TRICYCLIC ANTIDEPRESSANTS**

SNRIs have many of the serotonergic adverse effects associated with SSRIs. In addition, SNRIs may also have noradrenergic effects, including increased blood pressure and heart rate, and CNS activation, such as insomnia, anxiety, and agitation. The hemodynamic effects of SNRIs tend not to be problematic in most patients. A dose-related increase in blood pressure has been seen more commonly with the immediate-release form of venlafaxine than with other SNRIs. Likewise, there are more reports of cardiac toxicity with venlafaxine overdose than with either the other SNRIs or SSRIs. Duloxetine is rarely associated with hepatic toxicity in patients with a history of liver damage. All the SNRIs have been associated with a discontinuation syndrome resembling that seen with SSRI discontinuation.

The primary adverse effects of TCAs have been described in the previous text. Anticholinergic effects are perhaps the most common. These effects result in dry mouth, constipation, urinary retention, blurred vision, and confusion. They are more common with tertiary amine TCAs such as amitriptyline and imipramine than with the secondary amine TCAs desipramine and nortriptyline. The potent  $\alpha$ -blocking property of TCAs often results in orthostatic hypotension.  $H_1$  antagonism by the TCAs is associated with weight gain and sedation. The TCAs are class 1A antiarrhythmic agents (see Chapter 14) and are arrhythmogenic at higher doses. Sexual effects are common, particularly with highly serotonergic TCAs such as clomipramine. The TCAs have a prominent discontinuation syndrome characterized by cholinergic rebound and flu-like symptoms.

#### **5-HT<sub>2</sub> ANTAGONISTS**

The most common adverse effects associated with the 5-HT<sub>2</sub> antagonists are sedation and gastrointestinal disturbances. Sedative effects, particularly with trazodone, can be quite pronounced. Thus, it is not surprising that the treatment of insomnia is currently the primary application of trazodone. The gastrointestinal effects appear to be dose-related and are less pronounced than those seen with SNRIs or SSRIs. Sexual effects are uncommon with nefazodone or trazodone treatment as a result of the relatively selective serotonergic effects of these drugs on the 5-HT<sub>2</sub> receptor rather than on SERT. However, trazodone has rarely been associated with inducing priapism. The effects of both nefazodone and trazodone since  $\alpha$ -blocking agents result in a dose-related orthostatic hypotension in some patients. Nefazodone has been associated with hepatotoxicity, including rare fatalities and cases of fulminant hepatic failure requiring transplantation. The rate of serious hepatotoxicity with nefazodone has been estimated at 1 in 250,000 to 1 in 300,000 patient-years of nefazodone treatment.

#### **TETRACYCLICS AND UNICYCLICS**

Amoxapine is sometimes associated with a parkinsonian syndrome due to its D<sub>2</sub>-blocking action.

Mirtazapine has significant sedative effect. Maprotiline has a high affinity for NET, may cause TCA-like

adverse effects and, rarely, seizures. Bupropion is occasionally associated with agitation, insomnia, and anorexia.

### **MONOAMINE OXIDASE INHIBITORS**

The most common adverse effects of the MAOIs leading to discontinuation of these drugs are orthostatic hypotension and weight gain. In addition, the irreversible nonselective MAOIs are associated with the highest rates of sexual effects of all the antidepressants. Anorgasmia is fairly common with therapeutic doses of some MAOIs. The amphetamine-like properties of some MAOIs contribute to activation, insomnia, and restlessness in some patients. Phenelzine tends to be more sedating than either selegiline or tranylcypromine. Confusion is also sometimes associated with higher doses of MAOIs. Because they block metabolism of tyramine and similar ingested amines, MAOIs may cause dangerous interactions with certain foods and with serotonergic drugs (see Interactions). Finally, MAOIs have been associated with a sudden discontinuation syndrome manifested in a delirium-like presentation with psychosis, excitement, and confusion.

### **Overdose**

Suicide attempts are a common and unfortunate consequence of major depression. The lifetime risk of completing suicide in patients previously hospitalized with MDD may be as high as 15%. Overdose is the most common method used in suicide attempts, and antidepressants, especially the TCAs, are frequently involved. Overdose can induce lethal arrhythmias, including ventricular tachycardia and fibrillation. In addition, blood pressure changes and anticholinergic effects including altered mental status and seizures are sometimes seen in TCA overdoses. A 1500 mg dose of imipramine or amitriptyline (less than 7 days' supply at antidepressant doses) is enough to be lethal in many patients. Toddlers taking 100 mg will likely show evidence of toxicity. Treatment typically involves cardiac monitoring, airway support, and gastric lavage. Sodium bicarbonate is often administered to uncouple the TCA from cardiac sodium channels.

An overdose with an MAOI can produce a variety of effects including autonomic instability, hyperadrenergic symptoms, psychotic symptoms, confusion, delirium, fever, and seizures. Management of MAOI overdoses usually involves cardiac monitoring, vital support, and lavage.

Compared with TCAs and MAOIs, the other antidepressants are generally much safer in overdose. Fatalities with SSRI overdose alone are extremely uncommon. Similarly, SNRIs tend to be much safer in overdose than the TCAs. However, venlafaxine has been associated with some cardiac toxicity in overdose and appears to be less safe than SSRIs. Bupropion is associated with seizures in overdose, and mirtazapine may be associated with sedation, disorientation, and tachycardia. With the newer agents, fatal overdoses often involve the combination of the antidepressant with other drugs, including alcohol. Management of overdose with the newer antidepressants usually uses emptying of gastric contents and vital sign support as the initial intervention.

### **Drug Interactions**

Antidepressants are commonly prescribed with other psychotropic and nonpsychotropic agents. There is potential for drug interactions with all antidepressants, but the most serious of these involve the MAOIs and to a lesser extent the TCAs.

### **SELECTIVE SEROTONIN REUPTAKE INHIBITORS**

The most common interactions with SSRIs are pharmacokinetic interactions. For example, paroxetine and fluoxetine are potent CYP2D6 inhibitors (Table 30-4). Thus, administration with 2D6 substrates such as TCAs can lead to dramatic and sometimes unpredictable elevations in the tricyclic drug concentration. The result may be toxicity from the TCA. Similarly, fluvoxamine, a CYP3A4 inhibitor, may elevate the levels of concurrently administered substrates for this enzyme such as diltiazem and induce bradycardia or hypotension. Other SSRIs, such as citalopram and escitalopram, are relatively free of pharmacokinetic

interactions. The most serious interaction with the SSRIs are pharmacodynamic interactions with MAOIs that produce a serotonin syndrome (see below).

**Table 30â€”4 Antidepressantâ€”CYP450 Drug Interactions.**

<b>Enzyme</b>	<b>Substrates</b>	<b>Inhibitors</b>	<b>Inducers</b>
1A2	Tertiary amine TCAs, duloxetine, theophylline, phenacetin, TCAs (demethylation), clozapine, diazepam, caffeine	Fluvoxamine, fluoxetine, moclobemide, ramelteon	Tobacco, omeprazole
2C19	TCAs, citalopram (partly), warfarin, tolbutamide, phenytoin, diazepam	Fluoxetine, fluvoxamine, sertraline, imipramine, ketoconazole, omeprazole	Rifampin
2D6	Tricyclic antidepressants (TCAs), benztropine, perphenazine, clozapine, haloperidol, codeine/oxycodone, risperidone, class Ic antiarrhythmics, ß blockers, trazodone, paroxetine, maprotiline, amoxapine, duloxetine, mirtazapine (partly), venlafaxine, bupropion	Fluoxetine, paroxetine, duloxetine, hydroxybupropion, methadone, cimetidine, haloperidol, quinidine, ritonavir	Phenobarbital, rifampin
3A4	Citalopram, escitalopram, TCAs, glucocorticoids, androgens/estrogens, carbamazepine, erythromycin, Ca <sup>2+</sup> channel blockers, protease inhibitors, sildenafil, alprazolam, triazolam, vincristine/vinblastine, tamoxifen, zolpidem	Fluvoxamine, nefazodone, sertraline, fluoxetine, cimetidine, fluconazole, erythromycin, protease inhibitors, ketoconazole, verapamil	Barbiturates, glucocorticoids, rifampin, modafinil, carbamazepine

#### **SELECTIVE SEROTONIN-NOREPINEPHRINE REUPTAKE INHIBITORS AND TRICYCLIC ANTIDEPRESSANTS**

The SNRIs have relatively fewer CYP450 interactions than the SSRIs. Venlafaxine is a substrate but not an inhibitor of CYP2D6 or other isoenzymes, whereas desvenlafaxine is a minor substrate for CYP3A4.

Duloxetine is a moderate inhibitor of CYP2D6 and so may elevate TCA and other CYP2D6 substrate levels. Like all serotonergic antidepressants, SNRIs are contraindicated in combination with MAOIs.

Elevations of TCA levels may occur when combined with CYP2D6 inhibitors or from constitutional factors. About 7% of the Caucasian population in the USA has a CYP2D6 polymorphism that is associated with slow metabolism of TCAs and other 2D6 substrates. Combination of a known CYP2D6 inhibitor and a TCA in a patient who is a slow metabolizer may result in additive effects. Such an interaction has been implicated, though rarely, in cases of TCA toxicity. There may also be additive TCA effects such as anticholinergic or antihistamine effects when combined with other agents that share these properties such as benztropine or diphenhydramine. Similarly, antihypertensive drugs may exacerbate the orthostatic hypotension induced by TCAs.

#### **5-HT<sub>2</sub> ANTAGONISTS**

Nefazodone is an inhibitor of the CYP3A4 isoenzyme, so it can raise the level and thus exacerbate adverse effects of many 3A4-dependent drugs. For example, triazolam levels are increased by concurrent administration of nefazodone such that a reduction in triazolam dosage by 75% is recommended. Likewise, administration of nefazodone with simvastatin has been associated with 20-fold increase in plasma levels of simvastatin.

Trazodone is a substrate but not a potent inhibitor of CYP3A4. As a result, combining trazodone with potent

inhibitors of CYP3A4, such as ritonavir or ketoconazole, may lead to substantial increases in trazodone levels.

#### TETRACYCLIC AND UNICYCLIC ANTIDEPRESSANTS

Bupropion is metabolized primarily by CYP2B6, and its metabolism may be altered by drugs such as cyclophosphamide, which is a substrate of 2B6. The major metabolite of bupropion, hydroxybupropion, is a moderate inhibitor of CYP2D6 and so can raise desipramine levels. Bupropion should be avoided in patients taking MAOIs.

Mirtazapine is a substrate for several CYP450 enzymes including 2D6, 3A4, and 1A2. Consequently, drugs that inhibit these isozymes may raise mirtazapine levels. However, mirtazapine is not an inhibitor of these enzymes. The sedating effects of mirtazapine may be additive with those of CNS depressants such as alcohol and benzodiazepines.

Amoxapine and maprotiline share most drug interactions common to the TCA group. Both are CYP2D6 substrates and should be used with caution in combination with inhibitors such as fluoxetine. Amoxapine and maprotiline also both have anticholinergic and antihistaminic properties that may be additive with drugs that share a similar profile.

#### MONOAMINE OXIDASE INHIBITORS

MAOIs are associated with two classes of serious drug interactions. The first of these is the pharmacodynamic interaction of MAOIs with serotonergic agents including SSRIs, SNRIs, and most TCAs along with some analgesic agents such as meperidine. These combinations of an MAOI with a serotonergic agent may result in a life-threatening **serotonin syndrome** (see Chapter 16). The serotonin syndrome is thought to be caused by overstimulation of 5-HT receptors in the central gray nuclei and the medulla. Symptoms range from mild to lethal and include a triad of cognitive (delirium, coma), autonomic (hypertension, tachycardia, diaphoreses) and somatic (myoclonus, hyperreflexia, tremor) effects. Most serotonergic antidepressants should be discontinued at least 2 weeks before starting an MAOI. Fluoxetine, because of its long half-life, should be discontinued for 4–5 weeks before an MAOI is initiated. Conversely, an MAOI must be discontinued for at least 2 weeks before starting a serotonergic agent.

The second serious interaction with MAOIs occurs when an MAOI is combined with tyramine in the diet or with sympathomimetic substrates of MAO. An MAOI prevents the breakdown of tyramine in the gut, and this results in high serum levels that enhance peripheral noradrenergic effects, including raising blood pressure dramatically. Patients on an MAOI who ingest large amounts of dietary tyramine may experience malignant hypertension and subsequently a stroke or myocardial infarction. Thus, patients taking MAOIs require a low tyramine diet and should avoid foods such as aged cheeses, tap beer, soy products, and dried sausages, which contain high amounts of tyramine (see Chapter 9). Similar sympathomimetics also may cause significant hypertension when combined with MAOIs. Thus, over-the-counter cold preparations that contain pseudoephedrine and phenylpropanolamine are contraindicated in patients taking MAOIs.

#### SUMMARY: ANTIDEPRESSANTS

##### Antidepressants

Subclass	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>Selective serotonin reuptake inhibitors (SSRIs)</b>				
Fluoxetine	Highly selective	Acute increase	Major depression,	Half-lives from 15–75
Citalopram	blockade of	of serotonergic	anxiety disorders •	h • oral activity •

Escitalopram	serotonin transporter (SERT) • little effect on norepinephrine transporter (NET)	synaptic activity • slower changes in several signaling pathways and neurotrophic activity	panic disorder • obsessive-compulsive disorder • post-traumatic stress disorder • perimenopausal vasomotor symptoms • eating disorder (bulimia)	<i>Toxicity:</i> Well tolerated but cause sexual dysfunction • <i>Interactions:</i> Some CYP inhibition (fluoxetine 2D6, 3A4; fluvoxamine 1A2; paroxetine 2D6)
--------------	--	--	---	---

*Fluvoxamine: Similar to above but approved only for obsessive-compulsive behavior*

**Serotonin-norepinephrine reuptake inhibitors (SNRIs)**

Duloxetine	Moderately selective blockade of NET and SERT	Acute increase in serotonergic and adrenergic synaptic activity • otherwise like SSRIs	Major depression, chronic pain disorders • fibromyalgia, perimenopausal symptoms	<i>Toxicity:</i> Anticholinergic, sedation, hypertension (venlafaxine) • <i>Interactions:</i> Some CYP2D6 inhibition (duloxetine, desvenlafaxine)
------------	---	--	--	--

*Desvenlafaxine: Desmethyl metabolite of venlafaxine, metabolism is by phase II rather than CYP phase I*

**Tricyclic antidepressants (TCAs)**

Imipramine	Mixed and variable blockade of NET and SERT	Like SNRIs plus significant blockade of autonomic nervous system and histamine receptors	Major depression not responsive to other drugs • chronic pain disorders • incontinence • obsessive-compulsive disorder (clomipramine)	Long half-lives • CYP substrates • active metabolites • <i>Toxicity:</i> Anticholinergic, $\alpha$ -blocking effects, sedation, weight gain, arrhythmias, and seizures in overdose • <i>Interactions:</i> CYP inducers and inhibitors
------------	---	--	---	--

**5-HT<sub>2</sub> Antagonists**

Nefazodone	Inhibition of 5-HT <sub>2A</sub> receptor • nefazodone also blocks SERT weakly	Trazodone forms a metabolite (m-cpp) that blocks 5-HT <sub>2A,2C</sub> receptors	Major depression • sedation and hypnosis (trazodone)	Relatively short half-lives • active metabolites • <i>Toxicity:</i> Modest $\alpha$ - and H <sub>1</sub> -receptor blockade (trazodone) • <i>Interactions:</i> Nefazodone inhibits CYP3A4
------------	--	--	--	--

**Tetracyclics, unicyclic**

Bupropion	Increased norepinephrine and dopamine activity (bupropion) • NET > SERT inhibition (amoxapine, maprotiline) • increased release of	Presynaptic release of catecholamines but no effect on 5-HT (bupropion) • amoxapine and	Major depression • smoking cessation (bupropion) • sedation (mirtazapine) • amoxapine and maprotiline rarely used	Extensive metabolism in liver • <i>Toxicity:</i> Lowers seizure threshold (amoxapine, bupropion); sedation and weight gain (mirtazapine) • <i>Interactions:</i> CYP2D6 inhibitor (bupropion)
-----------	--	---	---	---

norepinephrine, 5-HT (mirtazapine)      maprotiline resemble TCAs

### **Monoamine oxidase inhibitors (MAOIs)**

Phenelzine	Blockade of MAO-A and MAO-B (phenelzine, nonselective) • MAO-B irreversible selective MAO-B inhibition (low dose selegiline)	Transdermal absorption of selegiline achieves levels that inhibit MAO-A	Major depression unresponsive to other drugs	Very slow elimination • <i>Toxicity:</i> Hypotension, insomnia • <i>Interactions:</i> Hypertensive crisis with tyramine, other indirect sympathomimetics • serotonin syndrome with serotonergic agents, meperidine
------------	--	---	--	--

## **PREPARATIONS AVAILABLE**

### **Selective Serotonin Reuptake Inhibitors**

**Citalopram** (generic, Celexa)

Oral: 10, 20, 40 mg tablets; 10 mg/5 mL solution

**Escitalopram** (Lexapro)

Oral: 5, 10, 20 mg tablets; 5 mg/5 mL solution

**Fluoxetine** (generic, Prozac)

Oral: 10, 20, 40 mg capsules; 10, 20 mg tablets; 20 mg/5 mL liquid

Oral delayed-release (Prozac Weekly): 90 mg capsules

**Fluvoxamine** (generic, labeled only for obsessive-compulsive disorder)

Oral: 25, 50, 100 mg tablets

**Paroxetine** (generic, Paxil)

Oral: 10, 20, 30, 40 mg tablets; 10 mg/5 mL suspension; 12.5, 25, 37.5 mg controlled-release tablets

**Sertraline** (generic, Zoloft)

Oral: 25, 50, 100 mg tablets; 20 mg/mL oral concentrate

### **Selective Norepinephrine Reuptake Inhibitors**

**Desvenlafaxine** (Pristique)

Oral: 50, 100 mg capsules

**Duloxetine** (Cymbalta)

Oral: 20, 30, 50 mg capsules

**Venlafaxine** (Effexor)

Oral: 25, 37.5, 50, 75, 100 mg tablets; 37.5, 75, 150 mg extended-release capsules

## 5-HT<sub>2</sub> Antagonists

### **Nefazodone** (generic)

Oral: 50, 100, 150, 200, 250 mg tablets

### **Trazodone** (generic, Desyrel)

Oral: 50, 100, 150, 300 mg tablets

## Tricyclics

### **Amitriptyline** (generic, Elavil)

Oral: 10, 25, 50, 75, 100, 150 mg tablets

Parenteral: 10 mg/mL for IM injection

### **Amoxapine** (generic)

Oral: 25, 50, 100, 150 mg tablets

### **Clomipramine** (generic, Anafranil; labeled only for obsessive-compulsive disorder)

Oral: 25, 50, 75 mg capsules

### **Desipramine** (generic, Norpramin)

Oral: 10, 25, 50, 75, 100, 150 mg tablets

### **Doxepin** (generic, Sinequan)

Oral: 10, 25, 50, 75, 100, 150 mg capsules; 10 mg/mL concentrate

### **Imipramine** (generic, Tofranil)

Oral: 10, 25, 50 mg tablets (as hydrochloride); 75, 100, 125, 150 mg capsules (as pamoate)

### **Protriptyline** (generic, Vivactil)

Oral: 5, 10 mg tablets

### **Trimipramine** (Surmontil)

Oral: 25, 50, 100 mg capsules

## Tetracyclic and Unicyclic Agents

### **Amoxipine** (generic)

Oral: 25, 50, 100, 150 mg tablets

### **Bupropion** (generic, Wellbutrin)

Oral: 75, 100 mg tablets; 100, 150, 200 mg 12-hour sustained-release tablets; 150, 300 mg 24-hour sustained-release tablets

Oral: 25, 50, 75 mg tablets

**Maprotiline** (generic, Remeron)

Oral: 7.5, 15, 30, 45 mg tablets; 15, 30, 45 mg oral disintegrating tablets

**Mirtazapine** (generic, Remeron)

Oral: 7.5, 15, 30, 45 mg tablets; 15, 30, 45 mg disintegrating tablets

## **Monoamine Oxidase Inhibitors**

**Isocarboxazid** (generic, Marplan)

Oral: 10 mg tablets

**Phenelzine** (generic, Nardil)

Oral: 15 mg tablets

**Selegiline**

Oral (generic, Eldepryl): 5 mg tablets, capsules; 1.25 oral disintegrating tablets

**Tranlycypromine** (generic, Parnate)

Oral: 10 mg tablets

Basic and Clinical Pharmacology > Chapter 31. Opioid Analgesics & Antagonists >

## Case Study

A 60-year-old man with a history of moderate chronic obstructive pulmonary disease presents in the emergency department with a broken hip suffered in an automobile accident. He complains of severe pain. What is the most appropriate immediate treatment for his pain? Are any special precautions needed?

## OPIOID ANALGESICS & ANTAGONISTS: INTRODUCTION

Morphine, the prototypical opioid agonist, has long been known to relieve severe pain with remarkable efficacy. The opium poppy is the source of crude opium from which Sertürner in 1803 isolated morphine, the pure alkaloid, naming it after Morpheus, the Greek god of dreams. It remains the standard against which all drugs that have strong analgesic action are compared. These drugs are collectively known as opioid analgesics and include not only the natural and semisynthetic alkaloid derivatives from opium but also synthetic surrogates, other opioid-like drugs whose actions are blocked by the nonselective antagonist naloxone, plus several endogenous peptides that interact with the different subtypes of opioid receptors.

## BASIC PHARMACOLOGY OF THE OPIOID ANALGESICS

### Source

Opium, the source of morphine, is obtained from the poppy, *Papaver somniferum* and *P. album*. After incision, the poppy seed pod exudes a white substance that turns into a brown gum that is crude opium. Opium contains many alkaloids, the principle one being morphine, which is present in a concentration of about 10%. Codeine is synthesized commercially from morphine.

### Classification & Chemistry

Opioid drugs include full agonists, partial agonists, and antagonists. Morphine is a full agonist at the  $\mu$  (mu)-opioid receptor, the major analgesic opioid receptor (Table 31-1). In contrast, codeine functions as a partial (or "weak")  $\mu$ -receptor agonist. Other opioid receptor subtypes include  $\delta$  (delta) and  $\kappa$  (kappa) receptors. Simple substitution of an allyl group on the nitrogen of the full *agonist* morphine plus addition of a single hydroxyl group results in naloxone, a strong  $\mu$ -receptor *antagonist*. The structures of some of these compounds are shown later in this chapter. Some opioids, eg, nalbuphine, are capable of producing an agonist (or partial agonist) effect at one opioid receptor subtype and an antagonist effect at another. The activating properties of opioid analgesics can be manipulated by pharmaceutical chemistry; in addition, certain opioid analgesics are modified in the liver, resulting in compounds with greater analgesic action. Chemically, the opioids derived from opium are phenanthrene derivatives and include four or more fused rings, while most of the synthetic opioids are simpler molecules.

**Table 31-1 Opioid Receptor Subtypes, Their Functions, and Their Endogenous Peptide Affinities.**

Receptor Subtype	Functions	Endogenous Opioid Peptide Affinity
$\mu$ (mu)	Supraspinal and spinal analgesia; sedation; inhibition of respiration; slowed gastrointestinal transit; modulation of hormone and neurotransmitter release	Endorphins > enkephalins > dynorphins
$\delta$ (delta)	Supraspinal and spinal analgesia; modulation of hormone and neurotransmitter release	Enkephalins > endorphins and

κ (kappa) Supraspinal and spinal analgesia; psychotomimetic effects; slowed gastrointestinal transit

dynorphins

Dynorphins > > endorphins and enkephalins

## Endogenous Opioid Peptides

Opioid alkaloids (eg, morphine) produce analgesia through actions at receptors in the central nervous system (CNS) that contain peptides with opioid-like pharmacologic properties. The general term currently used for these endogenous substances is **endogenous opioid peptides**.

Three families of endogenous opioid peptides have been described in detail: the **endorphins**, the pentapeptide **enkephalins** methionine-enkephalin (**met-enkephalin**) and leucine-enkephalin (**leu-enkephalin**), and the **dynorphins**. The three families of opioid receptors have overlapping affinities for these endogenous peptides (Table 31â€1).

The endogenous opioid peptides are derived from three precursor proteins: prepro-opiomelanocortin (POMC), preproenkephalin (proenkephalin A), and preprodynorphin (proenkephalin B). POMC contains the met-enkephalin sequence, β-endorphin, and several nonopioid peptides, including adrenocorticotrophic hormone (ACTH), β-lipotropin, and melanocyte-stimulating hormone. Preproenkephalin contains six copies of met-enkephalin and one copy of leu-enkephalin. Leu- and met-enkephalin have slightly higher affinity for the δ (delta) than for the μ-opioid receptor (Table 31â€1). Preprodynorphin yields several active opioid peptides that contain the leu-enkephalin sequence. These are **dynorphin A**, **dynorphin B**, and α and β **neopeptides**. The endogenous peptides **endomorphin-1** and **endomorphin-2** also possess many of the properties of opioid peptides, notably analgesia and high-affinity binding to the μ receptor. Endomorphin-1 and -2 selectively activate central and peripheral μ-opioid receptors but much about them remains unknown, including the identity of their preproendormorphin gene. Both the endogenous opioid precursor molecules and the endomorphins are present at CNS sites that have been implicated in pain modulation. Evidence suggests that they can be released during stressful conditions such as pain or the anticipation of pain and diminish the sensation of noxious stimuli. Whether acupuncture releases endogenous opioid peptides is under investigation.

In contrast to the analgesic role of leu- and met-enkephalin, an analgesic action of dynorphin Aâ€through its binding to κ (kappa) opioid receptorsâ€remains controversial. Dynorphin A is also found in the dorsal horn of the spinal cord, where it may play a critical role in the *sensitization* of nociceptive neurotransmission. Increased levels of dynorphin can be found in the dorsal horn after tissue injury and inflammation. This elevated dynorphin level is proposed to increase pain and induce a state of long-lasting hyperalgesia. The pronociceptive action of dynorphin in the spinal cord appears to be independent of the opioid receptor system but dependent on the activation of the bradykinin receptor. Moreover, dynorphin A can bind and activate the N-methyl-D-aspartate (NMDA) receptor complex, a site of action that is the focus of intense therapeutic development.

Recently, a novel receptor-ligand system homologous to the opioid peptides has been found. The principle receptor for this system is the G protein-coupled **orphanin opioid-receptor-like subtype 1 (ORL1)**. Its endogenous ligand has been termed **nociceptin** by one group of investigators and **orphanin FQ** by another group. This ligand-receptor system is currently known as the **N/OFQ** system. Nociceptin is structurally similar to dynorphin except for the absence of an N-terminal tyrosine; it acts only at the ORL1 receptor, now known as **NOP**. The N/OFQ system is widely expressed in the CNS and periphery, reflecting its equally diverse biology and pharmacology. As a result of experiments using highly selective NOP receptor ligands, the N/OFQ system has been implicated in both pro- and anti-nociceptive activity as well as in the modulation of drug reward, learning, mood, anxiety, and cough processes, and of parkinsonism.

## Pharmacokinetics

Some properties of clinically important opioids are summarized in Table 31â€2.

### Table 31â€2 Common Opioid Analgesics.

Generic Name	Receptor Effects <sup>1</sup>			Approximately Equivalent Dose (mg)	Oral:Parenteral Potency Ratio	Duration of Analgesia (hours)	Maximum Efficacy
	μ	δ	κ				
Morphine <sup>2</sup>	+++		+	10	Low	4-5	High
Hydromorphone	+++			1.5	Low	4-5	High
Oxymorphone	+++			1.5	Low	3-4	High
Methadone	+++			10	High	4-6	High
Meperidine	+++			60-100	Medium	2-4	High
Fentanyl	+++			0.1	Low	1-1.5	High
Sufentanil	+++	+	+	0.02	Parenteral only	1-1.5	High
Alfentanil	+++			Titrated	Parenteral only	0.25-0.75	High
Remifentanyl	+++			Titrated <sup>3</sup>	Parenteral only	0.05 <sup>4</sup>	High
Levorphanol	+++			2-3	High	4-5	High
Codeine	±			30-60	High	3-4	Low
Hydrocodone <sup>5</sup>	±			5-10	Medium	4-6	Moderate
Oxycodone <sup>2,6</sup>	±			4.5 <sup>7</sup>	Medium	3-4	Moderate
Propoxyphene	(+, very weak)			60-120 <sup>7</sup>	Oral only	4-5	Very low
Pentazocine	±		+	30-50 <sup>7</sup>	Medium	3-4	Moderate
Nalbuphine	~		++	10	Parenteral only	3-6	High
Buprenorphine	±	~	~	0.3	Low	4-8	High
Butorphanol	±		+++	2	Parenteral only	3-4	High

<sup>1</sup> +++, ++, +, strong agonist; ±, partial agonist; ~, ~, ~, antagonist.

<sup>2</sup> Available in sustained-release forms, morphine (MSContin); oxycodone (OxyContin).

<sup>3</sup> Administered as an infusion at 0.025-0.2 mcg/kg/min.

<sup>4</sup> Duration is dependent on a context-sensitive half-time of 3-4 minutes.

<sup>5</sup> Available in tablets containing acetaminophen (Norco, Vicodin, Lortab, others).

<sup>6</sup> Available in tablets containing acetaminophen (Percocet); aspirin (Percodan).

<sup>7</sup> Analgesic efficacy at this dose not equivalent to 10 mg of morphine. See text for explanation.

### ABSORPTION

Most opioid analgesics are well absorbed when given by subcutaneous, intramuscular, and oral routes. However, because of the first-pass effect, the oral dose of the opioid (eg, morphine) may need to be much higher than the parenteral dose to elicit a therapeutic effect. Considerable interpatient variability exists in first-pass opioid metabolism, making prediction of an effective oral dose difficult. Certain analgesics such as codeine and oxycodone

are effective orally because they have reduced first-pass metabolism. Nasal insufflation of certain opioids can result in rapid therapeutic blood levels by avoiding first-pass metabolism. Other routes of opioid administration include oral mucosa via lozenges, and transdermal via transdermal patches. The latter can provide delivery of potent analgesics over days.

### **DISTRIBUTION**

The uptake of opioids by various organs and tissues is a function of both physiologic and chemical factors. Although all opioids bind to plasma proteins with varying affinity, the drugs rapidly leave the blood compartment and localize in highest concentrations in tissues that are highly perfused such as the brain, lungs, liver, kidneys, and spleen. Drug concentrations in skeletal muscle may be much lower, but this tissue serves as the main reservoir because of its greater bulk. Even though blood flow to fatty tissue is much lower than to the highly perfused tissues, accumulation can be very important, particularly after frequent high-dose administration or continuous infusion of highly lipophilic opioids that are slowly metabolized, eg, fentanyl.

### **METABOLISM**

The opioids are converted in large part to polar metabolites (mostly glucuronides), which are then readily excreted by the kidneys. For example, morphine, which contains free hydroxyl groups, is primarily conjugated to morphine-3-glucuronide (M3G), a compound with neuroexcitatory properties. The neuroexcitatory effects of M3G do not appear to be mediated by  $\mu$  receptors but rather by the GABA/glycinergic system. In contrast, approximately 10% of morphine is metabolized to morphine-6-glucuronide (M6G), an active metabolite with analgesic potency four to six times that of its parent compound. However, these relatively polar metabolites have limited ability to cross the blood-brain barrier and probably do not contribute significantly to the usual CNS effects of morphine given acutely. Nevertheless, accumulation of these metabolites may produce unexpected adverse effects in patients with renal failure or when exceptionally large doses of morphine are administered or high doses are administered over long periods. This can result in M3G-induced CNS excitation (seizures) or enhanced and prolonged opioid action produced by M6G. CNS uptake of M3G and, to a lesser extent, M6G can be enhanced by coadministration with probenecid or with drugs that inhibit the P-glycoprotein drug transporter. Like morphine, hydromorphone is metabolized by conjugation, yielding hydromorphone-3-glucuronide (H3G), which has CNS excitatory properties. However, hydromorphone has not been shown to form significant amounts of a 6-glucuronide metabolite.

The effects of these active metabolites should be considered in patients with renal impairment before the administration of morphine or hydromorphone, especially when given at high doses.

Esters (eg, heroin, remifentanyl) are rapidly hydrolyzed by common tissue esterases. Heroin (diacetylmorphine) is hydrolyzed to monoacetylmorphine and finally to morphine, which is then conjugated with glucuronic acid.

Hepatic oxidative metabolism is the primary route of degradation of the phenylpiperidine opioids (meperidine, fentanyl, alfentanil, sufentanil) and eventually leaves only small quantities of the parent compound unchanged for excretion. However, accumulation of a demethylated metabolite of meperidine, normeperidine, may occur in patients with decreased renal function and in those receiving multiple high doses of the drug. In high concentrations, normeperidine may cause seizures. In contrast, no active metabolites of fentanyl have been reported. The P450 isozyme CYP3A4 metabolizes fentanyl by *N*-dealkylation in the liver. CYP3A4 is also present in the mucosa of the small intestine and contributes to the first-pass metabolism of fentanyl when it is taken orally. Codeine, oxycodone, and hydrocodone undergo metabolism in the liver by P450 isozyme CYP2D6, resulting in the production of metabolites of greater potency. For example, codeine is demethylated to morphine. Genetic polymorphism of CYP2D6 has been documented and linked to the variation in analgesic response seen among patients. Nevertheless, the metabolites of oxycodone and hydrocodone may be of minor consequence because the parent compounds are currently believed to be directly responsible for the majority of their analgesic actions. In the case of codeine, conversion to morphine may be of greater importance because codeine itself has relatively low affinity for opioid receptors. As a result, patients may experience either no significant analgesic effect or an exaggerated response based on differences in metabolic conversion. For this reason, routine use of codeine, especially in pediatric age groups, is being reconsidered.

### **EXCRETION**

Polar metabolites, including glucuronide conjugates of opioid analgesics, are excreted mainly in the urine. Small amounts of unchanged drug may also be found in the urine. In addition, glucuronide conjugates are found in the bile, but enterohepatic circulation represents only a small portion of the excretory process.

## **Pharmacodynamics**

### **MECHANISM OF ACTION**

Opioid agonists produce analgesia by binding to specific G protein-coupled receptors that are located in brain and spinal cord regions involved in the transmission and modulation of pain (Figure 31â€1). Some effects may be mediated by opioid receptors on peripheral sensory nerve endings.

### **Figure 31â€1**

Potential receptor mechanisms of analgesic drugs. The primary afferent neuron (cell body not shown) originates in the periphery and carries pain signals to the dorsal horn of the spinal cord, where it synapses via glutamate and neuropeptide transmitters with the secondary neuron. Pain stimuli can be attenuated in the periphery (under inflammatory conditions) by opioids acting at  $\mu$ -opioid receptors (MOR) or blocked in the afferent axon by local anesthetics (not shown). Action potentials reaching the dorsal horn can be attenuated at the presynaptic ending by opioids and by calcium blockers (ziconotide),  $\alpha_2$  agonists, and possibly, by drugs that increase synaptic concentrations of norepinephrine by blocking reuptake (tapentadol). Opioids also inhibit the postsynaptic neuron, as do certain neuropeptide antagonists acting at tachykinin (NK1) and other

neuropeptide receptors.

### Receptor Types

As noted previously, three major classes of opioid receptors ( $\mu$ ,  $\delta$ , and  $\kappa$ ) have been identified in various nervous system sites and in other tissues (Table 31-1). Each of the three major receptors has now been cloned. All are members of the G protein-coupled family of receptors and show significant amino acid sequence homologies. Multiple receptor subtypes have been proposed based on pharmacologic criteria, including  $\mu_1$ ,  $\mu_2$ ;  $\delta_1$ ,  $\delta_2$ ; and  $\kappa_1$ ,  $\kappa_2$ , and  $\kappa_3$ . However, genes encoding only one subtype from each of the  $\mu$ ,  $\delta$ , and  $\kappa$  receptor families have been isolated and characterized thus far. One plausible explanation is that  $\mu$ -receptor subtypes arise from alternate splice variants of a common gene. This idea has been supported by the identification of receptor splice variants in mice and humans. Since an opioid may function with different potencies as an agonist, partial agonist, or antagonist at more than one receptor class or subtype, it is not surprising that these agents are capable of diverse pharmacologic effects.

### Cellular Actions

At the molecular level, opioid receptors form a family of proteins that physically couple to G proteins and through this interaction affect ion channel gating, modulate intracellular  $\text{Ca}^{2+}$  disposition, and alter protein phosphorylation (see Chapter 2). The opioids have two well-established direct G protein-coupled actions on neurons: (1) they close voltage-gated  $\text{Ca}^{2+}$  channels on presynaptic nerve terminals and thereby reduce transmitter release, and (2) they hyperpolarize and thus inhibit postsynaptic neurons by opening  $\text{K}^+$  channels. Figure 31-1 schematically illustrates these effects. The presynaptic action "depressed transmitter release" has been demonstrated for release of a large number of neurotransmitters including glutamate, the principle excitatory amino acid released from nociceptive nerve terminals, as well as acetylcholine, norepinephrine, serotonin, and substance P.

### Relation of Physiologic Effects to Receptor Type

The majority of currently available opioid analgesics act primarily at the  $\mu$ -opioid receptor (Table 31-2). Analgesia, as well as the euphoriant, respiratory depressant, and physical dependence properties of morphine result principally from actions at  $\mu$  receptors. In fact, the  $\mu$  receptor was originally defined using the relative potencies for clinical analgesia of a series of opioid alkaloids. However, opioid analgesic effects are complex and include interaction with  $\delta$  and  $\kappa$  receptors. This is supported by the study of genetic knockouts of the  $\mu$ ,  $\delta$ , and  $\kappa$  genes in mice. Delta-receptor agonists retain analgesic properties in  $\mu$  receptor knockout mice. The development of  $\delta$ -receptor-selective agonists could be clinically useful if their side-effect profiles (respiratory depression, risk of dependence) were more favorable than those found with current  $\mu$ -receptor agonists, such as morphine. Although morphine does act at  $\kappa$  and  $\delta$  receptor sites, it is unclear to what extent this contributes to its analgesic action. The endogenous opioid peptides differ from most of the alkaloids in their affinity for the  $\delta$  and  $\kappa$  receptors (Table 31-1).

In an effort to develop opioid analgesics with a reduced incidence of respiratory depression or propensity for addiction and dependence, compounds that show preference for  $\kappa$  opioid receptors have been developed. Butorphanol and nalbuphine have shown some clinical success as analgesics, but they can cause dysphoric reactions and have limited potency. It is interesting that butorphanol has also been shown to cause significantly greater analgesia in women than in men. In fact, gender-based differences in analgesia mediated by  $\mu$ - and  $\delta$ -receptor activation have been widely reported.

### Receptor Distribution and Neural Mechanisms of Analgesia

Opioid receptor binding sites have been localized autoradiographically with high-affinity radioligands and with antibodies to unique peptide sequences in each receptor subtype. All three major receptors are present in high concentrations in the dorsal horn of the spinal cord. Receptors are present both on spinal cord pain transmission neurons and on the primary afferents that relay the pain message to them (Figure 31-2, sites A and B). Opioid agonists inhibit the release of excitatory transmitters from these primary afferents, and they directly inhibit the dorsal horn pain transmission neuron. Thus, opioids exert a powerful analgesic effect directly on the spinal cord. This **spinal action** has been exploited clinically by direct application of opioid agonists to the spinal cord, which provides a regional analgesic effect while reducing the unwanted respiratory depression, nausea and vomiting, and sedation that may occur from the **supraspinal actions** of systemically administered opioids.

Putative sites of action of opioid analgesics. Sites of action on the afferent pain transmission pathway from the periphery to the higher centers are shown. **A:** Direct action of opioids on inflamed or damaged peripheral tissues (see Figure 31â€1 for detail). **B:** Inhibition also occurs in the spinal cord (see Figure 31â€1). **C:** Possible sites of action in the thalamus.

Under most circumstances, opioids are given systemically and so act simultaneously at multiple sites. These include not only the ascending pathways of pain transmission beginning with specialized peripheral sensory terminals that transduce painful stimuli (Figure 31â€2) but also descending (modulatory) pathways (Figure 31â€3). At these sites as at others, opioids directly inhibit neurons; yet this action results in the *activation* of descending inhibitory neurons that send processes to the spinal cord and inhibit pain transmission neurons. This activation has been shown to result from the inhibition of inhibitory neurons in several locations (Figure 31â€4). Taken together, interactions at these sites increase the overall analgesic effect of opioid agonists.

Brainstem local circuitry underlying the modulating effect of  $\mu$ -opioid receptor (MOR)-mediated analgesia on descending pathways. The pain-inhibitory neuron is indirectly activated by opioids (exogenous or endogenous), which inhibit an inhibitory (GABAergic) interneuron. This results in *enhanced* inhibition of nociceptive processing in the dorsal horn of the spinal cord (see Figure 31-4).

**Figure 31-4**

Opioid analgesic action on the descending inhibitory pathway. Sites of action of opioids on pain-modulating neurons in the midbrain and medulla including the midbrain periaqueductal gray area (A), rostral ventral medulla (B), and the locus caeruleus indirectly control pain transmission pathways by enhancing descending inhibition to the dorsal horn (C).

When pain-relieving opioid drugs are given systemically, they presumably act upon neuronal circuits normally regulated by endogenous opioid peptides. Part of the pain-relieving action of exogenous opioids involves the release of endogenous opioid peptides. An exogenous opioid agonist (eg, morphine) may act primarily and directly at the  $\mu$  receptor, but this action may evoke the release of endogenous opioids that additionally act at  $\delta$  and  $\kappa$  receptors. Thus, even a receptor-selective ligand can initiate a complex sequence of events involving multiple synapses, transmitters, and receptor types.

Animal and human clinical studies demonstrate that both endogenous and exogenous opioids can also produce opioid-mediated analgesia at sites *outside* the CNS. Pain associated with inflammation seems especially sensitive to these peripheral opioid actions. The presence of functional  $\mu$  receptors on the peripheral terminals of sensory neurons supports this hypothesis. Furthermore, activation of peripheral  $\mu$  receptors results in a decrease in sensory neuron activity and transmitter release. The endogenous release of  $\beta$ -endorphin produced by immune cells within injured or inflamed tissue represents one source of physiologic peripheral  $\mu$ -receptor activation. Peripheral administration of opioids, eg, into the knees of patients following arthroscopic knee surgery, has shown clinical benefit up to 24 hours after administration. If they can be developed, opioids selective for a peripheral site would be useful adjuncts in the treatment of inflammatory pain (see Ion Channels & Novel Analgesic Targets). Such compounds could have the additional benefit of reducing unwanted effects such as constipation.

#### **Ion Channels & Novel Analgesic Targets**

Even the most severe *acute* pain (lasting hours to days) can usually be well controlled—“with significant but tolerable adverse effects”—using currently available analgesics, especially the opioids. *Chronic* pain (lasting

weeks to months), however, is not very satisfactorily managed with opioids. It is now known that in chronic pain, receptors on sensory nerve terminals in the periphery contribute to increased excitability of sensory nerve endings (peripheral sensitization). The hyperexcitable sensory neuron bombards the spinal cord, leading to increased excitability and synaptic alterations in the dorsal horn (central sensitization). Such changes appear to be important in chronic inflammatory and neuropathic pain states.

In the effort to discover better analgesic drugs for chronic pain, renewed attention is being paid to synaptic transmission in nociception and peripheral sensory transduction. Potentially important ion channels associated with these processes in the periphery include members of the transient receptor potential family such as the **capsaicin receptor, TRPV1** (which is activated by multiple noxious stimuli such as heat, protons, and products of inflammation) as well as TRPA1, activated by inflammatory mediators; and **P2X** receptors (which are responsive to purines released from tissue damage). A special type of tetrodotoxin-resistant voltage-gated sodium channel (**Nav1.8**), also known as the PN3/SNS channel, is apparently uniquely associated with nociceptive neurons in dorsal root ganglia. **Lidocaine** and **mexiletine**, which are useful in some chronic pain states, may act by blocking this channel. Because of the importance of their peripheral sites of action, therapeutic strategies that deliver agents that block peripheral pain transduction or transmission have been introduced in the form of transdermal patches and balms. Such products that specifically target peripheral capsaicin receptors and sodium channel function are becoming available.

**Ziconotide**, a blocker of voltage-gated N-type calcium channels, is approved for intrathecal analgesia in patients with refractory chronic pain. It is a synthetic peptide related to the marine snail toxin  $\omega$ -conotoxin, which selectively blocks these calcium channels. **Gabapentin/Pregabalin**, anticonvulsant analogs of GABA (see Chapter 24), are effective treatments for neuropathic (nerve injury) pain and inflammatory pain acting at voltage-gated calcium channels containing the  $\alpha_2\delta_1$  subunit. *N*-methyl-D-aspartate (NMDA) receptors appear to play a very important role in central sensitization at both spinal and supraspinal levels. Although certain NMDA antagonists have demonstrated analgesic activity (eg, **ketamine**), it has been difficult to find agents with an acceptably low profile of adverse effects or neurotoxicity. However, ketamine at very small doses appears to improve analgesia and reduce opioid requirements under conditions of opioid tolerance. In fact, ketamine applied topically has been claimed to have analgesic effects. GABA and acetylcholine (through nicotinic receptors) appear to control the central synaptic release of several transmitters involved in nociception. **Nicotine** itself and certain nicotine analogs cause analgesia, and their use for postoperative analgesia is under investigation. Finally, work on cannabinoids and vanilloids and their receptors suggest that  $\Delta^9$ -**tetrahydrocannabinol**, which acts primarily on CB<sub>1</sub> cannabinoid receptors, can synergize with  $\mu$ -receptor analgesics and interact with the TRPV1 capsaicin receptor to produce analgesia under certain circumstances.

As our understanding of peripheral and central pain transduction improves, additional therapeutic targets and strategies will become available. Combined with our present knowledge of opioid analgesics, a "multimodal" approach to pain therapy is emerging, which allows the use of complementary compounds resulting in improved analgesia with fewer adverse effects.

### **Tolerance and Physical Dependence**

With frequently repeated therapeutic doses of morphine or its surrogates, there is a gradual loss in effectiveness; this loss of effectiveness is denoted tolerance. To reproduce the original response, a larger dose must be administered. Along with tolerance, physical dependence develops. Physical dependence is defined as a characteristic **withdrawal** or **abstinence syndrome** when a drug is stopped or an antagonist is administered (see also Chapter 32).

The mechanism of development of tolerance and physical dependence is poorly understood, but persistent activation of  $\mu$  receptors such as occurs with the treatment of severe chronic pain appears to play a primary role in its induction and maintenance. Current concepts have shifted away from tolerance being driven by a simple up-regulation of the cyclic adenosine monophosphate (cAMP) system. Although this process is associated with tolerance, it is not sufficient to explain it. A second hypothesis for the development of opioid tolerance and dependence is based on the concept of **receptor recycling**. Normally, activation of  $\mu$  receptors by endogenous ligands results in endocytosis followed by resensitization and recycling of the receptor to the plasma membrane (see Chapter 2). However, using genetically modified mice, research now shows that the *failure* of morphine to induce endocytosis of the  $\mu$ -opioid receptor is an

important component of tolerance and dependence. In contrast, methadone, a  $\mu$ -receptor agonist used for the *treatment* of opioid tolerance and dependence, does induce receptor endocytosis. This suggests that maintenance of normal sensitivity of  $\mu$  receptors requires reactivation by endocytosis and recycling. Another area of research suggests that the  $\delta$  opioid receptor functions as an independent component in the maintenance of tolerance. In addition, the concept of **receptor uncoupling** has gained prominence. Under this hypothesis, tolerance is due to a dysfunction of structural interactions between the  $\mu$  receptor and G proteins, second-messenger systems, and their target ion channels. Uncoupling and recoupling of  $\mu$  receptor function is likely linked to receptor recycling. Moreover, the NMDA receptor ion channel complex has been shown to play a critical role in tolerance development and maintenance because NMDA-receptor antagonists such as ketamine can block tolerance development. Although a role in endocytosis is not yet clearly defined, the development of novel NMDA-receptor antagonists or other strategies to recouple  $\mu$  receptors to their target ion channels provides hope for achieving a clinically effective means to prevent or reverse opioid analgesic tolerance.

In addition to the development of tolerance, persistent administration of opioid analgesics has been observed to *increase* the sensation of pain leading to a state of hyperalgesia. This phenomenon has been observed with several opioid analgesics, including morphine, fentanyl, and remifentanyl. Spinal dynorphin and activation of the bradykinin receptor have emerged as important candidates for the mediation of opioid-induced hyperalgesia.

### ORGAN SYSTEM EFFECTS OF MORPHINE AND ITS SURROGATES

The actions described below for morphine, the prototypic opioid agonist, can also be observed with other opioid agonists, partial agonists, and those with mixed receptor effects. Characteristics of specific members of these groups are discussed below.

#### Central Nervous System Effects

The principal effects of opioid analgesics with affinity for  $\mu$  receptors are on the CNS; the more important ones include analgesia, euphoria, sedation, and respiratory depression. With repeated use, a high degree of tolerance occurs to all of these effects (Table 31-3).

**Table 31-3 Degrees of Tolerance that May Develop to Some of the Effects of the Opioids.**

High	Moderate	Minimal or None
Analgesia	Bradycardia	Miosis
Euphoria, dysphoria		Constipation
Mental clouding		Convulsions
Sedation		
Respiratory depression		
Antidiuresis		
Nausea and vomiting		
Cough suppression		

#### ANALGESIA

Pain consists of both sensory and affective (emotional) components. Opioid analgesics are unique in that they can reduce both aspects of the pain experience, especially the affective aspect. In contrast, nonsteroidal anti-inflammatory analgesic drugs have no significant effect on the emotional aspects of pain.

#### EUPHORIA

Typically, patients or intravenous drug users who receive intravenous morphine experience a pleasant floating sensation with lessened anxiety and distress. However, dysphoria, an unpleasant state characterized by restlessness and malaise, may sometimes occur.

#### SEDATION

Drowsiness and clouding of mentation are common effects of opioids. There is little or no amnesia. Sleep is induced

by opioids more frequently in the elderly than in young, healthy individuals. Ordinarily, the patient can be easily aroused from this sleep. However, the combination of morphine with other central depressant drugs such as the sedative-hypnotics may result in very deep sleep. Marked sedation occurs more frequently with compounds closely related to the phenanthrene derivatives and less frequently with the synthetic agents such as meperidine and fentanyl. In standard analgesic doses, morphine (a phenanthrene) disrupts normal rapid eye movement (REM) and non-REM sleep patterns. This disrupting effect is probably characteristic of all opioids. In contrast to humans, a number of species (cats, horses, cows, pigs) may manifest excitation rather than sedation when given opioids. These paradoxical effects are at least partially dose-dependent.

#### **RESPIRATORY DEPRESSION**

All of the opioid analgesics can produce significant respiratory depression by inhibiting brainstem respiratory mechanisms. Alveolar  $PCO_2$  may increase, but the most reliable indicator of this depression is a depressed response to a carbon dioxide challenge. The respiratory depression is dose-related and is influenced significantly by the degree of sensory input occurring at the time. For example, it is possible to partially overcome opioid-induced respiratory depression by stimulation of various sorts. When strongly painful stimuli that have prevented the depressant action of a large dose of an opioid are relieved, respiratory depression may suddenly become marked. A small to moderate decrease in respiratory function, as measured by  $Paco_2$  elevation, may be well tolerated in the patient without prior respiratory impairment. However, in individuals with increased intracranial pressure, asthma, chronic obstructive pulmonary disease, or cor pulmonale, this decrease in respiratory function may not be tolerated. Opioid-induced respiratory depression remains one of the most difficult clinical challenges in the treatment of severe pain. Research is ongoing to understand and develop analgesic agents and adjuncts that avoid this effect. Research to overcome this problem is focused on  $\delta$  receptor pharmacology and serotonin signaling pathways in the brainstem respiratory control centers.

#### **COUGH SUPPRESSION**

Suppression of the cough reflex is a well-recognized action of opioids. Codeine in particular has been used to advantage in persons suffering from pathologic cough and in patients in whom it is necessary to maintain ventilation via an endotracheal tube. However, cough suppression by opioids may allow accumulation of secretions and thus lead to airway obstruction and atelectasis.

#### **MIOSIS**

Constriction of the pupils is seen with virtually all opioid agonists. Miosis is a pharmacologic action to which little or no tolerance develops (Table 31-3); thus, it is valuable in the diagnosis of opioid overdose. Even in highly tolerant addicts, miosis is seen. This action, which can be blocked by opioid antagonists, is mediated by parasympathetic pathways, which, in turn, can be blocked by atropine.

#### **TRUNCAL RIGIDITY**

An intensification of tone in the large trunk muscles has been noted with a number of opioids. It was originally believed that truncal rigidity involved a spinal cord action of these drugs, but there is now evidence that it results from an action at supraspinal levels. Truncal rigidity reduces thoracic compliance and thus interferes with ventilation. The effect is most apparent when high doses of the highly lipid-soluble opioids (eg, fentanyl, sufentanil, alfentanil, remifentanil) are rapidly administered intravenously. Truncal rigidity may be overcome by administration of an opioid antagonist, which of course will also antagonize the analgesic action of the opioid. Preventing truncal rigidity while preserving analgesia requires the concomitant use of neuromuscular blocking agents.

#### **NAUSEA AND VOMITING**

The opioid analgesics can activate the brainstem chemoreceptor trigger zone to produce nausea and vomiting. There may also be a vestibular component in this effect because ambulation seems to increase the incidence of nausea and vomiting.

#### **TEMPERATURE**

Homeostatic regulation of body temperature is mediated in part by the action of endogenous opioid peptides in the brain. This has been supported by experiments demonstrating that administration of  $\mu$ -opioid receptor agonists such as morphine administered to the anterior hypothalamus produces hyperthermia, whereas administration of  $\kappa$  agonists induces hypothermia.

#### **Peripheral Effects**

## **CARDIOVASCULAR SYSTEM**

Most opioids have no significant direct effects on the heart and, other than bradycardia, no major effects on cardiac rhythm. Meperidine is an exception to this generalization because its antimuscarinic action can result in tachycardia. Blood pressure is usually well maintained in subjects receiving opioids unless the cardiovascular system is stressed, in which case hypotension may occur. This hypotensive effect is probably due to peripheral arterial and venous dilation, which has been attributed to a number of mechanisms including central depression of vasomotor-stabilizing mechanisms and release of histamine. No consistent effect on cardiac output is seen, and the electrocardiogram is not significantly affected. However, caution should be exercised in patients with decreased blood volume, because the above mechanisms make these patients susceptible to hypotension. Opioid analgesics affect cerebral circulation minimally except when PCO<sub>2</sub> rises as a consequence of respiratory depression. Increased PCO<sub>2</sub> leads to cerebral vasodilation associated with a decrease in cerebral vascular resistance, an increase in cerebral blood flow, and an increase in intracranial pressure.

## **GASTROINTESTINAL TRACT**

Constipation has long been recognized as an effect of opioids, an effect that does not diminish with continued use. That is, tolerance does not develop to opioid-induced constipation (Table 31-3). Opioid receptors exist in high density in the gastrointestinal tract, and the constipating effects of the opioids are mediated through an action on the enteric nervous system (see Chapter 6) as well as the CNS. In the stomach, motility (rhythmic contraction and relaxation) may decrease but tone (persistent contraction) may increase—particularly in the central portion; gastric secretion of hydrochloric acid is decreased. Small intestine resting tone is increased, with periodic spasms, but the amplitude of nonpropulsive contractions is markedly decreased. In the large intestine, propulsive peristaltic waves are diminished and tone is increased; this delays passage of the fecal mass and allows increased absorption of water, which leads to constipation. The large bowel actions are the basis for the use of opioids in the management of diarrhea, and constipation is a major problem in the use of opioids for control of severe cancer pain.

## **BILIARY TRACT**

The opioids contract biliary smooth muscle, which can result in biliary colic. The sphincter of Oddi may constrict, resulting in reflux of biliary and pancreatic secretions and elevated plasma amylase and lipase levels.

## **RENAL**

Renal function is depressed by opioids. It is believed that in humans this is chiefly due to decreased renal plasma flow. In addition,  $\mu$  opioids have been found to have an antidiuretic effect in humans. Mechanisms may involve both the CNS and peripheral sites. Opioids also enhance renal tubular sodium reabsorption. The role of opioid-induced changes in antidiuretic hormone (ADH) release is controversial. Ureteral and bladder tone are increased by therapeutic doses of the opioid analgesics. Increased sphincter tone may precipitate urinary retention, especially in postoperative patients. Occasionally, ureteral colic caused by a renal calculus is made worse by opioid-induced increase in ureteral tone.

## **UTERUS**

The opioid analgesics may prolong labor. The mechanism for this action is unclear, but both peripheral and central actions of the opioids can reduce uterine tone.

## **NEUROENDOCRINE**

Opioid analgesics stimulate the release of ADH, prolactin, and somatotropin but inhibit the release of luteinizing hormone. These effects suggest that endogenous opioid peptides, through effects in the hypothalamus, regulate these systems (Table 31-1).

## **PRURITUS**

Therapeutic doses of the opioid analgesics produce flushing and warming of the skin accompanied sometimes by sweating and itching; CNS effects and peripheral histamine release may be responsible for these reactions. Opioid-induced pruritus and occasionally urticaria appear more frequently when opioid analgesics are administered parenterally. In addition, when opioids such as morphine are administered to the neuraxis by the spinal or epidural route, their usefulness may be limited by intense pruritus over the lips and torso.

## **MISCELLANEOUS**

The opioids modulate the immune system by effects on lymphocyte proliferation, antibody production, and chemotaxis. In addition, leucocytes migrate to the site of tissue injury and release opioid peptides, which in turn help

counter inflammatory pain. However, natural killer cell cytolytic activity and lymphocyte proliferative responses to mitogens are usually inhibited by opioids. Although the mechanisms involved are complex, activation of central opioid receptors could mediate a significant component of the changes observed in peripheral immune function. In general, these effects are mediated by the sympathetic nervous system in the case of acute administration and by the hypothalamic-pituitary-adrenal system in the case of prolonged administration of opioids.

#### **EFFECTS OF OPIOIDS WITH BOTH AGONIST AND ANTAGONIST ACTIONS**

Buprenorphine is an opioid agonist that displays high binding affinity but low intrinsic activity at the  $\mu$  receptor. Its slow rate of dissociation from the  $\mu$  receptor has also made it an attractive alternative to methadone for the management of opioid withdrawal. It functions as an *antagonist* at the  $\delta$  and  $\kappa$  receptors and for this reason is referred to as a "mixed agonist-antagonist." Although buprenorphine is used as an analgesic, it can antagonize the action of more potent  $\mu$  agonists such as morphine. Buprenorphine also binds to ORL1, the orphanin receptor. Whether this property also participates in opposing  $\mu$  receptor function is under study. Pentazocine and nalbuphine are other examples of opioid analgesics with mixed agonist-antagonist properties. Psychotomimetic effects, with hallucinations, nightmares, and anxiety, have been reported after use of drugs with mixed agonist-antagonist actions.

### **CLINICAL PHARMACOLOGY OF THE OPIOID ANALGESICS**

Successful treatment of pain is a challenging task that begins with careful attempts to assess the source and magnitude of the pain. The amount of pain experienced by the patient is often measured by means of a numeric visual analog scale (VAS) with word descriptors ranging from no pain (0) to excruciating pain (10). A similar scale can be used with children and with patients who cannot speak; this scale depicts five faces ranging from smiling (no pain) to crying (maximum pain).

For a patient in severe pain, the administration of an opioid analgesic is usually considered a primary part of the overall management plan. Determining the route of administration (oral, parenteral, neuraxial), duration of drug action, ceiling effect (maximal intrinsic activity), duration of therapy, potential for adverse effects, and the patient's past experience with opioids all should be addressed. One of the principal errors made by physicians in this setting is failure to adequately assess a patient's pain and to match its severity with an appropriate level of therapy. Just as important is the principle that following delivery of the therapeutic plan, its effectiveness must be reevaluated and the plan modified, if necessary, if the response was excessive or inadequate.

Use of opioid drugs in acute situations may be contrasted with their use in chronic pain management, in which a multitude of other factors must be considered, including the development of tolerance to and physical dependence on opioid analgesics.

#### **Clinical Use of Opioid Analgesics**

##### **ANALGESIA**

Severe, *constant* pain is usually relieved with opioid analgesics with high intrinsic activity (see Table 31-2); whereas sharp, intermittent pain does not appear to be as effectively controlled.

The pain associated with cancer and other terminal illnesses must be treated aggressively and often requires a multidisciplinary approach for effective management. Such conditions may require continuous use of potent opioid analgesics and are associated with some degree of tolerance and dependence. However, this should not be used as a barrier to providing patients with the best possible care and quality of life. Research in the hospice movement has demonstrated that fixed-interval administration of opioid medication (ie, a regular dose at a scheduled time) is more effective in achieving pain relief than dosing on demand. New dosage forms of opioids that allow slower release of the drug are now available, eg, sustained-release forms of morphine (MSContin) and oxycodone (OxyContin). Their purported advantage is a longer and more stable level of analgesia.

If disturbances of gastrointestinal function prevent the use of oral sustained-release morphine, the fentanyl transdermal system (fentanyl patch) can be used over long periods. Furthermore, buccal transmucosal fentanyl can be used for short episodes of breakthrough pain (see Alternative Routes of Administration). Administration of strong opioids by nasal insufflation has been shown to be efficacious, and nasal preparations are now available in some countries. Approval of such formulations in the USA is growing. In addition, stimulant drugs such as the amphetamines have been shown to enhance the analgesic actions of the opioids and thus may be very useful

adjuncts in the patient with chronic pain.

Opioid analgesics are often used during obstetric labor. Because opioids cross the placental barrier and reach the fetus, care must be taken to minimize neonatal depression. If it occurs, immediate injection of the antagonist naloxone will reverse the depression. The phenylpiperidine drugs (eg, meperidine) appear to produce less depression, particularly respiratory depression, in newborn infants than does morphine; this may justify their use in obstetric practice.

The acute, severe pain of renal and biliary colic often requires a strong agonist opioid for adequate relief. However, the drug-induced increase in smooth muscle tone may cause a paradoxical *increase* in pain secondary to increased spasm. An increase in the dose of opioid is usually successful in providing adequate analgesia.

#### **ACUTE PULMONARY EDEMA**

The relief produced by intravenous morphine in dyspnea from pulmonary edema associated with left ventricular heart failure is remarkable. Proposed mechanisms include reduced anxiety (*perception* of shortness of breath), and reduced cardiac preload (reduced venous tone) and afterload (decreased peripheral resistance). However, if respiratory depression is a problem, furosemide may be preferred for the treatment of pulmonary edema. On the other hand, morphine can be particularly useful when treating painful myocardial ischemia with pulmonary edema.

#### **COUGH**

Suppression of cough can be obtained at doses lower than those needed for analgesia. However, in recent years the use of opioid analgesics to allay cough has diminished largely because a number of effective synthetic compounds have been developed that are neither analgesic nor addictive. These agents are discussed below.

#### **DIARRHEA**

Diarrhea from almost any cause can be controlled with the opioid analgesics, but if diarrhea is associated with infection such use must not substitute for appropriate chemotherapy. Crude opium preparations (eg, paregoric) were used in the past to control diarrhea, but now synthetic surrogates with more selective gastrointestinal effects and few or no CNS effects, eg, diphenoxylate or loperamide, are used. Several preparations are available specifically for this purpose (see Chapter 62).

#### **SHIVERING**

Although all opioid agonists have some propensity to reduce shivering, meperidine is reported to have the most pronounced anti-shivering properties. Meperidine apparently blocks shivering mainly through an action on subtypes of the  $\alpha_2$  adrenoceptor.

#### **APPLICATIONS IN ANESTHESIA**

The opioids are frequently used as premedicant drugs before anesthesia and surgery because of their sedative, anxiolytic, and analgesic properties. They are also used intraoperatively both as adjuncts to other anesthetic agents and, in high doses (eg, 0.02–0.075 mg/kg of fentanyl), as a primary component of the anesthetic regimen (see Chapter 25). Opioids are most commonly used in cardiovascular surgery and other types of high-risk surgery in which a primary goal is to minimize cardiovascular depression. In such situations, mechanical respiratory assistance must be provided.

Because of their direct action on the superficial neurons of the spinal cord dorsal horn, opioids can also be used as regional analgesics by administration into the epidural or subarachnoid spaces of the spinal column. A number of studies have demonstrated that long-lasting analgesia with minimal adverse effects can be achieved by epidural administration of 3–5 mg of morphine, followed by slow infusion through a catheter placed in the epidural space. It was initially assumed that the epidural application of opioids might selectively produce analgesia without impairment of motor, autonomic, or sensory functions other than pain. However, respiratory depression can occur after the drug is injected into the epidural space and may require reversal with naloxone. Effects such as pruritus and nausea and vomiting are common after epidural and subarachnoid administration of opioids and may also be reversed with naloxone if necessary. Currently, the epidural route is favored over subarachnoid administration because adverse effects are less common and robust outcome studies have shown a significant reduction in perioperative mortality and morbidity with the use of thoracic epidural analgesia. The use of low doses of local anesthetics in combination with fentanyl infused through a thoracic epidural catheter has become an accepted method of pain control in patients recovering from thoracic and major upper abdominal surgery. In rare cases, chronic pain management specialists may

elect to surgically implant a programmable infusion pump connected to a spinal catheter for continuous infusion of opioids or other analgesic compounds.

#### ALTERNATIVE ROUTES OF ADMINISTRATION

**Rectal suppositories** of morphine and hydromorphone have been used when oral and parenteral routes are undesirable. The **transdermal patch** provides stable blood levels of drug and better pain control while avoiding the need for repeated parenteral injections. Fentanyl has been the most successful opioid in transdermal application and is indicated for the management of persistent unremitting pain. Because of the complication of fentanyl-induced respiratory depression, the FDA recommends that introduction of transdermal fentanyl patch (25 mcg/h) be reserved for patients with an established oral morphine requirement of at least 60 mg/d for 1 week or more. Extreme caution must be exercised in any patient initiating therapy or undergoing a dose increase because the peak effects may not be realized until 24–48 hours after patch application. The **intranasal** route avoids repeated parenteral drug injections and the first-pass metabolism of orally administered drugs. Butorphanol is the only opioid currently available in the USA in a nasal formulation, but more are expected. Another alternative to parenteral administration is the **buccal transmucosal** route, which uses a fentanyl citrate lozenge or a "lollipop" mounted on a stick.

Another type of pain control called **patient-controlled analgesia (PCA)** is now in widespread use for the management of breakthrough pain. With PCA, the patient controls a parenteral (usually intravenous) infusion device by pressing a button to deliver a preprogrammed dose of the desired opioid analgesic. Claims of better pain control using less opioid are supported by well-designed clinical trials, making this approach very useful in postoperative pain control. However, health care personnel must be very familiar with the use of PCAs to avoid overdosage secondary to misuse or improper programming. There is a proven risk of PCA-associated respiratory depression and hypoxia that requires careful monitoring of vital signs and sedation level, and provision of supplemental oxygen.

#### Toxicity & Undesired Effects

Direct toxic effects of the opioid analgesics that are extensions of their acute pharmacologic actions include respiratory depression, nausea, vomiting, and constipation (Table 31–4). In addition, tolerance and dependence, diagnosis and treatment of overdosage, and contraindications must be considered.

#### Table 31–4 Adverse Effects of the Opioid Analgesics.

Behavioral restlessness, tremulousness, hyperactivity (in dysphoric reactions)  
Respiratory depression  
Nausea and vomiting  
Increased intracranial pressure  
Postural hypotension accentuated by hypovolemia  
Constipation  
Urinary retention  
Itching around nose, urticaria (more frequent with parenteral and spinal administration)

#### TOLERANCE AND DEPENDENCE

Drug dependence of the opioid type is marked by a relatively specific withdrawal or abstinence syndrome. Just as there are pharmacologic differences between the various opioids, there are also differences in psychologic dependence and the severity of withdrawal effects. For example, withdrawal from dependence on a strong agonist is associated with more severe withdrawal signs and symptoms than withdrawal from a mild or moderate agonist. Administration of an opioid *antagonist* to an opioid-dependent person is followed by brief but severe withdrawal symptoms (see antagonist-precipitated withdrawal, below). The potential for physical and psychologic dependence of the partial agonist-antagonist opioids appears to be less than that of the strong agonist drugs.

#### Tolerance

Although development of tolerance begins with the first dose of an opioid, tolerance generally does not become clinically manifest until after 2–3 weeks of frequent exposure to ordinary therapeutic doses. Nevertheless,

perioperative and critical care use of ultrapotent opioid analgesics such as remifentanyl have been shown to induce opioid tolerance within hours. Tolerance develops most readily when large doses are given at short intervals and is minimized by giving small amounts of drug with longer intervals between doses.

Depending on the compound and the effect measured, the degree of tolerance may be as great as 35-fold. Marked tolerance may develop to the analgesic, sedating, and respiratory depressant effects. It is possible to produce respiratory arrest in a nontolerant person with a dose of 60 mg of morphine, whereas in addicts maximally tolerant to opioids as much as 2000 mg of morphine taken over a 2- or 3-hour period may not produce significant respiratory depression. Tolerance also develops to the antidiuretic, emetic, and hypotensive effects but not to the miotic, convulsant, and constipating actions (Table 31-3).

Tolerance to the sedating and respiratory effects of the opioids dissipates within a few days after the drugs are discontinued. Tolerance to the emetic effects may persist for several months after withdrawal of the drug. The rates at which tolerance appears and disappears, as well as the degree of tolerance, may also differ considerably among the different opioid analgesics and among individuals using the same drug. For instance, tolerance to methadone develops more slowly and to a lesser degree than to morphine.

Tolerance also develops to analgesics with mixed receptor effects but to a lesser extent than to the agonists. Such effects as hallucinations, sedation, hypothermia, and respiratory depression are reduced after repeated administration of the mixed receptor drugs. However, tolerance to the latter agents does not generally include cross-tolerance to the agonist opioids. It is also important to note that tolerance does *not* develop to the antagonist actions of the mixed agents or to those of the pure antagonists.

Cross-tolerance is an extremely important characteristic of the opioids, ie, patients tolerant to morphine often show a reduction in analgesic response to other agonist opioids. This is particularly true of those agents with primarily  $\mu$ -receptor agonist activity. Morphine and its congeners exhibit cross-tolerance not only with respect to their analgesic actions but also to their euphoriant, sedative, and respiratory effects. However, the cross-tolerance existing among the  $\mu$ -receptor agonists can often be partial or incomplete. This clinical observation has led to the concept of "opioid rotation," which has been used in the treatment of cancer pain for many years. A patient who is experiencing decreasing effectiveness of one opioid analgesic regimen is "rotated" to a different opioid analgesic (eg, morphine to hydromorphone; hydromorphone to methadone) and typically experiences significantly improved analgesia at a reduced overall equivalent dosage. Another approach is to "recouple" opioid receptor function through the use of adjunctive nonopioid agents. NMDA-receptor antagonists (eg, ketamine) have shown promise in preventing or reversing opioid-induced tolerance in animals and humans. Use of ketamine is increasing because well-controlled studies have shown clinical efficacy in reducing postoperative pain and opioid requirements in opioid-tolerant patients. Agents that independently enhance  $\mu$ -receptor recycling may also hold promise to improve analgesia in the opioid-tolerant patient.

The novel use of  $\delta$ -receptor antagonists with  $\mu$ -receptor agonists is also emerging as a strategy to avoid the development of tolerance. This idea has developed around the observation that mice lacking the  $\delta$ -opioid receptor fail to develop tolerance to morphine.

### **Physical Dependence**

The development of physical dependence is an invariable accompaniment of tolerance to repeated administration of an opioid of the  $\mu$  type. Failure to continue administering the drug results in a characteristic withdrawal or abstinence syndrome that reflects an exaggerated rebound from the acute pharmacologic effects of the opioid.

The signs and symptoms of withdrawal include rhinorrhea, lacrimation, yawning, chills, gooseflesh (piloerection), hyperventilation, hyperthermia, mydriasis, muscular aches, vomiting, diarrhea, anxiety, and hostility. The number and intensity of the signs and symptoms are largely dependent on the degree of physical dependence that has developed. Administration of an opioid at this time suppresses abstinence signs and symptoms almost immediately.

The time of onset, intensity, and duration of abstinence syndrome depend on the drug previously used and may be related to its biologic half-life. With morphine or heroin, withdrawal signs usually start within 6-10 hours after the last dose. Peak effects are seen at 36-48 hours, after which most of the signs and symptoms gradually subside. By 5 days, most of the effects have disappeared, but some may persist for months. In the case of meperidine, the withdrawal syndrome largely subsides within 24 hours, whereas with methadone several days are required to reach

the peak of the abstinence syndrome, and it may last as long as 2 weeks. The slower subsidence of methadone effects is associated with a less intense immediate syndrome, and this is the basis for its use in the detoxification of heroin addicts. However, despite the loss of physical dependence on the opioid, craving for it may persist. In addition to methadone, buprenorphine and clonidine (an  $\alpha_2$ -noradrenergic receptor agonist) are FDA-approved treatments for opioid analgesic detoxification (see Chapter 32).

A transient, explosive abstinence syndrome—**antagonist-precipitated withdrawal**—can be induced in a subject physically dependent on opioids by administering naloxone or another antagonist. Within 3 minutes after injection of the antagonist, signs and symptoms similar to those seen after abrupt discontinuance appear, peaking in 10–20 minutes and largely subsiding after 1 hour. Even in the case of methadone, withdrawal of which results in a relatively mild abstinence syndrome, the antagonist-precipitated abstinence syndrome may be very severe.

In the case of agents with mixed effects, withdrawal signs and symptoms can be induced after repeated administration followed by abrupt discontinuance of pentazocine, cyclazocine, or nalorphine, but the syndrome appears to be somewhat different from that produced by morphine and other agonists. Anxiety, loss of appetite and body weight, tachycardia, chills, increase in body temperature, and abdominal cramps have been noted.

### **Psychologic Dependence**

The euphoria, indifference to stimuli, and sedation usually caused by the opioid analgesics, especially when injected intravenously, tend to promote their compulsive use. In addition, the addict experiences abdominal effects that have been likened to an intense sexual orgasm. These factors constitute the primary reasons for opioid abuse liability and are strongly reinforced by the development of physical dependence. This disorder has been linked to dysregulation of brain regions mediating reward and stress (see Chapter 32).

Obviously, the risk of causing dependence is an important consideration in the therapeutic use of these drugs. *Despite that risk, under no circumstances should adequate pain relief ever be withheld simply because an opioid exhibits potential for abuse or because legislative controls complicate the process of prescribing narcotics.* Furthermore, certain principles can be observed by the clinician to minimize problems presented by tolerance and dependence when using opioid analgesics:

- Establish therapeutic goals before starting opioid therapy. This tends to limit the potential for physical dependence. The patient and his or her family should be included in this process.
- Once an effective dose is established, attempt to limit dosage to this level. This goal is facilitated by use of a written treatment contract that specifically prohibits early refills and having multiple prescribing physicians.
- Instead of opioid analgesics—especially in chronic management—consider using other types of analgesics or compounds exhibiting less pronounced withdrawal symptoms on discontinuance.
- Frequently evaluate continuing analgesic therapy and the patient's need for opioids.

### **DIAGNOSIS AND TREATMENT OF OPIOID OVERDOSAGE**

Intravenous injection of naloxone dramatically reverses coma due to opioid overdose but not that due to other CNS depressants. Use of the antagonist should not, of course, delay the institution of other therapeutic measures, especially respiratory support.

See also the Antagonists section below and Chapter 58.

### **CONTRAINDICATIONS AND CAUTIONS IN THERAPY**

#### **Use of Pure Agonists with Weak Partial Agonists**

When a weak partial agonist such as pentazocine is given to a patient also receiving a full agonist (eg, morphine), there is a risk of diminishing analgesia or even inducing a state of withdrawal; combining full agonist with partial agonist opioids should be avoided.

#### **Use in Patients with Head Injuries**

Carbon dioxide retention caused by respiratory depression results in cerebral vasodilation. In patients with elevated intracranial pressure, this may lead to lethal alterations in brain function.

#### **Use during Pregnancy**

In pregnant women who are chronically using opioids, the fetus may become physically dependent in utero and manifest withdrawal symptoms in the early postpartum period. A daily dose as small as 6 mg of heroin (or equivalent) taken by the mother can result in a mild withdrawal syndrome in the infant, and twice that much may result in severe signs and symptoms, including irritability, shrill crying, diarrhea, or even seizures. Recognition of the problem is aided by a careful history and physical examination. When withdrawal symptoms are judged to be relatively mild, treatment is aimed at control of these symptoms using such drugs as diazepam; with more severe withdrawal, camphorated tincture of opium (paregoric; 0.4 mg of morphine/mL) in an oral dose of 0.12–0.24 mL/kg is used. Oral doses of methadone (0.1–0.5 mg/kg) have also been used.

#### Use in Patients with Impaired Pulmonary Function

In patients with borderline respiratory reserve, the depressant properties of the opioid analgesics may lead to acute respiratory failure.

#### Use in Patients with Impaired Hepatic or Renal Function

Because morphine and its congeners are metabolized primarily in the liver, their use in patients in prehepatic coma may be questioned. Half-life is prolonged in patients with impaired renal function, and morphine and its active glucuronide metabolite may accumulate; dosage can often be reduced in such patients.

#### Use in Patients with Endocrine Disease

Patients with adrenal insufficiency (Addison's disease) and those with hypothyroidism (myxedema) may have prolonged and exaggerated responses to opioids.

### Drug Interactions

Because seriously ill or hospitalized patients may require a large number of drugs, there is always a possibility of drug interactions when the opioid analgesics are administered. Table 31–5 lists some of these drug interactions and the reasons for not combining the named drugs with opioids.

**Table 31–5 Opioid Drug Interactions.**

Drug Group	Interaction with Opioids
Sedative-hypnotics	Increased central nervous system depression, particularly respiratory depression.
Antipsychotic tranquilizers	Increased sedation. Variable effects on respiratory depression. Accentuation of cardiovascular effects (antimuscarinic and $\alpha$ -blocking actions).
Monoamine oxidase inhibitors	Relative contraindication to all opioid analgesics because of the high incidence of hyperpyrexia; hypertension has also been reported.

### Specific Agents

The following section describes the most important and widely used opioid analgesics, along with features peculiar to specific agents. Data about doses approximately equivalent to 10 mg of intramuscular morphine, oral versus parenteral efficacy, duration of analgesia, and intrinsic activity (maximum efficacy) are presented in Table 31–2.

## STRONG AGONISTS

### Phenanthrenes

**Morphine, hydromorphone, and oxycodone** are strong agonists useful in treating severe pain. These prototypic agents have been described in detail above.

**Morphine**

**Heroin** (diamorphine, diacetylmorphine) is potent and fast-acting, but its use is prohibited in the USA and Canada. In recent years, there has been considerable agitation to revive its use. However, double-blind studies have not supported the claim that heroin is more effective than morphine in relieving severe chronic pain, at least when given by the intramuscular route.

### Phenylheptylamines

**Methadone** has undergone a dramatic revival as a potent and clinically useful analgesic. It can be administered by the oral, intravenous, subcutaneous, spinal, and rectal routes. It is well absorbed from the gastrointestinal tract and its bioavailability far exceeds that of oral morphine.

**Methadone**

Methadone is not only a potent  $\mu$ -receptor agonist but its racemic mixture of D- and L-methadone isomers can also block both NMDA receptors and monoaminergic reuptake transporters. These nonopioid receptor properties may help explain its ability to relieve difficult-to-treat pain (neuropathic, cancer pain), especially when a previous trial of morphine has failed. In this regard, when analgesic tolerance or intolerable side effects have developed with the use of increasing doses of morphine or hydromorphone, "opioid rotation" to methadone has provided superior analgesia at 10–20% of the morphine-equivalent daily dose. In contrast to its use in suppressing symptoms of opioid withdrawal, use of methadone as an analgesic typically requires administration at intervals of no more than 8 hours. However, given methadone's highly variable pharmacokinetics and long half-life (25–52 hours), initial administration should be closely monitored to avoid potentially harmful adverse effects, especially respiratory depression. Because methadone is metabolized by CYP3A4 and CYP2B6 isoforms in the liver, inhibition of its metabolic pathway or hepatic dysfunction have also been associated with overdose effects, including respiratory depression or, more rarely, prolonged QT-based cardiac arrhythmias.

Methadone is widely used in the treatment of opioid abuse. Tolerance and physical dependence develop more slowly with methadone than with morphine. The withdrawal signs and symptoms occurring after abrupt discontinuance of methadone are milder, although more prolonged, than those of morphine. These properties make methadone a useful drug for detoxification and for maintenance of the chronic relapsing heroin addict.

For detoxification of a heroin-dependent addict, low doses of methadone (5–10 mg orally) are given two or three times daily for 2 or 3 days. Upon discontinuing methadone, the addict experiences a mild but enduring withdrawal syndrome.

For maintenance therapy of the opioid recidivist, tolerance to 50–100 mg/d of oral methadone may be deliberately produced; in this state, the addict experiences cross-tolerance to heroin, which prevents most of the addiction-reinforcing effects of heroin. One rationale of maintenance programs is that blocking the reinforcement obtained from abuse of illicit opioids removes the drive to obtain them, thereby reducing criminal activity and making the addict more amenable to psychiatric and rehabilitative therapy. The pharmacologic basis for the use of methadone in maintenance programs is sound and the sociologic basis is rational, but some methadone programs fail because nonpharmacologic management is inadequate.

The concurrent administration of methadone to heroin addicts known to be recidivists has been questioned because of the increased risk of overdose death secondary to respiratory arrest. Buprenorphine, a partial  $\mu$ -receptor agonist with long-acting properties, has been found to be effective in opioid detoxification and maintenance programs and is presumably associated with a lower risk of such overdose fatalities.

### Phenylpiperidines

**Fentanyl** is one of the most widely used agents in the family of synthetic opioids. The fentanyl subgroup now

includes **sufentanil**, **alfentanil**, and **remifentanil** in addition to the parent compound, fentanyl.

**Fentanyl**

These opioids differ mainly in their potency and biodisposition. Sufentanil is five to seven times more potent than fentanyl. Alfentanil is considerably less potent than fentanyl, but acts more rapidly and has a markedly shorter duration of action. Remifentanil is metabolized very rapidly by blood and nonspecific tissue esterases, making its pharmacokinetic and pharmacodynamic half-lives extremely short. Such properties are useful when these compounds are used in anesthesia practice. Although fentanyl is now the predominant analgesic in the phenylpiperidine class, **meperidine** continues to be used. This older opioid has significant antimuscarinic effects, which may be a contraindication if tachycardia would be a problem. Meperidine is also reported to have a negative inotropic action on the heart. In addition, it has the potential for producing seizures secondary to accumulation of its metabolite, normeperidine, in patients receiving high doses or with concurrent renal failure. Given this undesirable profile, use of meperidine as a first-line analgesic is becoming increasingly rare.

### Morphinans

**Levorphanol** is a synthetic opioid analgesic closely resembling morphine in its action.

## MILD TO MODERATE AGONISTS

### Phenanthrenes

**Codeine**, **oxycodone**, **dihydrocodeine**, and **hydrocodone** are all somewhat less efficacious than morphine (they are partial agonists) or have adverse effects that limit the maximum tolerated dose when one attempts to achieve analgesia comparable to that of morphine.

**Codeine**

These compounds are rarely used alone but are combined in formulations containing aspirin, acetaminophen, or other drugs.

### Phenylheptylamines

**Propoxyphene** is chemically related to methadone but has low analgesic activity. Various studies have reported its potency at levels ranging from no better than placebo to half as potent as codeine; that is, 120 mg propoxyphene = 60 mg codeine. Its true potency probably lies somewhere between these extremes, and its analgesic effect is additive to that of an optimal dose of aspirin or acetaminophen. However, its low efficacy makes it unsuitable, even in combination with aspirin, for severe pain. The increasing incidence of deaths associated with its use and misuse has caused it to be scheduled as a controlled substance. Moreover, banning its use in the United States is under consideration.

### Phenylpiperidines

**Diphenoxylate** and its metabolite, **difenoxin**, are not used for analgesia but for the treatment of diarrhea. They are scheduled for minimal control (difenoxin is Schedule IV, diphenoxylate Schedule V; see inside front cover) because

the likelihood of their abuse is remote. The poor solubility of the compounds limits their use for parenteral injection. As antidiarrheal drugs, they are used in combination with atropine. The atropine is added in a concentration too low to have a significant antidiarrheal effect but is presumed to further reduce the likelihood of abuse.

**Loperamide** is a phenylpiperidine derivative used to control diarrhea. However, due to action on peripheral  $\mu$ -opioid receptors and lack of effect on CNS receptors, there is renewed interest in its potential for the treatment of neuropathic pain. Its potential for abuse is considered very low because of its limited access to the brain. It is therefore available without a prescription.

The usual dose with all of these antidiarrheal agents is two tablets to start and then one tablet after each diarrheal stool.

## OPIOIDS WITH MIXED RECEPTOR ACTIONS

Care should be taken not to administer any partial agonist or drug with mixed opioid receptor actions to patients receiving pure agonist drugs because of the unpredictability of both drugs' effects; reduction of analgesia or precipitation of an explosive abstinence syndrome may result.

### Phenanthrenes

**Nalbuphine** is a strong  $\kappa$ -receptor *agonist* and a  $\mu$ -receptor *antagonist*; it is given parenterally. At higher doses there seems to be a definite ceiling<sup>â</sup>not noted with morphine<sup>â</sup>to the respiratory depressant effect. Unfortunately, when respiratory depression does occur, it may be relatively resistant to naloxone reversal.

**Buprenorphine** is a potent and long-acting phenanthrene derivative that is a partial  $\mu$ -receptor agonist and a  $\kappa$   $\epsilon$ -receptor antagonist. Administration by the sublingual route is preferred to avoid significant first-pass effect. Its long duration of action is due to its slow dissociation from  $\mu$  receptors. This property renders its effects resistant to naloxone reversal. Its clinical applications are much like those of nalbuphine. In addition, studies continue to suggest that buprenorphine is as effective as methadone in the detoxification and maintenance of heroin abusers. Buprenorphine was approved by the FDA in 2002 for the management of opioid dependence. In contrast to methadone, high-dose administration of buprenorphine results in a  $\mu$ -opioid *antagonist* action, limiting its properties of analgesia and respiratory depression. Moreover, buprenorphine is also available combined with a pure  $\mu$ -opioid antagonist (Suboxone) to help prevent its diversion for illicit intravenous abuse.

### Morphinans

**Butorphanol** produces analgesia equivalent to nalbuphine and buprenorphine but appears to produce more sedation at equianalgesic doses. Butorphanol is considered to be predominantly a  $\kappa$  agonist. However, it may also act as a partial agonist or antagonist at the  $\mu$  receptor.

### Benzomorphans

**Pentazocine** is a  $\kappa$  agonist with weak  $\mu$  antagonist or partial agonist properties. It is the oldest mixed agent available. It may be used orally or parenterally. However, because of its irritant properties, the injection of pentazocine subcutaneously is not recommended.

## MISCELLANEOUS

**Tramadol** is a centrally acting analgesic whose mechanism of action is predominantly based on blockade of serotonin reuptake. Tramadol has also been found to inhibit norepinephrine transporter function. Because it is only partially antagonized by naloxone, it is believed to be only a weak  $\mu$ -receptor agonist. The recommended dosage is 50<sup>â</sup>100 mg orally four times daily. Toxicity includes association with seizures; the drug is relatively contraindicated in patients with a history of epilepsy and for use with other drugs that lower the seizure threshold. Other side effects include nausea and dizziness, but these symptoms typically abate after several days of therapy. It is surprising that no clinically significant effects on respiration or the cardiovascular system have thus far been reported. Given the fact that the analgesic action of tramadol is largely independent of  $\mu$  receptor action, tramadol may serve as an adjunct with pure opioid agonists in the treatment of chronic neuropathic pain.

**Tapentadol** is a newer analgesic with modest  $\mu$ -opioid receptor affinity and significant norepinephrine reuptake-inhibiting action. In animal models, its analgesic effects were only moderately reduced by naloxone but strongly reduced by an  $\alpha_2$  antagonist. Furthermore, its binding to the norepinephrine transporter (NET, see Chapter 6) was

stronger than that of tramadol, whereas its binding to the serotonin transporter (SERT) was less than that of tramadol. Tapentadol was approved in 2008 and was not yet available at the time of writing, and detailed comparisons with established analgesics in humans are not yet available.

## ANTITUSSIVES

The opioid analgesics are among the most effective drugs available for the suppression of cough. This effect is often achieved at doses below those necessary to produce analgesia. The receptors involved in the antitussive effect appear to differ from those associated with the other actions of opioids. For example, the antitussive effect is also produced by stereoisomers of opioid molecules that are devoid of analgesic effects and addiction liability (see below).

The physiologic mechanism of cough is complex, and little is known about the specific mechanism of action of the opioid antitussive drugs. It appears likely that both central and peripheral effects play a role.

The opioid derivatives most commonly used as antitussives are dextromethorphan, codeine, levopropoxyphene, and noscapine (levopropoxyphene and noscapine are not available in the USA). They should be used with caution in patients taking monoamine oxidase inhibitors (see Table 31-5). Antitussive preparations usually also contain expectorants to thin and liquefy respiratory secretions. Importantly, due to increasing reports of death in young children taking dextromethorphan in formulations of over-the-counter "cold/cough" medications, its use in children less than 6 years of age has been banned by the FDA. Moreover, due to variations in the metabolism of codeine, its use for any purpose in young children is being reconsidered.

**Dextromethorphan** is the dextrorotatory stereoisomer of a methylated derivative of levorphanol. It is purported to be free of addictive properties and produces less constipation than codeine. The usual antitussive dose is 15-30 mg three or four times daily. It is available in many over-the-counter products. Dextromethorphan has also been found to enhance the analgesic action of morphine and presumably other  $\mu$ -receptor agonists. However, abuse of its purified (powdered) form has been reported to lead to serious adverse events including death.

**Codeine**, as noted, has a useful antitussive action at doses lower than those required for analgesia. Thus, 15 mg are usually sufficient to relieve cough.

**Levopropoxyphene** is the stereoisomer of the weak opioid agonist dextropropoxyphene. It is devoid of opioid effects, although sedation has been described as a side effect. The usual antitussive dose is 50-100 mg every 4 hours.

## THE OPIOID ANTAGONISTS

The pure opioid antagonist drugs **naloxone**, **naltrexone**, and **nalmefene** are morphine derivatives with bulkier substituents at the N<sub>17</sub> position. These agents have a relatively high affinity for  $\mu$  opioid binding sites. They have lower affinity for the other receptors but can also reverse agonists at  $\delta$  and  $\kappa$  sites.

**Naloxone**

### Pharmacokinetics

Naloxone is usually given by injection and has a short duration of action (1-2 hours) when given by this route. Metabolic disposition is chiefly by glucuronide conjugation like that of the agonist opioids with free hydroxyl groups. Naltrexone is well absorbed after oral administration but may undergo rapid first-pass metabolism. It has a half-life of 10 hours, and a single oral dose of 100 mg blocks the effects of injected heroin for up to 48 hours. Nalmefene, the newest of these agents, is a derivative of naltrexone but is available only for intravenous administration. Like naloxone, nalmefene is used for opioid overdose but has a longer half-life (8-10 hours).

### Pharmacodynamics

When given in the absence of an agonist drug, these antagonists are almost inert at doses that produce marked antagonism of agonist opioid effects.

When given intravenously to a morphine-treated subject, the antagonist completely and dramatically reverses the opioid effects within 1–3 minutes. In individuals who are acutely depressed by an overdose of an opioid, the antagonist effectively normalizes respiration, level of consciousness, pupil size, bowel activity, and awareness of pain. In dependent subjects who appear normal while taking opioids, naloxone or naltrexone almost instantaneously precipitates an abstinence syndrome.

There is no tolerance to the antagonistic action of these agents, nor does withdrawal after chronic administration precipitate an abstinence syndrome.

### Clinical Use

Naloxone is a pure antagonist and is preferred over older weak agonist-antagonist agents that had been used primarily as antagonists, eg, nalorphine and levallorphan.

The major application of naloxone is in the treatment of acute opioid overdose (see also Chapter 58). *It is very important that the relatively short duration of action of naloxone be borne in mind, because a severely depressed patient may recover after a single dose of naloxone and appear normal, only to relapse into coma after 1–2 hours.*

The usual initial dose of naloxone is 0.1–0.4 mg intravenously for life-threatening respiratory and CNS depression. Maintenance is with the same drug, 0.4–0.8 mg given intravenously, and repeated whenever necessary. In using naloxone in the severely opioid-depressed newborn, it is important to start with doses of 5–10 mcg/kg and to consider a second dose of up to a total of 25 mcg/kg if no response is noted.

Low-dose naloxone (0.04 mg) has an increasing role in the treatment of adverse effects that are commonly associated with intravenous or epidural opioids. Careful titration of the naloxone dosage can often eliminate the itching, nausea, and vomiting while sparing the analgesia. For this purpose, oral naloxone, and more recently modified analogs of naloxone and naltrexone, have been approved by the FDA. These include **methylnaltrexone bromide** (Relistor) for the treatment of constipation in patients with late-stage advanced illness and **alvimopan** (Entereg) for the treatment of postoperative ileus following bowel resection surgery. The principal mechanism for this selective therapeutic effect is believed to be inhibition of peripheral  $\mu$  receptors in the gut with minimal CNS penetration.

Because of its long duration of action, naltrexone has been proposed as a maintenance drug for addicts in treatment programs. A single dose given on alternate days blocks virtually all of the effects of a dose of heroin. It might be predicted that this approach to rehabilitation would not be popular with a large percentage of drug users unless they are motivated to become drug-free. There is evidence that naltrexone decreases the craving for alcohol in chronic alcoholics by increasing baseline  $\beta$ -endorphin release, and it has been approved by the FDA for this purpose (see Chapter 23).

## SUMMARY: OPIOIDS, OPIOID SUBSTITUTES, AND OPIOID ANTAGONISTS

### Opioids, Opioid Substitutes, and Opioid Antagonists

Subclass	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities
<b>Strong opioid agonists</b>				
Morphine	Strong $\mu$ -receptor agonists • variable affinity for $\delta$ and $\kappa$ receptors	Analgesia • relief of anxiety • sedation • slowed gastrointestinal transit	Severe pain • adjunct in anesthesia (fentanyl, morphine) • pulmonary edema (morphine only) • maintenance in rehabilitation programs (methadone only)	First-pass effect • duration 1–4 h except methadone, 4–6 h • <i>Toxicity:</i> Respiratory depression • severe constipation • addiction liability • convulsions
Methadone				
Fentanyl				

*Hydromorphone, oxymorphone: Like morphine in efficacy, but higher potency*

*Meperidine: Strong agonist with anticholinergic effects*

*Sufentanil, alfentanil, remifentanil: Like fentanyl but shorter durations of action*

**Partial agonists**

Codeine	Less efficacious than morphine • can antagonize strong agonists	Like strong agonists • weaker effects	Mild-moderate pain • cough (codeine)	Like strong agonists, toxicity dependent on genetic variation of metabolism
Hydrocodone				

**Mixed opioid agonist-antagonists**

Buprenorphine	Partial $\mu$ agonist • $\kappa$ antagonist	Like strong agonists but can antagonize their effects • also reduces craving for alcohol	Moderate pain • some maintenance rehabilitation programs	Long duration of action 4-8 h • may precipitate abstinence syndrome
Nalbuphine	$\kappa$ Agonist • $\mu$ antagonist	Similar to buprenorphine	Moderate pain	Like buprenorphine

**Antitussives**

Dextromethorphan	Poorly understood but strong and partial $\mu$ agonists are also effective	Reduces cough reflex	Acute debilitating cough	30-60 min duration • <i>Toxicity:</i> Minimal when taken as directed
------------------	--	----------------------	--------------------------	--

*Codeine, levopropoxyphene: Similar to dextromethorphan*

**Opioid antagonists**

Naloxone	Antagonist at $\mu$ , $\delta$ , and $\kappa$ receptors	Rapidly antagonizes all opioid effects	Opioid overdose	Duration 1-2 h (may have to be repeated when treating overdose) • <i>Toxicity:</i> Precipitates abstinence syndrome in dependent users
----------	---	--	-----------------	--

*Naltrexone, nalmefene: Like naloxone but longer durations of action (10+ h); naltrexone is used in maintenance programs and can block heroin effects for up to 48 h*

*Alvimopan, methylnaltrexone bromide: Potent  $\mu$  antagonists with poor entry into the central nervous system; can be used to treat severe opioid-induced constipation without precipitating an abstinence syndrome*

**Other analgesics used in moderate pain**

Tramadol	Mixed effects: weak $\mu$ agonist, moderate SERT inhibitor, weak NET inhibitor	Analgesia	Moderate pain • adjunct to opioids in chronic pain syndromes	Duration 4-6 h • <i>Toxicity:</i> Seizures
----------	--	-----------	--	--

NET, norepinephrine reuptake transporter; SERT, serotonin reuptake transporter.

**PREPARATIONS AVAILABLE<sup>1</sup>**

## **ANALGESIC OPIOIDS**

### **Alfentanil** (generic, Alfenta)

Parenteral: 0.5 mg/mL for injection

### **Buprenorphine** (Buprenex, others)

Oral: 2, 8 mg sublingual tablets

Parenteral: 0.3 mg/mL for injection

### **Butorphanol** (generic, Stadol)

Parenteral: 1, 2 mg/mL for injection

Nasal (generic, Stadol NS): 10 mg/mL nasal spray

### **Codeine** (sulfate or phosphate) (generic)

Oral: 15, 30, 60 mg tablets, 15 mg/5 mL solution

Parenteral: 15, 30 mg/mL for injection

### **Fentanyl** (generic, other)

Parenteral (generic, Sublimaze): 50 mcg/mL for injection

Fentanyl Transdermal System (Duragesic): 12.5, 25, 50, 75, 100 mcg/h delivery

Fentanyl Buccal: 100, 200, 400, 600, 800 mcg oral lozenge

Fentanyl Actiq: 200, 400, 600, 800, 1200, 1600 mcg lozenge on a stick

Patient Controlled Transdermal Iontophoretic Fentanyl System: 40 mcg per dose for delivery

### **Hydromorphone** (generic, Dilaudid)

Oral: 2, 8 mg tablets; 1 mg/mL liquid

Parenteral: 1, 2, 4, 10 mg/mL for injection

### **Levomethadyl acetate** (Orlaam)

Oral: 10 mg/mL solution. *Note:* Orphan drug approved only for the treatment of narcotic addiction.

### **Levorphanol** (generic, Levo-Dromoran)

Oral: 2 mg tablets

Parenteral: 2 mg/mL for injection

### **Meperidine** (generic, Demerol)

Oral: 50, 100 mg tablets; 50 mg/5 mL syrup

Parenteral: 10, 25, 50, 75, 100 mg per dose for injection

### **Methadone** (generic, Dolophine)

Oral: 5, 10 mg tablets; 40 mg dispersible tablets; 1, 2, 10 mg/mL solutions

Parenteral: 10 mg/mL for injection

**Morphine sulfate** (generic, others)

Oral: 15, 30 mg tablets; 15, 30 mg capsules; 10, 20, 100 mg/5 mL solution

Oral sustained-release tablets (MS-Contin, others): 15, 30, 60, 100, 200 mg tablets

Oral sustained-release capsules (Avinza, Kadian): 20, 30, 50, 60, 90, 100, 120 mg capsules

Parenteral: 0.5, 1, 2, 4, 5, 8, 10, 15, 25, 50 mg/mL for injection

Rectal: 5, 10, 20, 30 mg suppositories

**Nalbuphine** (generic, Nubain)

Parenteral: 10, 20 mg/mL for injection

**Oxycodone** (generic)

Oral: 5, 10, 15, 20, 30 mg tablets, capsules; 1, 20 mg/mL solutions

Oral sustained-release (generic, OxyContin): 10, 20, 40, 80 mg tablets

**Oxymorphone** (Numorphan)

Parenteral: 1, 1.5 mg/mL for injection

Rectal: 5 mg suppositories

**Pentazocine** (Talwin)

Oral: See combinations

Parenteral: 30 mg/mL for injection

**Propoxyphene** (generic, Darvon Pulvules, others)

Oral: 65 mg capsules, 100 mg tablets. *Note:* This product is not recommended.

**Remifentanil** (Ultiva)

Parenteral: 1, 2, 5 mg powder for reconstitution for injection

**Sufentanil** (generic, Sufenta)

Parenteral: 50 mcg /mL for injection

**OTHER ANALGESIC**

**Tramadol** (generic, Ultram)

Oral: 50 mg tablets; 100, 200, 300 mg extended-release tablets

**Ziconotide** (Prialt)

Intrathecal: 25, 100 mcg/mL for programmable pump

## ANALGESIC COMBINATIONS<sup>2</sup>

### **Codeine/acetaminophen** (generic, Tylenol with Codeine, others)

Oral: 15, 30, 60 mg codeine plus 300 or 325 mg acetaminophen tablets or capsules; 12 mg codeine plus 120 mg acetaminophen tablets

### **Codeine/aspirin** (generic, Empirin Compound, others)

Oral: 30, 60 mg codeine plus 325 mg aspirin tablets

### **Hydrocodone/acetaminophen** (generic, Norco, Vicodin, Lortab, others)

Oral: 2.5, 5, 7.5, 10 mg hydrocodone plus 500 or 650 mg acetaminophen tablets

### **Hydrocodone/ibuprofen** (Vicoprofen)

Oral: 7.5 mg hydrocodone plus 200 mg ibuprofen

### **Oxycodone/acetaminophen** (generic, Percocet, Tylox, others)

Oral: 5 mg oxycodone plus 325 or 500 mg acetaminophen tablets. *Note:* High-dose acetaminophen has potential for hepatic toxicity with repeated use.

### **Oxycodone/aspirin** (generic, Percodan)

Oral: 4.9 mg oxycodone plus 325 mg aspirin

### **Propoxyphene/aspirin** or **Propoxyphene/acetaminophen** (Darvon Compound-65, others)

Oral: 65 mg propoxyphene plus 389 mg aspirin plus 32.4 mg caffeine; 50, 65, 100 mg propoxyphene plus 325 or 650 mg acetaminophen. *Note:* This product is not recommended.

## OPIOID ANTAGONISTS

### **Alvimopan** (Entereg)

Oral: 12 mg capsules

### **Methylnaltrexone** (Relistor)

Parenteral: 12 mg/0.6 mL for injection

### **Nalmefene** (Revex)

Parenteral: 0.1, 1 mg/mL for injection

### **Naloxone** (Narcan, various)

Parenteral: 0.4, 1 mg/mL; 0.02 mg/mL (for neonatal use) for injection

### **Naltrexone** (ReVia, Depade)

Oral: 50 mg tablets

Parenteral: 380 mg suspension for injection

## ANTITUSSIVES

### **Codeine** (generic)

Oral: 15, 30, 60 mg tablets; constituent of many proprietary syrups<sup>2</sup>

**Dextromethorphan** (generic, Benylin DM, Delsym, others)

Oral: 5, 7.5 mg lozenges; 7.5, 10, 15, 30 mg/5 mL syrup; 30 mg sustained-action liquid; constituent of many proprietary syrups<sup>2</sup>

<sup>1</sup>Antidiarrheal opioid preparations are listed in Chapter 63.

<sup>2</sup>Dozens of combination products are available; only a few of the most commonly prescribed are listed here. Codeine combination products available in several strengths are usually denoted No. 2 (15 mg codeine), No. 3 (30 mg codeine), and No. 4 (60 mg codeine). Prescribers should be aware of the possible danger of renal and hepatic injury with acetaminophen, aspirin, and nonsteroidal anti-inflammatory drugs contained in these analgesic combinations.

Basic and Clinical Pharmacology > Chapter 32. Drugs of Abuse >

## CASE STUDY

A retired accountant developed a tremor and slowing of movements and was diagnosed with Parkinson's disease at age 67. At that time, his neurologist prescribed levodopa to restore dopamine levels. A couple of years later, motor symptoms start to fluctuate and the dopamine receptor agonist ropinirole is added to his treatment.\* A few months later, he develops a strong interest in gambling, first buying lottery tickets and then visiting a casino almost every day. He conceals his gambling activity until he has lost more than \$100,000. When he came for a consultation 5 weeks ago, ropinirole was replaced with monoamine oxidase inhibitor therapy. He now reports that his interest in gambling has disappeared. What may be the link between the dopamine agonist treatment and gambling addiction?

\*The treatment of Parkinson's disease is discussed in Chapter 28.

## DRUGS OF ABUSE: INTRODUCTION

Drugs are abused (used in ways that are not medically approved) because they cause strong feelings of euphoria or alter perception. However, repetitive exposure induces widespread adaptive changes in the brain. As a consequence drug use may become compulsive—the hallmark of addiction.

## BASIC NEUROBIOLOGY OF DRUG ABUSE

### DEPENDENCE VERSUS ADDICTION

Recent neurobiologic research has led to the conceptual and mechanistic separation of "dependence" and "addiction." The older term "physical dependence" is now denoted as **dependence**, whereas "psychological dependence" is more simply called **addiction**.

Every addictive drug causes its own characteristic spectrum of acute effects, but all have in common that they induce strong feelings of euphoria and reward. With repetitive exposure, addictive drugs induce adaptive changes such as tolerance (ie, escalation of dose to maintain effect). Once the abused drug is no longer available, signs of withdrawal become apparent. A combination of such signs, referred to as the withdrawal syndrome, defines *dependence*. Dependence is not always a correlate of drug abuse—it can also occur with many classes of nonpsychoactive drugs, eg, sympathomimetic vasoconstrictors and bronchodilators, and organic nitrate vasodilators. *Addiction*, on the other hand, consists of compulsive, relapsing drug use despite negative consequences, at times triggered by cravings that occur in response to contextual cues (see Animal Models in Addiction Research). Although dependence invariably occurs with chronic exposure, only a small percentage of subjects develop a habit, lose control, and become addicted. For example, very few patients who receive opioids as analgesics desire the drug after withdrawal. And only one person out of six becomes addicted within 10 years of first use of cocaine. Conversely, relapse is very common in addicts after a successful withdrawal when, by definition, they are no longer dependent.

#### Animal Models in Addiction Research

Many of the recent advances in addiction research have been made possible by the use of animal models. Since drugs of abuse are not only rewarding but also reinforcing, an animal will learn a behavior (eg, press a lever) when paired with drug administration. In such a self-administration paradigm, the number of times an animal is willing to press the lever in order to obtain a single dose reflects the strength of reinforcement and is therefore a measure of the rewarding properties of a drug. Observing withdrawal signs specific for rodents (eg, escape jumps or "wet-dog" shakes after abrupt termination of chronic morphine administration) allows the quantification of dependence. Behavioral tests for addiction in the rodent have proven difficult to develop and so far no test fully captures the complexity of the disease. However it is possible to model core components of addiction, for example by monitoring behavioral sensitization and conditioned place preference. In the first test, an increase in locomotor activity is observed with intermittent drug exposure. The latter tests for the preference of a particular environment associated with drug exposure by measuring the time an animal spends in the compartment where a drug was received compared with the compartment where only saline was injected (conditioned place preference). Both tests have in common that they are sensitive to cue-conditioned effects of addictive drugs. Subsequent exposures to the environment without the drug lead to extinction of the place preference, which can be reinstated with a low dose of the drug. These persistent changes serve as a model of relapse and have been linked to synaptic plasticity of excitatory transmission in the ventral tegmental area and nucleus accumbens (see also The Dopamine Hypothesis of Addiction). Recent findings suggest that prolonged self-administration of cocaine leads to behaviors in rats that closely resemble human addiction. Such "addicted rats" are very strongly motivated to seek cocaine, continue looking for the drug even when no longer available, and self-administer cocaine in spite of negative consequences, such as an electric foot shock. These findings suggest that addiction is a disease that does not respect species boundaries.

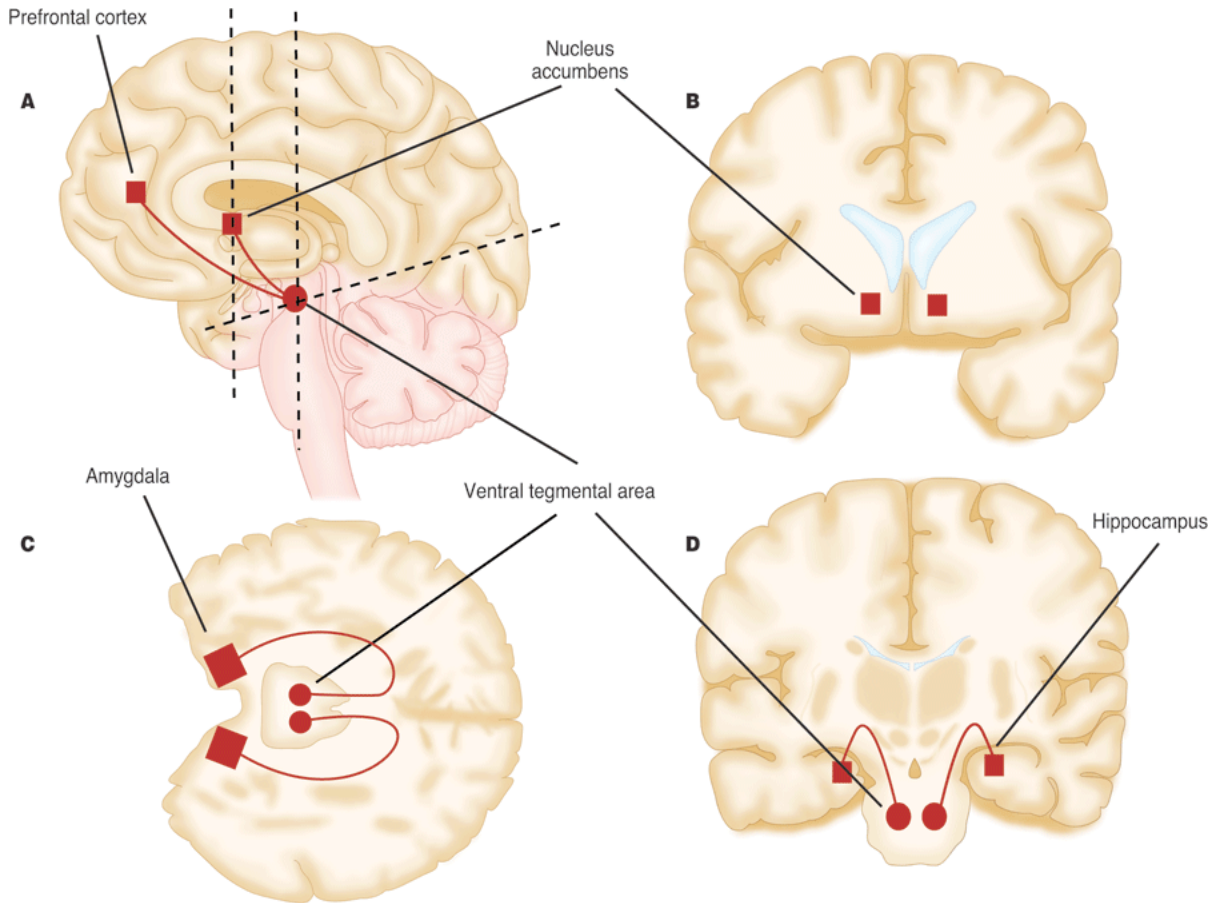

### ADDICTIVE DRUGS INCREASE THE LEVEL OF DOPAMINE: REINFORCEMENT

To understand the long-term changes induced by drugs of abuse, their initial molecular and cellular targets must be identified. A combination of approaches in animals and humans, including functional imaging, has revealed the mesolimbic dopamine system as the prime target of addictive drugs. This system originates in the **ventral tegmental area (VTA)**, a tiny structure at the tip of the brain stem, which projects to the **nucleus accumbens**, the amygdala, the hippocampus, and the prefrontal cortex (Figure 32-1). Most projection neurons of the VTA are dopamine-producing neurons. When the dopamine neurons of the VTA begin to fire in bursts, large quantities of dopamine are released in the nucleus

accumbens and the prefrontal cortex. Early animal studies pairing electrical stimulation of the VTA with operant responses (eg, lever pressing) that result in strong reinforcement established the central role of the mesolimbic dopamine system in reward processing. Direct application of drugs into the VTA also acts as a strong reinforcer, and systemic administration of drugs of abuse causes release of dopamine.

**Figure 32â€1**

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 11th Edition: <http://www.accessmedicine.com>

Major connections of the mesolimbic dopamine system in the brain. Schematic diagram of brain sections illustrating that the dopamine projections originate in the ventral tegmental area and target the nucleus accumbens, prefrontal cortex, amygdala, and hippocampus. The dashed lines on the sagittal section indicate where the horizontal and coronal sections were made.

*As a general rule, all addictive drugs activate the mesolimbic dopamine system.* The behavioral significance of this increase of dopamine is still debated. An appealing hypothesis is that mesolimbic dopamine codes for the difference between expected and actual reward and thus constitutes a strong learning signal (see The Dopamine Hypothesis of Addiction).

Since each addictive drug has a specific molecular target that engages distinct cellular mechanisms to activate the mesolimbic system, three classes can be distinguished: A first group binds to **G<sub>10</sub> protein-coupled receptors**, a second group interacts with **ionotropic receptors or ion channels**, and a third group targets the **dopamine transporter** (Table 32â€1 and Figure 32â€2). G protein-coupled receptors (GPCRs) of the G<sub>10</sub> family inhibit neurons through postsynaptic hyperpolarization and presynaptic regulation of transmitter release. In the VTA, the action of these drugs is preferentially on the  $\gamma$ -aminobutyric acid (GABA) neurons that act as local inhibitory interneurons. Addictive drugs that bind to ionotropic receptors and ion channels can have combined effects on dopamine neurons and GABA neurons, eventually leading to enhanced release of dopamine. Finally, addictive drugs that interfere with monoamine transporters block reuptake or stimulate nonvesicular release of dopamine, causing an accumulation of extracellular dopamine in target structures. Since neurons of the VTA also express somatodendritic transporters, which normally clear dopamine released by the dendrites, class III drugs also increase dopamine level in the VTA. Although drugs of this class also affect transporters of other monoamines (norepinephrine, serotonin), it is the action on the dopamine system that remains central for addiction. This is consistent with the observations that antidepressants that block serotonin and norepinephrine uptake, but not dopamine uptake, do not cause

addiction even after prolonged use.

**Table 32â€1 The Mechanistic Classification of Drugs of Abuse.<sup>1</sup>**

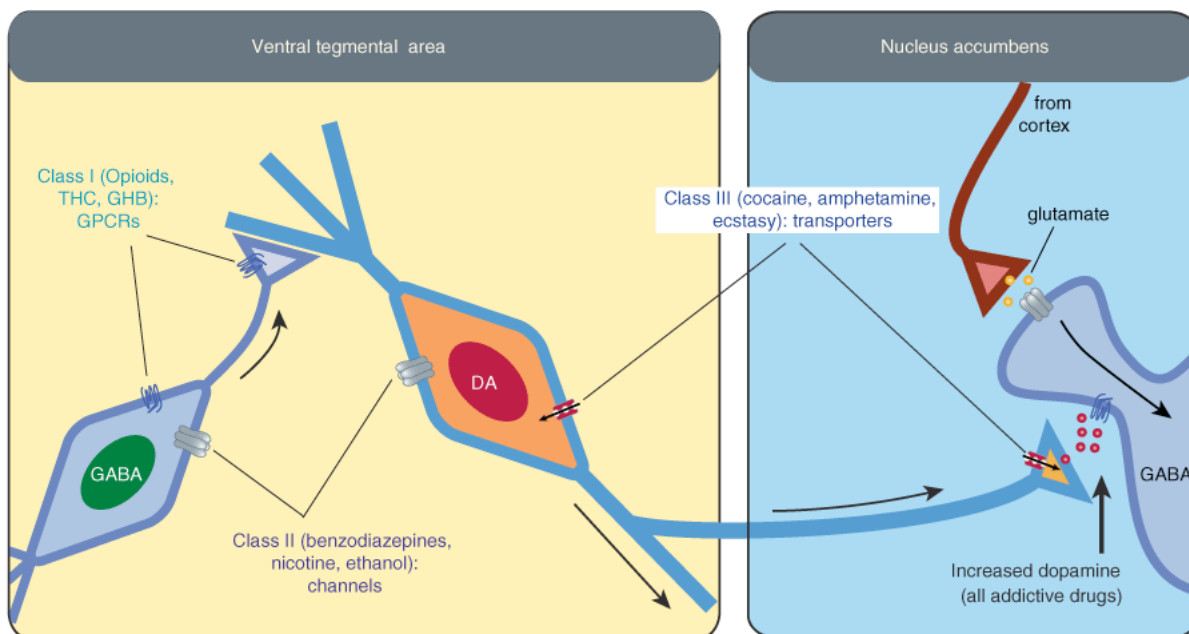

Name	Main Molecular Target	Pharmacology	Effect on Dopamine (DA) Neurons	RR <sup>2</sup>
<b>Drugs That Activate G Protein-Coupled Receptors</b>				
Opioids	$\mu$ -OR ( $G_{i\theta}$ )	Agonist	Disinhibition	4
Cannabinoids	CB1R ( $G_{i\theta}$ )	Agonist	Disinhibition	2
$\Upsilon$ -Hydroxybutyric acid (GHB)	GABA <sub>B</sub> R ( $G_{i\theta}$ )	Weak agonist	Disinhibition	?
LSD, mescaline, psilocybin	5-HT <sub>2A</sub> R ( $G_q$ )	Partial agonist	. . .	1
<b>Drugs That Bind to Ionotropic Receptors and Ion Channels</b>				
Nicotine	nAChR ( $\alpha_2\beta_2$ )	Agonist	Excitation	4
Alcohol	GABA <sub>A</sub> R, 5-HT <sub>3</sub> R, nAChR, NMDAR, Kir3 channels		Excitation, disinhibition (?)	3
Benzodiazepines	GABA <sub>A</sub> R	Positive modulator	Disinhibition	3
Phencyclidine, ketamine	NMDAR	Antagonist	. . .	1
<b>Drugs That Bind to Transporters of Biogenic Amines</b>				
Cocaine	DAT, SERT, NET	Inhibitor	Blocks DA uptake	5
Amphetamine	DAT, NET, SERT, VMAT	Reverses transport	Blocks DA uptake, synaptic depletion	5
Ecstasy	SERT > DAT, NET	Reverses transport	Blocks DA uptake, synaptic depletion	?

5-HT<sub>2A</sub>R, serotonin receptor; CB1R, cannabinoid-1; DAT, dopamine transporter; GABA,  $\Upsilon^3$ -aminobutyric acid; Kir3 channels, G protein-coupled inwardly rectifying potassium channels; LSD, lysergic acid diethylamide;  $\mu$ -OR,  $\mu$ -opioid receptor; nAChR, nicotinic acetylcholine receptor; NET, norepinephrine transporter; NMDAR, *N*-methyl-D-aspartate receptor; SERT, serotonin transporter; VMAT, vesicular monoamine transporter; ? indicates data not available.

<sup>1</sup>Drugs fall into one of three categories, targeting either G protein-coupled receptors, ionotropic receptors or ion channels, or biogenic amine transporters.

<sup>2</sup>RR, relative risk of addiction; 1 = nonaddictive; 5 = highly addictive.

Neuropharmacologic classification of addictive drugs by primary target (see text and Table 32-1). DA, dopamine; GABA,  $\gamma$ -aminobutyric acid; GHB,  $\gamma$ -hydroxybutyric acid; GPCRs, G protein-coupled receptors; THC,  $\Delta^9$ -tetrahydrocannabinol.

### The Dopamine Hypothesis of Addiction

In the earliest version of the hypothesis described in this chapter, mesolimbic dopamine was believed to be the neurochemical correlate of pleasure and reward. However, during the past decade, experimental evidence has led to several revisions. Phasic dopamine release may actually code for the *prediction error* of reward rather than the reward itself. This distinction is based on pioneering observations in monkeys that dopamine neurons in the ventral tegmental area (VTA) are most efficiently activated by a reward (eg, a few drops of fruit juice) that is not anticipated. When the animal learns to predict the occurrence of a reward (eg, by pairing it with a stimulus such as a sound), dopamine neurons stop responding to the reward itself (juice), but increase their firing rate when the conditioned stimulus (sound) occurs. Finally, if reward is predicted but not delivered (sound but no juice), dopamine neurons are inhibited below their baseline activity and become completely silent. In other words, the mesolimbic system continuously scans the reward situation. It increases its activity when reward is larger than expected, and shuts down in the opposite case, thus coding for the prediction error of reward.

Under physiologic conditions the mesolimbic dopamine signal could represent a learning signal responsible for reinforcing constructive behavioral adaptation (eg, learning to press a lever for food). Addictive drugs, by directly increasing dopamine, would generate a strong but inappropriate learning signal, thus hijacking the reward system and leading to pathologic reinforcement. As a consequence, behavior becomes compulsive; that is decisions are no longer planned and under control, but automatic, which is the hallmark of addiction.

This appealing hypothesis has been challenged based on the observation that some reward and drug-related learning is still possible in the absence of dopamine. Another intriguing observation is that mice genetically modified to lack the primary molecular target of cocaine, the dopamine transporter DAT, still self-administer the drug. Only when transporters of other biogenic amines are also knocked out does cocaine completely lose its rewarding properties. However, in  $DAT^{\Delta C}/\Delta C$  mice, in which basal synaptic dopamine levels are high, cocaine still leads to increased dopamine release, presumably because other cocaine-sensitive monoamine transporters (NET, SERT) are able to clear some dopamine. When cocaine is given, these transporters are also inhibited and dopamine is again increased. As a consequence of this substitution among monoamine transporters, fluoxetine (a selective serotonin reuptake inhibitor, see Chapter 30) becomes addictive in  $DAT^{\Delta C}/\Delta C$  mice. This concept is supported by newer evidence showing that deletion of the cocaine binding site on DAT leaves basal dopamine levels unchanged but abolishes the rewarding effect of cocaine.

The dopamine hypothesis of addiction has also been challenged by the observation that salient stimuli that are not rewarding (they may actually even be aversive and therefore negative reinforcers) also activate the VTA. However, the neurons in the VTA that are activated by aversive stimuli do not release dopamine, and dopamine neurons are actually inhibited by aversive stimuli. These findings suggest that the controversy can be resolved in favor of dopamine reward theories.

Whatever the precise role of dopamine under physiologic conditions, all addictive drugs strongly increase its concentration in target structures of the mesolimbic projection. This suggests that high levels of dopamine may actually be at the origin of the adaptive changes

that underlie dependence and addiction.

## DEPENDENCE: TOLERANCE & WITHDRAWAL

With chronic exposure to addictive drugs, the brain shows signs of adaptation. For example, if morphine is used at short intervals, the dose has to be progressively increased over the course of several days to maintain rewarding or analgesic effects. This phenomenon is called tolerance. It may become a serious problem because of increasing side effects—eg, respiratory depression—that do not show much tolerance and may lead to fatalities associated with overdose.

Tolerance to opioids may be due to a reduction of the concentration of a drug or a shorter duration of action in a target system (pharmacokinetic tolerance). Alternatively, it may involve changes of  $\mu$ -opioid receptor function (pharmacodynamic tolerance). In fact, many  $\mu$ -opioid receptor agonists promote strong receptor phosphorylation that triggers the recruitment of the adaptor protein  $\beta$ -arrestin, causing G proteins to uncouple from the receptor and to internalize within minutes (see Chapter 2). Since this decreases signaling, it is tempting to explain tolerance by such a mechanism. However, morphine, which strongly induces tolerance, does not recruit  $\beta$ -arrestins and fails to promote receptor internalization. Conversely, other agonists that drive receptor internalization very efficiently induce only modest tolerance. Based on these observations, it has been hypothesized that desensitization and receptor internalization actually protect the cell from overstimulation. In this model, morphine, by failing to trigger receptor endocytosis, disproportionately stimulates adaptive processes, which eventually cause tolerance. Although the molecular identity of these processes is still under investigation, they may be similar to the ones involved in withdrawal (see below).

Adaptive changes become fully apparent once drug exposure is terminated. This state is called **withdrawal** and is observed to varying degrees after chronic exposure to most drugs of abuse. Withdrawal from opioids in humans is particularly strong (described below). Studies in rodents have added significantly to our understanding of the neural and molecular mechanisms that underlie dependence. For example, signs of dependence, as well as analgesia and reward, are abolished in knockout mice lacking the  $\mu$ -opioid receptor, but not in mice lacking other opioid receptors ( $\delta$ ,  $\kappa$ ). Although activation of the  $\mu$ -opioid receptor initially strongly inhibits adenylyl cyclase, this inhibition becomes weaker after several days of repeated exposure. The weaning of the inhibition of adenylyl cyclase is due to a counter-adaptation of the enzyme system during exposure to the drug, which results in overproduction of cAMP during subsequent withdrawal. Several mechanisms exist for this adenylyl cyclase compensatory response, including up-regulation of transcription of the enzyme. Increased cAMP concentrations in turn strongly activate the transcription factor cyclic AMP response element binding protein (CREB), leading to the regulation of downstream genes. Of the few such genes identified to date, one of the most interesting is the gene for the endogenous  $\kappa$  opioid ligand dynorphin. During withdrawal, neurons of the nucleus accumbens produce high levels of dynorphin, which is then co-released with GABA onto the projection neurons of the VTA (Figure 32-3). These cells express  $\kappa$  opioid receptors on their synaptic terminals and on the dendrites. As a consequence, they are inhibited and dopamine release is reduced. This mechanism exemplifies the adaptive processes engaged during dependence and may underlie the intense dysphoria typically observed during withdrawal.

CREB-mediated up-regulation of dynorphin during withdrawal from dependence. Supersensitization of adenylyl cyclase (AC) leads to an increase of cAMP

concentration in medium spiny neurons of the accumbens. This activates the transcription factor CREB, which turns on several genes, including that for dynorphin. Dynorphin is then co-released with  $\gamma$ -aminobutyric acid (GABA), activating the  $\kappa$ -opioid receptor (KOR) located on dopamine neurons of the ventral tegmental area (VTA), thereby leading to pre- and postsynaptic inhibition. D<sub>2</sub>R, dopamine D<sub>2</sub> receptor.

## **ADDICTION: A DISEASE OF MALADAPTIVE LEARNING**

Addiction is characterized by a high motivation to obtain and use a drug despite negative consequences. With time, drug use becomes compulsive ("wanting without liking"). Addiction is a recalcitrant, chronic, and stubbornly relapsing disease that is very difficult to treat.

The central problem is that even after successful withdrawal and prolonged drug-free periods, addicted individuals have a high risk of relapsing. Relapse is typically triggered by one of the following three conditions: reexposure to the addictive drug, stress, or a context that recalls prior drug use. It appears that when paired with drug use, a neutral stimulus may undergo a switch and motivate ("trigger") addiction-related behavior. This phenomenon may involve synaptic plasticity in the target nuclei of the mesolimbic projection (eg, nucleus accumbens). Several recent studies suggest that the recruitment of the dorsal striatum is responsible for the compulsion. This switch may depend on synaptic plasticity in the nucleus accumbens of the ventral striatum, where mesolimbic dopamine afferents and cortical glutamatergic afferents converge. If dopamine release codes for the prediction error of reward (see The Dopamine Hypothesis of Addiction), pharmacologic stimulation of the mesolimbic dopamine systems will generate an unusually strong learning signal. Unlike natural rewards, addictive drugs continue to increase dopamine even when reward is expected. Such overriding of the prediction error signal may eventually be responsible for the usurping of memory processes by addictive drugs.

The involvement of learning and memory systems in addiction is also suggested by clinical studies. For example, the role of context in relapse is supported by the report that soldiers who became addicted to heroin during the Vietnam War had significantly better outcomes when treated after their return home, compared with addicts who remained in the environment where they had taken the drug. In other words, cravings may recur at the presentation of contextual cues (eg, people, places, or drug paraphernalia). Current research therefore focuses on the effects of drugs on associative forms of synaptic plasticity, such as long-term potentiation (LTP), which underlie learning and memory (see Synaptic Plasticity & Addiction).

### **Synaptic Plasticity & Addiction**

Long-term potentiation (LTP) is a form of experience-dependent synaptic plasticity that is induced by activating glutamate receptors of the *N*-methyl-D-aspartate (NMDA) type. Since NMDA receptors are blocked by magnesium at negative potentials, their activation requires the concomitant release of glutamate (presynaptic activity) onto a receiving neuron that is depolarized (post-synaptic activity). Correlated pre- and postsynaptic activity durably enhances synaptic efficacy and triggers the formation of new connections. Because associativity is a critical component, LTP has become a leading candidate mechanism underlying learning and memory. LTP can be elicited at glutamatergic synapses of the mesolimbic reward system and is modulated by dopamine. Drugs of abuse could therefore interfere with LTP at sites of convergence of dopamine and glutamate projections (eg, ventral tegmental area [VTA], nucleus accumbens, or prefrontal cortex). Interestingly, exposure to an addictive drug triggers LTP at excitatory afferents and reduces GABA<sub>A</sub> receptor-mediated inhibition of the VTA, thus increasing the excitability of dopamine neurons. Genetic manipulations in mice that abolish LTP at this synapse also have effects on persistent changes of drug-associated behavioral paradigms such as reinstatement of conditioned place preference, further supporting the idea that LTP is involved in context-dependent components of relapse. Similarly, interfering with transcriptional signaling implicated in the late phases of LTP affects conditioned place preference.

Non- $\kappa$  substance-dependent disorders, such as pathologic gambling and compulsive shopping, share many features of addiction. Several lines of arguments suggest that they also share the underlying neurobiologic mechanisms. This conclusion is supported by the clinical observation that, as an adverse effect of dopamine agonist medication, patients with Parkinson's disease may become pathologic gamblers (see Case Study). Others patients may develop a habit for recreational activities, such as shopping, eating compulsively, or becoming excessively involved in sexual activity (hypersexuality). Although large-scale studies are not yet available, an estimated 1 of 7 parkinsonian patients develops an addiction-like behavior when receiving dopamine agonists.

Large individual differences exist also in vulnerability to substance-related addiction. Whereas one person may become "hooked" after a few doses, others may be able to use a drug occasionally during their entire lives without ever having difficulty in stopping. Even when dependence is induced with chronic exposure, only a small percentage of dependent users progress to addiction. Recent studies in rats suggest that impulsivity may be a crucial trait that represents a risk for addiction. The transition to addiction is determined by a combination of environmental and genetic factors. Heritability of addiction, as determined by comparing monozygotic with dizygotic twins, is relatively modest for cannabinoids but very high for cocaine. It is of interest that the relative risk for addiction (addiction liability) of a drug (Table 32-1) correlates with its heritability, suggesting that the neurobiologic basis of addiction common to all drugs is what is being inherited. Further genomic analysis indicates that only a few alleles (or perhaps even a single recessive allele) need to function in combination to produce the phenotype. However, identification of the genes involved remains elusive. Although some substance-specific candidate genes have been identified (eg, alcohol dehydrogenase), future research will also focus on genes implicated in the neurobiologic mechanisms common to all addictive drugs.

## **NONADDICTIVE DRUGS OF ABUSE**

Some drugs of abuse do not lead to addiction. This is the case for substances that alter perception without causing sensations of reward and euphoria, such as the hallucinogens and the dissociative anesthetics (Table 32-1). Unlike addictive drugs, which primarily target the mesolimbic dopamine system, these agents primarily target cortical and thalamic circuits. Lysergic acid diethylamide (LSD), for example, activates the serotonin 5-HT<sub>2A</sub> receptor in the prefrontal cortex, enhancing glutamatergic transmission onto pyramidal neurons. These excitatory afferents mainly come from the thalamus and carry sensory information of different modalities, which may constitute a link to enhanced perception. Phencyclidine (PCP) and ketamine produce a feeling of separation of mind and body (which is why they are called dissociative anesthetics) and, at higher doses, stupor and coma. The principal mechanism of action is a use-dependent inhibition of glutamate receptors of the *N*-methyl-D-aspartate (NMDA) type.

The classification of NMDA antagonists as nonaddictive drugs was based on early assessments, which, in the case of PCP, have recently been questioned. In fact, animal research shows that PCP can increase mesolimbic dopamine concentrations and has some reinforcing properties in rodents. Concurrent effects on both thalamocortical and mesolimbic systems also exist for other addictive drugs. Psychosis-like symptoms can be observed with cannabinoids, amphetamines, and cocaine, which may reflect their effects on thalamocortical structures. For example, cannabinoids, in addition to their documented effects on the mesolimbic dopamine system, also enhance excitation in cortical circuits through presynaptic inhibition of GABA release.

Hallucinogens and NMDA antagonists, even if they do not produce dependence or addiction, can still have long-term effects. Flashbacks of altered perception can occur years after LSD use. Moreover, chronic use of PCP may lead to an irreversible schizophrenia-like psychosis.

## BASIC PHARMACOLOGY OF DRUGS OF ABUSE

Since all addictive drugs increase dopamine concentrations in target structures of the mesolimbic projections, we classify them on the basis of their molecular targets and the underlying mechanisms (Table 32-1 and Figure 32-2). The first group contains the **opioids, cannabinoids,  $\gamma$ -hydroxybutyric acid (GHB), and the hallucinogens**, which all exert their action through  $G_{i/o}$  protein-coupled receptors. The second group includes **nicotine, alcohol, the benzodiazepines, dissociative anesthetics**, and some **inhalants**, which interact with ionotropic receptors or ion channels. The last group comprises **cocaine, amphetamines, and ecstasy**, which all bind to monoamine transporters. The nonaddictive drugs are classified using the same criteria.

## DRUGS THAT ACTIVATE $G_{L/O}$ -COUPLED RECEPTORS

### OPIOIDS

Although opioids may have been the first drugs to be abused (preceding stimulants), they are still among the most commonly used for nonmedical purposes.

#### Pharmacology & Clinical Aspects

As described in Chapter 31, opioids comprise a large family of endogenous and exogenous agonists at three G protein-coupled receptors: the  $\mu$ -,  $\kappa$ -, and  $\delta$ -opioid receptors. Although all three receptors couple to inhibitory G proteins (ie, they all inhibit adenylyl cyclase), they have distinct, sometimes even opposing effects, mainly because of the cell type-specific expression throughout the brain. In the VTA, for example,  $\mu$ -opioid receptors are selectively expressed on GABA neurons (which they inhibit), whereas  $\kappa$ -opioid receptors are expressed on and inhibit dopamine neurons. This may explain why  $\mu$ -opioid agonists cause euphoria, whereas  $\kappa$  agonists induce dysphoria.

In line with the latter observations, the rewarding effects of morphine are absent in knockout mice lacking  $\mu$  receptors but persist when either of the other opioid receptors are ablated. In the VTA,  $\mu$  opioids cause an inhibition of GABAergic inhibitory interneurons, which leads eventually to a disinhibition of dopamine neurons.

The most commonly abused  $\mu$  opioids include **morphine, heroin** (diacetylmorphine, which is rapidly metabolized to morphine), **codeine**, and **oxycodone**. **Meperidine** abuse is common among health professionals. All of these drugs induce strong tolerance and dependence. The withdrawal syndrome may be very severe (except for codeine) and includes intense dysphoria, nausea or vomiting, muscle aches, lacrimation, rhinorrhea, mydriasis, piloerection, sweating, diarrhea, yawning, and fever. Beyond the withdrawal syndrome, which usually lasts no longer than a few days, individuals who have received opioids as analgesics only rarely develop addiction. In contrast, when taken for recreational purposes, opioids are highly addictive. The relative risk of addiction is 4 out of 5 on a scale of 1 = nonaddictive, 5 = highly addictive.

### Treatment

The opioid antagonist **naloxone** reverses the effects of a dose of morphine or heroin within minutes. This may be life-saving in the case of a massive overdose (see Chapters 31 and 59). Naloxone administration also provokes an acute withdrawal (precipitated abstinence) syndrome in a dependent person who has recently taken an opioid.

In the treatment of opioid addiction, a long-acting opioid (eg, **methadone, buprenorphine**) is often substituted for the shorter-acting, more rewarding, opioid (eg, heroin). For substitution therapy, methadone is given orally once daily, facilitating supervised intake. Using a partial agonist (buprenorphine) and the much longer half-life (methadone and buprenorphine) may also have some beneficial effects (eg, weaker drug sensitization, which typically requires intermittent exposures), but it is important to realize that abrupt termination of methadone administration invariably precipitates a withdrawal syndrome; that is, the subject on substitution therapy remains dependent. Some countries (eg, Switzerland, Netherlands) even allow substitution of heroin by heroin. A follow-up of a cohort of addicts who receive heroin injections in a controlled setting and have access to counseling indicates that addicts under heroin substitution have an improved health status and are better integrated in society.

## CANNABINOIDS

Endogenous cannabinoids that act as neurotransmitters include 2-arachidonyl glycerol (2-AG) and anandamide, both of which bind to CB1 receptors. These very lipid-soluble compounds are released at the postsynaptic somatodendritic membrane, and diffuse through the extracellular space to bind at presynaptic CB1 receptors, where they inhibit the release of either glutamate or GABA. Because of such backward signaling, endocannabinoids are called retrograde messengers. In the hippocampus, release of endocannabinoids from pyramidal neurons selectively affects inhibitory transmission and may contribute to the induction of synaptic plasticity during learning and memory formation.

Exogenous cannabinoids, eg in **marijuana**, include several pharmacologically active substances including  $\Delta^9$ -**tetrahydrocannabinol (THC)**, a powerful psychoactive substance. Like opioids, THC causes disinhibition of dopamine neurons, mainly by presynaptic inhibition of GABA neurons in the VTA. The half-life of THC is about 4 hours. The onset of effects of THC after smoking marijuana occurs within minutes and reaches a maximum after 1-2 hours. The most prominent effects are euphoria and relaxation. Users also report feelings of well-being, grandiosity, and altered perception of passage of time. Dose-dependent perceptual changes (eg, visual distortions, drowsiness, diminished coordination, and memory

impairment may occur. Cannabinoids can also create a dysphoric state and, in rare cases following the use of very high doses, may result in visual hallucinations, depersonalization, and frank psychotic episodes. Additional effects of THC, eg, increased appetite, attenuation of nausea, decreased intraocular pressure, and relief of chronic pain, have led to the use of cannabinoids in medical therapeutics. The justification of medicinal use of marijuana was comprehensively examined by the Institute of Medicine (IOM) of the National Academy of Sciences in its 1999 report, *Marijuana & Medicine*. This continues to be a controversial issue, mainly because of the fear that cannabinoids may serve as a gateway to the consumption of "hard" drugs or cause schizophrenia in individuals with a predisposition.

Chronic exposure to marijuana leads to dependence, which is revealed by a distinctive, but mild and short-lived, withdrawal syndrome that includes restlessness, irritability, mild agitation, insomnia, nausea, and cramping. The relative risk for addiction is 2.

The synthetic  $\Delta^9$ -THC analog **dronabinol** is a Food and Drug Administration (FDA)-approved cannabinoid agonist currently marketed in the USA and some European countries. **Nabilone**, an older commercial  $\Delta^9$ -THC analog, was recently reintroduced in the USA for adjunctive therapy in chronic pain management. The cannabinoid system is likely to emerge as an important drug target in the future because of its apparent involvement in several therapeutically desirable effects.

### **GAMMA-HYDROXYBUTYRIC ACID**

Gamma-hydroxybutyric acid (GHB) is produced during the metabolism of GABA, but the function of this endogenous agent is unknown at present. The pharmacology of GHB is complex because there are two distinct binding sites. The protein that contains a high-affinity binding site (1  $\mu$ M) for GHB has recently been cloned, but its involvement in the cellular effects of GHB at pharmacologic concentrations remains unclear. The low-affinity binding site (1 mM) has been identified as the GABA<sub>B</sub> receptor. In mice that lack GABA<sub>B</sub> receptors, even very high doses of GHB have no effect; this suggests that GABA<sub>B</sub> receptors are the sole mediators of GHB's pharmacologic action.

GHB was first synthesized in 1960 and introduced as a general anesthetic. Because of its narrow safety margin and its addictive potential, it is not available in the USA for this purpose at present. Before causing sedation and coma, GHB causes euphoria, enhanced sensory perceptions, a feeling of social closeness, and amnesia. These properties have made it a popular "club drug" that goes by colorful street names such as "liquid ecstasy," "grievous bodily harm," or "date rape drug." As the latter name suggests, GHB has been used in date rapes because it is odorless and can be readily dissolved in beverages. It is rapidly absorbed after ingestion and reaches a maximal plasma concentration 20–30 minutes after ingestion of a 10–20 mg/kg dose. The elimination half-life is about 30 minutes.

Although GABA<sub>B</sub> receptors are expressed on all neurons of the VTA, GABA neurons are much more sensitive to GHB than dopamine neurons. This is reflected by the EC<sub>50</sub>s, which differ by about one order of magnitude and indicates the difference in coupling efficiency of the GABA<sub>B</sub> receptor and the potassium channels responsible for the hyperpolarization. Because GHB is a weak agonist, only GABA neurons are inhibited at the concentrations typically obtained with recreational use. This feature may underlie the reinforcing effects of GHB and the basis for addiction to the drug. At higher doses, however, GHB also hyperpolarizes dopamine neurons, eventually completely inhibiting dopamine release. Such an inhibition of the VTA may in turn preclude its activation by other addictive drugs and may explain why GHB might have some usefulness as an "anticraving" compound.

### **LSD, Mescaline, & Psilocybin**

The three drugs, LSD, mescaline, and psilocybin are commonly called hallucinogens because of their ability to alter consciousness such that the individual senses things that are not present. They induce, often in an unpredictable way, perceptual symptoms, including shape and color distortion. Psychosis-like manifestations (depersonalization, hallucinations, distorted time perception) have led some to classify these drugs as psychotomimetics. They also produce somatic symptoms (dizziness, nausea, paresthesias, and blurred vision). Some users have reported intense reexperiencing of perceptual effects (flashbacks) up to several years after the last drug exposure.

Hallucinogens differ from most other drugs described in this chapter in that they induce neither dependence nor addiction. However, repetitive exposure still leads to rapid tolerance (also called tachyphylaxis). Animals do not self-administer hallucinogens, suggesting that they are not rewarding to them. Additional studies show that these drugs also fail to stimulate dopamine release, further supporting the idea that only drugs that activate the mesolimbic dopamine system are addictive. Instead, hallucinogens increase glutamate release in the cortex, presumably by enhancing excitatory afferent input from the thalamus.

LSD is an ergot alkaloid. After synthesis, blotter paper or sugar cubes are sprinkled with the liquid and allowed to dry. When LSD is swallowed, psychoactive effects typically appear after 30 minutes and last 6–12 hours. During this time, subjects have impaired ability to make rational judgments and understand common dangers, which puts them at risk for accidents and personal injury.

In an adult, a typical dose is 20–30 mcg. LSD is considered neurotoxic and like most ergot alkaloids, may lead to strong contractions of the uterus that can induce abortion.

The main molecular target of LSD and other hallucinogens is the 5-HT<sub>2A</sub> receptor. This receptor couples to G proteins of the G<sub>q</sub> type and generates inositol trisphosphate (IP<sub>3</sub>), leading to a release of intracellular calcium. Although hallucinogens, and LSD in particular, have been proposed for several therapeutic indications, efficacy has never been demonstrated.

### **Drugs that Mediate Their Effects Via Iontropic Receptors**

#### **NICOTINE**

In terms of numbers affected, addiction to nicotine exceeds all other forms of addiction, touching more than 50% of all adults in some countries. Nicotine exposure occurs primarily through smoking of tobacco, which causes associated diseases that are responsible for many preventable deaths. The chronic use of chewing tobacco and snuff tobacco is also addictive.

Nicotine is a selective agonist of the nicotinic acetylcholine receptor (nAChR) that is normally activated by acetylcholine (see Chapter 6). Based on nicotine's enhancement of cognitive performance and the association of Alzheimer's dementia with a loss of ACh-releasing neurons from the nucleus

basalis of Meynert, nAChRs are believed to play an important role in many cognitive processes. The rewarding effect of nicotine requires involvement of the VTA, in which nAChRs are expressed on dopamine neurons. When nicotine excites projection neurons, dopamine is released in the nucleus accumbens and the prefrontal cortex, thus fulfilling the dopamine requirement of addictive drugs. Recent work has identified  $\alpha_4\beta_2$ -containing channels in the VTA as the nAChRs that are required for the rewarding effects of nicotine. This statement is based on the observation that knockout mice deficient for the  $\beta_2$  subunit lose interest in self-administering nicotine, and that in these mice, this behavior can be restored through an in vivo transfection of the  $\beta_2$  subunit in neurons of the VTA. Electrophysiologic evidence suggests that homomeric nAChRs made exclusively of  $\alpha_7$  subunits also contribute to the reinforcing effects of nicotine. These receptors are mainly expressed on synaptic terminals of excitatory afferents projecting onto the dopamine neurons. They also contribute to nicotine-evoked dopamine release and the long-term changes induced by the drugs related to addiction (eg, long-term synaptic potentiation of excitatory inputs).

Nicotine withdrawal is mild compared with opioid withdrawal and involves irritability and sleep problems. However, nicotine is among the most addictive drugs (relative risk = 4), and relapse after attempted cessation is very common.

### Treatment

Treatments for nicotine addiction include nicotine itself in forms that are slowly absorbed and several other drugs. Nicotine that is chewed, inhaled, or transdermally delivered can be substituted for the nicotine in cigarettes, thus slowing the pharmacokinetics and eliminating the many complications associated with the toxic substances found in tobacco smoke. Recently, two partial agonists of  $\alpha_4\beta_2$ -containing nAChRs have been characterized; the plant-extract **cytisine** and its synthetic derivative **varenicline**. Both work by occupying nAChRs on dopamine neurons of the VTA, thus preventing nicotine from exerting its action. Varenicline may impair the capacity to drive and has been associated with suicidal ideation. The antidepressant **bupropion** is approved for nicotine cessation therapy. It is most effective when combined with behavioral therapies.

Many countries have banned smoking in public places to create smoke-free environments. This important step not only reduces passive smoking and the hazards of secondhand smoke, but also the risk that ex-smokers will be exposed to smoke, which as a contextual cue, may trigger relapse.

## BENZODIAZEPINES

Benzodiazepines are commonly prescribed as anxiolytics and sleep medications. They represent a moderate risk for abuse, which has to be weighed against their beneficial effects. Benzodiazepines are abused by some persons for their euphoriant effects, but most often abuse occurs concomitant with other drugs, eg, to attenuate anxiety during withdrawal from opioids.

**Barbiturates**, which preceded benzodiazepines as the most commonly abused sedative hypnotics (after ethanol), are now rarely prescribed to outpatients and therefore constitute a less common prescription drug problem than they did in the past. Street sales of barbiturates, however, continue. Management of barbiturate withdrawal and addiction is similar to that of benzodiazepines.

Although benzodiazepine dependence is very common, cases that fulfill all the diagnostic criteria for addiction are rare. Withdrawal from benzodiazepines occurs within days of stopping the medication and varies as a function of the half-life of elimination. Symptoms include irritability, insomnia, phono- and photophobia, depression, muscle cramps, and even seizures. Typically, these symptoms taper off within 1–2 weeks.

Benzodiazepines are positive modulators of the GABA<sub>A</sub> receptor, increasing both single-channel conductance and open-channel probability. GABA<sub>A</sub> receptors are pentameric structures consisting of  $\alpha$ ,  $\beta$ , and  $\gamma$  subunits (see Chapter 22). GABA receptors on dopamine neurons of the VTA lack  $\alpha_1$ , a subunit that is typically present in GABA neurons. In addition, GABA<sub>A</sub> receptors are expressed in much higher density on interneurons, so that a disinhibition of the mesolimbic dopamine system may explain the rewarding effects of benzodiazepines. Receptors containing  $\alpha_5$  subunits seem to be required for tolerance to the sedative effects of benzodiazepines, and studies in humans link  $\alpha_2\gamma_3$ -containing receptors to alcohol dependence (the GABA<sub>A</sub> receptor is also a target of alcohol, see following text). Taken together, a picture is emerging linking GABA<sub>A</sub> receptors of specific subunit isoform composition to their therapeutic effects and to dependence and addiction induced with chronic exposure.

## ALCOHOL

Alcohol (ethanol, see Chapter 23) is regularly used by a majority of the population in many Western countries. Although only a minority becomes dependent and addicted, abuse is a very serious public health problem because of the many diseases associated with alcoholism.

### Pharmacology

The pharmacology of alcohol is complex, and no single receptor mediates all of its effects. On the contrary, alcohol alters the function of several receptors and cellular functions, including GABA<sub>A</sub> receptors, Kir3/GIRK channels, adenosine reuptake (through the equilibrative nucleoside transporter, ENT1), glycine receptor, NMDA receptor, and 5-HT<sub>3</sub> receptor. They are all, with the exception of ENT1, either ionotropic receptors or ion channels. It is not clear which of these targets is responsible for the increase of dopamine release from the mesolimbic reward system. The inhibition of ENT1 is probably not responsible for the rewarding effects (ENT1 knockout mice drink more than controls) but seems to be involved in alcohol dependence through an accumulation of adenosine, stimulation of adenosine A2 receptors, and ensuing enhanced CREB signaling.

Dependence becomes apparent 6–12 hours after cessation of heavy drinking as a withdrawal syndrome that may include tremor (mainly of the hands), nausea and vomiting, excessive sweating, agitation, and anxiety. In some individuals, this is followed by visual, tactile, and auditory hallucinations 12–24 hours after cessation. Generalized seizures may manifest after 24–48 hours. Finally, 48–72 hours after cessation, an alcohol withdrawal delirium (delirium tremens) may become apparent in which the person hallucinates, is disoriented, and shows evidence of autonomic instability. Delirium tremens is associated with 5–15% mortality.

### Treatment

Treatment of ethanol withdrawal is supportive and relies on **benzodiazepines**, taking care to use compounds such as oxazepam and lorazepam, which are not as dependent on hepatic metabolism as most other benzodiazepines. In patients in whom monitoring is not reliable and liver function

is adequate, a longer-acting benzodiazepine such as chlordiazepoxide is preferred.

As in the treatment of all chronic drug abuse problems, heavy reliance is placed on psychosocial approaches to alcohol addiction. This is perhaps even more important for the alcoholic patient because of the ubiquitous presence of alcohol in many social contexts.

The pharmacologic treatment of alcohol addiction is limited, although several compounds, with different goals, have been used. Therapy is discussed in Chapter 23.

### **KETAMINE & PHENCYCLIDINE (PCP)**

Ketamine and PCP were developed as general anesthetics (see Chapter 25), but only ketamine is still used for this application. Both drugs, along with others, are now classified as "club drugs" and sold under names such as "angel dust," "Hog," and "Special K." They owe their effects to their use-dependent, noncompetitive antagonism of the NMDA receptor. The effects of these substances became apparent when patients undergoing surgery reported unpleasant vivid dreams and hallucinations after anesthesia. Ketamine and PCP are white crystalline powders in their pure forms, but on the street they are also sold as liquids, capsules, or pills, which can be snorted, ingested, injected, or smoked. Psychedelic effects last for about 1 hour and also include increased blood pressure, impaired memory function, and visual alterations. At high doses, unpleasant out-of-body and near-death experiences have been reported. Although ketamine and phencyclidine do not cause dependence and addiction (relative risk = 1), chronic exposure, particularly to PCP, may lead to long-lasting psychosis closely resembling schizophrenia, which may persist beyond drug exposure.

### **INHALANTS**

Inhalant abuse is defined as recreational exposure to chemical vapors, such as **nitrites**, **ketones**, and aliphatic and aromatic **hydrocarbons**. These substances are present in a variety of household and industrial products that are inhaled by "sniffing," "huffing," or "bagging." Sniffing refers to inhalation from an open container, huffing to the soaking of a cloth in the volatile substance before inhalation, and bagging to breathing in and out of a paper or plastic bag filled with fumes. It is common for novices to start with sniffing and progress to huffing and bagging as addiction develops. Inhalant abuse is particularly prevalent in children and young adults.

The exact mechanism of action of most volatile substances remains unknown. Altered function of ionotropic receptors and ion channels throughout the central nervous system has been demonstrated for a few. Nitrous oxide, for example, binds to NMDA receptors and fuel additives enhance GABA<sub>A</sub> receptor function. Most inhalants produce euphoria; increased excitability of the VTA has been documented for toluene and may underlie its addiction risk. Other substances, such as amyl nitrite ("poppers"), primarily produce smooth muscle relaxation and enhance erection, but are not addictive. With chronic exposure to the aromatic hydrocarbons (eg, benzene, toluene), toxic effects can be observed in many organs, including white matter lesions in the central nervous system. Management of overdose remains supportive.

## **Drugs That Bind to Transporters of Biogenic Amines**

### **COCAINE**

The prevalence of cocaine abuse has increased greatly over the last decade and now represents a major public health problem worldwide. Cocaine is highly addictive (relative risk = 5), and its use is associated with a number of complications.

Cocaine is an alkaloid found in the leaves of *Erythroxylon coca*, a shrub indigenous to the Andes. For more than 100 years, it has been extracted and used in clinical medicine, mainly as a local anesthetic and to dilate pupils in ophthalmology. Sigmund Freud famously proposed its use to treat depression and alcohol dependence, but addiction quickly brought an end to this idea.

Cocaine hydrochloride is a water-soluble salt that can be injected or absorbed by any mucosal membrane (eg, nasal snorting). When heated in an alkaline solution, it is transformed into the free base, "crack cocaine," which can then be smoked. Inhaled crack cocaine is rapidly absorbed in the lungs and penetrates swiftly into the brain, producing an almost instantaneous "rush."

In the peripheral nervous system, cocaine inhibits voltage-gated sodium channels, thus blocking initiation and conduction of action potentials (see Chapter 26). This effect, however, seems responsible for neither the acute rewarding nor the addictive effects. In the central nervous system, cocaine blocks the uptake of dopamine, noradrenaline, and serotonin through their respective transporters. The block of the **dopamine transporter (DAT)**, by increasing dopamine concentrations in the nucleus accumbens, has been implicated in the rewarding effects of cocaine (Figures 32-4 and 32-5). In fact, the rewarding effects of cocaine are abolished in mice with a cocaine-insensitive DAT. The activation of the sympathetic nervous system results mainly from blockage of the norepinephrine transporter (NET) and leads to an acute increase in arterial pressure, tachycardia, and often, ventricular arrhythmias. Users typically lose their appetite, are hyperactive, and sleep little. Cocaine exposure increases the risk for intracranial hemorrhage, ischemic stroke, myocardial infarction, and seizures. Cocaine overdose may lead to hyperthermia, coma, and death.

### **Figure 32-4**

Disinhibition of dopamine (DA) neurons in the ventral tegmental area (VTA) through drugs that act via  $G_{i/o}$ -coupled receptors. **Top:** Opioids target  $\mu$ -opioid receptors (MORs) that in the VTA are located exclusively on  $\gamma$ -aminobutyric acid (GABA) neurons. MORs are expressed on the presynaptic terminal of these cells and the somatodendritic compartment of the postsynaptic cells. Each compartment has distinct effectors (*insets*). G protein- $\beta\gamma$ -mediated inhibition of voltage-gated calcium channels (VGCC) is the major mechanism in the presynaptic terminal. Conversely, in dendrites MORs activate K channels. **Middle:**  $\Delta^9$ -tetrahydrocannabinol (THC) and other cannabinoids mainly act through presynaptic inhibition. **Bottom:** Gama-hydroxybutyric acid (GHB) targets  $GABA_B$  receptors, which are located on both cell types. However, GABA neurons are more sensitive to GHB than are DA neurons, leading to disinhibition at concentrations typically obtained with recreational use. CB1R, cannabinoid receptors.

**Figure 32â€5**

Mechanism of action of cocaine and amphetamine on synaptic terminal of dopamine (DA) neurons. **Left:** Cocaine inhibits the dopamine transporter (DAT),

decreasing DA clearance from the synaptic cleft and causing an increase in extracellular DA concentration. **Right:** Since amphetamine (Amph) is a substrate of the DAT, it competitively inhibits DA transport. In addition, once in the cell, amphetamine interferes with the vesicular monoamine transporter (VMAT) and impedes the filling of synaptic vesicles. As a consequence, vesicles are depleted and cytoplasmic DA increases. This leads to a reversal of DAT direction, strongly increasing nonvesicular release of DA, and further increasing extracellular DA concentrations.

Susceptible individuals may become dependent and addicted after only a few exposures to cocaine. Although a withdrawal syndrome is reported, it is not as strong as that observed with opioids. Tolerance may develop, but in some users a reverse tolerance is observed; that is, they become sensitized to small doses of cocaine. This behavioral sensitization is in part context-dependent. Cravings are very strong and underline the very high addiction liability of cocaine. To date, no specific antagonist is available, and the management of intoxication remains supportive. Developing a pharmacologic treatment for cocaine addiction is a top priority.

## AMPHETAMINES

Amphetamines are a group of synthetic, indirect-acting sympathomimetic drugs that cause the release of endogenous biogenic amines, such as dopamine and noradrenaline (see Chapters 6 and 9). Amphetamine, methamphetamine, and their many derivatives exert their effects by reversing the action of biogenic amine transporters at the plasma membrane. Amphetamines are substrates of these transporters and are taken up into the cell (Figure 32-5). Once in the cell, amphetamines interfere with the vesicular monoamine transporter (VMAT; see Figure 6-4), depleting synaptic vesicles of their neurotransmitter content. As a consequence, levels of dopamine (or other transmitter amine) in the cytoplasm increase and quickly become sufficient to cause release into the synapse by reversal of the plasma membrane DAT. Normal vesicular release of dopamine consequently decreases (because synaptic vesicles contain less transmitter), whereas nonvesicular release increases. Similar mechanisms apply for other biogenic amines (serotonin and norepinephrine).

Together with GHB and ecstasy, amphetamines are often referred to as "club drugs," because they are increasingly popular in the club scene. They are often produced in small clandestine laboratories, which makes their precise chemical identification difficult. They differ from ecstasy chiefly in the context of use: intravenous administration and "hard core" addiction is far more common with amphetamines, especially methamphetamine. In general, amphetamines lead to elevated catecholamine levels that increase arousal and reduce sleep, whereas the effects on the dopamine system mediate euphoria but may also cause abnormal movements and precipitate psychotic episodes. Effects on serotonin transmission may play a role in the hallucinogenic and anorexigenic functions as well as in the hyperthermia often caused by amphetamines.

Unlike many other abused drugs, amphetamines are neurotoxic. The exact mechanism is not known, but neurotoxicity depends on the NMDA receptor and affects mainly serotonin and dopamine neurons.

Amphetamines are typically taken initially in pill form by abusers, but can also be smoked or injected. Heavy users often progress rapidly to intravenous administration. Within hours after oral ingestion, amphetamines increase alertness, cause euphoria, agitation, and confusion. Bruxism (tooth grinding) and skin flushing may occur. Effects on heart rate may be minimal with some compounds (eg, methamphetamine), but with increasing dosage these agents often lead to tachycardia and dysrhythmias. Hypertensive crisis and vasoconstriction may lead to stroke. Spread of HIV and hepatitis infection in inner cities has been closely associated with needle sharing by intravenous users of methamphetamine.

With chronic use, amphetamine tolerance may develop, leading to dose escalation. Withdrawal consists of dysphoria, drowsiness (in some cases, insomnia), and general irritability.

## ECSTASY (MDMA)

Ecstasy is the name of a class of drugs that includes a large variety of derivatives of the amphetamine-related compound methylenedioxymethamphetamine (MDMA). MDMA was originally used in some forms of psychotherapy but no medically useful effects were documented. This is perhaps not surprising, because the main effect of ecstasy appears to be to foster feelings of intimacy and empathy without impairing intellectual capacities. Today, MDMA and its many derivatives are often produced in small quantities in ad hoc laboratories and distributed at parties or "raves," where it is taken orally. Ecstasy therefore is the prototypical designer drug and, as such, is increasingly popular.

Similar to the amphetamines, MDMA causes release of biogenic amines by reversing the action of their respective transporters. It has a preferential affinity for the **serotonin transporter (SERT)** and therefore most strongly increases the extracellular concentration of serotonin. This release is so profound that there is a marked intracellular depletion for 24 hours after a single dose. With repetitive administration, serotonin depletion may become permanent, which has triggered a debate on its neurotoxicity. Although direct proof from animal models for neurotoxicity remains weak, several studies report long-term cognitive impairment in heavy users of MDMA.

In contrast, there is a wide consensus that MDMA has several acute toxic effects, in particular hyperthermia, which along with dehydration (eg, caused by an all-night dance party) may be fatal. Other complications include serotonin syndrome (mental status change, autonomic hyperactivity, and neuromuscular abnormalities, see Chapter 16) and seizures. Following warnings about the dangers of MDMA, some users have attempted to compensate for hyperthermia by drinking excessive amounts of water, causing water intoxication involving severe hyponatremia, seizures, and even death.

Withdrawal is marked by a mood "offset" characterized by depression lasting up to several weeks. There have also been reports of increased aggression during periods of abstinence in chronic MDMA users.

Taken together, the evidence for irreversible damage to the brain, although not completely convincing, implies that even occasional recreational use of MDMA cannot be considered safe.

## CLINICAL PHARMACOLOGY OF DEPENDENCE & ADDICTION

To date no single pharmacologic treatment (even in combination with behavioral interventions) efficiently eliminates addiction. This is not to say that addiction is irreversible. Pharmacologic interventions may in fact be useful at all stages of the disease. This is particularly true in the case of a massive overdose, in which reversal of drug action may be a life-saving measure. However, in this regard, FDA-approved antagonists are available only for opioids and benzodiazepines.

Pharmacologic interventions may also aim to alleviate the withdrawal syndrome, particularly after opioid exposure. On the assumption that withdrawal reflects at least in part a hyperactivity of central adrenergic systems, the  $\alpha_2$ -adrenoceptor agonist clonidine (also used as a centrally active antihypertensive drug, see Chapter 11) has been used with some success to attenuate withdrawal. Today, most clinicians prefer to manage opioid withdrawal by very slowly tapering the administration of long-acting opioids.

Another widely accepted treatment is substitution of a legally available agonist that acts at the same receptor as the abused drug. This approach has been approved for opioids and nicotine. For example, heroin addicts may receive methadone to replace heroin; smoking addicts may receive nicotine continuously via a transdermal patch system to replace smoking. In general, a rapid-acting substance is replaced with one that acts or is absorbed more slowly. Substitution treatments are largely justified by the benefits of reducing associated health risks, the reduction of drug-associated crime, and better social integration. Although dependence persists, it may be possible, with the support of behavioral interventions, to motivate drug users to gradually reduce the dose and become abstinent.

The biggest challenge is the treatment of addiction itself. Several approaches have been proposed, but all remain experimental. One approach is to pharmacologically reduce cravings. The  $\mu$ -opioid receptor antagonist and partial agonist **naltrexone** is FDA-approved for this indication in opioid and alcohol addiction. Its effect is modest and may involve a modulation of endogenous opioid systems.

Clinical trials are currently being conducted with a number of drugs, including the high-affinity GABA<sub>B</sub>-receptor agonist **baclofen**, and initial results have shown a significant reduction of craving. This effect may be mediated by the inhibition of the dopamine neurons of the VTA, which is possible at baclofen concentrations obtained by oral administration because of its very high affinity for the GABA<sub>B</sub> receptor.

**Rimonabant** is an inverse agonist of the CB<sub>1</sub> receptor, initially developed for smoking cessation and to facilitate weight loss. The drug is currently approved in Europe and the USA for use in conjunction with diet and exercise for patients with a body mass index above 30 kg/m<sup>2</sup> (27 kg/m<sup>2</sup> if associated risk factors, such as type 2 diabetes or dyslipidemia are present). Although a recent large-scale study confirmed that rimonabant is effective for smoking cessation and the prevention of weight gain in smokers who quit, this indication has not been approved. In fact, because of frequent adverse effects—most notably severe depression carrying a substantial risk of suicide—the future of rimonabant remains unclear. Although the cellular mechanism of rimonabant remains to be elucidated, data in rodents convincingly demonstrate that this compound can reduce self-administration in naive as well as drug-experienced animals.

## SUMMARY: DRUGS USED TO TREAT DEPENDENCE AND ADDICTION

### Drugs Used to Treat Dependence and Addiction

Subclass	Mechanism of Action	Effects	Clinical Application	Pharmacokinetics, Toxicities, Interactions
<b>Opioid receptor antagonist</b>				
Naloxone	Nonselective antagonist of opioid receptors	Reverses the acute effects of opioids; can precipitate severe abstinence syndrome	Opioid overdose	Effect much shorter than morphine (1 h), therefore several injections required
Naltrexone	Antagonist of opioid receptors	Blocks effects of illicit opioids	Treatment of alcoholism	Half-life ~ 4 h
<b>Synthetic opioid</b>				
Methadone	Slow-acting agonist of $\mu$ -opioid receptor	Acute effects similar to morphine (see text)	Substitution therapy for opioid addicts	High oral bioavailability • half-life highly variable among individuals (range 4 h–130 h) • <i>Toxicity:</i> Respiratory depression, constipation, miosis, tolerance, dependence, and withdrawal symptoms
<b>Partial <math>\mu</math>-opioid receptor agonist</b>				
Buprenorphine	Partial agonist at $\mu$ -opioid receptors	Attenuates acute effects of morphine	Oral substitution therapy for opioid-addicts	Long half-life (40 h) • formulated together with naloxone to avoid illicit IV injections
<b>Nicotinic receptor partial agonist</b>				
Varenicline	Partial agonist of nicotinic acetylcholine receptor of the $\alpha_4\beta_2$ -type	Occludes "rewarding" effects of smoking • heightened awareness of colors	Smoking cessation	<i>Toxicity:</i> Nausea and vomiting, convulsions, psychiatric changes
<i>Cytisine: Natural analog (extracted from laburnum flowers) of varenicline</i>				
<b>Benzodiazepines</b>				
Oxazepam, others	Positive modulators of the GABA <sub>A</sub> receptors, increase frequency of	Enhances GABAergic synaptic transmission; attenuates withdrawal symptoms (tremor, hallucinations, anxiety) in alcoholics • prevents	Delirium tremens	Half-life 4 h–15 h • pharmacokinetics not affected by decreased liver function

channel opening withdrawal seizures

*Lorazepam: Alternate to oxazepam with similar properties*

#### **N-methyl-D-aspartate (NMDA)**

Acamprosate	Antagonist of NMDA glutamate receptors	May interfere with forms of synaptic plasticity that depend on NMDA receptors	Treatment of alcoholism • effective only in combination with counseling	Allergic reactions, arrhythmia, and low or high blood pressure, headaches, insomnia, and impotence • hallucinations, particularly in elderly patients
-------------	--	---	---	---

#### **Cannabinoid receptor agonist**

Rimonabant	CB <sub>1</sub> receptor agonist	Decreases neurotransmitter release at GABAergic and glutamatergic synapses	Approved in USA and Europe to treat obesity • Smoking cessation is an off-label indication	Major depression, including increased risk of suicide
------------	----------------------------------	--	--	---

Basic and Clinical Pharmacology > Chapter 33. Agents Used in Anemias; Hematopoietic Growth Factors >

## CASE STUDY

A 65-year-old woman with a long-standing history of poorly controlled type 2 diabetes mellitus presents with increasing numbness and paresthesias in her extremities, generalized weakness, a sore tongue, and gastrointestinal discomfort. Physical examination reveals a frail-looking, pale woman with diminished vibration sensation, diminished spinal reflexes, and a positive Babinski sign. Examination of her oral cavity reveals Hunter's glossitis, in which the tongue appears deep red in color and abnormally smooth and shiny due to atrophy of the lingual papillae. Laboratory testing reveals a macrocytic anemia based on a hematocrit of 30% (normal for women, 37%–48%), a hemoglobin concentration of 9.4 g/dL (normal for elderly women, 11.7–13.8 g/dL), an erythrocyte mean cell volume (MCV) of 113 fL (normal, 84–99 fL), an erythrocyte mean cell hemoglobin concentration (MCHC) of 34% (normal, 31–36%), and a low reticulocyte count. Further laboratory testing reveals a normal serum folate concentration and a serum vitamin B12 (cobalamin) concentration of 98 pg/mL (normal, 250–1100 pg/mL). Results of a Schilling test indicate a diagnosis of pernicious anemia. Once megaloblastic anemia was identified, why was it important to measure serum concentrations of both folic acid and cobalamin? Should this patient be treated with oral or parenteral vitamin B<sub>12</sub>?

## AGENTS USED IN ANEMIAS; HEMATOPOIETIC GROWTH FACTORS:

### INTRODUCTION

Hematopoiesis, the production from undifferentiated stem cells of circulating erythrocytes, platelets, and leukocytes, is a remarkable process that produces over 200 billion new blood cells per day in the normal person and even greater numbers of cells in people with conditions that cause loss or destruction of blood cells. The hematopoietic machinery resides primarily in the bone marrow in adults and requires a constant supply of three essential nutrients—**iron, vitamin B<sub>12</sub>, and folic acid**—as well as the presence of **hematopoietic growth factors**, proteins that regulate the proliferation and differentiation of hematopoietic cells. Inadequate supplies of either the essential nutrients or the growth factors result in deficiency of functional blood cells. **Anemia**, a deficiency in oxygen-carrying erythrocytes, is the most common and several forms are easily treated. Sickle cell anemia, a condition resulting from a genetic alteration in the hemoglobin molecule, is common but is not easily treated. It is discussed in the Box: Sickle Cell Disease and Hydroxyurea. **Thrombocytopenia** and **neutropenia** are not rare and some forms are amenable to drug therapy. In this chapter, we first consider treatment of anemia due to deficiency of iron, vitamin B<sub>12</sub>, or folic acid and then turn to the medical use of hematopoietic growth factors to combat anemia, thrombocytopenia, and neutropenia, and to support stem cell transplantation.

### AGENTS USED IN ANEMIAS

#### IRON

##### Basic Pharmacology

Iron deficiency is the most common cause of chronic anemia. Like other forms of chronic anemia, iron deficiency anemia leads to pallor, fatigue, dizziness, exertional dyspnea, and other generalized symptoms of tissue hypoxia. The cardiovascular adaptations to chronic anemia—tachycardia, increased cardiac output, vasodilation—can worsen the condition of patients with underlying cardiovascular disease.

Iron forms the nucleus of the iron-porphyrin heme ring, which together with globin chains forms hemoglobin. Hemoglobin reversibly binds oxygen and provides the critical mechanism for oxygen delivery from the lungs to

other tissues. In the absence of adequate iron, small erythrocytes with insufficient hemoglobin are formed, giving rise to **microcytic hypochromic anemia**.

### Pharmacokinetics

Free inorganic iron is extremely toxic, but iron is required for essential proteins such as hemoglobin; therefore, evolution has provided an elaborate system for regulating iron absorption, transport, and storage (Figure 33â€1). The system uses specialized transport, storage, ferroreductase, and ferroxidase proteins whose concentrations are controlled by the body's demand for hemoglobin synthesis and adequate iron stores (Table 33â€1). Nearly all of the iron used to support hematopoiesis is reclaimed from catalysis of the hemoglobin in senescent or damaged erythrocytes. Normally, only a small amount of iron is lost from the body each day, so dietary requirements are small and easily fulfilled by the iron available in a wide variety of foods. However, in special populations with either increased iron requirements (eg, growing children, pregnant women) or increased losses of iron (eg, menstruating women), iron requirements can exceed normal dietary supplies and iron deficiency can develop.

**Figure 33â€1**

Absorption, transport, and storage of iron. Intestinal epithelial cells actively absorb inorganic iron and heme iron (H). Ferrous iron that is absorbed or released from absorbed heme iron in the intestine (1) is actively transported into the blood or complexed with apoferritin (AF) and stored as ferritin (F). In the blood, iron is transported by transferrin (Tf) to erythroid precursors in the bone marrow for synthesis of hemoglobin (Hgb) (2) or to hepatocytes for storage as ferritin (3). The transferrin-iron complexes bind to transferrin receptors (TfR) in erythroid precursors and hepatocytes and are internalized. After release of the iron, the TfR-Tf complex is recycled to the plasma membrane and Tf is released. Macrophages that phagocytize senescent erythrocytes (RBC) reclaim the iron from the RBC hemoglobin and either export it or store it as ferritin (4). Hepatocytes use several mechanisms to take up iron and store the iron as ferritin. DMT1, divalent

metal transporter; FP, ferroportin; FR, ferrereductase; HCP1, heme carrier protein 1. See text.

**Table 33â€1 Iron Distribution in Normal Adults.<sup>1</sup>**

	Iron Content (mg)	
	Men	Women
Hemoglobin	3050	1700
Myoglobin	430	300
Enzymes	10	8
Transport (transferrin)	8	6
Storage (ferritin and other forms)	750	300
Total	4248	2314

<sup>1</sup>Values are based on data from various sources and assume that normal men weigh 80 kg and have a hemoglobin level of 16 g/dL and that normal women weigh 55 kg and have a hemoglobin level of 14 g/dL.

Adapted, with permission, from Brown EB: Iron deficiency anemia. In: Wyngaarden JB, Smith LH (editors). *Cecil Textbook of Medicine*, 16th ed. Saunders, 1982.

#### **ABSORPTION**

The average diet in the USA contains 10â€15 mg of elemental iron daily. A normal individual absorbs 5â€10% of this iron, or about 0.5â€1 mg daily. Iron is absorbed in the duodenum and proximal jejunum, although the more distal small intestine can absorb iron if necessary. Iron absorption increases in response to low iron stores or increased iron requirements. Total iron absorption increases to 1â€2 mg/d in menstruating women and may be as high as 3â€4 mg/d in pregnant women.

Iron is available in a wide variety of foods but is especially abundant in meat. The iron in meat protein can be efficiently absorbed, because heme iron in meat hemoglobin and myoglobin can be absorbed intact without first having to be dissociated into elemental iron (Figure 33â€1). Iron in other foods, especially vegetables and grains, is often tightly bound to organic compounds and is much less available for absorption. Nonheme iron in foods and iron in inorganic iron salts and complexes must be reduced by a ferreductase to ferrous iron (Fe<sup>2+</sup>) before it can be absorbed by intestinal mucosal cells.

Iron crosses the luminal membrane of the intestinal mucosal cell by two mechanisms: active transport of ferrous iron and absorption of iron complexed with heme (Figure 33â€1). The divalent metal transporter, DMT1, efficiently transports ferrous iron across the luminal membrane of the intestinal enterocyte. The rate of iron uptake is regulated by mucosal cell iron stores such that more iron is transported when stores are low. Together with iron split from absorbed heme, the newly absorbed iron can be actively transported into the blood across the basolateral membrane by a transporter known as ferroportin and oxidized to ferric iron (Fe<sup>3+</sup>) by a ferroxidase. Excess iron can be stored in intestinal epithelial cells as ferritin, a water-soluble complex consisting of a core of ferric hydroxide covered by a shell of a specialized storage protein called apoferritin. In general, when total body iron stores are high and iron requirements by the body are low, newly absorbed iron is diverted into ferritin in the intestinal mucosal cells. When iron stores are low or iron requirements are high, newly absorbed iron is immediately transported from the mucosal cells to the bone marrow to support hemoglobin production.

#### **TRANSPORT**

Iron is transported in the plasma bound to **transferrin**, a  $\beta$ -globulin that specifically binds two molecules of ferric iron (Figure 33â€1). The transferrin-iron complex enters maturing erythroid cells by a specific receptor mechanism. Transferrin receptorsâ€integral membrane glycoproteins present in large numbers on proliferating erythroid cellsâ€bind and internalize the transferrin-iron complex through the process of receptor-mediated endocytosis. In endosomes, the ferric iron is released, reduced to ferrous iron, and transported by DMT1 into the

cell, where it is funneled into hemoglobin synthesis or stored as ferritin. The transferrin-transferrin receptor complex is recycled to the plasma membrane, where the transferrin dissociates and returns to the plasma. This process provides an efficient mechanism for supplying the iron required by developing red blood cells.

Increased erythropoiesis is associated with an increase in the number of transferrin receptors on developing erythroid cells. Iron store depletion and iron deficiency anemia are associated with an increased concentration of serum transferrin.

#### STORAGE

In addition to the storage of iron in intestinal mucosal cells, iron is also stored, primarily as ferritin, in macrophages in the liver, spleen, and bone, and in parenchymal liver cells (Figure 33â€1). Apoferritin synthesis is regulated by the levels of free iron. When these levels are low, apoferritin synthesis is inhibited and the balance of iron binding shifts toward transferrin. When free iron levels are high, more apoferritin is produced to sequester more iron and protect organs from the toxic effects of excess free iron.

Ferritin is detectable in serum. Since the ferritin present in serum is in equilibrium with storage ferritin in reticuloendothelial tissues, the serum ferritin level can be used to estimate total body iron stores.

#### ELIMINATION

There is no mechanism for excretion of iron. Small amounts are lost in the feces by exfoliation of intestinal mucosal cells, and trace amounts are excreted in bile, urine, and sweat. These losses account for no more than 1 mg of iron per day. Because the body's ability to excrete iron is so limited, regulation of iron balance must be achieved by changing intestinal absorption and storage of iron, in response to the body's needs. As noted below, impaired regulation of iron absorption leads to serious pathology.

### Clinical Pharmacology

#### INDICATIONS FOR THE USE OF IRON

The only clinical indication for the use of iron preparations is the treatment or prevention of iron deficiency anemia. This manifests as a hypochromic, microcytic anemia in which the erythrocyte mean cell volume (MCV) and the mean cell hemoglobin concentration are low (Table 33â€2). Iron deficiency is commonly seen in populations with increased iron requirements. These include infants, especially premature infants; children during rapid growth periods; pregnant and lactating women; and patients with chronic kidney disease who lose erythrocytes at a relatively high rate during hemodialysis and also form them at a high rate as a result of treatment with the erythrocyte growth factor erythropoietin (see below). Inadequate iron absorption can also cause iron deficiency. This is seen frequently after gastrectomy and in patients with severe small bowel disease that results in generalized malabsorption. Iron deficiency in these gastrointestinal conditions is due to inadequate iron absorption.

**Table 33â€2 Distinguishing Features of the Nutritional Anemias.**

Nutritional Deficiency	Type of Anemia	Laboratory Abnormalities
Iron	Microcytic, hypochromic with MCV < 80 fL and MCHC < 30%	Low SI < 30 mcg/dL with increased TIBC, resulting in a % transferrin saturation (SI/TIBC) of < 10%; low serum ferritin level (< 20 mcg/L)
Folic acid	Macrocytic, normochromic with MCV > 100 fL and normal or elevated MCHC	Low serum folic acid (< 4 ng/mL)
Vitamin B12		Low serum cobalamin (< 150 pmol/L) accompanied by increased serum homocysteine (> 13 µmol/L), and increased serum (> 0.4 µmol/L) and urine (> 3.6 mmol/mol creatinine) methylmalonic acid

MCV, mean cell volume; MCHC, mean cell hemoglobin concentration; SI, serum iron; TIBC, transferrin iron-binding capacity.

The most common cause of iron deficiency in adults is blood loss. Menstruating women lose about 30 mg of iron with each menstrual period; women with heavy menstrual bleeding may lose much more. Thus, many

premenopausal women have low iron stores or even iron deficiency. In men and postmenopausal women, the most common site of blood loss is the gastrointestinal tract. Patients with unexplained iron deficiency anemia should be evaluated for occult gastrointestinal bleeding.

## TREATMENT

Iron deficiency anemia is treated with oral or parenteral iron preparations. Oral iron corrects the anemia just as rapidly and completely as parenteral iron in most cases if iron absorption from the gastrointestinal tract is normal. An exception is the high requirement for iron of patients with advanced chronic kidney disease who are undergoing hemodialysis and treatment with erythropoietin; for these patients, parenteral iron administration is preferred.

### Oral Iron Therapy

A wide variety of oral iron preparations is available. Because ferrous iron is most efficiently absorbed, only ferrous salts should be used. Ferrous sulfate, ferrous gluconate, and ferrous fumarate are all effective and inexpensive and are recommended for the treatment of most patients.

Different iron salts provide different amounts of elemental iron, as shown in Table 33-3. In an iron-deficient individual, about 50-100 mg of iron can be incorporated into hemoglobin daily, and about 25% of oral iron given as ferrous salt can be absorbed. Therefore, 200-400 mg of elemental iron should be given daily to correct iron deficiency most rapidly. Patients unable to tolerate such large doses of iron can be given lower daily doses of iron, which results in slower but still complete correction of iron deficiency. Treatment with oral iron should be continued for 3-6 months after correction of the cause of the iron loss. This corrects the anemia and replenishes iron stores.

**Table 33-3 Some Commonly Used Oral Iron Preparations.**

Preparation	Tablet Size	Elemental Iron per Tablet	Usual Adult Dosage (Tablets per Day)
Ferrous sulfate, hydrated	325 mg	65 mg	3-4
Ferrous sulfate, desiccated	200 mg	65 mg	3-4
Ferrous gluconate	325 mg	36 mg	3-4
Ferrous fumarate	100 mg	33 mg	6-8
	325 mg	106 mg	2-3

Common adverse effects of oral iron therapy include nausea, epigastric discomfort, abdominal cramps, constipation, and diarrhea. These effects are usually dose-related and can often be overcome by lowering the daily dose of iron or by taking the tablets immediately after or with meals. Some patients have less severe gastrointestinal adverse effects with one iron salt than another and benefit from changing preparations. Patients taking oral iron develop black stools; this has no clinical significance in itself but may obscure the diagnosis of continued gastrointestinal blood loss.

### Parenteral Iron Therapy

Parenteral therapy should be reserved for patients with documented iron deficiency who are unable to tolerate or absorb oral iron and for patients with extensive chronic anemia who cannot be maintained with oral iron alone. This includes patients with advanced chronic renal disease requiring hemodialysis and treatment with erythropoietin, various postgastrectomy conditions and previous small bowel resection, inflammatory bowel disease involving the proximal small bowel, and malabsorption syndromes.

The challenge with parenteral iron therapy is that parenteral administration of inorganic free ferric iron produces serious dose-dependent toxicity, which severely limits the dose of that can be administered. However, when the ferric iron is formulated as a colloid containing particles with a core of iron oxyhydroxide surrounded by a core of carbohydrate, bioactive iron is released slowly from the stable colloid particles. In the USA, the three available forms of parenteral iron are **iron dextran**, **sodium ferric gluconate complex**, and **iron sucrose**.

**Iron dextran** is a stable complex of ferric oxyhydroxide and dextran polymers containing 50 mg of elemental iron

per milliliter of solution. It can be given by deep intramuscular injection or by intravenous infusion, although the intravenous route is used most commonly. Intravenous administration eliminates the local pain and tissue staining that often occur with the intramuscular route and allows delivery of the entire dose of iron necessary to correct the iron deficiency at one time. Adverse effects of intravenous iron dextran therapy include headache, light-headedness, fever, arthralgias, nausea and vomiting, back pain, flushing, urticaria, bronchospasm, and, rarely, anaphylaxis and death. Owing to the risk of a hypersensitivity reaction, a small test dose of iron dextran should always be given before full intramuscular or intravenous doses are given. Patients with a strong history of allergy and patients who have previously received parenteral iron dextran are more likely to have hypersensitivity reactions after treatment with parenteral iron dextran. The iron dextran formulations used clinically are distinguishable as high-molecular-weight and low-molecular-weight forms. In the USA, the InFeD preparation is a low-molecular-weight form while DexFerrum is a high-molecular-weight form. Clinical data<sup>1</sup> primarily from observational studies<sup>2</sup> indicate that the risk of anaphylaxis is largely associated with high-molecular-weight iron dextran formulations.

**Sodium ferric gluconate complex** and **iron-sucrose complex** are alternative parenteral iron preparations. These agents can be given only by the intravenous route. They appear to be less likely than high-molecular-weight iron dextran to cause hypersensitivity reactions.

For patients who are treated chronically with parenteral iron, it is important to monitor iron storage levels to avoid the serious toxicity associated with iron overload. Unlike oral iron therapy, which is subject to the regulatory mechanism provided by the intestinal uptake system, parenteral administration, which bypasses this regulatory system, can deliver more iron than can be safely stored. Iron stores can be estimated on the basis of serum concentrations of ferritin and the transferrin saturation, which is the ratio of the total serum iron concentration to the total iron-binding capacity (TIBC).

## Clinical Toxicity

### ACUTE IRON TOXICITY

Acute iron toxicity is seen almost exclusively in young children who accidentally ingest iron tablets. Although adults are able to tolerate large doses of oral iron without serious consequences, as few as 10 tablets of any of the commonly available oral iron preparations can be lethal in young children. Adult patients taking oral iron preparations should be instructed to store tablets in child-proof containers out of the reach of children. Children who are poisoned with oral iron experience necrotizing gastroenteritis, with vomiting, abdominal pain, and bloody diarrhea followed by shock, lethargy, and dyspnea. Subsequently, improvement is often noted, but this may be followed by severe metabolic acidosis, coma, and death. Urgent treatment is necessary. **Whole bowel irrigation** (see Chapter 58) should be performed to flush out unabsorbed pills. **Deferoxamine**, a potent iron-chelating compound, can be given systemically to bind iron that has already been absorbed and to promote its excretion in urine and feces. Activated charcoal, a highly effective adsorbent for most toxins, **does not** bind iron and thus is ineffective. Appropriate supportive therapy for gastrointestinal bleeding, metabolic acidosis, and shock must also be provided.

### CHRONIC IRON TOXICITY

Chronic iron toxicity (iron overload), also known as **hemochromatosis**, results when excess iron is deposited in the heart, liver, pancreas, and other organs. It can lead to organ failure and death. It most commonly occurs in patients with inherited hemochromatosis, a disorder characterized by excessive iron absorption, and in patients who receive many red cell transfusions over a long period of time (eg, patients with thalassemia major).

Chronic iron overload in the absence of anemia is most efficiently treated by intermittent phlebotomy. One unit of blood can be removed every week or so until all of the excess iron is removed. Iron chelation therapy using parenteral deferoxamine is much less efficient as well as more complicated, expensive, and hazardous, but it may be the only option for iron overload that cannot be managed by phlebotomy, such as the iron overload experienced by patients with thalassemia major.

The oral iron chelator **deferasirox** is approved for treatment of iron overload. Deferasirox appears to be as effective as deferoxamine at reducing liver iron concentrations and is much more convenient. However, it is not clear yet whether deferasirox is as effective as deferoxamine at protecting the heart from iron overload.

## VITAMIN B<sub>12</sub>

Vitamin B<sub>12</sub> (cobalamin) serves as a cofactor for several essential biochemical reactions in humans. Deficiency of vitamin B<sub>12</sub> leads to megaloblastic anemia (Table 33â€"2), gastrointestinal symptoms, and neurologic abnormalities. Although deficiency of vitamin B<sub>12</sub> due to an inadequate supply in the diet is unusual, deficiency of B<sub>12</sub> in adultsâ€"especially older adultsâ€"due to inadequate absorption of dietary vitamin B<sub>12</sub> is a relatively common and easily treated disorder.

### Chemistry

Vitamin B<sub>12</sub> consists of a porphyrin-like ring with a central cobalt atom attached to a nucleotide. Various organic groups may be covalently bound to the cobalt atom, forming different cobalamins. Deoxyadenosylcobalamin and methylcobalamin are the active forms of the vitamin in humans. **Cyanocobalamin** and **hydroxocobalamin** (both available for therapeutic use) and other cobalamins found in food sources are converted to the active forms. The ultimate source of vitamin B<sub>12</sub> is from microbial synthesis; the vitamin is not synthesized by animals or plants. The chief dietary source of vitamin B<sub>12</sub> is microbially derived vitamin B<sub>12</sub> in meat (especially liver), eggs, and dairy products. Vitamin B<sub>12</sub> is sometimes called **extrinsic factor** to differentiate it from **intrinsic factor**, a protein normally secreted by the stomach that is required for gastrointestinal uptake of dietary vitamin B<sub>12</sub>.

### Pharmacokinetics

The average diet in the USA contains 5â€"30 mcg of vitamin B<sub>12</sub> daily, 1â€"5 mcg of which is usually absorbed. The vitamin is avidly stored, primarily in the liver, with an average adult having a total vitamin B<sub>12</sub> storage pool of 3000â€"5000 mcg. Only trace amounts of vitamin B<sub>12</sub> are normally lost in urine and stool. Because the normal daily requirements of vitamin B<sub>12</sub> are only about 2 mcg, it would take about 5 years for all of the stored vitamin B<sub>12</sub> to be exhausted and for megaloblastic anemia to develop if B<sub>12</sub> absorption were stopped. Vitamin B<sub>12</sub> in physiologic amounts is absorbed only after it complexes with intrinsic factor, a glycoprotein secreted by the parietal cells of the gastric mucosa. Intrinsic factor combines with the vitamin B<sub>12</sub> that is liberated from dietary sources in the stomach and duodenum, and the intrinsic factor-vitamin B<sub>12</sub> complex is subsequently absorbed in the distal ileum by a highly selective receptor-mediated transport system. Vitamin B<sub>12</sub> deficiency in humans most often results from malabsorption of vitamin B<sub>12</sub> due either to lack of intrinsic factor or to loss or malfunction of the specific absorptive mechanism in the distal ileum. Nutritional deficiency is rare but may be seen in strict vegetarians after many years without meat, eggs, or dairy products.

Once absorbed, vitamin B<sub>12</sub> is transported to the various cells of the body bound to a family of specialized glycoproteins, transcobalamin I, II, and III. Excess vitamin B<sub>12</sub> is transported to the liver for storage.

### Pharmacodynamics

Two essential enzymatic reactions in humans require vitamin B<sub>12</sub> (Figure 33â€"2). In one, methylcobalamin serves as an intermediate in the transfer of a methyl group from *N*<sup>5</sup>-methyltetrahydrofolate to homocysteine, forming methionine (Figure 33â€"2A; Figure 33â€"3, section 1). Without vitamin B<sub>12</sub>, conversion of the major dietary and storage folate, *N*<sup>5</sup>-methyltetrahydrofolate, to tetrahydrofolate, the precursor of folate cofactors, cannot occur. As a result, a deficiency of folate cofactors necessary for several biochemical reactions involving the transfer of one-carbon groups develops. In particular, the depletion of tetrahydrofolate prevents synthesis of adequate supplies of the deoxythymidylate (dTTP) and purines required for DNA synthesis in rapidly dividing cells, as shown in Figure 33â€"3, section 2. The accumulation of folate as *N*<sup>5</sup>-methyltetrahydrofolate and the associated depletion of tetrahydrofolate cofactors in vitamin B<sub>12</sub> deficiency have been referred to as the "methylfolate trap." This is the biochemical step whereby vitamin B<sub>12</sub> and folic acid metabolism are linked, and it explains why the megaloblastic anemia of vitamin B<sub>12</sub> deficiency can be partially corrected by ingestion of relatively large amounts of folic acid. Folic acid can be reduced to dihydrofolate by the enzyme dihydrofolate reductase (Figure 33â€"3, section 3) and

thus serve as a source of the tetrahydrofolate required for synthesis of the purines and dTMP that are needed for DNA synthesis.

Enzymatic reactions that use folates. **Section 1** shows the vitamin B<sub>12</sub>-dependent reaction that allows most dietary folates to enter the tetrahydrofolate cofactor pool and becomes the "folate trap" in vitamin B<sub>12</sub> deficiency. **Section 2** shows the dTMP cycle. **Section 3** shows the pathway by which folic acid enters the tetrahydrofolate cofactor pool. Double arrows indicate pathways with more than one intermediate step.

A deficiency of vitamin B<sub>12</sub> causes the accumulation of homocysteine due to reduced formation of methylcobalamin, which is required for the conversion of homocysteine to methionine (Figure 33â€"3, section 1). The increase in serum homocysteine can be used to help establish a diagnosis of vitamin B<sub>12</sub> deficiency (Table 33â€"2). There is concern that elevated serum homocysteine increases the risk of atherosclerotic cardiovascular disease. The concern is based on observational studies showing an association between elevated serum homocysteine and cardiovascular disease. However, randomized clinical trials have not shown a definitive reduction in cardiovascular events (myocardial infarction, stroke) in patients receiving vitamin supplementation that lowers serum homocysteine.

The other reaction that requires vitamin B<sub>12</sub> is isomerization of methylmalonyl-CoA to succinyl-CoA by the enzyme methylmalonyl-CoA mutase (Figure 33â€"2B). In vitamin B<sub>12</sub> deficiency, this conversion cannot take place and the substrate, methylmalonyl-CoA, as well as methylmalonic acid accumulate. The increase in serum and urine concentrations of methylmalonic acid can be used to support a diagnosis of vitamin B<sub>12</sub> deficiency (Table 33â€"2). In the past, it was thought that abnormal accumulation of methylmalonyl-CoA causes the neurologic manifestations

of vitamin B<sub>12</sub> deficiency. However, newer evidence instead implicates the disruption of the methionine synthesis pathway as the cause of neurologic problems. Whatever the biochemical explanation for neurologic damage, the important point is that administration of folic acid in the setting of vitamin B<sub>12</sub> deficiency will not prevent *neurologic* manifestations even though it will largely correct the *anemia* caused by the vitamin B<sub>12</sub> deficiency.

### **Clinical Pharmacology**

Vitamin B<sub>12</sub> is used to treat or prevent deficiency. The most characteristic clinical manifestation of vitamin B<sub>12</sub> deficiency is megaloblastic, macrocytic anemia (Table 33-2), often with associated mild or moderate leukopenia or thrombocytopenia (or both), and a characteristic hypercellular bone marrow with an accumulation of megaloblastic erythroid and other precursor cells. The neurologic syndrome associated with vitamin B<sub>12</sub> deficiency usually begins with paresthesias in peripheral nerves and weakness and progresses to spasticity, ataxia, and other central nervous system dysfunctions. Correction of vitamin B<sub>12</sub> deficiency arrests the progression of neurologic disease, but it may not fully reverse neurologic symptoms that have been present for several months. Although most patients with neurologic abnormalities caused by vitamin B<sub>12</sub> deficiency have megaloblastic anemia when first seen, occasional patients have few if any hematologic abnormalities.

Once a diagnosis of megaloblastic anemia is made, it must be determined whether vitamin B<sub>12</sub> or folic acid deficiency is the cause. (Other causes of megaloblastic anemia are very rare.) This can usually be accomplished by measuring serum levels of the vitamins. The Schilling test, which measures absorption and urinary excretion of radioactively labeled vitamin B<sub>12</sub>, can be used to further define the mechanism of vitamin B<sub>12</sub> malabsorption when this is found to be the cause of the megaloblastic anemia.

The most common causes of vitamin B<sub>12</sub> deficiency are pernicious anemia, partial or total gastrectomy, and conditions that affect the distal ileum, such as malabsorption syndromes, inflammatory bowel disease, or small bowel resection.

**Pernicious anemia** results from defective secretion of intrinsic factor by the gastric mucosal cells. Patients with pernicious anemia have gastric atrophy and fail to secrete intrinsic factor (as well as hydrochloric acid). The Schilling test shows diminished absorption of radioactively labeled vitamin B<sub>12</sub>, which is corrected when intrinsic factor is administered with radioactive B<sub>12</sub>, since the vitamin can then be normally absorbed.

Vitamin B<sub>12</sub> deficiency also occurs when the region of the distal ileum that absorbs the vitamin B<sub>12</sub>-intrinsic factor complex is damaged, as when the ileum is involved with inflammatory bowel disease or when the ileum is surgically resected. In these situations, radioactively labeled vitamin B<sub>12</sub> is not absorbed in the Schilling test, even when intrinsic factor is added. Other rare causes of vitamin B<sub>12</sub> deficiency include bacterial overgrowth of the small bowel, chronic pancreatitis, and thyroid disease. Rare cases of vitamin B<sub>12</sub> deficiency in children have been found to be secondary to congenital deficiency of intrinsic factor or to defects of the receptor sites for vitamin B<sub>12</sub>-intrinsic factor complex located in the distal ileum.

Almost all cases of vitamin B<sub>12</sub> deficiency are caused by malabsorption of the vitamin; therefore, parenteral injections of vitamin B<sub>12</sub> are required for therapy. For patients with potentially reversible diseases, the underlying disease should be treated after initial treatment with parenteral vitamin B<sub>12</sub>. Most patients, however, do not have curable deficiency syndromes and require lifelong treatment with vitamin B<sub>12</sub>.

Vitamin B<sub>12</sub> for parenteral injection is available as cyanocobalamin or hydroxocobalamin. Hydroxocobalamin is preferred because it is more highly protein-bound and therefore remains longer in the circulation. Initial therapy should consist of 100-1000 mcg of vitamin B<sub>12</sub> intramuscularly daily or every other day for 2 weeks to replenish body stores. Maintenance therapy consists of 100-1000 mcg intramuscularly once a month for life. If neurologic abnormalities are present, maintenance therapy injections should be given every 2 weeks for 6 months before switching to monthly injections. Oral vitamin B<sub>12</sub>-intrinsic factor mixtures and liver extracts should not be used to treat vitamin B<sub>12</sub> deficiency; however, oral doses of 1000 mcg of vitamin B<sub>12</sub> daily are usually

sufficient to treat patients with pernicious anemia who refuse or cannot tolerate the injections. After pernicious anemia is in remission following parenteral vitamin B<sub>12</sub> therapy, the vitamin can be administered intranasally as a spray or gel.

## **FOLIC ACID**

Reduced forms of folic acid are required for essential biochemical reactions that provide precursors for the synthesis of amino acids, purines, and DNA. Folate deficiency is not uncommon, even though the deficiency is easily corrected by administration of folic acid. The consequences of folate deficiency go beyond the problem of anemia because folate deficiency is implicated as a cause of congenital malformations in newborns and may play a role in vascular disease (see Folic Acid Supplementation: A Public Health Dilemma).

### **Folic Acid Supplementation: A Public Health Dilemma**

Starting in January 1998, all products made from enriched grains in the USA were required to be supplemented with folic acid. This FDA ruling was issued to reduce the incidence of congenital neural tube defects (NTDs). Epidemiologic studies show a strong correlation between maternal folic acid deficiency and the incidence of NTDs such as spina bifida and anencephaly. The FDA requirement for folic acid supplementation is a public health measure aimed at the significant number of women in the USA who do not receive prenatal care and are not aware of the importance of adequate folic acid ingestion for preventing birth defects in their infants. Observational studies from the USA and from other countries that supplement grains with folic acid have found that supplementation is associated with a significant (30–75%) reduction in NTD rates. These studies indicate that the reduction in NTDs is dose-dependent and that supplementation of grains in the USA with higher levels of folic acid could result in an even greater reduction in the rate of NTDs. Observational studies also suggest that rates of other types of congenital anomalies (heart and orofacial) have fallen after supplementation began.

There may be an added benefit for adults. N<sup>5</sup>-Methyltetrahydrofolate is required for the conversion of homocysteine to methionine (Figure 33-2; Figure 33-3, reaction 1). Impaired synthesis of N<sup>5</sup>-methyltetrahydrofolate results in elevated serum concentrations of homocysteine. Data from several sources suggest a positive correlation between elevated serum homocysteine and occlusive vascular diseases such as ischemic heart disease and stroke. Clinical data suggest that the folate supplementation program has improved the folate status and reduced the prevalence of hyperhomocysteinemia in a population of middle-aged and older adults who did not use vitamin supplements. It is possible, although the evidence thus far has been negative, that the increased ingestion of folic acid will also reduce the risk of vascular disease in this population.

Although the potential benefits of supplemental folic acid during pregnancy are compelling, the decision to require folic acid in grains was controversial. As described in the text, ingestion of folic acid can partially or totally correct the anemia caused by vitamin B<sub>12</sub> deficiency. However, folic acid supplementation does not prevent the potentially irreversible neurologic damage caused by vitamin B<sub>12</sub> deficiency. People with pernicious anemia and other forms of vitamin B<sub>12</sub> deficiency are usually identified because of signs and symptoms of anemia, which typically occur before neurologic symptoms. The opponents of folic acid supplementation were concerned that increased folic acid intake in the general population would mask vitamin B<sub>12</sub> deficiency and increase the prevalence of neurologic disease in the elderly population. To put this in perspective, approximately 4000 pregnancies, including 2500 live births, in the USA each year are affected by neural tube defects. In contrast, it is estimated that over 10% of the elderly population in the USA, or several million people, are at risk for the neuropsychiatric complications of vitamin B<sub>12</sub> deficiency. In acknowledgment of this controversy, the FDA kept its requirements for folic acid supplementation at a somewhat low level. There now is evidence that the current level of folic acid supplementation in the USA has not masked a significant amount of vitamin B<sub>12</sub>-associated anemia, and there is some discussion about increasing the amount of folic acid supplementation of grains in an effort to further reduce the rates of NTDs.

## Chemistry

Folic acid (pteroylglutamic acid) is composed of a heterocycle (pteridine), *p*-aminobenzoic acid, and glutamic acid (Figure 33â€³4). Various numbers of glutamic acid moieties may be attached to the pteroyl portion of the molecule, resulting in monoglutamates, triglutamates, or polyglutamates. Folic acid can undergo reduction, catalyzed by the enzyme dihydrofolate reductase ("folate reductase"), to give dihydrofolic acid (Figure 33â€³3, section 3). Tetrahydrofolate can subsequently be transformed to folate cofactors possessing one-carbon units attached to the 5-nitrogen, to the 10-nitrogen, or to both positions (Figure 33â€³3). The folate cofactors are interconvertible by various enzymatic reactions and serve the important biochemical function of donating one-carbon units at various levels of oxidation. In most of these, tetrahydrofolate is regenerated and becomes available for reutilization.

The structure of folic acid.

(Reproduced, with permission, from Murray RK et al: *Harper's Biochemistry*, 24th ed. McGraw-Hill, 1996.)

## Pharmacokinetics

The average diet in the USA contains 500â€³700 mcg of folates daily, 50â€³200 mcg of which is usually absorbed, depending on metabolic requirements. Pregnant women may absorb as much as 300â€³400 mcg of folic acid daily. Various forms of folic acid are present in a wide variety of plant and animal tissues; the richest sources are yeast, liver, kidney, and green vegetables. Normally, 5â€³20 mg of folates are stored in the liver and other tissues. Folates are excreted in the urine and stool and are also destroyed by catabolism, so serum levels fall within a few days when intake is diminished. Because body stores of folates are relatively low and daily requirements high, folic acid deficiency and megaloblastic anemia can develop within 1â€³6 months after the intake of folic acid stops, depending on the patient's nutritional status and the rate of folate utilization.

Unaltered folic acid is readily and completely absorbed in the proximal jejunum. Dietary folates, however, consist primarily of polyglutamate forms of *N*<sup>5</sup>-methyltetrahydrofolate. Before absorption, all but one of the glutamyl residues of the polyglutamates must be hydrolyzed by the enzyme  $\alpha$ -1-glutamyl transferase ("conjugase") within the brush border of the intestinal mucosa. The monoglutamate *N*<sup>5</sup>-methyltetrahydrofolate is subsequently transported into the bloodstream by both active and passive transport and is then widely distributed throughout the body. Inside cells, *N*<sup>5</sup>-methyltetrahydrofolate is converted to tetrahydrofolate by the demethylation reaction that requires vitamin B<sub>12</sub> (Figure 33â€³3, section 1).

## Pharmacodynamics

Tetrahydrofolate cofactors participate in one-carbon transfer reactions. As described earlier in the discussion of

vitamin B12, one of these essential reactions produces the dTMP needed for DNA synthesis. In this reaction, the enzyme thymidylate synthase catalyzes the transfer of the one-carbon unit of  $N^5,N^{10}$ -methylenetetrahydrofolate to deoxyuridine monophosphate (dUMP) to form dTMP (Figure 33-3, section 2). Unlike all the other enzymatic reactions that use folate cofactors, in this reaction the cofactor is oxidized to dihydrofolate, and for each mole of dTMP produced, 1 mole of tetrahydrofolate is consumed. In rapidly proliferating tissues, considerable amounts of tetrahydrofolate are consumed in this reaction, and continued DNA synthesis requires continued regeneration of tetrahydrofolate by reduction of dihydrofolate, catalyzed by the enzyme dihydrofolate reductase. The tetrahydrofolate thus produced can then reform the cofactor  $N^5,N^{10}$ -methylenetetrahydrofolate by the action of serine transhydroxymethylase and thus allow for the continued synthesis of dTMP. The combined catalytic activities of dTMP synthase, dihydrofolate reductase, and serine transhydroxymethylase are referred to as the *dTMP synthesis cycle*. Enzymes in the dTMP cycle are the targets of two anticancer drugs; methotrexate inhibits dihydrofolate reductase, and a metabolite of 5-fluorouracil inhibits thymidylate synthase (see Chapter 54).

Cofactors of tetrahydrofolate participate in several other essential reactions.  $N^5$ -Methylenetetrahydrofolate is required for the vitamin B12-dependent reaction that generates methionine from homocysteine (Figure 33-2A; Figure 33-3, section 1). In addition, tetrahydrofolate cofactors donate one-carbon units during the de novo synthesis of essential purines. In these reactions, tetrahydrofolate is regenerated and can reenter the tetrahydrofolate cofactor pool.

### Clinical Pharmacology

Folate deficiency results in a megaloblastic anemia that is microscopically indistinguishable from the anemia caused by vitamin B12 deficiency (see above). However, folate deficiency does not cause the characteristic neurologic syndrome seen in vitamin B<sub>12</sub> deficiency. In patients with megaloblastic anemia, folate status is assessed with assays for serum folate or for red blood cell folate. Red blood cell folate levels are often of greater diagnostic value than serum levels, because serum folate levels tend to be labile and do not necessarily reflect tissue levels.

Folic acid deficiency, unlike vitamin B12 deficiency, is often caused by inadequate dietary intake of folates. Patients with alcohol dependence and patients with liver disease can develop folic acid deficiency because of poor diet and diminished hepatic storage of folates. Pregnant women and patients with hemolytic anemia have increased folate requirements and may become folic acid-deficient, especially if their diets are marginal. Evidence implicates maternal folic acid deficiency in the occurrence of fetal neural tube defects, eg, spina bifida. (See Folic Acid Supplementation: A Public Health Dilemma.) Patients with malabsorption syndromes also frequently develop folic acid deficiency. Patients who require renal dialysis develop folic acid deficiency because folates are removed from the plasma during the dialysis procedure.

Folic acid deficiency can be caused by drugs. Methotrexate and, to a lesser extent, trimethoprim and pyrimethamine, inhibit dihydrofolate reductase and may result in a deficiency of folate cofactors and ultimately in megaloblastic anemia. Long-term therapy with phenytoin can also cause folate deficiency, but only rarely causes megaloblastic anemia.

Parenteral administration of folic acid is rarely necessary, since oral folic acid is well absorbed even in patients with malabsorption syndromes. A dose of 1 mg folic acid orally daily is sufficient to reverse megaloblastic anemia, restore normal serum folate levels, and replenish body stores of folates in almost all patients. Therapy should be continued until the underlying cause of the deficiency is removed or corrected. Therapy may be required indefinitely for patients with malabsorption or dietary inadequacy. Folic acid supplementation to prevent folic acid deficiency should be considered in high-risk patients, including pregnant women, patients with alcohol dependence, hemolytic anemia, liver disease, or certain skin diseases, and patients on renal dialysis.

### Sickle Cell Disease and Hydroxyurea

Sickle cell disease is an important genetic cause of hemolytic anemia, a form of anemia due to increased erythrocyte destruction, instead of the reduced mature erythrocyte production seen with iron, folic acid, and vitamin B12 deficiency. Patients with sickle cell disease are homozygous for the aberrant  $\beta$ -hemoglobin S (HbS) allele or heterozygous for HbS and a second mutated  $\beta$ -hemoglobin gene such as hemoglobin C

(HbC) or  $\beta$ -thalassemia. Sickle cell disease has an increased prevalence in individuals of African descent presumably because the heterozygous trait confers resistance to malaria.

In the majority of patients with sickle cell disease, anemia is not the major problem; the anemia is generally well compensated even though such individuals have a chronically low hematocrit (20%–30%), a low serum hemoglobin level (7–10 g/dL), and an elevated reticulocyte count. Instead, the primary problem is that deoxygenated HbS chains form polymeric structures that dramatically change erythrocyte shape, reduce deformability, and elicit membrane permeability changes that further promote hemoglobin polymerization. Abnormal erythrocytes aggregate in the microvasculature where oxygen tension is low and hemoglobin is deoxygenated and cause veno-occlusive damage. The clinical manifestations of sickle cell disease reflect organ damage by veno-occlusive events. In the musculoskeletal system, this results in characteristic, extremely painful bone and joint pain. In the cerebral vascular system, it causes ischemic stroke. Damage to the spleen increases the risk of infection, particularly by encapsulated bacteria such as *Streptococcus pneumoniae*. In the pulmonary system, there is an increased risk of infection and, in adults, an increase in embolism and pulmonary hypertension. In the male genitourinary system, priapism can occur. Supportive treatment includes analgesics, antibiotics, pneumococcal vaccination, and blood transfusions. In addition, the cancer chemotherapeutic drug hydroxyurea (hydroxycarbamide) reduces veno-occlusive events. It is approved in the USA for treatment of adults with recurrent sickle cell crises and approved in Europe in adults and children with recurrent vaso-occlusive events. As an anticancer drug used in the treatment of chronic and acute myelogenous leukemia, hydroxyurea inhibits ribonucleotide reductase and thereby depletes deoxynucleoside triphosphate and arrests cells in the S phase of the cell cycle (see Chapter 54). In the treatment of sickle cell disease, hydroxyurea acts through poorly defined pathways to increase the production of fetal hemoglobin  $\gamma$  (HbF), which interferes with the polymerization of HbS. Clinical trials have shown that hydroxyurea decreases painful crises in adults and children with severe sickle cell disease. Its adverse effects include hematopoietic depression, gastrointestinal effects, and teratogenicity in pregnant women.

## HEMATOPOIETIC GROWTH FACTORS

The hematopoietic growth factors are glycoprotein hormones that regulate the proliferation and differentiation of hematopoietic progenitor cells in the bone marrow. The first growth factors to be identified were called colony-stimulating factors because they could stimulate the growth of colonies of various bone marrow progenitor cells in vitro. Many of these growth factors have been purified and cloned, and their effects on hematopoiesis have been extensively studied. Quantities of these growth factors sufficient for clinical use are produced by recombinant DNA technology.

Of the known hematopoietic growth factors, **erythropoietin (epoetin alfa and epoetin beta)**, **granulocyte colony-stimulating factor (G-CSF)**, **granulocyte-macrophage colony-stimulating factor (GM-CSF)**, and **interleukin-11 (IL-11)** are currently in clinical use. **Romiplostim (AMG-531)** is a novel biologic agent that activates the thrombopoietin receptor.

The hematopoietic growth factors and drugs that mimic their action have complex effects on the function of a wide variety of cell types, including nonhematologic cells. Their usefulness in other areas of medicine, particularly as potential anticancer and anti-inflammatory drugs, is being investigated.

## ERYTHROPOIETIN

### Chemistry & Pharmacokinetics

Erythropoietin, a 34–39 kDa glycoprotein, was the first human hematopoietic growth factor to be isolated. It was originally purified from the urine of patients with severe anemia. Recombinant human erythropoietin (rHuEPO, epoetin alfa) is produced in a mammalian cell expression system. After intravenous administration, erythropoietin has a serum half-life of 4–13 hours in patients with chronic renal failure. It is not cleared by dialysis. It is measured in international units (IU). Darbepoetin alfa is a modified form of erythropoietin that is more heavily glycosylated as a result of changes in amino acids. Darbepoetin alfa has a twofold to threefold longer half-life than epoetin alfa. Methoxy polyethylene glycol epoetin beta is an isoform of erythropoietin covalently attached to a long

polyethylene glycol polymer. This long-lived recombinant product is administered as a single intravenous or subcutaneous dose at 2-week or monthly intervals whereas epoetin alfa is generally administered three times a week and darbepoetin is administered weekly.

### Pharmacodynamics

Erythropoietin stimulates erythroid proliferation and differentiation by interacting with erythropoietin receptors on red cell progenitors. The erythropoietin receptor is a member of the JAK/STAT superfamily of cytokine receptors that use protein phosphorylation and transcription factor activation to regulate cellular function (see Chapter 2). Erythropoietin also induces release of reticulocytes from the bone marrow. Endogenous erythropoietin is primarily produced in the kidney. In response to tissue hypoxia, more erythropoietin is produced through an increased rate of transcription of the erythropoietin gene. This results in correction of the anemia, provided that the bone marrow response is not impaired by red cell nutritional deficiency (especially iron deficiency), primary bone marrow disorders (see below), or bone marrow suppression from drugs or chronic diseases.

Normally, an inverse relationship exists between the hematocrit or hemoglobin level and the serum erythropoietin level. Nonanemic individuals have serum erythropoietin levels of less than 20 IU/L. As the hematocrit and hemoglobin levels fall and anemia becomes more severe, the serum erythropoietin level rises exponentially. Patients with moderately severe anemia usually have erythropoietin levels in the 100–500 IU/L range, and patients with severe anemia may have levels of thousands of IU/L. The most important exception to this inverse relationship is in the anemia of chronic renal failure. In patients with renal disease, erythropoietin levels are usually low because the kidneys cannot produce the growth factor. These are the patients most likely to respond to treatment with exogenous erythropoietin. In most primary bone marrow disorders (aplastic anemia, leukemias, myeloproliferative and myelodysplastic disorders, etc) and most nutritional and secondary anemias, endogenous erythropoietin levels are high, so there is less likelihood of a response to exogenous erythropoietin (but see below).

### Clinical Pharmacology

The availability of erythropoiesis-stimulating agents (ESAs) has had a significant positive impact for patients with several different types of anemia (Table 33–4). The ESAs consistently improve the hematocrit and hemoglobin level, often eliminate the need for transfusions, and reliably improve quality of life indices. The ESAs are used routinely in patients with anemia secondary to chronic kidney disease. In patients treated with an ESA, an increase in reticulocyte count is usually observed in about 10 days and an increase in hematocrit and hemoglobin levels in 2–6 weeks. Dosages of ESAs are adjusted to maintain a target hemoglobin up to, but not exceeding, 10–12 g/dL. To support the increased erythropoiesis, nearly all patients with chronic kidney disease will require oral or parenteral iron supplementation. Folate supplementation may also be necessary in some patients.

**Table 33–4 Clinical Uses of Hematopoietic Growth Factors and Agents That Mimic Their Actions.**

Hematopoietic Growth Factor	Clinical Condition Being Treated or Prevented	Recipients
Erythropoietin, darbepoetin alfa	Anemia	Patients with chronic renal failure HIV-infected patients treated with zidovudine Cancer patients treated with myelosuppressive cancer chemotherapy Patients scheduled to undergo elective, noncardiac, nonvascular surgery
Granulocyte colony-stimulating factor (G-CSF; filgrastim)	Neutropenia	Cancer patients treated with myelosuppressive cancer chemotherapy
Granulocyte-macrophage colony-stimulating factor (GM-CSF; sargramostim)	Stem cell transplantation	Patients with severe chronic neutropenia Patients with nonmyeloid malignancies treated with stem cell transplantation

	Mobilization of peripheral blood progenitor cells (PBPCs)	treated with stem cell transplantation Mobilization of peripheral blood progenitor cells (PBPCs) Patients with nonmyeloid malignancies Donors of stem cells for allogeneic or autologous transplantation
Interleukin-11 (IL-11, oprelvekin)	Thrombocytopenia	Patients with nonmyeloid malignancies who receive myelosuppressive cancer chemotherapy
Romiplostim	Thrombocytopenia	Patients with idiopathic thrombocytopenic purpura

In selected patients, erythropoietin is also useful for the treatment of anemia due to **primary bone marrow disorders** and **secondary anemias**. This includes patients with aplastic anemia and other bone marrow failure states, myeloproliferative and myelodysplastic disorders, multiple myeloma and perhaps other chronic bone marrow malignancies, and the anemias associated with chronic inflammation, AIDS, and myelosuppressive cancer chemotherapy. Patients with these disorders who have disproportionately low serum erythropoietin levels for their degree of anemia are most likely to respond to treatment with this growth factor. Patients with endogenous erythropoietin levels of less than 100 IU/L have the best chance of response, although patients with erythropoietin levels between 100 and 500 IU/L respond occasionally. These patients generally require higher erythropoietin doses to achieve a response, and responses are often incomplete. Methoxy polyethylene glycol epoetin beta should not be used for treatment of anemia caused by cancer chemotherapy because a clinical trial found significantly more deaths among patients receiving this form of erythropoietin.

Erythropoietin has been used successfully to offset the anemia produced by zidovudine treatment in patients with HIV infection and in the treatment of the anemia of prematurity. It can also be used to reduce the need for transfusion in high-risk patients undergoing elective, noncardiac, nonvascular surgery; to accelerate erythropoiesis after phlebotomies for autologous transfusion for elective surgery; or for treatment of iron overload (hemochromatosis).

Erythropoietin is one of the drugs banned by the International Olympic Committee. The use of erythropoietin by athletes is based on their hope that increased red blood cell concentration will increase oxygen delivery to muscles and improve performance.

### Toxicity

The most common adverse effects of erythropoietin are hypertension and thrombotic complications. In March 2007, the FDA issued a warning that patients with chronic renal failure or cancer whose serum hemoglobin is raised to more than 12 g/dL with an ESA face a greater risk of a thrombotic event or, in patients with advanced head and neck cancers, faster tumor growth. The warning was primarily based on clinical trial data from patients with chronic kidney disease indicating an increased rate of mortality and cardiovascular events (stroke, myocardial infarction, worsening congestive heart failure, and hypertension) in patients dosed with an ESA to a target hemoglobin level of 12–16 g/dL or dosed to maintain a normal hematocrit (42%) versus a lower target hematocrit of 30%. In addition, a meta-analysis of 51 placebo-controlled trials of ESAs in cancer patients reported an increased rate of all-cause mortality and venous thrombosis in those receiving an ESA. Based on the accumulated evidence, it is recommended that the hemoglobin level not exceed 12 g/dL in patients with chronic kidney disease receiving an ESA, and that ESAs be used conservatively in cancer patients (eg, when hemoglobin levels are < 10 g/dL) and with the lowest dose needed to avoid transfusion.

Allergic reactions to ESAs have been infrequent. There have been a small number of cases of pure red cell aplasia (PRCA) accompanied by neutralizing antibodies to erythropoietin. PRCA was most commonly seen in dialysis patients treated subcutaneously for a long period with a particular form of epoetin alfa (Eprex with a polysorbate 80 stabilizer rather than human serum albumin) that is not available in the USA. After regulatory agencies required that Eprex be administered intravenously rather than subcutaneously, the rate of ESA-associated PRCA diminished.

However, rare cases have still been seen with all ESAs administered subcutaneously for long periods to patients with chronic kidney disease.

## MYELOID GROWTH FACTORS

### Chemistry & Pharmacokinetics

**G-CSF** and **GM-CSF**, the two myeloid growth factors currently available for clinical use, were originally purified from cultured human cell lines (Table 33â€4). Recombinant human G-CSF (**rHuG-CSF; filgrastim**) is produced in a bacterial expression system. It is a nonglycosylated peptide of 175 amino acids, with a molecular weight of 18 kDa. Recombinant human GM-CSF (**rHuGM-CSF; sargramostim**) is produced in a yeast expression system. It is a partially glycosylated peptide of 127 amino acids, with three molecular species with molecular weights of 15,500; 15,800; and 19,500. These preparations have serum half-lives of 2â€7 hours after intravenous or subcutaneous administration. **Pegfilgrastim**, a covalent conjugation product of filgrastim and a form of polyethylene glycol, has a much longer serum half-life than recombinant G-CSF, and it can be injected once per myelosuppressive chemotherapy cycle instead of daily for several days.

### Pharmacodynamics

The myeloid growth factors stimulate proliferation and differentiation by interacting with specific receptors found on various myeloid progenitor cells. Like the erythropoietin receptor, these receptors are members of the JAK/STAT superfamily (see Chapter 2). G-CSF stimulates proliferation and differentiation of progenitors already committed to the neutrophil lineage. It also activates the phagocytic activity of mature neutrophils and prolongs their survival in the circulation. G-CSF also has a remarkable ability to mobilize hematopoietic stem cells, ie, to increase their concentration in peripheral blood. This biologic effect underlies a major advance in transplantationâ€the use of **peripheral blood stem cells (PBSCs)** rather than bone marrow stem cells for autologous and allogeneic hematopoietic stem cell transplantation (see below).

GM-CSF has broader biologic actions than G-CSF. It is a multipotential hematopoietic growth factor that stimulates proliferation and differentiation of early and late granulocytic progenitor cells as well as erythroid and megakaryocyte progenitors. Like G-CSF, GM-CSF also stimulates the function of mature neutrophils. GM-CSF acts together with interleukin-2 to stimulate T-cell proliferation and appears to be a locally active factor at the site of inflammation. GM-CSF mobilizes peripheral blood stem cells, but it is significantly less efficacious than G-CSF in this regard.

### Clinical Pharmacology

#### CANCER CHEMOTHERAPY-INDUCED NEUTROPENIA

Neutropenia is a common adverse effect of the cytotoxic drugs used to treat cancer and increases the risk of serious infection in patients receiving chemotherapy. Unlike the treatment of anemia and thrombocytopenia, transfusion of neutropenic patients with granulocytes collected from donors is performed rarely and with limited success. The introduction of G-CSF in 1991 represented a milestone in the treatment of chemotherapy-induced neutropenia. This growth factor dramatically accelerates the rate of neutrophil recovery after dose-intensive myelosuppressive chemotherapy (Figure 33â€5). It reduces the duration of neutropenia and usually raises the nadir count, the lowest neutrophil count seen following a cycle of chemotherapy.

#### Figure 33â€5

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 11th Edition: <http://www.accessmedicine.com>

Effects of granulocyte colony-stimulating factor (G-CSF; red line) or placebo (green line) on absolute neutrophil count (ANC) after cytotoxic chemotherapy for lung cancer. Doses of chemotherapeutic drugs were administered on days 1 and 3. G-CSF or placebo injections were started on day 4 and continued daily through day 12 or 16. The first peak in ANC reflects the recruitment of mature cells by G-CSF. The second peak reflects a marked increase in new neutrophil production by the bone marrow under stimulation by G-CSF. (Normal ANC is  $2.2 \times 10^9/L$ .)

(Modified and reproduced, with permission, from Crawford et al: Reduction by granulocyte colony-stimulating factor of fever and neutropenia induced by chemotherapy in patients with small-cell lung cancer. *N Engl J Med* 1991;325:164.)

The ability of G-CSF to increase neutrophil counts after myelosuppressive chemotherapy is nearly universal, but its impact on clinical outcomes is more variable. Many, but not all, clinical trials and meta-analyses have shown that G-CSF reduces episodes of febrile neutropenia, requirements for broad-spectrum antibiotics, infections, and days of hospitalization. Clinical trials have not shown improved survival in cancer patients treated with G-CSF. Clinical guidelines for the use of G-CSF after cytotoxic chemotherapy recommend reserving G-CSF for patients at high risk for febrile neutropenia based on age, medical history, and disease characteristics; patients receiving dose-intensive chemotherapy regimens that carry a greater than 40% risk of causing febrile neutropenia; patients with a prior episode of febrile neutropenia after cytotoxic chemotherapy; patients at high risk for febrile neutropenia; and patients who are unlikely to survive an episode of febrile neutropenia. Pegfilgrastim is an alternative to G-CSF for prevention of chemotherapy-induced febrile neutropenia. Pegfilgrastim can be administered less frequently, and it may shorten the period of severe neutropenia slightly more than G-CSF.

Like G-CSF and pegfilgrastim, GM-CSF also reduces the duration of neutropenia after cytotoxic chemotherapy. It has been more difficult to show that GM-CSF reduces the incidence of febrile neutropenia, probably because GM-CSF itself can induce fever. In the treatment of chemotherapy-induced neutropenia, G-CSF, 5 mcg/kg/d, or GM-CSF, 250 mcg/m<sup>2</sup>/d, is usually started within 24–72 hours after completing chemotherapy and is continued until the absolute neutrophil count is greater than 10,000 cells/ $\mu$ L. Pegfilgrastim is given as a single dose instead of daily injections.

The utility and safety of the myeloid growth factors in the postchemotherapy supportive care of patients with acute myeloid leukemia (AML) have been the subject of a number of clinical trials. Because leukemic cells arise from progenitors whose proliferation and differentiation are normally regulated by hematopoietic growth factors, including GM-CSF and G-CSF, there was concern that myeloid growth factors could stimulate leukemic cell growth and increase the rate of relapse. The results of randomized clinical trials suggest that both G-CSF and GM-CSF are safe following induction and consolidation treatment of myeloid and lymphoblastic leukemia. There has been no evidence that these growth factors reduce the rate of remission or increase relapse rate. On the contrary, the growth factors accelerate neutrophil recovery and reduce infection rates and days of hospitalization. Both G-CSF and GM-CSF have FDA approval for treatment of patients with AML.

#### OTHER APPLICATIONS

G-CSF and GM-CSF have also proved to be effective in treating the neutropenia associated with **congenital neutropenia, cyclic neutropenia, myelodysplasia, and aplastic anemia**. Many patients with these disorders respond with a prompt and sometimes dramatic increase in neutrophil count. In some cases, this results in a

decrease in the frequency of infections. Because neither G-CSF nor GM-CSF stimulates the formation of erythrocytes and platelets, they are sometimes combined with other growth factors for treatment of pancytopenia.

The myeloid growth factors play an important role in **autologous stem cell transplantation** for patients undergoing high-dose chemotherapy. High-dose chemotherapy with autologous stem cell support is increasingly used to treat patients with tumors that are resistant to standard doses of chemotherapeutic drugs. The high-dose regimens produce extreme myelosuppression; the myelosuppression is then counteracted by reinfusion of the patient's own hematopoietic stem cells (which are collected prior to chemotherapy). The administration of G-CSF or GM-CSF early after autologous stem cell transplantation has been shown to reduce the time to engraftment and to recovery from neutropenia in patients receiving stem cells obtained either from bone marrow or from peripheral blood. These effects are seen in patients being treated for lymphoma or for solid tumors. G-CSF and GM-CSF are also used to support patients who have received allogeneic bone marrow transplantation for treatment of hematologic malignancies or bone marrow failure states. In this setting, the growth factors speed the recovery from neutropenia without increasing the incidence of acute graft-versus-host disease.

Perhaps the most important role of the myeloid growth factors in transplantation is for mobilization of PBSCs. Stem cells collected from peripheral blood have nearly replaced bone marrow as the hematopoietic preparation used for autologous transplantation, and the use of PBSCs for allogeneic transplantation is also being investigated. The cells can be collected in an outpatient setting with a procedure that avoids much of the risk and discomfort of bone marrow collection, including the need for general anesthesia. In addition, there is evidence that PBSC transplantation results in more rapid engraftment of all hematopoietic cell lineages and in reduced rates of graft failure or delayed platelet recovery.

G-CSF is the cytokine most commonly used for PBSC mobilization because of its increased efficacy and reduced toxicity compared with GM-CSF. To mobilize stem cells, patients or donors are given  $5 \times 10^{10}$  mcg/kg/d subcutaneously for 4 days. On the fifth day, they undergo leukapheresis. The success of PBSC transplantation depends on transfusion of adequate numbers of stem cells. CD34, an antigen present on early progenitor cells and absent from later, committed, cells, is used as a marker for the requisite stem cells. The goal is to reinfuse at least  $5 \times 10^6$  CD34 cells/kg; this number of CD34 cells usually results in prompt and durable engraftment of all cell lineages. It can take several separate leukaphereses to collect enough CD34 cells, especially from older patients and patients who have been exposed to radiation therapy or chemotherapy.

### **Toxicity**

Although the three growth factors have similar effects on neutrophil counts, G-CSF and pegfilgrastim are used more frequently than GM-CSF because they are better tolerated. G-CSF and pegfilgrastim can cause bone pain, which clears when the drugs are discontinued. GM-CSF can cause more severe side effects, particularly at higher doses. These include fever, malaise, arthralgias, myalgias, and a capillary leak syndrome characterized by peripheral edema and pleural or pericardial effusions. Allergic reactions may occur but are infrequent. Splenic rupture is a rare but serious complication of the use of G-CSF for PBSC.

### **MEGAKARYOCYTE GROWTH FACTORS**

Patients with thrombocytopenia have a high risk of hemorrhage. Although platelet transfusion is commonly used to treat thrombocytopenia, this procedure can cause adverse reactions in the recipient; furthermore, a significant number of patients fail to exhibit the expected increase in platelet count. **Thrombopoietin** and **IL-11** both appear to be key endogenous regulators of platelet production. A recombinant form of IL-11 was the first agent to gain FDA approval for treatment of thrombocytopenia. Recombinant human thrombopoietin and a pegylated form of a shortened human thrombopoietin protein underwent extensive clinical investigation in the 1990s. However, further development was abandoned after autoantibodies to the native thrombopoietin formed in healthy human subjects and caused thrombocytopenia. Efforts shifted to investigation of novel, nonimmunogenic peptide agonists of the thrombopoietin receptor, which is known as Mpl. The first of these—**romiplostim**—was approved by the FDA for idiopathic thrombocytopenic purpura in 2008.

### **Chemistry & Pharmacokinetics**

**Interleukin-11** is a 65–85 kDa protein produced by fibroblasts and stromal cells in the bone marrow.

**Oprelvekin**, the recombinant form of IL-11 approved for clinical use (Table 33â€4), is produced by expression in *Escherichia coli*. The half-life of IL-11 is 7â€8 hours when the drug is injected subcutaneously.

**Romiplostim** (AMG 531) is a member of new class of therapeutics called "peptibodies," which are peptides with key biologic activities covalently linked to antibody fragments that serve to extend the peptide's half-life. Romiplostim contains two disulfide-bonded human F<sub>c</sub> fragments, each covalently attached through a polyglycine sequence to a peptide chain containing two Mpl-binding peptides that are linked to one another by a second polyglycine sequence. The Mpl-binding peptide was selected from a peptide library based on its ability in cell assays to activate the thrombopoietin receptor. The Mpl-binding peptide has no sequence homology with human thrombopoietin and there is no evidence in animal or human studies that the Mpl-binding peptide or romiplostim induces antibodies to thrombopoietin. After subcutaneous administration, romiplostim is eliminated by the reticuloendothelial system with an average half-life of 3â€4 days. Its half-life is inversely related to the serum platelet count; it has a longer half-life in patients with thrombocytopenia and a shorter half-life in patients whose platelet counts have recovered to normal levels.

**Eltrombopag** is a new orally active small molecule agonist at the thrombopoietin receptor licensed for use in idiopathic thrombocytopenia. Because of toxicity concerns, eltrombopag is restricted to use by registered physicians and patients.

### Pharmacodynamics

Interleukin-11 acts through a specific cell surface cytokine receptor to stimulate the growth of multiple lymphoid and myeloid cells. It acts synergistically with other growth factors to stimulate the growth of primitive megakaryocytic progenitors and, most importantly, increases the number of peripheral platelets and neutrophils.

Romiplostim has high affinity for the human Mpl receptor. It causes a dose-dependent increase in platelet count that begins on day 5 after subcutaneous administration and peaks at days 12â€15.

### Clinical Pharmacology

Interleukin-11 is approved for the secondary prevention of thrombocytopenia in patients receiving cytotoxic chemotherapy for treatment of nonmyeloid cancers. Clinical trials show that it reduces the number of platelet transfusions required by patients who experience severe thrombocytopenia after a previous cycle of chemotherapy. Although IL-11 has broad stimulatory effects on hematopoietic cell lineages in vitro, it does not appear to have significant effects on the leukopenia caused by myelosuppressive chemotherapy. Interleukin-11 is given by subcutaneous injection at a dose of 50 mcg/kg/d. It is started 6â€24 hours after completion of chemotherapy and continued for 14â€21 days or until the platelet count passes the nadir and rises to more than 50,000 cells/ $\mu$ L.

In patients with chronic idiopathic thrombocytopenia (ITP) who failed to respond adequately to previous treatment with steroids, immunoglobulins, or splenectomy, romiplostim significantly increased platelet count in most patients. In a 6-week placebo-controlled study in which patients were treated weekly with 1 or 3 mcg/kg, 12 of 16 patients reached the targeted platelet range of 50,000â€450,000 platelets/mL. Romiplostim does not appear to decrease the rate of platelet destruction in ITP as platelet counts returned to pretreatment levels after the drug's discontinuation. An open label trial found that many patients maintained a platelet count of 100,000 platelets/mL or higher over a 48-week period and that over half of the patients were able to discontinue other therapies. Romiplostim is initiated as a weekly subcutaneous dose of 1 mcg/kg and then continued at the lowest dose required to maintain a platelet count of at least 50,000 platelets/mL.

### Toxicity

The most common adverse effects of IL-11 are fatigue, headache, dizziness, and cardiovascular effects. The cardiovascular effects include anemia (due to hemodilution), dyspnea (due to fluid accumulation in the lungs), and transient atrial arrhythmias. Hypokalemia has also been seen in some patients. All of these adverse effects appear to be reversible.

Romiplostim appears to be well tolerated except for a mild headache on the day of administration. A potential long-term concern is that two patients treated with romiplostim had an increase in bone marrow reticulin, a possible marker of myelodysplastic or myeloproliferative processes. However, neither patient had evidence of increased

collagenfibrosis or of abnormal bone marrow cytogenetics.

## SUMMARY: AGENTS USED IN ANEMIAS AND HEMATOPOIETIC GROWTH FACTORS

### Agents Used in Anemias and Hematopoietic Growth Factors

Subclass	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>Iron</b>				
Ferrous sulfate	Required for the biosynthesis of heme and heme-containing proteins, including hemoglobin and myoglobin	Adequate supplies are required for normal heme synthesis • deficiency results in inadequate heme production	Treatment of iron deficiency, which manifests as microcytic anemia	Complicated endogenous system for absorbing, storing, and transporting iron • no mechanism for iron excretion other than cell and blood loss • <i>Toxicity:</i> Acute overdose results in necrotizing gastroenteritis, abdominal pain, bloody diarrhea, shock, lethargy, and dyspnea • chronic iron overload results in hemochromatosis, with damage to the heart, liver, pancreas, and other organs • organ failure and death can ensue
<i>Ferrous gluconate and ferrous fumarate: Oral iron preparations</i>				
<i>Iron dextran, iron sucrose complex, and sodium ferric gluconate complex: Parenteral preparations; can cause hypersensitivity reactions</i>				
<b>Iron chelators</b>				
Deferoxamine (see also Chapters 58 and 59)	Chelates excess iron	Reduces the toxicity associated with acute or chronic iron overload	Treatment of acute iron poisoning and for inherited or acquired hemochromatosis that is not adequately treated by phlebotomy	Preferred route of administration is IM or SC • <i>Toxicity:</i> Rapid IV administration may cause hypotension • acute respiratory distress has been observed with long infusions • neurotoxicity and increased susceptibility to certain infections has occurred with long-term use
<i>Deferasirox: Orally administered iron chelator for treatment of hemochromatosis that is not adequately treated by phlebotomy</i>				
<b>Vitamin B12</b>				
Cyanocobalamin Hydroxocobalamin	A cofactor required for essential enzymatic reactions that form tetrahydrofolate, convert homocysteine to methionine, and	Adequate supplies are required for amino acid metabolism, and DNA synthesis	Treatment of vitamin B12 deficiency, which manifests as megaloblastic anemia and is the basis of pernicious anemia	Parenteral vitamin B12 is required for pernicious anemia and other malabsorption syndromes • <i>Toxicity:</i> No toxicity associated with excess vitamin B12

metabolize L-methylmalonyl-CoA

### Folic acid

Folacin (pteroylglutamic acid)	A precursor of an essential donor of methyl groups used for synthesis of amino acids, purines, and deoxynucleotide	Adequate supplies are required for essential biochemical reactions involving amino acid metabolism, and purine and DNA synthesis	Treatment of folic acid deficiency, which manifests as megaloblastic anemia, and prevention of congenital neural tube defects	Oral; well-absorbed; need for parenteral administration is rare • <i>Toxicity:</i> While folic acid is not toxic in overdose, large amounts can partially compensate for vitamin B <sub>12</sub> deficiency and put people with unrecognized B <sub>12</sub> deficiency at risk of neurologic consequences of vitamin B <sub>12</sub> deficiency that are not compensated by folic acid
--------------------------------	--	--	---	---

### Erythrocyte-stimulating agents

Epoetin alfa	Agonist of erythropoietin receptors expressed by red cell progenitors	Stimulates erythroid proliferation and differentiation, and induces the release of reticulocytes from the bone marrow	Treatment of anemia, especially anemia associated with chronic renal failure, HIV infection, cancer, and prematurity • prevention of the need for transfusion in patients undergoing certain types of elective surgery	IV or SC administration 1â€³3 times per week • <i>Toxicity:</i> Hypertension, thrombotic complications, and, very rarely, pure red cell aplasia • to reduce the risk of serious CV events, hemoglobin levels should be maintained < 12 g/dL
--------------	---	---	--	---

*Darbepoetin alfa: Long-acting glycosylated form administered weekly*

*Methoxy polyethylene glycol-epoetin beta: Long-acting form administered 1â€³2 times per month*

### Myeloid growth factors

Granulocyte-macrophage colony-stimulating factor (G-CSF; filgrastim)	Stimulates G-CSF receptors expressed on mature neutrophils and their progenitors	Stimulates the proliferation and differentiation of neutrophil progenitors • activates the phagocytic activity of mature neutrophils and extends their survival • mobilizes hematopoietic stem cells	Neutropenia associated with congenital neutropenia, cyclic neutropenia, myelodysplasia, and aplastic anemia • secondary prevention of neutropenia in patients undergoing cytotoxic chemotherapy • mobilization of peripheral blood cells in preparation for autologous and allogenic stem cell transplantation	Daily subcutaneous administration • <i>Toxicity:</i> Bone pain • rarely, splenic rupture
--	--	--	--	--

*Pegfilgrastim: Long-acting form of filgrastim that is covalently linked to a type of polyethylene glycol*

*GM-CSF (sargramostim): Myeloid growth factor that acts through a distinct GM-CSF receptor to stimulate proliferation and differentiation of early and late granulocytic progenitor cells, and erythroid and megakaryocyte progenitors; clinical uses are similar to those of G-CSF but it is more likely than G-CSF to cause fever, arthralgia,*

myalgia, and capillary leak syndrome

### Megakaryocyte growth factors

Oprelvekin (interleukin-11; IL-11)	Recombinant form of an endogenous cytokine • activates IL-11 receptors	Stimulates the growth of multiple lymphoid and myeloid cells, including megakaryocyte progenitors • increases the number of circulating platelets and neutrophils	Secondary prevention of thrombocytopenia in patients undergoing cytotoxic chemotherapy for nonmyeloid cancers	Administered daily by SC injection • <i>Toxicity</i> : Fatigue, headache, dizziness, anemia, fluid accumulation in the lungs, and transient atrial arrhythmias
------------------------------------	--	---	---	---

*Romiplostim*: Genetically engineered protein in which the  $F_c$  component of a human antibody is fused to two copies of a peptide that stimulates the thrombopoietin receptors; approved for treatment of idiopathic thrombocytopenic purpura

## PREPARATIONS AVAILABLE

### **Darbepoetin alfa** (Aranesp)

Parenteral: 25, 40, 60, 100, 200, 300, 500 mcg/mL for IV or SC injection

### **Deferasirox** (Exjade)

Oral: 125, 250, 500 mg tablets

### **Deferoxamine** (generic, Desferal)

Parenteral: 500, 2000 mg vials for IM, SC, or IV injection

### **Epoetin alfa (erythropoietin, EPO)** (Epogen, Procrit)

Parenteral: 2000, 3000, 4000, 10000, 20000, 40000 IU/mL vials for IV or SC injection

### **Epoetin beta (Methoxy polyethylene glycol-epoetin beta)** (Mircera)

Parenteral: 50, 100, 200, 300, 400, 600, 1000 mcg/mL in single-dose vials and prefilled syringes for IV or SC injection

### **Filgrastim (G-CSF)** (Neupogen)

Parenteral: 300 mcg vials and prefilled syringes for IV or SC injection

### **Folic acid** (folacin, pteroylglutamic acid) (generic)

Oral: 0.4, 0.8, 1 mg tablets

Parenteral: 5 mg/mL for injection

### **Iron** (generic)

Oral: See Table 33-3.

Parenteral (Iron dextran) (InFeD, DexFerrum): 50 mg elemental iron/mL

Parenteral (Sodium ferric gluconate complex) (Ferrlecit): 12.5 mg elemental iron/mL

Parenteral (Iron sucrose) (Venofer): 20 mg elemental iron/mL

**Oprelvekin (IL-11)** (Neumega)

Parenteral: 5 mg single-dose vials for SC injection

**Pegfilgrastim** (Neulasta)

Parenteral: 10 mg/mL solution in single-dose syringe

**Romiplostim** (Nplate)

Parenteral: 250, 500 mcg in single-dose vials for SC injection

**Sargramostim (GM-CSF)** (Leukine)

Parenteral: 250, 500 mcg vials for IV infusion

**Vitamin B12** (generic cyanocobalamin or hydroxocobalamin)

Oral (cyanocobalamin): 100, 500, 1000, 5000 mcg tablets, 50, 100, 250, 500 mcg lozenges

Nasal (Nascobal, CaloMist): 2500, 5000 mcg/mL (250, 500 mcg/spray)

Parenteral (cyanocobalamin): 100, 1000 mcg/mL for IM or SC injection

Parenteral (hydroxocobalamin): 1000 mcg/mL for IM injection only

Basic and Clinical Pharmacology > Chapter 34. Drugs Used in Disorders of Coagulation >

## CASE STUDY

A 25-year-old woman presents to the emergency department complaining of acute onset of shortness of breath and pleuritic pain. She had been in her usual state of health until 2 days prior when she noted that her left leg was swollen and red. Her only medication was oral contraceptives. Family history was significant for a history of "blood clots" in multiple members of the maternal side of her family. Physical examination demonstrates an anxious woman with stable vital signs. The left lower extremity demonstrates erythema and edema and is tender to touch. Ultrasound reveals a deep vein thrombosis in the left lower extremity; chest computed tomography scan confirms the presence of pulmonary emboli. What are the likely risk factors in this woman—hereditary, acquired, or both? What therapy is indicated acutely? What are the long-term therapy options? How long should she be treated? Should this individual use oral contraceptives?

## DRUGS USED IN DISORDERS OF COAGULATION: INTRODUCTION

Hemostasis refers to the finely regulated dynamic process of maintaining fluidity of the blood, repairing vascular injury, and limiting blood loss while avoiding vessel occlusion (thrombosis) and inadequate perfusion of vital organs. Either extreme—excessive bleeding or thrombosis—represents a breakdown of the hemostatic mechanism. Common causes of dysregulated hemostasis include hereditary or acquired defects in the clotting mechanism and secondary effects of infection or cancer. The drugs used to limit abnormal bleeding and to inhibit thrombosis are the subjects of this chapter.

## MECHANISMS OF BLOOD COAGULATION

The vascular endothelial cell layer lining blood vessels has an anticoagulant phenotype, and circulating blood platelets and clotting factors do not normally adhere to it to an appreciable extent. In the setting of vascular injury, the endothelial cell layer rapidly undergoes a series of changes resulting in a more procoagulant phenotype. Injury exposes reactive subendothelial matrix proteins such as collagen and von Willebrand factor, which results in platelet adherence and activation, and secretion and synthesis of vasoconstrictors and platelet-recruiting and activating molecules. Thus, **thromboxane A<sub>2</sub> (TXA<sub>2</sub>)** is synthesized from arachidonic acid within platelets and is a platelet activator and potent vasoconstrictor. Products secreted from platelet granules include **adenosine diphosphate (ADP)**, a powerful inducer of platelet aggregation, and **serotonin (5-HT)**, which stimulates aggregation and vasoconstriction. Activation of platelets results in a conformational change in the  $\alpha_{IIb}\beta_{III}$  integrin (IIb/IIIa) receptor, enabling it to bind fibrinogen, which cross-links adjacent platelets, resulting in aggregation and formation of a platelet plug (Figure 34-1). Simultaneously, the coagulation system cascade is activated, resulting in thrombin generation and a fibrin clot, which stabilizes the platelet plug (see below). Knowledge of the hemostatic mechanism is important for diagnosis of bleeding disorders. Patients with defects in the formation of the primary platelet plug (defects in primary hemostasis, eg, platelet function defects, von Willebrand disease) typically bleed from surface sites (gingiva, skin, heavy menses) with injury. In contrast, patients with defects in the clotting mechanism (secondary hemostasis, eg, hemophilia A) tend to bleed into deep tissues (joints, muscle, retroperitoneum), often with no apparent inciting event, and bleeding may recur unpredictably.

Thrombus formation at the site of the damaged vascular wall (EC, endothelial cell) and the role of platelets and clotting factors. Platelet membrane receptors include the glycoprotein (GP) Ia receptor, binding to collagen (C); GP Ib receptor, binding von Willebrand factor (vWF); and GP IIb/IIIa, which binds fibrinogen and other macromolecules. Antiplatelet prostacyclin (PGI<sub>2</sub>) is released from the endothelium. Aggregating substances released from the degranulating platelet include adenosine diphosphate (ADP), thromboxane A<sub>2</sub> (TXA<sub>2</sub>), and serotonin (5-HT). Production of factor Xa is detailed in Figure 34â€2.

(Redrawn and reproduced, with permission, from Simoons ML, Decker JW: New directions in anticoagulant and antiplatelet treatment. [Editorial.] *Br Heart J* 1995;74:337.)

The platelet is central to normal hemostasis and thromboembolic disease, and is the target of many therapies discussed in this chapter. Platelet-rich thrombi (**white thrombi**) form in the high flow rate and high shear force environment of arteries. Occlusive arterial thrombi cause serious disease by producing downstream ischemia of extremities or vital organs, and can result in limb amputation or organ failure. Venous clots tend to be more fibrin-rich, contain large numbers of trapped red blood cells, and are recognized pathologically as **red thrombi**. Venous thrombi can cause severe swelling and pain of the affected extremity, but the most feared consequence is pulmonary embolism. This occurs when part or all of the clot breaks off from its location in the deep venous system and travels as an embolus through the right side of the heart and into the pulmonary arterial circulation. Sudden occlusion of a large pulmonary artery can cause acute right heart failure and sudden death. In addition lung ischemia or infarction will occur distal to the occluded pulmonary arterial segment. Such emboli usually arise from the deep venous system of the proximal lower extremities or pelvis. Although all thrombi are mixed, the platelet nidus dominates the arterial thrombus and the fibrin tail dominates the venous thrombus.

## BLOOD COAGULATION CASCADE

Blood coagulates due to the transformation of soluble fibrinogen into insoluble fibrin by the enzyme thrombin. Several circulating proteins interact in a cascading series of limited proteolytic reactions (Figure 34â€2). At each step, a clotting factor zymogen undergoes limited proteolysis and becomes an active protease (eg, factor VII is converted to factor VIIa). Each protease factor activates the next clotting factor in the sequence, culminating in the formation of thrombin (factor IIa). Several of these factors are targets for drug therapy (Table 34â€1).

### Figure 34â€2

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 11th Edition: <http://www.accessmedicine.com>

A model of blood coagulation. With tissue factor (TF), factor VII forms an activated complex (VIIa-TF) that catalyzes the activation of factor IX to factor IXa. Activated factor XIa also catalyzes this reaction. Tissue factor pathway inhibitor (TFPI) inhibits the catalytic action of the VIIa-TF complex. The cascade proceeds as shown, resulting ultimately in the conversion of fibrinogen to fibrin, an essential component of a functional clot. The two major anticoagulant drugs, heparin and warfarin, have very different actions. Heparin, acting in the blood, directly activates anticlotting factors, specifically antithrombin, which inactivates the factors enclosed in rectangles. Warfarin, acting in the liver, inhibits the synthesis of the factors enclosed in circles. Proteins C and S exert anticlotting effects by inactivating activated factors Va and VIIIa.

**Table 34-1 Blood Clotting Factors and Drugs That Affect Them.<sup>1</sup>**

Component or Factor	Common Synonym	Target for the Action of:
I	Fibrinogen	
II	Prothrombin	Heparin (IIa); warfarin (synthesis)
III	Tissue thromboplastin	
IV	Calcium	
V	Proaccelerin	
VII	Proconvertin	Warfarin (synthesis)
VIII	Antihemophilic factor (AHF)	
IX	Christmas factor, plasma thromboplastin component (PTC)	Warfarin (synthesis)
X	Stuart-Prower factor	Heparin (Xa); warfarin (synthesis)
XI	Plasma thromboplastin antecedent (PTA)	
XII	Hageman factor	
XIII	Fibrin-stabilizing factor	
Proteins C and S		Warfarin (synthesis)
Plasminogen		Thrombolytic enzymes, aminocaproic

<sup>1</sup>See Figure 34â€"2 and text for additional details.

Thrombin has a central role in hemostasis and has many functions. In clotting, thrombin proteolytically cleaves small peptides from fibrinogen, allowing fibrinogen to polymerize and form a fibrin clot. Thrombin also activates many upstream clotting factors, leading to more thrombin generation, and activates factor XIII, a transaminase that cross-links the fibrin polymer and stabilizes the clot. Thrombin is a potent platelet activator and mitogen. Thrombin also exerts *anticoagulant* effects by activating the protein C pathway, which attenuates the clotting response (Figure 34â€"2). It should therefore be apparent that the response to vascular injury is a complex and precisely modulated process that ensures that under normal circumstances, repair of vascular injury occurs without thrombosis and downstream ischemia; that is, the response is proportionate and reversible. Eventually vascular remodeling and repair occur with reversion to the quiescent resting anticoagulant endothelial cell phenotype.

### Initiation of Clotting: The Tissue Factor-VIIa Complex

The main initiator of blood coagulation *in vivo* is the tissue factor (TF)-factor VIIa pathway (Figure 34â€"2). Tissue factor is a transmembrane protein ubiquitously expressed outside the vasculature, but not normally expressed in an active form within vessels. The exposure of TF on damaged endothelium or to blood that has extravasated into tissue binds TF to factor VIIa. This complex, in turn, activates factors X and IX. Factor Xa along with factor Va forms the prothrombinase complex on activated cell surfaces, which catalyzes the conversion of prothrombin (factor II) to thrombin (factor IIa). Thrombin, in turn, activates upstream clotting factors, primarily factors V, VIII, and XI, resulting in amplification of thrombin generation. The TF-factor VIIa-catalyzed activation of factor Xa is regulated by tissue factor pathway inhibitor (TFPI). Thus after initial activation of factor X to Xa by TF-VIIa, further propagation of the clot is by feedback amplification of thrombin through the intrinsic pathway factors VIII and IX (this provides an explanation of why patients with deficiency of factor VIII or IXâ€"hemophilia A and hemophilia B, respectivelyâ€"have a severe bleeding disorder).

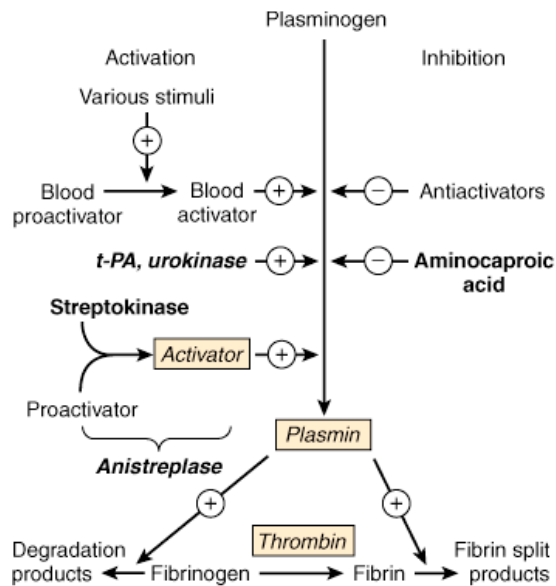

It is also important to note that the coagulation mechanism *in vivo* does not occur in solution, but is localized to activated *cell surfaces* expressing anionic phospholipids such as phosphatidylserine, and is mediated by  $Ca^{2+}$  bridging between the anionic phospholipids and  $\gamma$ -carboxyglutamic acid residues of the clotting factors. This is the basis for using calcium chelators such as ethylenediamine tetraacetic acid (EDTA) or citrate to prevent blood from clotting in a test tube.

**Antithrombin (AT)** is an endogenous anticoagulant and a member of the serine protease inhibitor (serpin) family; it inactivates the serine proteases IIa, IXa, Xa, XIa, and XIIa. The endogenous anticoagulants **protein C** and **protein S** attenuate the blood clotting cascade by proteolysis of the two cofactors Va and VIIIa. From an evolutionary standpoint, it is of interest that factors V and VIII have an identical overall domain structure and considerable homology, consistent with a common ancestor gene; likewise the serine proteases are descendents of a trypsin-like common ancestor. Thus, the TF-VIIa initiating complex, serine proteases, and cofactors each have their own lineage-specific attenuation mechanism (Figure 34â€"2). Defects in natural anticoagulants result in an increased risk of venous thrombosis. The most common defect in the natural anticoagulant system is a mutation in factor V (factor V Leiden), which results in resistance to inactivation by the protein C, protein S mechanism.

### Fibrinolysis

Fibrinolysis refers to the process of fibrin digestion by the fibrin-specific protease, plasmin. The fibrinolytic system is similar to the coagulation system in that the precursor form of the serine protease plasmin circulates in an inactive form as plasminogen. In response to injury, endothelial cells synthesize and release tissue plasminogen activator (t-PA), which converts plasminogen to plasmin (Figure 34â€"3). Plasmin remodels the thrombus and limits its extension by proteolytic digestion of fibrin.

### Figure 34â€"3

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 11th Edition: <http://www.accessmedicine.com>

Schematic representation of the fibrinolytic system. Plasmin is the active fibrinolytic enzyme. Several clinically useful activators are shown on the left in bold. Anistreplase is a combination of streptokinase and the proactivator plasminogen. Aminocaproic acid (right) inhibits the activation of plasminogen to plasmin and is useful in some bleeding disorders. t-PA, tissue plasminogen activator.

Both plasminogen and plasmin have specialized protein domains (kringles) that bind to exposed lysines on the fibrin clot and impart clot specificity to the fibrinolytic process. It should be noted that this clot specificity is only observed at *physiologic* levels of t-PA. At the *pharmacologic* levels of t-PA used in thrombolytic therapy, clot specificity is lost and a systemic lytic state is created, with attendant increase in bleeding risk. As in the coagulation cascade, there are negative regulators of fibrinolysis: endothelial cells synthesize and release plasminogen activator inhibitor (PAI), which inhibits t-PA; in addition  $\alpha_2$  antiplasmin circulates in the blood at high concentrations and under physiologic conditions will rapidly inactivate any plasmin that is not clot-bound. However, this regulatory system is overwhelmed by therapeutic doses of plasminogen activators.

If the coagulation and fibrinolytic systems are pathologically activated, the hemostatic system may careen out of control, leading to generalized intravascular clotting and bleeding. This process is called **disseminated intravascular coagulation (DIC)** and may follow massive tissue injury, advanced cancers, obstetric emergencies such as abruptio placentae or retained products of conception, or bacterial sepsis. The treatment of DIC is to control the underlying disease process; if this is not possible, DIC is often fatal.

Regulation of the fibrinolytic system is useful in therapeutics. Increased fibrinolysis is effective therapy for thrombotic disease. **Tissue plasminogen activator, urokinase, and streptokinase** all activate the fibrinolytic system (Figure 34â€³). Conversely, decreased fibrinolysis protects clots from lysis and reduces the bleeding of hemostatic failure.

**Aminocaproic acid** is a clinically useful inhibitor of fibrinolysis. Heparin and the oral anticoagulant drugs do not affect the fibrinolytic mechanism.

## BASIC PHARMACOLOGY OF THE ANTICOAGULANT DRUGS

The ideal anticoagulant drug would prevent pathologic thrombosis and limit reperfusion injury, yet allow a normal response to vascular injury and limit bleeding. Theoretically this could be accomplished by preservation of the TF-VIIa initiation phase of the clotting mechanism with attenuation of the secondary intrinsic pathway propagation phase of clot development. At this time such a drug does not exist; all anticoagulants and fibrinolytic drugs have an increased bleeding risk as their principle toxicity.

### Indirect Thrombin Inhibitors

The indirect thrombin inhibitors are so-named because their antithrombotic effect is exerted by their interaction with a separate protein, antithrombin. **Unfractionated heparin (UFH), low-molecular-weight heparin (LMWH)**, and the

synthetic pentasaccharide **fondaparinux** bind to antithrombin and enhance its inactivation of factor Xa (Figure 34â€4). Unfractionated heparin and to a lesser extent LMWH also enhance antithrombin's inactivation of thrombin.

**Figure 34â€4**

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 11th Edition: <http://www.accessmedicine.com>

Cartoon illustrating differences between fondaparinux, low-molecular-weight heparins (LMWH), and high-molecular-weight heparin (HMWH, unfractionated heparin). Activated antithrombin III (AT III) degrades thrombin, factor X, and several other factors. Binding of these drugs to AT III can increase the catalytic action of AT III 1000-fold. The combination of AT III with unfractionated heparin increases degradation of both factor Xa and thrombin. Combination with fondaparinux or LMWH more selectively increases degradation of Xa.

## HEPARIN

### Chemistry & Mechanism of Action

Heparin is a heterogeneous mixture of sulfated mucopolysaccharides. It binds to endothelial cell surfaces and a variety of plasma proteins. Its biologic activity is dependent upon the endogenous anticoagulant **antithrombin**. Antithrombin inhibits clotting factorproteases, especially thrombin (IIa), IXa, and Xa, by forming equimolar stable complexes with them. In the absence of heparin, these reactions are slow; in the presence of heparin, they are accelerated 1000-fold. Only about a third of the molecules in commercial heparin preparations have an accelerating effect because the remainder lack the unique pentasaccharide sequence needed for high-affinity binding to antithrombin. The active heparin molecules bind tightly to antithrombin and cause a conformational change in this inhibitor. The conformational change of antithrombin exposes its active site for more rapid interaction with the proteases (the activated clotting factors). Heparin functions as a cofactor for the antithrombin-protease reaction without being consumed. Once the antithrombin protease complex is formed, heparin is released intact for renewed binding to more antithrombin.

The antithrombin binding region of commercial unfractionated heparin consists of repeating sulfated disaccharide units composed of D -glucosamine-L -iduronic acid and D -glucosamine-D -glucuronic acid. High-molecular-weight (HMW) fractions of heparin with high affinity for antithrombin markedly inhibit blood coagulation by inhibiting all three factors, especially thrombin and factor Xa. Unfractionated heparin has a molecular weight range of 5000â€30,000. In contrast, the shorter-chain low-molecular-weight (LMW) fractions of heparin inhibit activated factor X but have less effect on thrombin than the HMW species. Nevertheless, numerous studies have demonstrated that LMW heparins such as **enoxaparin**, **dalteparin**, and **tinzaparin** are effective in several thromboembolic conditions. In fact, these LMW heparinsâ€in comparison with UFHâ€have equal efficacy, increased bioavailability from the subcutaneous site of injection, and less frequent dosing requirements (once or twice daily is sufficient).

Because commercial heparin consists of a family of molecules of different molecular weights, the correlation between the concentration of a given heparin preparation and its effect on coagulation often is poor. Therefore, UFH is standardized by bioassay. Heparin sodium USP must contain at least 120 USP units per milligram. Heparin is generally used as the sodium salt, but calcium heparin is equally effective. Lithium heparin is used in vitro as an anticoagulant for blood samples. Commercial heparin is extracted from porcine intestinal mucosa and bovine lung. Enoxaparin is obtained from the same

sources as regular heparin, but doses are specified in milligrams. Dalteparin, tinzaparin, and danaparoid (an LMW heparanoid containing heparan sulfate, dermatan sulfate, and chondroitin sulfate), on the other hand, are specified in antifactor Xa units.

### **Monitoring of Heparin Effect**

Close monitoring of the **activated partial thromboplastin time (aPTT or PTT)** is necessary in patients receiving UFH. Levels of UFH may also be determined by protamine titration (therapeutic levels 0.2â€”0.4 unit/mL) or anti-Xa units (therapeutic levels 0.3â€”0.7 unit/mL). Weight-based dosing of the LMW heparins results in predictable pharmacokinetics and plasma levels in patients with normal renal function. Therefore, LMW heparin levels are not generally measured except in the setting of renal insufficiency, obesity, and pregnancy. LMW heparin levels can be determined by anti-Xa units. Peak therapeutic levels should be 0.5â€”1 unit/mL for twice-daily dosing, determined 4 hours after administration, and approximately 1.5 units/mL for once-daily dosing.

### **Toxicity**

#### **BLEEDING & MISCELLANEOUS EFFECTS**

The major adverse effect of heparin is bleeding. This risk can be decreased by scrupulous patient selection, careful control of dosage, and close monitoring. Elderly women and patients with renal failure are more prone to hemorrhage. Heparin is of animal origin and should be used cautiously in patients with allergy. Increased loss of hair and reversible alopecia have been reported. Long-term heparin therapy is associated with osteoporosis and spontaneous fractures. Heparin accelerates the clearing of postprandial lipemia by causing the release of lipoprotein lipase from tissues, and long-term use is associated with mineralocorticoid deficiency.

#### **HEPARIN-INDUCED THROMBOCYTOPENIA**

Heparin-induced thrombocytopenia (HIT) is a systemic hypercoagulable state that occurs in 1â€”4% of individuals treated with UFH for a minimum of 7 days. Surgical patients are at greatest risk. The reported incidence of HIT is lower in pediatric populations outside the critical care setting and is relatively rare in pregnant women. The risk of HIT may be higher in individuals treated with UFH of bovine origin compared with porcine heparin and is lower in those treated exclusively with LMWH.

Morbidity and mortality in HIT are related to thrombotic events. Venous thrombosis occurs most commonly, but occlusion of peripheral or central arteries is not infrequent. If an indwelling catheter is present, the risk of thrombosis is increased in that extremity. Skin necrosis has been described, particularly in individuals treated with warfarin in the absence of a direct thrombin inhibitor, presumably due to acute depletion of the vitamin K-dependent anticoagulant protein C occurring in the presence of high levels of procoagulant proteins and an active hypercoagulable state.

The following points should be considered in all patients receiving heparin: Platelet counts should be performed frequently; thrombocytopenia appearing in a time frame consistent with an immune response to heparin should be considered suspicious for HIT; and any new thrombus occurring in a patient receiving heparin therapy should raise suspicion of HIT. Patients who develop HIT are treated by discontinuance of heparin and administration of a direct thrombin inhibitor or fondaparinux (see below).

### **Contraindications**

Heparin is contraindicated in patients with HIT, hypersensitivity to the drug, active bleeding, hemophilia, significant thrombocytopenia, purpura, severe hypertension, intracranial hemorrhage, infective endocarditis, active tuberculosis, ulcerative lesions of the gastrointestinal tract, threatened abortion, visceral carcinoma, or advanced hepatic or renal disease. Heparin should be avoided in patients who have recently had surgery of the brain, spinal cord, or eye, and in patients who are undergoing lumbar puncture or regional anesthetic block. Despite the apparent lack of placental transfer, heparin should be used in pregnant women only when clearly indicated.

### **Administration & Dosage**

The indications for the use of heparin are described in the section on clinical pharmacology. A plasma concentration of heparin of 0.2â€”0.4 unit/mL (by protamine titration) or 0.3â€”0.7 unit/mL (anti-Xa units) usually prevents pulmonary emboli in patients with established venous thrombosis. This concentration generally corresponds to a PTT of 2â€”3 times baseline. However, the use of the PTT for heparin monitoring is problematic. There is no standardization scheme for the PTT as there is for the prothrombin time (PT) and its international normalized ratio (INR). Currently more than 300 reagent-instrument combinations are in use, and the actual ratios required to obtain an anti-Xa activity of 0.3â€”0.7 units/mL are variable, ranging from 1.6â€”6 times control PTT. Thus, if the PTT is used for monitoring, the laboratory should determine the clotting time that corresponds to the therapeutic range by protamine titration or anti-Xa activity, as listed above.

In addition, some patients have a prolonged baseline PTT due to factor deficiency or inhibitors (which could increase bleeding

risk) or lupus anticoagulant (which is not associated with bleeding risk but may be associated with thrombosis risk). Using the PTT to assess heparin effect in such patients is very difficult. An alternative is to use anti-Xa activity to assess heparin concentration, a test now widely available on automated coagulation instruments. This approach more accurately measures the heparin concentration; however, it does not provide the global assessment of intrinsic pathway integrity of the PTT.

The following strategy is recommended: prior to initiating anticoagulant therapy of any type, the integrity of the patient's hemostatic system should be assessed by a careful history of prior bleeding events, and baseline PT and PTT. If there is a prolonged clotting time, the cause of this (deficiency or inhibitor) should be determined prior to initiating therapy, and treatment goals stratified to a risk-benefit assessment. In high-risk patients measuring both the PTT and anti-Xa activity may be useful. When *intermittent* heparin administration is used, the aPTT or anti-Xa activity should be measured 6 hours after the administered dose to maintain prolongation of the aPTT to 2–2.5 times that of the control value. However, LMW heparin therapy is the preferred option in this case, as no monitoring is required in most patients.

Continuous intravenous administration of heparin is accomplished via an infusion pump. After an initial bolus injection of 80–100 units/kg, a continuous infusion of about 15–22 units/kg/h is required to maintain the anti-Xa activity in the range of 0.3–0.7 units/mL. Low-dose prophylaxis is achieved with subcutaneous administration of heparin, 5000 units every 8–12 hours. Because of the danger of hematoma formation at the injection site, heparin must never be administered intramuscularly.

Prophylactic enoxaparin is given subcutaneously in a dosage of 30 mg twice daily or 40 mg once daily. Full-dose enoxaparin therapy is 1 mg/kg subcutaneously every 12 hours. This corresponds to a therapeutic anti-factor Xa level of 0.5–1 unit/mL. Selected patients may be treated with enoxaparin 1.5 mg/kg once a day, with a target anti-Xa level of 1.5 units/mL. The prophylactic dose of dalteparin is 5000 units subcutaneously once a day; therapeutic dosing is 200 units/kg once a day for venous disease or 120 units/kg every 12 hours for acute coronary syndrome. LMWH should be used with caution in patients with renal insufficiency or body weight greater than 150 kg. Measurement of the anti-Xa level is useful to guide dosing in these individuals.

The synthetic pentasaccharide molecule fondaparinux (Figure 34–4) avidly binds antithrombin with high specific activity, resulting in efficient inactivation of factor Xa. Fondaparinux has a long half-life of 15 hours, allowing for once-daily dosing by subcutaneous administration. Fondaparinux is effective in the prevention and treatment of venous thromboembolism, and appears to not cross-react with pathologic HIT antibodies in most individuals. The use of fondaparinux as an alternative anticoagulant in HIT is currently being tested in clinical trials.

A major focus of drug development has been to develop orally active anticoagulants that do not require monitoring.

**Rivaroxiban** is the first oral factor Xa inhibitor to reach phase III clinical trials. The safety and efficacy of rivaroxiban appears to be at least equivalent, and possibly superior, to LMW heparins for prevention of deep vein thrombosis; no routine monitoring is required. This drug is also in clinical trials for treatment of deep vein thrombosis and prevention of stroke in atrial fibrillation.

### Reversal of Heparin Action

Excessive anticoagulant action of heparin is treated by discontinuance of the drug. If bleeding occurs, administration of a specific antagonist such as **protamine sulfate** is indicated. Protamine is a highly basic peptide that combines with heparin as an ion pair to form a stable complex devoid of anticoagulant activity. For every 100 units of heparin remaining in the patient, 1 mg of protamine sulfate is given intravenously; the rate of infusion should not exceed 50 mg in any 10-minute period. Excess protamine must be avoided; it also has an anticoagulant effect. Neutralization of LMW heparin by protamine is incomplete. Limited experience suggests that 1 mg of protamine sulfate may be used to partially neutralize 1 mg of enoxaparin. Protamine will not reverse the activity of fondaparinux. Excess danaparoid can be removed by plasmapheresis.

### Direct Thrombin Inhibitors

The direct thrombin inhibitors (DTIs) exert their anticoagulant effect by directly binding to the active site of thrombin, thereby inhibiting thrombin's downstream effects. This is in contrast to indirect thrombin inhibitors such as heparin and LMWH (see above), which act through antithrombin. **Hirudin** and **bivalirudin** are bivalent DTIs in that they bind at both the catalytic or active site of thrombin as well as at a substrate recognition site. **Argatroban** and **melagatran** are small molecules that bind only at the thrombin active site.

### PARENTERAL DIRECT THROMBIN INHIBITORS

Leeches have been used for bloodletting since the age of Hippocrates. More recently, surgeons have used medicinal leeches (*Hirudo medicinalis*) to prevent thrombosis in the fine vessels of reattached digits. **Hirudin** is a specific, irreversible thrombin inhibitor from leech saliva that is now available in recombinant form as **lepirudin**. Its action is independent of

antithrombin, which means it can reach and inactivate fibrin-bound thrombin in thrombi. Lepirudin has little effect on platelets or the bleeding time. Like heparin, it must be administered parenterally and is monitored by the aPTT. Lepirudin is approved by the FDA for use in patients with thrombosis related to heparin-induced thrombocytopenia. Lepirudin is excreted by the kidney and should be used with great caution in patients with renal insufficiency as no antidote exists. Up to 40% of patients who receive long-term infusions develop an antibody directed against the thrombin-lepirudin complex. These antigen-antibody complexes are not cleared by the kidney and may result in an enhanced anticoagulant effect. Some patients re-exposed to the drug have developed life-threatening anaphylactic reactions.

**Bivalirudin**, another bivalent inhibitor of thrombin, is administered intravenously, with a rapid onset and offset of action. The drug has a short half-life with clearance that is 20% renal and the remainder metabolic. Bivalirudin also inhibits platelet activation and has been FDA-approved for use in percutaneous coronary angioplasty.

**Argatroban** is a small molecule thrombin inhibitor that is FDA-approved for use in patients with HIT with or without thrombosis and coronary angioplasty in patients with HIT. It, too, has a short half-life, is given by continuous intravenous infusion, and is monitored by aPTT. Its clearance is not affected by renal disease but is dependent on liver function; dose reduction is required in patients with liver disease. Patients on argatroban will demonstrate elevated INRs, rendering the transition to warfarin difficult (ie, the INR will reflect contributions from both warfarin and argatroban). (INR is discussed in detail in the discussion of warfarin administration.) A nomogram is supplied by the manufacturer to assist in this transition. No properly designed head-to-head trials have been performed to determine whether argatroban or lepirudin is superior in the treatment of HIT. However, in practice, the choice of which DTI to use in a patient with HIT is usually dictated by the condition of the clearing organ. If the patient has severe renal insufficiency, then argatroban would be preferred. If there is severe hepatic insufficiency, then lepirudin would be a better choice.

## ORAL DIRECT THROMBIN INHIBITORS

Advantages of oral direct thrombin inhibitors include predictable pharmacokinetics and bioavailability, which allow for fixed dosing and predictable anticoagulant response, and make routine coagulation monitoring unnecessary. In addition, these agents do not interact with P450-interacting drugs, and their rapid onset and offset of action allow for immediate anticoagulation, thus avoiding the need for overlap with additional anticoagulant drugs.

**Ximelagatran** was the first oral direct thrombin inhibitor approved; however, it was subsequently withdrawn from the market because concerns of hepatic toxicity. Recently a new oral direct thrombin inhibitor, **dabigatran**, was approved for use in Europe for prevention of venous thromboembolism in patients who have undergone hip or knee replacement surgery. This drug has been shown to have equivalent efficacy and safety to LMWH. No routine monitoring is required. Thus, as for the oral anti-Xa inhibitor rivaroxiban (see above), this drug has significant advantages over warfarin (discussed next), which has a narrow therapeutic window, is affected by diet and many drugs, and requires monitoring for dosage adjustment. It appears that the oral anti-Xa drugs and direct thrombin inhibitors are poised to challenge warfarin's dominance in the prevention and therapy of thrombotic disease.

## Warfarin & the Coumarin Anticoagulants

### Chemistry & Pharmacokinetics

The clinical use of the coumarin anticoagulants began with the discovery of an anticoagulant substance formed in spoiled sweet clover silage which caused hemorrhagic disease in cattle. At the behest of local farmers, a chemist at the University of Wisconsin identified the toxic agent as bishydroxycoumarin. A synthesized derivative, dicumarol and its congeners, most notably warfarin (**W**isconsin **A**lumni **R**esearch **F**oundation, with "arin" from coumarin added; Figure 34-5), were initially used as rodenticides. In the 1950s warfarin (under the brand name Coumadin) was introduced as an antithrombotic agent in humans. Warfarin is one of the most commonly prescribed drugs, used by approximately 1.5 million individuals, and several studies have indicated that the drug is significantly underused in clinical situations where it has proven benefit.

### Figure 34-5

Structural formulas of several oral anticoagulant drugs and of vitamin K. The carbon atom of warfarin shown at the asterisk is an asymmetric center.

Warfarin is generally administered as the sodium salt and has 100% bioavailability. Over 99% of racemic warfarin is bound to plasma albumin, which may contribute to its small volume of distribution (the albumin space), its long half-life in plasma (36 hours), and the lack of urinary excretion of unchanged drug. Warfarin used clinically is a racemic mixture composed of equal amounts of two enantiomorphs. The levorotatory *S*-warfarin is four times more potent than the dextrorotatory *R*-warfarin. This observation is useful in understanding the stereoselective nature of several drug interactions involving warfarin.

### Mechanism of Action

Coumarin anticoagulants block the  $\gamma$ -carboxylation of several glutamate residues in prothrombin and factors VII, IX, and X as well as the endogenous anticoagulant proteins C and S (Figure 34-2, Table 34-1). The blockade results in incomplete coagulation factor molecules that are biologically inactive. The protein carboxylation reaction is coupled to the oxidation of vitamin K. The vitamin must then be reduced to reactivate it. Warfarin prevents reductive metabolism of the inactive vitamin K epoxide back to its active hydroquinone form (Figure 34-6). Mutational change of the responsible enzyme, vitamin K epoxide reductase, can give rise to genetic resistance to warfarin in humans and especially in rats.

### Figure 34-6

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 11th Edition: <http://www.accessmedicine.com>

Vitamin K cycle—metabolic interconversions of vitamin K associated with the synthesis of vitamin K-dependent clotting factors. Vitamin K<sub>1</sub> or K<sub>2</sub> is activated by reduction to the hydroquinone form (KH<sub>2</sub>). Stepwise oxidation to vitamin K epoxide (KO) is coupled to prothrombin carboxylation by the enzyme carboxylase. The reactivation of vitamin K epoxide is the warfarin-sensitive step (warfarin). The R on the vitamin K molecule represents a 20-carbon phytyl side chain in vitamin K<sub>1</sub> and a 30- to 65-carbon polyprenyl side chain in vitamin K<sub>2</sub>.

There is an 8- to 12-hour delay in the action of warfarin. Its anticoagulant effect results from a balance between partially inhibited synthesis and unaltered degradation of the four vitamin K-dependent clotting factors. The resulting inhibition of coagulation is dependent on their degradation half-lives in the circulation. These half-lives are 6, 24, 40, and 60 hours for factors VII, IX, X, and II, respectively. Larger initial doses of warfarin—up to about 0.75 mg/kg—hasten the onset of the anticoagulant effect. Beyond this dosage, the speed of onset is independent of the dose size. The only effect of a larger loading dose is to prolong the time that the plasma concentration of drug remains above that required for suppression of clotting factor synthesis. The only difference among oral anticoagulants in producing and maintaining hypoprothrombinemia is the half-life of each drug.

### Toxicity

Warfarin crosses the placenta readily and can cause a hemorrhagic disorder in the fetus. Furthermore, fetal proteins with  $\gamma$ -carboxyglutamate residues found in bone and blood may be affected by warfarin; the drug can cause a serious birth defect characterized by abnormal bone formation. Thus, warfarin should never be administered during pregnancy. Cutaneous necrosis with reduced activity of protein C sometimes occurs during the first weeks of therapy. Rarely, the same process causes frank infarction of the breast, fatty tissues, intestine, and extremities. The pathologic lesion associated with the hemorrhagic infarction is venous thrombosis, suggesting that it is caused by warfarin-induced depression of protein C synthesis.

### Administration & Dosage

Treatment with warfarin should be initiated with standard doses of 5–10 mg rather than the large loading doses formerly used. The initial adjustment of the prothrombin time takes about 1 week, which usually results in a maintenance dose of 5–7 mg/d. The **prothrombin time (PT)** should be increased to a level representing a reduction of prothrombin activity to 25% of normal and maintained there for long-term therapy. When the activity is less than 20%, the warfarin dosage should be reduced or omitted until the activity rises above 20%.

The therapeutic range for oral anticoagulant therapy is defined in terms of an international normalized ratio (INR). The INR is

the prothrombin time ratio (patient prothrombin time/mean of normal prothrombin time for lab)<sup>ISI</sup>, where the ISI exponent refers to the International Sensitivity Index, and is dependent on the specific reagents and instruments used for the determination. The ISI serves to relate measured prothrombin times to a World Health Organization reference standard thromboplastin; thus the prothrombin times performed on different properly calibrated instruments with a variety of thromboplastin reagents should give the same INR results for a given sample. For most reagent and instrument combinations in current use, the ISI is close to 1, making the INR roughly the ratio of the patient prothrombin time to the mean normal prothrombin time. The recommended INR for prophylaxis and treatment of thrombotic disease is 2–3. Patients with some types of artificial heart valves (eg, tilting disk) or other medical conditions increasing thrombotic risk have a recommended range of 2.5–3.5.

Occasionally patients exhibit warfarin resistance, defined as progression or recurrence of a thrombotic event while in the therapeutic range. These individuals may have their INR target raised (which is accompanied by an increase in bleeding risk) or be changed to an alternative form of anticoagulation (eg, daily injections of LMWH). Warfarin resistance is most commonly seen in patients with advanced cancers, typically of gastrointestinal origin (Trousseau's syndrome). A recent study has demonstrated the superiority of LMWH over warfarin in preventing recurrent venous thromboembolism in patients with cancer.

## Drug Interactions

The oral anticoagulants often interact with other drugs and with disease states. These interactions can be broadly divided into pharmacokinetic and pharmacodynamic effects (Table 34–2). Pharmacokinetic mechanisms for drug interaction with oral anticoagulants are mainly enzyme induction, enzyme inhibition, and reduced plasma protein binding. Pharmacodynamic mechanisms for interactions with warfarin are synergism (impaired hemostasis, reduced clotting factor synthesis, as in hepatic disease), competitive antagonism (vitamin K), and an altered physiologic control loop for vitamin K (hereditary resistance to oral anticoagulants).

**Table 34–2 Pharmacokinetic and Pharmacodynamic Drug and Body Interactions with Oral Anticoagulants.**

Increased Prothrombin Time		Decreased Prothrombin Time	
Pharmacokinetic	Pharmacodynamic	Pharmacokinetic	Pharmacodynamic
Amiodarone	<b>Drugs</b>	Barbiturates	<b>Drugs</b>
Cimetidine	Aspirin (high doses)	Cholestyramine	Diuretics
Disulfiram	Cephalosporins, third-generation	Rifampin	Vitamin K
Metronidazole <sup>1</sup>	Heparin		<b>Body factors</b>
Fluconazole <sup>1</sup>	<b>Body factors</b>		Hereditary resistance
Phenylbutazone <sup>1</sup>	Hepatic disease		Hypothyroidism
Sulfinpyrazone <sup>1</sup>	Hyperthyroidism		
Trimethoprim-sulfamethoxazole			

<sup>1</sup>Stereoselectively inhibits the oxidative metabolism of the *S*-warfarin enantiomorph of racemic warfarin.

The most serious interactions with warfarin are those that increase the anticoagulant effect and the risk of bleeding. The most dangerous of these interactions are the pharmacokinetic interactions with the pyrazolones phenylbutazone and sulfinpyrazone. These drugs not only augment the hypoprothrombinemia but also inhibit platelet function and may induce peptic ulcer disease (see Chapter 36). The mechanisms for their hypoprothrombinemic interaction are a stereoselective inhibition of oxidative metabolic transformation of *S*-warfarin (the more potent isomer) and displacement of albumin-bound warfarin, increasing the free fraction. For this and other reasons, neither phenylbutazone nor sulfinpyrazone is in common use in the USA. Metronidazole, fluconazole, and trimethoprim-sulfamethoxazole also stereoselectively inhibit the metabolic transformation of *S*-warfarin, whereas amiodarone, disulfiram, and cimetidine inhibit metabolism of both enantiomorphs of

warfarin, aspirin, hepatic disease, and hyperthyroidism augment warfarin pharmacodynamically— aspirin by its effect on platelet function and the latter two by increasing the turnover rate of clotting factors. The third-generation cephalosporins eliminate the bacteria in the intestinal tract that produce vitamin K and, like warfarin, also directly inhibit vitamin K epoxide reductase.

Barbiturates and rifampin cause a marked *decrease* of the anticoagulant effect by induction of the hepatic enzymes that transform racemic warfarin. Cholestyramine binds warfarin in the intestine and reduces its absorption and bioavailability.

Pharmacodynamic reductions of anticoagulant effect occur with vitamin K (increased synthesis of clotting factors), the diuretics chlorthalidone and spironolactone (clotting factor concentration), hereditary resistance (mutation of vitamin K reactivation cycle molecules), and hypothyroidism (decreased turnover rate of clotting factors).

Drugs with *no* significant effect on anticoagulant therapy include ethanol, phenothiazines, benzodiazepines, acetaminophen, opioids, indomethacin, and most antibiotics.

### Reversal of Warfarin Action

Excessive anticoagulant effect and bleeding from warfarin can be reversed by stopping the drug and administering oral or parenteral vitamin K1 (phytonadione), fresh-frozen plasma, prothrombin complex concentrates such as Bebulin and Proplex T, and recombinant factor VIIa (rFVIIa). The disappearance of excessive effect is not correlated with plasma warfarin concentrations but rather with reestablishment of normal activity of the clotting factors. A modest excess of anticoagulant effect without bleeding may require no more than cessation of the drug. The warfarin effect can be rapidly reversed in the setting of severe bleeding with the administration of prothrombin complex or rFVIIa coupled with intravenous vitamin K. It is important to note that due to the long half-life of warfarin, a single dose of vitamin K or rFVIIa may not be sufficient.

## BASIC PHARMACOLOGY OF THE FIBRINOLYTIC DRUGS

Fibrinolytic drugs rapidly lyse thrombi by catalyzing the formation of the serine protease **plasmin** from its precursor zymogen, plasminogen (Figure 34-3). These drugs create a generalized lytic state when administered intravenously. Thus, both protective hemostatic thrombi and target thromboemboli are broken down. Thrombolytic Drugs for Acute Myocardial Infarction describes the use of these drugs in one major application.

### Thrombolytic Drugs for Acute Myocardial Infarction

The paradigm shift in 1980 on the causation of acute myocardial infarction to acute coronary occlusion by a thrombus created the rationale for thrombolytic therapy of this common lethal disease. At that time—and for the first time—intravenous thrombolytic therapy for acute myocardial infarction in the European Cooperative Study Group trial was found to reduce mortality significantly. Later studies, with thousands of patients in each trial, provided enough statistical power for the 20% reduction in mortality to be considered statistically significant. Although the standard of care in areas with adequate facilities and experience in percutaneous coronary intervention (PCI) now favors catheterization and placement of a stent, thrombolytic therapy is still very important where PCI is not readily available.

The proper selection of patients for thrombolytic therapy is critical. The diagnosis of acute myocardial infarction is made clinically and is confirmed by electrocardiography. Patients with ST-segment elevation and bundle branch block on electrocardiography have the best outcomes. All trials to date show the greatest benefit for thrombolytic therapy when it is given early, within 6 hours after symptomatic onset of acute myocardial infarction.

Thrombolytic drugs reduce the mortality of acute myocardial infarction. The early and appropriate use of any thrombolytic drug probably transcends possible advantages of a particular drug. Adjunctive drugs such as aspirin, heparin,  $\beta$  blockers, and angiotensin-converting enzyme (ACE) inhibitors reduce mortality even further. The principles of management are outlined in Antman, et al, 2008 (see References).

## Pharmacology

**Streptokinase** is a protein (but not an enzyme in itself) synthesized by streptococci that combines with the proactivator plasminogen. This enzymatic complex catalyzes the conversion of inactive plasminogen to active plasmin. **Urokinase** is a human enzyme synthesized by the kidney that directly converts plasminogen to active plasmin. Plasmin itself cannot be used because naturally occurring inhibitors in plasma prevent its effects. However, the absence of inhibitors for urokinase and the streptokinase-proactivator complex permits their use clinically. Plasmin formed inside a thrombus by these activators is protected from plasma antiplasmins, which allows it to lyse the thrombus from within.

**Anistreplase** (anisoylated plasminogen streptokinase activator complex; APSAC) consists of a complex of purified human plasminogen and bacterial streptokinase that has been acylated to protect the enzyme's active site. When administered, the

acyl group spontaneously hydrolyzes, freeing the activated streptokinase-proactivator complex. This product (recently discontinued in the USA) allows for rapid intravenous injection, greater clot selectivity (ie, more activity on plasminogen associated with clots than on free plasminogen in the blood), and more thrombolytic activity.

Plasminogen can also be activated endogenously by **tissue plasminogen activators (t-PAs)**. These activators preferentially activate plasminogen that is bound to fibrin, which (in theory) confines fibrinolysis to the formed thrombus and avoids systemic activation. Human t-PA is manufactured as **alteplase** by means of recombinant DNA technology.

**Retepase** is another recombinant human t-PA from which several amino acid sequences have been deleted. Reteplase is less expensive to produce than t-PA. Because it lacks the major fibrin-binding domain, reteplase is less fibrin-specific than t-PA. **Tenecteplase** is a mutant form of t-PA that has a longer half-life, and it can be given as an intravenous bolus. Tenecteplase is slightly more fibrin-specific than t-PA.

### Indications & Dosage

Administration of fibrinolytic drugs by the intravenous route is indicated in cases of **pulmonary embolism with hemodynamic instability**, severe **deep venous thrombosis** such as the superior vena caval syndrome, and **ascending thrombophlebitis** of the iliofemoral vein with severe lower extremity edema. These drugs are also given intra-arterially, especially for peripheral vascular disease.

Thrombolytic therapy in the management of **acute myocardial infarction** requires careful patient selection, the use of a specific thrombolytic agent, and the benefit of adjuvant therapy. Streptokinase is administered by intravenous infusion of a loading dose of 250,000 units, followed by 100,000 units/h for 24–72 hours. Patients with antistreptococcal antibodies can develop fever, allergic reactions, and therapeutic resistance. Urokinase requires a loading dose of 300,000 units given over 10 minutes and a maintenance dose of 300,000 units/h for 12 hours. Alteplase (t-PA) is given by intravenous infusion of 60 mg over the first hour and then 40 mg at a rate of 20 mg/h. Reteplase is given as two intravenous bolus injections of 10 units each, separated by 30 minutes. Tenecteplase is given as a single intravenous bolus of 0.5 mg/kg. Anistreplase (where available) is given as a single intravenous injection of 30 units over 3–5 minutes. A single course of fibrinolytic drugs is expensive: hundreds of dollars for streptokinase and thousands for urokinase and t-PA.

Recombinant t-PA has also been approved for use in acute ischemic stroke within 3 hours of symptom onset. In patients without hemorrhagic infarct or other contraindications, this therapy has been demonstrated to provide better outcomes in several randomized clinical trials. The recommended dose is 0.9 mg/kg, not to exceed 90 mg, with 10% given as a bolus and the remainder during a 1 hour infusion. Streptokinase has been associated with increased bleeding risk in acute ischemic stroke when given at a dose of 1.5 million units, and its use is not recommended in this setting.

## BASIC PHARMACOLOGY OF ANTIPLATELET AGENTS

Platelet function is regulated by three categories of substances. The first group consists of agents generated outside the platelet that interact with platelet membrane receptors, eg, catecholamines, collagen, thrombin, and prostacyclin. The second category contains agents generated within the platelet that interact with membrane receptors, eg, ADP, prostaglandin D<sub>2</sub>, prostaglandin E<sub>2</sub>, and serotonin. The third group comprises agents generated within the platelet that act within the platelet, eg, prostaglandin endoperoxides and thromboxane A<sub>2</sub>, the cyclic nucleotides cAMP and cGMP, and calcium ion. From this list of agents, several targets for platelet inhibitory drugs have been identified (Figure 34–1): inhibition of prostaglandin synthesis (aspirin), inhibition of ADP-induced platelet aggregation (clopidogrel, ticlopidine), and blockade of glycoprotein IIb/IIIa receptors on platelets (abciximab, tirofiban, and eptifibatid). Dipyridamole and cilostazol are additional antiplatelet drugs.

### ASPIRIN

The prostaglandin **thromboxane A<sub>2</sub>** is an arachidonate product that causes platelets to change shape, release their granules, and aggregate (see Chapter 18). Drugs that antagonize this pathway interfere with platelet aggregation in vitro and prolong the bleeding time in vivo. Aspirin is the prototype of this class of drugs.

As described in Chapter 18, aspirin inhibits the synthesis of thromboxane A<sub>2</sub> by irreversible acetylation of the enzyme cyclooxygenase. Other salicylates and nonsteroidal anti-inflammatory drugs also inhibit cyclooxygenase but have a shorter duration of inhibitory action because they cannot acetylate cyclooxygenase; that is, their action is reversible.

The FDA has approved the use of 325 mg/d for *primary* prophylaxis of myocardial infarction but urges caution in this use of aspirin by the general population except when prescribed as an adjunct to risk factor management by smoking cessation and lowering of blood cholesterol and blood pressure. Meta-analysis of many published trials of aspirin and other antiplatelet

agents confirms the value of this intervention in the *secondary* prevention of vascular events among patients with a history of vascular events.

## **CLOPIDOGREL & TICLOPIDINE**

Clopidogrel and ticlopidine reduce platelet aggregation by inhibiting the ADP pathway of platelets. These drugs are thienopyridine derivatives that achieve their antiplatelet effects by irreversibly blocking the ADP receptor on platelets. Unlike aspirin, these drugs have no effect on prostaglandin metabolism. Randomized clinical trials with both drugs report efficacy in the prevention of vascular events among patients with transient ischemic attacks, completed strokes, and unstable angina pectoris. Use of clopidogrel or ticlopidine to prevent thrombosis is now considered standard practice in patients undergoing placement of a coronary stent.

Adverse effects of ticlopidine include nausea, dyspepsia, and diarrhea in up to 20% of patients, hemorrhage in 5%, and, most seriously, leukopenia in 1%. The leukopenia is detected by regular monitoring of the white blood cell count during the first 3 months of treatment. Development of thrombotic thrombocytopenic purpura has also been associated with the ingestion of ticlopidine. The dosage of ticlopidine is 250 mg twice daily. It is particularly useful in patients who cannot tolerate aspirin. Doses of ticlopidine less than 500 mg/d may be efficacious with fewer adverse effects.

Clopidogrel has fewer adverse effects than ticlopidine and is rarely associated with neutropenia. Thrombotic thrombocytopenic purpura associated with clopidogrel has been reported. Because of its superior side effect profile and dosing requirements, clopidogrel is preferred over ticlopidine. The antithrombotic effects of clopidogrel are dose-dependent; within 5 hours after an oral loading dose of 300 mg, 80% of platelet activity will be inhibited. The maintenance dose of clopidogrel is 75 mg/d, which achieves maximum platelet inhibition. The duration of the antiplatelet effect is 7–10 days.

## **Aspirin & Clopidogrel Resistance**

The reported incidence of resistance to these drugs varies greatly, from less than 5% to 75%. In part this tremendous variation in incidence reflects the definition of resistance (recurrent thrombosis while on antiplatelet therapy vs in vitro testing), methods by which drug response is measured, and patient compliance. Several methods for testing aspirin and clopidogrel resistance in vitro are now FDA-approved; however, their utility outside of clinical trials remains controversial.

## **BLOCKADE OF PLATELET GLYCOPROTEIN IIB/IIIA RECEPTORS**

The glycoprotein IIB/IIIA inhibitors are used in patients with acute coronary syndromes. These drugs target the platelet IIB/IIIA receptor complex (Figure 34-1). The IIB/IIIA complex functions as a receptor mainly for fibrinogen and vitronectin but also for fibronectin and von Willebrand factor. Activation of this receptor complex is the "final common pathway" for platelet aggregation. There are approximately 50,000 copies of this complex on the surface of each platelet. Persons lacking this receptor have a bleeding disorder called Glanzmann's thrombasthenia.

**Abciximab**, a chimeric monoclonal antibody directed against the IIB/IIIA complex including the vitronectin receptor, was the first agent approved in this class of drugs. It has been approved for use in percutaneous coronary intervention and in acute coronary syndromes. **Eptifibatid** is an analog of the sequence at the extreme carboxyl terminal of the delta chain of fibrinogen, which mediates the binding of fibrinogen to the receptor. **Tirofiban** is a smaller molecule with similar properties. Eptifibatid and tirofiban inhibit ligand binding to the IIB/IIIA receptor by their occupancy of the receptor but do not block the vitronectin receptor.

The three agents described above are administered parenterally. Oral formulations of IIB/IIIA antagonists are in various stages of development.

## **ADDITIONAL ANTIPLATELET-DIRECTED DRUGS**

**Dipyridamole** is a vasodilator that inhibits platelet function by inhibiting adenosine uptake and cGMP phosphodiesterase activity. Dipyridamole by itself has little or no beneficial effect. Therefore, therapeutic use of this agent is primarily in combination with aspirin to prevent cerebrovascular ischemia. It may also be used in combination with warfarin for primary prophylaxis of thromboemboli in patients with prosthetic heart valves. A combination of dipyridamole complexed with 25 mg of aspirin is now available for secondary prophylaxis of cerebrovascular disease.

**Cilostazol** is a newer phosphodiesterase inhibitor that promotes vasodilation and inhibition of platelet aggregation. Cilostazol is used primarily to treat intermittent claudication.

## **CLINICAL PHARMACOLOGY OF DRUGS USED TO PREVENT CLOTTING**

### **VENOUS THROMBOSIS**

## **Risk Factors**

### **INHERITED DISORDERS**

The inherited disorders characterized by a tendency to form thrombi (thrombophilia) derive from either quantitative or qualitative abnormalities of the natural anticoagulant system. Deficiencies (loss of function mutations) in the natural anticoagulants antithrombin, protein C, and protein S account for approximately 15% of selected patients with juvenile or recurrent thrombosis and 5%–10% of unselected cases of acute venous thrombosis. Additional causes of thrombophilia include gain of function mutations such as the factor V Leiden mutation and the prothrombin 20210 mutation, elevated clotting factor and cofactor levels, and hyperhomocysteinemia that together account for the greater number of hypercoagulable patients. Although the loss of function mutations is less common, they are associated with the greatest thrombosis risk. Some patients have multiple inherited risk factors or combinations of inherited and acquired risk factors as discussed below. These individuals are at higher risk for recurrent thrombotic events and are often considered candidates for lifelong therapy.

### **ACQUIRED DISEASE**

The increased risk of thromboembolism associated with atrial fibrillation and with the placement of mechanical heart valves has long been recognized. Similarly, prolonged bed rest, high-risk surgical procedures, and the presence of cancer are clearly associated with an increased incidence of deep venous thrombosis and embolism. Antiphospholipid antibody syndrome is another important acquired risk factor. Drugs may function as synergistic risk factors in concert with inherited risk factors. For example, women who have the factor V Leiden mutation and take oral contraceptives have a synergistic increase in risk.

## **Antithrombotic Management**

### **PREVENTION**

Primary prevention of venous thrombosis reduces the incidence of and mortality rate from pulmonary emboli. Heparin and warfarin may be used to prevent venous thrombosis. Subcutaneous administration of low-dose unfractionated heparin, low-molecular-weight heparin, or fondaparinux provides effective prophylaxis. Warfarin is also effective but requires laboratory monitoring of the prothrombin time.

### **TREATMENT OF ESTABLISHED DISEASE**

Treatment for established venous thrombosis is initiated with unfractionated or low-molecular-weight heparin for the first 5–7 days, with an overlap with warfarin. Once therapeutic effects of warfarin have been established, therapy with warfarin is continued for a minimum of 3–6 months. Patients with recurrent disease or identifiable, nonreversible risk factors may be treated indefinitely. Small thrombi confined to the calf veins may be managed without anticoagulants if there is documentation over time that the thrombus is not extending.

Warfarin readily crosses the placenta. It can cause hemorrhage at any time during pregnancy as well as developmental defects when administered during the first trimester. Therefore, venous thromboembolic disease in pregnant women is generally treated with heparin, best administered by subcutaneous injection.

## **ARTERIAL THROMBOSIS**

Activation of platelets is considered an essential process for arterial thrombosis. Thus, treatment with platelet-inhibiting drugs such as aspirin and clopidogrel or ticlopidine is indicated in patients with transient ischemic attacks and strokes or unstable angina and acute myocardial infarction. In angina and infarction, these drugs are often used in conjunction with  $\beta$  blockers, calcium channel blockers, and fibrinolytic drugs.

## **DRUGS USED IN BLEEDING DISORDERS**

### **VITAMIN K**

Vitamin K confers biologic activity upon prothrombin and factors VII, IX, and X by participating in their postribosomal modification. Vitamin K is a fat-soluble substance found primarily in leafy green vegetables. The dietary requirement is low, because the vitamin is additionally synthesized by bacteria that colonize the human intestine. Two natural forms exist: vitamins K<sub>1</sub> and K<sub>2</sub>. Vitamin K<sub>1</sub> (phytonadione; Figure 34–5) is found in food. Vitamin K<sub>2</sub> (menaquinone) is found in human tissues and is synthesized by intestinal bacteria.

Vitamins K<sub>1</sub> and K<sub>2</sub> require bile salts for absorption from the intestinal tract. Vitamin K<sub>1</sub> is available clinically in oral and parenteral forms. Onset of effect is delayed for 6 hours but the effect is complete by 24 hours when treating depression of prothrombin activity by excess warfarin or vitamin K deficiency. Intravenous administration of vitamin K<sub>1</sub> should be slow, because rapid infusion can produce dyspnea, chest and back pain, and even death. Vitamin K repletion is best achieved with intravenous or oral administration, because its bioavailability after subcutaneous administration is erratic. Vitamin K<sub>1</sub> is

currently administered to all newborns to prevent the hemorrhagic disease of vitamin K deficiency, which is especially common in premature infants. *The water-soluble salt of vitamin K<sub>3</sub> (menadione) should never be used in therapeutics.* It is particularly ineffective in the treatment of warfarin overdosage. Vitamin K deficiency frequently occurs in hospitalized patients in intensive care units because of poor diet, parenteral nutrition, recent surgery, multiple antibiotic therapy, and uremia. Severe hepatic failure results in diminished protein synthesis and a hemorrhagic diathesis that is unresponsive to vitamin K.

## PLASMA FRACTIONS

### Sources & Preparations

Deficiencies in plasma coagulation factors can cause bleeding (Table 34-3). Spontaneous bleeding occurs when factor activity is less than 5-10% of normal. Factor VIII deficiency (**classic hemophilia, or hemophilia A**) and factor IX deficiency (**Christmas disease, or hemophilia B**) account for most of the heritable coagulation defects. Concentrated plasma fractions are available for the treatment of these deficiencies. Administration of plasma-derived, heat- or detergent-treated factor concentrates and recombinant factor concentrates are the standard treatments for bleeding associated with hemophilia. Lyophilized factor VIII concentrates are prepared from large pools of plasma. Transmission of viral diseases such as hepatitis B and C and HIV is reduced or eliminated by pasteurization and by extraction of plasma with solvents and detergents. However, this treatment does not remove other potential causes of transmissible diseases such as prions. For this reason, recombinant clotting factor preparations are recommended whenever possible for factor replacement. The best use of these therapeutic materials requires diagnostic specificity of the deficient factor and quantitation of its activity in plasma. Intermediate purity factor VIII concentrates (as opposed to recombinant or high purity concentrates) contain significant amounts of von Willebrand factor. Humate-P is a factor VIII concentrate that is approved by the FDA for the treatment of bleeding associated with von Willebrand disease.

**Table 34-3 Therapeutic Products for the Treatment of Coagulation Disorders.**

Factor	Deficiency State	Hemostatic Levels	Half-Life of Infused Factor	Replacement Source
I	Hypofibrinogenemia	1 g/dL	4 days	Cryoprecipitate FFP
II	Prothrombin deficiency	30-40%	3 days	Prothrombin complex concentrates (intermediate purity factor IX concentrates)
V	Factor V deficiency	20%	1 day	FFP
VII	Factor VII deficiency	30%	4-6 hours	FFP Prothrombin complex concentrates (intermediate purity factor IX concentrates) Recombinant factor VIIa
VIII	Hemophilia A	30-50% 100% for major bleeding or trauma	12 hours	Recombinant factor VIII products Plasma-derived high purity concentrates Cryoprecipitate <sup>1</sup> Some patients with mild deficiency will respond to DDAVP
IX	Hemophilia B Christmas disease	30-50% 100% for major bleeding or trauma	24 hours	Recombinant factor IX products Plasma-derived high purity concentrates
X	Stuart-Prower defect	25%	36 hours	FFP Prothrombin complex concentrates
XI	Hemophilia C	30-50%	3 days	FFP
XII	Hageman defect	Not required		Treatment not necessary
Von Willebrand disease	Von Willebrand disease	30%	Approximately 10 hours	Intermediate purity factor VIII concentrates that contain von Willebrand factor.

				Some patients respond to DDAVP
				Cryoprecipitate <sup>1</sup>
XIII	Factor XIII deficiency	5%	6 days	FFP Cryoprecipitate

FFP, fresh frozen plasma; DDAVP, 1-deamino-8-D-arginine vasopressin.

Antithrombin and activated protein C concentrates are available for the appropriate indications that include thrombosis in the setting of antithrombin deficiency and sepsis respectively.

<sup>1</sup>Cryoprecipitate should be used to treat bleeding in the setting of factor VIII deficiency and von Willebrand disease only in an emergency in which pathogen-inactivated products are not available.

### Clinical Uses

An uncomplicated hemorrhage into a joint should be treated with sufficient factor VIII or factor IX replacement to maintain a level of at least 30–50% of the normal concentration for 24 hours. Soft tissue hematomas require a minimum of 100% activity for 7 days. Hematuria requires at least 10% activity for 3 days. Surgery and major trauma require a minimum of 100% activity for 10 days. The initial loading dose for factor VIII is 50 units/kg of body weight to achieve 100% activity of factor VIII from a baseline of 1% or less, assuming a normal hemoglobin. Each unit of factor VIII per kilogram of body weight raises its activity in plasma 2%. Replacement should be administered every 12 hours. Factor IX therapy requires twice the dose of factor VIII, but with an administration of about every 24 hours because of its longer half-life. Recombinant factor IX has only 80% recovery compared with plasma-derived factor IX products. Therefore, dosing with recombinant factor IX requires 120% of the dose used with the plasma-derived product.

**Desmopressin acetate** increases the factor VIII activity of patients with mild hemophilia A or von Willebrand disease. It can be used in preparation for minor surgery such as tooth extraction without any requirement for infusion of clotting factors if the patient has a documented adequate response. High-dose intranasal desmopressin (see Chapter 17) is available and has been shown to be efficacious and well tolerated by patients.

Freeze-dried concentrates of plasma containing prothrombin, factors IX and X, and varied amounts of factor VII (Proplex, etc) are commercially available for treating deficiencies of these factors (Table 34–3). Each unit of factor IX per kilogram of body weight raises its activity in plasma 1.5%. Heparin is often added to inhibit coagulation factors activated by the manufacturing process. However, addition of heparin does not eliminate all thromboembolic risk.

Some preparations of factor IX concentrate contain *activated* clotting factors, which has led to their use in treating patients with inhibitors or antibodies to factor VIII or factor IX. Two products are available expressly for this purpose: **Autoplex** (with factor VIII correctional activity) and **FEIBA** (Factor Eight Inhibitor Bypassing Activity). These products are not uniformly successful in arresting hemorrhage, and the factor IX inhibitor titers often rise after treatment with them. Acquired inhibitors of coagulation factors may also be treated with porcine factor VIII (for factor VIII inhibitors) and recombinant activated factor VII. Recombinant activated factor VII (**NovoSeven**) is being increasingly used to treat coagulopathy associated with liver disease and major blood loss in trauma and surgery. These recombinant and plasma-derived factor concentrates are very expensive, and the indications for them are very precise. Therefore, close consultation with a hematologist knowledgeable in this area is essential.

**Cryoprecipitate** is a plasma protein fraction obtainable from whole blood. It is used to treat deficiencies or qualitative abnormalities of fibrinogen, such as that which occurs with disseminated intravascular coagulation and liver disease. A single unit of cryoprecipitate contains 300 mg of fibrinogen.

Cryoprecipitate may also be used for patients with factor VIII deficiency and von Willebrand disease if desmopressin is not indicated and a pathogen-inactivated, recombinant, or plasma-derived product is not available. The concentration of factor VIII and von Willebrand factor in cryoprecipitate is not as great as that found in the concentrated plasma fractions. Moreover, cryoprecipitate is not treated in any manner to decrease the risk of viral exposure. For infusion, the frozen cryoprecipitate unit is thawed and dissolved in a small volume of sterile citrate-saline solution and pooled with other units. Rh-negative women with potential for childbearing should receive only Rh-negative cryoprecipitate because of possible contamination of the product with Rh-positive blood cells.

### FIBRINOLYTIC INHIBITORS: AMINOCAPROIC ACID

Aminocaproic acid (EACA), which is chemically similar to the amino acid lysine, is a synthetic inhibitor of fibrinolysis. It competitively inhibits plasminogen activation (Figure 34-3). It is rapidly absorbed orally and is cleared from the body by the kidney. The usual oral dosage of EACA is 6 g four times a day. When the drug is administered intravenously, a 5 g loading dose should be infused over 30 minutes to avoid hypotension. **Tranexamic acid** is an analog of aminocaproic acid and has the same properties. It is administered orally with a 15 mg/kg loading dose followed by 30 mg/kg every 6 hours, but the drug is not currently available in the USA.

Clinical uses of EACA are as adjunctive therapy in hemophilia, as therapy for bleeding from fibrinolytic therapy, and as prophylaxis for rebleeding from intracranial aneurysms. Treatment success has also been reported in patients with postsurgical gastrointestinal bleeding and postprostatectomy bleeding and bladder hemorrhage secondary to radiation- and drug-induced cystitis. Adverse effects of the drug include intravascular thrombosis from inhibition of plasminogen activator, hypotension, myopathy, abdominal discomfort, diarrhea, and nasal stuffiness. The drug should not be used in patients with disseminated intravascular coagulation or genitourinary bleeding of the upper tract, eg, kidney and ureters, because of the potential for excessive clotting.

### **SERINE PROTEASE INHIBITORS: APROTININ**

Aprotinin is a serine protease inhibitor (serpin) that inhibits fibrinolysis by free plasmin and may have other antihemorrhagic effects as well. It also inhibits the plasmin-streptokinase complex in patients who have received that thrombolytic agent. Aprotinin was shown to reduce bleeding by as much as 50% from many types of surgery, especially that involving extracorporeal circulation for open heart procedures and liver transplantation. However, clinical trials and internal data from the manufacturer suggested that use of the drug was associated with an increased risk of renal failure, heart attack, and stroke. A prospective trial was initiated in Canada but halted early because of concerns that use of the drug was associated with increased mortality. The drug was removed from the market in 2007.

### **PREPARATIONS AVAILABLE**

#### **Abciximab** (ReoPro)

Parenteral: 2 mg/mL for IV injection

#### **Alteplase recombinant** [t-PA] (Activase\*)

Parenteral: 50, 100 mg lyophilized powder to reconstitute for IV injection; 2 mg for catheter clots

#### **Aminocaproic acid** (generic, Amicar)

Oral: 500 mg tablets; 250 mg/mL syrup

Parenteral: 250 mg/mL for IV injection

#### **Anisindione** (Miradon)

Oral: 50 mg tablets

#### **Antihemophilic factor** [factor VIII, AHF] (Alphanate, Bioclone,\* Helixate,\* Hemofil M, Koate-HP, Kogenate,\* Monoclate, Recombinate,\* others)

Parenteral: in vials

#### **Anti-inhibitor coagulant complex** (Autoplex T, Feiba VH Immuno)

Parenteral: in vials

#### **Antithrombin III** (Thrombate III)

Parenteral: 500, 1000 IU powder to reconstitute for IV injection

#### **Argatroban**

Parenteral: 100 mg/mL in 2.5 mL vials

**Bivalirudin** (Angiomax)

Parenteral: 250 mg per vial

**Cilostazol** (generic, Pletal)

Oral: 50, 100 mg tablets

**Clopidogrel** (generic, Plavix)

Oral: 75 mg tablets

**Coagulation factor VIIa recombinant** (Novo-Seven\*)

Parenteral: 1.2, 4.8 mg powder/vial for IV injection

**Dalteparin** (Fragmin)

Parenteral: 2500, 5000, 10000, 15000, 18000 anti-factor Xa units/0.2 mL for SC injection only

**Danaparoid** (Orgaran)

Parenteral: 750 anti-Xa units/vial

Desirudin (Iprivask)

Parenteral: 15 mg for injection

**Dipyridamole** (generic, Persantine)

Oral: 25, 50, 75 mg tablets

Oral combination product (Aggrenox): 200 mg extended-release dipyridamole plus 25 mg extended-release dipyridamole plus 25 mg aspirin

**Enoxaparin** (low-molecular-weight heparin, Lovenox)

Parenteral: pre-filled, multiple-dose syringes for SC injection only

**Eptifibatide** (Integrilin)

Parenteral: 0.75, 2 mg/mL for IV infusion

**Factor VIIa:** see Coagulation factor VIIa recombinant

**Factor VIII:** see Antihemophilic factor

**Factor IX** complex, human (AlphaNine SD, Bebulin VH, BeneFix\*, Konyne 80, Mononine, Profilnine SD, Proplex T, Proplex SX-T)

Parenteral: in vials

**Fondaparinux** (Arixtra)

Parenteral: 2.5, 5, 7.5, 10 mg in single-dose pre-filled syringes

**Heparin sodium** (generic, Liquaemin)

Parenteral: 1000, 2000, 2500, 5000, 10,000, 20,000, 40,000 units/mL for injection

**Lepirudin** (Refludan\*)

Parenteral: 50 mg powder for IV injection

**Phytonadione [K<sub>1</sub> ]** (generic, Mephyton, Aqua-Mephyton)

Oral: 5 mg tablets

Parenteral: 2, 10 mg/mL aqueous colloidal solution or suspension for injection

**Protamine** (generic)

Parenteral: 10 mg/mL for injection

**Retepase** (Retavase\*)

Parenteral: 10.4 IU powder for injection

**Streptokinase** (Streptase)

Parenteral: 250,000, 750,000, 1,500,000 IU per vial powders to reconstitute for injection

**Tenecteplase** (TNKase\*)

Parenteral: 50 mg powder for injection

**Ticlopidine** (Ticlid)

Oral: 250 mg tablets

**Tinzaparin** (Innohep)

Parenteral: 20,000 anti-Xa units/mL for subcutaneous injection only

**Tirofiban** (Aggrastat)

Parenteral: 50, 250 mcg/mL for IV infusion

**Tranexamic acid** (Cyklokapron)

Oral: 500 mg tablets

Parenteral: 100 mg/mL for IV infusion

**Urokinase** (Abbokinase)

Parenteral: 250,000 IU per vial for systemic use

**Warfarin** (generic, Coumadin)

Oral: 1, 2, 2.5, 3, 4, 5, 6, 7.5, 10 mg tablets

\*Recombinant product.

## ACRONYMS

**Apo:** Apolipoprotein

**CETP:** Cholesteryl ester transfer protein

**CK:** Creatine kinase

**HDL:** High-density lipoproteins

**HMG-CoA:** 3-Hydroxy-3-methylglutarylcoenzyme A

**IDL:** Intermediate-density lipoproteins

**LCAT:** Lecithin:cholesterol acyltransferase

**LDL:** Low-density lipoproteins

**Lp(a):** Lipoprotein(a)

**LPL:** Lipoprotein lipase

**PPAR:** Peroxisome proliferator-activated receptor

**VLDL:** Very-low-density lipoproteins

## CASE STUDY

RL, a 42-year-old man with moderately severe coronary artery disease, has a body mass index (BMI) of 29, increased abdominal girth, and hypertension that is well controlled. In addition to medicine for hypertension, he is taking 40 mg atorvastatin. Current lipid panel (mg/dL): cholesterol 184, triglycerides 200, low-density lipoprotein cholesterol (LDL-C) 110, HDL-C 34, non-HDL-C 150. Lipoprotein(a) (Lp[a]) is twice normal. Fasting glucose is 102 mg/dL, and fasting insulin is 38  $\mu$ U/mL. Liver enzymes are normal. Creatine kinase level is mildly elevated. The patient is referred for help with management of his dyslipidemia. You advise dietary measures, exercise, and weight loss. Which additional drugs would help him achieve his lipoprotein treatment goals (LDL-C  $\leq$  70 mg/dL, triglycerides < 120 mg/dL, HDL > 45 mg/dL, and reduced level of Lp[a])? Would this patient benefit also from a drug to manage insulin resistance? If so, which drug?

## AGENTS USED IN DYSLIPIDEMIA: INTRODUCTION

Plasma lipids are transported in complexes called **lipoproteins**. Metabolic disorders that involve elevations in any lipoprotein species are termed **hyperlipoproteinemias** or **hyperlipidemias**. **Hyperlipemia** denotes increased levels of triglycerides.

The two major clinical sequelae of hyperlipidemias are acute pancreatitis and atherosclerosis. The former occurs in patients with marked hyperlipemia. Control of triglycerides can prevent recurrent attacks of this life-threatening disease.

Atherosclerosis is the leading cause of death for both genders in the USA and other Western countries. Lipoproteins that contain **apolipoprotein (apo) B-100** convey lipids into the artery wall. These are **low-density (LDL)**, **intermediate-density (IDL)**, **very-low-density (VLDL)**, and **lipoprotein(a) (Lp[a])**.

Cellular components in atherosclerotic plaques include foam cells, which are transformed macrophages, and smooth

muscle cells filled with **cholesteryl esters**. These cellular alterations result from endocytosis of modified lipoproteins via at least four species of **scavenger receptors**. Chemical modification of lipoproteins by free radicals creates ligands for these receptors. The atheroma grows with the accumulation of foam cells, collagen, fibrin, and frequently calcium. Whereas such lesions can slowly occlude coronary vessels, clinical symptoms are more frequently precipitated by rupture of unstable atheromatous plaques, leading to activation of platelets and formation of occlusive thrombi.

Although treatment of hyperlipidemia can cause slow physical regression of plaques, the well-documented reduction in acute coronary events that follows vigorous lipid-lowering treatment is attributable chiefly to mitigation of the inflammatory activity of macrophages and is evident within 2–3 months after starting therapy.

**High-density lipoproteins (HDL)** exert several *anti*atherogenic effects. They participate in retrieval of cholesterol from the artery wall and inhibit the oxidation of atherogenic lipoproteins. Low levels of HDL (hypoalphalipoproteinemia) are an independent risk factor for atherosclerotic disease and thus are a target for intervention.

Cigarette smoking is a major risk factor for coronary disease. It is associated with reduced levels of HDL, impairment of cholesterol retrieval, cytotoxic effects on the endothelium, increased oxidation of lipoproteins, and stimulation of thrombogenesis. Diabetes, also a major risk factor, is another source of oxidative stress.

Normal coronary arteries can dilate in response to ischemia, increasing delivery of oxygen to the myocardium. This process is mediated by nitric oxide, acting on smooth muscle cells of the arterial media. This function is impaired by atherogenic lipoproteins, thus aggravating ischemia. Reducing levels of atherogenic lipoproteins and inhibiting their oxidation restores endothelial function.

Because atherogenesis is multifactorial, therapy should be directed toward all modifiable risk factors. Atherogenesis is a dynamic process. Quantitative angiographic trials have demonstrated net regression of plaques during aggressive lipid-lowering therapy. Primary and secondary prevention trials have shown significant reduction in mortality from new coronary events and in all-cause mortality.

## **PATHOPHYSIOLOGY OF HYPERLIPOPROTEINEMIA**

### **Normal Lipoprotein Metabolism**

#### **Structure**

Lipoproteins have hydrophobic core regions containing cholesteryl esters and triglycerides surrounded by unesterified cholesterol, phospholipids, and apoproteins. Certain lipoproteins contain very high-molecular-weight B proteins that exist in two forms: **B-48**, formed in the intestine and found in chylomicrons and their remnants; and **B-100**, synthesized in liver and found in **VLDL**, **VLDL remnants (IDL)**, **LDL** (formed from VLDL), and **Lp(a) lipoproteins**. HDL consist of at least 15 discrete molecular species. All species contain apolipoprotein A-I (apoA-I). Fifty-three other proteins are known to be distributed variously among the HDL species.

#### **Synthesis & Catabolism**

##### **CHYLOMICRONS**

Chylomicrons are formed in the intestine and carry **triglycerides** of dietary origin, **unesterified cholesterol**, and **cholesteryl esters**. They transit the thoracic duct to the bloodstream.

Triglycerides are removed in extrahepatic tissues through a pathway shared with VLDL that involves hydrolysis by the **lipoprotein lipase (LPL)** system. Decrease in particle diameter occurs as triglycerides are depleted. Surface lipids and small apoproteins are transferred to HDL. The resultant chylomicron remnants are taken up by receptor-mediated endocytosis into hepatocytes.

##### **VERY-LOW-DENSITY LIPOPROTEINS**

VLDL are secreted by liver and export triglycerides to peripheral tissues (Figure 35–1). VLDL triglycerides are hydrolyzed by LPL, yielding free fatty acids for storage in adipose tissue and for oxidation in tissues such as cardiac and skeletal muscle. Depletion of triglycerides produces remnants (IDL), some of which undergo endocytosis directly by liver. The remainder is converted to LDL by further removal of triglycerides mediated by hepatic lipase. This

process explains the "beta shift" phenomenon, the increase of LDL (beta-lipoprotein) in serum with hypertriglyceridemia subsides. Increased levels of LDL can also result from increased secretion of VLDL and from decreased LDL catabolism.

**Figure 35-1**

Metabolism of lipoproteins of hepatic origin. The heavy arrows show the primary pathways. Nascent VLDL are secreted via the Golgi apparatus. They acquire additional apoC lipoproteins and apolipoprotein E (apoE) from HDL. Very-low-density lipoproteins (VLDL) are converted to VLDL remnants (IDL) by lipolysis via lipoprotein lipase in the vessels of peripheral tissues. In the process, C apolipoproteins and a portion of the apoE are given back to high-density lipoproteins (HDL). Some of the VLDL remnants are converted to LDL by further loss of triglycerides and loss of apoE. A major pathway for LDL degradation involves the endocytosis of LDL by LDL receptors in the liver and the peripheral tissues, for which apo B-100 is the ligand. Dark color denotes cholesteryl esters; light color denotes triglycerides; the asterisk denotes a functional ligand for LDL receptors; triangles indicate apoE; circles and squares represent C apolipoproteins. FFA, free fatty acid; RER, rough endoplasmic reticulum.

(Modified and redrawn, with permission, from Kane J, Malloy M: Disorders of lipoproteins. In: Rosenberg RN et al [editors]: *The Molecular and Genetic Basis of Neurological Disease*. Butterworth-Heinemann, 1993.)

### LOW-DENSITY LIPOPROTEINS

LDL is catabolized chiefly in hepatocytes and other cells by receptor-mediated endocytosis. Cholesteryl esters from

LDL are hydrolyzed, yielding free cholesterol for the synthesis of cell membranes. Cells also obtain cholesterol by synthesis via a pathway involving the formation of mevalonic acid by HMG-CoA reductase. Production of this enzyme and of LDL receptors is transcriptionally regulated by the content of cholesterol in the cell. Normally, about 70% of LDL is removed from plasma by hepatocytes. Even more cholesterol is delivered to the liver via IDL and chylomicrons. Unlike other cells, hepatocytes can eliminate cholesterol by secretion in bile and by conversion to bile acids.

### LP(A) LIPOPROTEIN

Lp(a) lipoprotein is formed from LDL and the (a) protein, linked by a disulfide bridge. The (a) protein is highly homologous with plasminogen but is not activated by tissue plasminogen activator. It occurs in a number of isoforms of different molecular weights. Levels of Lp(a) vary from nil to over 500 mg/dL and are determined chiefly by genetic factors. Lp(a) can be found in atherosclerotic plaques and may also contribute to coronary disease by inhibiting thrombolysis. Levels are elevated in certain inflammatory states. The risk of coronary disease is strongly related to the apo(a) genotype at a single polymorphic site in the coding region (SNP rs3798220).

### HIGH-DENSITY LIPOPROTEINS

The apoproteins of HDL are secreted by the liver and intestine. Much of the lipid comes from the surface monolayers of chylomicrons and VLDL during lipolysis. HDL also acquires cholesterol from peripheral tissues, protecting the cholesterol homeostasis of cells. Free cholesterol is transported from the cell membrane by a transporter, ABCA1, acquired by a small particle termed prebeta-1 HDL, and then esterified by lecithin:cholesterol acyltransferase (LCAT), leading to the formation of larger HDL species. Cholesterol is also exported from macrophages by the ABCG1 transporter to large HDL particles. The cholesteryl esters are transferred to VLDL, IDL, LDL, and chylomicron remnants with the aid of cholesteryl ester transfer protein (CETP). Much of the cholesteryl ester thus transferred is ultimately delivered to the liver by endocytosis of the acceptor lipoproteins. HDL can also deliver cholesteryl esters directly to the liver via a docking receptor (scavenger receptor, SR-BI) that does not cause endocytosis of the lipoproteins.

## Lipoprotein Disorders

Lipoprotein disorders are detected by measuring lipids in serum after a 10-hour fast. Risk of heart disease increases with concentrations of the atherogenic lipoproteins, is inversely related to levels of HDL, and is modified by other risk factors (Table 35-1). Evidence from clinical trials suggests that LDL cholesterol levels of 60 mg/dL may be optimal for patients with coronary disease. Ideally, triglycerides should be below 120 mg/dL. Differentiation of the disorders requires identification of the lipoproteins involved (Table 35-2). Diagnosis of a primary disorder usually requires further clinical and genetic data as well as ruling out secondary hyperlipidemias (Table 35-3).

**Table 35-1 National Cholesterol Education Program: Adult Treatment Guidelines (2001).**

	<b>Desirable</b>	<b>Borderline to High<sup>1</sup></b>	<b>High</b>
Total cholesterol	< 200 (5.2) <sup>2</sup>	200-239 (5.2-6.2) <sup>2</sup>	> 240 (6.2) <sup>2</sup>
LDL cholesterol	< 130 (3.4) <sup>3</sup>	130-159 (3.4-4.1)	> 160 (4.1)
HDL cholesterol			> 60 (1.55)
Men	> 40 (1.04)		
Women	> 50 (1.30)		
Triglycerides	< 120 (1.4)	120-199 (1.4-2.3)	> 200 (2.3)

<sup>1</sup>Consider as high if coronary disease or more than 2 risk factors are present.

<sup>2</sup>mg/dL (mmol/L).

<sup>3</sup>Optimal level is < 100 (2.6); if known atherosclerotic disease, goal is 60–70 mg/dL.

**Table 35–2 The Primary Hyperlipoproteinemias and Their Drug Treatment.**

Disorder	Manifestations	Single Drug <sup>1</sup>	Drug Combination	
Primary chylomicronemia (familial lipoprotein lipase or cofactor deficiency)	Chylomicrons, VLDL increased	Dietary management (niacin, fibrate)	Niacin plus fibrate	
Familial hypertriglyceridemia—Severe	VLDL, chylomicrons increased	Niacin, fibrate	Niacin plus fibrate	
Moderate	VLDL increased; chylomicrons may be increased	Niacin, fibrate		
Familial combined hyperlipoproteinemia	VLDL predominantly increased	Niacin, fibrate, reductase inhibitor	Two or three of the individual drugs	
	LDL predominantly increased	Niacin, reductase inhibitor, ezetimibe	Two or three of the individual drugs	
	VLDL, LDL increased	Niacin, reductase inhibitor	Niacin or fibrate plus reductase inhibitor <sup>2</sup>	
Familial dysbetalipoproteinemia	VLDL remnants, chylomicron remnants increased	Fibrate, niacin	Fibrate plus niacin, or either, plus reductase inhibitor	
Familial hypercholesterolemia	LDL increased	Heterozygous	Reductase inhibitor, resin, niacin, ezetimibe	Two or three of the individual drugs
		Homozygous	Niacin, atorvastatin, ezetimibe, rosuvastatin	Niacin plus reductase inhibitor plus ezetimibe
Familial ligand-defective apo B	LDL increased	Niacin, reductase inhibitor, ezetimibe	Niacin plus reductase inhibitor or ezetimibe	
Lp(a) hyperlipoproteinemia	Lp(a) increased	Niacin		

<sup>1</sup>Single-drug therapy should be evaluated before drug combinations are used.

<sup>2</sup>Select pharmacologically compatible reductase inhibitor (see text).

**Table 35–3 Secondary Causes of Hyperlipoproteinemia.**

**Hypertriglyceridemia**

Diabetes mellitus  
 Alcohol ingestion  
 Severe nephrosis  
 Estrogens  
 Uremia

**Hypercholesterolemia**

Hypothyroidism  
 Early nephrosis  
 Resolving lipemia  
 Immunoglobulin-lipoprotein complex disorders  
 Anorexia nervosa

Corticosteroid excess	Cholestasis
Myxedema	Hypopituitarism
Glycogen storage disease	Corticosteroid excess
Hypopituitarism	
Acromegaly	
Immunoglobulin-lipoprotein complex disorders	
Lipodystrophy	
Isotretinoin	
Protease inhibitors	

Phenotypes of abnormal lipoprotein distribution are described in this section. Drugs mentioned for use in these conditions are described in the following section on basic and clinical pharmacology.

## The Primary Hypertriglyceridemias

Hypertriglyceridemia is associated with increased risk of coronary disease. VLDL and IDL have been found in atherosclerotic plaques. These patients tend to have cholesterol-rich VLDL of small-particle diameter and small, dense LDL. Hypertriglyceridemic patients with coronary disease or risk equivalents should be treated aggressively. Patients with triglycerides above 700 mg/dL should be treated to prevent acute pancreatitis because the LPL clearance mechanism is saturated at about this level.

Hypertriglyceridemia is an essential component of the metabolic syndrome, which also includes low levels of HDL-C, insulin resistance, hypertension, and abdominal obesity. Hyperuricemia is also frequently present. Insulin resistance appears to be central to this process. Management of these patients frequently requires, in addition to a fibrate or niacin, the use of metformin or a peroxisome proliferator-activated receptor $\gamma$  (PPAR- $\gamma$ ) agonist or both (see Chapter 41). In the latter case, pioglitazone is the drug of choice because it reduces triglycerides and does not increase levels of LDL. The severity of hypertriglyceridemia of any cause is increased in the presence of the metabolic syndrome or type 2 diabetes.

### Primary Chylomicronemia

Chylomicrons are not present in the serum of normal individuals who have fasted 10 hours. The recessive traits of deficiency of LPL or its cofactor are usually associated with severe lipemia (2000–3000 mg/dL of triglycerides when the patient is consuming a typical American diet). These disorders might not be diagnosed until an attack of acute pancreatitis occurs. Patients may have eruptive xanthomas, hepatosplenomegaly, hypersplenism, and lipid-laden foam cells in bone marrow, liver, and spleen. The lipemia is aggravated by estrogens because they stimulate VLDL production, and pregnancy may cause marked increases in triglycerides despite strict dietary control. Although these patients have a predominant chylomicronemia, they may also have moderately elevated VLDL, presenting with a pattern called mixed lipemia (fasting chylomicronemia and elevated VLDL). LPL deficiency is diagnosed by assay of lipolytic activity after intravenous injection of heparin. A presumptive diagnosis is made by demonstrating a pronounced decrease in triglycerides a few days after reduction of daily fat intake below 15 g. Marked restriction of total dietary fat is the basis of effective long-term treatment. Niacin or a fibrate may be of some benefit if VLDL levels are increased. Genetic variants at other loci that participate in intravascular lipolysis, including LMF1, apoA-V, and apoC-III, can have profound effects on triglyceride levels.

### Familial Hypertriglyceridemia

#### SEVERE (USUALLY MIXED LIPEMIA)

Mixed lipemia usually results from impaired removal of triglyceride-rich lipoproteins. Factors that increase VLDL production aggravate the lipemia because VLDL and chylomicrons are competing substrates for LPL. The primary mixed lipemias probably reflect a variety of genetic determinants. Most patients have centripetal obesity with insulin resistance. Other factors that increase secretion of VLDL also worsen the lipemia. Eruptive xanthomas, lipemia retinalis, epigastric pain, and pancreatitis are variably present depending on the severity of the lipemia. Treatment is primarily dietary, with restriction of total fat, avoidance of alcohol and exogenous estrogens, weight reduction,

exercise, and supplementation with marine omega-3 fatty acids. Most patients also require treatment with a fibrate or niacin.

#### **MODERATE**

Primary increases of VLDL also reflect a genetic predisposition and are worsened by factors that increase the rate of VLDL secretion from liver, ie, obesity, alcohol, diabetes, and estrogens. Treatment includes addressing these issues and the use of fibrates or niacin as needed. Marine omega-3 fatty acids are a valuable adjuvant.

#### **Familial Combined Hyperlipoproteinemia**

In this common disorder associated with an increased incidence of coronary disease, individuals may have elevated levels of VLDL, LDL, or both, and the pattern may change with time. Familial combined hyperlipoproteinemia involves an approximate doubling in VLDL secretion and appears to be transmitted as a semidominant trait. Triglycerides can be increased by the factors noted above. Elevations of cholesterol and triglycerides are generally moderate, and xanthomas are usually absent. Diet alone does not normalize lipid levels. A reductase inhibitor alone, or in combination with niacin or fenofibrate, is usually required to treat these patients. When fenofibrate is combined with a reductase inhibitor, either pravastatin or rosuvastatin is recommended because neither is metabolized via CYP3A4.

#### **Familial Dysbetalipoproteinemia**

In this disorder, remnants of chylomicrons and VLDL accumulate and levels of LDL are decreased. Because remnants are rich in cholesteryl esters, the level of cholesterol may be as high as that of triglycerides. Diagnosis is confirmed by the absence of the  $\epsilon 3$  and  $\epsilon 4$  alleles of apoE, the  $\epsilon 2/\epsilon 2$  genotype. Patients often develop tuberous or tuberoeruptive xanthomas, or characteristic planar xanthomas of the palmar creases. They tend to be obese, and some have impaired glucose tolerance. These factors, as well as hypothyroidism, can aggravate the lipemia. Coronary and peripheral atherosclerosis occur with increased frequency. Weight loss, together with decreased fat, cholesterol, and alcohol consumption, may be sufficient, but a fibrate or niacin is usually needed to control the condition. These agents can be given together in more resistant cases, or a reductase inhibitor may be added.

ApoE is also secreted by glia in the central nervous system and plays a role in sterol transport. The  $\epsilon 4$  allele is associated in a dose-dependent manner with early-onset Alzheimer's disease (see Chapter 60).

### **The Primary Hypercholesterolemias**

#### **Familial Hypercholesterolemia**

Familial hypercholesterolemia is an autosomal dominant trait. Although levels of LDL tend to increase throughout childhood, the diagnosis can often be made on the basis of elevated umbilical cord blood cholesterol. In most heterozygotes, cholesterol levels range from 260 to 500 mg/dL. Triglycerides are usually normal, tendon xanthomas are often present, and arcus corneae and xanthelasma may appear in the third decade. Coronary disease tends to occur prematurely. In homozygous familial hypercholesterolemia, which can lead to coronary disease in childhood, levels of cholesterol often exceed 1000 mg/dL and early tuberous and tendinous xanthomas occur. These patients may also develop elevated plaque-like xanthomas of the aortic valve, digital webs, buttocks, and extremities.

Defects of LDL receptors underlie familial hypercholesterolemia. Some individuals have combined heterozygosity for alleles producing nonfunctional and kinetically impaired receptors. In heterozygous patients, LDL can be normalized with combined drug regimens (Figure 35â€2). Homozygotes and those with combined heterozygosity whose receptors retain even minimal function may partially respond to niacin, ezetimibe, or reductase inhibitors.

#### **Figure 35â€2**

Sites of action of HMG-CoA reductase inhibitors, niacin, ezetimibe, and resins used in treating hyperlipidemias. Low-density lipoprotein (LDL) receptors are increased by treatment with resins and HMG-CoA reductase inhibitors. VLDL, very-low-density lipoproteins; R, LDL receptor.

### Familial Ligand-Defective Apolipoprotein B

Defects in the domain of apo B-100 that binds to the LDL receptor impair the endocytosis of LDL, leading to hypercholesterolemia of moderate severity. Tendon xanthomas may occur. These disorders are as prevalent as familial hypercholesterolemia. Response to reductase inhibitors is variable. Up-regulation of LDL receptors in liver increases endocytosis of LDL precursors but does not increase uptake of ligand-defective LDL particles. Niacin often has beneficial effects by reducing VLDL production.

### Familial Combined Hyperlipoproteinemia

As described, some persons with familial combined hyperlipoproteinemia have only an elevation in LDL. Serum cholesterol is usually less than 350 mg/dL. Dietary and drug treatment, usually with a reductase inhibitor, is indicated. It may be necessary to add niacin or ezetimibe to normalize LDL.

### LP(a) Hyperlipoproteinemia

This familial disorder, which is associated with increased atherogenesis, is determined chiefly by alleles that dictate increased production of the (a) protein moiety. Niacin reduces levels of Lp(a) in many patients.

### Other Disorders

Deficiency of cholesterol 7 $\alpha$ -hydroxylase can increase LDL in the heterozygous state. Homozygotes can also have elevated triglycerides, resistance to reductase inhibitors, and increased risk of gallstones and coronary disease. Autosomal recessive hypercholesterolemia is due to mutations in a protein that normally assists in endocytosis of

LDL. Some mutations in the *PCSK9* gene also cause isolated elevations of LDL. Niacin, ezetimibe, and reductase inhibitors may be useful, variably, in these disorders.

### **HDL Deficiency**

Rare genetic disorders, including Tangier disease and LCAT (lecithin:cholesterol acyltransferase) deficiency, are associated with extremely low levels of HDL. Familial hypoalphalipoproteinemia is a more common disorder with levels of HDL cholesterol usually below 35 mg/dL in men and 45 mg/dL in women. These patients tend to have premature atherosclerosis, and the low HDL may be the only identified risk factor. Management should include special attention to avoidance or treatment of other risk factors. Niacin increases HDL in many of these patients. Reductase inhibitors and fibric acid derivatives exert lesser effects.

In the presence of hypertriglyceridemia, HDL cholesterol is low because of exchange of cholesteryl esters from HDL into triglyceride-rich lipoproteins. Treatment of the hypertriglyceridemia may increase or normalize the HDL level.

### **Secondary Hyperlipoproteinemia**

Before primary disorders can be diagnosed, secondary causes of the phenotype must be considered. The more common conditions are summarized in Table 35-3. The lipoprotein abnormality usually resolves if the underlying disorder can be treated successfully.

## **DIETARY MANAGEMENT OF HYPERLIPOPROTEINEMIA**

Dietary measures are initiated first unless the patient has evident coronary or peripheral vascular disease and may obviate the need for drugs. Patients with familial hypercholesterolemia or familial combined hyperlipidemia always require drug therapy. Cholesterol and saturated and *trans*-fats are the principal factors that increase LDL, whereas total fat, alcohol, and excess calories increase triglycerides.

Sucrose and fructose raise VLDL. Alcohol can cause significant hypertriglyceridemia by increasing hepatic secretion of VLDL. Synthesis and secretion of VLDL are increased by excess calories. During weight loss, LDL and VLDL levels may be much lower than can be maintained during neutral caloric balance. The conclusion that diet suffices for management can be made only after weight has stabilized for at least 1 month.

General recommendations include limiting total calories from fat to 20-25% of daily intake, saturated fats to less than 8%, and cholesterol to less than 200 mg/d. Reductions in serum cholesterol range from 10% to 20% on this regimen. Use of complex carbohydrates and fiber is recommended, and *cis*-monounsaturated fats should predominate. Weight reduction, caloric restriction, and avoidance of alcohol are especially important for patients with elevated VLDL and IDL.

The effect of dietary fats on hypertriglyceridemia is dependent on the disposition of double bonds in the fatty acids. Omega-3 fatty acids found in fish oils, but not those from plant sources, activate peroxisome proliferator-activated receptor- $\alpha$  (PPAR- $\alpha$ ) and can induce profound reduction of triglycerides in some patients. They also have anti-inflammatory and antiarrhythmic activities. In contrast, the omega-6 fatty acids present in vegetable oils may cause triglycerides to increase.

Patients with primary chylomicronemia and some with mixed lipemia must consume a diet severely restricted in total fat (10-20 g/d, of which 5 g should be vegetable oils rich in essential fatty acids), and fat-soluble vitamins should be given.

Homocysteine, which initiates proatherogenic changes in endothelium, can be reduced in many patients by restriction of total protein intake to the amount required for amino acid replacement. Supplementation with folic acid plus other B vitamins is indicated in severe homocysteinemia.

## **BASIC & CLINICAL PHARMACOLOGY OF DRUGS USED IN HYPERLIPIDEMIA**

The decision to use drug therapy for hyperlipidemia is based on the specific metabolic defect and its potential for causing atherosclerosis or pancreatitis. Suggested regimens for the principal lipoprotein disorders are presented in Table 35-2. Diet should be continued to achieve the full potential of the drug regimen. These drugs should be avoided in pregnant and lactating women and those likely to become pregnant. All drugs that alter plasma

lipoprotein concentrations may require adjustment of doses of warfarin and indandione anticoagulants. Children with heterozygous familial hypercholesterolemia may be treated with a resin or reductase inhibitor, usually after 7 or 8 years of age, when myelination of the central nervous system is essentially complete. The decision to treat a child should be based on the level of LDL, other risk factors, the family history, and the child's age. Drugs are rarely indicated before age 16.

### Competitive Inhibitors of HMG-CoA Reductase (Reductase Inhibitors; "Statins")

These compounds are structural analogs of HMG-CoA (3-hydroxy-3-methylglutaryl-coenzyme A, Figure 35â€³). **Lovastatin, atorvastatin, fluvastatin, pravastatin, simvastatin, and rosuvastatin** belong to this class. They are most effective in reducing LDL. Other effects include decreased oxidative stress and vascular inflammation with increased stability of atherosclerotic lesions. It has become standard practice to initiate reductase inhibitor therapy immediately after acute coronary syndromes, regardless of lipid levels.

**Figure 35â€³**

Inhibition of HMG-CoA reductase. **Top:** The HMG-CoA intermediate that is the immediate precursor of mevalonate, a critical compound in the synthesis of cholesterol. **Bottom:** The structure of lovastatin and its active form, showing the similarity to the normal HMG-CoA intermediate (shaded areas).

### Chemistry & Pharmacokinetics

Lovastatin and simvastatin are inactive lactone prodrugs that are hydrolyzed in the gastrointestinal tract to the active  $\beta$ -hydroxyl derivatives, whereas pravastatin has an open, active lactone ring. Atorvastatin, fluvastatin, and rosuvastatin are fluorine-containing congeners that are active as given. Absorption of the ingested doses of the

reductase inhibitors varies from 40% to 75% with the exception of fluvastatin, which is almost completely absorbed. All have high first-pass extraction by the liver. Most of the absorbed dose is excreted in the bile; 5%–20% is excreted in the urine. Plasma half-lives of these drugs range from 1 to 3 hours except for atorvastatin, which has a half-life of 14 hours, and rosuvastatin, whose half-life is 19 hours.

### **Mechanism of Action**

HMG-CoA reductase mediates the first committed step in sterol biosynthesis. The active forms of the reductase inhibitors are structural analogs of the HMG-CoA intermediate (Figure 35-3) that is formed by HMG-CoA reductase in the synthesis of mevalonate. These analogs cause partial inhibition of the enzyme and thus may impair the synthesis of isoprenoids such as ubiquinone and dolichol and the prenylation of proteins. It is not known whether this has biologic significance. However, the reductase inhibitors clearly induce an increase in high-affinity LDL receptors. This effect increases both the fractional catabolic rate of LDL and the liver's extraction of LDL precursors (VLDL remnants) from the blood, thus reducing LDL (Figure 35-2). Because of marked first-pass hepatic extraction, the major effect is on the liver. Preferential activity in liver of some congeners appears to be attributable to tissue-specific differences in uptake. Modest decreases in plasma triglycerides and small increases in HDL also occur.

Clinical trials have demonstrated significant reduction of new coronary events and atherothrombotic stroke with statin therapy. Mechanisms other than reduction of lipoprotein levels appear to be involved. The availability of isoprenyl groups from the HMG-CoA pathway for prenylation of proteins is reduced by statins, resulting in reduced prenylation of Rho and Rab proteins. Prenylated Rho activates Rho kinase, which mediates a number of mechanisms in vascular biology. The observation that reduction in new coronary events occurs more rapidly than changes in morphology of arterial plaques suggests that these pleiotropic effects may be important. Likewise, decreased prenylation of Rab reduces the accumulation of A $\beta$  protein in neurons, possibly mitigating the manifestations of Alzheimer's disease.

### **Therapeutic Uses & Dosage**

Reductase inhibitors are useful alone or with resins, niacin, or ezetimibe in reducing levels of LDL. Women with hyperlipidemia who are pregnant, lactating, or likely to become pregnant should not be given these agents. Use in children is restricted to selected patients with familial hypercholesterolemia or familial combined hyperlipidemia.

Because cholesterol synthesis occurs predominantly at night, reductase inhibitors—except atorvastatin and rosuvastatin—should be given in the evening if a single daily dose is used. Absorption generally (with the exception of pravastatin) is enhanced by food. Daily doses of lovastatin vary from 10 to 80 mg. Pravastatin is nearly as potent on a mass basis as lovastatin with a maximum recommended daily dose of 80 mg. Simvastatin is twice as potent and is given in doses of 5–80 mg daily. Fluvastatin appears to be about half as potent as lovastatin on a mass basis and is given in doses of 10–80 mg daily. Atorvastatin is given in doses of 10–80 mg/d, and rosuvastatin, the most efficacious agent for severe hypercholesterolemia, at 5–40 mg/d. The dose-response curves of pravastatin and especially of fluvastatin tend to level off in the upper part of the dosage range in patients with moderate to severe hypercholesterolemia. Those of other statins are somewhat more linear.

### **Toxicity**

Elevations of serum aminotransferase activity (up to three times normal) occur in some patients. This is often intermittent and usually not associated with other evidence of hepatic toxicity. Therapy may be continued in such patients in the absence of symptoms if aminotransferase levels are monitored and stable. In some patients, who may have underlying liver disease or a history of alcohol abuse, levels may exceed three times normal. This finding portends more severe hepatic toxicity. These patients may present with malaise, anorexia, and precipitous decreases in LDL. Medication should be discontinued immediately in these patients and in asymptomatic patients whose aminotransferase activity is persistently elevated to more than three times the upper limit of normal. These agents should be used with caution and in reduced dosage in patients with hepatic parenchymal disease, Asians, and the elderly. In general, aminotransferase activity should be measured at baseline, at 1–2 months, and then every 6–12 months (if stable).

Minor increases in creatine kinase (CK) activity in plasma are observed in some patients receiving reductase inhibitors, frequently associated with heavy physical activity. Rarely, patients may have marked elevations in CK

activity, often accompanied by generalized discomfort or weakness in skeletal muscles. If the drug is not discontinued, myoglobinuria can occur, leading to renal injury. Myopathy may occur with monotherapy, but there is an increased incidence in patients also receiving certain other drugs. Genetic variation in an anion transporter (OATP1B1) is associated with severe myopathy and rhabdomyolysis induced by statins.

The catabolism of lovastatin, simvastatin, and atorvastatin proceeds chiefly through CYP3A4, whereas that of fluvastatin and rosuvastatin is mediated by CYP2C9. Pravastatin is catabolized through other pathways, including sulfation. The 3A4-dependent reductase inhibitors tend to accumulate in plasma in the presence of drugs that inhibit or compete for the 3A4 cytochrome. These include the macrolide antibiotics, cyclosporine, ketoconazole and its congeners, HIV protease inhibitors, tacrolimus, nefazodone, fibrates, and others (see Chapter 4). Concomitant use of reductase inhibitors with amiodarone or verapamil also causes an increased risk of myopathy.

Conversely, drugs such as phenytoin, griseofulvin, barbiturates, rifampin, and thiazolidinediones increase expression of CYP3A4 and can reduce the plasma concentrations of the 3A4-dependent reductase inhibitors. Inhibitors of CYP2C9 such as ketoconazole and its congeners, metronidazole, sulfapyrazone, amiodarone, and cimetidine may increase plasma levels of fluvastatin and rosuvastatin. Pravastatin and rosuvastatin appear to be the statins of choice for use with verapamil, the ketoconazole group of antifungal agents, macrolides, and cyclosporine. Plasma levels of lovastatin, simvastatin, and atorvastatin may be elevated in patients ingesting more than 1 liter of grapefruit juice daily.

Creatine kinase activity should be measured in patients receiving potentially interacting drug combinations. In all patients, CK should be measured at baseline. If muscle pain, tenderness, or weakness appears, CK should be measured immediately and the drug discontinued if activity is elevated significantly over baseline. The myopathy usually reverses promptly upon cessation of therapy. If the association is unclear, the patient can be rechallenged under close surveillance. Myopathy in the absence of elevated CK has been reported. Rarely, hypersensitivity syndromes have been reported that include a lupus-like disorder and peripheral neuropathy.

Reductase inhibitors should be temporarily discontinued in the event of serious illness, trauma, or major surgery.

## **Niacin (Nicotinic Acid)**

Niacin (but not niacinamide) decreases VLDL and LDL levels, and Lp(a) in most patients. It often increases HDL levels significantly.

### **Chemistry & Pharmacokinetics**

Niacin (vitamin B<sub>3</sub>) is converted in the body to the amide, which is incorporated into niacinamide adenine dinucleotide (NAD). It is excreted in the urine unmodified and as several metabolites.

### **Mechanism of Action**

Niacin inhibits VLDL secretion, in turn decreasing production of LDL (Figure 35-2). Increased clearance of VLDL via the LPL pathway contributes to reduction of triglycerides. Niacin has no effect on bile acid production. Excretion of neutral sterols in the stool is increased acutely as cholesterol is mobilized from tissue pools and a new steady state is reached. The catabolic rate for HDL is decreased. Fibrinogen levels are reduced, and levels of tissue plasminogen activator appear to increase. Niacin inhibits the intracellular lipase of adipose tissue via receptor-mediated signaling, possibly reducing VLDL production by decreasing the flux of free fatty acids to the liver. Sustained inhibition of lipolysis has not been established, however.

### **Therapeutic Uses & Dosage**

In combination with a resin or reductase inhibitor, niacin normalizes LDL in most patients with heterozygous familial hypercholesterolemia and other forms of hypercholesterolemia. These combinations are also indicated in some cases of nephrosis. In severe mixed lipemia that is incompletely responsive to diet, niacin often produces marked reduction of triglycerides, an effect enhanced by marine omega-3 fatty acids. It is useful in patients with combined hyperlipidemia and in those with dysbetalipoproteinemia. It is clearly the most effective agent for increasing HDL and the only agent that may reduce Lp(a).

For treatment of heterozygous familial hypercholesterolemia, most patients require 2-6 g of niacin daily; more

than this should not be given. For other types of hypercholesterolemia and for hypertriglyceridemia, 1.5–3.5 g daily is often sufficient. Crystalline niacin should be given in divided doses with meals, starting with 100 mg two or three times daily and increasing gradually.

### **Toxicity**

Most persons experience a harmless cutaneous vasodilation and sensation of warmth after each dose when niacin is started or the dose increased. Taking 81–325 mg of aspirin one half hour beforehand blunts this prostaglandin-mediated effect. Ibuprofen, once daily, also mitigates the flush. Tachyphylaxis to flushing usually occurs within a few days at doses above 1.5–3 g daily. Patients should be warned to expect the flush and understand that it is a harmless side effect. Pruritus, rashes, dry skin or mucous membranes, and acanthosis nigricans have been reported. The latter contraindicates use of niacin because of its association with insulin resistance. Some patients experience nausea and abdominal discomfort. Many can continue the drug at reduced dosage, with inhibitors of gastric acid secretion or with antacids not containing aluminum. Niacin should be avoided in most patients with severe peptic disease.

Reversible elevations in aminotransferases up to twice normal may occur, usually not associated with liver toxicity. However, liver function should be monitored at baseline and at appropriate intervals. Rarely, true hepatotoxicity may occur, and in these cases the drug should be discontinued. The association of severe hepatic dysfunction, including acute necrosis, with the use of over-the-counter sustained-release preparations of niacin has been reported. This effect has not been noted to date with an extended-release preparation, Niaspan, given at bedtime in doses of 2 g or less. Carbohydrate tolerance may be moderately impaired, but this is usually reversible except in some patients with latent diabetes. Niacin may be given to diabetics who are receiving insulin and to some receiving oral agents if insulin resistance is not increased. Hyperuricemia occurs in some patients and occasionally precipitates gout. Allopurinol can be given with niacin if needed. Rarely, niacin is associated with arrhythmias, mostly atrial, and a reversible toxic amblyopia. Patients should be instructed to report blurring of distance vision. Niacin may potentiate the action of antihypertensive agents, requiring adjustment of their dosages. Birth defects have been reported in animals given very high dosages.

### **Fibric Acid Derivatives (Fibrates)**

**Gemfibrozil** and **fenofibrate** decrease levels of VLDL and, in some patients, LDL as well. Another fibrate, **bezafibrate**, is not yet available in the USA.

### **Chemistry & Pharmacokinetics**

Gemfibrozil is absorbed quantitatively from the intestine and is tightly bound to plasma proteins. It undergoes enterohepatic circulation and readily passes the placenta. The plasma half-life is 1.5 hours. Seventy percent is eliminated through the kidneys, mostly unmodified. The liver modifies some of the drug to hydroxymethyl, carboxyl, or quinol derivatives. Fenofibrate is an isopropyl ester that is hydrolyzed completely in the intestine. Its plasma half-life is 20 hours. Sixty percent is excreted in the urine as the glucuronide, and about 25% in feces.

**Gemfibrozil**

**Fenofibrate**

### Mechanism of Action

Fibrates function primarily as ligands for the nuclear transcription receptor, PPAR- $\alpha$ . They transcriptionally up-regulate LPL, apoA-I and apoA-II, and down regulate apoCIII, an inhibitor of lipolysis. A major effect is an increase in oxidation of fatty acids in liver and striated muscle (Figure 35-4). They increase lipolysis of lipoprotein triglyceride via LPL. Intracellular lipolysis in adipose tissue is decreased. Levels of VLDL decrease, in part as a result of decreased secretion by the liver. Only modest reductions of LDL occur in most patients. In others, especially those with combined hyperlipidemia, LDL often increases as triglycerides are reduced. HDL cholesterol increases moderately. Part of this apparent increase is a consequence of decreasing triglycerides in plasma, with reduction in exchange of triglycerides into HDL in place of cholesteryl esters.

**Figure 35-4**

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 11th Edition: <http://www.accessmedicine.com>

Hepatic and peripheral effects of fibrates. These effects are mediated by activation of peroxisome proliferator-activated receptor- $\alpha$ , which modulates the expression of several proteins. LPL, lipoprotein lipase; VLDL, very-low-density lipoproteins.

### Therapeutic Uses & Dosage

Fibrates are useful drugs in hypertriglyceridemias in which VLDL predominate and in dysbetalipoproteinemia. They also may be of benefit in treating the hypertriglyceridemia that results from treatment with viral protease inhibitors. The usual dose of gemfibrozil is 600 mg orally once or twice daily. The dosage of fenofibrate (as Tricor) is one to three 48 mg tablets (or a single 145 mg tablet) daily. Absorption of gemfibrozil is improved when the drug is taken with food.

### Toxicity

Rare adverse effects of fibrates include rashes, gastrointestinal symptoms, myopathy, arrhythmias, hypokalemia, and high blood levels of aminotransferases or alkaline phosphatase. A few patients show decreases in white blood count or hematocrit. Both agents potentiate the action of coumarin and indanedione anticoagulants, and doses of these agents should be adjusted. Rhabdomyolysis has occurred rarely. Risk of myopathy increases when fibrates are given with reductase inhibitors. The use of fenofibrate with rosuvastatin appears to minimize this risk. Fibrates should be avoided in patients with hepatic or renal dysfunction. There appears to be a modest increase in the risk of cholesterol gallstones, reflecting an increase in the cholesterol content of bile. Therefore, fibrates should be used with caution in patients with biliary tract disease or in those at high risk such as women, obese patients, and Native Americans.

### Bile Acid-Binding Resins

**Colestipol**, **cholestyramine**, and **colesevelam** are useful only for isolated increases in LDL. In patients who also have hypertriglyceridemia, VLDL levels may be further increased during treatment with resins.

### Chemistry & Pharmacokinetics

The bile acid-binding agents are large polymeric cationic exchange resins that are insoluble in water. They bind bile acids in the intestinal lumen and prevent their reabsorption. The resin itself is not absorbed.

## Mechanism of Action

The bile acids, metabolites of cholesterol, are normally efficiently reabsorbed in the jejunum and ileum (Figure 35â€²). Excretion is increased up to tenfold when resins are given, resulting in enhanced conversion of cholesterol to bile acids in liver via 7 $\alpha$ -hydroxylation, which is normally controlled by negative feedback by bile acids. Decreased activation of the FXR receptor by bile acids may result in a modest increase in plasma triglycerides but can also improve glucose metabolism in diabetics. Increased uptake of LDL and IDL from plasma results from up-regulation of LDL receptors, particularly in liver. Therefore, the resins are without effect in patients with homozygous familial hypercholesterolemia who have no functioning receptors but may be useful in patients with receptor-defective combined heterozygous states.

## Therapeutic Uses & Dosage

The resins are used in treatment of patients with primary hypercholesterolemia, producing approximately 20% reduction in LDL cholesterol in maximal dosage. If resins are used to treat LDL elevations in persons with combined hyperlipidemia, they may cause an increase in VLDL, requiring the addition of a second agent such as niacin. Resins are also used in combination with other drugs to achieve further hypocholesterolemic effect (see below). They may be helpful in relieving pruritus in patients who have cholestasis and bile salt accumulation. Because the resins bind digitalis glycosides, they may be useful in digitalis toxicity.

Colestipol and cholestyramine are available as granular preparations. A gradual increase of dosage of granules from 4 or 5 g/d to 20 g/d is recommended. Total dosages of 30â€”32 g/d may be needed for maximum effect. The usual dosage for a child is 10â€”20 g/d. Granular resins are mixed with juice or water and allowed to hydrate for 1 minute. Colestipol is also available in 1 g tablets that must be swallowed whole, with a maximum dose of 16 g daily. Colesevelam is available in 625 mg tablets. The maximum dose is six tablets daily. Resins should be taken in two or three doses with meals. They lack effect when taken between meals.

## Toxicity

Common complaints are constipation and bloating, usually relieved by increasing dietary fiber or mixing psyllium seed with the resin. Resins should be avoided in patients with diverticulitis. Heartburn and diarrhea are occasionally reported. In patients who have preexisting bowel disease or cholestasis, steatorrhea may occur. Malabsorption of vitamin K occurs rarely, leading to hypoprothrombinemia. Prothrombin time should be measured frequently in patients who are taking resins and anticoagulants. Malabsorption of folic acid has been reported rarely. Increased formation of gallstones, particularly in obese persons, was an anticipated adverse effect but has rarely occurred in practice.

Absorption of certain drugs, including those with neutral or cationic charge as well as anions, may be impaired by the resins. These include digitalis glycosides, thiazides, warfarin, tetracycline, thyroxine, iron salts, pravastatin, fluvastatin, folic acid, phenylbutazone, aspirin, and ascorbic acid. Any additional medication (except niacin) should be given 1 hour before or at least 2 hours after the resin to ensure adequate absorption. Colesevelam does not bind digoxin, warfarin, or reductase inhibitors.

## Inhibitors of Intestinal Sterol Absorption

**Ezetimibe** is the first member of a group of drugs that inhibit intestinal absorption of phytosterols and cholesterol. Its primary clinical effect is reduction of LDL levels. In one trial, patients receiving ezetimibe in combination with simvastatin had marginal, but not statistically significant, increases in carotid intimal-medial thickness (IMT) compared with those receiving simvastatin alone. Interpretation of this observation is difficult for several reasons, including the fact that baseline IMT was unexpectedly small, probably due to prior lipid-lowering therapy. Because reducing LDL levels by virtually every modality has been associated with reduced risk of coronary events, it is reasonable to assume that reduction of LDL by ezetimibe will have a similar impact. Further studies are pending.

## Chemistry & Pharmacokinetics

Ezetimibe is readily absorbed and conjugated in the intestine to an active glucuronide, reaching peak blood levels in 12â€”14 hours. It undergoes enterohepatic circulation, and its half-life is 22 hours. Approximately 80% of the drug is excreted in feces. Plasma concentrations are substantially increased when it is administered with fibrates and

reduced when it is given with cholestyramine. Other resins may also decrease its absorption. There are no significant interactions with warfarin or digoxin.

**Ezetimibe**

### **Mechanism of Action**

Ezetimibe is a selective inhibitor of intestinal absorption of cholesterol and phytosterols. A transport protein, NPC1L1, appears to be the target of the drug. It is effective even in the absence of dietary cholesterol because it inhibits reabsorption of cholesterol excreted in the bile.

### **Therapeutic Uses & Dosage**

The effect of ezetimibe on cholesterol absorption is constant over the dosage range of 5–20 mg/d. Therefore, a single daily dose of 10 mg is used. Average reduction in LDL cholesterol with ezetimibe alone in patients with primary hypercholesterolemia is about 18%, with minimal increases in HDL cholesterol. It is also effective in patients with phytosterolemia. Ezetimibe is synergistic with reductase inhibitors, producing decrements as great as 25% in LDL cholesterol beyond that achieved with the reductase inhibitor alone.

### **Toxicity**

Ezetimibe does not appear to be a substrate for cytochrome P450 enzymes. Experience to date reveals a low incidence of reversible impaired hepatic function with a small increase in incidence when given with a reductase inhibitor. Myositis has been reported rarely.

### **Treatment with Drug Combinations**

Combined drug therapy is useful (1) when VLDL levels are significantly increased during treatment of hypercholesterolemia with a resin; (2) when LDL and VLDL levels are both elevated initially; (3) when LDL or VLDL levels are not normalized with a single agent, or (4) when an elevated level of Lp(a) or an HDL deficiency coexists with other hyperlipidemias.

### **FIBRIC ACID DERIVATIVES & BILE ACID-BINDING RESINS**

This combination is sometimes useful in treating patients with familial combined hyperlipidemia who are intolerant of niacin or statins. However, it may increase the risk of cholelithiasis.

### **HMG-COA REDUCTASE INHIBITORS & BILE ACID-BINDING RESINS**

This synergistic combination is useful in the treatment of familial hypercholesterolemia but may not control levels of VLDL in some patients with familial combined hyperlipoproteinemia. Statins should be given at least 1 hour before or 4 hours after the resin to ensure their absorption.

### **NIACIN & BILE ACID-BINDING RESINS**

This combination effectively controls VLDL levels during resin therapy of familial combined hyperlipoproteinemia or other disorders involving both increased VLDL and LDL levels. When VLDL and LDL levels are both initially increased, doses of niacin as low as 1–3 g/d may be sufficient in combination with a resin. The niacin-resin combination is effective for treating heterozygous familial hypercholesterolemia.

The drugs may be taken together, because niacin does not bind to the resins. LDL levels in patients with heterozygous familial hypercholesterolemia require daily doses of up to 6 g of niacin with 24–30 g of resin.

## NIACIN & REDUCTASE INHIBITORS

This regimen is more effective than either agent alone in treating hypercholesterolemia. Experience indicates that it is an efficacious and practical combination for treatment of familial combined hyperlipoproteinemia.

## REDUCTASE INHIBITORS & EZETIMIBE

This combination is highly synergistic in treating primary hypercholesterolemia and has some use in the treatment of patients with homozygous familial hypercholesterolemia who have some receptor function.

## REDUCTASE INHIBITORS & FENOFIBRATE

Fenofibrate appears to be complementary with certain statins in the treatment of familial combined hyperlipoproteinemia and other conditions involving elevations of both LDL and VLDL. The combination of fenofibrate with rosuvastatin is particularly effective. Some other statins may interact unfavorably owing to effects on cytochrome P450 metabolism.

## TERNARY COMBINATION OF RESINS, EZETIMIBE, NIACIN, & REDUCTASE INHIBITORS

These agents act in a complementary fashion to normalize cholesterol in patients with severe disorders involving elevated LDL. The effects are sustained, and little compound toxicity has been observed. Effective doses of the individual drugs may be lower than when each is used alone; for example, as little as 1 g of niacin may substantially increase the effects of the other agents.

## SUMMARY: DRUGS USED IN DYSLIPIDEMIA

### Drugs Used in Dyslipidemia

Subclass	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>Statins</b>				
<ul style="list-style-type: none"> <li>Atorvastatin, simvastatin, rosuvastatin</li> </ul>	Inhibit HMG-CoA reductase	Reduce cholesterol synthesis and up-regulate low-density lipoprotein (LDL) receptors on hepatocytes • modest reduction in triglycerides	Atherosclerotic vascular disease (primary and secondary prevention) • acute coronary syndromes	Oral • duration 12–24 h • <i>Toxicity:</i> Myopathy, hepatic dysfunction • <i>Interactions:</i> CYP-dependent metabolism (3A4, 2C9) interacts with CYP inhibitors
<ul style="list-style-type: none"> <li><i>Fluvastatin, pravastatin, lovastatin: Similar but somewhat less efficacious</i></li> </ul>				
<b>Fibrates</b>				
<ul style="list-style-type: none"> <li>Fenofibrate, gemfibrozil</li> </ul>	Peroxisome proliferator-activated receptor-alpha (PPAR- $\alpha$ ) agonists	Decrease secretion of very-low-density lipoproteins (VLDL) • increase lipoprotein lipase activity • increase high-density lipoproteins (HDL)	Hypertriglyceridemia, low HDL	Oral • duration 3–24 h • <i>Toxicity:</i> Myopathy, hepatic dysfunction
<b>Bile acid sequestrants</b>				
<ul style="list-style-type: none"> <li>Colestipol</li> </ul>	Binds bile acids in gut • prevents reabsorption • increases cholesterol catabolism • up-regulates LDL receptors	Decreases LDL	Elevated LDL, digitalis toxicity, pruritus	Oral • taken with meals • not absorbed • <i>Toxicity:</i> Constipation, bloating • interferes with absorption of some drugs and vitamins
<ul style="list-style-type: none"> <li><i>Cholestyramine, colestevlam: Similar to colestipol</i></li> </ul>				

### **Sterol absorption inhibitor**

- **Ezetimibe** Blocks sterol transporter NPC1L1 in intestine brush border  
Inhibits reabsorption of cholesterol excreted in bile  
Elevated LDL, phytosterolemia  
• decreases LDL and phytosterols  
Oral • duration 24 h  
• *Toxicity*: Low incidence of hepatic dysfunction, myositis

### **Niacin**

- Decreases catabolism of apo AI • reduces VLDL secretion from liver  
Increases HDL • decreases lipoprotein(a) [Lp(a)], LDL and triglycerides  
Low HDL • elevated VLDL, LDL, Lp(a)  
Oral • large doses  
• *Toxicity*: Gastric irritation, flushing, low incidence of hepatic toxicity • may reduce glucose tolerance

- *Extended-release niacin: Similar to regular niacin*

- *Sustained-release niacin (not the same as extended-release product): Should be avoided*

## **PREPARATIONS AVAILABLE**

### **Atorvastatin** (Lipitor)

Oral: 10, 20, 40, 80 mg tablets

### **Cholestyramine** (generic, Questran, Questran Light)

Oral: 4 g packets anhydrous granules cholestyramine resin

### **Colesevelam** (Welchol)

Oral: 625 mg tablets

### **Colestipol** (Colestid)

Oral: 5 g packets granules; 1 g tablets

### **Ezetimibe** (Zetia)

Oral: 10 mg tablets

### **Fenofibrate** (generic, Tricor, Antara, Lofibra)

Oral: 48, 50, 54, 107, 145, 160 mg tablets; 43, 50, 67, 100, 130, 134, 156, 200 mg capsules

### **Fluvastatin** (Lescol)

Oral: 20, 40 mg capsules; extended release (Lescol XL): 80 mg capsules

### **Gemfibrozil** (generic, Lopid)

Oral: 600 mg tablets

### **Lovastatin** (generic, Mevacor)

Oral: 10, 20, 40 mg tablets; extended release (Altoprev): 10, 20, 40, 60 mg

### **Niacin, nicotinic acid, vitamin B<sub>3</sub>** (generic, others)

Oral: 100, 250, 500, 1000 mg tablets; extended release (Niaspan): 500, 750, 1000 mg

**Pravastatin** (generic, Pravachol)

Oral: 10, 20, 40, 80 mg tablets

**Rosuvastatin** (Crestor)

Oral: 5, 10, 20, 40 mg tablets

**Simvastatin** (generic, Zocor)

Oral: 5, 10, 20, 40, 80 mg tablets

## COMBINATION TABLETS<sup>1</sup>

**Simcor** (extended release niacin plus simvastatin)

Oral: 500/20, 750/20, 1000/20 mg tablets

**Vytorin** (ezetimibe plus simvastatin)

Oral: 10/10, 10/20, 10/40, 10/80 mg tablets

<sup>1</sup>A selection; others available.

**Basic and Clinical Pharmacology** > Chapter 36. Nonsteroidal Anti-Inflammatory Drugs, Disease-Modifying Antirheumatic Drugs, Nonopioid Analgesics, & Drugs Used in Gout >

## CASE STUDY

A 48-year-old man presents with complaints of bilateral morning stiffness in his wrists and knees and pain in these joints on exercise. On physical examination, the joints are slightly swollen. The rest of the examination is unremarkable. His laboratory findings are also negative except for slight anemia, elevated erythrocyte sedimentation rate, and positive rheumatoid factor. With the diagnosis of rheumatoid arthritis, he is started on a regimen of naproxen, 220 mg twice daily. After 1 week, the dosage is increased to 440 mg twice daily. His symptoms are reduced at this dosage, but he complains of significant heartburn that is not controlled by antacids. He is then switched to celecoxib, 200 mg twice daily, and on this regimen his joint symptoms and heartburn resolve. Two years later, he returns with increased joint symptoms. His hands, wrists, elbows, feet, and knees are all now involved and appear swollen, warm, and tender. What therapeutic options should be considered at this time? What are the possible complications?

## NONSTEROIDAL ANTI-INFLAMMATORY DRUGS, DISEASE-MODIFYING ANTIRHEUMATIC DRUGS, NONOPIOID ANALGESICS, & DRUGS USED IN GOUT: INTRODUCTION

### THE IMMUNE RESPONSE

The immune response occurs when immunologically competent cells are activated in response to foreign organisms or antigenic substances liberated during the acute or chronic inflammatory response. The outcome of the immune response for the host may be beneficial, as when it causes invading organisms to be phagocytosed or neutralized. On the other hand, the outcome may be deleterious if it leads to chronic inflammation without resolution of the underlying injurious process (see Chapter 55). Chronic inflammation involves the release of a number of mediators that are not prominent in the acute response. One of the most important conditions involving these mediators is rheumatoid arthritis, in which chronic inflammation results in pain and destruction of bone and cartilage that can lead to severe disability and in which systemic changes occur that can result in shortening of life.

The cell damage associated with inflammation acts on cell membranes to cause leukocytes to release lysosomal enzymes; arachidonic acid is then liberated from precursor compounds, and various eicosanoids are synthesized. As discussed in Chapter 18, the cyclooxygenase (COX) pathway of arachidonate metabolism produces prostaglandins, which have a variety of effects on blood vessels, on nerve endings, and on cells involved in inflammation. The lipoxygenase pathway of arachidonate metabolism yields leukotrienes, which have a powerful chemotactic effect on eosinophils, neutrophils, and macrophages and promote bronchoconstriction and alterations in vascular permeability.

The discovery of two cyclooxygenase isoforms (COX-1 and COX-2) led to the concept that the constitutive COX-1 isoform tends to be homeostatic in function, while COX-2 is induced during inflammation and tends to facilitate the inflammatory response. On this basis, highly selective COX-2 inhibitors have been developed and marketed on the assumption that such selective inhibitors would be safer than nonselective COX-1 inhibitors but without loss of efficacy.

Kinins, neuropeptides, and histamine are also released at the site of tissue injury, as are complement components, cytokines, and other products of leukocytes and platelets. Stimulation of the neutrophil membranes produces oxygen-derived free radicals. Superoxide anion is formed by the reduction of molecular oxygen, which may stimulate the production of other reactive molecules such as hydrogen peroxide and hydroxyl radicals. The interaction of these substances with arachidonic acid results in the generation of chemotactic substances, thus perpetuating the inflammatory process.

### THERAPEUTIC STRATEGIES

The treatment of patients with inflammation involves two primary goals: first, the relief of symptoms and the maintenance of function, which are usually the major continuing complaints of the patient; and second, the slowing or arrest of the tissue-damaging process. In rheumatoid arthritis, response to therapy can be quantitated using several measures including of the American College of Rheumatology scoring system values ACR20, ACR50, and ACR70, which denote the percentage of patients showing an improvement of 20%, 50%, or 70% in a global assessment of signs and symptoms.

Reduction of inflammation with **nonsteroidal anti-inflammatory drugs (NSAIDs)** often results in relief of pain for significant periods. Furthermore, most of the nonopioid analgesics (aspirin, etc) have anti-inflammatory effects, so they are appropriate for the treatment of both acute and chronic inflammatory conditions.

The **glucocorticoids** also have powerful anti-inflammatory effects and when first introduced were considered to be the ultimate answer to the treatment of inflammatory arthritis. Although there are increasing data that low-dose corticosteroids have disease-modifying properties, the toxicity associated with chronic corticosteroid therapy usually limits their use. However, the glucocorticoids continue to have a significant role in the long-term treatment of arthritis.

Another important group of agents is characterized as **disease-modifying antirheumatic drugs (DMARDs)**. They decrease inflammation,

usually improve symptoms, and slow the bone damage associated with rheumatoid arthritis. They are thought to affect more basic inflammatory mechanisms than do glucocorticoids or the NSAIDs. They may also be more toxic than those alternative medications.

## NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Salicylates and other similar agents used to treat rheumatic disease share the capacity to suppress the signs and symptoms of inflammation. These drugs also exert antipyretic and analgesic effects, but it is their anti-inflammatory properties that make them most useful in the management of disorders in which pain is related to the intensity of the inflammatory process.

Since aspirin, the original NSAID, has a number of adverse effects, many other NSAIDs have been developed in attempts to improve upon aspirin's efficacy and decrease its toxicity.

### Chemistry & Pharmacokinetics

The NSAIDs are grouped in several chemical classes, as shown in Figure 36â€1. This chemical diversity yields a broad range of pharmacokinetic characteristics (Table 36â€1). Although there are many differences in the kinetics of NSAIDs, they have some general properties in common. All but one of the NSAIDs are weak organic acids as given; the exception, nabumetone, is a ketone prodrug that is metabolized to the acidic active drug.

Chemical structures of some NSAIDs.

**Table 36â€1 Properties of Aspirin and Some Other Nonsteroidal Anti-Inflammatory Drugs.**

Drug	Half-Life (hours)	Urinary Excretion of Unchanged Drug	Recommended Anti-inflammatory Dosage
Aspirin	0.25	< 2%	1200-1500 mg tid
Salicylate <sup>1</sup>	2-19	30%	See footnote 2
Celecoxib	11	27% <sup>3</sup>	100-200 mg bid
Diclofenac	1.1	< 1%	50-75 mg qid
Diflunisal	13	3-9%	500 mg bid
Etodolac	6.5	< 1%	200-300 mg qid
Fenoprofen	2.5	30%	600 mg qid
Flurbiprofen	3.8	< 1%	300 mg tid
Ibuprofen	2	< 1%	600 mg qid
Indomethacin	4-5	16%	50-70 mg tid
Ketoprofen	1.8	< 1%	70 mg tid
Ketorolac	4-10	58%	10 mg qid <sup>4</sup>
Meloxicam	20	Data not found	7.5-15 mg qd
Nabumetone <sup>5</sup>	26	1%	1000-2000 mg qd <sup>6</sup>
Naproxen	14	< 1%	375 mg bid
Oxaprozin	58	1-4%	1200-1800 mg qd <sup>6</sup>
Piroxicam	57	4-10%	20 mg qd <sup>6</sup>
Sulindac	8	7%	200 mg bid
Tolmetin	1	7%	400 mg qid

<sup>1</sup>Major anti-inflammatory metabolite of aspirin.

<sup>2</sup>Salicylate is usually given in the form of aspirin.

<sup>3</sup>Total urinary excretion including metabolites.

<sup>4</sup>Recommended for treatment of acute (eg, surgical) pain only.

<sup>5</sup>Nabumetone is a prodrug; the half-life and urinary excretion are for its active metabolite.

<sup>6</sup>A single daily dose is sufficient because of the long half-life.

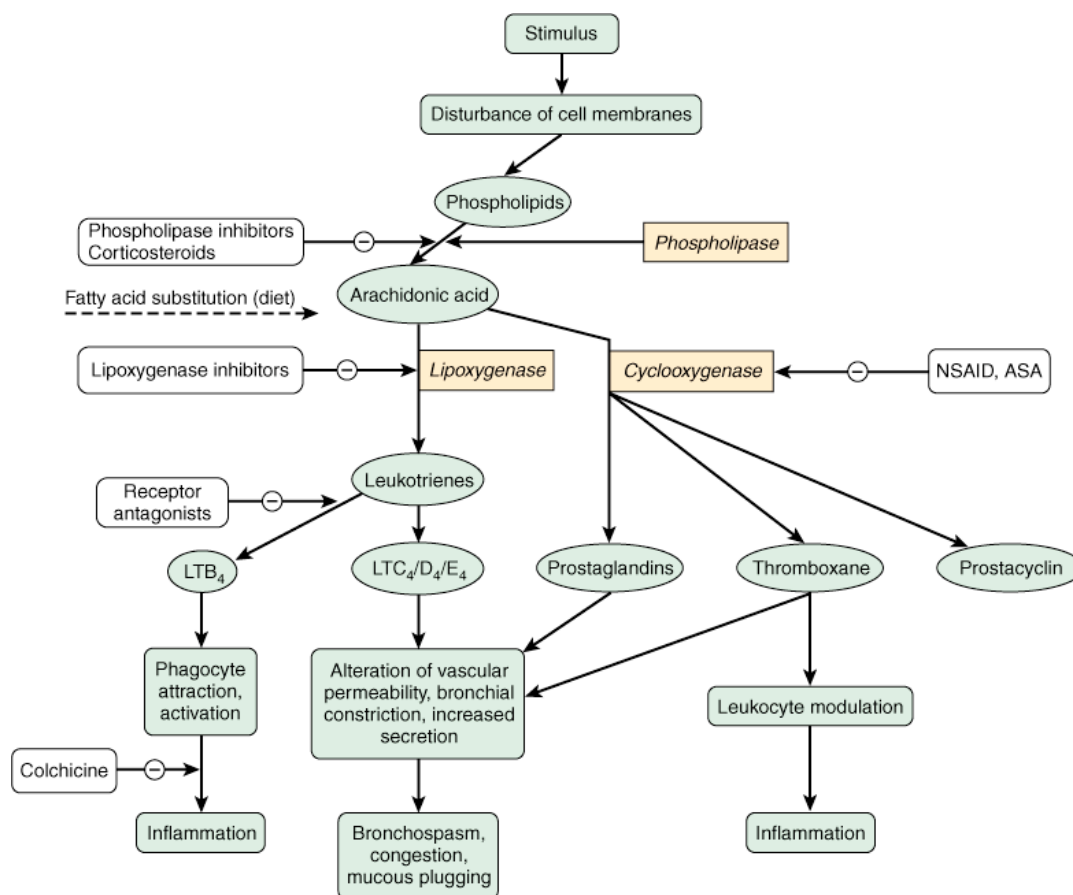

Most of these drugs are well absorbed, and food does not substantially change their bioavailability. Most of the NSAIDs are highly metabolized, some by phase I followed by phase II mechanisms and others by direct glucuronidation (phase II) alone. NSAID metabolism proceeds, in large part, by way of the CYP3A or CYP2C families of P450 enzymes in the liver. While renal excretion is the most important route for final elimination, nearly all undergo varying degrees of biliary excretion and reabsorption (enterohepatic circulation). In fact, the degree of lower gastrointestinal tract irritation correlates with the amount of enterohepatic circulation. Most of the NSAIDs are highly protein-bound (~98%), usually to albumin. Most of the NSAIDs (eg, ibuprofen, ketoprofen) are racemic mixtures, while one, naproxen, is provided as a single enantiomer and a few have no chiral center (eg, diclofenac).

All NSAIDs can be found in synovial fluid after repeated dosing. Drugs with short half-lives remain in the joints longer than would be predicted from their half-lives, while drugs with longer half-lives disappear from the synovial fluid at a rate proportionate to their half-lives.

### Pharmacodynamics

The anti-inflammatory activity of the NSAIDs is mediated chiefly through inhibition of biosynthesis of prostaglandins (Figure 36-2). Various NSAIDs have additional possible mechanisms of action, including inhibition of chemotaxis, down-regulation of interleukin-1 production, decreased production of free radicals and superoxide, and interference with calcium-mediated intracellular events. Aspirin irreversibly acetylates and blocks platelet cyclooxygenase, while most non-COX-selective NSAIDs are reversible inhibitors.

### Figure 36-2

Prostanoid mediators derived from arachidonic acid and sites of drug action. ASA, acetylsalicylic acid (aspirin); LT, leukotriene; NSAID, nonsteroidal anti-inflammatory drug.

Selectivity for COX-1 versus COX-2 is variable and incomplete for the older NSAIDs, but many selective COX-2 inhibitors have been synthesized. The selective COX-2 inhibitors do not affect platelet function at their usual doses. In testing using human whole blood, aspirin, ibuprofen, indomethacin, piroxicam, and sulindac are somewhat more effective in inhibiting COX-1. The efficacy of COX-2-selective drugs equals that of the older NSAIDs, while gastrointestinal safety may be improved. On the other hand, selective COX-2 inhibitors may increase the incidence of edema and hypertension. As of December 2008, celecoxib and the less selective meloxicam are the only COX-2 inhibitors marketed in the USA. Rofecoxib and valdecoxib, two previously marketed, selective COX-2 inhibitors, have been withdrawn from the market due to their association with increased cardiovascular thrombotic events. Celecoxib has an FDA-initiated "black box" warning concerning cardiovascular risks. It has been recommended that all NSAID product labels be revised to include cardiovascular risks.

The NSAIDs decrease the sensitivity of vessels to bradykinin and histamine, affect lymphokine production from T lymphocytes, and reverse the vasodilation of inflammation. To varying degrees, all newer NSAIDs are analgesic, anti-inflammatory, and antipyretic, and all (except the COX-2-selective agents and the nonacetylated salicylates) inhibit platelet aggregation. NSAIDs are all gastric irritants and can be associated with gastrointestinal ulcers and bleeds as well, although as a group the newer agents tend to cause less gastrointestinal irritation than aspirin. Nephrotoxicity has been observed for all of the drugs for which extensive experience has been reported. Nephrotoxicity is due, in part, to interference with the autoregulation of renal blood flow, which is modulated by prostaglandins. Hepatotoxicity can also occur with any NSAID.

Although these drugs effectively inhibit inflammation, there is no evidence that they alter the course of any arthritic disorder.

Several NSAIDs (including aspirin) appear to reduce the incidence of colon cancer when taken chronically. Several large epidemiologic studies have shown a 50% reduction in relative risk when the drugs are taken for 5 years or longer. The mechanism for this protective effect is unclear.

The NSAIDs have a number of commonalities. Although not all NSAIDs are approved by the FDA for the whole range of rheumatic diseases, most are probably effective in rheumatoid arthritis, seronegative spondyloarthropathies (eg, psoriatic arthritis and arthritis associated with

inflammatory bowel disease), osteoarthritis, localized musculoskeletal syndromes (eg, sprains and strains, low back pain), and gout (except tolmetin, which appears to be ineffective in gout).

Adverse effects are generally quite similar for all of the NSAIDs:

1. **Central nervous system:** Headaches, tinnitus, and dizziness.
2. **Cardiovascular:** Fluid retention hypertension, edema, and rarely, congestive heart failure.
3. **Gastrointestinal:** Abdominal pain, dysplasia, nausea, vomiting, and rarely, ulcers or bleeding.
4. **Hematologic:** Rare thrombocytopenia, neutropenia, or even aplastic anemia.
5. **Hepatic:** Abnormal liver function tests and rare liver failure.
6. **Pulmonary:** Asthma.
7. **Rashes:** All types, pruritus.
8. **Renal:** Renal insufficiency, renal failure, hyperkalemia, and proteinuria.

## ASPIRIN

Aspirin's long use and availability without prescription diminishes its glamour compared with that of the newer NSAIDs. Aspirin is now rarely used as an anti-inflammatory medication and will be reviewed only in terms of its anti-platelet effects (ie, doses of 81â€³325 mg once daily).

### Pharmacokinetics

Salicylic acid is a simple organic acid with a pKa of 3.0. Aspirin (acetylsalicylic acid; ASA) has a pKa of 3.5 (see Table 1â€³3). The salicylates are rapidly absorbed from the stomach and upper small intestine yielding a peak plasma salicylate level within 1â€³2 hours. Aspirin is absorbed as such and is rapidly hydrolyzed (serum half-life 15 minutes) to acetic acid and salicylate by esterases in tissue and blood (Figure 36â€³3). Salicylate is nonlinearly bound to albumin. Alkalinization of the urine increases the rate of excretion of free salicylate and its water-soluble conjugates.

### Mechanisms of Action

Aspirin irreversibly inhibits platelet COX so that aspirin's antiplatelet effect lasts 8â€³10 days (the life of the platelet). In other tissues, synthesis of new COX replaces the inactivated enzyme so that ordinary doses have a duration of action of 6â€³12 hours.

### Clinical Uses

Aspirin decreases the incidence of transient ischemic attacks, unstable angina, coronary artery thrombosis with myocardial infarction, and thrombosis after coronary artery bypass grafting (see Chapter 34).

Epidemiologic studies suggest that long-term use of aspirin at low dosage is associated with a lower incidence of colon cancer, possibly related to its COX-inhibiting effects.

### Adverse Effects

In addition to the common side effects listed above, aspirin's main adverse effects at antithrombotic doses are gastric upset (intolerance) and gastric and duodenal ulcers. Hepatotoxicity, asthma, rashes, gastrointestinal bleeding, and renal toxicity rarely if ever occur at antithrombotic doses.

The antiplatelet action of aspirin contraindicates its use by patients with hemophilia. Although previously not recommended during pregnancy, aspirin may be valuable in treating preeclampsia-eclampsia.

### NONACETYLATED SALICYLATES

These drugs include magnesium choline salicylate, sodium salicylate, and salicyl salicylate. All nonacetylated salicylates are effective anti-inflammatory drugs, although they may be less effective analgesics than aspirin. Because they are much less effective than aspirin as COX inhibitors and they do not inhibit platelet aggregation, they may be preferable when COX inhibition is undesirable such as in patients with asthma, those with bleeding tendencies, and even (under close supervision) those with renal dysfunction.

The nonacetylated salicylates are administered in doses up to 3â€”4 g of salicylate a day and can be monitored using serum salicylate measurements.

### COX-2 SELECTIVE INHIBITORS

COX-2 selective inhibitors, or coxibs, were developed in an attempt to inhibit prostaglandin synthesis by the COX-2 isozyme induced at sites of inflammation without affecting the action of the constitutively active "housekeeping" COX-1 isozyme found in the gastrointestinal tract, kidneys, and platelets. Coxibs selectively bind to and block the active site of the COX-2 enzyme much more effectively than that of COX-1. COX-2 inhibitors have analgesic, antipyretic, and anti-inflammatory effects similar to those of nonselective NSAIDs but with an approximate halving of gastrointestinal adverse effects. Likewise, COX-2 inhibitors at usual doses have been shown to have no impact on platelet aggregation, which is mediated by thromboxane produced by the COX-1 isozyme. In contrast, they do inhibit COX-2-mediated prostacyclin synthesis in the vascular endothelium. As a result, COX-2 inhibitors do not offer the cardioprotective effects of traditional nonselective NSAIDs, which has resulted in some patients taking low-dose aspirin in addition to a coxib regimen to maintain this effect. Unfortunately, because COX-2 is constitutively active within the kidney, recommended doses of COX-2 inhibitors cause renal toxicities similar to those associated with traditional NSAIDs. Clinical data have suggested a higher incidence of cardiovascular thrombotic events associated with COX-2 inhibitors such as rofecoxib and valdecoxib, resulting in their withdrawal from the market.

#### Celecoxib

Celecoxib is a selective COX-2 inhibitorâ€”about 10â€”20 times more selective for COX-2 than for COX-1. Pharmacokinetic and dosage considerations are given in Table 36â€”1.

Celecoxib is associated with fewer endoscopic ulcers than most other NSAIDs. Probably because it is a sulfonamide, celecoxib may cause rashes. It does not affect platelet aggregation at usual doses. It interacts occasionally with warfarinâ€”as would be expected of a drug metabolized via CYP2C9. Adverse effects are the common toxicities listed above.

Celecoxib

#### Meloxicam

Meloxicam is an enolcarboxamide related to piroxicam that preferentially inhibits COX-2 over COX-1, particularly at its lowest therapeutic dose of 7.5 mg/d. It is not as selective as celecoxib and may be considered "preferentially" selective rather than "highly" selective. The drug is popular in Europe and many other countries for the treatment of most rheumatic diseases and approved for treatment of osteoarthritis in the USA. It is associated with fewer clinical gastrointestinal symptoms and complications than piroxicam, diclofenac, and naproxen. Similarly, while meloxicam is known to inhibit synthesis of thromboxane A<sub>2</sub>, even at supratherapeutic doses its blockade of thromboxane A<sub>2</sub> does not reach levels that result in decreased in vivo platelet function (see common adverse effects above).

### NONSELECTIVE COX INHIBITORS

#### Diclofenac

Diclofenac is a phenylacetic acid derivative that is relatively nonselective as a COX inhibitor. Pharmacokinetic and dosage characteristics are set forth in Table 36â€¹1.

Gastrointestinal ulceration may occur less frequently than with some other NSAIDs. A preparation combining diclofenac and misoprostol decreases upper gastrointestinal ulceration but may result in diarrhea. Another combination of diclofenac and omeprazole was also effective with respect to the prevention of recurrent bleeding, but renal adverse effects were common in high-risk patients. Diclofenac, 150 mg/d, appears to impair renal blood flow and glomerular filtration rate. Elevation of serum aminotransferases occurs more commonly with this drug than with other NSAIDs.

A 0.1% ophthalmic preparation is recommended for prevention of postoperative ophthalmic inflammation and can be used after intraocular lens implantation and strabismus surgery. A topical gel containing 3% diclofenac is effective for solar keratoses. Diclofenac in rectal suppository form can be considered for preemptive analgesia and postoperative nausea. In Europe, diclofenac is also available as an oral mouthwash and for intramuscular administration.

### **Diflunisal**

Although diflunisal is derived from salicylic acid, it is not metabolized to salicylic acid or salicylate. It undergoes an enterohepatic cycle with reabsorption of its glucuronide metabolite followed by cleavage of the glucuronide to again release the active moiety. Diflunisal is subject to capacity-limited metabolism, with serum half-lives at various dosages approximating that of salicylates (Table 36â€¹1). In rheumatoid arthritis the recommended dose is 500â€¹1000 mg daily in two divided doses. It is claimed to be particularly effective for cancer pain with bone metastases and for pain control in dental (third molar) surgery. A 2% diflunisal oral ointment is a clinically useful analgesic for painful oral lesions.

Because its clearance depends on renal function as well as hepatic metabolism, diflunisal's dosage should be limited in patients with significant renal impairment.

### **Etodolac**

Etodolac is a racemic acetic acid derivative with an intermediate half-life (Table 36â€¹1). Etodolac does not undergo chiral inversion in the body. The dosage of etodolac is 200â€¹400 mg three to four times daily.

### **Flurbiprofen**

Flurbiprofen is a propionic acid derivative with a possibly more complex mechanism of action than other NSAIDs. Its (*S*)(â€¹) enantiomer inhibits COX nonselectively, but it has been shown in rat tissue to also affect tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and nitric oxide synthesis. Hepatic metabolism is extensive; its (*R*)(+) and (*S*)(â€¹) enantiomers are metabolized differently, and it does not undergo chiral conversion. It does demonstrate enterohepatic circulation.

Flurbiprofen is also available in a topical ophthalmic formulation for inhibition of intraoperative miosis. Flurbiprofen intravenously is effective for perioperative analgesia in minor ear, neck, and nose surgery and in lozenge form for sore throat.

Although its adverse effect profile is similar to that of other NSAIDs in most ways, flurbiprofen is also associated rarely with cogwheel rigidity, ataxia, tremor, and myoclonus.

### **Ibuprofen**

Ibuprofen is a simple derivative of phenylpropionic acid (Figure 36â€¹1). In doses of about 2400 mg daily, ibuprofen is equivalent to 4 g of aspirin in anti-inflammatory effect. Pharmacokinetic characteristics are given in Table 36â€¹1.

Oral ibuprofen is often prescribed in lower doses (< 2400 mg/d), at which it has analgesic but not anti-inflammatory efficacy. It is available over the counter in low-dose forms under several trade names.

Ibuprofen is effective in closing patent ductus arteriosus in preterm infants, with much the same efficacy and safety as indomethacin. The oral and intravenous routes are equally effective for this indication. A topical cream preparation appears to be absorbed into fascia and muscle; an (*S*)(â€¹) formulation has been tested. Ibuprofen cream was more effective than placebo cream in the treatment of primary knee osteoarthritis. A liquid gel preparation of ibuprofen, 400 mg, provides prompt relief and good overall efficacy in postsurgical dental pain.

In comparison with indomethacin, ibuprofen decreases urine output less and also causes less fluid retention. The drug is relatively contraindicated in individuals with nasal polyps, angioedema, and bronchospastic reactivity to aspirin. Aseptic meningitis (particularly in patients with systemic lupus erythematosus), and fluid retention have been reported. Interaction with anticoagulants is uncommon. The concomitant administration of ibuprofen and aspirin antagonizes the irreversible platelet inhibition induced by aspirin. Thus, treatment with ibuprofen in patients with increased cardiovascular risk may limit the cardioprotective effects of aspirin. Furthermore, the use of ibuprofen concomitantly with aspirin may *decrease* the total anti-inflammatory effect. Common adverse effects are listed on page 624; rare hematologic effects include agranulocytosis and aplastic anemia.

### **Indomethacin**

Indomethacin, introduced in 1963, is an indole derivative (Figure 36â€¹1). It is a potent nonselective COX inhibitor and may also inhibit phospholipase A and C, reduce neutrophil migration, and decrease T-cell and B-cell proliferation.

It differs somewhat from other NSAIDs in its indications and toxicities.

Indomethacin was particularly popular for gout and ankylosing spondylitis. In addition, it has been used to accelerate closure of patent ductus arteriosus. Indomethacin has been tried in numerous small or uncontrolled trials for many other conditions, including Sweet's syndrome, juvenile rheumatoid arthritis, pleurisy, nephrotic syndrome, diabetes insipidus, urticarial vasculitis, postepistiotomy pain, and prophylaxis of

heterotopic ossification in arthroplasty.

An ophthalmic preparation seems to be efficacious for conjunctival inflammation and to reduce pain after traumatic corneal abrasion. Gingival inflammation is reduced after administration of indomethacin oral rinse. Epidural injections produce a degree of pain relief similar to that achieved with methylprednisolone in postlaminectomy syndrome.

At usual doses, indomethacin has the common side effects listed above. At higher doses, at least a third of patients have reactions to indomethacin requiring discontinuance. The gastrointestinal effects may include pancreatitis. Headache is experienced by 15%–25% of patients and may be associated with dizziness, confusion, and depression. Rarely, psychosis with hallucinations has been reported. Serious hematologic reactions have been noted, including thrombocytopenia and aplastic anemia. Renal papillary necrosis has also been observed. A number of interactions with other drugs have been reported (see Chapter 66). Probenecid prolongs indomethacin's half-life by inhibiting both renal and biliary clearance.

### **Ketoprofen**

Ketoprofen is a propionic acid derivative that inhibits both COX (nonselectively) and lipoxygenase. Its pharmacokinetic characteristics are given in Table 36-1. Concurrent administration of probenecid elevates ketoprofen levels and prolongs its plasma half-life.

The effectiveness of ketoprofen at dosages of 100–300 mg/d is equivalent to that of other NSAIDs. In spite of its dual effect on prostaglandins and leukotrienes, ketoprofen is not superior to other NSAIDs in clinical efficacy. Its major adverse effects are on the gastrointestinal tract and the central nervous system (see common adverse effects above).

### **Ketorolac**

Ketorolac is an NSAID promoted for systemic use mainly as an analgesic, not as an anti-inflammatory drug (although it has typical NSAID properties). Pharmacokinetics are presented in Table 36-1. The drug is an effective analgesic and has been used successfully to replace morphine in some situations involving mild to moderate postsurgical pain. It is most often given intramuscularly or intravenously, but an oral dose formulation is available. When used with an opioid, it may decrease the opioid requirement by 25%–50%. An ophthalmic preparation is available for ocular inflammatory conditions. Toxicities are similar to those of other NSAIDs, although renal toxicity may be more common with chronic use.

### **Nabumetone**

Nabumetone is the only nonacid NSAID in current use; it is converted to the active acetic acid derivative in the body. It is given as a ketone prodrug that resembles naproxen in structure (Figure 36-1). Its half-life of more than 24 hours (Table 36-1) permits once-daily dosing, and the drug does not appear to undergo enterohepatic circulation. Renal impairment results in a doubling of its half-life and a 30% increase in the area under the curve.

Its properties are very similar to those of other NSAIDs, though it may be less damaging to the stomach than some other NSAIDs when given at a dosage of 1000 mg/d. Unfortunately, higher dosages (eg, 1500–2000 mg/d) are often needed, and this is a very expensive NSAID. Like naproxen, nabumetone has been reported to cause pseudoporphyria and photosensitivity in some patients. Other adverse effects mirror those of other NSAIDs.

### **Naproxen**

Naproxen is a naphthylpropionic acid derivative. It is the only NSAID presently marketed as a single enantiomer. Naproxen's free fraction is significantly higher in women than in men, but half-life is similar in both sexes (Table 36-1). Naproxen is effective for the usual rheumatologic indications and is available in a slow-release formulation, as an oral suspension, and over the counter. A topical preparation and an ophthalmic solution are also available.

The incidence of upper gastrointestinal bleeding in over-the-counter use is low but still double that of over-the-counter ibuprofen (perhaps due to a dose effect). Rare cases of allergic pneumonitis, leukocytoclastic vasculitis, and pseudoporphyria as well as the common NSAID-associated adverse effects have been noted.

### **Oxaprozin**

Oxaprozin is another propionic acid derivative NSAID. As noted in Table 36-1, its major difference from the other members of this subgroup is a very long half-life (50–60 hours), although oxaprozin does not undergo enterohepatic circulation. It is mildly uricosuric, making it potentially more useful in gout than some other NSAIDs. The drug has the same benefits and risks that are associated with other NSAIDs.

### **Piroxicam**

Piroxicam, an oxicam (Figure 36-1), is a nonselective COX inhibitor that at high concentrations also inhibits polymorphonuclear leukocyte migration, decreases oxygen radical production, and inhibits lymphocyte function. Its long half-life (Table 36-1) permits once-daily dosing.

Piroxicam can be used for the usual rheumatic indications. When piroxicam is used in dosages higher than 20 mg/d, an increased incidence of peptic ulcer and bleeding is encountered. Epidemiologic studies suggest that this risk is as much as 9.5 times higher with piroxicam than with other NSAIDs (see common adverse effects above).

### **Sulindac**

Sulindac is a sulfoxide prodrug. It is reversibly metabolized to the active sulfide metabolite, which is excreted in bile and then reabsorbed from the intestine. The enterohepatic cycling prolongs the duration of action to 12–16 hours.

In addition to its rheumatic disease indications, sulindac suppresses familial intestinal polyposis and it may inhibit the development of colon, breast, and prostate cancer in humans. It appears to inhibit the occurrence of gastrointestinal cancer in rats. The latter effect may be caused

by the sulfone rather than the sulfide.

Among the more severe adverse reactions, Stevens-Johnson epidermal necrolysis syndrome, thrombocytopenia, agranulocytosis, and nephrotic syndrome have all been observed. Like diclofenac, sulindac may have some propensity to cause elevation of serum aminotransferases; it is also sometimes associated with cholestatic liver damage, which disappears when the drug is stopped.

### **Tolmetin**

Tolmetin is a nonselective COX inhibitor with a short half-life (1½–2 hours) and is not often used. Its efficacy and toxicity profiles are similar to those of other NSAIDs with the following exceptions: it is ineffective (for unknown reasons) in the treatment of gout, and it may cause (rarely) thrombocytopenic purpura.

### **Other NSAIDs**

**Azapropazone, carprofen, meclofenamate, and tenoxicam** are rarely used and are not reviewed here.

### **CHOICE OF NSAID**

All NSAIDs, including aspirin, are about equally efficacious with a few exceptions—tolmetin seems not to be effective for gout, and aspirin is less effective than other NSAIDs (eg, indomethacin) for ankylosing spondylitis.

Thus, NSAIDs tend to be differentiated on the basis of toxicity and cost-effectiveness. For example, the gastrointestinal and renal side effects of ketorolac limit its use. Some surveys suggest that indomethacin or tolmetin are the NSAIDs associated with the greatest toxicity, while salsalate, aspirin, and ibuprofen are least toxic. The selective COX-2 inhibitors were not included in these analyses.

For patients with renal insufficiency, nonacetylated salicylates may be best. Diclofenac and sulindac are associated with more liver function test abnormalities than other NSAIDs. The relatively expensive, selective COX-2 inhibitor celecoxib, is probably safest for patients at high risk for gastrointestinal bleeding but may have a higher risk of cardiovascular toxicity. Celecoxib or a nonselective NSAID plus omeprazole or misoprostol may be appropriate in patients at highest risk for gastrointestinal bleeding; in this subpopulation of patients, they are cost-effective despite their high acquisition costs.

The choice of an NSAID thus requires a balance of efficacy, cost-effectiveness, safety, and numerous personal factors (eg, other drugs also being used, concurrent illness, compliance, medical insurance coverage), so that there is no best NSAID for all patients. There may, however, be one or two best NSAIDs for a specific person.

## **DISEASE-MODIFYING ANTIRHEUMATIC DRUGS (DMARDS)**

Careful clinical and epidemiologic studies have shown that rheumatoid arthritis is an immunologic disease that causes significant systemic effects which shorten life in addition to the joint disease that reduces mobility and quality of life. NSAIDs offer mainly symptomatic relief; they reduce inflammation and the pain it causes and often preserve function, but they have little effect on the progression of bone and cartilage destruction. Interest has therefore centered on finding treatments that might arrest—or at least slow—this progression by modifying the disease itself. The effects of disease-modifying therapies may take 6 weeks to 6 months to become evident although some biologics are effective within 2 weeks; generally, they are slow-acting compared with NSAIDs.

These therapies include methotrexate, a T-cell-modulating biologic (abatacept), azathioprine, chloroquine and hydroxychloroquine, cyclophosphamide, cyclosporine, leflunomide, mycophenolate mofetil, a B-cell cytotoxic agent (rituximab), sulfasalazine, and the TNF- $\alpha$ -blocking agents. These drugs comprise both biologically derived and nonbiologic agents and will be listed alphabetically, independent of origin. Gold salts, which were once extensively used, are no longer recommended because of their significant toxicities and questionable efficacy.

### **ABATACEPT**

#### **Mechanism of Action**

Abatacept is a costimulation modulator that inhibits the activation of T cells (see also Chapter 55). After a T cell has engaged an antigen-presenting cell (APC), a signal is produced by CD28 on the T cell that interacts with CD80 or CD86 on the APC, leading to T-cell activation. Abatacept (which contains the endogenous ligand CTLA-4) binds to CD80 and 86, thereby inhibiting the binding to CD28 and preventing the activation of T cells.

#### **Pharmacokinetics**

Abatacept is given as an intravenous infusion in three initial doses (day 0, week 2, and week 4), followed by monthly infusions. The dose is based on body weight, with patients weighing less than 60 kg receiving 500 mg, those 60–100 kg receiving 750 mg, and those more than 100 kg receiving 1000 mg. Dosing regimens in any adult group can be increased if needed. The terminal serum half-life is 13–16 days. Coadministration with methotrexate, NSAIDs, and corticosteroids does not influence abatacept clearance.

#### **Indications**

Abatacept can be used as monotherapy or in combination with other DMARDS in patients with moderate to severe rheumatoid arthritis who have had an inadequate response to other DMARDS. It reduces the clinical signs and symptoms of rheumatoid arthritis, including slowing of radiographic progression. It is also being tested in early rheumatoid arthritis.

#### **Adverse Effects**

There is a slightly increased risk of infection (as with other biologic DMARDS), predominantly of the upper respiratory tract. Concomitant use with TNF- $\alpha$  antagonists is not recommended due to the increased incidence of serious infection with this combination. Infusion-related reactions and hypersensitivity reactions, including anaphylaxis, have been reported but are rare. Anti-abatacept antibody formation is

infrequent (< 5%) and has no effect on clinical outcomes. The incidence of malignancies is similar to placebo with the exception of a possible increase in lymphomas. The role of abatacept in this increase is unknown.

## **AZATHIOPRINE**

### **Mechanism of Action**

Azathioprine acts through its major metabolite, 6-thioguanine. 6-Thioguanine suppresses inosinic acid synthesis, B-cell and T-cell function, immunoglobulin production, and interleukin-2 secretion (see Chapter 55).

### **Pharmacokinetics**

The metabolism of azathioprine is bimodal in humans, with rapid metabolizers clearing the drug four times faster than slow metabolizers. Production of 6-thioguanine is dependent on thiopurine methyltransferase (TPMT), and patients with low or absent TPMT activity (0.3% of the population) are at particularly high risk of myelosuppression by excess concentrations of the parent drug if dosage is not adjusted.

### **Indications**

Azathioprine is approved for use in rheumatoid arthritis and is used at a dosage of 2 mg/kg/d. Controlled trials show efficacy in psoriatic arthritis, reactive arthritis, polymyositis, systemic lupus erythematosus, and Behçet's disease.

### **Adverse Effects**

Azathioprine's toxicity includes bone marrow suppression, gastrointestinal disturbances, and some increase in infection risk. As noted in Chapter 55, lymphomas may be increased with azathioprine use. Rarely, fever, rash, and hepatotoxicity signal acute allergic reactions.

## **CHLOROQUINE & HYDROXYCHLOROQUINE**

### **Mechanism of Action**

Chloroquine and hydroxychloroquine are used mainly in malaria (see Chapter 52) and in the rheumatic diseases. The mechanism of the anti-inflammatory action of these drugs in rheumatic diseases is unclear. The following mechanisms have been proposed: suppression of T-lymphocyte responses to mitogens, decreased leukocyte chemotaxis, stabilization of lysosomal enzymes, inhibition of DNA and RNA synthesis, and the trapping of free radicals.

### **Pharmacokinetics**

Antimalarials are rapidly absorbed and 50% protein-bound in the plasma. They are very extensively tissue-bound, particularly in melanin-containing tissues such as the eyes. The drugs are deaminated in the liver and have blood elimination half-lives of up to 45 days.

### **Indications**

Antimalarials are approved for rheumatoid arthritis, but they are not considered very effective DMARDs. Dose-response and serum concentration-response relationships have been documented for hydroxychloroquine and dose-loading may increase rate of response. Although antimalarials improve symptoms, there is no evidence that these compounds alter bony damage in rheumatoid arthritis at their usual dosages (up to 6.4 mg/kg/d for hydroxychloroquine or 200 mg/d for chloroquine). It usually takes 3-6 months to obtain a response. Antimalarials are often used in the treatment of the skin manifestations, serositis, and joint pains of systemic lupus erythematosus, and they have been used in Sjögren's syndrome.

### **Adverse Effects**

Although ocular toxicity (see Chapter 52) may occur at dosages greater than 250 mg/d for chloroquine and greater than 6.4 mg/kg/d for hydroxychloroquine, it rarely occurs at lower doses. Nevertheless, ophthalmologic monitoring every 6-12 months is advised. Other toxicities include dyspepsia, nausea, vomiting, abdominal pain, rashes, and nightmares. These drugs appear to be relatively safe in pregnancy.

## **CYCLOPHOSPHAMIDE**

### **Mechanism of Action**

Cyclophosphamide's major active metabolite is phosphoramidate mustard, which cross-links DNA to prevent cell replication. It suppresses T-cell and B-cell function by 30-40%; T-cell suppression correlates with clinical response in the rheumatic diseases. Its pharmacokinetics and toxicities are discussed in Chapter 54.

### **Indications**

Cyclophosphamide is active against rheumatoid arthritis when given orally at dosages of 2 mg/kg/d but not when given intravenously. It is used regularly to treat systemic lupus erythematosus, vasculitis, Wegener's granulomatosis, and other severe rheumatic diseases.

## **CYCLOSPORINE**

### **Mechanism of Action**

Through regulation of gene transcription, cyclosporine inhibits interleukin-1 and interleukin-2 receptor production and secondarily inhibits macrophage-T-cell interaction and T-cell responsiveness (see Chapter 55). T-cell-dependent B-cell function is also affected.

### **Pharmacokinetics**

Cyclosporine absorption is incomplete and somewhat erratic, although a microemulsion formulation improves its consistency and provides 20-30% bioavailability. Grapefruit juice increases cyclosporine bioavailability by as much as 62%. Cyclosporine is metabolized by CYP3A and consequently is subject to a large number of drug interactions (see Chapters 55 and 66).

## Indications

Cyclosporine is approved for use in rheumatoid arthritis and retards the appearance of new bony erosions. Its usual dosage is 3–5 mg/kg/d divided into two doses. Anecdotal reports suggest that it may be useful in systemic lupus erythematosus, polymyositis and dermatomyositis, Wegener's granulomatosis, and juvenile chronic arthritis.

## Adverse Effects

Cyclosporine has significant nephrotoxicity, and its toxicity can be increased by drug interactions with diltiazem, potassium-sparing diuretics, and other drugs inhibiting CYP3A. Serum creatinine should be closely monitored. Other toxicities include hypertension, hyperkalemia, hepatotoxicity, gingival hyperplasia, and hirsutism.

## LEFLUNOMIDE

### Mechanism of Action

Leflunomide undergoes rapid conversion, both in the intestine and in the plasma, to its active metabolite, A77-1726. This metabolite inhibits dihydroorotate dehydrogenase, leading to a decrease in ribonucleotide synthesis and the arrest of stimulated cells in the G<sub>1</sub> phase of cell growth. Consequently, leflunomide inhibits T-cell proliferation and production of autoantibodies by B cells. Secondary effects include increases of interleukin-10 receptor mRNA, decreased interleukin-8 receptor type A mRNA, and decreased TNF- $\alpha$ -dependent nuclear factor kappa B (NF- $\kappa$ B) activation.

### Pharmacokinetics

Leflunomide is completely absorbed and has a mean plasma half-life of 19 days. A77-1726, the active metabolite of leflunomide, is thought to have approximately the same half-life and is subject to enterohepatic recirculation. Cholestyramine can enhance leflunomide excretion and increases total clearance by approximately 50%.

## Indications

Leflunomide is as effective as methotrexate in rheumatoid arthritis, including inhibition of bony damage. In one study, combined treatment with methotrexate and leflunomide resulted in a 46.2% ACR20 response compared with 19.5% in patients receiving methotrexate alone.

## Adverse Effects

Diarrhea occurs in approximately 25% of patients given leflunomide, although only about 3–5% discontinue the drug because of this effect. Elevation in liver enzymes also occurs. Both effects can be reduced by decreasing the dose of leflunomide. Other adverse effects associated with leflunomide are mild alopecia, weight gain, and increased blood pressure. Leukopenia and thrombocytopenia occur rarely. This drug is contraindicated in pregnancy.

## METHOTREXATE

Methotrexate is now considered the DMARD of first choice to treat rheumatoid arthritis and is used in 50–70% of patients. It is active in this condition at much lower doses than those needed in cancer chemotherapy (see Chapter 54).

### Mechanism of Action

Methotrexate's principal mechanism of action at the low doses used in the rheumatic diseases probably relates to inhibition of aminoimidazolecarboxamide ribonucleotide (AICAR) transformylase and thymidylate synthetase, with secondary effects on polymorphonuclear chemotaxis. There is some effect on dihydrofolate reductase and this affects lymphocyte and macrophage function, but this is not its principal mechanism of action. Methotrexate has direct inhibitory effects on proliferation and stimulates apoptosis in immune-inflammatory cells. Additionally, inhibition of proinflammatory cytokines linked to rheumatoid synovitis has been shown, leading to decreased inflammation seen with rheumatoid arthritis.

### Pharmacokinetics

The drug is approximately 70% absorbed after oral administration (see Chapter 54). It is metabolized to a less active hydroxylated metabolite, and both the parent compound and the metabolite are polyglutamated within cells, where they stay for prolonged periods. Methotrexate's serum half-life is usually only 6–9 hours, although it may be as long as 24 hours in some individuals. Methotrexate's concentration is increased in the presence of hydroxychloroquine, which can reduce the clearance or increase the tubular reabsorption of methotrexate. This drug is excreted principally in the urine, but up to 30% may be excreted in bile.

## Indications

Although the most common methotrexate dosing regimen for the treatment of rheumatoid arthritis is 15–25 mg weekly, there is an increased effect up to 30–35 mg weekly. The drug decreases the rate of appearance of new erosions. Evidence supports its use in juvenile chronic arthritis, and it has been used in psoriasis, psoriatic arthritis, ankylosing spondylitis, polymyositis, dermatomyositis, Wegener's granulomatosis, giant cell arteritis, systemic lupus erythematosus, and vasculitis.

## Adverse Effects

Nausea and mucosal ulcers are the most common toxicities. Progressive dose-related hepatotoxicity in the form of enzyme elevation occurs frequently, but cirrhosis is rare (< 1%). Liver toxicity is not related to serum methotrexate concentrations, and liver biopsy follow-up is only recommended every 5 years. A rare hypersensitivity-like lung reaction with acute shortness of breath is documented, as are pseudolymphomatous reactions. The incidence of gastrointestinal and liver function test abnormalities can be reduced by the use of leucovorin 24 hours after each weekly dose or by the use of daily folic acid, although this may decrease the efficacy of the methotrexate. This drug is contraindicated in pregnancy.

## **MYCOPHENOLATE MOFETIL**

### **Mechanism of Action**

Mycophenolate mofetil (MMF) is converted to mycophenolic acid, the active form of the drug. The active product inhibits cytosine monophosphate dehydrogenase and, secondarily, inhibits T-cell lymphocyte proliferation; downstream, it interferes with leukocyte adhesion to endothelial cells through inhibition of E-selectin, P-selectin, and intercellular adhesion molecule 1. MMF's pharmacokinetics and toxicities are discussed in Chapter 55.

### **Indications**

MMF is effective for the treatment of renal disease due to systemic lupus erythematosus and may be useful in vasculitis and Wegener's granulomatosis. Although MMF is occasionally used at a dosage of 2 g/d to treat rheumatoid arthritis, there are no well-controlled data regarding its efficacy in this disease.

## **RITUXIMAB**

### **Mechanism of Action**

Rituximab is a chimeric monoclonal antibody that targets CD20 B lymphocytes (see Chapter 55). This depletion takes place through cell-mediated and complement-dependent cytotoxicity and stimulation of cell apoptosis. Depletion of B lymphocytes reduces inflammation by decreasing the presentation of antigens to T lymphocytes and inhibiting the secretion of proinflammatory cytokines. Rituximab rapidly depletes peripheral B cells although this depletion neither correlates with efficacy nor with toxicity.

Rituximab has shown benefit in the treatment of rheumatoid arthritis refractory to anti-TNF agents. It has been approved for the treatment of active rheumatoid arthritis when combined with methotrexate.

### **Pharmacokinetics**

Rituximab is given as two intravenous infusions of 1000 mg, separated by 2 weeks. It may be repeated every 6–9 months, as needed. Repeated courses remain effective. Pretreatment with glucocorticoids given intravenously 30 minutes prior to infusion (usually 100 mg of methylprednisolone) decreases the incidence and severity of infusion reactions.

### **Indications**

Rituximab is indicated for the treatment of moderately to severely active rheumatoid arthritis in combination with methotrexate in patients with an inadequate response to one or more TNF- $\alpha$  antagonists.

### **Adverse Effects**

About 30% of patients develop rashes with the first 1000 mg treatment; this incidence decreases to about 10% with the second infusion and progressively decreases with each course of therapy thereafter. These rashes do not usually require discontinuation of therapy although urticarial or anaphylactoid reactions, of course, preclude further therapy. Immunoglobulins (particularly IgG and IgM) may decrease with repeated courses of therapy and infections can occur, although they do not seem directly associated with the decreases in immunoglobulins. Rituximab has not been associated with activation of tuberculosis, nor with the occurrence of lymphomas or other tumors (see Chapter 55). Other adverse effects, eg, cardiovascular events, are rare.

## **SULFASALAZINE**

### **Mechanism of Action**

Sulfasalazine is metabolized to sulfapyridine and 5-aminosalicylic acid, and it is thought that the sulfapyridine is probably the active moiety when treating rheumatoid arthritis (unlike inflammatory bowel disease, see Chapter 62). Some authorities believe that the parent compound, sulfasalazine, also has an effect. In treated arthritis patients, IgA and IgM rheumatoid factor production are decreased. Suppression of T-cell responses to concanavalin and inhibition of in vitro B-cell proliferation have also been documented. In vitro studies have shown that sulfasalazine or its metabolites inhibit the release of inflammatory cytokines, including those produced by monocytes or macrophages, eg, interleukins-1, -6, and -12, and TNF- $\alpha$ . These findings suggest a possible mechanism for the clinical efficacy of sulfasalazine in rheumatoid arthritis.

### **Pharmacokinetics**

Only 10–20% of orally administered sulfasalazine is absorbed, although a fraction undergoes enterohepatic recirculation into the bowel where it is reduced by intestinal bacteria to liberate sulfapyridine and 5-aminosalicylic acid (see Figure 62–8). Sulfapyridine is well absorbed while 5-aminosalicylic acid remains unabsorbed. Some sulfasalazine is excreted unchanged in the urine whereas sulfapyridine is excreted after hepatic acetylation and hydroxylation. Sulfasalazine's half-life is 6–17 hours.

### **Indications**

Sulfasalazine is effective in rheumatoid arthritis and reduces radiologic disease progression. It has been used in juvenile chronic arthritis and in ankylosing spondylitis and its associated uveitis. The usual regimen is 2–3 g/d.

### **Adverse Effects**

Approximately 30% of patients using sulfasalazine discontinue the drug because of toxicity. Common adverse effects include nausea, vomiting, headache, and rash. Hemolytic anemia and methemoglobinemia also occur, but rarely. Neutropenia occurs in 1–5% of patients, while thrombocytopenia is very rare. Pulmonary toxicity and positive double-stranded DNA are occasionally seen, but drug-induced lupus is rare. Reversible infertility occurs in men, but sulfasalazine does not affect fertility in women. The drug does not appear to be teratogenic.

## TNF- $\alpha$ BLOCKING AGENTS

Cytokines play a central role in the immune response (see Chapter 56) and in rheumatoid arthritis. Although a wide range of cytokines are expressed in the joints of rheumatoid arthritis patients, TNF- $\alpha$  appears to be particularly important in the inflammatory process.

TNF- $\alpha$  affects cellular function via activation of specific membrane-bound TNF receptors (TNFR<sub>1</sub>, TNFR<sub>2</sub>). Three drugs interfering with TNF- $\alpha$  have been approved for the treatment of rheumatoid arthritis and other rheumatic diseases (Figure 36-4).

Figure 36-4

Red regions, human derived; blue regions, mouse derived.

### Adalimumab

#### MECHANISM OF ACTION

Adalimumab is a fully human IgG<sub>1</sub> anti-TNF monoclonal antibody. This compound complexes with soluble TNF- $\alpha$  and prevents its interaction with p55 and p75 cell surface receptors. This results in down-regulation of macrophage and T cell function.

#### PHARMACOKINETICS

Adalimumab is given subcutaneously and has a half-life of 10-20 days. Its clearance is decreased by more than 40% in the presence of methotrexate, and the formation of human antimonoal antibody is decreased when methotrexate is given at the same time. The usual dose in rheumatoid arthritis is 40 mg every other week, although increased responses may be evident at higher dosages. In psoriasis, 80 mg is given at week 0, 40 mg at week 1, and then 40 mg every other week thereafter.

#### INDICATIONS

The compound is approved for the treatment of rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, juvenile idiopathic arthritis, plaque psoriasis, and Crohn's disease. It decreases the rate of formation of new erosions. It is effective both as monotherapy and in combination with methotrexate and other DMARDs.

#### ADVERSE EFFECTS

In common with the other TNF- $\alpha$  blocking agents, the risk of bacterial infections and macrophage-dependent infection (including tuberculosis and other opportunistic infections) is increased, although it remains very low. Patients should be screened for latent or active tuberculosis before starting adalimumab or other TNF- $\alpha$  blocking agents. There is no evidence of an increased incidence of solid malignancies. It is not clear if the incidence of lymphomas is increased by adalimumab. A low incidence of newly formed double-stranded DNA (dsDNA) antibodies and antinuclear antibodies (ANAs) has been documented when using adalimumab, but clinical lupus is extremely rare. Rare leukopenias and vasculitis, apparently associated with adalimumab, have been documented.

### Infliximab

#### MECHANISM OF ACTION

Infliximab (Figure 36-4) is a chimeric (25% mouse, 75% human) IgG<sub>1</sub> monoclonal antibody that binds with high affinity to soluble and possibly membrane-bound TNF- $\alpha$ . Its mechanism of action probably is the same as that of adalimumab.

#### PHARMACOKINETICS

Infliximab is given as an intravenous infusion at doses of 3-10 mg/kg, although the usual dose is 3-5 mg/kg every 8 weeks. There is a

relationship between serum concentration and effect, although individual clearances vary markedly. The terminal half-life is 9â€”12 days without accumulation after repeated dosing at the recommended interval of 8 weeks. After intermittent therapy, infliximab elicits human antichimeric antibodies in up to 62% of patients. Concurrent therapy with methotrexate markedly decreases the prevalence of human antichimeric antibodies.

#### **INDICATIONS**

Infliximab is approved for use in rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, and Crohn's disease. It is being used in other diseases, including psoriasis, ulcerative colitis, juvenile chronic arthritis, Wegener's granulomatosis, giant cell arteritis, and sarcoidosis. In rheumatoid arthritis, a regimen of infliximab plus methotrexate decreases the rate of formation of new erosions more than methotrexate alone over 12â€”24 months. Although it is recommended that methotrexate be used in conjunction with infliximab, a number of other DMARDs, including antimalarials, azathioprine, leflunomide, and cyclosporine, can be used as background therapy for this drug.

#### **ADVERSE EFFECTS**

Like other TNF- $\alpha$  blocking agents, infliximab is associated with an increased incidence of bacterial infections, including upper respiratory tract infections. As a potent macrophage inhibitor, infliximab can be associated with activation of latent tuberculosis, and patients should be screened for latent or active tuberculosis before starting therapy. Other infections have been documented, although rarely. There is no evidence for an increased incidence of solid malignancies and it is not clear if the incidence of lymphoma is increased with infliximab. Because rare demyelinating syndromes have been reported, patients with multiple sclerosis should not use infliximab. Rare cases of leukopenia, hepatitis, activation of hepatitis B, and vasculitis have been documented. The incidence of positive ANA and dsDNA antibodies is increased, although clinical lupus erythematosus remains an extremely rare occurrence and the presence of ANA and dsDNA does not contraindicate the use of infliximab. Infusion site reactions correlate with anti-infliximab antibodies. These reactions occur in approximately 3â€”11% of patients, and the combined use of antihistamines and H<sub>2</sub> blocking agents apparently prevents some of these reactions.

#### **Etanercept**

##### **MECHANISM OF ACTION**

Etanercept is a recombinant fusion protein consisting of two soluble TNF p75 receptor moieties linked to the F<sub>c</sub> portion of human IgG<sub>1</sub> (Figure 36â€”4); it binds TNF- $\alpha$  molecules and also inhibits lymphotoxin- $\alpha$ .

##### **PHARMACOKINETICS**

Etanercept is given subcutaneously in a dosage of 25 mg twice weekly or 50 mg weekly. In psoriasis, 50 mg is given twice weekly for 12 weeks followed by 50 mg weekly. The drug is slowly absorbed, with peak concentration 72 hours after drug administration. Etanercept has a mean serum elimination half-life of 4.5 days. Fifty milligrams given once weekly gives the same area under the curve and minimum serum concentrations as 25 mg twice weekly.

##### **INDICATIONS**

Etanercept is approved for the treatment of rheumatoid arthritis, juvenile chronic arthritis, psoriasis, psoriatic arthritis, and ankylosing spondylitis. It can be used as monotherapy although over 70% of patients taking etanercept are also using methotrexate. Etanercept decreases the rate of formation of new erosions relative to methotrexate alone. It is also being used in other rheumatic syndromes such as scleroderma, Wegener's granulomatosis, giant cell arteritis, and sarcoidosis.

##### **ADVERSE EFFECTS**

The incidence of bacterial infections is slightly increased, especially soft tissue infections and septic arthritis. Activation of latent tuberculosis is lower with etanercept than with other TNF-blocking agents. Nevertheless, patients should be screened for latent or active tuberculosis before starting this medication. Similarly, opportunistic infections can rarely occur when using etanercept. The incidence of solid malignancies is not increased, but as with other TNF-blocking agents one must be alert for lymphomas (although their incidence may not be increased compared with other DMARDs or active rheumatoid arthritis itself). While positive ANAs and dsDNAs may be found in patients receiving this drug, these findings do not contraindicate continued use if clinical lupus symptoms do not occur. Injection site reactions occur in 20â€”40% of patients, although they rarely result in discontinuation of therapy. Anti-etanercept antibodies are present in up to 16% of treated patients, but they do not interfere with efficacy or predict toxicity.

#### **COMBINATION THERAPY WITH DMARDs**

In a 1998 study, approximately half of North American rheumatologists treated moderately aggressive rheumatoid arthritis with combination therapy, and the use of drug combinations is probably much higher now. Combinations of DMARDs can be designed rationally on the basis of complementary mechanisms of action, nonoverlapping pharmacokinetics, and nonoverlapping toxicities.

When added to methotrexate background therapy, cyclosporine, chloroquine, hydroxychloroquine, leflunomide, infliximab, adalimumab, rituximab, and etanercept have all shown improved efficacy. In contrast, azathioprine, auranofin, or sulfasalazine plus methotrexate results in no additional therapeutic benefit. Other combinations have occasionally been used, including the combination of intramuscular gold with hydroxychloroquine.

While it might be anticipated that combination therapy might result in more toxicity, this is often not the case. Combination therapy for patients not responding adequately to monotherapy is becoming the rule in the treatment of rheumatoid arthritis.

#### **GLUCOCORTICOID DRUGS**

The general pharmacology of corticosteroids, including mechanism of action, pharmacokinetics, and other applications, is discussed in Chapter 39.

#### **Indications**

Corticosteroids have been used in 60–70% of rheumatoid arthritis patients. Their effects are prompt and dramatic, and they are capable of slowing the appearance of new bone erosions. Corticosteroids may be administered for certain serious extra-articular manifestations of rheumatoid arthritis such as pericarditis or eye involvement or during periods of exacerbation. When prednisone is required for long-term therapy, the dosage should not exceed 7.5 mg daily, and gradual reduction of the dose should be encouraged. Alternate-day corticosteroid therapy is usually unsuccessful in rheumatoid arthritis.

Other rheumatic diseases in which the corticosteroids' potent anti-inflammatory effects may be useful include vasculitis, systemic lupus erythematosus, Wegener's granulomatosis, psoriatic arthritis, giant cell arteritis, sarcoidosis, and gout.

Intra-articular corticosteroids are often helpful to alleviate painful symptoms and, when successful, are preferable to increasing the dosage of systemic medication.

### Adverse Effects

Prolonged use of these drugs leads to serious and disabling toxic effects as described in Chapter 39. There is controversy over whether many of these side effects occur at doses below 7.5 mg prednisone equivalent daily, although many experts believe that even 5 mg/d can cause these effects in susceptible individuals when this class of drugs is used over prolonged periods.

## OTHER ANALGESICS

Acetaminophen is one of the most important drugs used in the treatment of mild to moderate pain when an anti-inflammatory effect is not necessary. Phenacetin, a prodrug that is metabolized to acetaminophen, is more toxic than its active metabolite and has no rational indications.

### ACETAMINOPHEN

Acetaminophen is the active metabolite of phenacetin and is responsible for its analgesic effect. It is a weak COX-1 and COX-2 inhibitor in peripheral tissues and possesses no significant anti-inflammatory effects.

**N-Acetyl-p-aminophenol  
(acetaminophen)**

### Pharmacokinetics

Acetaminophen is administered orally. Absorption is related to the rate of gastric emptying, and peak blood concentrations are usually reached in 30–60 minutes. Acetaminophen is slightly bound to plasma proteins and is partially metabolized by hepatic microsomal enzymes and converted to acetaminophen sulfate and glucuronide, which are pharmacologically inactive (see Figure 4–5). Less than 5% is excreted unchanged. A minor but highly active metabolite (*N*-acetyl-*p*-benzoquinone) is important in large doses because it is toxic to both liver and kidney. The half-life of acetaminophen is 2–3 hours and is relatively unaffected by renal function. With toxic doses or liver disease, the half-life may be increased twofold or more.

### Indications

Although said to be equivalent to aspirin as an analgesic and antipyretic agent, acetaminophen differs in that it lacks anti-inflammatory properties. It does not affect uric acid levels and lacks platelet-inhibiting properties. The drug is useful in mild to moderate pain such as headache, myalgia, postpartum pain, and other circumstances in which aspirin is an effective analgesic. Acetaminophen alone is inadequate therapy for inflammatory conditions such as rheumatoid arthritis, although it may be used as an analgesic adjunct to anti-inflammatory therapy. For mild analgesia, acetaminophen is the preferred drug in patients allergic to aspirin or when salicylates are poorly tolerated. It is preferable to aspirin in patients with hemophilia or a history of peptic ulcer and in those in whom bronchospasm is precipitated by aspirin. Unlike aspirin, acetaminophen does not antagonize the effects of uricosuric agents; it may be used concomitantly with probenecid in the treatment of gout. It is preferred to aspirin in children with viral infections.

### Adverse Effects

In therapeutic doses, a mild increase in hepatic enzymes may occasionally occur in the absence of jaundice; this is reversible when the drug is withdrawn. With larger doses, dizziness, excitement, and disorientation can be seen. Ingestion of 15 g of acetaminophen may be fatal, death being caused by severe hepatotoxicity with centrilobular necrosis, sometimes associated with acute renal tubular necrosis (see Chapters 4 and 58). Doses greater than 4–6 g/d are not recommended and a history of alcoholism contraindicates even this dose. Early symptoms of hepatic damage include nausea, vomiting, diarrhea, and abdominal pain. Cases of renal damage without hepatic damage have occurred, even after usual doses of acetaminophen. Therapy is much less satisfactory than for aspirin overdose. In addition to supportive therapy, the measure that has proved most useful is the provision of sulfhydryl groups in the form of acetylcysteine to neutralize the toxic metabolites (see Chapter 58).

Hemolytic anemia and methemoglobinemia are very rare adverse events. Interstitial nephritis and papillary necrosis—serious complications of phenacetin—have not occurred nor has gastrointestinal bleeding. Caution is necessary in patients with any type of liver disease.

### Dosage

Acute pain and fever may be effectively treated with 325–500 mg four times daily and proportionately less for children.

## DRUGS USED IN GOUT

Gout is a metabolic disease characterized by recurrent episodes of acute arthritis due to deposits of monosodium urate in joints and cartilage. Uric acid renal calculi, tophi, and interstitial nephritis may also occur. Gout is usually associated with hyperuricemia, high serum levels of uric acid, a poorly soluble substance that is the major end product of purine metabolism. In most mammals, uricase converts uric acid to the more soluble allantoin; this enzyme is absent in humans. While clinical gouty episodes are associated with hyperuricemia, most individuals with hyperuricemia may never develop a clinical event from urate crystal deposition.

The treatment of gout aims to relieve acute gouty attacks and to prevent recurrent gouty episodes and urate lithiasis. Therapy for an attack of acute gouty arthritis is based on our current understanding of the pathophysiologic events that occur in this disease (Figure 36â€5). Urate crystals are initially phagocytosed by synoviocytes, which then release prostaglandins, lysosomal enzymes, and interleukin-1. Attracted by these chemotactic mediators, polymorphonuclear leukocytes migrate into the joint space and amplify the ongoing inflammatory process. In the later phases of the attack, increased numbers of mononuclear phagocytes (macrophages) appear, ingest the urate crystals, and release more inflammatory mediators. This sequence of events suggests that the most effective agents for the management of acute urate crystal-induced inflammation are those that suppress different phases of leukocyte activation.

**Figure 36â€5**

Pathophysiologic events in a gouty joint. Synoviocytes phagocytose urate crystals and then secrete inflammatory mediators, which attract and activate polymorphonuclear leukocytes (PMN) and mononuclear phagocytes (MNP) (macrophages). Drugs active in gout inhibit crystal phagocytosis and polymorphonuclear leukocyte and macrophage release of inflammatory mediators. PG, prostaglandin; IL-1, interleukin-1; LTB<sub>4</sub>, leukotriene B<sub>4</sub>.

Before starting chronic therapy for gout, patients in whom hyperuricemia is associated with gout and urate lithiasis must be clearly distinguished from those who have only hyperuricemia. In an asymptomatic person with hyperuricemia, the efficacy of long-term drug treatment is unproved. In some individuals, uric acid levels may be elevated up to 2 standard deviations above the mean for a lifetime without adverse consequences.

Colchicine, NSAIDs, glucocorticoids and a number of other agents have been used to treat acute gout.

## COLCHICINE

Although NSAIDs are now the first-line drugs for acute gout, colchicine was the primary treatment for many years. Colchicine is an alkaloid isolated from the autumn crocus, *Colchicum autumnale*. Its structure is shown in Figure 36â€6.

**Figure 36â€6**

**Colchicine**

**Probenecid**

Colchicine and uricosuric drugs.

## Pharmacokinetics

Colchicine is absorbed readily after oral administration, reaches peak plasma levels within 2 hours, and is eliminated with a serum half-life of 9 hours. Metabolites are excreted in the intestinal tract and urine.

## Pharmacodynamics

Colchicine relieves the pain and inflammation of gouty arthritis in 12–24 hours without altering the metabolism or excretion of urates and without other analgesic effects. Colchicine produces its anti-inflammatory effects by binding to the intracellular protein tubulin, thereby preventing its polymerization into microtubules and leading to the inhibition of leukocyte migration and phagocytosis. It also inhibits the formation of leukotriene B<sub>4</sub>. Several of colchicine's adverse effects are produced by its inhibition of tubulin polymerization and cell mitosis.

## Indications

Although colchicine is more specific in gout than the NSAIDs, NSAIDs (eg, indomethacin and other NSAIDs [except aspirin]) have replaced it in the treatment of acute gout because of the troublesome diarrhea sometimes associated with colchicine therapy. Colchicine is now used for the prophylaxis of recurrent episodes of gouty arthritis, is effective in preventing attacks of acute Mediterranean fever, and may have a mild beneficial effect in sarcoid arthritis and in hepatic cirrhosis. Although it can be given intravenously, this route should be used cautiously because of increased bone marrow toxicity.

## Adverse Effects

Colchicine often causes diarrhea and may occasionally cause nausea, vomiting, and abdominal pain. Hepatic necrosis, acute renal failure, disseminated intravascular coagulation, and seizures have also been observed. Colchicine may rarely cause hair loss and bone marrow depression as well as peripheral neuritis, myopathy, and in some cases death. The more severe adverse events have been associated with the intravenous administration of colchicine.

Acute intoxication after overdoses is characterized by burning throat pain, bloody diarrhea, shock, hematuria, and oliguria. Fatal ascending central nervous system depression has been reported. Treatment is supportive.

## Dosage

In prophylaxis (the most common use), the dosage of colchicine is 0.6 mg one to three times daily. For terminating an attack of gout, the

traditional initial dose of colchicine is usually 0.6 or 1.2 mg, followed by 0.6 mg every 2 hours until pain is relieved or nausea and diarrhea appear. Recently a regimen of 1.2 mg followed by a single 0.6 mg oral dose was shown to be as effective as the higher dose therapy above. Adverse events were less with the lower dose regimen. The total dose can be given intravenously if necessary, but it should be remembered that as little as 8 mg in 24 hours may be fatal. In February 2008, the FDA requested that intravenous preparations containing colchicine be discontinued in the USA due to their potential life-threatening adverse effects. Therefore, intravenous use of colchicine is not recommended.

## NSAIDS IN GOUT

In addition to inhibiting prostaglandin synthase, indomethacin and other NSAIDs also inhibit urate crystal phagocytosis. Aspirin is not used due to its renal retention of uric acid at low doses ( $\approx 2.6$  g/d). It is uricosuric at doses greater than 3.6 g/d. Indomethacin is commonly used in the initial treatment of gout as the replacement for colchicine. For acute gout, 50 mg is given three times daily; when a response occurs, the dosage is reduced to 25 mg three times daily for 5–7 days.

All other NSAIDs except aspirin, salicylates, and tolmetin have been successfully used to treat acute gouty episodes. Oxaprozin, which lowers serum uric acid, is theoretically a good choice although it should not be given to patients with uric acid stones because it increases uric acid excretion in the urine. These agents appear to be as effective and safe as the older drugs.

## URICOSURIC AGENTS

**Probenecid** and **sulfinpyrazone** are uricosuric drugs employed to decrease the body pool of urate in patients with tophaceous gout or in those with increasingly frequent gouty attacks. In a patient who excretes large amounts of uric acid, the uricosuric agents should not be used.

### Chemistry

Uricosuric drugs are organic acids (Figure 36–6) and, as such, act at the anion transport sites of the renal tubule (see Chapter 15). Sulfinpyrazone is a metabolite of an analog of phenylbutazone.

### Pharmacokinetics

Probenecid is completely reabsorbed by the renal tubules and is metabolized slowly with a terminal serum half-life of 5–8 hours. Sulfinpyrazone or its active hydroxylated derivative is rapidly excreted by the kidneys. Even so, the duration of its effect after oral administration is almost as long as that of probenecid, which is given once or twice daily.

### Pharmacodynamics

Uric acid is freely filtered at the glomerulus. Like many other weak acids, it is also both reabsorbed and secreted in the middle segment ( $S_2$ ) of the proximal tubule. Uricosuric drugs—probenecid, sulfinpyrazone, and large doses of aspirin—affect these active transport sites so that net reabsorption of uric acid in the proximal tubule is decreased. Because aspirin in doses of less than 2.6 g daily causes net *retention* of uric acid by inhibiting the secretory transporter, it should not be used for analgesia in patients with gout. The secretion of other weak acids (eg, penicillin) is also reduced by uricosuric agents. Probenecid was originally developed to prolong penicillin blood levels.

As the urinary excretion of uric acid increases, the size of the urate pool decreases, although the plasma concentration may not be greatly reduced. In patients who respond favorably, tophaceous deposits of urate are reabsorbed, with relief of arthritis and remineralization of bone. With the ensuing increase in uric acid excretion, a predisposition to the formation of renal stones is augmented rather than decreased; therefore, the urine volume should be maintained at a high level, and at least early in treatment the urine pH should be kept above 6.0 by the administration of alkali.

### Indications

Uricosuric therapy should be initiated in gouty underexcretion of uric acid when allopurinol (or febuxostat, discussed below) is contraindicated or when tophi are present. Therapy should not be started until 2–3 weeks after an acute attack.

### Adverse Effects

Adverse effects do not provide a basis for preferring one or the other of the uricosuric agents. Both of these organic acids cause gastrointestinal irritation, but sulfinpyrazone is more active in this regard. A rash may appear after the use of either compound. Nephrotic syndrome has occurred after the use of probenecid. Both sulfinpyrazone and probenecid may rarely cause aplastic anemia.

### Contraindications & Cautions

It is essential to maintain a large urine volume to minimize the possibility of stone formation.

### Dosage

Probenecid is usually started at a dosage of 0.5 g orally daily in divided doses, progressing to 1 g daily after 1 week. Sulfinpyrazone is started at a dosage of 200 mg orally daily, progressing to 400–800 mg daily. It should be given in divided doses with food to reduce adverse gastrointestinal effects.

## ALLOPURINOL

The preferred and standard-of-care therapy for gout in the intercritical period (the period between acute episodes) is allopurinol, which reduces total uric acid body burden by inhibiting xanthine oxidase.

### Chemistry

The structure of allopurinol, an isomer of hypoxanthine, is shown in Figure 36–7.

### Figure 36–7

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 11th Edition: <http://www.accessmedicine.com>

Inhibition of uric acid synthesis by allopurinol.

(Modified and reproduced, with permission, from Meyers FH, Jawetz E, Goldfien A: *Review of Medical Pharmacology*, 7th ed. McGraw-Hill, 1980.)

## Pharmacokinetics

Allopurinol is approximately 80% absorbed after oral administration and has a terminal serum half-life of 12 hours. Like uric acid, allopurinol is itself metabolized by xanthine oxidase, but the resulting compound, alloxanthine, retains the capacity to inhibit xanthine oxidase and has a long enough duration of action so that allopurinol is given only once a day.

## Pharmacodynamics

Dietary purines are not an important source of uric acid. Quantitatively important amounts of purine are formed from amino acids, formate, and carbon dioxide in the body. Those purine ribonucleotides not incorporated into nucleic acids and derived from nucleic acid degradation are converted to xanthine or hypoxanthine and oxidized to uric acid (Figure 36-7). Allopurinol inhibits this last step, resulting in a fall in the plasma urate level and a decrease in the size of the urate pool. The more soluble xanthine and hypoxanthine are increased.

## Indications

Treatment of patients in the intercritical period of gout with allopurinol, as with uricosuric agents, is begun with the expectation that it will be continued for years if not for life. Allopurinol is often the first urate-lowering drug used. When starting allopurinol, colchicine or an NSAID should also be used until steady-state serum uric acid is normalized or decreased to less than 6 mg/dL. Thereafter colchicine or the NSAID can be stopped, while allopurinol is continued. Aside from gout, allopurinol is used as an antiprotozoal agent (see Chapter 52) and is indicated to prevent the massive uricosuria following therapy of blood dyscrasias that could otherwise lead to renal calculi.

## Adverse Effects

See above for protection against an acute attack during the initial use of allopurinol. Gastrointestinal intolerance, including nausea, vomiting, and diarrhea, may occur. Peripheral neuritis and necrotizing vasculitis, depression of bone marrow elements, and, rarely, aplastic anemia may also occur. Hepatic toxicity and interstitial nephritis have been reported. An allergic skin reaction characterized by pruritic maculopapular lesions occurs in 3% of patients. Isolated cases of exfoliative dermatitis have been reported. In very rare cases, allopurinol has become bound to the lens, resulting in cataracts.

## Interactions & Cautions

When chemotherapeutic mercaptopurines (eg, azathioprine) are given concomitantly with allopurinol, their dosage must be reduced by about 75%. Allopurinol may also increase the effect of cyclophosphamide. Allopurinol inhibits the metabolism of probenecid and oral anticoagulants and may increase hepatic iron concentration. Safety in children and during pregnancy has not been established.

## Dosage

The initial dosage of allopurinol is 100 mg/d. It may be titrated upward until serum uric acid is below 6 mg/dL; this level is commonly achieved at 300 mg/d but is not restricted to this dose.

As noted above, colchicine or an NSAID should be given during the first weeks of allopurinol therapy to prevent the gouty arthritis episodes that sometimes occur.

## FEBUXOSTAT

Febuxostat is the first nonpurine inhibitor of xanthine oxidase and has recently been approved by the FDA.

## Pharmacokinetics

Febuxostat is more than 80% absorbed following oral administration. Maximum concentration is reached in approximately 1 hour. Febuxostat is extensively metabolized in the liver. All of the drug and its metabolites appear in the urine although less than 5% appears as unchanged drug. Because it is highly metabolized to inactive metabolites, no dosage adjustment is necessary for patients with renal impairment.

### **Pharmacodynamics**

Febuxostat is a potent and selective inhibitor of xanthine oxidase, and thereby reduces the formation of xanthine and uric acid. No other enzymes involved in purine or pyrimidine metabolism are inhibited. In clinical trials, febuxostat at a daily dose of 80 mg or 120 mg was more effective than allopurinol at a standard 300 mg daily dose in lowering serum urate levels. The urate-lowering effect was comparable regardless of the pathogenic cause of hyperuricemia—overproduction or underexcretion.

### **Indications**

Febuxostat is approved at its 80 mg and 120 mg dose for the treatment of chronic gout. It is the first new drug for the treatment of the intercritical period of gout in over 40 years.

### **Adverse Effects**

As with allopurinol, prophylactic treatment with colchicine or NSAIDs should start at the beginning of treatment to avoid gout flares. The most frequent treatment-related adverse events are liver function abnormalities, diarrhea, headache, and nausea. Febuxostat appears to be well tolerated in patients with a history of allopurinol intolerance.

### **GLUCOCORTICOIDS**

Corticosteroids are sometimes used in the treatment of severe symptomatic gout, by intra-articular, systemic, or subcutaneous routes, depending on the degree of pain and inflammation. The most commonly used oral corticosteroid is prednisone. The recommended dose is 30–50 mg/d for 1–2 days, tapered over 7–10 days. Intra-articular injection of 10 mg (small joints), 30 mg (wrist, ankle, elbow), and 40 mg (knee) of triamcinolone acetonide can be given if the patient is unable to take oral medications.

### **INTERLEUKIN-1 INHIBITORS**

Drugs targeting interleukin-1, such as Anakinra, are being investigated for potential benefits in the treatment of gout. However, the data are currently limited, and this application is still in the investigational stages. The use of interleukin-1-targeted drugs for gout is not recommended.

### **PREPARATIONS AVAILABLE**

#### **NONSTEROIDAL ANTI-INFLAMMATORY DRUGS**

##### **Aspirin, acetylsalicylic acid** (generic, Easprin, others)

Oral (regular, enteric-coated, buffered): 81, 165, 325, 500, 650, 800 mg tablets; 81, 650, 800 mg timed- or extended-release tablets  
Rectal: 120, 200, 300, 600 mg suppositories

##### **Bromfenac** (Xibrom)

Ophthalmic: 0.09% solution

##### **Celecoxib** (Celebrex)

Oral: 50, 100, 200, 400 mg capsules

##### **Choline salicylate** (various)

Oral: 870 mg/5 mL liquid

##### **Diclofenac** (generic, Cataflam, Voltaren)

Oral: 50 mg tablets; 25, 50, 75 mg delayed-release tablets; 100 mg extended-release tablets  
Ophthalmic: 0.1% solution

##### **Diflunisal** (generic, Dolobid)

Oral: 500 mg tablets

##### **Etodolac** (generic, Lodine)

Oral: 200, 300 mg capsules; 400, 500 mg tablets; 400, 500, 600 mg extended-release tablets

##### **Fenoprofen** (generic, Nalfon)

Oral: 200, 300 mg capsules; 600 mg tablets

**Flurbiprofen** (generic, Ansaid)

Oral: 50, 100 mg tablets

Ophthalmic (generic, Ocufer): 0.03% solution

**Ibuprofen** (generic, Motrin, Rufen, Advil [otc], Nuprin [otc], others)

Oral: 100, 200, 400, 600, 800 mg tablets; 50, 100 mg chewable tablets; 200 mg capsules; 100 mg/2.5 mL suspension, 100 mg/5 mL suspension; 40 mg/mL drops

**Indomethacin** (generic, Indocin)

Oral: 25, 50 mg capsules; 75 mg sustained-release capsules; 25 mg/5 mL suspension

Rectal: 50 mg suppositories

**Ketoprofen** (generic, Orudis)

Oral: 12.5 mg tablets; 25, 50, 75 mg capsules; 100, 150, 200 mg extended-release capsules

**Ketorolac tromethamine** (generic, Toradol)

Oral: 10 mg tablets

Parenteral: 15, 30 mg/mL for IM injection

Ophthalmic: 0.4, 0.5% solution

**Magnesium salicylate** (Doan's Pills, Magan, Mobidin)

Oral: 545, 600 mg tablets; 467, 500, 580 mg caplets

**Meclofenamate sodium** (generic)

Oral: 50, 100 mg capsules

**Mefenamic acid** (Ponstel)

Oral: 250 mg capsules

**Meloxicam** (Mobic)

Oral: 7.5, 15 mg tablets; 7.5 mg/5 mL suspension

**Nabumetone** (generic)

Oral: 500, 750 mg tablets

**Naproxen** (generic, Naprosyn, Anaprox, Aleve [otc])

Oral: 200, 220, 250, 375, 500 mg tablets; 375, 550 mg controlled-release tablets; 375, 500 mg delayed-release tablets; 125 mg/5 mL suspension

**Oxaprozin** (generic, Daypro)

Oral: 600 mg tablets, capsules

**Piroxicam** (generic, Feldene)

Oral: 10, 20 mg capsules

**Salsalate, salicylsalicylic acid** (generic, Disalcid)

Oral: 500, 750 mg tablets; 500 mg capsules

**Sodium salicylate** (generic)

Oral: 325, 650 mg enteric-coated tablets

**Sodium thiosalicylate** (generic, Rexolate)

Parenteral: 50 mg/mL for IM injection

**Sulindac** (generic, Clinoril)

Oral: 150, 200 mg tablets

**Suprofen** (Profenal)

Topical: 1% ophthalmic solution

**Tolmetin** (generic, Tolectin)

Oral: 200, 600 mg tablets; 400 mg capsules

**DISEASE-MODIFYING ANTIRHEUMATIC DRUGS**

**Abatacept** (Orencia)

Parenteral: 250 mg/vial lyophilized, for reconstitution for IV injection

**Adalimumab** (Humira)

Parenteral: 40 mg/0.8 mL for SC injection

**Auranofin** (Ridaura)

Oral: 3 mg capsules

**Aurothioglucose** (Solganal)

Parenteral: 50 mg/mL suspension for injection

**Etanercept** (Enbrel)

Parenteral: 50 mg/mL, 25 mg powder for SC injection

**Gold sodium thiomalate** (generic, Aurolate)

Parenteral: 50 mg/mL for injection

**Infliximab** (Remicade)

Parenteral: 100 mg powder for IV infusion

**Leflunomide** (Arava)

Oral: 10, 20, 100 mg tablets

**Methotrexate** (generic, Rheumatrex)

Oral: 2.5 mg tablet dose packs; 5, 7.5, 10, 15 mg tablets

**Penicillamine** (Cuprimine, Depen)

Oral: 125, 250 mg capsules; 250 mg tablets

**Rituximab** (Rituxan)

Parenteral: 10 mg/mL for IV infusion

**Sulfasalazine** (generic, Azulfidine)

Oral: 500 mg tablets; 500 mg delayed-release tablets

**ACETAMINOPHEN**

**Acetaminophen** (generic, Tylenol, Tempra, Panadol, Acephen, others)

Oral: 160, 325, 500, 650 mg tablets; 80 mg chewable tablets; 160, 500, 650 mg caplets; 325, 500 mg capsules; 80, 120, 160 mg/5 mL elixir; 500 mg/15 mL elixir; 80 mg/1.66 mL, 100 mg/mL solution

Rectal: 80, 120, 125, 300, 325, 650 mg suppositories

## DRUGS USED IN GOUT

### **Allopurinol** (generic, Zyloprim)

Oral: 100, 300 mg tablets

### **Colchicine** (generic)

Oral: 0.6 mg tablets

### **Febuxostat** (Uloric)

Oral: 40, 80 mg tablets

### **Probenecid** (generic)

Oral: 500 mg tablets

### **Sulfinpyrazone** (generic, Anturane)

Oral: 100 mg tablets; 200 mg capsules

## ACRONYMS

**ACTH:** Adrenocorticotrophic hormone (corticotropin)

**CRH:** Corticotropin-releasing hormone

**FSH:** Follicle-stimulating hormone

**GH:** Growth hormone

**GHRH:** Growth hormone-releasing hormone

**GnRH:** Gonadotropin-releasing hormone

**hCG:** Human chorionic gonatropin

**hMG:** Human menopausal gonadotropins

**IGF:** Insulin-like growth factor

**LH:** Luteinizing hormone

**PRL:** Prolactin

**rhGH:** Recombinant human growth hormone

**SST:** Somatostatin

**TRH:** Thyrotropin-releasing hormone

**TSH:** Thyroid-stimulating hormone (thyrotropin)

\*The author is grateful for the contributions of the previous author, Dr. P. A. Fitzgerald.

## CASE STUDY

An 8-year-old, 23-kg (50.7-lb) girl presents with Turner syndrome, a genetic disorder with partial or complete absence of one X chromosome. Karyotyping reveals a 45,X karyotype. At the time of her diagnosis, she is in the second percentile for height and has a bone age of 6.8 years. In addition to her short stature, she has a bicuspid aortic valve and orthodontic anomalies characteristic of the syndrome. She is doing well in school and seems well adjusted socially. Her thyroid function is normal. Although girls

with Turner syndrome have normal growth hormone (GH) levels, they have reduced responsiveness to GH that often responds to supraphysiologic concentrations of the hormone. The patient is started on a daily dose of 0.05 mg/kg of subcutaneously administered recombinant human GH (Humatrope). After 1 year of therapy, her height velocity has increased from 4.0 cm/year to 8.2 cm/year. To help this patient achieve a maximal final height, the plan is to continue GH treatment until she reaches a bone age of 14 years and to begin estrogen supplementation when she reaches age 12. How does recombinant GH stimulate growth in children? Why is this patient likely to also require supplementation with estrogen?

## **HYPOTHALAMIC & PITUITARY HORMONES: INTRODUCTION**

The control of metabolism, growth, and reproduction is mediated by a combination of neural and endocrine systems located in the hypothalamus and pituitary gland. The pituitary weighs about 0.6 g and rests at the base of the brain in the bony sella turcica near the optic chiasm and the cavernous sinuses. The pituitary consists of an anterior lobe (adenohypophysis) and a posterior lobe (neurohypophysis) (Figure 37-1). It is connected to the overlying hypothalamus by a stalk of neurosecretory fibers and blood vessels, including a portal venous system that drains the hypothalamus and perfuses the anterior pituitary. The portal venous system carries small regulatory hormones (Figure 37-1, Table 37-1) from the hypothalamus to the anterior pituitary.

### **Figure 37-1**

The hypothalamic-pituitary endocrine system. Except for prolactin, hormones released from the anterior pituitary stimulate the production of hormones by a peripheral endocrine gland or the liver. Prolactin and the hormones released from the posterior pituitary (vasopressin and oxytocin) act directly on target tissues. Hypothalamic factors regulate the release of anterior pituitary hormones. ACTH, adrenocorticotropin; ADH, antidiuretic hormone [vasopressin]; CRH, corticotropin-releasing hormone; DA, dopamine; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; PRL, prolactin; SST, somatostatin; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

**Table 37-1 Links between Hypothalamic, Anterior Pituitary, and Target Organ Hormone or Mediator.<sup>1</sup>**

<b>Anterior Pituitary Hormone</b>	<b>Hypothalamic Hormone</b>	<b>Target Organ</b>	<b>Primary Target Organ Hormone or Mediator</b>
Growth hormone (GH, somatotropin)	Growth hormone-releasing hormone (GHRH) (+) Somatostatin (â€)	Liver, muscle, bone, kidney, and others	Insulin-like growth factor-1 (IGF-1)
Thyroid-stimulating hormone (TSH)	Thyrotropin-releasing hormone (TRH) (+)	Thyroid	Thyroxine, triiodothyronine
Adrenocorticotropin (ACTH)	Corticotropin-releasing hormone (CRH) (+)	Adrenal cortex	Glucocorticoids, mineralocorticoids, androgens
Follicle-stimulating hormone (FSH) Luteinizing hormone (LH)	Gonadotropin-releasing hormone (GnRH) (+) <sup>2</sup>	Gonads	Estrogen, progesterone, testosterone
Prolactin (PRL)	Dopamine (â€)	Breast	â€

<sup>1</sup>All of these hormones act through G protein-coupled receptors except growth hormone and prolactin, which act through JAK/STAT receptors.

<sup>2</sup>Endogenous GnRH, which is released in pulses, stimulates LH and FSH release. When administered continuously as a drug, GnRH and its analogs inhibit LH and FSH release.

(+), stimulant; (â€), inhibitor.

The posterior lobe hormones are synthesized in the hypothalamus and transported via the neurosecretory fibers in the stalk of the pituitary to the posterior lobe, from which they are released into the circulation.

Drugs that mimic or block the effects of hypothalamic and pituitary hormones have pharmacologic applications in three primary areas: (1) as replacement therapy for hormone deficiency states; (2) as antagonists for diseases that result from excess production of pituitary hormones; and (3) as diagnostic tools for identifying several endocrine abnormalities.

## **ANTERIOR PITUITARY HORMONES & THEIR HYPOTHALAMIC REGULATORS**

All the hormones produced by the anterior pituitary except prolactin (PRL) are key participants in hormonal systems in which they regulate the production by peripheral tissues of hormones that perform the ultimate regulatory functions. In these systems, the secretion of the pituitary hormone is under the control of a hypothalamic hormone. Each hypothalamic-pituitary-endocrine gland system or axis provides multiple opportunities for complex neuroendocrine regulation of growth, development, and reproductive functions.

### **Anterior Pituitary & Hypothalamic Hormone Receptors**

The anterior pituitary hormones can be classified according to hormone structure and the types of receptors that they activate. **Growth hormone (GH)** and **prolactin**, single-chain protein hormones with significant homology, form one group. Both hormones activate receptors of the JAK/STAT superfamily (see Chapter 2). Three pituitary hormones—**thyroid-stimulating hormone (TSH, thyrotropin)**, **follicle-stimulating hormone (FSH)**, and **luteinizing hormone (LH)**—are dimeric proteins that activate G protein-coupled receptors (see Chapter 2). TSH, FSH, and LH share a common  $\alpha$  chain. Their  $\beta$  chains, though somewhat similar to each other, differ enough to confer receptor specificity. Finally, **adrenocorticotrophic hormone (ACTH)**, a single peptide that is cleaved from a larger precursor that also contains the peptide  $\beta$ -endorphin (see Chapter 31), represents a third category. It does, however, like TSH, LH, and FSH, act through a G protein-coupled receptor.

TSH, FSH, LH, and ACTH share similarities in the regulation of their release from the pituitary. Each is under the control of a distinctive hypothalamic peptide that stimulates their production by acting on G protein-coupled receptors (Table 37-1). TSH release is regulated by **thyrotropin-releasing hormone (TRH)**, whereas the release of LH and FSH (known collectively as gonadotropins) is stimulated by pulses of **gonadotropin-releasing hormone (GnRH)**. ACTH release is stimulated by **corticotropin-releasing hormone (CRH)**. The final important regulatory feature shared by these three structurally related hormones is that they and their hypothalamic releasing factors are subject to feedback inhibitory regulation by the hormones whose production they control. TSH and TRH production is inhibited by the two key thyroid hormones, thyroxine and

triiodothyronine (see Chapter 38). Gonadotropin and GnRH production is inhibited in women by estrogen and progesterone, and in men by androgens such as testosterone. Production of ACTH is inhibited by cortisol. Feedback regulation is critical to the physiologic control of thyroid, adrenal cortical, and gonadal function and is also important in pharmacologic treatments that affect these systems.

The hypothalamic hormonal control of GH and prolactin differs from the regulatory system for TSH, FSH, LH, and ACTH. The hypothalamus secretes two hormones that regulate GH; **growth hormone-releasing hormone (GHRH)** stimulates GH production, whereas the peptide **somatostatin (SST)** inhibits GH production. GH and its primary peripheral mediator, insulin-like growth factor-1 (IGF-1), also provide feedback to inhibit GH release. Prolactin production is inhibited by the catecholamine **dopamine** acting through the D<sub>2</sub> subtype of dopamine receptors. The hypothalamus does not produce a hormone that stimulates prolactin production.

Whereas all the pituitary and hypothalamic hormones described previously are available for use in humans, only a few are of major clinical importance. Because of the greater ease of administration of target endocrine gland hormones or their synthetic analogs, the related hypothalamic and pituitary hormones (TRH, TSH, CRH, ACTH, GHRH) are either not used clinically or are used rarely for specialized diagnostic testing. These agents are described in Tables 37-2 and 37-3 and are not discussed further in this chapter. In contrast, GH, SST, LH, FSH, GnRH, and dopamine or analogs of these hormones are commonly used and are described in the following text.

**Table 37-2 Clinical Uses of Hypothalamic Hormones and Their Analogs.**

**Hypothalamic Clinical Uses**  
**Hormone**

Growth hormone-releasing hormone (GHRH)	Used rarely as a diagnostic test for GH responsiveness
Thyrotropin-releasing hormone (TRH, protirelin)	Used rarely to diagnose hyper- or hypothyroidism
Corticotropin-releasing hormone	Used rarely to distinguish Cushing's disease from ectopic ACTH secretion

(CRH)

Gonadotropin-releasing hormone (GnRH) Used rarely in pulses to treat infertility caused by hypothalamic dysfunction

Analogs used in long-acting formulations to inhibit gonadal function in men with prostate cancer and women undergoing assisted reproductive technology (ART) or women who require ovarian suppression for a gynecologic disorder

Dopamine Dopamine agonists used for treatment of hyperprolactinemia

### **Table 37-3 Diagnostic Uses of Thyroid-Stimulating Hormone and Adrenocorticotropin.**

<b>Hormone</b>	<b>Diagnostic Use</b>
Thyroid-stimulating hormone (TSH; thyrotropin)	In patients who have been treated surgically for thyroid carcinoma, to test for recurrence by assessing TSH-stimulated whole-body $^{131}\text{I}$ scans and serum thyroglobulin determinations
Adrenocorticotropin (ACTH)	In patients suspected of adrenal insufficiency, to test for a cortisol response  In patients suspected of congenital adrenal hyperplasia, to identify 21-hydroxylase deficiency, 11-hydroxylase deficiency, and 3 $\beta$ -hydroxy- $\Delta^5$ steroid dehydrogenase deficiency, based on the steroids that accumulate in response to ACTH administration (see Figure 39-1 and Chapter 39)

## **GROWTH HORMONE (SOMATOTROPIN)**

Growth hormone, one of the peptide hormones produced by the anterior pituitary, is required during childhood and adolescence for attainment of normal adult size and has important effects throughout postnatal life on lipid and carbohydrate metabolism, and on lean body mass. Its effects are primarily mediated via **insulin-like growth factor 1 (IGF-1, somatomedin C)** and, to a lesser extent, both directly and through **insulin-like growth factor 2 (IGF-2)**. Individuals with congenital or acquired deficiency of GH during childhood or adolescence fail to reach their predicted adult height and have disproportionately increased body fat and decreased muscle mass. Adults with GH deficiency also have disproportionately low lean body mass.

## Chemistry & Pharmacokinetics

### STRUCTURE

Growth hormone is a 191-amino-acid peptide with two sulfhydryl bridges. Its structure closely resembles that of prolactin. In the past, medicinal GH was isolated from the pituitaries of human cadavers. However, this form of GH was found to be contaminated with prions that could cause Creutzfeldt-Jakob disease. For this reason, it is no longer used. **Somatropin**, the recombinant form of GH, has a 191-amino acid sequence that is identical with the predominant native form of human GH.

### ABSORPTION, METABOLISM, AND EXCRETION

Circulating endogenous GH has a half-life of 20–25 minutes and is predominantly cleared by the liver. Recombinant human GH (rhGH) is administered subcutaneously 3–7 times per week. Peak levels occur in 2–4 hours and active blood levels persist for approximately 36 hours.

### Pharmacodynamics

Growth hormone mediates its effects via cell surface receptors of the JAK/STAT cytokine receptor superfamily. Dimerization of two GH receptors is stimulated by a single GH molecule and activates signaling cascades mediated by receptor-associated JAK tyrosine kinases and STATs (see Chapter 2). GH has complex effects on growth, body composition, and carbohydrate, protein, and lipid metabolism. The growth-promoting effects are mediated through an increase in the production of IGF-1. Much of the circulating IGF-1 is produced in the liver. GH also stimulates production of IGF-1 in bone, cartilage, muscle, and the kidney, where it plays autocrine or paracrine roles. GH stimulates longitudinal bone growth until the epiphyses close—near the end of puberty. In both children and adults, GH has anabolic effects in muscle and catabolic effects in lipid cells that shift the balance of body mass to an increase in muscle mass and a reduction in central adiposity. The effects of GH on carbohydrate metabolism are mixed, in part because GH and IGF-1 have opposite effects on insulin sensitivity. GH reduces insulin sensitivity, which results in mild hyperinsulinemia. In contrast, in patients who are unable to respond to endogenous GH because of mutated GH receptors, IGF-1 acting through its own IGF-1 receptors and through insulin receptors lowers serum glucose and reduces circulating insulin.

### Clinical Pharmacology

#### GROWTH HORMONE DEFICIENCY

GH deficiency can have a genetic basis or can be acquired as a result of damage to the pituitary or hypothalamus by a tumor, infection, surgery, or radiation therapy. In childhood, GH deficiency presents as short stature and adiposity. (Neonates with isolated GH deficiency are of normal size at birth, presumably because fetal GH is not required for normal prenatal growth.) Another early sign of GH deficiency is hypoglycemia due to

unopposed action of insulin, to which young children are especially sensitive. Criteria for diagnosis of GH deficiency usually include (1) a growth rate below 4 cm per year and (2) the absence of a serum GH response to two GH secretagogues. The incidence of congenital GH deficiency is approximately 1:4000 live births. Therapy with rhGH permits many children with short stature due to GH deficiency to achieve normal adult height.

In the past, it was believed that adults with GH deficiency do not exhibit a significant syndrome. However, more detailed studies suggest that adults with GH deficiency often have generalized obesity, reduced muscle mass, asthenia, and reduced cardiac output. GH-deficient adults who have been treated with GH have been shown to experience a reversal of many of these manifestations.

### **GROWTH HORMONE TREATMENT OF PEDIATRIC PATIENTS WITH SHORT STATURE**

Although the greatest improvement in growth occurs in patients with GH deficiency, exogenous GH has some effect on height in children with short stature that is due to factors other than GH deficiency. GH has been approved for several conditions (Table 37â€4) and has been used experimentally or off-label in many others. **Prader-Willi syndrome** is an autosomal dominant genetic disease that is associated with growth failure, obesity, and carbohydrate intolerance. In pediatric patients with Prader-Willi syndrome and growth failure, GH treatment decreases body fat and increases lean body mass, linear growth, and energy expenditure.

#### **Table 37â€4 Clinical Uses of Recombinant Human Growth Hormone.**

##### **Primary Therapeutic Objective**

Growth

##### **Clinical Condition**

Growth failure in pediatric patients associated with:

Growth hormone deficiency

Chronic renal failure

Noonan syndrome

Prader-Willi syndrome

Short stature homeobox-containing gene deficiency

Turner syndrome

Small for gestational age with failure to catch up by age 2

Idiopathic short stature in pediatric patients

Improved metabolic state, increased lean body mass, sense of well-being	Growth hormone deficiency in adults
Increased lean body mass, weight, and physical endurance	Wasting in patients with HIV infection
Improved gastrointestinal function	Short bowel syndrome in patients who are also receiving specialized nutritional support

GH treatment has also been shown to have a strong beneficial effect on final height of girls with **Turner syndrome**, the syndrome associated with a 45,X karyotype. In clinical trials, GH treatment has been shown to increase final height in girls with Turner syndrome by 10–15 cm (4–6 inches). Because girls with Turner syndrome also have either absent or rudimentary ovaries, GH must be judiciously combined with gonadal steroids to achieve the maximal height effect, as in the case study patient. Other conditions of growth failure for which GH treatment is approved include chronic renal failure in pediatric patients and small-for-gestational-age condition at birth in which the child has failed to catch up by age 2. In all of these pediatric patients as well as in patients with GH deficiency, it is critical to start GH treatment before the long bone epiphyses have closed.

The most controversial approved use of GH is for children with **idiopathic short stature**, also known as non-growth-hormone-deficient short stature. This is a heterogeneous population that is defined clinically by a height that is 2.25 standard deviations or more below the national norm for children of the same age. Eligible children also have growth rates that are unlikely to result in an adult height in the normal range and the absence of a condition known to be associated with impaired growth. In this group of children, many years of GH therapy result in an average increase in adult height of 4–7 cm (1.57–2.76 inches) at an average cost of \$35,000 per inch of height gained. The complex issues involved in the cost-risk-benefit relationship of this use of GH are important because an estimated 400,000 children in the USA fit the diagnostic criteria for idiopathic short stature.

Treatment of children with short stature should be carried out by specialists experienced in the use of GH. Treatment is begun with 0.025 mg/kg daily and may be increased to a maximum of 0.045 mg/kg daily. Children must be observed closely for slowing of growth velocity, which could indicate a need to increase the dosage or the possibility of epiphyseal fusion or intercurrent problems such as hypothyroidism or malnutrition. Children with Turner syndrome or chronic renal insufficiency require somewhat higher doses.

### **Other Uses of Growth Hormone**

Growth hormone affects many organ systems and also has a net anabolic effect. It has

been tested in a number of conditions that are associated with a severe catabolic state and is approved for the treatment of wasting in patients with AIDS. In 2004, GH was approved for treatment of patients with short bowel syndrome who are dependent on total parenteral nutrition (TPN). After intestinal resection or bypass, the remaining functional intestine in many patients undergoes extensive adaptation that allows it to adequately absorb nutrients. However, other patients fail to adequately adapt and develop a malabsorption syndrome. GH has been shown in experimental animals to increase intestinal growth and improve its function. Results of GH treatment of patients with short bowel syndrome and dependence on total parenteral nutrition have been mixed in the clinical studies that have been published to date. Growth hormone is administered with glutamine, which also has trophic effects on the intestinal mucosa.

GH is a popular component of anti-aging programs. Serum levels of GH normally decline with aging; anti-aging programs claim that injection of GH or administration of drugs purported to increase GH release are effective anti-aging remedies. These claims are largely unsubstantiated. It is interesting that a number of studies in mice and the nematode *C elegans* have clearly demonstrated that analogs of human GH and IGF-1 consistently *shorten* life span and that loss-of-function mutations in the signaling pathways for the GH and IGF-1 analogs lengthen life span. Another use of GH is by athletes for a purported increase in muscle mass and athletic performance. GH is one of the drugs banned by the Olympic Committee.

Although GH has important effects on lipid and carbohydrate metabolism and on lean body mass, it does not seem likely to be a fruitful direct target for efforts to develop new drugs to treat obesity. However, some of the hormonal and neuroendocrine systems that regulate GH secretion are being investigated as possible targets for antiobesity drugs (see Treatment of Obesity).

In 1993, the FDA approved the use of recombinant bovine growth hormone (rbGH) in dairy cattle to increase milk production. Although milk and meat from rbGH-treated cows appear to be safe, these cows have a higher incidence of mastitis, which could increase antibiotic use and result in greater antibiotic residues in milk and meat.

### **Treatment of Obesity**

*Contributed by B.G. Katzung.*

It is said that the developed world is experiencing an "epidemic of obesity." This statement is based on statistics showing that in the USA, for example, 30â€"40% of the population is above optimal weight and that the excess weight (especially abdominal fat) is associated with increased risks of heart disease and diabetes. Since eating behavior is an expression of endocrine, neurophysiologic, and psychological processes, prevention and treatment of obesity are complex. It is not surprising that there is considerable interest in developing

pharmacologic therapy for the condition.

Although obesity can be defined as excess adipose tissue, it is currently quantitated by means of the body mass index (BMI), calculated from  $\text{BMI} = \text{height in meters} / \text{weight in kilograms squared}$ . Using this measure, a normal BMI is defined as 18.5–24.9; overweight, 25–29.9; obese, 30–39.9; and morbidly obese (ie, at very high risk)  $\text{BMI} \geq 40$ . Some extremely muscular individuals may have a BMI higher than 25 and no excess fat; however, the BMI scale generally correlates with the degree of obesity and with risk.

Although the cause of obesity can be simply stated as energy intake (dietary calories) exceeding energy output (resting metabolism plus exercise), the actual physiology of weight control is extremely complex, and the pathophysiology of obesity is still poorly understood. Many hormones and neuronal mechanisms regulate intake (appetite, satiety), processing (absorption, conversion to fat, glycogen, etc), and output (thermogenesis, muscle work). The fact that a large number of hormones reduce appetite (Table 37–4.1) might appear to offer many targets for weight-reducing drug therapy, but despite intensive research, no available pharmacologic therapy has succeeded in maintaining a weight loss of over 10% for 1 year. Furthermore, the social and psychological aspects of eating are powerful influences that are independent of or only partially dependent on the physiologic control mechanisms. In contrast, bariatric (weight-reducing) surgery readily achieves a sustained weight loss of 10–40%. However, even a 5–10% loss of weight is associated with a reduction in blood pressure and improved glycemic control.

#### **Table 37–4.1. Hormonal Control of Appetite and Satiety.**

<b>Appetite Stimulants (Source)</b>	<b>Appetite Suppressants (Source)</b>
Adiponectin (adipocytes)	5-HT (hypothalamus)
Agouti-related peptide (hypothalamus)	Adiponectin (adipocytes)
Cannabinoids (CNS, possibly peripheral tissues)	Amylin (pancreas)
Ghrelin (stomach)	CART (hypothalamus)
Neuropeptide Y (hypothalamus)	Cholecystikinin (gut, CNS)
Orexin (hypothalamus)	Corticotropin-releasing hormone (hypothalamus)
$\beta$ -Endorphin (hypothalamus)	Gastrin-releasing peptide (gut)
	Glucagon-like peptide-1 (gut)

Leptin (adipocytes)  
 Melanocortins (CNS)  
 Norepinephrine (CNS)  
 Oxyntomodulin (gut)  
 Peptide YY (gut)  
 Somatostatin (hypothalamus)

CART, cocaine and amphetamine-regulated transcript; CNS, central nervous system.

Until approximately 10 years ago, the most popular and successful appetite suppressants were the nonselective 5-HT<sub>2</sub> agonists: fenfluramine and dexfenfluramine. Combined with phentermine as Fen-Phen and Dex-Phen, they were moderately effective. However, these drugs were found to cause pulmonary hypertension and cardiac valve defects and were withdrawn.

Older drugs still available in some countries include phenylpropanolamine, benzphetamine, amphetamine, methamphetamine, phentermine, diethylpropion, mazindol, and phendimetrazine. These drugs are all amphetamine mimics and are central nervous system appetite suppressants; they are generally helpful only during the first few weeks of therapy. Their toxicity is significant and includes hypertension (with a risk of cerebral hemorrhage) and addiction liability.

Some newer drugs are listed in Table 37-5. Clinical trials and phase 4 reports suggest that these agents are effective for the duration of therapy (up to 1 year) and are probably safer than the amphetamine mimics. However, they do not produce more than a 5-10% loss of weight.

**Table 37-5 Newer Antiobesity Drugs and Their Effects.**

	<b>Orlistat</b>	<b>Sibutramine</b>	<b>Rimonabant</b>
Target organ	Gut	CNS	CNS (peripheral ?)
Target molecule	GI lipase inhibitor	SERT and NET inhibitor	CB <sub>1</sub> receptor antagonist
Mechanism of action	Reduces absorption of fats since triglycerides not split	Reduces appetite	Reduces appetite

Toxicity	GI: Flatulence, steatorrhea, fecal incontinence	Cardiovascular: Tachycardia, hypertension	CNS: Depression, anxiety, nausea
Dosage	130 mg tid	10–15 mg qd	20 mg qd
Availability	Over the counter	Prescription	Prescription in Europe; investigational in USA

CNS, central nervous system; GI, gastrointestinal; SERT, serotonin reuptake transporter; NET, norepinephrine reuptake transporter; CB, cannabinoid; tid, three times daily; qd, daily.

Because of the low efficacy of the drugs listed in Table 37–5, intensive research continues. (Some drugs approved for other indications that reduce appetite and possible future weight loss drugs are set forth in Table 37–5.1, see online version of this book). Because of the redundancy of the physiologic mechanisms for control of body weight, it seems likely that polypharmacy targeting multiple pathways will be needed to achieve success.

### **Table 37–5.1. Other Drugs that Decrease Food Intake or Reduce Weight.**

<b>Drug</b>	<b>Putative Target or Mechanism of Action, Comment</b>
APD 356	Selective 5-HT <sub>2c</sub> agonist
GW 856464	Melanocortin-4 receptor antagonist
Antidiabetic agents:	
Pramlintide <sup>1</sup>	Amylin agonist, see Chapter 41
Exenatide, <sup>1</sup> liraglutide (investigational)	GLP1 analog agonists
Metformin	See Chapter 41
Cetlistat	Like orlistat
Leptin	Lipid status messenger, doesn't work as obesity

Beta <sub>3</sub> adrenoceptor agonists	drug due to leptin resistance in obese people Increased lipolysis and thermogenesis in adipose tissue, but disappointing results in clinical trials
H <sub>3</sub> antagonists	H <sub>3</sub> receptors in CNS appear to mediate hunger
Colestimide (colestilan) <sup>2</sup>	Bile acid binding resin improves glycemic control and reduces weight in an obese DM-2 model
Antighrelin vaccine	Active in mouse model but not in human trials
Ghrelin receptor antagonist	Active in mouse model
Miscellaneous CNS drugs: bupropion, <sup>1</sup> fluoxetine, <sup>1</sup> zonisamide, <sup>1</sup> atomoxetine <sup>1</sup>	Alterations in CNS neurotransmitter activity
C75	Fatty acid synthase inhibitor

<sup>1</sup>Drugs approved for other indications.

<sup>2</sup>Available outside the USA.

## Toxicity & Contraindications

Children generally tolerate GH treatment well. A rarely reported adverse effect is intracranial hypertension, which may manifest as vision changes, headache, nausea, or vomiting. Some children develop scoliosis during rapid growth. Patients with Turner syndrome have an increased risk of otitis media while taking GH. Hypothyroidism is commonly discovered during GH treatment, so periodic assessment of thyroid function is indicated. Pancreatitis, gynecomastia, and nevus growth have occurred in patients receiving GH. Adults tend to have more adverse effects from GH therapy. Peripheral edema, myalgias, and arthralgias (especially in the hands and wrists) occur commonly but remit with dosage reduction. Carpal tunnel syndrome can occur. GH treatment increases the activity of cytochrome P450 isoforms, which could reduce the serum levels of drugs metabolized by that enzyme system (see Chapter 4). There has been no increased incidence of malignancy among patients receiving GH therapy, but GH

treatment is contraindicated in a patient with a known malignancy. Proliferative retinopathy may rarely occur. GH treatment of critically ill patients appears to *increase* mortality.

## **MECASERMIN**

A small number of children with growth failure have severe IGF-1 deficiency that is not responsive to exogenous GH. Causes include mutations in the GH receptor and development of neutralizing antibodies to GH. In 2005, the FDA approved mecaseimerin for treatment of severe IGF-1 deficiency that is not responsive to GH. Mecasermin is a complex of recombinant human IGF-1 (rhIGF-1) and recombinant human insulin-like growth factor-binding protein-3 (rhIGFBP-3). The IGF-1 activates transmembrane receptors that, like insulin and EGF receptors, manifest tyrosine kinase activity at their intracellular domains (see Chapters 2 and 41). The binding protein rhIGFBP-3 is needed to maintain an adequate half-life of rhIGF-1. Normally, over 80% of the circulating IGF-1 is bound to IGFBP-3, which is produced by the liver under the control of GH. Patients with severe IGF-1 deficiency that is secondary to aberrant GH signaling also have deficiency of IGFBP-3, so it is important to supply this with the IGF-1 replacement. Mecasermin is administered subcutaneously twice daily at a recommended starting dosage of 0.04–0.08 mg/kg and increased weekly up to a maximum twice-daily dosage of 0.12 mg/kg.

The most important adverse effect observed with mecaseimerin is hypoglycemia. To avoid hypoglycemia, the prescribing instructions require consumption of a meal or snack 20 minutes before or after mecaseimerin administration. Several patients have experienced intracranial hypertension and asymptomatic elevation of liver enzymes.

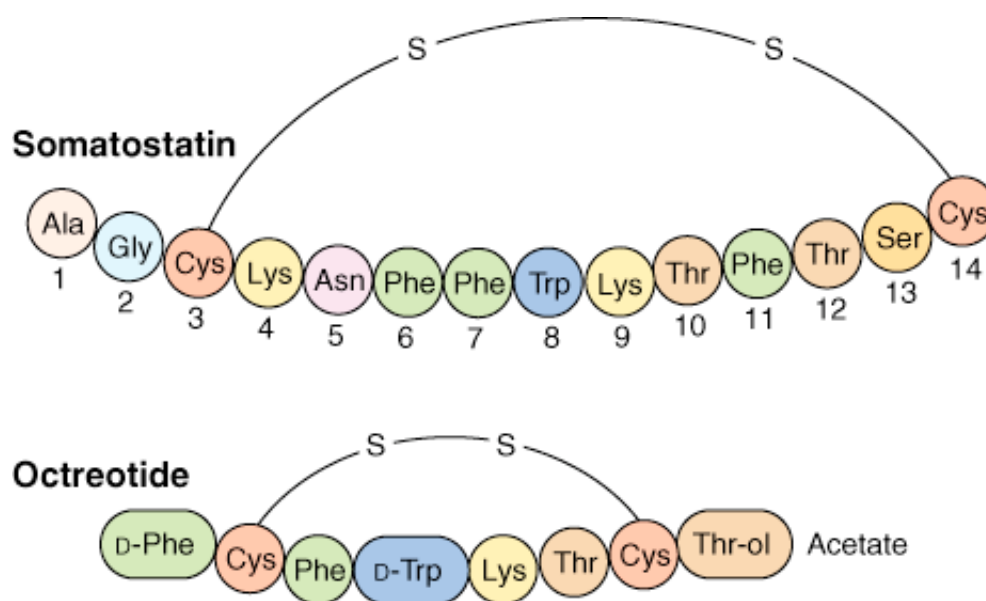

## **GROWTH HORMONE ANTAGONISTS**

The need for antagonists of GH stems from the tendency of GH-producing cells (somatotrophs) in the anterior pituitary to form secreting tumors. Pituitary adenomas occur most commonly in adults. In adults, GH-secreting adenomas cause **acromegaly**, which is characterized by abnormal growth of cartilage and bone tissue, and many organs including skin, muscle, heart, liver, and the gastrointestinal tract. Acromegaly adversely affects the skeletal, muscular, cardiovascular, respiratory, and metabolic systems. When a GH-secreting adenoma occurs before the long bone epiphyses close, it leads to the rare condition, **gigantism**. Small GH-secreting adenomas can be treated with GH antagonists. Somatostatin analogs and dopamine receptor agonists reduce the production of GH, whereas the novel GH receptor antagonist **pegvisomant** prevents GH from activating its receptor. Larger pituitary adenomas, which produce greater amounts of GH and also can impair visual and central nervous system function by encroaching on nearby brain structures, are treated with transsphenoidal surgery or radiation.

### **Somatostatin Analogs**

Somatostatin, a 14-amino-acid peptide (Figure 37â€²), is found in the hypothalamus, other parts of the central nervous system, the pancreas, and other sites in the gastrointestinal tract. It inhibits the release of GH, glucagon, insulin, and gastrin.

**Figure 37â€²**

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 11th Edition: <http://www.accessmedicine.com>

Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

**Above:** Amino acid sequence of somatostatin. **Below:** Sequence of the synthetic analog, octreotide.

Exogenous somatostatin is rapidly cleared from the circulation, with an initial half-life of 1â€³ minutes. The kidney appears to play an important role in its metabolism and excretion.

Somatostatin has limited therapeutic usefulness because of its short duration of action and its multiple effects in many secretory systems. A series of longer-acting somatostatin analogs that retain biologic activity have been developed. **Octreotide**, the most widely used somatostatin analog (Figure 37â€²), is 45 times more potent than somatostatin in inhibiting GH release but only twice as potent in reducing insulin secretion. Because of this relatively reduced effect on pancreatic beta cells, hyperglycemia rarely occurs during treatment. The plasma elimination half-life of octreotide is about 80 minutes, 30 times longer in humans than that of somatostatin.

Octreotide, 50â€³200 mcg given subcutaneously every 8 hours, reduces symptoms

caused by a variety of hormone-secreting tumors: acromegaly; the carcinoid syndrome; gastrinoma; glucagonoma; nesidioblastosis; the watery diarrhea, hypokalemia, and achlorhydria (WDHA) syndrome; and diabetic diarrhea. Somatostatin receptor scintigraphy, using radiolabeled octreotide, is useful in localizing neuroendocrine tumors having somatostatin receptors and helps predict the response to octreotide therapy. Octreotide is also useful for the acute control of bleeding from esophageal varices.

Octreotide acetate injectable long-acting suspension is a slow-release microsphere formulation. It is instituted only after a brief course of shorter-acting octreotide has been demonstrated to be effective and tolerated. Injections into alternate gluteal muscles are repeated at 4-week intervals in doses of 20–40 mg.

Adverse effects of octreotide therapy include nausea, vomiting, abdominal cramps, flatulence, and steatorrhea with bulky bowel movements. Biliary sludge and gallstones may occur after 6 months of use in 20–30% of patients. However, the yearly incidence of symptomatic gallstones is about 1%. Cardiac effects include sinus bradycardia (25%) and conduction disturbances (10%). Pain at the site of injection is common, especially with the long-acting octreotide suspension. Vitamin B12 deficiency may occur with long-term use of octreotide.

A long-acting formulation of **lanreotide**, another octapeptide somatostatin analog, was approved by the FDA in 2007 for treatment of acromegaly. Lanreotide appears to have effects comparable to those of octreotide on reducing GH levels and normalizing IGF-1 concentrations.

### **Pegvisomant**

Pegvisomant is a GH receptor antagonist that is useful for the treatment of acromegaly. Pegvisomant is the polyethylene glycol (PEG) derivative of a mutant GH, B2036, which has increased affinity for one site of the GH receptor but a reduced affinity at its second binding site. This allows dimerization of the receptor but blocks the conformational changes required for signal transduction. Pegvisomant is a less potent GH receptor antagonist than is B2036, but pegylation reduces its clearance and improves its overall clinical effectiveness. When pegvisomant was administered subcutaneously to 160 patients with acromegaly daily for 12 months or more, serum levels of IGF-1 fell into the normal range in 97%; two patients experienced growth of their GH-secreting pituitary tumors, and two patients developed increases in liver enzymes.

## **THE GONADOTROPINS (FOLLICLE-STIMULATING HORMONE & LUTEINIZING HORMONE) & HUMAN CHORIONIC GONADOTROPIN**

The gonadotropins are produced by a single type of pituitary cell, the gonadotroph. These hormones serve complementary functions in the reproductive process. In women,

the principal function of FSH is to direct ovarian follicle development. Both FSH and LH are needed for ovarian steroidogenesis. In the ovary, LH stimulates androgen production by theca cells in the follicular stage of the menstrual cycle, whereas FSH stimulates the conversion by granulosa cells of androgens to estrogens. In the luteal phase of the menstrual cycle, estrogen and progesterone production is primarily under the control first of LH and then, if pregnancy occurs, under the control of human chorionic gonadotropin (hCG). Human chorionic gonadotropin is a placental protein nearly identical with LH; its actions are mediated through LH receptors.

In men, FSH is the primary regulator of spermatogenesis, whereas LH is the main stimulus for the production of testosterone by Leydig cells. FSH helps to maintain high local androgen concentrations in the vicinity of developing sperm by stimulating the production of androgen-binding protein by Sertoli cells. FSH also stimulates the conversion by Sertoli cells of testosterone to estrogen.

FSH, LH, and hCG are commercially available in several forms. They are used in states of infertility to stimulate spermatogenesis in men and to induce ovulation in women. Their most common clinical use is for the controlled ovulation hyperstimulation that is the cornerstone of assisted reproductive technologies such as in vitro fertilization (IVF, see below).

## Chemistry & Pharmacokinetics

All three hormones—FSH, LH, and hCG—are heterodimers that share an identical  $\alpha$  chain in addition to a distinct  $\beta$  chain that confers receptor specificity. The  $\beta$  chains of hCG and LH are nearly identical, and these two hormones are used interchangeably. All the gonadotropin preparations are administered by subcutaneous or intramuscular injection, usually on a daily basis. Half-lives vary by preparation and route of injection from 10 to 40 hours.

### MENOTROPINS

The first commercial gonadotropin product was extracted from the urine of postmenopausal women, which contains a substance with FSH-like properties (but with 4% of the potency of FSH) and an LH-like substance. This purified extract of FSH and LH is known as **menotropins**, or human menopausal gonadotropins (**hMG**).

### FOLLICLE-STIMULATING HORMONE

Three forms of purified FSH are available. **Urofollitropin**, also known as uFSH, is a purified preparation of human FSH that is extracted from the urine of postmenopausal women. Virtually all the LH activity has been removed through a form of immunoaffinity chromatography that uses anti-hCG antibodies. Two recombinant forms of FSH (**rFSH**) are also available: **follitropin alfa** and **follitropin beta**. The amino acid sequences of these two products are identical to that of human FSH. They differ from each other and urofollitropin in the composition of the carbohydrate side chains. The rFSH preparations

have a shorter half-life than preparations derived from human urine but stimulate estrogen secretion at least as efficiently and, in some studies, more efficiently. The rFSH preparations are considerably more expensive.

### **LUTEINIZING HORMONE**

**Lutropin alfa**, the recombinant form of human LH, was introduced in the USA in 2004. When given by subcutaneous injection, it has a half-life of about 10 hours. Lutropin has only been approved for use in combination with follitropin alfa for stimulation of follicular development in infertile women with profound LH deficiency. It has not been approved for use with the other preparations of FSH nor for simulating the endogenous LH surge that is needed to complete follicular development and precipitate ovulation.

### **HUMAN CHORIONIC GONADOTROPIN**

hCG is produced by the human placenta and excreted into the urine, whence it can be extracted and purified. It is a glycoprotein consisting of a 92-amino-acid  $\alpha$  chain virtually identical to that of FSH, LH, and TSH, and a  $\beta$  chain of 145 amino acids that resembles that of LH except for the presence of a carboxyl terminal sequence of 30 amino acids not present in LH. **Choriogonadotropin alfa** (rhCG) is a recombinant form of hCG. Because of its greater consistency in biologic activity, rhCG is packaged and dosed on the basis of weight rather than units of activity. All of the other gonadotropins, including rFSH, are packaged and dosed on the basis of units of activity. The preparation of hCG that is purified from human urine is administered by intramuscular injection, whereas rhCG is administered by subcutaneous injection.

### **Pharmacodynamics**

The gonadotropins and hCG exert their effects through G protein-coupled receptors. LH and FSH have complex effects on reproductive tissues in both sexes. In women, these effects change over the time course of a menstrual cycle as a result of a complex interplay between concentration-dependent effects of the gonadotropins, cross-talk between LH, FSH, and gonadal steroids, and the influence of other ovarian hormones. A coordinated pattern of FSH and LH secretion during the menstrual cycle (see Figure 40â€1) is required for normal follicle development, ovulation, and pregnancy.

During the first 8 weeks of pregnancy, the progesterone and estrogen required to maintain pregnancy are produced by the ovarian corpus luteum. For the first few days after ovulation, the corpus luteum is maintained by maternal LH. However, as maternal LH concentrations fall owing to increasing concentrations of progesterone and estrogen, the corpus luteum will continue to function only if the role of maternal LH is taken over by hCG produced by the embryo and its new placenta.

### **Clinical Pharmacology**

#### **OVULATION INDUCTION**

The gonadotropins are used to induce ovulation in women with anovulation that is

secondary to hypogonadotropic hypogonadism, polycystic ovary syndrome, obesity, and other causes. Because of the high cost of gonadotropins and the need for close monitoring during their administration, gonadotropins are generally reserved for anovulatory women who fail to respond to other less complicated forms of treatment (eg, clomiphene; see Chapter 40). Gonadotropins are also used for **controlled ovarian hyperstimulation** in assisted reproductive technology procedures. A number of protocols make use of gonadotropins in ovulation induction and controlled ovulation hyperstimulation, and new protocols are continually being developed to improve the rates of success and to decrease the two primary risks of ovulation induction: multiple pregnancies and the **ovarian hyperstimulation syndrome** (OHSS; see below).

Although the details differ, all of these protocols are based on the complex physiology that underlies a normal menstrual cycle. Like a menstrual cycle, ovulation induction is discussed in relation to a cycle that begins on the first day of a menstrual bleed (Figure 37â€³). Shortly after the first day (usually on day 3), daily injections with one of the FSH preparations (hMG, urofollitropin) are begun and are continued for approximately 7â€³12 days. In women with hypogonadotropic hypogonadism, follicle development requires treatment with a combination of FSH and LH because these women do not produce the basal level of LH that is required for adequate ovarian estrogen production and normal follicle development. The dose and duration of FSH treatment are based on the response as measured by the serum estradiol concentration and by ultrasound evaluation of ovarian follicle development and endometrial thickness. When exogenous gonadotropins are used to stimulate follicle development, there is risk of a premature endogenous surge in LH owing to the rapidly changing hormonal milieu. To prevent this, gonadotropins are almost always administered in conjunction with a drug that blocks the effects of endogenous GnRHâ€³either continuous administration of a GnRH agonist, which down-regulates GnRH receptors, or a GnRH receptor antagonist (see below and Figure 37â€³).

### **Figure 37â€³**

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 11th Edition: <http://www.accessmedicine.com>

Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

Controlled ovarian hyperstimulation in preparation for an assisted reproductive technology such as in vitro fertilization. Follicular phase: Follicle development is stimulated with gonadotropin injections that begin about 3 days after menses begin. When the follicles are ready, as assessed by measurement of serum estrogen concentration and ultrasound measurement of follicle size, final oocyte maturation is induced by an injection of hCG. Luteal phase: Shortly thereafter oocytes are retrieved and fertilized in vitro. The recipient's luteal phase is supported with injections of progesterone. To prevent a premature luteinizing-hormone surge, endogenous gonadotropin secretion is inhibited during the follicular phase with either a GnRH agonist or a GnRH antagonist. In most protocols, the GnRH agonist is started midway through the preceding luteal cycle.

When appropriate follicular maturation has occurred, the FSH and GnRH agonist or GnRH antagonist injections are discontinued; the following day, hCG (5000–10,000 IU) is administered intramuscularly to induce final follicular maturation and, in ovulation induction protocols, ovulation. The hCG administration is followed by insemination in ovulation induction and by oocyte retrieval in assisted reproductive technology procedures. Because use of GnRH agonists or antagonists during the follicular phase of ovulation induction suppresses endogenous LH production, it is important to provide exogenous hormonal support of the luteal phase. In clinical trials, exogenous progesterone, hCG, or a combination of the two have been effective at providing

adequate luteal support. However, progesterone is preferred for luteal support because hCG carries a higher risk of the ovarian hyperstimulation syndrome (see below).

### **MALE INFERTILITY**

Most of the signs and symptoms of hypogonadism in males (eg, delayed puberty, retention of prepubertal secondary sex characteristics after puberty) can be adequately treated with exogenous androgen; however, treatment of infertility in hypogonadal men requires the activity of both LH and FSH. For many years, conventional therapy has consisted of initial treatment for 8–12 weeks with injections of 1000–2500 IU hCG several times per week. After the initial phase, hMG is injected at a dose of 75–150 units three times per week. In men with hypogonadal hypogonadism, it takes an average of 4–6 months of such treatment for sperm to appear in the ejaculate. With the more recent availability of urofollitropin, rFSH, and rLH, a number of alternative protocols have been developed. An advance that has indirectly benefited gonadotropin treatment of male infertility is intracytoplasmic sperm injection (ICSI), in which a single sperm is injected directly into a mature oocyte that has been retrieved after controlled ovarian hyperstimulation of a female partner. With the advent of ICSI, the minimum threshold of spermatogenesis required for pregnancy is greatly lowered.

### **Toxicity & Contraindications**

In women treated with gonadotropins and hCG, the two most serious complications are the **ovarian hyperstimulation syndrome** and **multiple pregnancies**. Overstimulation of the ovary during ovulation induction often leads to uncomplicated ovarian enlargement that usually resolves spontaneously. The ovarian hyperstimulation syndrome is a more serious complication that occurs in 0.5–4% of patients. It is characterized by ovarian enlargement, ascites, hydrothorax, and hypovolemia, sometimes resulting in shock. Hemoperitoneum (from a ruptured ovarian cyst), fever, and arterial thromboembolism can occur.

The probability of multiple pregnancies is greatly increased when ovulation induction and assisted reproductive technologies are used. In ovulation induction, the risk of multiple pregnancy is estimated to be 15–20%, whereas the percentage of multiple pregnancies in the general population is closer to 1%. Multiple pregnancies carry an increased risk of complications, such as gestational diabetes, preeclampsia, and preterm labor. For in vitro fertilization procedures, the risk of multiple pregnancy is primarily determined by the number of embryos transferred to the recipient. A strong trend in recent years has been to transfer fewer embryos.

Other reported adverse effects of gonadotropin treatment are headache, depression, edema, precocious puberty, and (rarely) production of antibodies to hCG. In men treated with gonadotropins, the risk of gynecomastia is directly correlated with the level of testosterone produced in response to treatment. An association between ovarian cancer,

infertility, and fertility drugs has been reported. However, it is not known which, if any, fertility drugs are causally related to cancer.

## **GONADOTROPIN-RELEASING HORMONE & ITS ANALOGS**

Gonadotropin-releasing hormone is secreted by neurons in the hypothalamus. It travels through the hypothalamic-pituitary venous portal plexus to the anterior pituitary, where it binds to G protein-coupled receptors on the plasma membranes of gonadotroph cells. *Pulsatile* GnRH secretion is required to stimulate the gonadotroph cell to produce and release LH and FSH.

Sustained *nonpulsatile* administration of GnRH or GnRH analogs *inhibits* the release of FSH and LH by the pituitary in both women and men, resulting in hypogonadism. GnRH agonists are used to produce gonadal suppression in men with prostate cancer. They are also used in women who are undergoing assisted reproductive technology procedures or who have a gynecologic problem that is benefited by ovarian suppression.

### **Chemistry & Pharmacokinetics**

#### **STRUCTURE**

GnRH is a decapeptide found in all mammals. **Gonadorelin** is an acetate salt of synthetic human GnRH. Synthetic analogs include **goserelin, histrelin, leuprolide, nafarelin,** and **triptorelin**. These analogs all have D-amino acids at position 6, and all but nafarelin have ethylamide substituted for glycine at position 10. Both modifications make them more potent and longer-lasting than native GnRH and gonadorelin.

#### **PHARMACOKINETICS**

Gonadorelin can be administered intravenously or subcutaneously. GnRH analogs can be administered subcutaneously, intramuscularly, via nasal spray (nafarelin), or as a subcutaneous implant. The half-life of intravenous gonadorelin is 4 minutes, and the half-lives of subcutaneous and intranasal GnRH analogs are approximately 3 hours. The duration of clinical uses of GnRH agonists varies from a few days for ovulation induction to a number of years for treatment of metastatic prostate cancer. Therefore, preparations have been developed with a range of durations of action from several hours (for daily administration) to 1, 4, 6, or 12 months (depot forms).

### **Pharmacodynamics**

The physiologic actions of GnRH exhibit complex dose-response relationships that change dramatically from the fetal period through the end of puberty. This is not surprising in view of the complex role that GnRH plays in normal reproduction, particularly in female reproduction. Pulsatile GnRH release occurs and is responsible for stimulating LH and FSH production during the fetal and neonatal period. Subsequently, from the age of 2 years until the onset of puberty, GnRH secretion falls off and the pituitary simultaneously exhibits very low sensitivity to GnRH. Just before puberty, an

increase in the frequency and amplitude of GnRH release occurs and then, in early puberty, pituitary sensitivity to GnRH increases, which is due in part to the effect of increasing concentrations of gonadal steroids. In females, it usually takes several months to a year after the onset of puberty for the hypothalamic-pituitary system to produce an LH surge and ovulation. By the end of puberty, the system is well established so that menstrual cycles proceed at relatively constant intervals. The amplitude and frequency of GnRH pulses vary in a regular pattern through the menstrual cycle with the highest amplitudes occurring during the luteal phase and the highest frequency occurring late in the follicular phase. Lower pulse frequencies favor FSH secretion, whereas higher pulse frequencies favor LH secretion. Gonadal steroids as well as the peptide hormones activin and inhibin have complex modulatory effects on the gonadotropin response to GnRH.

In the pharmacologic use of GnRH and its analogs, pulsatile intravenous administration of gonadorelin every 1–4 hours stimulates FSH and LH secretion. Continuous administration of gonadorelin or its longer-acting analogs produces a biphasic response. During the first 7–10 days, an agonist effect results in increased concentrations of gonadal hormones in males and females; this initial phase is referred to as a *flare*. After this period, the continued presence of GnRH results in an inhibitory action that manifests as a drop in the concentration of gonadotropins and gonadal steroids. The inhibitory action is due to a combination of receptor down-regulation and changes in the signaling pathways activated by GnRH.

## **Clinical Pharmacology**

The GnRH agonists are occasionally used for stimulation of gonadotropin production. They are used far more commonly for suppression of gonadotropin release.

### **STIMULATION**

#### **Female Infertility**

In the current era of widespread availability of gonadotropins and assisted reproductive technology, the use of pulsatile GnRH administration to treat infertility is uncommon. Although pulsatile GnRH is less likely than gonadotropins to cause multiple pregnancies and the ovarian hyperstimulation syndrome, the inconvenience and cost associated with continuous use of an intravenous pump and difficulties obtaining native GnRH (gonadorelin) are barriers to pulsatile GnRH. When this approach is used, a portable battery-powered programmable pump and intravenous tubing deliver pulses of gonadorelin every 90 minutes.

Gonadorelin or a GnRH agonist analog can be used to initiate an LH surge and ovulation in women with infertility who are undergoing ovulation induction with gonadotropins. Traditionally, hCG has been used to initiate ovulation in this situation. However, there is some evidence that gonadorelin or a GnRH agonist is less likely than hCG to cause

multiple ova to be released and less likely to cause the ovarian hyperstimulation syndrome.

### **Male Infertility**

It is possible to use pulsatile gonadorelin for infertility in men with hypothalamic hypogonadotropic hypogonadism. A portable pump infuses gonadorelin intravenously every 90 minutes. Serum testosterone levels and semen analyses must be done regularly. At least 3–6 months of pulsatile infusions are required before significant numbers of sperm are seen. The preferable alternative to intravenous gonadorelin treatment is the gonadotropin treatment with hCG and hMG or their recombinant equivalents described above.

### **Diagnosis of LH Responsiveness**

GnRH can be useful in determining whether delayed puberty in a hypogonadotropic adolescent is due to constitutional delay or to hypogonadotropic hypogonadism. The LH response (but not the FSH response) to a single dose of GnRH can distinguish between these two conditions. Serum LH levels are measured before and at various times after an intravenous or subcutaneous bolus of GnRH. An increase in serum LH with a peak that exceeds 15.6 mIU/mL is normal and suggests impending puberty. An impaired LH response suggests hypogonadotropic hypogonadism due to either pituitary or hypothalamic disease, but does not rule out constitutional delay of adolescence.

## **SUPPRESSION OF GONADOTROPIN PRODUCTION**

### **Controlled Ovarian Hyperstimulation**

In the controlled ovarian hyperstimulation that provides multiple mature oocytes for assisted reproductive technologies such as in vitro fertilization, it is critical to suppress an endogenous LH surge that could prematurely trigger ovulation. This suppression is most commonly achieved by daily subcutaneous injections of leuprolide or daily nasal applications of nafarelin. For leuprolide, treatment is commonly initiated with 1.0 mg daily for about 10 days or until menstrual bleeding occurs. At that point, the dose is reduced to 0.5 mg daily until hCG is administered (Figure 37–3). For nafarelin, the beginning dosage is generally 400 mcg twice a day, which is decreased to 200 mcg when menstrual bleeding occurs. In women who respond poorly to the standard protocol, alternative protocols that use shorter courses and lower doses of GnRH agonists may improve the follicular response to gonadotropins.

### **Endometriosis**

Endometriosis is a syndrome of cyclical abdominal pain in premenopausal women that is due to the presence of estrogen-sensitive endometrium-like tissue outside the uterus. The pain of endometriosis is often reduced by abolishing exposure to the cyclical changes in the concentrations of estrogen and progesterone that are a normal part of the menstrual cycle. The ovarian suppression induced by continuous treatment with a GnRH agonist greatly reduces estrogen and progesterone concentrations and prevents cyclical

changes. The recommended duration of treatment with a GnRH agonist is limited to 6 months because ovarian suppression beyond this period can result in decreased bone density. Leuprolide, goserelin, and nafarelin are approved for this indication. Leuprolide and goserelin are administered as depot preparations that provide 1 or 3 months of continuous GnRH agonist activity. Nafarelin is administered twice daily as a nasal spray at a dose of 0.2 mg per spray.

### **Uterine Leiomyomata (Uterine Fibroids)**

Uterine leiomyomata are benign, estrogen-sensitive, fibrous growths in the uterus that can cause menorrhagia, with associated anemia and pelvic pain. Treatment for 3–6 months with a GnRH agonist reduces fibroid size and, when combined with supplemental iron, improves anemia. Leuprolide, goserelin, and nafarelin are approved for this indication. The doses and routes of administration are similar to those described for treatment of endometriosis.

### **Prostate Cancer**

Antiandrogen therapy is the primary medical therapy for prostate cancer. Combined antiandrogen therapy with continuous GnRH agonist and an androgen receptor antagonist such as flutamide (see Chapter 40) is as effective as surgical castration in reducing serum testosterone concentrations and effects. Leuprolide, goserelin, histrelin, and triptorelin are approved for this indication. The preferred formulation is one of the long-acting depot forms that provide 1, 3, 4, 6, or 12 months of active drug therapy. During the first 7–10 days of GnRH analog therapy, serum testosterone levels increase because of the agonist action of the drug; this can precipitate pain in patients with bone metastases, and tumor growth and neurologic symptoms in patients with vertebral metastases. It can also temporarily worsen symptoms of urinary obstruction. Such tumor flares can usually be avoided with the concomitant administration of bicalutamide or one of the other androgen receptor antagonists (see Chapter 40). Within about 2 weeks, serum testosterone levels fall to the hypogonadal range.

### **Central Precocious Puberty**

Continuous administration of a GnRH agonist is indicated for treatment of central precocious puberty (onset of secondary sex characteristics before 8 years in girls or 9 years in boys). Before administering a GnRH agonist, one must confirm central precocious puberty by demonstrating a pubertal, not childhood, gonadotropin response to GnRH and a bone age at least 1 year beyond chronologic age. Pretreatment evaluation must also include gonadal steroid levels compatible with precocious puberty and not congenital adrenal hyperplasia; an hCG level that is low enough to exclude a chronic gonadotropin-secreting tumor; an MRI of the brain to exclude an intracranial tumor; and ultrasound examination of the adrenals and ovaries or testes to exclude a steroid-secreting tumor.

Treatment can be carried out with injections of leuprolide or nasal application of nafarelin. Leuprolide treatment is usually initiated at a dosage of 0.05 mg/kg body weight injected subcutaneously daily and then adjusted on the basis of the clinical response. Pediatric depot preparations of leuprolide are also available. The recommended initial dosage of nafarelin for central precocious puberty is 1.6 mg/d. This is achieved with two-unit dose sprays (each spray contains 0.1 mL, 0.2 mg) into each nostril twice daily. Treatment with a GnRH agonist is generally continued to age 11 in females and age 12 in males.

### **Other**

Other clinical uses for the gonadal suppression provided by continuous GnRH agonist treatment include advanced breast and ovarian cancer; thinning of the endometrial lining in preparation for an endometrial ablation procedure in women with dysfunctional uterine bleeding; and treatment of amenorrhea and infertility in women with polycystic ovary disease.

### **Toxicity**

Gonadorelin can cause headache, light-headedness, nausea, and flushing. Local swelling often occurs at subcutaneous injection sites. Generalized hypersensitivity dermatitis has occurred after long-term subcutaneous administration. Rare acute hypersensitivity reactions include bronchospasm and anaphylaxis. Sudden pituitary apoplexy and blindness have been reported following administration of GnRH to a patient with a gonadotropin-secreting pituitary tumor.

Continuous treatment of women with a GnRH analog (leuprolide, nafarelin, goserelin) causes the typical symptoms of menopause, which include hot flushes, sweats, and headaches. Depression, diminished libido, generalized pain, vaginal dryness, and breast atrophy may also occur. Ovarian cysts may develop within the first 2 months of therapy and generally resolve after an additional 6 weeks; however, the cysts may persist and require discontinuation of therapy. Reduced bone density and osteoporosis may occur with prolonged use, so patients should be monitored with bone densitometry before repeated treatment courses. Depending on the condition being treated with the GnRH agonist, it may be possible to ameliorate the signs and symptoms of the hypoestrogenic state without losing clinical efficacy by adding back a small dose of a progestin and an estrogen. Contraindications to the use of GnRH agonists in women include pregnancy and breast-feeding.

In men treated with continuous GnRH agonist administration, adverse effects include hot flushes and sweats, edema, gynecomastia, decreased libido, decreased hematocrit, reduced bone density, asthenia, and injection site reactions. GnRH analog treatment of children is generally well tolerated. However, temporary exacerbation of precocious puberty may occur during the first few weeks of therapy. Nafarelin nasal spray may

cause or aggravate sinusitis.

## **GNRH RECEPTOR ANTAGONISTS**

Four synthetic decapeptides that function as competitive antagonists of GnRH receptors are available for clinical use. **Ganirelix, cetrorelix, abarelix,** and **degarelix** inhibit the secretion of FSH and LH in a dose-dependent manner. Ganirelix and cetrorelix are approved for use in controlled ovarian hyperstimulation procedures, whereas abarelix and degarelix are approved for men with advanced prostate cancer.

### **Pharmacokinetics**

Ganirelix and cetrorelix are absorbed rapidly after subcutaneous injection. Administration of 0.25 mg daily maintains GnRH antagonism. Alternatively, a single 3.0-mg dose of cetrorelix suppresses LH secretion for 96 hours. Abarelix is absorbed slowly after intramuscular injection and reaches a peak concentration 3 days after injection. It has a half-life of 13 days. After three initial doses on days 1, 13, and 28, abarelix is administered every 4 weeks.

### **Clinical Pharmacology**

#### **SUPPRESSION OF GONADOTROPIN PRODUCTION**

GnRH antagonists are approved for preventing the LH surge during controlled ovarian hyperstimulation. They offer several advantages over continuous treatment with a GnRH agonist. Because GnRH antagonists produce an immediate antagonist effect, their use can be delayed until day 6<sup>–8</sup> of the in vitro fertilization cycle (Figure 37<sup>–3</sup>), and thus the duration of administration is shorter. They also appear to have a less negative impact on the ovarian response to gonadotropin stimulation, which permits a decrease in the total duration and dose of gonadotropin. Finally, GnRH antagonists are associated with a lower risk of ovarian hyperstimulation syndrome, which can lead to cycle cancellation. On the other hand, because their antagonist effects reverse more quickly after their discontinuation, adherence to the treatment regimen is critical. The antagonists produce a more complete suppression of gonadotropin secretion than agonists. There is concern that the suppression of LH may inhibit ovarian steroidogenesis to an extent that impairs follicular development when recombinant or the purified form of FSH is used during the follicular phase of an in vitro fertilization cycle. Clinical trials have shown a slightly lower rate of pregnancy in in vitro fertilization cycles that used GnRH antagonist treatment compared with cycles that used GnRH agonist treatment.

#### **ADVANCED PROSTATE CANCER**

Abarelix is approved for the treatment of symptomatic advanced prostate cancer in men for whom a GnRH agonist is not appropriate (eg, in men who experience a severe tumor flare in response to the surge of LH and testosterone that occurs during the first 2<sup>–3</sup> days of GnRH agonist therapy) and who decline surgical castration. This GnRH antagonist reduces concentrations of gonadotropins and androgens significantly more

rapidly than GnRH agonists and avoids the testosterone surge seen with GnRH agonist therapy. Abarelix reduced symptoms in patients with vertebral or skeletal metastasis, or bladder outlet obstruction. Degarelix appears to be similar.

### **Toxicity**

When used for controlled ovarian hyperstimulation, ganirelix and cetrorelix are well tolerated. The most common adverse effects are nausea and headache. During the treatment of men with prostate cancer, abarelix has elicited immediate-onset allergic responses that manifested as skin reactions or as hypotension and syncope, and it also prolonged the QT interval. Like continuous treatment with a GnRH agonist, abarelix leads to signs and symptoms of androgen deprivation, including hot flushes and sweats, gynecomastia, decreased libido, decreased hematocrit, and reduced bone density.

### **PROLACTIN**

Prolactin is a 198-amino-acid peptide hormone produced in the anterior pituitary. Its structure resembles that of GH. Prolactin is the principal hormone responsible for lactation. Milk production is stimulated by prolactin when appropriate circulating levels of estrogens, progestins, corticosteroids, and insulin are present. A deficiency of prolactinâ€™ which can occur in rare states of pituitary deficiencyâ€™ is manifested by failure to lactate or by a luteal phase defect. In rare cases of hypothalamic destruction, prolactin levels may be elevated as a result of impaired transport of dopamine (prolactin-inhibiting hormone) to the pituitary. Much more commonly, however, prolactin is elevated as a result of prolactin-secreting adenomas. Hyperprolactinemia produces a syndrome of amenorrhea and galactorrhea in women, and loss of libido and infertility in men. In the case of large tumors (macroadenomas), it can be associated with symptoms of a pituitary mass, including visual changes due to compression of the optic nerves. The hypogonadism and infertility associated with hyperprolactinemia result from inhibition of GnRH release.

No preparation of prolactin is available for use in prolactin-deficient patients. For patients with symptomatic hyperprolactinemia, inhibition of prolactin secretion can be achieved with dopamine agonists, which act in the pituitary to inhibit prolactin release.

### **DOPAMINE AGONISTS**

Adenomas that secrete excess prolactin usually retain the sensitivity to inhibition by dopamine exhibited by the normal pituitary. **Bromocriptine** and **cabergoline** are ergot derivatives (see Chapters 16 and 28) with a high affinity for dopamine D<sub>2</sub> receptors.

**Quinagolide**, a drug approved in Europe, is a nonergot agent with similarly high D<sub>2</sub> receptor affinity. The chemical structure and pharmacokinetic features of ergot alkaloids are presented in Chapter 16.

Dopamine agonists suppress prolactin release very effectively in patients with hyperprolactinemia. GH release is reduced in patients with acromegaly, although not as effectively. Cabergoline and bromocriptine are also used in Parkinson's disease to improve motor function and reduce levodopa requirements (see Chapter 28). Newer, nonergot D<sub>2</sub> agonists used in Parkinson's disease (pramipexole and ropinirole; see Chapter 28) have been reported to interfere with lactation, but they are not approved for use in hyperprolactinemia.

### **Pharmacokinetics**

All available dopamine agonists are active as oral preparations, and all are eliminated by metabolism. They can also be absorbed systemically after vaginal insertion of tablets. Cabergoline, with a half-life of approximately 65 hours, has the longest duration of action. Quinagolide has a half-life of about 20 hours, whereas the half-life of bromocriptine is about 7 hours. After vaginal administration, serum levels peak more slowly.

### **Clinical Pharmacology**

#### **HYPERPROLACTINEMIA**

A dopamine agonist is the standard medical treatment for hyperprolactinemia. These drugs shrink pituitary prolactin-secreting tumors, lower circulating prolactin levels, and restore ovulation in approximately 70% of women with microadenomas and 30% of women with macroadenomas (Figure 37-4). Cabergoline is initiated at 0.25 mg twice weekly orally or vaginally. It can be increased gradually, according to serum prolactin determinations, up to a maximum of 1 mg twice weekly. Bromocriptine is generally taken daily after the evening meal at the initial dose of 1.25 mg; the dose is then increased as tolerated. Most patients require 2.5–7.5 mg daily. Long-acting oral bromocriptine formulations (Parlodel SRO) and intramuscular formulations (Parlodel L.A.R.) are available outside the USA.

Results from a clinical trial of cabergoline in women with hyperprolactinemia and anovulation.

**A:** The dotted line indicates the upper limit of normal serum prolactin concentrations. **B:** Complete success was defined as pregnancy or at least two consecutive menses with evidence of ovulation at least once. Partial success was two menstrual cycles without evidence of ovulation or just one ovulatory cycle. The most common reasons for withdrawal from the trial were nausea, headache, dizziness, abdominal pain, and fatigue.

(Modified and reproduced, with permission, from Webster J et al: A comparison of cabergoline and bromocriptine in the treatment of hyperprolactinemic amenorrhea. *N Engl J Med* 1994;331:904.)

## **PHYSIOLOGIC LACTATION**

Dopamine agonists were used in the past to prevent breast engorgement when breast-feeding was not desired. Their use for this purpose has been discouraged because of toxicity (see Toxicity & Contraindications).

## **ACROMEGALY**

A dopamine agonist alone or in combination with pituitary surgery, radiation therapy, or octreotide administration can be used to treat acromegaly. The doses required are higher than those used to treat hyperprolactinemia. For example, patients with acromegaly require 20–30 mg/d of bromocriptine and seldom respond adequately to bromocriptine alone unless the pituitary tumor secretes prolactin as well as GH.

## **Toxicity & Contraindications**

Dopamine agonists can cause nausea, headache, light-headedness, orthostatic hypotension, and fatigue. Psychiatric manifestations occasionally occur, even at lower doses, and may take months to resolve. Erythromelalgia occurs rarely. High dosages of ergot-derived preparations can cause cold-induced peripheral digital vasospasm. Pulmonary infiltrates have occurred with chronic high-dosage therapy. Cabergoline appears to cause nausea less often than bromocriptine. Vaginal administration can reduce nausea, but may cause local irritation.

Dopamine agonist therapy during the early weeks of pregnancy has not been associated with an increased risk of spontaneous abortion or congenital malformations. Although there has been a longer experience with the safety of bromocriptine during early pregnancy, there is growing evidence that cabergoline is also safe in women with macroadenomas who must continue a dopamine agonist during pregnancy. In patients with small pituitary adenomas, dopamine agonist therapy is discontinued upon conception because growth of microadenomas during pregnancy is rare. Patients with very large adenomas require vigilance for tumor progression and often require a dopamine agonist throughout pregnancy. There have been rare reports of stroke or coronary thrombosis in postpartum women taking bromocriptine to suppress postpartum lactation.

## **POSTERIOR PITUITARY HORMONES**

The two posterior pituitary hormones—vasopressin and oxytocin—are synthesized in neuronal cell bodies in the hypothalamus and transported via their axons to the posterior pituitary, where they are stored and then released into the circulation. Each has limited but important clinical uses.

## **OXYTOCIN**

Oxytocin is a peptide hormone secreted by the posterior pituitary that participates in

labor and delivery and elicits milk ejection in lactating women. During the second half of pregnancy, uterine smooth muscle shows an increase in the expression of oxytocin receptors and becomes increasingly sensitive to the stimulant action of endogenous oxytocin. Pharmacologic concentrations of oxytocin powerfully stimulate uterine contraction.

## Chemistry & Pharmacokinetics

### STRUCTURE

Oxytocin is a 9-amino-acid peptide with an intrapeptide disulfide cross-link (Figure 37â€5). Its amino acid sequence differs from that of vasopressin at positions 3 and 8.

**Figure 37â€5**

Posterior pituitary hormones and desmopressin.

(Modified and reproduced, with permission, from Ganong WF: *Review of Medical Physiology*, 21st ed. McGraw-Hill, 2003.)

### ABSORPTION, METABOLISM, AND EXCRETION

Oxytocin is administered intravenously for initiation and augmentation of labor. It also can be administered intramuscularly for control of postpartum bleeding. Oxytocin is not bound to plasma proteins and is eliminated by the kidneys and liver, with a circulating

half-life of 5 minutes.

## **Pharmacodynamics**

Oxytocin acts through G protein-coupled receptors and the phosphoinositide-calcium second-messenger system to contract uterine smooth muscle. Oxytocin also stimulates the release of prostaglandins and leukotrienes that augment uterine contraction.

Oxytocin in small doses increases both the frequency and the force of uterine contractions. At higher doses, it produces sustained contraction.

Oxytocin also causes contraction of myoepithelial cells surrounding mammary alveoli, which leads to milk ejection. Without oxytocin-induced contraction, normal lactation cannot occur. At high concentrations, oxytocin has weak antidiuretic and pressor activity due to activation of vasopressin receptors.

## **Clinical Pharmacology**

Oxytocin is used to induce labor for conditions requiring early vaginal delivery such as Rh problems, maternal diabetes, preeclampsia, or ruptured membranes. It is also used to augment abnormal labor that is protracted or displays an arrest disorder. Oxytocin has several uses in the immediate postpartum period, including the control of uterine hemorrhage after vaginal or cesarean delivery. It is sometimes used during second-trimester abortions.

Before delivery, oxytocin is usually administered intravenously via an infusion pump with appropriate fetal and maternal monitoring. For induction of labor, an initial infusion rate of 0.5–2 mU/min is increased every 30–60 minutes until a physiologic contraction pattern is established. The maximum infusion rate is 20 mU/min. For postpartum uterine bleeding, 10–40 units are added to 1 L of 5% dextrose, and the infusion rate is titrated to control uterine atony. Alternatively, 10 units of oxytocin can be administered by intramuscular injection after delivery of the placenta.

During the antepartum period, oxytocin induces uterine contractions that transiently reduce placental blood flow to the fetus. The oxytocin challenge test measures the fetal heart rate response to a standardized oxytocin infusion and provides information about placental circulatory reserve. An abnormal response, seen as late decelerations in the fetal heart rate, indicates fetal hypoxia and may warrant immediate cesarean delivery.

## **Toxicity & Contraindications**

When oxytocin is used judiciously, serious toxicity is rare. The toxicity that does occur is due either to excessive stimulation of uterine contractions or to inadvertent activation of vasopressin receptors. Excessive stimulation of uterine contractions before delivery can cause fetal distress, placental abruption, or uterine rupture. These complications can be detected early by means of standard fetal monitoring equipment. High concentrations of oxytocin with activation of vasopressin receptors can cause excessive fluid retention, or

water intoxication, leading to hyponatremia, heart failure, seizures, and death. Bolus injections of oxytocin can cause hypotension. To avoid hypotension, oxytocin is administered intravenously as dilute solutions at a controlled rate.

Contraindications to oxytocin include fetal distress, prematurity, abnormal fetal presentation, cephalopelvic disproportion, and other predispositions for uterine rupture.

## **OXYTOCIN ANTAGONIST**

**Atosiban** is an antagonist of the oxytocin receptor that has been approved outside the USA as a treatment for preterm labor (tocolysis). Atosiban is a modified form of oxytocin that is administered by IV infusion for 2–48 hours. In a small number of published clinical trials, atosiban appears to be as effective as  $\beta$ -adrenoceptor-agonist tocolytics and to produce fewer adverse effects. In 1998, the FDA decided not to approve atosiban based on concerns about efficacy and safety.

## **VASOPRESSIN (ANTIDIURETIC HORMONE, ADH)**

Vasopressin is a peptide hormone released by the posterior pituitary in response to rising plasma tonicity or falling blood pressure. Vasopressin possesses antidiuretic and vasopressor properties. A deficiency of this hormone results in diabetes insipidus (see Chapters 15 and 17).

## **Chemistry & Pharmacokinetics**

### **STRUCTURE**

Vasopressin is a nonapeptide with a 6-amino-acid ring and a 3-amino-acid side chain. The residue at position 8 is arginine in humans and in most other mammals except pigs and related species, whose vasopressin contains lysine at position 8 (Figure 37–5). Desmopressin acetate (DDAVP, 1-desamino-8-D-arginine vasopressin) is a long-acting synthetic analog of vasopressin with minimal  $V_1$  activity and an antidiuretic-to-pressor ratio 4000 times that of vasopressin. **Desmopressin** is modified at position 1 and contains a D-amino acid at position 8. Like vasopressin and oxytocin, desmopressin has a disulfide linkage between positions 1 and 6.

### **ABSORPTION, METABOLISM, AND EXCRETION**

Vasopressin is administered by intravenous or intramuscular injection. The half-life of circulating vasopressin is approximately 15 minutes, with renal and hepatic metabolism via reduction of the disulfide bond and peptide cleavage.

Desmopressin can be administered intravenously, subcutaneously, intranasally, or orally. The half-life of circulating desmopressin is 1.5–2.5 hours. Nasal desmopressin is available as a unit dose spray that delivers 0.1 mL per spray; it is also available with a calibrated nasal tube that can be used to deliver a more precise dose. Nasal bioavailability of desmopressin is 3–4%, whereas oral bioavailability is less than 1%.

## Pharmacodynamics

Vasopressin activates two subtypes of G protein-coupled receptors (see Chapter 17).  $V_1$  receptors are found on vascular smooth muscle cells and mediate vasoconstriction.  $V_2$  receptors are found on renal tubule cells and reduce diuresis through increased water permeability and water resorption in the collecting tubules. Extrarenal  $V_2$ -like receptors regulate the release of coagulation factor VIII and von Willebrand factor.

## Clinical Pharmacology

Vasopressin and desmopressin are treatments of choice for pituitary diabetes insipidus. The dosage of desmopressin is 10–40 mcg (0.1–0.4 mL) in two to three divided doses as a nasal spray or, as an oral tablet, 0.1–0.2 mg two to three times daily. The dosage by injection is 1–4 mcg (0.25–1 mL) every 12–24 hours as needed for polyuria, polydipsia, or hypernatremia. Bedtime desmopressin therapy, by intranasal or oral administration, ameliorates nocturnal enuresis by decreasing nocturnal urine production. Vasopressin infusion is effective in some cases of esophageal variceal bleeding and colonic diverticular bleeding.

Desmopressin is also used for the treatment of coagulopathy in hemophilia A and von Willebrand's disease (see Chapter 34).

## Toxicity & Contraindications

Headache, nausea, abdominal cramps, agitation, and allergic reactions occur rarely. Overdosage can result in hyponatremia and seizures.

Vasopressin (but not desmopressin) can cause vasoconstriction and should be used cautiously in patients with coronary artery disease. Nasal insufflation of desmopressin may be less effective when nasal congestion is present.

## VASOPRESSIN ANTAGONISTS

A group of nonpeptide antagonists of vasopressin receptors is being investigated for use in patients with hyponatremia or acute heart failure, which is often associated with elevated concentrations of vasopressin. **Conivaptan** has high affinity for both  $V_{1a}$  and  $V_2$  receptors. **Tolvaptan** has a 30-fold higher affinity for  $V_2$  than for  $V_1$  receptors. In several clinical trials, both agents relieved symptoms and reduced objective signs of hyponatremia and heart failure. Conivaptan is approved by the FDA for intravenous administration in hyponatremia but not in congestive heart failure. Several other nonselective nonpeptide vasopressin receptor antagonists are being investigated for these conditions.

## SUMMARY: HYPOTHALAMIC AND PITUITARY HORMONES

## Hypothalamic and Pituitary Hormones<sup>1</sup>

Subclass	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>Growth hormone (GH)</b>				
Somatropin	Recombinant form of human GH • acts through GH receptors to increase production of insulin-like growth factor-1 (IGF-1)	Restores normal growth and metabolic GH effects in GH-deficient individuals • increases final adult height in some children with short stature not due to GH deficiency	Replacement in GH deficiency • increased final adult height in children with certain conditions associated with short stature (see Table 37-4) • wasting in HIV infection • short bowel syndrome	SC injection 3x/wk • <i>Toxicity:</i> Scoliosis, edema, gynecomastia, intracranial hypertension, myalgia, arthralgia, carpal tunnel syndrome, increased CYP450 activity
<b>IGF-1 agonist</b>				
Mecasermin	Recombinant form of IGF-1 that stimulates IGF-1 receptors	Restores normal growth and metabolic IGF-1 effects in individuals with IGF-1 deficiency	Replacement in IGF-1 deficiency that is not responsive to exogenous GH	SC injection 2 x/d • also contains recombinant human IGF-binding protein-3, which prolongs the half-life of the rIGF-1 • <i>Toxicity:</i> Hypoglycemia, intracranial hypertension, increased liver enzymes
<b>Somatostatin analogs</b>				
Octreotide	Agonist of somatostatin receptors	Inhibits production of GH and, to a lesser extent, of glucagon, insulin, and gastrin	Acromegaly and several other hormone-secreting tumors • acute control of bleeding from esophageal varices	SC injection 3x/d • long-acting formulation injected IM monthly • <i>Toxicity:</i> Gastrointestinal disturbances,

gallstones, bradycardia, and other cardiac conduction problems

*Lanreotide: Similar to octreotide and available as a long-acting formulation for acromegaly*

**GH receptor antagonist**

Pegvisomant	Blocks GH receptors	Ameliorates effects of excess GH production	Acromegaly	SC injection 3x/wk • <i>Toxicity:</i> Increased liver enzymes
-------------	---------------------	---	------------	---

**Gonadotropins: Follicle-stimulating hormone (FSH) analogs**

Follitropin alfa	Activates FSH receptors	Mimics effects of endogenous FSH	Controlled ovulation hyperstimulation in women • infertility due to hypogonadism in men	SC injection 3x/wk • <i>Toxicity:</i> Ovarian hyperstimulation syndrome and multiple pregnancies in women • gynecomastia in men • headache, depression, edema in both sexes
------------------	-------------------------	----------------------------------	---	---

*Follitropin beta: A recombinant product with the same peptide sequence as follitropin alfa but differs in its carbohydrate side chains*

*Urofollitropin: Human FSH purified from the urine of postmenopausal women*

*Menotropins (hMG): Extract of the urine of postmenopausal women; contains both FSH and LH activity*

**Gonadotropins: Luteinizing hormone (LH) analogs**

Human chorionic gonadotropin (hCG)	Agonist of the LH receptor	Mimics effects of endogenous LH	Initiation of ovulation during controlled ovulation hyperstimulation • ovarian follicle development in women with hypogonadotropic	IM • <i>Toxicity:</i> Ovarian hyperstimulation syndrome and multiple pregnancies in women • gynecomastia in men • headache,
------------------------------------	----------------------------	---------------------------------	--	---

hypogonadism

depression, edema  
in both sexes

*Choriogonadotropin alfa: Recombinant form of hCG*

*Lutropin: Recombinant form of human LH*

*Menotropins (hMG): Extract of the urine of postmenopausal women that contains both FSH and LH activity*

### **(GnRH) analogs**

Leuprolide	Agonist of GnRH receptors	Increased LH and FSH secretion with intermittent administration • reduced LH and FSH secretion with prolonged continuous administration	Ovarian suppression, controlled ovarian hyperstimulation, central precocious puberty • advanced prostate cancer	Administered IV, SC, IM or intranasally • depot formulations are available • <i>Toxicity:</i> Headache, light-headedness, nausea, injection site reactions • symptoms of hypogonadism with continuous treatment
------------	---------------------------	---	---	---

*Gonadorelin is synthetic human GnRH*

*Other GnRH analogs: Goserelin, histrelin, nafarelin, and triptorelin*

### **Gonadotropin-releasing hormone (GnRH) receptor antagonists**

Ganirelix	Blocks GnRH receptors	Reduces endogenous production of LH and FSH	Prevention of premature LH surges during controlled ovulation hyperstimulation	SC injection • <i>Toxicity:</i> Nausea, headache
-----------	-----------------------	---	--	--

*Cetrorelix: Similar to ganirelix and approved for controlled ovarian hyperstimulation*

*Abarelix, degarelix: Approved for advanced prostate cancer; can cause immediate-type hypersensitivity reactions*

### **Dopamine agonists**

Bromocriptine	Activates dopamine D <sub>2</sub> receptors	Suppresses pituitary secretion of prolactin • dopaminergic effects on CNS	Treatment of hyperprolactinemia and Parkinson's disease (see Chapter 28)	Administered orally or vaginally • <i>Toxicity:</i> Gastrointestinal disturbances, orthostatic
---------------	---	---	--	--

motor control  
and behavior

hypotension,  
headache,  
psychiatric  
disturbances,  
vasospasm and  
pulmonary  
infiltrates in high  
doses

*Cabergoline: Another ergot derivative with similar effects*

Oxytocin	Activates oxytocin receptors	Increased uterine contractions	Induction and augmentation of labor • control of uterine hemorrhage after delivery	IV infusion • <i>Toxicity:</i> Fetal distress, placental abruption, uterine rupture, fluid retention, hypotension
----------	------------------------------	--------------------------------	--	---

#### **Oxytocin receptor antagonist**

Atosiban	Blocks oxytocin receptors	Decreased uterine contractions	Tocolysis for preterm labor	IV infusion • <i>Toxicity:</i> Concern about rates of infant death
----------	---------------------------	--------------------------------	-----------------------------	--

#### **Vasopressin receptor agonists**

Desmopressin	Activates vasopressin V <sub>2</sub> receptors much more than V <sub>1</sub> receptors	Acts in the kidney to decrease the excretion of water • acts on extrarenal V <sub>2</sub> receptors to increase factor VIII and von Willebrand factor	Pituitary diabetes insipidus • hemophilia A and von Willebrand disease	Oral, IV, SC, or intranasal • <i>Toxicity:</i> Gastrointestinal disturbances, headache, hyponatremia, allergic reactions
--------------	--	---	--	--

*Vasopressin: Available for treatment of diabetes insipidus and sometimes used to control bleeding from esophageal varices*

#### **Vasopressin receptor antagonist**

Conivaptan	Antagonist of vasopressin V <sub>1a</sub> and V <sub>2</sub>	Reduced renal excretion of water in conditions	Hyponatremia in hospitalized patients	IV infusion • <i>Toxicity:</i> Infusion site reactions
------------	--	--	---------------------------------------	--

receptors associated with  
increased  
vasopressin

*Tolvaptan: Similar but more selective for vasopressin V<sub>2</sub> receptors*

<sup>1</sup>See Tables 37â€² and 37â€³ for summaries of the clinical uses of the rarely used hypothalamic and pituitary hormones not described in this table.

## **PREPARATIONS AVAILABLE**

### **Growth Hormone Agonists & Antagonists**

**Lanreotide acetate** (Somatuline Depot)

Parenteral: 60, 90, 120 mg in single-use prefilled syringe for subcutaneous injection

**Mecasermin rinfabate** (Iplex)

Parenteral: 36 mg per 0.6 mL for subcutaneous injection

**Mecasermin** (Increlex)

Parenteral: 10 mg/mL for subcutaneous injection

**Octreotide** (generic, Sandostatin)

Parenteral: 0.05, 0.1, 0.2, 0.5, 1.0 mg/mL for subcutaneous or IV injection

Parenteral depot injection (Sandostatin LAR Depot): 10, 20, 30 mg powder in single-use vials to reconstitute for IM injection

**Pegvisomant** (Somavert)

Parenteral: 10, 15, 20 mg powder in single-use vials to reconstitute for subcutaneous injection

**Somatropin** (Accretropin, Genotropin, Humatrope, Nutropin, Norditropin, Omnitrope, Saizen, Serostim, Tev-Tropin, Zorbtive)

Parenteral: 0.2, 0.4, 0.6, 0.8, 1.0, 1.2, 1.4, 1.5, 1.6, 1.8, 2, 4, 5, 5.8, 6, 8.8, 10, 12, 13.8, 24 mg for subcutaneous or IM injection

### **Gonadotropin Agonists & Antagonists**

**Abarelix** (Plenaxis)

Parenteral: 113 mg powder to reconstitute for IM injection

**Cetrorelix** (Cetrotide)

Parenteral: 0.25, 3.0 mg in single-use vials for subcutaneous injection

**Choriogonadotropin alfa [rhCG]** (Ovidrel)

Parenteral: 250 mcg in single-dose prefilled syringes for subcutaneous injection

**Chorionic gonadotropin [hCG]** (generic, Profasi, Pregnyl, others)

Parenteral: powder to reconstitute 500, 1000, 2000 IU/mL for IM injection

**Follitropin alfa [rFSH]** (Gonal-f)

Parenteral: 82, 600, 1200 IU powder in single-dose vials or 415, 568, 1026 IU in prefilled pens with needles for subcutaneous injection

**Follitropin beta [rFSH]** (Follistim)

Parenteral: 37.5, 150 IU/mL in single-dose vials or 175, 350, 650, 975 IU in a solution of benzyl alcohol in cartridges for subcutaneous injection

**Ganirelix** (Antagon)

Parenteral: 500 mcg/mL in prefilled syringes for subcutaneous injection

**Gonadorelin acetate** (Lutrepulse)

Parenteral: 0.8, 3.2 mg for injection

**Gonadorelin hydrochloride [GnRH]** (Factrel)

Parenteral: 100, 500 mcg powder to reconstitute for subcutaneous or intravenous injection

**Goserelin** (Zoladex)

Parenteral: 3.6, 10.8 mg in prefilled syringes for subcutaneous implantation

**Histrelin acetate** (Supprelin LA, Vantas)

Parenteral: 50 mg subcutaneous implant; 0.2, 0.5, 1 mg/mL for injection

**Leuprolide** (generic, Eligard, Lupron, others)

Parenteral: 5 mg/mL in multiple-dose vials, or 7.5 mg powder in a single-use kit, or 30 mg (4-month depot), 45 mg (6-month depot) in a single-dose kit for subcutaneous injection

Parenteral depot polymeric delivery system: 7.5, 22.5, 30, 45 mg in a single-dose kit for subcutaneous injection

Parenteral depot microspheres suspension: 3.75, 7.5, 11.25, 15, 22.5, 30 mg in a single-dose kit for IM injection

**Lutropin [rLH]** (Luveris)

Parenteral: 82.5 IU powder for subcutaneous injection

**Menotropins [hMG]** (Menopur, Repronex)

Parenteral: 75 IU FSH and 75 IU LH activity, 150 IU FSH and 150 IU LH activity for subcutaneous or IM injection

**Nafarelin** (Synarel)

Nasal: 2 mg/mL (200 mcg/spray)

**Triptorelin** (Trelstar)

Parenteral: 3.75, 11.25 mg microgranules for IM injection

**Urofollitropin** (Bravelle)

Parenteral: 75 IU FSH for subcutaneous injection

**Prolactin Antagonists (Dopamine Agonists)**

**Bromocriptine** (generic, Parlodel)

Oral: 2.5 mg tablets, 5 mg capsules

**Cabergoline** (generic, Dostinex)

Oral: 0.5 mg scored tablets

**Oxytocin**

**Oxytocin** (generic, Pitocin)

Parenteral: 10 units/mL for intravenous or IM injection

## **Vasopressin Agonists and Antagonists**

### **Conivaptan** (Vaprisol)

Parenteral: 5 mg/mL solution for IV injection

### **Desmopressin** (DDAVP, generic, Stimate)

Nasal: 0.1, 1.5 mg/mL solution

Parenteral: 4 mcg/mL solution for IV or subcutaneous injection

Oral: 0.1, 0.2 mg tablets

### **Vasopressin** (generic, Pitressin)

Parenteral: 20 pressor IU/mL for IM or subcutaneous administration

## **Other**

### **Corticotropin ovine** (Acthrel)

Parenteral: 100 mcg for IV injection

### **Corticotropin** (H.P. Acthar Gel)

Parenteral: 80 IU/mL

### **Cosyntropin** (Cortrosyn)

Parenteral: 0.25 mg/vial for IV or IM injection

### **Thyrotropin alfa** (Thyrogen)

Parenteral: 1.1 mg (4 IU) for IM injection

Basic and Clinical Pharmacology > Chapter 38. Thyroid & Antithyroid Drugs >

## CASE STUDY

A 33-year-old woman presents with complaints of fatigue, sluggishness, weight gain, cold intolerance, dry skin, and muscle weakness for the last 2 months. She is so tired that she has to take several naps during the day to complete her tasks. These complaints are new for her since she used to feel warm all the time, had boundless energy causing her some insomnia, and states she felt like her heart was going to jump out of her chest. She also states that she would like to become pregnant in the near future. Her past medical history is significant for radioactive iodine therapy (RAI) about 1 year ago after a short trial of methimazole and propranolol therapy. She underwent RAI due to her poor medication adherence and did not attend routine scheduled appointments afterward. On physical examination, her blood pressure is 130/89 mm Hg with a pulse of 50 bpm. Her weight is 136 lb (61.8 kg), an increase of 10 lb (4.5 kg) in the last year. Her thyroid gland is not palpable and her reflexes are delayed. Laboratory findings include a thyroid-stimulating hormone (TSH) level of 14.9  $\mu\text{IU/mL}$  and a free thyroxine level of 8 pmol/L. Evaluate the management of her past history of hyperthyroidism. Identify the available treatment options for control of her current thyroid status.

## THYROID PHYSIOLOGY

The normal thyroid gland secretes sufficient amounts of the thyroid hormones **triiodothyronine (T<sub>3</sub>)** and **tetraiodothyronine (T<sub>4</sub>, thyroxine)** to normalize growth and development, body temperature, and energy levels. These hormones contain 59% and 65% (respectively) of iodine as an essential part of the molecule. Calcitonin, the second type of thyroid hormone, is important in the regulation of calcium metabolism and is discussed in Chapter 42.

### Iodide Metabolism

The recommended daily adult iodide ( $\text{I}^-$ )\* intake is 150 mcg (200 mcg during pregnancy).

Iodide, ingested from food, water, or medication, is rapidly absorbed and enters an extracellular fluid pool. The thyroid gland removes about 75 mcg a day from this pool for hormone synthesis, and the balance is excreted in the urine. If iodide intake is increased, the fractional iodine uptake by the thyroid is diminished.

### Biosynthesis of Thyroid Hormones

Once taken up by the thyroid gland, iodide undergoes a series of enzymatic reactions that incorporate it into active thyroid hormone (Figure 38-1). The first step is the transport of iodide into the thyroid gland by an intrinsic follicle cell basement membrane protein called the sodium/iodide symporter (NIS). This can be inhibited by such anions as thiocyanate ( $\text{SCN}^-$ ), pertechnetate ( $\text{TcO}_4^-$ ), and perchlorate ( $\text{ClO}_4^-$ ). At the apical cell membrane a second  $\text{I}^-$  transport enzyme called pendrin controls the flow of iodide across the membrane. Pendrin is also found in the cochlea of the inner ear and if deficient or absent, a syndrome of deafness and goiter, called Pendred's syndrome, ensues. At the apical cell membrane, iodide is oxidized by thyroidal peroxidase to iodine, in which form it rapidly iodinates tyrosine residues within the thyroglobulin molecule to form monoiodotyrosine (MIT) and diiodotyrosine (DIT). This process is called **iodide organification**. Thyroidal peroxidase is transiently blocked by high levels of intrathyroidal iodide and blocked more persistently by thioamide drugs.

### Figure 38-1

Biosynthesis of thyroid hormones. The sites of action of various drugs that interfere with thyroid hormone biosynthesis are shown.

Two molecules of DIT combine within the thyroglobulin molecule to form L-thyroxine ( $T_4$ ). One molecule of MIT and one molecule of DIT combine to form  $T_3$ . In addition to thyroglobulin, other proteins within the gland may be iodinated, but these iodoproteins do not have hormonal activity. Thyroxine,  $T_3$ , MIT, and DIT are released from thyroglobulin by exocytosis and proteolysis of thyroglobulin at the apical colloid border. The MIT and DIT are deiodinated within the gland, and the iodine is reutilized. This process of proteolysis is also blocked by high levels of intrathyroidal iodide. The ratio of  $T_4$  to  $T_3$  within thyroglobulin is approximately 5:1, so that most of the hormone released is thyroxine. Most of the  $T_3$  circulating in the blood is derived from peripheral metabolism of thyroxine (see below, Figure 38â€²).

**Figure 38â€²**

Serum levels		
Total	4.8â€“10.4 mcg/dL	79â€“149 ng/dL (1.2â€“2.3 nmol/L) (62â€“134 nmol/L)
Free	0.7â€“1.86 ng/dL	145â€“348 ng/dL (9â€“24 pmol/L) (2.2â€“5.4 pmol/L)
Amount bound	99.96%	99.6%
Biologic potency	1	4
Oral absorption	80%	95%

### Evaluation of Thyroid Function

The tests used to evaluate thyroid function are listed in Table 38â€“2.

**Table 38â€“2 Typical Values for Thyroid Function Tests.**

Name of Test	Normal Value <sup>1</sup>	Results in Hypothyroidism	Results in Hyperthyroidism
Total thyroxine (T <sub>4</sub> )	4.8â€“10.4 mcg/dL (62â€“134 nmol/L)	Low	High
Total triiodothyronine (T <sub>3</sub> )	79â€“149 ng/dL (1.2â€“2.3 nmol/L)	Normal or low	High
Free T <sub>4</sub> (FT <sub>4</sub> )	0.7â€“1.86 ng/dL (9â€“24 pmol/L)	Low	High
Free T <sub>3</sub> (FT <sub>3</sub> )	145â€“348 pg/dL (2.2â€“5.4 pmol/L)	Low	High
Thyrotropic hormone (TSH)	0.4â€“4 µIU/mL (0.4â€“4 mIU/L)	High <sup>2</sup>	Low
<sup>123</sup> I uptake at 24 hours	5â€“35%	Low	High
Thyroglobulin autoantibodies (Tg-ab)	< 20 IU/mL	Often present	Usually present
Thyroid peroxidase antibodies (TPA)	< 0.8 IU/mL	Often present	Usually present
Isotope scan with <sup>123</sup> I or <sup>99m</sup> TcO <sub>4</sub>	Normal pattern	Test not indicated	Diffusely enlarged gland
Fine-needle aspiration biopsy (FNA)	Normal pattern	Test not indicated	Test not indicated
Serum thyroglobulin	< 56 ng/mL	Test not indicated	Test not indicated
Serum calcitonin	Men: < 8 ng/L (< 2.3 pmol/L); women: < 4 ng/L (< 1.17 pmol/L)	Test not indicated	Test not indicated
TSH receptor-stimulating antibody or thyroid-stimulating immunoglobulin (TSI)	< 125%	Test not indicated	Elevated in Graves' disease

<sup>1</sup>Results may vary with different laboratories.

<sup>2</sup>Exception is central hypothyroidism.

### THYROID-PITUITARY RELATIONSHIPS

Control of thyroid function via thyroid-pituitary feedback is also discussed in Chapter 37. Briefly, hypothalamic cells secrete thyrotropin-releasing hormone (TRH) (Figure 38â€“3). TRH is secreted into capillaries of the pituitary portal venous system, and in the pituitary gland, TRH stimulates the synthesis and release of thyrotropin (thyroid-stimulating hormone/TSH). TSH in turn stimulates an adenylyl cyclaseâ€“mediated mechanism in the thyroid cell to increase the synthesis and release of T<sub>4</sub> and T<sub>3</sub>. These thyroid hormones act in a negative feedback fashion in the pituitary to block the action of TRH and in the

hypothalamus to inhibit the synthesis and secretion of TRH. Other hormones or drugs may also affect the release of TRH or TSH.

**Figure 38â€³**

The hypothalamic-pituitary-thyroid axis. Acute psychosis or prolonged exposure to cold may activate the axis. Hypothalamic thyroid-releasing hormone (TRH) stimulates pituitary thyroid-stimulating hormone (TSH) release, while somatostatin and dopamine inhibit it. TSH stimulates T<sub>4</sub> and T<sub>3</sub> synthesis and release from the thyroid, and they in turn inhibit both TRH and TSH synthesis and release. Small amounts of iodide are necessary for hormone production, but large amounts inhibit T<sub>3</sub> and T<sub>4</sub> production and release. Solid arrows, stimulatory influence; dashed arrows, inhibitory influence. H, hypothalamus, AP, anterior pituitary.

**AUTOREGULATION OF THE THYROID GLAND**

The thyroid gland also regulates its uptake of iodide and thyroid hormone synthesis by intrathyroidal mechanisms that are independent of TSH. These mechanisms are primarily related to the level of iodine in the blood. Large doses of iodine inhibit iodide organification (Wolff-Chaikoff block, see Figure 38â€¹). In certain disease states (eg, Hashimoto's thyroiditis), this can inhibit thyroid hormone synthesis and result in hypothyroidism. Hyperthyroidism can result from the loss of the Wolff-Chaikoff block in susceptible individuals (eg, multinodular goiter).

**ABNORMAL THYROID STIMULATORS**

In Graves' disease (see below), lymphocytes secrete a TSH receptor-stimulating antibody (TSH-R Ab [stim]), also known as thyroid-stimulating immunoglobulin (TSI). This immunoglobulin binds to the TSH receptor and stimulates the gland in the same fashion as TSH itself. The duration of its effect, however, is much longer than that of TSH. TSH receptors are also found in orbital fibrocytes, which may be stimulated by high levels of TSH-R Ab [stim].

\*In this chapter, the term "iodine" denotes all forms of the element; the term "iodide" denotes only the ionic form, I<sup>-</sup>.

**BASIC PHARMACOLOGY OF THYROID & ANTITHYROID DRUGS**

## THYROID HORMONES

### Chemistry

The structural formulas of thyroxine and triiodothyronine as well as reverse triiodothyronine ( $rT_3$ ) are shown in Figure 38â€²2. All of these naturally occurring molecules are levo (L) isomers. The synthetic dextro (D) isomer of thyroxine, dextrothyroxine, has approximately 4% of the biologic activity of the L-isomer as evidenced by its lesser ability to suppress TSH secretion and correct hypothyroidism.

### Pharmacokinetics

Thyroxine is absorbed best in the duodenum and ileum; absorption is modified by intraluminal factors such as food, drugs, gastric acidity, and intestinal flora. Oral bioavailability of current preparations of L-thyroxine averages 80% (Table 38â€²1). In contrast,  $T_3$  is almost completely absorbed (95%).  $T_4$  and  $T_3$  absorption appears not to be affected by mild hypothyroidism but may be impaired in severe myxedema with ileus. These factors are important in switching from oral to parenteral therapy. For parenteral use, the intravenous route is preferred for both hormones.

In patients with hyperthyroidism, the metabolic clearances of  $T_4$  and  $T_3$  are increased and the half-lives decreased; the opposite is true in patients with hypothyroidism. Drugs that induce hepatic microsomal enzymes (eg, rifampin, phenobarbital, carbamazepine, phenytoin, imatinib, protease inhibitors) increase the metabolism of both  $T_4$  and  $T_3$  (Table 38â€²3). Despite this change in clearance, the normal hormone concentration is maintained in euthyroid patients as a result of compensatory hyperfunction of the thyroid. However, patients receiving  $T_4$  replacement medication may require increased dosages to maintain clinical effectiveness. A similar compensation occurs if binding sites are altered. If TBG sites are increased by pregnancy, estrogens, or oral contraceptives, there is an initial shift of hormone from the free to the bound state and a decrease in its rate of elimination until the normal hormone concentration is restored. Thus, the concentration of total and bound hormone will increase, but the concentration of free hormone and the steady-state elimination will remain normal. The reverse occurs when thyroid binding sites are decreased.

**Table 38â€²3 Drug Effects and Thyroid Function.**

Drug Effect	Drugs
<b>Change in thyroid hormone synthesis</b>	
Inhibition of TRH or TSH secretion without induction of hypothyroidism or hyperthyroidism	Dopamine, levodopa, corticosteroids, somatostatin, metformin, bexarotene
Inhibition of thyroid hormone synthesis or release with the induction of hypothyroidism (or occasionally hyperthyroidism)	Iodides (including amiodarone), lithium, aminoglutethimide, thioamides, ethionamide
<b>Alteration of thyroid hormone transport and serum total <math>T_3</math> and <math>T_4</math> levels, but usually no modification of FT<sub>4</sub> or TSH</b>	
Increased TBG	Estrogens, tamoxifen, heroin, methadone, mitotane, fluorouracil
Decreased TBG	Androgens, glucocorticoids
Displacement of $T_3$ and $T_4$ from TBG with transient hyperthyroxinemia	Salicylates, fenclofenac, mefenamic acid, furosemide
<b>Alteration of <math>T_4</math> and <math>T_3</math> metabolism with modified serum <math>T_3</math> and <math>T_4</math> levels but not FT<sub>4</sub> or TSH levels</b>	
Induction of increased hepatic enzyme activity	Nicardipine, imatinib, protease inhibitors, phenytoin, carbamazepine, phenobarbital, rifampin, rifabutin
Inhibition of 5'-deiodinase with decreased $T_3$ , increased $rT_3$	Iopanoic acid, ipodate, amiodarone, $\beta$ blockers, corticosteroids, propylthiouracil, flavonoids
<b>Other interactions</b>	
Interference with $T_4$ absorption	Cholestyramine, chromium picolinate, colestipol, ciprofloxacin, proton pump

inhibitors, sucralfate, sodium polystyrene sulfonate, raloxifene, sevelamer hydrochloride, aluminum hydroxide, ferrous sulfate, calcium carbonate, bran, soy, coffee.

Induction of autoimmune thyroid disease with hypothyroidism or hyperthyroidism

Interferon- $\alpha$ , interleukin-2, interferon- $\beta$ , lithium, amiodarone

#### Effect of thyroid function on drug effects

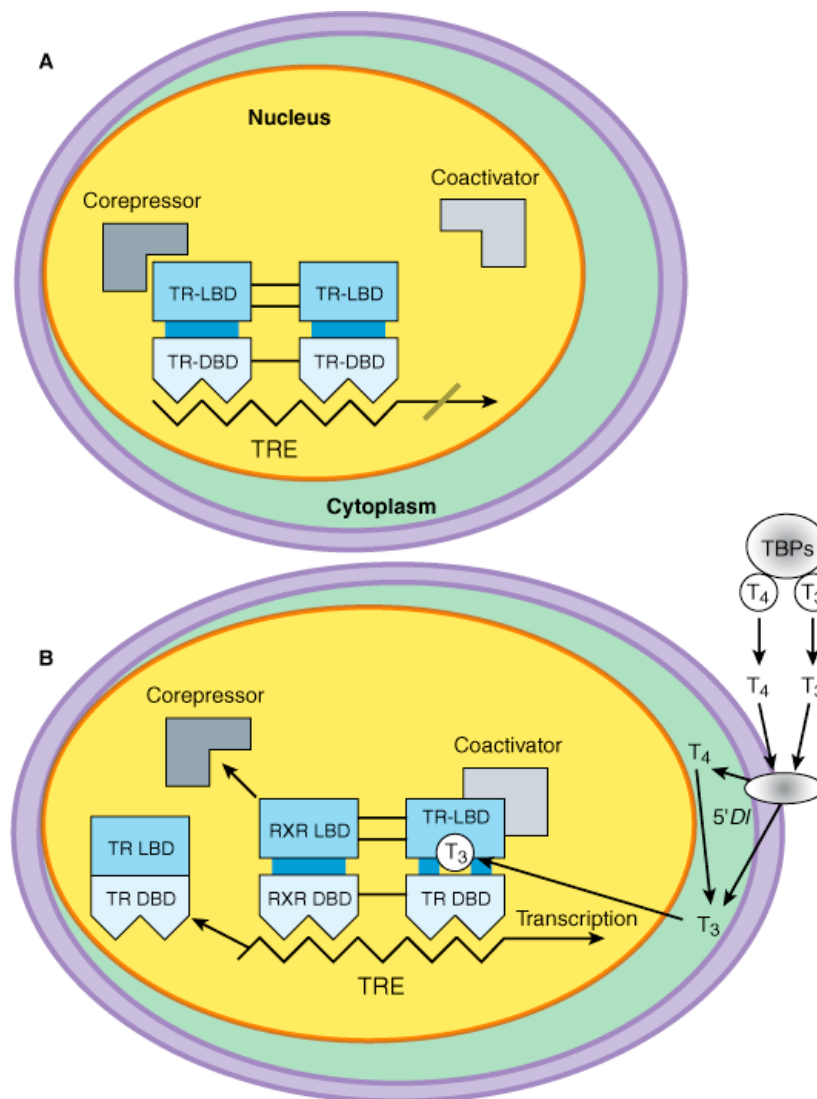

Anticoagulation	Lower doses of warfarin required in hyperthyroidism, higher doses in hypothyroidism
Glucose control	Increased hepatic glucose production and glucose intolerance in hyperthyroidism; impaired insulin action and glucose disposal in hypothyroidism
Cardiac drugs	Higher doses of digoxin required in hyperthyroidism; lower doses in hypothyroidism
Sedatives; analgesics	Increased sedative and respiratory depressant effects from sedatives and opioids in hypothyroidism; converse in hyperthyroidism

#### Mechanism of Action

A model of thyroid hormone action is depicted in Figure 38-4, which shows the free forms of thyroid hormones,  $T_4$  and  $T_3$ , dissociated from thyroid-binding proteins, entering the cell by active transport. Within the cell,  $T_4$  is converted to  $T_3$  by 5'-deiodinase, and the  $T_3$  enters the nucleus, where  $T_3$  binds to a specific  $T_3$  receptor protein, a member of the *c-erb* oncogene family. (This family also includes the steroid hormone receptors and receptors for vitamins A and D.) The  $T_3$  receptor exists in two forms,  $\alpha$  and  $\beta$ . Differing concentrations of receptor forms in different tissues may account for variations in  $T_3$  effect on different tissues.

#### Figure 38-4

Model of the interaction of  $T_3$  with the  $T_3$  receptor. **A:** *Inactive phase* – the unliganded  $T_3$  receptor dimer bound to the thyroid hormone response element (TRE) along with corepressors acts as a suppressor of gene transcription. **B:** *Active phase* –  $T_3$  and  $T_4$  circulate bound to thyroid-binding proteins (TBPs). The free hormones are transported into the cell by a specific transport system. Within the cytoplasm,  $T_4$  is converted to  $T_3$  by 5'-deiodinase;  $T_3$  then moves into the nucleus. There it binds to the ligand-binding domain of the thyroid receptor (TR) monomer. This promotes disruption of the TR homodimer and heterodimerization with retinoid X receptor (RXR) on the TRE, displacement of corepressors, and binding of coactivators. The TR-coactivator complex activates gene transcription, which leads to alteration in protein synthesis and cellular phenotype. TR-LBD,  $T_3$  receptor ligand-binding domain; TR-DBD,  $T_3$  receptor DNA-binding domain; RXR-LBD, retinoid X receptor ligand-binding domain; RXR-DBD, retinoid X receptor DNA-binding domain;  $T_3$ , triiodothyronine;  $T_4$ , tetraiodothyronine, L-thyroxine; 5'DI, 5'-deiodinase.

(Modified and reproduced, with permission, from Gardner DG, Shoback D [editors]: *Greenspan's Basic & Clinical Endocrinology*, 8th ed. McGraw-Hill, 2007.)

Most of the effects of thyroid on metabolic processes appear to be mediated by activation of nuclear receptors that lead to increased formation of RNA and subsequent protein synthesis, eg, increased formation of  $Na^+, K^+$  ATPase. This is consistent with the observation that the action of thyroid is manifested in vivo with a time lag of hours or days after its administration.

Large numbers of thyroid hormone receptors are found in the most hormone-responsive tissues (pituitary, liver, kidney, heart, skeletal muscle, lung, and intestine), while few receptor sites occur in hormone-unresponsive tissues (spleen, testes). The brain, which lacks an anabolic response to T<sub>3</sub>, contains an intermediate number of receptors. In congruence with their biologic potencies, the affinity of the receptor site for T<sub>4</sub> is about ten times lower than that for T<sub>3</sub>. Under some conditions, the number of nuclear receptors may be altered to preserve body homeostasis. For example, starvation lowers both circulating T<sub>3</sub> hormone and cellular T<sub>3</sub> receptors.

## Effects of Thyroid Hormones

The thyroid hormones are responsible for optimal growth, development, function, and maintenance of all body tissues. Excess or inadequate amounts result in the signs and symptoms of hyperthyroidism or hypothyroidism, respectively (Table 38â€4). Since T<sub>3</sub> and T<sub>4</sub> are qualitatively similar, they may be considered as one hormone in the discussion that follows.

**Table 38â€4 Manifestations of Thyrotoxicosis and Hypothyroidism.**

System	Thyrotoxicosis	Hypothyroidism
Skin and appendages	Warm, moist skin; sweating; heat intolerance; fine, thin hair; Plummer's nails; pretibial dermopathy (Graves' disease)	Pale, cool, puffy skin; dry and brittle hair; brittle nails
Eyes, face	Retraction of upper lid with wide stare; periorbital edema; exophthalmos; diplopia (Graves' disease)	Drooping of eyelids; periorbital edema; loss of temporal aspects of eyebrows; puffy, nonpitting facies; large tongue
Cardiovascular system	Decreased peripheral vascular resistance; increased heart rate, stroke volume, cardiac output, pulse pressure; high-output heart failure; increased inotropic and chronotropic effects; arrhythmias; angina	Increased peripheral vascular resistance; decreased heart rate, stroke volume, cardiac output, pulse pressure; low-output heart failure; ECG: bradycardia, prolonged PR interval, flat T wave, low voltage; pericardial effusion
Respiratory system	Dyspnea; decreased vital capacity	Pleural effusions; hypoventilation and CO <sub>2</sub> retention
Gastrointestinal system	Increased appetite; increased frequency of bowel movements; hypoproteinemia	Decreased appetite; decreased frequency of bowel movements; ascites
Central nervous system	Nervousness; hyperkinesia; emotional lability	Lethargy; general slowing of mental processes; neuropathies
Musculoskeletal system	Weakness and muscle fatigue; increased deep tendon reflexes; hypercalcemia; osteoporosis	Stiffness and muscle fatigue; decreased deep tendon reflexes; increased alkaline phosphatase, LDH, AST
Renal system	Mild polyuria; increased renal blood flow; increased glomerular filtration rate	Impaired water excretion; decreased renal blood flow; decreased glomerular filtration rate
Hematopoietic system	Increased erythropoiesis; anemia <sup>1</sup>	Decreased erythropoiesis; anemia <sup>1</sup>
Reproductive system	Menstrual irregularities; decreased fertility; increased gonadal steroid metabolism	Hypermenorrhea; infertility; decreased libido; impotence; oligospermia; decreased gonadal steroid metabolism
Metabolic system	Increased basal metabolic rate; negative nitrogen balance; hyperglycemia; increased free fatty acids; decreased cholesterol and triglycerides; increased hormone degradation; increased requirements for fat- and water-soluble vitamins; increased drug metabolism; decreased warfarin requirement	Decreased basal metabolic rate; slight positive nitrogen balance; delayed degradation of insulin with increased sensitivity; increased cholesterol and triglycerides; decreased hormone degradation; decreased requirements for fat- and water-soluble vitamins; decreased drug metabolism; increased warfarin requirement

<sup>1</sup>The anemia of hyperthyroidism is usually normochromic and caused by increased red blood cell turnover. The anemia of hypothyroidism may be normochromic, hyperchromic, or hypochromic and may be due to decreased production rate, decreased iron absorption, decreased folic acid absorption, or to autoimmune pernicious anemia. LDH, lactic dehydrogenase; AST, aspartate aminotransferase.

Thyroid hormone is critical for the development and functioning of nervous, skeletal, and reproductive tissues. Its effects depend on protein synthesis as well as potentiation of the secretion and action of growth hormone. Thyroid deprivation in early life results in irreversible mental retardation and dwarfism—typical of congenital cretinism.

Effects on growth and calorogenesis are accompanied by a pervasive influence on metabolism of drugs as well as carbohydrates, fats, proteins, and vitamins. Many of these changes are dependent upon or modified by activity of other hormones. Conversely, the secretion and degradation rates of virtually all other hormones, including catecholamines, cortisol, estrogens, testosterone, and insulin, are affected by thyroid status.

Many of the manifestations of thyroid hyperactivity resemble sympathetic nervous system overactivity (especially in the cardiovascular system), although catecholamine levels are not increased. Changes in catecholamine-stimulated adenylyl cyclase activity as measured by cAMP are found with changes in thyroid activity. Possible explanations include increased numbers of  $\beta$  receptors or enhanced amplification of the  $\beta$  receptor signal. Other clinical symptoms reminiscent of excessive epinephrine activity (and partially alleviated by adrenoceptor antagonists) include lid lag and retraction, tremor, excessive sweating, anxiety, and nervousness. The opposite constellation of effects is seen in hypothyroidism (Table 38â€4).

### Thyroid Preparations

See the Preparations Available section at the end of this chapter for a list of available preparations. These preparations may be synthetic (levothyroxine, liothyronine, liotrix) or of animal origin (desiccated thyroid).

Thyroid hormones are not effective and can be detrimental in the management of obesity, abnormal vaginal bleeding, or depression if thyroid hormone levels are normal. Anecdotal reports of a beneficial effect of  $T_3$  administered with antidepressants were not confirmed in a controlled study.

Synthetic levothyroxine is the preparation of choice for thyroid replacement and suppression therapy because of its stability, content uniformity, low cost, lack of allergenic foreign protein, easy laboratory measurement of serum levels, and long half-life (7 days), which permits once-daily administration. In addition,  $T_4$  is converted to  $T_3$  intracellularly; thus, administration of  $T_4$  produces both hormones. Generic levothyroxine preparations provide comparable efficacy and are more cost-effective than branded preparations.

Although liothyronine ( $T_3$ ) is three to four times more potent than levothyroxine, it is not recommended for routine replacement therapy because of its shorter half-life (24 hours), which requires multiple daily doses; its higher cost; and the greater difficulty of monitoring its adequacy of replacement by conventional laboratory tests. Furthermore, because of its greater hormone activity and consequent greater risk of cardiotoxicity,  $T_3$  should be avoided in patients with cardiac disease. It is best used for short-term suppression of TSH. Because oral administration of  $T_3$  is unnecessary, use of the more expensive mixture of thyroxine and liothyronine (liotrix) instead of levothyroxine is never required.

The use of desiccated thyroid rather than synthetic preparations is never justified, since the disadvantages of protein antigenicity, product instability, variable hormone concentrations, and difficulty in laboratory monitoring far outweigh the advantage of lower cost. Significant amounts of  $T_3$  found in some thyroid extracts and liotrix may produce significant elevations in  $T_3$  levels and toxicity. Equi-effective doses are 100 mg of desiccated thyroid, 100 mcg of levothyroxine, and 37.5 mcg of liothyronine.

The shelf life of synthetic hormone preparations is about 2 years, particularly if they are stored in dark bottles to minimize spontaneous deiodination. The shelf life of desiccated thyroid is not known with certainty, but its potency is better preserved if it is kept dry.

### Antithyroid Agents

Reduction of thyroid activity and hormone effects can be accomplished by agents that interfere with the production of thyroid hormones, by agents that modify the tissue response to thyroid hormones, or by glandular destruction with radiation or surgery. Goitrogens are agents that suppress secretion of  $T_3$  and  $T_4$  to subnormal levels and thereby increase TSH, which in turn produces glandular enlargement (goiter). The antithyroid compounds used clinically include the thioamides, iodides, and radioactive iodine.

#### THIOAMIDES

The thioamides methimazole and propylthiouracil are major drugs for treatment of thyrotoxicosis. In the United Kingdom, carbimazole, which is converted to methimazole in vivo, is widely used. Methimazole is about ten times more potent than propylthiouracil.

The chemical structures of these compounds are shown in Figure 38â€5. The thiocarbamide group is essential for antithyroid activity.

**Figure 38â€5**

Structure of thioamides. The thiocarbamide moiety is shaded in color.

### Pharmacokinetics

Propylthiouracil is rapidly absorbed, reaching peak serum levels after 1 hour. The bioavailability of 50â€80% may be due to incomplete absorption or a large first-pass effect in the liver. The volume of distribution approximates total body water with accumulation in the thyroid gland. Most of an ingested dose of propylthiouracil is excreted by the kidney as the inactive glucuronide within 24 hours.

In contrast, methimazole is completely absorbed but at variable rates. It is readily accumulated by the thyroid gland and has a volume of distribution similar to that of propylthiouracil. Excretion is slower than with propylthiouracil; 65â€70% of a dose is recovered in the urine in 48 hours.

The short plasma half-life of these agents (1.5 hours for propylthiouracil and 6 hours for methimazole) has little influence on the duration of the antithyroid action or the dosing interval because both agents are accumulated by the thyroid gland. For propylthiouracil, giving the drug every 6â€8 hours is reasonable since a single 100 mg dose can inhibit iodine organification by 60% for 7 hours. Since a single 30 mg dose of methimazole exerts an antithyroid effect for longer than 24 hours, a single daily dose is effective in the management of mild to moderate hyperthyroidism.

Both thioamides cross the placental barrier and are concentrated by the fetal thyroid, so that caution must be employed when using these drugs in pregnancy. Because of the risk of fetal hypothyroidism, both thioamides are classified as pregnancy category D (evidence of human fetal risk based on adverse reaction data from investigational or marketing experience). Of the two, propylthiouracil is preferable in pregnancy because it is more strongly protein-bound and, therefore, crosses the placenta less readily. In addition, methimazole has been, albeit rarely, associated with congenital malformations. Both thioamides are secreted in low concentrations in breast milk but are considered safe for the nursing infant.

### Pharmacodynamics

The thioamides act by multiple mechanisms. The major action is to prevent hormone synthesis by inhibiting the thyroid peroxidase-catalyzed reactions and blocking iodine organification. In addition, they block coupling of the iodotyrosines. They do not block uptake of iodide by the gland. Propylthiouracil and (to a much lesser extent) methimazole inhibit the peripheral deiodination of T<sub>4</sub> and T<sub>3</sub> (Figure 38â€1). Since the synthesis rather than the release of hormones is affected, the onset of these agents is slow, often requiring 3â€4 weeks before stores of T<sub>4</sub> are depleted.

## Toxicity

Adverse reactions to the thioamides occur in 3â€”12% of treated patients. Most reactions occur early, especially nausea and gastrointestinal distress. An altered sense of taste or smell may occur with methimazole. The most common adverse effect is a maculopapular pruritic rash (4â€”6%), at times accompanied by systemic signs such as fever. Rare adverse effects include an urticarial rash, vasculitis, a lupus-like reaction, lymphadenopathy, hypoprothrombinemia, exfoliative dermatitis, polyserositis, and acute arthralgia. Hepatitis (more common with propylthiouracil) and cholestatic jaundice (more common with methimazole) can be fatal, although asymptomatic elevations in transaminase levels also occur.

The most dangerous complication is agranulocytosis (granulocyte count < 500 cells/mm<sup>3</sup>), an infrequent but potentially fatal adverse reaction. It occurs in 0.1â€”0.5% of patients taking thioamides, but the risk may be increased in older patients and in those receiving high-dose methimazole therapy (> 40 mg/d). The reaction is usually rapidly reversible when the drug is discontinued, but broad-spectrum antibiotic therapy may be necessary for complicating infections. Colony-stimulating factors (eg, G-CSF; see Chapter 33) may hasten recovery of the granulocytes. The cross-sensitivity between propylthiouracil and methimazole is about 50%; therefore, switching drugs in patients with severe reactions is not recommended.

## ANION INHIBITORS

Monovalent anions such as perchlorate (ClO<sub>4</sub><sup>â€”</sup>), pertechnetate (TcO<sub>4</sub><sup>â€”</sup>), and thiocyanate (SCN<sup>â€”</sup>) can block uptake of iodide by the gland through competitive inhibition of the iodide transport mechanism. Since these effects can be overcome by large doses of iodides, their effectiveness is somewhat unpredictable.

The major clinical use for potassium perchlorate is to block thyroidal reuptake of I<sup>â€”</sup> in patients with iodide-induced hyperthyroidism (eg, amiodarone-induced hyperthyroidism). However, potassium perchlorate is rarely used clinically because it is associated with aplastic anemia.

## IODIDES

Prior to the introduction of the thioamides in the 1940s, iodides were the major antithyroid agents; today they are rarely used as sole therapy.

### Pharmacodynamics

Iodides have several actions on the thyroid. They inhibit organification and hormone release and decrease the size and vascularity of the hyperplastic gland. In susceptible individuals, iodides can induce hyperthyroidism (Jod-Basedow phenomenon) or precipitate hypothyroidism.

In pharmacologic doses (> 6 mg/d), the major action of iodides is to inhibit hormone release, possibly through inhibition of thyroglobulin proteolysis. Improvement in thyrotoxic symptoms occurs rapidlyâ€”“within 2â€”7 days”â€”hence the value of iodide therapy in thyroid storm. In addition, iodides decrease the vascularity, size, and fragility of a hyperplastic gland, making the drugs valuable as preoperative preparation for surgery.

### Clinical Use of Iodide

Disadvantages of iodide therapy include an increase in intraglandular stores of iodine, which may delay onset of thioamide therapy or prevent use of radioactive iodine therapy for several weeks. Thus, iodides should be initiated after onset of thioamide therapy and avoided if treatment with radioactive iodine seems likely. Iodide should not be used alone, because the gland will escape from the iodide block in 2â€”8 weeks, and its withdrawal may produce severe exacerbation of thyrotoxicosis in an iodine-enriched gland. Chronic use of iodides in pregnancy should be avoided, since they cross the placenta and can cause fetal goiter. In radiation emergencies, the thyroid-blocking effects of potassium iodide can protect the gland from subsequent damage if administered before radiation exposure.

## Toxicity

Adverse reactions to iodine (iodism) are uncommon and in most cases reversible upon discontinuance. They include acneiform rash (similar to that of bromism), swollen salivary glands, mucous membrane ulcerations, conjunctivitis, rhinorrhea, drug fever, metallic taste, bleeding disorders and, rarely, anaphylactoid reactions.

## RADIOACTIVE IODINE

<sup>131</sup>I is the only isotope used for treatment of thyrotoxicosis (others are used in diagnosis). Administered orally in solution as sodium <sup>131</sup>I, it is rapidly absorbed, concentrated by the thyroid, and incorporated into storage follicles. Its therapeutic effect depends on emission of  $\beta^-$  rays with an effective half-life of 5 days and a penetration range of 400â€”2000  $\mu$ m. Within a few weeks after administration, destruction of the thyroid parenchyma is evidenced by epithelial swelling and necrosis, follicular

disruption, edema, and leukocyte infiltration. Advantages of radioiodine include easy administration, effectiveness, low expense, and absence of pain. Fears of radiation-induced genetic damage, leukemia, and neoplasia have not been realized after more than 50 years of clinical experience with radioiodine therapy for hyperthyroidism. Radioactive iodine should not be administered to pregnant women or nursing mothers, since it crosses the placenta to destroy the fetal thyroid gland and is excreted in breast milk.

### ADRENOCEPTOR-BLOCKING AGENTS

Beta blockers without intrinsic sympathomimetic activity (eg, metoprolol, propranolol, atenolol) are effective therapeutic adjuncts in the management of thyrotoxicosis since many of these symptoms mimic those associated with sympathetic stimulation. Propranolol has been the  $\beta$  blocker most widely studied and used in the therapy of thyrotoxicosis. Beta blockers cause clinical improvement of hyperthyroid symptoms but do not typically alter thyroid hormone levels. Propranolol at doses greater than 160 mg/d may also reduce  $T_3$  levels approximately 20% by inhibiting the peripheral conversion of  $T_4$  to  $T_3$ .

## CLINICAL PHARMACOLOGY OF THYROID & ANTITHYROID DRUGS

### Hypothyroidism

Hypothyroidism is a syndrome resulting from deficiency of thyroid hormones and is manifested largely by a reversible slowing down of all body functions (Table 38â€4). In infants and children, there is striking retardation of growth and development that results in dwarfism and irreversible mental retardation.

The etiology and pathogenesis of hypothyroidism are outlined in Table 38â€5. Hypothyroidism can occur with or without thyroid enlargement (goiter). The laboratory diagnosis of hypothyroidism in the adult is easily made by the combination of a low free thyroxine and elevated serum TSH (Table 38â€2).

**Table 38â€5 Etiology and Pathogenesis of Hypothyroidism.**

Cause	Pathogenesis	Goiter	Degree of Hypothyroidism
Hashimoto's thyroiditis	Autoimmune destruction of thyroid	Present early, absent later	Mild to severe
Drug-induced <sup>1</sup>	Blocked hormone formation <sup>2</sup>	Present	Mild to moderate
Dyshormonogenesis	Impaired synthesis of $T_4$ due to enzyme deficiency	Present	Mild to severe
Radiation, $^{131}I$ , x-ray, thyroidectomy	Destruction or removal of gland	Absent	Severe
Congenital (cretinism)	Athyreosis or ectopic thyroid, iodine deficiency; TSH receptor-blocking antibodies	Absent or present	Severe
Secondary (TSH deficit)	Pituitary or hypothalamic disease	Absent	Mild

<sup>1</sup>Iodides, lithium, fluoride, thioamides, aminosalicic acid, phenylbutazone, amiodarone, perchlorate, ethionamide, thiocyanate, cytokines (interferons, interleukins), bexarotene, etc.

<sup>2</sup>See Table 38â€3 for specific pathogenesis.

The most common cause of hypothyroidism in the USA at this time is probably Hashimoto's thyroiditis, an immunologic disorder in genetically predisposed individuals. In this condition, there is evidence of humoral immunity in the presence of antithyroid antibodies and lymphocyte sensitization to thyroid antigens. Certain medications can also cause hypothyroidism (Table 38â€5).

### Management of Hypothyroidism

Except for hypothyroidism caused by drugs, which can be treated in some cases by simply removing the depressant agent, the general strategy of replacement therapy is appropriate. The most satisfactory preparation is levothyroxine, administered as either a branded or generic preparation. Treatment with combination levothyroxine plus liothyronine has not been found to be superior to levothyroxine alone. Infants and children require more  $T_4$  per kilogram of body weight than adults. The average dosage for an infant 1â€6 months of age is 10â€15 mcg/kg/d, whereas the average dosage for an adult is about

1.7 mcg/kg/d. Older adults (> 65 years of age) may require less thyroxine for replacement. There is some variability in the absorption of thyroxine, so this dosage will vary from patient to patient. Since interactions with certain foods (eg, bran, soy, coffee) and drugs (Table 38â€³) can impair its absorption, thyroxine should be administered on an empty stomach (eg, 30 minutes before meals or 1 hour after meals). Its long half-life of 7 days permits once-daily dosing. Children should be monitored for normal growth and development. Serum TSH and free thyroxine should be measured at regular intervals and TSH maintained within an optimal range of 0.5â€².5 mU/L. It takes 6â€²8 weeks after starting a given dose of thyroxine to reach steady-state levels in the bloodstream. Thus, dosage changes should be made slowly.

In long-standing hypothyroidism, in older patients, and in patients with underlying cardiac disease, it is imperative to start treatment with reduced dosages. In such adult patients, levothyroxine is given in a dosage of 12.5â€²25 mcg/d for 2 weeks, increasing the daily dose by 25 mcg every 2 weeks until euthyroidism or drug toxicity is observed. In older patients, the heart is very sensitive to the level of circulating thyroxine, and if angina pectoris or cardiac arrhythmia develops, it is essential to stop or reduce the dose of thyroxine immediately. In younger patients or those with very mild disease, full replacement therapy may be started immediately.

The toxicity of thyroxine is directly related to the hormone level. In children, restlessness, insomnia, and accelerated bone maturation and growth may be signs of thyroxine toxicity. In adults, increased nervousness, heat intolerance, episodes of palpitation and tachycardia, or unexplained weight loss may be the presenting symptoms. If these symptoms are present, it is important to monitor serum TSH (Table 38â€²), which will determine whether the symptoms are due to excess thyroxine blood levels. Chronic overtreatment with T<sub>4</sub>, particularly in elderly patients, can increase the risk of atrial fibrillation and accelerated osteoporosis.

## **Special Problems in Management of Hypothyroidism**

### **MYXEDEMA AND CORONARY ARTERY DISEASE**

Since myxedema frequently occurs in older persons, it is often associated with underlying coronary artery disease. In this situation, the low levels of circulating thyroid hormone actually protect the heart against increasing demands that could result in angina pectoris or myocardial infarction. Correction of myxedema must be done cautiously to avoid provoking arrhythmia, angina, or acute myocardial infarction. If coronary artery surgery is indicated, it should be done first, prior to correction of the myxedema by thyroxine administration.

### **MYXEDEMA COMA**

Myxedema coma is an end state of untreated hypothyroidism. It is associated with progressive weakness, stupor, hypothermia, hypoventilation, hypoglycemia, hyponatremia, water intoxication, shock, and death.

Myxedema coma is a medical emergency. The patient should be treated in the intensive care unit, since tracheal intubation and mechanical ventilation may be required. Associated illnesses such as infection or heart failure must be treated by appropriate therapy. It is important to give all preparations intravenously, because patients with myxedema coma absorb drugs poorly from other routes. Intravenous fluids should be administered with caution to avoid excessive water intake. These patients have large pools of empty T<sub>3</sub> and T<sub>4</sub> binding sites that must be filled before there is adequate free thyroxine to affect tissue metabolism. Accordingly, the treatment of choice in myxedema coma is to give a loading dose of levothyroxine intravenouslyâ€²usually 300â€²400 mcg initially, followed by 50â€²100 mcg daily. Intravenous T<sub>3</sub> can also be used but may be more cardiotoxic and more difficult to monitor. Intravenous hydrocortisone is indicated if the patient has associated adrenal or pituitary insufficiency but is probably not necessary in most patients with primary myxedema. Opioids and sedatives must be used with extreme caution.

### **HYPOTHYROIDISM AND PREGNANCY**

Hypothyroid women frequently have anovulatory cycles and are therefore relatively infertile until restoration of the euthyroid state. This has led to the widespread use of thyroid hormone for infertility, although there is no evidence for its usefulness in infertile euthyroid patients. In a pregnant hypothyroid patient receiving thyroxine, it is extremely important that the daily dose of thyroxine be adequate because early development of the fetal brain depends on maternal thyroxine. In many hypothyroid patients, an increase in the thyroxine dose (about 30â€²50%) is required to normalize the serum TSH level during pregnancy. Because of the elevated maternal TBG levels and, therefore, elevated total T<sub>4</sub> levels, adequate maternal thyroxine dosages warrant maintenance of TSH between 0.5 and 3.0 mU/L and the total T<sub>4</sub> at or above the upper range of normal.

### **SUBCLINICAL HYPOTHYROIDISM**

Subclinical hypothyroidism, defined as an elevated TSH level and normal thyroid hormone levels, is found in 4â€²10% of the general population but increases to 20% in women older than age 50. The consensus of expert thyroid organizations concluded that thyroid hormone therapy should be considered for patients with TSH levels greater than 10 mIU/L while close

TSH monitoring is appropriate for those with lower TSH elevations.

#### **DRUG-INDUCED HYPOTHYROIDISM**

Drug-induced hypothyroidism (Table 38â€³) can be satisfactorily managed with levothyroxine therapy if the offending agent cannot be stopped. In the case of amiodarone-induced hypothyroidism, levothyroxine therapy may be necessary even after discontinuance because of amiodarone's very long half-life.

### **Hyperthyroidism**

Hyperthyroidism (thyrotoxicosis) is the clinical syndrome that results when tissues are exposed to high levels of thyroid hormone (Table 38â€²4).

#### **GRAVES' DISEASE**

The most common form of hyperthyroidism is Graves' disease, or diffuse toxic goiter. The presenting signs and symptoms of Graves' disease are set forth in Table 38â€²4.

#### **Pathophysiology**

Graves' disease is considered to be an autoimmune disorder in which helper T lymphocytes stimulate B lymphocytes to synthesize antibodies to thyroidal antigens. The antibody described previously (TSH-R Ab [stim]) is directed against the TSH receptor site in the thyroid cell membrane and has the capacity to stimulate growth and biosynthetic activity of the thyroid cell. Spontaneous remission occurs but some patients require years of antithyroid therapy.

#### **Laboratory Diagnosis**

In most patients with hyperthyroidism, T<sub>3</sub>, T<sub>4</sub>, FT<sub>4</sub>, and FT<sub>3</sub> are elevated and TSH is suppressed (Table 38â€²2). Radioiodine uptake is usually markedly elevated as well. Antithyroglobulin, thyroid peroxidase, and TSH-R Ab [stim] antibodies are usually present.

#### **Management of Graves' Disease**

The three primary methods for controlling hyperthyroidism are antithyroid drug therapy, surgical thyroidectomy, and destruction of the gland with radioactive iodine.

#### **ANTITHYROID DRUG THERAPY**

Drug therapy is most useful in young patients with small glands and mild disease. Methimazole or propylthiouracil is administered until the disease undergoes spontaneous remission. This is the only therapy that leaves an intact thyroid gland, but it does require a long period of treatment and observation (12â€²18 months), and there is a 50â€²68% incidence of relapse.

Methimazole is preferable to propylthiouracil (except in pregnancy) because it can be administered once daily, which may enhance adherence. Antithyroid drug therapy is usually begun with divided doses, shifting to maintenance therapy with single daily doses when the patient becomes clinically euthyroid. However, mild to moderately severe thyrotoxicosis can often be controlled with methimazole given in a single morning dose of 20â€²40 mg initially for 4â€²8 weeks to normalize hormone levels. Maintenance therapy requires 5â€²15 mg once daily. Alternatively, therapy is started with propylthiouracil, 100â€²150 mg every 6 or 8 hours until the patient is euthyroid, followed by gradual reduction of the dose to the maintenance level of 50â€²150 mg once daily. In addition to inhibiting iodine organification, propylthiouracil also inhibits the conversion of T<sub>4</sub> to T<sub>3</sub>, so it brings the level of activated thyroid hormone down more quickly than does methimazole. The best clinical guide to remission is reduction in the size of the goiter. Laboratory tests most useful in monitoring the course of therapy are serum FT<sub>3</sub>, FT<sub>4</sub>, and TSH levels.

Reactions to antithyroid drugs have been described above. A minor rash can often be controlled by antihistamine therapy. Because the more severe reaction of agranulocytosis is often heralded by sore throat or high fever, patients receiving antithyroid drugs must be instructed to discontinue the drug and seek immediate medical attention if these symptoms develop. White cell and differential counts and a throat culture are indicated in such cases, followed by appropriate antibiotic therapy.

#### **THYROIDECTOMY**

A near-total thyroidectomy is the treatment of choice for patients with very large glands or multinodular goiters. Patients are treated with antithyroid drugs until euthyroid (about 6 weeks). In addition, for 10â€²14 days prior to surgery, they receive saturated solution of potassium iodide, 5 drops twice daily, to diminish vascularity of the gland and simplify surgery. About 80â€²90% of patients will require thyroid supplementation following near-total thyroidectomy.

#### **RADIOACTIVE IODINE**

Radioiodine therapy utilizing  $^{131}\text{I}$  is the preferred treatment for most patients over 21 years of age. In patients without heart disease, the therapeutic dose may be given immediately in a range of 80–120  $\mu\text{Ci/g}$  of estimated thyroid weight corrected for uptake. In patients with underlying heart disease or severe thyrotoxicosis and in elderly patients, it is desirable to treat with antithyroid drugs (preferably methimazole) until the patient is euthyroid. The medication is then stopped for 5–7 days before the appropriate dose of  $^{131}\text{I}$  is administered. Iodides should be avoided to ensure maximal  $^{131}\text{I}$  uptake. Six to 12 weeks following the administration of radioiodine, the gland will shrink in size and the patient will usually become euthyroid or hypothyroid. A second dose may be required in some patients. Hypothyroidism occurs in about 80% of patients following radioiodine therapy. Serum  $\text{FT}_4$  and TSH levels should be monitored regularly. When hypothyroidism develops, prompt replacement with oral levothyroxine, 50–150 mcg daily, should be instituted.

#### **ADJUNCTS TO ANTITHYROID THERAPY**

During the acute phase of thyrotoxicosis,  $\beta$ -adrenoceptor blocking agents without intrinsic sympathomimetic activity are extremely helpful. Propranolol, 20–40 mg orally every 6 hours, will control tachycardia, hypertension, and atrial fibrillation. Propranolol is gradually withdrawn as serum thyroxine levels return to normal. Diltiazem, 90–120 mg three or four times daily, can be used to control tachycardia in patients in whom  $\beta$  blockers are contraindicated, eg, those with asthma. Other calcium channel blockers may not be as effective as diltiazem. Adequate nutrition and vitamin supplements are essential. Barbiturates accelerate  $\text{T}_4$  breakdown (by hepatic enzyme induction) and may be helpful both as sedatives and to lower  $\text{T}_4$  levels. Bile acid sequestrants (eg, cholestyramine) can also rapidly lower  $\text{T}_4$  levels by increasing the fecal excretion of  $\text{T}_4$ .

#### **TOXIC UNINODULAR GOITER & TOXIC MULTINODULAR GOITER**

These forms of hyperthyroidism occur often in older women with nodular goiters.  $\text{FT}_4$  is moderately elevated or occasionally normal, but  $\text{FT}_3$  or  $\text{T}_3$  is strikingly elevated. Single toxic adenomas can be managed with either surgical excision of the adenoma or with radioiodine therapy. Toxic multinodular goiter is usually associated with a large goiter and is best treated by preparation with methimazole or propylthiouracil followed by subtotal thyroidectomy.

#### **SUBACUTE THYROIDITIS**

During the acute phase of a viral infection of the thyroid gland, there is destruction of thyroid parenchyma with transient release of stored thyroid hormones. A similar state may occur in patients with Hashimoto's thyroiditis. These episodes of transient thyrotoxicosis have been termed *spontaneously resolving hyperthyroidism*. Supportive therapy is usually all that is necessary, such as  $\beta$ -adrenoceptor blocking agents without intrinsic sympathomimetic activity (eg, propranolol) for tachycardia and aspirin or nonsteroidal anti-inflammatory drugs to control local pain and fever. Corticosteroids may be necessary in severe cases to control the inflammation.

#### **SPECIAL PROBLEMS**

##### **Thyroid Storm**

Thyroid storm, or thyrotoxic crisis, is sudden acute exacerbation of all of the symptoms of thyrotoxicosis, presenting as a life-threatening syndrome. Vigorous management is mandatory. Propranolol, 1–2 mg slowly intravenously or 40–80 mg orally every 6 hours, is helpful to control the severe cardiovascular manifestations. If propranolol is contraindicated by the presence of severe heart failure or asthma, hypertension and tachycardia may be controlled with diltiazem, 90–120 mg orally three or four times daily or 5–10 mg/h by intravenous infusion (asthmatic patients only). Release of thyroid hormones from the gland is retarded by the administration of saturated solution of potassium iodide, 10 drops orally daily. Hormone synthesis is blocked by the administration of propylthiouracil, 250 mg orally every 6 hours. If the patient is unable to take propylthiouracil by mouth, a rectal formulation\* can be prepared and administered in a dosage of 400 mg every 6 hours as a retention enema. Methimazole may also be prepared for rectal administration in a dose of 60 mg daily. Hydrocortisone, 50 mg intravenously every 6 hours, will protect the patient against shock and will block the conversion of  $\text{T}_4$  to  $\text{T}_3$ , rapidly bringing down the level of thyroactive material in the blood.

Supportive therapy is essential to control fever, heart failure, and any underlying disease process that may have precipitated the acute storm. In rare situations, where the above methods are not adequate to control the problem, plasmapheresis or peritoneal dialysis has been used to lower the levels of circulating thyroxine.

##### **Ophthalmopathy**

Although severe ophthalmopathy is rare, it is difficult to treat. Management requires effective treatment of the thyroid disease, usually by total surgical excision or  $^{131}\text{I}$  ablation of the gland plus oral prednisone therapy (see below). In addition, local therapy may be necessary, eg, elevation of the head to diminish periorbital edema and artificial tears to relieve corneal drying. Smoking cessation should be advised to prevent progression of the ophthalmopathy. For the severe, acute

inflammatory reaction, a short course of prednisone, 60–100 mg orally daily for about a week and then 60–100 mg every other day, tapering the dose over a period of 6–12 weeks, may be effective. If steroid therapy fails or is contraindicated, irradiation of the posterior orbit, using well-collimated high-energy x-ray therapy, will frequently result in marked improvement of the acute process. Threatened loss of vision is an indication for surgical decompression of the orbit. Eyelid or eye muscle surgery may be necessary to correct residual problems after the acute process has subsided.

### **Dermopathy**

Dermopathy or pretibial myxedema will often respond to topical corticosteroids applied to the involved area and covered with an occlusive dressing.

### **Thyrotoxicosis during Pregnancy**

Ideally, women in the childbearing period with severe disease should have definitive therapy with <sup>131</sup>I or subtotal thyroidectomy *prior* to pregnancy in order to avoid an acute exacerbation of the disease during pregnancy or following delivery. If thyrotoxicosis does develop during pregnancy, radioiodine is contraindicated because it crosses the placenta and may injure the fetal thyroid. In the first trimester, the patient can be prepared with propylthiouracil and a subtotal thyroidectomy performed safely during the mid trimester. It is essential to give the patient a thyroid supplement during the balance of the pregnancy. However, most patients are treated with propylthiouracil during the pregnancy, and the decision regarding long-term management can be made after delivery. The dosage of propylthiouracil must be kept to the minimum necessary for control of the disease (ie, < 300 mg/d), because it may affect the function of the fetal thyroid gland. Methimazole is a potential alternative, although there is concern about a possible risk of fetal scalp defects.

### **Neonatal Graves' Disease**

Graves' disease may occur in the newborn infant, either due to passage of maternal TSH-R Ab [stim] through the placenta, stimulating the thyroid gland of the neonate, or to genetic transmission of the trait to the fetus. Laboratory studies reveal an elevated free T<sub>4</sub>, a markedly elevated T<sub>3</sub>, and a low TSH—in contrast to the normal infant, in whom TSH is elevated at birth. TSH-R Ab [stim] is usually found in the serum of both the child and the mother.

If caused by maternal TSH-R Ab [stim], the disease is usually self-limited and subsides over a period of 4–12 weeks, coinciding with the fall in the infant's TSH-R Ab [stim] level. However, treatment is necessary because of the severe metabolic stress the infant experiences. Therapy includes propylthiouracil in a dose of 5–10 mg/kg/d in divided doses at 8-hour intervals; Lugol's solution (8 mg of iodide per drop), 1 drop every 8 hours; and propranolol, 2 mg/kg/d in divided doses. Careful supportive therapy is essential. If the infant is very ill, oral prednisone, 2 mg/kg/d in divided doses, will help block conversion of T<sub>4</sub> to T<sub>3</sub>. These medications are gradually reduced as the clinical picture improves and can be discontinued by 6–12 weeks.

### **Subclinical Hyperthyroidism**

Subclinical hyperthyroidism is defined as a suppressed TSH level (below the normal range) in conjunction with normal thyroid hormone levels. Cardiac toxicity (eg, atrial fibrillation), especially in older persons, is of greatest concern. The consensus of thyroid experts concluded that hyperthyroidism treatment is appropriate in those with TSH less than 0.1 mIU/L, while close monitoring of the TSH level is appropriate for those with less TSH suppression.

### **Amiodarone-Induced Thyrotoxicosis**

Approximately 3% of patients receiving amiodarone will develop hyperthyroidism. Two types of amiodarone-induced thyrotoxicosis have been reported: iodine-induced (type I), which often occurs in persons with underlying thyroid disease (eg, multinodular goiter); and an inflammatory thyroiditis (type II) that occurs in patients without thyroid disease due to leakage of thyroid hormone into the circulation. Treatment of type I requires therapy with thioamides while type II responds best to glucocorticoids. Since it is not always possible to differentiate between the two types, thioamides and glucocorticoids are often administered together. If possible, amiodarone should be discontinued; however, rapid improvement does not occur due to its long half-life.

### **Nontoxic Goiter**

Nontoxic goiter is a syndrome of thyroid enlargement without excessive thyroid hormone production. Enlargement of the thyroid gland is often due to TSH stimulation from inadequate thyroid hormone synthesis. The most common cause of nontoxic goiter worldwide is iodide deficiency, but in the USA, it is Hashimoto's thyroiditis. Other causes include germline or acquired mutations in genes involved in hormone synthesis, dietary goitrogens, and neoplasms (see below).

Goiter due to iodide deficiency is best managed by prophylactic administration of iodide. The optimal daily iodide intake is 150–200 mcg. Iodized salt and iodate used as preservatives in flour and bread are excellent sources of iodine in the diet. In

areas where it is difficult to introduce iodized salt or iodate preservatives, a solution of iodized poppy-seed oil has been administered intramuscularly to provide a long-term source of inorganic iodine.

Goiter due to ingestion of goitrogens in the diet is managed by elimination of the goitrogen or by adding sufficient thyroxine to shut off TSH stimulation. Similarly, in Hashimoto's thyroiditis and dysmorphonogenesis, adequate thyroxine therapy (150-200 mcg/d orally) will suppress pituitary TSH and result in slow regression of the goiter as well as correction of hypothyroidism.

## Thyroid Neoplasms

Neoplasms of the thyroid gland may be benign (adenomas) or malignant. The primary diagnostic test is a fine needle aspiration biopsy and cytologic examination. Benign lesions may be monitored for growth or symptoms of local obstruction, which would mandate surgical excision. Management of thyroid carcinoma requires a total thyroidectomy, postoperative radioiodine therapy in selected instances, and lifetime replacement with levothyroxine. The evaluation for recurrence of some thyroid malignancies often involves withdrawal of thyroxine replacement for 4-6 weeks accompanied by the development of hypothyroidism. Tumor recurrence is likely if there is a rise in serum thyroglobulin (ie, a tumor marker) or a positive <sup>131</sup>I scan when TSH is elevated. Alternatively, administration of recombinant human TSH (Thyrogen) can produce comparable TSH elevations without discontinuing thyroxine and avoiding hypothyroidism. Recombinant human TSH is administered intramuscularly once daily for 2 days. A rise in serum thyroglobulin or a positive <sup>131</sup>I scan will indicate a recurrence of the thyroid cancer.

\*To prepare a water suspension propylthiouracil enema, grind eight 50 mg tablets and suspend the powder in 90 mL of sterile water.

## SUMMARY: DRUGS USED IN THE MANAGEMENT OF THYROID DISEASE

### Drugs Used in the Management of Thyroid Disease

Class	Mechanism of Action and Effects	Indications	Pharmacokinetics, Toxicities, Interactions
<b>Thyroid Preparations</b>			
Levothyroxine (T <sub>4</sub> )	Activation of nuclear receptors results in gene expression with RNA formation and protein synthesis	Hypothyroidism	See Table 38-1 • maximum effect seen after 6-8 weeks of therapy • <i>Toxicity</i> : See Table 38-4 for symptoms of thyroid excess
Liothyronine (T <sub>3</sub> )			
<b>Antithyroid Agents</b>			
<b>Thioamides</b>			
Propylthiouracil (PTU)	Inhibit thyroid peroxidase reactions • block iodine organification • inhibit peripheral deiodination of T <sub>4</sub> and T <sub>3</sub>	Hyperthyroidism	Oral • duration of action: 6-8 h • delayed onset of action • <i>Toxicity</i> : Nausea, gastrointestinal distress, rash, agranulocytosis, hepatitis, hypothyroidism
<b>Iodides</b>			
Lugol solution Potassium iodide	Inhibit organification and hormone release • reduce the size and vascularity of the gland	Preparation for surgical thyroidectomy	Oral • acute onset within 2-7 days • <i>Toxicity</i> : Rare (see text)
<b>Beta blockers</b>			
Propranolol	Inhibition of β adrenoreceptors • inhibit T <sub>4</sub> to T <sub>3</sub> conversion (only propranolol)	Hyperthyroidism, especially thyroid storm • adjunct to control tachycardia, hypertension, and atrial fibrillation	Onset within hours • duration of 4-6 h (oral propranolol) • <i>Toxicity</i> : Asthma, AV blockade, hypotension, bradycardia

## Radioactive iodine $^{131}\text{I}$ (RAI)

Radiation destruction of thyroid parenchyma

Hyperthyroidism • patients should be euthyroid or on  $\beta$  blockers before RAI • avoid in pregnancy or in nursing mothers

Oral • half-life 5 days • onset of effect 12 weeks • maximum effect in 3–6 months  
• *Toxicity*: Sore throat, sialitis, hypothyroidism

## PREPARATIONS AVAILABLE

### Thyroid Agents

**Levothyroxine [T<sub>4</sub>]** (generic, Levoxyl, Levo-T, Levotheroid, Levolet, Novothyrox, Synthroid, Unithroid)

Oral: 0.025, 0.05, 0.075, 0.088, 0.1, 0.112, 0.125, 0.137, 0.15, 0.175, 0.2, 0.3 mg tablets

Parenteral: 200, 500 mcg per vial (100 mcg/mL when reconstituted) for injection

**Liothyronine [T<sub>3</sub>]** (Cytomel)

Oral: 5, 25, 50 mcg tablets

Parenteral: 10 mcg/mL

**Liotrix [a 4:1 ratio of T<sub>4</sub>: T<sub>3</sub>]** (Thyrolar)

Oral: tablets containing 12.5, 25, 30, 50, 100, 150 mcg T<sub>4</sub> and one fourth as much T<sub>3</sub>

**Thyroid desiccated [USP]** (generic, Armour Thyroid)

Oral: tablets containing 15, 30, 60, 90, 120, 180, 240, 300 mg; capsules containing 120, 180, 300 mg

### Antithyroid Agents

**Radioactive iodine ( $^{131}\text{I}$ ) sodium** (Iodotope, Sodium Iodide I 131 Therapeutic)

Oral: available as capsules and solution

**Methimazole** (generic, Tapazole)

Oral: 5, 10 mg tablets

**Potassium iodide**

Oral solution (generic, SSKI): 1 g/mL

Oral solution (Lugol's solution): 100 mg/mL potassium iodide plus 50 mg/mL iodine

Oral potassium iodide tablets (generic, IOSAT, Thyro-Block): 130 mg

**Propylthiouracil [PTU]** (generic)

Oral: 50 mg tablets

**Thyrotropin; recombinant human TSH** (Thyrogen)

Parenteral: 1.1 mg per vial

Basic and Clinical Pharmacology > Chapter 39. Adrenocorticosteroids & Adrenocortical Antagonists >

## CASE STUDY

A 19-year-old man complains of anorexia, fatigue, dizziness and weight loss of 8 months' duration. The examining physician discovers postural hypotension and moderate vitiligo (depigmented areas of skin) and obtains routine blood tests. She finds hyponatremia, hyperkalemia, and acidosis and suspects Addison's disease. She performs a standard ACTH 1-24 stimulation test, which reveals an insufficient plasma cortisol response, compatible with primary adrenal insufficiency. The diagnosis of autoimmune Addison's disease is made, and the patient is placed on replacement oral hydrocortisone at 10 mg/m<sup>2</sup>/d and fludrocortisone at 75 mcg/d. The patient is given a MedicAlert bracelet and instructions for minor and major stress glucocorticoid coverage at 2 times and 10 times replacement of hydrocortisone over 24 and 48 hours, respectively.

## ADRENOCORTICOSTEROIDS & ADRENOCORTICAL ANTAGONISTS: INTRODUCTION

The natural adrenocortical hormones are steroid molecules produced and released by the adrenal cortex. Both natural and synthetic corticosteroids are used for the diagnosis and treatment of disorders of adrenal function. They are also used more often and in much larger doses for treatment of a variety of inflammatory and immunologic disorders.

Secretion of adrenocortical steroids is controlled by the pituitary release of corticotropin (ACTH). Secretion of the salt-retaining hormone aldosterone is primarily under the influence of angiotensin. Corticotropin has some actions that do not depend on its effect on adrenocortical secretion. However, its pharmacologic value as an anti-inflammatory agent and its use in testing adrenal function depend on its secretory action. Its pharmacology is discussed in Chapter 37 and is reviewed only briefly here.

Inhibitors of the synthesis or antagonists of the action of the adrenocortical steroids are important in the treatment of several conditions. These agents are described at the end of this chapter.

## ADRENOCORTICOSTEROIDS

The adrenal cortex releases a large number of steroids into the circulation. Some have minimal biologic activity and function primarily as precursors, and there are some for which no function has been established. The hormonal steroids may be classified as those having important effects on intermediary metabolism and immune function (**glucocorticoids**), those having principally salt-retaining activity (**mineralocorticoids**), and those having **androgenic** or **estrogenic** activity (see Chapter 40). In humans, the major glucocorticoid is **cortisol** and the most important mineralocorticoid is **aldosterone**. Quantitatively, dehydroepiandrosterone (DHEA) in its sulfated form (DHEAS) is the major adrenal androgen, since about 20 mg is secreted daily. However, DHEA and two other adrenal androgens, androstenediol and androstenedione, are weak androgens or (by conversion) estrogens. Adrenal androgens constitute the major endogenous precursors of estrogen in women after menopause and in younger patients in whom ovarian function is deficient or absent.

### The Naturally Occurring Glucocorticoids; Cortisol (Hydrocortisone)

#### Pharmacokinetics

Cortisol (also called hydrocortisone, compound F) exerts a wide range of physiologic effects, including regulation of intermediary metabolism, cardiovascular function, growth, and immunity. Its synthesis and secretion are tightly regulated by the central nervous system, which is very sensitive to negative feedback by the circulating cortisol and exogenous (synthetic) glucocorticoids. Cortisol is synthesized from cholesterol (as shown in Figure 39-1). The mechanisms controlling its secretion are discussed in Chapter 37.

Outline of major pathways in adrenocortical hormone biosynthesis. The major secretory products are underlined. Pregnenolone is the major precursor of corticosterone and aldosterone, and 17-hydroxypregnenolone is the major precursor of cortisol. The enzymes and cofactors for the reactions progressing down each column are shown on the left and across columns at the top of the figure. When a particular enzyme is deficient, hormone production is blocked at the points indicated by the shaded bars.

(Modified after Weliky et al; reproduced, with permission, from Ganong WF: *Review of Medical Physiology*, 17th ed. Originally published by Appleton & Lange. Copyright © 1995 by The McGraw-Hill Companies, Inc.)

In the normal adult, in the absence of stress, 10–20 mg of cortisol is secreted daily. The rate of secretion follows a circadian rhythm governed by pulses of ACTH that peak in the early morning hours and after meals (Figure 39–2). In plasma, cortisol is bound to circulating proteins. Corticosteroid-binding globulin (CBG), an  $\alpha_2$  globulin synthesized by the liver, binds about 90% of the circulating hormone under normal circumstances. The remainder is free (about 5–10%) or loosely bound to albumin (about 5%) and is available to exert its effect on target cells. When plasma cortisol levels exceed 20–30 mcg/dL, CBG is saturated, and the concentration of free cortisol rises rapidly. CBG is increased in pregnancy and with estrogen administration and in hyperthyroidism. It is decreased by hypothyroidism, genetic defects in synthesis, and protein deficiency states. Albumin has a large capacity but low affinity for cortisol, and for practical purposes albumin-bound cortisol should be considered free. Synthetic corticosteroids such as dexamethasone are largely bound to albumin rather than CBG.

**Figure 39–2**

Fluctuations in plasma ACTH and glucocorticoids throughout the day in a normal girl (age 16). The ACTH was measured by immunoassay and the glucocorticoids as 11-oxysteroids (11-OHCS). Note the marked ACTH and glucocorticoid rises in the morning, before awakening from sleep.

(Reproduced, with permission, from Krieger DT et al: Characterization of the normal temporal pattern of plasma corticosteroid levels. *J Clin Endocrinol Metab* 1971;32:266.)

The half-life of cortisol in the circulation is normally about 60–90 minutes; it may be increased when hydrocortisone (the pharmaceutical preparation of cortisol) is administered in large amounts or when stress, hypothyroidism, or liver disease is present. Only 1% of cortisol is excreted unchanged in the urine as free cortisol; about 20% of cortisol is converted to cortisone by 11-hydroxysteroid dehydrogenase in the kidney and other tissues with mineralocorticoid receptors (see below) before reaching the liver. Most cortisol is metabolized in the liver. About one third of the cortisol produced daily is excreted in the urine as dihydroxy ketone metabolites and is measured as 17-hydroxysteroids (see Figure 39-3 for carbon numbering). Many cortisol metabolites are conjugated with glucuronic acid or sulfate at the C<sub>3</sub> and C<sub>21</sub> hydroxyls, respectively, in the liver; they are then excreted in the urine.

**Figure 39-3**

Chemical structures of several glucocorticoids. The acetone-substituted derivatives (eg, triamcinolone acetone) have increased surface activity and are useful in dermatology. Dexamethasone is identical to betamethasone except for the configuration of the methyl group at C<sub>16</sub>: in betamethasone it is beta (projecting up from the plane of the rings); in dexamethasone it is alpha.

In some species (eg, the rat), corticosterone is the major glucocorticoid. It is less firmly bound to protein and therefore metabolized more rapidly. The pathways of its degradation are similar to those of cortisol.

## Pharmacodynamics

### MECHANISM OF ACTION

Most of the known effects of the glucocorticoids are mediated by widely distributed glucocorticoid receptors. These proteins are members of the superfamily of nuclear receptors, which includes steroid, sterol (vitamin D), thyroid, retinoic acid, and many other receptors with unknown or nonexistent ligands (orphan receptors). All these receptors interact with the promoters of target genes (Figure 39-4). In the absence of the hormonal ligand, glucocorticoid receptors are primarily cytoplasmic, in oligomeric complexes with heat shock proteins (Hsp). The most important of these are two molecules of Hsp90, although other proteins are certainly involved. Free hormone from the plasma and interstitial fluid enters the cell and binds to the receptor, inducing conformational changes that allow it to dissociate from the heat shock proteins. The ligand-bound receptor complex then is actively transported into the nucleus, where it interacts with DNA and nuclear proteins. As a homodimer, it binds to **glucocorticoid receptor elements (GRE)** in the promoters of responsive genes. The GRE is composed of two palindromic sequences that bind to the hormone receptor dimer.

**Figure 39-4**

A model of the interaction of a steroid, S (eg, cortisol), and its receptor, R, and the subsequent events in a target cell. The steroid is present in the blood in bound form on the corticosteroid-binding globulin (CBG) but enters the cell as the free molecule. The intracellular receptor is bound to stabilizing proteins, including two molecules of heat shock protein 90 (Hsp90) and several others, denoted as "X" in the figure. This receptor complex is incapable of activating transcription. When the complex binds a molecule of cortisol, an unstable complex is created and the Hsp90 and associated molecules are released. The steroid-receptor complex is now able to dimerize, enter the nucleus, bind to a glucocorticoid response element (GRE) on the regulatory region of the gene, and regulate transcription by RNA polymerase II and associated transcription factors. A variety of regulatory factors (not shown) may participate in facilitating (coactivators) or inhibiting (corepressors) the steroid response. The resulting mRNA is edited and exported to the cytoplasm for the production of protein that brings about the final hormone response. An alternative to the steroid-receptor complex interaction with a GRE is an interaction with and altering the function of other transcription factors, such as NF- $\kappa$ B in the nucleus of cells.

In addition to binding to GREs, the ligand-bound receptor also forms complexes with and influences the function of other transcription factors, such as AP1 and NF- $\kappa$ B, which act on non-GRE-containing promoters, to contribute to the regulation of transcription of their responsive genes. These transcription factors have broad actions on the regulation of growth factors, proinflammatory cytokines, etc, and to a great extent mediate the anti-growth, anti-inflammatory, and immunosuppressive effects of glucocorticoids.

Two genes for the corticoid receptor have been identified: one encoding the classic glucocorticoid receptor and the other encoding the mineralocorticoid receptor. Alternative splicing of human glucocorticoid receptor pre-mRNA generates two highly homologous isoforms, termed hGR alpha and hGR beta. hGR alpha is the classic ligand-activated glucocorticoid receptor which, in the hormone-bound state, modulates the expression of glucocorticoid-responsive genes. In contrast, hGR beta does not bind glucocorticoids and is transcriptionally inactive. However, hGR beta is able to inhibit the effects of hormone-activated hGR alpha on glucocorticoid-responsive genes, playing the role of a physiologically relevant endogenous inhibitor of glucocorticoid action.

The glucocorticoid receptor is composed of about 800 amino acids and can be divided into three functional domains (see Figure 26-6). The glucocorticoid-binding domain is located at the carboxyl terminal of the molecule. The DNA-binding domain is located in the middle of the protein and contains nine cysteine residues. This region folds into a "two-finger" structure stabilized by zinc ions connected to cysteines to form two tetrahedrons. This part of the molecule binds to the GREs that regulate glucocorticoid action on glucocorticoid-regulated genes. The zinc fingers represent the basic structure by which the DNA-binding domain recognizes specific nucleic acid sequences. The amino-terminal domain is involved in the transactivation activity of the receptor and increases its specificity.

The interaction of glucocorticoid receptors with GREs or other transcription factors is facilitated or inhibited by several families of proteins called steroid receptor *coregulators*, divided into *coactivators* and *corepressors*. The coregulators do this by serving as bridges between the receptors and other nuclear proteins and by expressing enzymatic activities such as histone acetylase or deacetylase, which alter the conformation of nucleosomes and the transcribability of genes.

Between 10% and 20% of expressed genes in a cell are regulated by glucocorticoids. The number and affinity of receptors for the hormone, the complement of transcription factors and coregulators, and post-transcription events determine the relative specificity of these hormones'

actions in various cells. The effects of glucocorticoids are mainly due to proteins synthesized from mRNA transcribed from their target genes.

Some of the effects of glucocorticoids can be attributed to their binding to aldosterone receptors (ARs). Indeed, ARs bind aldosterone and cortisol with similar affinity. A mineralocorticoid effect of cortisol is avoided in some tissues by expression of  $11\beta$ -hydroxysteroid dehydrogenase type 2, the enzyme responsible for biotransformation to its 11-keto derivative (cortisone), which has minimal affinity for aldosterone receptors.

Prompt effects such as initial feedback suppression of pituitary ACTH occur in minutes and are too rapid to be explained on the basis of gene transcription and protein synthesis. It is not known how these effects are mediated. Among the proposed mechanisms are direct effects on cell membrane receptors for the hormone or nongenomic effects of the classic hormone-bound glucocorticoid receptor. The putative membrane receptors might be entirely different from the known intracellular receptors.

#### **PHYSIOLOGIC EFFECTS**

The glucocorticoids have widespread effects because they influence the function of most cells in the body. The major metabolic consequences of glucocorticoid secretion or administration are due to direct actions of these hormones in the cell. However, some important effects are the result of homeostatic responses by insulin and glucagon. Although many of the effects of glucocorticoids are dose-related and become magnified when large amounts are administered for therapeutic purposes, there are also other effects called *permissive effects* without which many normal functions become deficient. For example, the response of vascular and bronchial smooth muscle to catecholamines is diminished in the absence of cortisol and restored by physiologic amounts of this glucocorticoid. Similarly, the lipolytic responses of fat cells to catecholamines, ACTH, and growth hormone are attenuated in the absence of glucocorticoids.

#### **METABOLIC EFFECTS**

The glucocorticoids have important dose-related effects on carbohydrate, protein, and fat metabolism. The same effects are responsible for some of the serious adverse effects associated with their use in therapeutic doses. Glucocorticoids stimulate and are required for gluconeogenesis and glycogen synthesis in the fasting state. They stimulate phosphoenolpyruvate carboxykinase, glucose-6-phosphatase, and glycogen synthase and the release of amino acids in the course of muscle catabolism.

Glucocorticoids increase serum glucose levels and thus stimulate insulin release and inhibit the uptake of glucose by muscle cells, while they stimulate hormone sensitive lipase and thus lipolysis. The increased insulin secretion stimulates lipogenesis and to a lesser degree inhibits lipolysis, leading to a net increase in fat deposition combined with increased release of fatty acids and glycerol into the circulation.

The net results of these actions are most apparent in the fasting state, when the supply of glucose from gluconeogenesis, the release of amino acids from muscle catabolism, the inhibition of peripheral glucose uptake, and the stimulation of lipolysis all contribute to maintenance of an adequate glucose supply to the brain.

#### **CATABOLIC AND ANTIANABOLIC EFFECTS**

Although glucocorticoids stimulate RNA and protein synthesis in the liver, they have catabolic and antianabolic effects in lymphoid and connective tissue, muscle, peripheral fat, and skin. Supraphysiologic amounts of glucocorticoids lead to decreased muscle mass and weakness and thinning of the skin. Catabolic and antianabolic effects on bone are the cause of osteoporosis in Cushing's syndrome and impose a major limitation in the long-term therapeutic use of glucocorticoids. In children, glucocorticoids reduce growth. This effect may be partially prevented by administration of growth hormone in high doses.

#### **ANTI-INFLAMMATORY AND IMMUNOSUPPRESSIVE EFFECTS**

Glucocorticoids dramatically reduce the manifestations of inflammation. This is due to their profound effects on the concentration, distribution, and function of peripheral leukocytes and to their suppressive effects on the inflammatory cytokines and chemokines and on other mediators of inflammation. Inflammation, regardless of its cause, is characterized by the extravasation and infiltration of leukocytes into the affected tissue. These events are mediated by a complex series of interactions of white cell adhesion molecules with those on endothelial cells and are inhibited by glucocorticoids. After a single dose of a short-acting glucocorticoid, the concentration of neutrophils in the circulation increases while the lymphocytes (T and B cells), monocytes, eosinophils, and basophils decrease. The changes are maximal at 6 hours and are dissipated in 24 hours. The increase in neutrophils is due both to the increased influx into the blood from the bone marrow and to the decreased migration from the blood vessels, leading to a reduction in the number of cells at the site of inflammation. The reduction in circulating lymphocytes, monocytes, eosinophils, and basophils is primarily the result of their movement from the vascular bed to lymphoid tissue.

Glucocorticoids also inhibit the functions of tissue macrophages and other antigen-presenting cells. The ability of these cells to respond to antigens and mitogens is reduced. The effect on macrophages is particularly marked and limits their ability to phagocytose and kill microorganisms and to produce tumor necrosis factor- $\alpha$ , interleukin-1, metalloproteinases, and plasminogen activator. Both macrophages and lymphocytes produce less interleukin-12 and interferon- $\gamma$ , important inducers of TH1 cell activity, and cellular immunity.

In addition to their effects on leukocyte function, glucocorticoids influence the inflammatory response by reducing the prostaglandin, leukotriene, and platelet-activating factor synthesis that results from activation of phospholipase  $A_2$ . Finally, glucocorticoids reduce expression of cyclooxygenase-2, the inducible form of this enzyme, in inflammatory cells, thus reducing the amount of enzyme available to produce prostaglandins (see Chapters 18 and 36).

Glucocorticoids cause vasoconstriction when applied directly to the skin, possibly by suppressing mast cell degranulation. They also decrease capillary permeability by reducing the amount of histamine released by basophils and mast cells.

The anti-inflammatory and immunosuppressive effects of glucocorticoids are largely due to the actions described above. In humans, complement activation is unaltered, but its effects are inhibited. Antibody production can be reduced by large doses of steroids, although it is

unaffected by moderate doses (eg, 20 mg/d of prednisone).

The anti-inflammatory and immunosuppressive effects of these agents are widely useful therapeutically but are also responsible for some of their most serious adverse effects (see text that follows).

#### OTHER EFFECTS

Glucocorticoids have important effects on the nervous system. Adrenal insufficiency causes marked slowing of the alpha rhythm of the electroencephalogram and is associated with depression. Increased amounts of glucocorticoids often produce behavioral disturbances in humans: initially insomnia and euphoria and subsequently depression. Large doses of glucocorticoids may increase intracranial pressure (pseudotumor cerebri).

Glucocorticoids given chronically suppress the pituitary release of ACTH, growth hormone, thyroid-stimulating hormone, and luteinizing hormone.

Large doses of glucocorticoids have been associated with the development of peptic ulcer, possibly by suppressing the local immune response against *Helicobacter pylori*. They also promote fat redistribution in the body, with increase of visceral, facial, nuchal, and supraclavicular fat, and they appear to antagonize the effect of vitamin D on calcium absorption. The glucocorticoids also have important effects on the hematopoietic system. In addition to their effects on leukocytes, they increase the number of platelets and red blood cells.

Cortisol deficiency results in impaired renal function (particularly glomerular filtration), augmented vasopressin secretion, and diminished ability to excrete a water load.

Glucocorticoids have important effects on the development of the fetal lungs. Indeed, the structural and functional changes in the lungs near term, including the production of pulmonary surface-active material required for air breathing (surfactant), are stimulated by glucocorticoids.

### Synthetic Corticosteroids

Glucocorticoids have become important agents for use in the treatment of many inflammatory, immunologic, hematologic, and other disorders. This has stimulated the development of many synthetic steroids with anti-inflammatory and immunosuppressive activity.

#### Pharmacokinetics

##### SOURCE

Pharmaceutical steroids are usually synthesized from cholic acid obtained from cattle or steroid sapogenins found in plants. Further modifications of these steroids have led to the marketing of a large group of synthetic steroids with special characteristics that are pharmacologically and therapeutically important (Table 39-1; Figure 39-3).

**Table 39-1 Some Commonly Used Natural and Synthetic Corticosteroids for General Use.**

Agent	Activity <sup>1</sup>				Forms Available
	Anti-Inflammatory	Topical	Salt-Retaining	Equivalent Oral Dose (mg)	
<b>Short- to medium-acting glucocorticoids</b>					
Hydrocortisone (cortisol)	1	1	1	20	Oral, injectable, topical
Cortisone	0.8	0	0.8	25	Oral
Prednisone	4	0	0.3	5	Oral
Prednisolone	5	4	0.3	5	Oral, injectable
Methylprednisolone	5	5	0.25	4	Oral, injectable
Meprednisone <sup>2</sup>	5		0	4	Oral, injectable
<b>Intermediate-acting glucocorticoids</b>					
Triamcinolone	5	5 <sup>3</sup>	0	4	Oral, injectable, topical
Paramethasone <sup>2</sup>	10		0	2	Oral, injectable
Fluprednisolone <sup>2</sup>	15	7	0	1.5	Oral
<b>Long-acting glucocorticoids</b>					
Betamethasone	25-40	10	0	0.6	Oral, injectable, topical
Dexamethasone	30	10	0	0.75	Oral, injectable, topical
<b>Mineralocorticoids</b>					
Fludrocortisone	10	0	250	2	Oral
Desoxycorticosterone acetate <sup>2 0</sup>		0	20		Injectable, pellets

<sup>1</sup>Potency relative to hydrocortisone.

<sup>2</sup>Outside USA.

<sup>3</sup>Acetonide: Up to 100.

#### **DISPOSITION**

The metabolism of the naturally occurring adrenal steroids has been discussed above. The synthetic corticosteroids (Table 39â€”1) are in most cases rapidly and completely absorbed when given by mouth. Although they are transported and metabolized in a fashion similar to that of the endogenous steroids, important differences exist.

Alterations in the glucocorticoid molecule influence its affinity for glucocorticoid and mineralocorticoid receptors as well as its protein-binding affinity, side chain stability, rate of elimination, and metabolic products. Halogenation at the 9 position, unsaturation of the  $\Delta^1$  bond of the A ring, and methylation at the 2 or 16 position prolong the half-life by more than 50%. The  $\Delta^1$  compounds are excreted in the free form. In some cases, the agent given is a prodrug; for example, prednisone is rapidly converted to the active product prednisolone in the body.

#### **Pharmacodynamics**

The actions of the synthetic steroids are similar to those of cortisol (see above). They bind to the specific intracellular receptor proteins and produce the same effects but have different ratios of glucocorticoid to mineralocorticoid potency (Table 39â€”1).

### **CLINICAL PHARMACOLOGY**

#### **DIAGNOSIS AND TREATMENT OF DISTURBED ADRENAL FUNCTION**

##### **Adrenocortical Insufficiency**

##### **CHRONIC (ADDISON'S DISEASE)**

Chronic adrenocortical insufficiency is characterized by weakness, fatigue, weight loss, hypotension, hyperpigmentation, and inability to maintain the blood glucose level during fasting. In such individuals, minor noxious, traumatic, or infectious stimuli may produce acute adrenal insufficiency with circulatory shock and even death.

In primary adrenal insufficiency, about 20â€”30 mg of hydrocortisone must be given daily, with increased amounts during periods of stress. Although hydrocortisone has some mineralocorticoid activity, this must be supplemented by an appropriate amount of a salt-retaining hormone such as fludrocortisone. Synthetic glucocorticoids that are long-acting and devoid of salt-retaining activity should not be administered to these patients.

##### **ACUTE**

When acute adrenocortical insufficiency is suspected, treatment must be instituted immediately. Therapy consists of large amounts of parenteral hydrocortisone in addition to correction of fluid and electrolyte abnormalities and treatment of precipitating factors.

Hydrocortisone sodium succinate or phosphate in doses of 100 mg intravenously is given every 8 hours until the patient is stable. The dose is then gradually reduced, achieving maintenance dosage within 5 days.

The administration of salt-retaining hormone is resumed when the total hydrocortisone dosage has been reduced to 50 mg/d.

##### **Adrenocortical Hypo- and Hyperfunction**

##### **CONGENITAL ADRENAL HYPERPLASIA**

This group of disorders is characterized by specific defects in the synthesis of cortisol. In pregnancies at high risk for congenital adrenal hyperplasia, fetuses can be protected from genital abnormalities by administration of dexamethasone to the mother. The most common defect is a decrease in or lack of P450c21 (21 $\beta$ -hydroxylase) activity.\*

As can be seen in Figure 39â€”1, this would lead to a reduction in cortisol synthesis and thus produce a compensatory increase in ACTH release. The gland becomes hyperplastic and produces abnormally large amounts of precursors such as 17-hydroxyprogesterone that can be diverted to the androgen pathway, leading to virilization. Metabolism of this compound in the liver leads to pregnanetriol, which is characteristically excreted into the urine in large amounts in this disorder and can be used to make the diagnosis and to monitor efficacy of glucocorticoid substitution. However, the most reliable method of detecting this disorder is the increased response of plasma 17-hydroxyprogesterone to ACTH stimulation.

If the defect is in 11-hydroxylation, large amounts of deoxycorticosterone are produced, and because this steroid has mineralocorticoid activity, hypertension with or without hypokalemic alkalosis ensues. When 17-hydroxylation is defective in the adrenals and gonads, hypogonadism is also present. However, increased amounts of 11-deoxycorticosterone are formed, and the signs and symptoms associated with mineralocorticoid excess—such as hypertension and hypokalemia—are also observed.

When first seen, the infant with congenital adrenal hyperplasia may be in acute adrenal crisis and should be treated as described above, using appropriate electrolyte solutions and an intravenous preparation of hydrocortisone in stress doses.

Once the patient is stabilized, oral hydrocortisone, 12â€”18 mg/m<sup>2</sup>/d in two unequally divided doses (two thirds in the morning, one third in late afternoon) is begun. The dosage is adjusted to allow normal growth and bone maturation and to prevent androgen excess. Alternate-day therapy with prednisone has also been used to achieve greater ACTH suppression without increasing growth inhibition. Fludrocortisone, 0.05â€”0.2 mg/d, should also be administered by mouth, with added salt to maintain normal blood pressure, plasma renin activity, and electrolytes.

\*Names for the adrenal steroid synthetic enzymes include the following: P450c11 (11-hydroxylase) P450c17 (17-hydroxylase) P450c21 (21-hydroxylase)

#### **CUSHING'S SYNDROME**

Cushing's syndrome is usually the result of bilateral adrenal hyperplasia secondary to an ACTH-secreting pituitary adenoma (Cushing's disease) but occasionally is due to tumors or nodular hyperplasia of the adrenal gland or ectopic production of ACTH by other tumors. The manifestations are those associated with the chronic presence of excessive glucocorticoids. When glucocorticoid hypersecretion is marked and prolonged, a rounded, plethoric face and trunk obesity are striking in appearance. The manifestations of protein loss are often found and include muscle wasting; thinning, purple striae, and easy bruising of the skin; poor wound healing; and osteoporosis. Other serious disturbances include mental disorders, hypertension, and diabetes. This disorder is treated by surgical removal of the tumor producing ACTH or cortisol, irradiation of the pituitary tumor, or resection of one or both adrenals. These patients must receive large doses of cortisol during and after the surgical procedure. Doses of up to 300 mg of soluble hydrocortisone may be given as a continuous intravenous infusion on the day of surgery. The dose must be reduced slowly to normal replacement levels, since rapid reduction in dose may produce withdrawal symptoms, including fever and joint pain. If adrenalectomy has been performed, long-term maintenance is similar to that outlined above for adrenal insufficiency.

#### **ALDOSTERONISM**

Primary aldosteronism usually results from the excessive production of aldosterone by an adrenal adenoma. However, it may also result from abnormal secretion by hyperplastic glands or from a malignant tumor. The clinical findings of hypertension, weakness, and tetany are related to the continued renal loss of potassium, which leads to hypokalemia, alkalosis, and elevation of serum sodium concentrations. This syndrome can also be produced in disorders of adrenal steroid biosynthesis by excessive secretion of deoxycorticosterone, corticosterone, or 18-hydroxycorticosterone—all compounds with inherent mineralocorticoid activity.

In contrast to patients with secondary aldosteronism (see text that follows), these patients have low (suppressed) levels of plasma renin activity and angiotensin II. When treated with fludrocortisone (0.2 mg twice daily orally for 3 days) or deoxycorticosterone acetate (20 mg/d intramuscularly for 3 days—but not available in the USA), patients fail to retain sodium and the secretion of aldosterone is not significantly reduced. When the disorder is mild, it may escape detection if serum potassium levels are used for screening. However, it may be detected by an increased ratio of plasma aldosterone to renin. Patients generally improve when treated with spironolactone, an aldosterone receptor-blocking agent, and the response to this agent is of diagnostic and therapeutic value.

#### **Use of Glucocorticoids for Diagnostic Purposes**

It is sometimes necessary to suppress the production of ACTH to identify the source of a particular hormone or to establish whether its production is influenced by the secretion of ACTH. In these circumstances, it is advantageous to use a very potent substance such as dexamethasone because the use of small quantities reduces the possibility of confusion in the interpretation of hormone assays in blood or urine. For example, if complete suppression is achieved by the use of 50 mg of cortisol, the urinary 17-hydroxycorticosteroids will be 15–18 mg/24 h, since one third of the dose given will be recovered in urine as 17-hydroxycorticosteroid. If an equivalent dose of 1.5 mg of dexamethasone is used, the urinary excretion will be only 0.5 mg/24 h and blood levels will be low.

The **dexamethasone suppression test** is used for the diagnosis of Cushing's syndrome and has also been used in the differential diagnosis of depressive psychiatric states. As a screening test, 1 mg dexamethasone is given orally at 11 PM, and a plasma sample is obtained the following morning. In normal individuals, the morning cortisol concentration is usually less than 3 mcg/dL, whereas in Cushing's syndrome the level is usually greater than 5 mcg/dL. The results are not reliable in the patient with depression, anxiety, concurrent illness, and other stressful conditions or in the patient who is receiving a medication that enhances the catabolism of dexamethasone in the liver. To distinguish between hypercortisolism due to anxiety, depression, and alcoholism (pseudo-Cushing syndrome) and bona fide Cushing's syndrome, a combined test is carried out, consisting of dexamethasone (0.5 mg orally every 6 hours for 2 days) followed by a standard corticotropin-releasing hormone (CRH) test (1 mg/kg given as a bolus intravenous infusion 2 hours after the last dose of dexamethasone).

In patients in whom the diagnosis of Cushing's syndrome has been established clinically and confirmed by a finding of elevated free cortisol in the urine, suppression with large doses of dexamethasone will help to distinguish patients with Cushing's disease from those with steroid-producing tumors of the adrenal cortex or with the ectopic ACTH syndrome. Dexamethasone is given in a dosage of 0.5 mg orally every 6 hours for 2 days, followed by 2 mg orally every 6 hours for 2 days, and the urine is then assayed for cortisol or its metabolites (Liddle's test); or dexamethasone is given as a single dose of 8 mg at 11 PM, and the plasma cortisol is measured at 8 AM the following day. In patients with Cushing's disease, the suppressant effect of dexamethasone usually produces a 50% reduction in hormone levels. In patients in whom suppression does not occur, the ACTH level will be low in the presence of a cortisol-producing adrenal tumor and elevated in patients with an ectopic ACTH-producing tumor.

#### **CORTICOSTEROIDS AND STIMULATION OF LUNG MATURATION IN THE FETUS**

Lung maturation in the fetus is regulated by the fetal secretion of cortisol. Treatment of the mother with large doses of glucocorticoid reduces the incidence of respiratory distress syndrome in infants delivered prematurely. When delivery is anticipated before 34 weeks of gestation, intramuscular betamethasone, 12 mg, followed by an additional dose of 12 mg 18–24 hours later, is commonly used. Betamethasone is chosen because maternal protein binding and placental metabolism of this corticosteroid is less than that of cortisol, allowing increased transfer across the placenta to the fetus.

#### **CORTICOSTEROIDS AND NONADRENAL DISORDERS**

The synthetic analogs of cortisol are useful in the treatment of a diverse group of diseases unrelated to any known disturbance of adrenal function (Table 39–2). The usefulness of corticosteroids in these disorders is a function of their ability to suppress inflammatory and immune responses and to alter leukocyte function, as previously described and as described in Chapter 55. These agents are useful in disorders in

which host response is the cause of the major manifestations of the disease. In instances in which the inflammatory or immune response is important in controlling the pathologic process, therapy with corticosteroids may be dangerous but justified to prevent irreparable damage from an inflammatory responseâ€”if used in conjunction with specific therapy for the disease process.

**Table 39â€”2 Some Therapeutic Indications for the Use of Glucocorticoids in Nonadrenal Disorders.**

<b>Disorder</b>	<b>Examples</b>
Allergic reactions	Angioneurotic edema, asthma, bee stings, contact dermatitis, drug reactions, allergic rhinitis, serum sickness, urticaria
Collagen-vascular disorders	Giant cell arteritis, lupus erythematosus, mixed connective tissue syndromes, polymyositis, polymyalgia rheumatica, rheumatoid arthritis, temporal arteritis
Eye diseases	Acute uveitis, allergic conjunctivitis, choroiditis, optic neuritis
Gastrointestinal diseases	Inflammatory bowel disease, nontropical sprue, subacute hepatic necrosis
Hematologic disorders	Acquired hemolytic anemia, acute allergic purpura, leukemia, autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura, multiple myeloma
Systemic inflammation	Acute respiratory distress syndrome (sustained therapy with moderate dosage accelerates recovery and decreases mortality)
Infections	Acute respiratory distress syndrome, sepsis
Inflammatory conditions of bones and joints	Arthritis, bursitis, tenosynovitis
Neurologic disorders	Cerebral edema (large doses of dexamethasone are given to patients following brain surgery to minimize cerebral edema in the postoperative period), multiple sclerosis
Organ transplants	Prevention and treatment of rejection (immunosuppression)
Pulmonary diseases	Aspiration pneumonia, bronchial asthma, prevention of infant respiratory distress syndrome, sarcoidosis
Renal disorders	Nephrotic syndrome
Skin diseases	Atopic dermatitis, dermatoses, lichen simplex chronicus (localized neurodermatitis), mycosis fungoides, pemphigus, seborrheic dermatitis, xerosis
Thyroid diseases	Malignant exophthalmos, subacute thyroiditis
Miscellaneous	Hypercalcemia, mountain sickness

Since corticosteroids are not usually curative, the pathologic process may progress while clinical manifestations are suppressed. Therefore, chronic therapy with these drugs should be undertaken with great care and only when the seriousness of the disorder warrants their use and when less hazardous measures have been exhausted.

In general, attempts should be made to bring the disease process under control using medium- to intermediate-acting glucocorticoids such as prednisone and prednisolone (Table 39â€”1), as well as all ancillary measures possible to keep the dose low. Where possible, alternate-day therapy should be used (see the following text). Therapy should not be decreased or stopped abruptly. When prolonged therapy is anticipated, it is helpful to obtain chest x-rays and a tuberculin test, since glucocorticoid therapy can reactivate dormant tuberculosis. The presence of diabetes, peptic ulcer, osteoporosis, and psychological disturbances should be taken into consideration, and cardiovascular function should be assessed.

Treatment for transplant rejection is a very important application of glucocorticoids. The efficacy of these agents is based on their ability to reduce antigen expression from the grafted tissue, delay revascularization, and interfere with the sensitization of cytotoxic T lymphocytes and the generation of primary antibody-forming cells.

### **Toxicity**

The benefits obtained from glucocorticoids vary considerably. Use of these drugs must be carefully weighed in each patient against their widespread effects on every part of the organism. The major undesirable effects of glucocorticoids are the result of their hormonal actions, which lead to the clinical picture of iatrogenic Cushing's syndrome (see later in text).

When glucocorticoids are used for short periods (< 2 weeks), it is unusual to see serious adverse effects even with moderately large doses. However, insomnia, behavioral changes (primarily hypomania), and acute peptic ulcers are occasionally observed even after only a few days of treatment. Acute pancreatitis is a rare but serious acute adverse effect of high-dose glucocorticoids.

### **METABOLIC EFFECTS**

Most patients who are given daily doses of 100 mg of hydrocortisone or more (or the equivalent amount of synthetic steroid) for longer than 2 weeks undergo a series of changes that have been termed iatrogenic Cushing's syndrome. The rate of development is a function of the dosage and the genetic background of the patient. In the face, rounding, puffiness, fat deposition, and plethora usually appear (moon facies). Similarly, fat tends to be redistributed from the extremities to the trunk, the back of the neck, and the supraclavicular fossae. There is an increased growth of fine hair over the face, thighs and trunk. Steroid-induced punctate acne may appear, and insomnia and increased appetite are noted. In the treatment of dangerous or disabling disorders, these changes may not require cessation of therapy. However, the underlying metabolic changes accompanying them can be very serious by the time they become obvious. The continuing breakdown of protein

and diversion of amino acids to glucose production increase the need for insulin and over time result in weight gain; visceral fat deposition; myopathy and muscle wasting; thinning of the skin, with striae and bruising; hyperglycemia; and eventually osteoporosis, diabetes, and aseptic necrosis of the hip. Wound healing is also impaired under these circumstances. When diabetes occurs, it is treated with diet and insulin. These patients are often resistant to insulin but rarely develop ketoacidosis. In general, patients treated with corticosteroids should be on high protein and potassium-enriched diets.

#### **OTHER COMPLICATIONS**

Other serious adverse effects of glucocorticoids include peptic ulcers and their consequences. The clinical findings associated with certain disorders, particularly bacterial and mycotic infections, may be masked by the corticosteroids, and patients must be carefully monitored to avoid serious mishap when large doses are used. Severe myopathy is more frequent in patients treated with long-acting glucocorticoids. The administration of such compounds has been associated with nausea, dizziness, and weight loss in some patients. It is treated by changing drugs, reducing dosage, and increasing potassium and protein intake.

Hypomania or acute psychosis may occur, particularly in patients receiving very large doses of corticosteroids. Long-term therapy with intermediate- and long-acting steroids is associated with depression and the development of posterior subcapsular cataracts. Psychiatric follow-up and periodic slit-lamp examination is indicated in such patients. Increased intraocular pressure is common, and glaucoma may be induced. Benign intracranial hypertension also occurs. In dosages of 45 mg/m<sup>2</sup>/d or more of hydrocortisone or its equivalent, growth retardation occurs in children. Medium-, intermediate-, and long-acting glucocorticoids have greater growth-suppressing potency than the natural steroid at equivalent doses.

When given in larger than physiologic amounts, steroids such as cortisone and hydrocortisone, which have mineralocorticoid effects in addition to glucocorticoid effects, cause some sodium and fluid retention and loss of potassium. In patients with normal cardiovascular and renal function, this leads to a hypokalemic, hypochloremic alkalosis and eventually to a rise in blood pressure. In patients with hypoproteinemia, renal disease, or liver disease, edema may also occur. In patients with heart disease, even small degrees of sodium retention may lead to heart failure. These effects can be minimized by using synthetic non-salt-retaining steroids, sodium restriction, and judicious amounts of potassium supplements.

#### **ADRENAL SUPPRESSION**

When corticosteroids are administered for more than 2 weeks, adrenal suppression may occur. If treatment extends over weeks to months, the patient should be given appropriate supplementary therapy at times of minor stress (two-fold dosage increases for 24–48 hours) or severe stress (up to ten-fold dosage increases for 48–72 hours) such as accidental trauma or major surgery. If corticosteroid dosage is to be reduced, it should be tapered slowly. If therapy is to be stopped, the reduction process should be quite slow when the dose reaches replacement levels. It may take 2–12 months for the hypothalamic-pituitary-adrenal axis to function acceptably, and cortisol levels may not return to normal for another 6–9 months. The glucocorticoid-induced suppression is not a pituitary problem, and treatment with ACTH does not reduce the time required for the return of normal function.

If the dosage is reduced too rapidly in patients receiving glucocorticoids for a certain disorder, the symptoms of the disorder may reappear or increase in intensity. However, patients without an underlying disorder (eg, patients cured surgically of Cushing's disease) also develop symptoms with rapid reductions in corticosteroid levels. These symptoms include anorexia, nausea or vomiting, weight loss, lethargy, headache, fever, joint or muscle pain, and postural hypotension. Although many of these symptoms may reflect true glucocorticoid deficiency, they may also occur in the presence of normal or even elevated plasma cortisol levels, suggesting glucocorticoid dependence.

#### **Contraindications & Cautions**

##### **SPECIAL PRECAUTIONS**

Patients receiving glucocorticoids must be monitored carefully for the development of hyperglycemia, glycosuria, sodium retention with edema or hypertension, hypokalemia, peptic ulcer, osteoporosis, and hidden infections.

The dosage should be kept as low as possible, and intermittent administration (eg, alternate-day) should be used when satisfactory therapeutic results can be obtained on this schedule. Even patients maintained on relatively low doses of corticosteroids may require supplementary therapy at times of stress, such as when surgical procedures are performed or intercurrent illness or accidents occur.

##### **CONTRAINDICATIONS**

**Glucocorticoids** must be used with great caution in patients with peptic ulcer, heart disease or hypertension with heart failure, certain infectious illnesses such as varicella and tuberculosis, psychoses, diabetes, osteoporosis, or glaucoma.

#### **Selection of Drug & Dosage Schedule**

Glucocorticoid preparations differ with respect to relative anti-inflammatory and mineralocorticoid effect, duration of action, cost, and dosage forms available (Table 39-1), and these factors should be taken into account in selecting the drug to be used.

##### **ACTH VERSUS ADRENOCORTICAL STEROIDS**

In patients with normal adrenals, ACTH was used in the past to induce the endogenous production of cortisol to obtain similar effects. However, except when an increase in androgens is desirable, the use of ACTH as a therapeutic agent has been abandoned. Instances in which ACTH was claimed to be more effective than glucocorticoids were probably due to the administration of smaller amounts of corticosteroids than were produced by the dosage of ACTH.

##### **DOSAGE**

In determining the dosage regimen to be used, the physician must consider the seriousness of the disease, the amount of drug likely to be required to obtain the desired effect, and the duration of therapy. In some diseases, the amount required for maintenance of the desired

therapeutic effect is less than the dose needed to obtain the initial effect, and the lowest possible dosage for the needed effect should be determined by gradually lowering the dose until a small increase in signs or symptoms is noted.

When it is necessary to maintain continuously elevated plasma corticosteroid levels to suppress ACTH, a slowly absorbed parenteral preparation or small oral doses at frequent intervals are required. The opposite situation exists with respect to the use of corticosteroids in the treatment of inflammatory and allergic disorders. The same total quantity given in a few doses may be more effective than that given in many smaller doses or in a slowly absorbed parenteral form.

Severe autoimmune conditions involving vital organs must be treated aggressively, and undertreatment is as dangerous as overtreatment. To minimize the deposition of immune complexes and the influx of leukocytes and macrophages, 1 mg/kg/d of prednisone in divided doses is required initially. This dosage is maintained until the serious manifestations respond. The dosage can then be gradually reduced.

When large doses are required for prolonged periods of time, alternate-day administration of the compound may be tried after control is achieved. When used in this manner, very large amounts (eg, 100 mg of prednisone) can sometimes be administered with less marked adverse effects because there is a recovery period between each dose. The transition to an alternate-day schedule can be made after the disease process is under control. It should be done gradually and with additional supportive measures between doses.

When selecting a drug for use in large doses, a medium- or intermediate-acting synthetic steroid with little mineralocorticoid effect is advisable. If possible, it should be given as a single morning dose.

#### **SPECIAL DOSAGE FORMS**

Local therapy, such as topical preparations for skin disease, ophthalmic forms for eye disease, intra-articular injections for joint disease, inhaled steroids for asthma, and hydrocortisone enemas for ulcerative colitis, provides a means of delivering large amounts of steroid to the diseased tissue with reduced systemic effects.

Beclomethasone dipropionate, and several other glucocorticoids—primarily budesonide and flunisolide and mometasone furoate, administered as aerosols—have been found to be extremely useful in the treatment of asthma (see Chapter 20).

Beclomethasone dipropionate, triamcinolone acetonide, budesonide, flunisolide, and mometasone furoate are available as nasal sprays for the topical treatment of allergic rhinitis. They are effective at doses (one or two sprays one, two, or three times daily) that in most patients result in plasma levels that are too low to influence adrenal function or have any other systemic effects.

Corticosteroids incorporated in ointments, creams, lotions, and sprays are used extensively in dermatology. These preparations are discussed in more detail in Chapter 61.

#### **MINERALOCORTICIDS (ALDOSTERONE, DEOXYCORTICOSTERONE, FLUDROCORTISONE)**

The most important mineralocorticoid in humans is aldosterone. However, small amounts of DOC (deoxycorticosterone) are also formed and released. Although the amount is normally insignificant, DOC was of some importance therapeutically in the past. Its actions, effects, and metabolism are qualitatively similar to those described below for aldosterone.

Fludrocortisone, a synthetic corticosteroid, is the most commonly prescribed salt-retaining hormone.

#### **Aldosterone**

Aldosterone is synthesized mainly in the zona glomerulosa of the adrenal cortex. Its structure and synthesis are illustrated in Figure 39-1.

The rate of aldosterone secretion is subject to several influences. ACTH produces a moderate stimulation of its release, but this effect is not sustained for more than a few days in the normal individual. Although aldosterone is no less than one third as effective as cortisol in suppressing ACTH, the quantities of aldosterone produced by the adrenal cortex and its plasma concentrations are insufficient to participate in any significant feedback control of ACTH secretion.

Without ACTH, aldosterone secretion falls to about half the normal rate, indicating that other factors, eg, angiotensin, are able to maintain and perhaps regulate its secretion (see Chapter 17). Independent variations between cortisol and aldosterone secretion can also be demonstrated by means of lesions in the nervous system such as decerebration, which decreases the secretion of cortisol while increasing the secretion of aldosterone.

#### **PHYSIOLOGIC & PHARMACOLOGIC EFFECTS**

Aldosterone and other steroids with mineralocorticoid properties promote the reabsorption of sodium from the distal part of the distal convoluted tubule and from the cortical collecting renal tubules, loosely coupled to the excretion of potassium and hydrogen ion. Sodium reabsorption in the sweat and salivary glands, gastrointestinal mucosa, and across cell membranes in general is also increased. Excessive levels of aldosterone produced by tumors or overdosage with synthetic mineralocorticoids lead to hypokalemia, metabolic alkalosis, increased plasma volume, and hypertension.

Mineralocorticoids act by binding to the mineralocorticoid receptor in the cytoplasm of target cells, especially principal cells of the distal convoluted and collecting tubules of the kidney. The drug-receptor complex activates a series of events similar to those described above for the glucocorticoids and illustrated in Figure 39-4. It is of interest that this receptor has the same affinity for cortisol, which is present in much higher concentrations in the extracellular fluid. The specificity for mineralocorticoids in the kidney appears to be conferred, at least in part, by the presence of the enzyme 11 $\beta$ -hydroxysteroid dehydrogenase type 2, which converts cortisol to cortisone. The latter has low affinity for the receptor and is inactive as a mineralocorticoid or glucocorticoid. The major effect of activation of the aldosterone receptor is increased expression of Na<sup>+</sup>,K<sup>+</sup> ATPase and the epithelial sodium channel (ENaC).

#### **METABOLISM**

Aldosterone is secreted at the rate of 100–200 mcg/d in normal individuals with a moderate dietary salt intake. The plasma level in men (resting supine) is about 0.007 mcg/dL. The half-life of aldosterone injected in tracer quantities is 15–20 minutes, and it does not appear to be firmly bound to serum proteins.

The metabolism of aldosterone is similar to that of cortisol, about 50 mcg/24 h appearing in the urine as conjugated tetrahydroaldosterone. Approximately 5–15 mcg/24 h is excreted free or as the 3-oxo glucuronide.

### **Deoxycorticosterone (DOC)**

DOC, which also serves as a precursor of aldosterone (Figure 39–1), is normally secreted in amounts of about 200 mcg/d. Its half-life when injected into the human circulation is about 70 minutes. Preliminary estimates of its concentration in plasma are approximately 0.03 mcg/dL. The control of its secretion differs from that of aldosterone in that the secretion of DOC is primarily under the control of ACTH. Although the response to ACTH is enhanced by dietary sodium restriction, a low-salt diet does not increase DOC secretion. The secretion of DOC may be markedly increased in abnormal conditions such as adrenocortical carcinoma and congenital adrenal hyperplasia with reduced P450c11 or P450c17 activity.

### **Fludrocortisone**

This compound, a potent steroid with both glucocorticoid and mineralocorticoid activity, is the most widely used mineralocorticoid. Oral doses of 0.1 mg two to seven times weekly have potent salt-retaining activity and are used in the treatment of adrenocortical insufficiency associated with mineralocorticoid deficiency. These dosages are too small to have important anti-inflammatory or antigrowth effects.

### **ADRENAL ANDROGENS**

The adrenal cortex secretes large amounts of DHEA and smaller amounts of androstenedione and testosterone. Although these androgens are thought to contribute to the normal maturation process, they do not stimulate or support major androgen-dependent pubertal changes in humans. Recent studies suggest that DHEA and its sulfate may have other important physiologic actions. If that is correct, these results are probably due to the peripheral conversion of DHEA to more potent androgens or to estrogens and interaction with androgen and estrogen receptors, respectively. Additional effects may be exerted through an interaction with the GABA<sub>A</sub> and glutamate receptors in the brain or with a nuclear receptor in several central and peripheral sites. The therapeutic use of DHEA in humans has been explored, but the substance has already been adopted with uncritical enthusiasm by members of the sports drug culture and the vitamin and food supplement culture.

The results of a placebo-controlled trial of DHEA in patients with systemic lupus erythematosus were recently reported as well as those of a study of DHEA replacement in women with adrenal insufficiency. In both studies a small beneficial effect was seen, with significant improvement of the disease in the former and a clearly added sense of well-being in the latter. The androgenic or estrogenic actions of DHEA could explain the effects of the compound in both situations.

### **ANTAGONISTS OF ADRENOCORTICAL AGENTS**

#### **SYNTHESIS INHIBITORS & GLUCOCORTICOID ANTAGONISTS**

Inhibitors of steroid synthesis act at several different steps and one glucocorticoid antagonist acts at the receptor level.

#### **Aminoglutethimide**

Aminoglutethimide (Figure 39–5) blocks the conversion of cholesterol to pregnenolone (see Figure 39–1) and causes a reduction in the synthesis of all hormonally active steroids. It has been used in conjunction with dexamethasone or hydrocortisone to reduce or eliminate estrogen production in patients with carcinoma of the breast. In a dosage of 1 g/d it was well tolerated; however, with higher dosages, lethargy and skin rash was a common effect. The use of aminoglutethimide in breast cancer patients has now been supplanted by tamoxifen or by another class of drugs, the aromatase inhibitors (see Chapters 40 and 54). Aminoglutethimide can be used in conjunction with metyrapone or ketoconazole to reduce steroid secretion in patients with Cushing's syndrome due to adrenocortical cancer who do not respond to mitotane.

#### **Figure 39–5**

**Mitotane**

**Metyrapone**

**Aminoglutethimide**

**Ketoconazole**

Some adrenocortical antagonists. Because of their toxicity, some of these compounds are no longer available in the USA.

Aminoglutethimide also apparently increases the clearance of some steroids. It has been shown to enhance the metabolism of dexamethasone, reducing its half-life from 4½ hours to 2 hours.

### Ketoconazole

Ketoconazole, an antifungal imidazole derivative (see Chapter 48), is a potent and rather nonselective inhibitor of adrenal and gonadal steroid synthesis. This compound inhibits the cholesterol side-chain cleavage, P450c17, C17,20-lyase, 3β-hydroxysteroid dehydrogenase, and P450c11 enzymes required for steroid hormone synthesis. The sensitivity of the P450 enzymes to this compound in mammalian tissues is much lower than that needed to treat fungal infections, so that its inhibitory effects on steroid biosynthesis are seen only at high doses.

Ketoconazole has been used for the treatment of patients with Cushing's syndrome due to several causes. Dosages of 200–1200 mg/d have produced a reduction in hormone levels and clinical improvement in some patients. This drug has some hepatotoxicity and should be started at 200 mg/d and slowly increased by 200 mg/d every 2–3 days up to a total daily dose of 1000 mg.

### Metyrapone

Metyrapone (Figure 39–5) is a relatively selective inhibitor of steroid 11-hydroxylation, interfering with cortisol and corticosterone synthesis. In the presence of a normal pituitary gland, there is a compensatory increase in pituitary ACTH release and adrenal 11-deoxycortisol secretion. This response is a measure of the capacity of the anterior pituitary to produce ACTH and has been adapted for clinical use as a diagnostic test. Although the toxicity of metyrapone is much lower than that of mitotane (see text that follows), the drug may produce transient dizziness and gastrointestinal disturbances. This agent has not been widely used for the treatment of Cushing's syndrome. However, in doses of 0.25 g twice daily to 1 g four times daily, metyrapone can reduce cortisol production to normal levels in some patients with endogenous Cushing's syndrome. Thus, it may be useful in the management of severe manifestations of cortisol excess while the cause of this condition is being determined or in conjunction with radiation or surgical treatment. Metyrapone is the only adrenal-inhibiting medication that can be administered to pregnant women with Cushing's syndrome. The major adverse effects observed are salt and water retention and hirsutism resulting from diversion of the 11-deoxycortisol precursor to DOC and androgen synthesis.

Metyrapone is commonly used in tests of adrenal function. The blood levels of 11-deoxycortisol and the urinary excretion of 17-hydroxycorticoids are measured before and after administration of the compound. Normally, there is a twofold or greater increase in the urinary 17-hydroxycorticoid excretion. A dose of 300–500 mg every 4 hours for six doses is often used, and urine collections are made on the day before and the day after treatment. In patients with Cushing's syndrome, a normal response to metyrapone indicates that the cortisol excess is not the result of a cortisol-secreting adrenal carcinoma or adenoma, since secretion by such tumors produces suppression of ACTH and atrophy of normal adrenal cortex.

Pituitary function may also be tested by administering metyrapone, 2–3 g orally at midnight and by measuring the level of ACTH or 11-deoxycortisol in blood drawn at 8 AM or by comparing the excretion of 17-hydroxycorticosteroids in the urine during the 24-hour periods preceding and following administration of the drug. In patients with suspected or known lesions of the pituitary, this procedure is a means of estimating the ability of the gland to produce ACTH. Metyrapone has been withdrawn from the market in the USA but is available on a

compassionate basis.

### **Trilostane**

Trilostane is a 3 $\beta$ -17 hydroxysteroid dehydrogenase inhibitor that interferes with the synthesis of adrenal and gonadal hormones and is comparable to aminoglutethimide. Trilostane's adverse effects are predominantly gastrointestinal; adverse effects occur in about 50% of patients with both trilostane and aminoglutethimide. There is no cross-resistance or crossover of side effects between these compounds. Trilostane is not available in the USA.

### **Abiraterone**

Abiraterone is the newest of the steroid synthesis inhibitors to enter clinical trials. It blocks 17 $\alpha$ -hydroxylase (P450c17) and 17,20-lyase (Figure 39â€"1), and predictably reduces synthesis of cortisol and gonadal steroids in the adrenal and gonadal steroids in the gonads. A compensatory increase occurs in ACTH and aldosterone synthesis, but this can be prevented by concomitant administration of dexamethasone. Abiraterone is an orally active steroid prodrug and has been studied in the treatment of refractory prostate cancer.

### **Mifepristone (RU-486)**

The search for a glucocorticoid receptor antagonist finally succeeded in the early 1980s with the development of the 11 $\beta$ -aminophenyl-substituted 19-norsteroid called RU-486, later named mifepristone. Unlike the enzyme inhibitors previously discussed, mifepristone is a pharmacologic antagonist at the steroid receptor. This compound has strong antiprogesterin activity and initially was proposed as a contraceptive-contragestive agent. High doses of mifepristone exert antiglucocorticoid activity by blocking the glucocorticoid receptor, since mifepristone binds to it with high affinity, causing (1) some stabilization of the Hsp-glucocorticoid receptor complex and inhibition of the dissociation of the RU-486â€"bound glucocorticoid receptor from the Hsp chaperone proteins; and (2) alteration of the interaction of the glucocorticoid receptor with coregulators, favoring the formation of a transcriptionally inactive complex in the cell nucleus. The result is inhibition of glucocorticoid receptor activation.

The mean half-life of mifepristone is 20 hours. This is longer than that of many natural and synthetic glucocorticoid agonists (dexamethasone has a half-life of 4â€"5 hours). Less than 1% of the daily dose is excreted in the urine, suggesting a minor role of kidneys in the clearance of the compound. The long plasma half-life of mifepristone results from extensive and strong binding to plasma proteins. Less than 5% of the compound is found in the free form when plasma is analyzed by equilibrium dialysis. Mifepristone can bind to albumin and  $\alpha_1$ -acid glycoprotein, but it has no affinity for CBG.

In humans, mifepristone causes generalized glucocorticoid resistance. Given orally to several patients with Cushing's syndrome due to ectopic ACTH production or adrenal carcinoma, it was able to reverse the cushingoid phenotype, to eliminate carbohydrate intolerance, normalize blood pressure, to correct thyroid and gonadal hormone suppression, and to ameliorate the psychological sequelae of hypercortisolism in these patients. At present, this use of mifepristone can only be recommended for inoperable patients with ectopic ACTH secretion or adrenal carcinoma who have failed to respond to other therapeutic manipulations. Its pharmacology and use in women as a progesterone antagonist are discussed in Chapter 40.

### **Mitotane**

Mitotane (Figure 39â€"5), a drug related to the DDT class of insecticides, has a nonselective cytotoxic action on the adrenal cortex in dogs and to a lesser extent in humans. This drug is administered orally in divided doses up to 12 g daily. About one third of patients with adrenal carcinoma show a reduction in tumor mass. In 80% of patients, the toxic effects are sufficiently severe to require dose reduction. These include diarrhea, nausea, vomiting, depression, somnolence, and skin rashes. The drug has been withdrawn from the market in the USA but is available on a compassionate basis.

## **MINERALOCORTICOID ANTAGONISTS**

In addition to agents that interfere with aldosterone synthesis (see above), there are steroids that compete with aldosterone for its receptor and decrease its effect peripherally. Progesterone is mildly active in this respect.

**Spirolactone** is a 7 $\alpha$ -acetylthiospirolactone. Its onset of action is slow, and the effects last for 2â€"3 days after the drug is discontinued. It is used in the treatment of primary aldosteronism in dosages of 50â€"100 mg/d. This agent reverses many of the manifestations of aldosteronism. It has been useful in establishing the diagnosis in some patients and in ameliorating the signs and symptoms when surgical removal of an adenoma is delayed. When used diagnostically for the detection of aldosteronism in hypokalemic patients with hypertension, dosages of 400â€"500 mg/d for 4â€"8 daysâ€"with an adequate intake of sodium and potassiumâ€"restore potassium levels to or toward normal. Spirolactone is also useful in preparing these patients for surgery. Dosages of 300â€"400 mg/d for 2 weeks are used for this purpose and may reduce the incidence of cardiac arrhythmias.

**Spironolactone**

Spironolactone is also an androgen antagonist and as such is sometimes used in the treatment of hirsutism in women. Dosages of 50–200 mg/d cause a reduction in the density, diameter, and rate of growth of facial hair in patients with idiopathic hirsutism or hirsutism secondary to androgen excess. The effect can usually be seen in 2 months and becomes maximal in about 6 months.

Spironolactone as a diuretic is discussed in Chapter 15. The drug has benefits in heart failure greater than those predicted from its diuretic effects alone (see Chapter 13). Adverse effects reported for spironolactone include hyperkalemia, cardiac arrhythmia, menstrual abnormalities, gynecomastia, sedation, headache, gastrointestinal disturbances, and skin rashes.

**Eplerenone**, another aldosterone antagonist, is approved for the treatment of hypertension (see Chapters 11 and 15). This aldosterone receptor antagonist is somewhat more selective than spironolactone and has no reported effects on androgen receptors. The standard dosage in hypertension is 50–100 mg/d. The most common toxicity is hyperkalemia but this is usually mild.

**Drospirenone**, a progestin in an oral contraceptive, also antagonizes the effects of aldosterone.

## PREPARATIONS AVAILABLE<sup>1</sup>

### GLUCOCORTICOIDS FOR ORAL & PARENTERAL USE

**Betamethasone** (Celestone)

Oral: 0.6 mg/5 mL syrup

**Betamethasone sodium phosphate** (Celestone Phosphate)

Parenteral: 4 mg/mL for IV, IM, intralesional, or intra-articular injection

**Cortisone** (generic, Cortone Acetate)

Oral: 25 mg tablets

**Dexamethasone** (generic, Decadron)

Oral: 0.25, 0.5, 0.75, 1, 1.5, 2, 4, 6 mg tablets; 0.5 mg/5 mL elixir; 0.5 mg/5 mL, 1 mg/mL solution

**Dexamethasone acetate** (generic, Decadron-LA)

Parenteral: 8 mg/mL suspension for IM, intralesional, or intra-articular injection; 16 mg/mL suspension for intralesional injection

**Dexamethasone sodium phosphate** (generic, Decadron Phosphate)

Parenteral: 4, 10, 20 mg/mL for IV, IM, intralesional, or intra-articular injection; 24 mg/mL for IV use only

**Hydrocortisone [cortisol]** (generic, Cortef)

Oral: 5, 10, 20 mg tablets

**Hydrocortisone acetate** (generic)

Parenteral: 25, 50 mg/mL suspension for intralesional, soft tissue, or intra-articular injection

**Hydrocortisone cypionate** (Cortef)

Oral: 10 mg/5 mL suspension

**Hydrocortisone sodium phosphate** (Hydrocortone)

Parenteral: 50 mg/mL for IV, IM, or SC injection

**Hydrocortisone sodium succinate** (generic, SoluCortef)

Parenteral: 100, 250, 500, 1000 mg/vial for IV, IM injection

**Methylprednisolone** (generic, Medrol)

Oral: 2, 4, 8, 16, 24, 32 mg tablets

**Methylprednisolone acetate** (generic, DepoMedrol)

Parenteral: 20, 40, 80 mg/mL for IM, intralesional, or intra-articular injection

**Methylprednisolone sodium succinate** (generic, Solu-Medrol)

Parenteral: 40, 125, 500, 1000, 2000 mg/vial

**Prednisolone** (generic, Delta-Cortef, Prelone)

Oral: 5 mg tablets; 5, 15 mg/5 mL syrup

**Prednisolone acetate** (generic)

Parenteral: 25, 50 mg/mL for soft tissue or intra-articular injection

**Prednisolone sodium phosphate** (generic, Hydeltrasol)

Oral: 5 mg/5 mL solution

Parenteral: 20 mg/mL for IV, IM, intra-articular, or intralesional injection

**Prednisone** (generic, Meticorten)

Oral: 1, 2.5, 5, 10, 20, 50 mg tablets; 1, 5 mg/mL solution and syrup

**Triamcinolone acetonide** (generic, Kenalog)

Parenteral: 3, 10, 40 mg/mL for IM, intra-articular, or intralesional injection

**Triamcinolone hexacetonide** (Aristospan)

Parenteral: 5, 20 mg/mL for intra-articular, intralesional, or sublesional injection

## MINERALOCORTICOIDS

**Fludrocortisone acetate** (generic, Florinef Acetate)

Oral: 0.1 mg tablets

## ADRENAL STEROID INHIBITORS

**Ketoconazole** (generic, Nizoral)

Oral: 200 mg tablets (unlabeled use)

**Mifepristone** (Mifeprex)

Oral: 200 mg tablets

**Mitotane** (Lysodren)

Oral: 500 mg tablets

<sup>1</sup>Glucocorticoids for aerosol use: See Chapter 20. Glucocorticoids for dermatologic use: See Chapter 61. Glucocorticoids for gastrointestinal use: See Chapter 62.

Basic and Clinical Pharmacology > Chapter 40. The Gonadal Hormones & Inhibitors >

## ACRONYMS

**CBG** Corticosteroid-binding globulin (transcortin)

**DHEA** Dehydroepiandrosterone

**DHEAS** Dehydroepiandrosterone sulfate

**ERE** Estrogen response element

**FSH** Follicle-stimulating hormone

**GnRH** Gonadotropin-releasing hormone

**HDL** High-density lipoprotein

**HRT** Hormone replacement therapy (also called HT)

**LDL** Low-density lipoprotein

**LH** Luteinizing hormone

**PRE** Progesterone response element

**SERM** Selective estrogen receptor modulator

**SHBG** Sex hormone-binding globulin

**TBG** Thyroxine-binding globulin

## CASE STUDY

A 25-year-old woman with menarche at 13 years and normal menstrual periods until about 1 year ago complains of hot flushes, skin and vaginal dryness, weakness, poor sleep, and scanty and infrequent menstrual periods. She visits her gynecologist who obtains plasma levels of follicle-stimulating hormone and luteinizing hormone, both of which are moderately elevated. She is diagnosed with premature ovarian failure and recommended estrogen and progesterone replacement therapy. She is advised to start taking daily transdermal estradiol therapy (100 mcg/d) along with oral natural progesterone (200 mg/d) for the last 12 days of each 28-day cycle. She is also advised to get adequate exercise and increase her calcium and vitamin D intake. On this regimen, her symptoms disappear and she has normal monthly uterine bleeding.

## THE OVARY (ESTROGENS, PROGESTINS, OTHER OVARIAN HORMONES, ORAL CONTRACEPTIVES, INHIBITORS & ANTAGONISTS, & OVULATION-INDUCING AGENTS)

The ovary has important gametogenic functions that are integrated with its hormonal activity. In the human female, the gonad is relatively quiescent during childhood, the period of rapid growth and maturation. At puberty, the ovary begins a 30- to 40-year period of cyclic function called the **menstrual cycle** because of the regular episodes of bleeding that are its most obvious manifestation. It then fails to respond to gonadotropins secreted by the anterior pituitary gland, and the cessation of cyclic bleeding that occurs is called the **menopause**.

The mechanism responsible for the onset of ovarian function at the time of puberty is thought to be neural in origin, because the immature gonad can be stimulated by gonadotropins already present in the pituitary and because the pituitary is responsive to exogenous hypothalamic gonadotropin-releasing hormone. The maturation of centers in the brain may withdraw a childhood-related inhibitory effect upon hypothalamic arcuate nucleus neurons, allowing them to produce **gonadotropin-releasing hormone (GnRH)** in pulses with the appropriate amplitude, which stimulates the release of **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)** (see Chapter 37). At first, small amounts of the latter two hormones are released during the night, and the limited quantities of ovarian estrogen secreted in response start to cause breast development. Subsequently, FSH and LH are secreted throughout the day and night, causing secretion of higher amounts of estrogen and leading to further breast enlargement, alterations in fat distribution, and a growth spurt that culminates in epiphyseal closure in the long bones. The change of ovarian function at puberty is called **gonadarche**.

A year or so after gonadarche, sufficient estrogen is produced to induce endometrial changes and periodic bleeding. After the first few irregular cycles, which may be anovulatory, normal cyclic function is established.

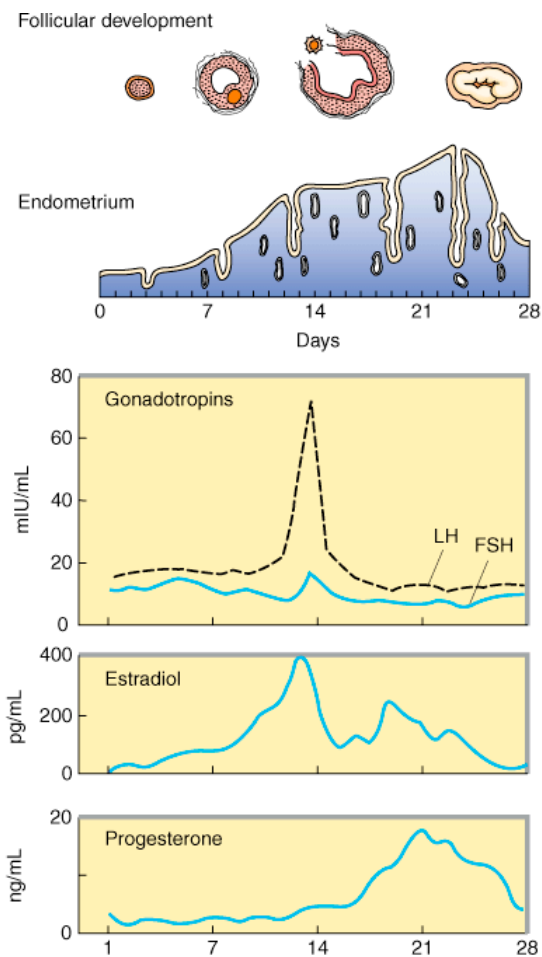

At the beginning of each cycle, a variable number of follicles (vesicular follicles), each containing an ovum, begin to enlarge in response to

FSH. After 5 or 6 days, one follicle, called the dominant follicle, begins to develop more rapidly. The outer theca and inner granulosa cells of this follicle multiply and, under the influence of LH, synthesize and release estrogens at an increasing rate. The estrogens appear to inhibit FSH release and may lead to regression of the smaller, less mature follicles. The mature dominant ovarian follicle consists of an ovum surrounded by a fluid-filled antrum lined by granulosa and theca cells. The estrogen secretion reaches a peak just before midcycle, and the granulosa cells begin to secrete progesterone. These changes stimulate the brief surge in LH and FSH release that precedes and causes ovulation. When the follicle ruptures, the ovum is released into the abdominal cavity near the opening of the uterine tube.

Following the above events, the cavity of the ruptured follicle fills with blood (corpus hemorrhagicum), and the luteinized theca and granulosa cells proliferate and replace the blood to form the corpus luteum. The cells of this structure produce estrogens and progesterone for the remainder of the cycle, or longer if pregnancy occurs.

If pregnancy does not occur, the corpus luteum begins to degenerate and ceases hormone production, eventually becoming a corpus albicans. The endometrium, which proliferated during the follicular phase and developed its glandular function during the luteal phase, is shed in the process of menstruation. These events are summarized in Figure 40â€1.

**Figure 40â€1**

The menstrual cycle, showing plasma levels of pituitary and ovarian hormones and histologic changes.

The ovary normally ceases its gametogenic and endocrine function with time. This change is accompanied by a cessation in uterine bleeding (menopause) and occurs at a mean age of 52 years in the USA. Although the ovary ceases to secrete estrogen, significant levels of estrogen persist in many women as a result of conversion of adrenal and ovarian steroids such as androstenedione to estrone and estradiol in adipose and possibly other nonendocrine tissues.

## Disturbances in Ovarian Function

Disturbances of cyclic function are common even during the peak years of reproduction. A minority of these result from inflammatory or neoplastic processes that influence the functions of the uterus, ovaries, or pituitary. Many of the minor disturbances leading to periods of amenorrhea or anovulatory cycles are self-limited. They are often associated with emotional or physical stress and reflect temporary alterations in the stress centers in the brain that control the secretion of GnRH. Anovulatory cycles are also associated with eating disorders (bulimia, anorexia nervosa) and with severe exercise such as distance running and swimming. Among the more common organic causes of persistent ovulatory disturbances are pituitary prolactinomas and syndromes and tumors characterized by excessive ovarian or adrenal androgen production. Normal ovarian function can be modified by androgens produced by the adrenal cortex or tumors arising from it. The ovary also gives rise to androgen-producing neoplasms such as arrhenoblastomas, as well as to estrogen-producing granulosa cell tumors.

## The Estrogens

Estrogenic activity is shared by a large number of chemical substances. In addition to the variety of steroidal estrogens derived from animal sources, numerous nonsteroidal estrogens have been synthesized. Many phenols are estrogenic, and estrogenic activity has been identified in such diverse forms of life as those found in ocean sediments. Estrogen-mimetic compounds (flavonoids) are found in many plants, including saw palmetto, and soybeans and other foods. Studies have shown that a diet rich in these plant products may produce slight estrogenic effects. Additionally, some compounds used in the manufacture of plastics (bisphenols, alkylphenols, phthalate phenols) have been found to be estrogenic. It has been proposed that these agents are associated with an increased breast cancer incidence in both women and men in the industrialized world.

## Natural Estrogens

The major estrogens produced by women are **estradiol** (estradiol-17 $\beta$ , E<sub>2</sub>), **estrone** (E<sub>1</sub>), and **estriol** (E<sub>3</sub>) (Figure 40â€"2). Estradiol is the major secretory product of the ovary. Although some estrone is produced in the ovary, most estrone and estriol are formed in the liver from estradiol or in peripheral tissues from androstenedione and other androgens (see Figure 39â€"1). As noted above, during the first part of the menstrual cycle estrogens are produced in the ovarian follicle by the theca and granulosa cells. After ovulation, the estrogens as well as progesterone are synthesized by the luteinized granulosa and theca cells of the corpus luteum, and the pathways of biosynthesis are slightly different.

Compounds with estrogenic activity.

**Table 40-1 Commonly Used Estrogens.**

Preparation	Average Replacement Dosage
Ethinyl estradiol	0.005-0.02 mg/d
Micronized estradiol	1-2 mg/d
Estradiol cypionate	2-5 mg every 3-4 weeks
Estradiol valerate	2-20 mg every other week
Estropipate	1.25-2.5 mg/d
Conjugated, esterified, or mixed estrogenic substances:	
Oral	0.3-1.25 mg/d
Injectable	0.2-2 mg/d
Transdermal	Patch
Quinestrol	0.1-0.2 mg/week
Chlorotrianisene	12-25 mg/d
Methallenestril	3-9 mg/d

In addition to the steroidal estrogens, a variety of nonsteroidal compounds with estrogenic activity have been synthesized and used clinically. These include dienestrol, diethylstilbestrol, benzestrol, hexestrol, methestrol, methallenestril, and chlorotrianisene (Figure 40-3).

## Pharmacokinetics

When released into the circulation, estradiol binds strongly to an  $\alpha_2$  globulin (sex hormone-binding globulin [SHBG]) and with lower affinity to albumin. Bound estrogen is relatively unavailable for diffusion into cells, and it is the free fraction that is physiologically active. Estradiol is converted by the liver and other tissues to estrone and estriol (Figure 40â€²2) and their 2-hydroxylated derivatives and conjugated metabolites (which are too insoluble in lipid to cross the cell membrane readily) and excreted in the bile. Estrone and estriol have low affinity for the estrogen receptor. However, the conjugates may be hydrolyzed in the intestine to active, reabsorbable compounds. Estrogens are also excreted in small amounts in the breast milk of nursing mothers.

Because significant amounts of estrogens and their active metabolites are excreted in the bile and reabsorbed from the intestine, the resulting enterohepatic circulation ensures that orally administered estrogens will have a high ratio of hepatic to peripheral effects. As noted below, the hepatic effects are thought to be responsible for some undesirable actions such as synthesis of increased clotting factors and plasma renin substrate. The hepatic effects of estrogen can be minimized by routes that avoid first-pass liver exposure, ie, vaginal, transdermal, or by injection.

## Physiologic Effects

### MECHANISM

Plasma estrogens in the blood and interstitial fluid are bound to SHBG, from which they dissociate to enter the cell and bind to their receptor. Two genes code for two estrogen receptor isoforms,  $\alpha$  and  $\beta$ , which are members of the superfamily of steroid, sterol, retinoic acid, and thyroid receptors. The estrogen receptors are found predominantly in the nucleus bound to heat shock proteins that stabilize them (see Figure 39â€²4).

Binding of the hormone to its receptor alters its conformation and releases it from the stabilizing proteins (predominantly Hsp90). The receptor-hormone complex forms homodimers that bind to a specific sequence of nucleotides called **estrogen response elements (EREs)** in the promoters of various genes and regulate their transcription. The ERE is composed of two half-sites arranged as a palindrome separated by a small group of nucleotides called the spacer. The interaction of a receptor dimer with the ERE also involves a number of nuclear proteins, the coregulators, as well as components of the transcription machinery. The receptor may also bind to other transcription factors to influence the effects of these factors on their responsive genes.

The relative concentrations and types of receptors, receptor coregulators, and transcription factors confer the cell specificity of the hormone's actions. The genomic effects of estrogens are mainly due to proteins synthesized by translation of RNA transcribed from a responsive gene. Some of the effects of estrogens are indirect, mediated by the autocrine and paracrine actions of autacoids such as growth factors, lipids, glycolipids, and cytokines produced by the target cells in response to estrogen.

Rapid estrogen-induced effects such as granulosa cell  $\text{Ca}^{2+}$  uptake and increased uterine blood flow do not require gene activation. These appear to be mediated by nongenomic effects of the classic estrogen receptor-estrogen complex, influencing several intracellular signaling pathways.

### FEMALE MATURATION

Estrogens are required for the normal sexual maturation and growth of the female. They stimulate the development of the vagina, uterus, and uterine tubes as well as the secondary sex characteristics. They stimulate stromal development and ductal growth in the breast and are responsible for the accelerated growth phase and the closing of the epiphyses of the long bones that occur at puberty. They contribute to the growth of axillary and pubic hair and alter the distribution of body fat to produce typical female body contours. Larger quantities also stimulate development of pigmentation in the skin, most prominent in the region of the nipples and areolae and in the genital region.

### ENDOMETRIAL EFFECTS

In addition to its growth effects on uterine muscle, estrogen plays an important role in the development of the endometrial lining. When estrogen production is properly coordinated with the production of progesterone during the normal human menstrual cycle, regular periodic bleeding and shedding of the endometrial lining occur. Continuous exposure to estrogens for prolonged periods leads to hyperplasia of the endometrium that is usually associated with abnormal bleeding patterns.

### METABOLIC AND CARDIOVASCULAR EFFECTS

Estrogens have a number of important metabolic and cardiovascular effects. They seem to be partially responsible for maintenance of the normal structure and function of the skin and blood vessels in women. Estrogens also decrease the rate of resorption of bone by promoting the apoptosis of osteoclasts and by antagonizing the osteoclastogenic and pro-osteoclastic effects of parathyroid hormone and interleukin-6. Estrogens also stimulate adipose tissue production of leptin and are in part responsible for the higher levels of this hormone in women than in men.

In addition to stimulating the synthesis of enzymes and growth factors leading to uterine and breast growth and differentiation, estrogens alter the production and activity of many other proteins in the body. Metabolic alterations in the liver are especially important, so that there is a higher circulating level of proteins such as transcortin (corticosteroid-binding globulin, CBG), thyroxine-binding globulin (TBG), SHBG, transferrin, renin substrate, and fibrinogen. This leads to increased circulating levels of thyroxine, estrogen, testosterone, iron, copper, and other substances.

Alterations in the composition of the plasma lipids caused by estrogens are characterized by an increase in the high-density lipoproteins (HDL), a slight reduction in the low-density lipoproteins (LDL), and a reduction in total plasma cholesterol levels. Plasma triglyceride levels are increased. Estrogens decrease hepatic oxidation of adipose tissue lipid to ketones and increase synthesis of triglycerides.

## **EFFECTS ON BLOOD COAGULATION**

Estrogens enhance the coagulability of blood. Many changes in factors influencing coagulation have been reported, including increased circulating levels of factors II, VII, IX, and X and decreased antithrombin III, partially as a result of the hepatic effects mentioned above. Increased plasminogen levels and decreased platelet adhesiveness have also been found (see Hormonal Contraception, below).

## **OTHER EFFECTS**

Estrogens induce the synthesis of progesterone receptors. They are responsible for estrous behavior in animals and may influence behavior and libido in humans. Administration of estrogens stimulates central components of the stress system, including the production of corticotropin-releasing hormone and the activity of the sympathetic system, and promotes a sense of well-being when given to women who are estrogen-deficient. They also facilitate the loss of intravascular fluid into the extracellular space, producing edema. The resulting decrease in plasma volume causes a compensatory retention of sodium and water by the kidney. Estrogens also modulate sympathetic nervous system control of smooth muscle function.

## **Clinical Uses\***

### **PRIMARY HYPOGONADISM**

Estrogens have been used extensively for replacement therapy in estrogen-deficient patients. The estrogen deficiency may be due to primary failure of development of the ovaries, premature menopause, castration, or menopause.

Treatment of primary hypogonadism is usually begun at 11-13 years of age in order to stimulate the development of secondary sex characteristics and menses, to stimulate optimal growth, to prevent osteoporosis and to avoid the psychologic consequences of delayed puberty and estrogen deficiency. Treatment attempts to mimic the physiology of puberty. It is initiated with small doses of estrogen (0.3 mg conjugated estrogens or 5-10 mcg ethinyl estradiol) on days 1-21 each month and is slowly increased to adult doses and then maintained until the age of menopause (approximately 51 years of age). A progestin is added after the first uterine bleeding. When growth is completed, chronic therapy consists mainly of the administration of adult doses of both estrogens and progestins, as described below.

\*The use of estrogens in contraception is discussed later in this chapter.

### **POSTMENOPAUSAL HORMONAL THERAPY**

In addition to the signs and symptoms that follow closely upon the cessation of normal ovarian function—such as loss of periods, vasomotor symptoms, sleep disturbances, and genital atrophy—there are longer-lasting changes that influence the health and well-being of postmenopausal women. These include an acceleration of bone loss, which in susceptible women may lead to vertebral, hip, and wrist fractures; and lipid changes, which may contribute to the acceleration of atherosclerotic cardiovascular disease noted in postmenopausal women. The effects of estrogens on bone have been extensively studied, and the effects of hormone withdrawal have been well-characterized. However, the role of estrogens and progestins in the cause and prevention of cardiovascular disease, which is responsible for 350,000 deaths per year, and breast cancer, which causes 35,000 deaths per year, is less well understood.

When normal ovulatory function ceases and the estrogen levels fall after menopause, oophorectomy, or premature ovarian failure, there is an accelerated rise in plasma cholesterol and LDL concentrations, while LDL receptors decline. HDL is not much affected, and levels remain higher than in men. Very-low-density lipoprotein and triglyceride levels are also relatively unaffected. Since cardiovascular disorders account for most deaths in this age group, the risk for these disorders constitutes a major consideration in deciding whether or not hormonal "replacement" therapy (HRT, also correctly called HT) is indicated and influences the selection of hormones to be administered. Estrogen replacement therapy has a beneficial effect on circulating lipids and lipoproteins, and this was earlier thought to be accompanied by a reduction in myocardial infarction by about 50% and of fatal strokes by as much as 40%. These findings, however, have been recently disputed by the results of a large study from the Women's Health Initiative (WHI) project showing no cardiovascular benefit from estrogen plus progestin replacement therapy in perimenopausal or older postmenopausal patients. In fact, there may be a small increase in cardiovascular problems as well as breast cancer in women who received the replacement therapy. Interestingly, a small protective effect against colon cancer was observed. Although current clinical guidelines do not recommend routine hormone therapy in postmenopausal women, the validity of the WHI report has been questioned. In any case, there is no increased risk for breast cancer if therapy is given immediately after menopause and for the first 7 years, while the cardiovascular risk depends on the degree of atherosclerosis at the onset of therapy. Transdermal or vaginal administration of estrogen may be associated with decreased cardiovascular risk because it bypasses the liver circulation. Women with premature menopause should definitely receive hormone therapy.

In other recent studies, a protective effect of estrogen replacement therapy against Alzheimer's disease was observed.

Progestins antagonize estrogen's effects on LDL and HDL to a variable extent. However, one large study has shown that the addition of a progestin to estrogen replacement therapy does not influence the cardiovascular risk.

Optimal management of the postmenopausal patient requires careful assessment of her symptoms as well as consideration of her age and the presence of (or risks for) cardiovascular disease, osteoporosis, breast cancer, and endometrial cancer. Bearing in mind the effects of the gonadal hormones on each of these disorders, the goals of therapy can then be defined and the risks of therapy assessed and discussed with the patient.

If the main indication for therapy is hot flashes and sleep disturbances, therapy with the lowest dose of estrogen required for symptomatic relief is recommended. Treatment may be required for only a limited period of time and the possible increased risk for breast cancer avoided. In women who have undergone hysterectomy, estrogens alone can be given 5 days per week or continuously, since progestins are not required to reduce the risk for endometrial hyperplasia and cancer. Hot flashes, sweating, insomnia, and atrophic vaginitis are generally relieved by estrogens; many patients experience some increased sense of well-being; and climacteric depression and other

psychopathologic states are improved.

The role of estrogens in the prevention and treatment of osteoporosis has been carefully studied (see Chapter 42). The amount of bone present in the body is maximal in the young active adult in the third decade of life and begins to decline more rapidly in middle age in both men and women. The development of osteoporosis also depends on the amount of bone present at the start of this process, on vitamin D and calcium intake, and on the degree of physical activity. The risk of osteoporosis is highest in smokers who are thin, Caucasian, and inactive and have a low calcium intake and a strong family history of osteoporosis. Depression also is a major risk factor for development of osteoporosis in women.

Estrogens should be used in the smallest dosage consistent with relief of symptoms. In women who have not undergone hysterectomy, it is most convenient to prescribe estrogen on the first 21 to 25 days of each month. The recommended dosages of estrogen are 0.3 to 1.25 mg/d of conjugated estrogen or 0.01 to 0.02 mg/d of ethinyl estradiol. Dosages in the middle of these ranges have been shown to be maximally effective in preventing the decrease in bone density occurring at menopause. From this point of view, it is important to begin therapy as soon as possible after the menopause for maximum effect. In these patients and others not taking estrogen, calcium supplements that bring the total daily calcium intake up to 1500 mg are useful.

Patients at low risk of developing osteoporosis who manifest only mild atrophic vaginitis can be treated with topical preparations. The vaginal route of application is also useful in the treatment of urinary tract symptoms in these patients. It is important to realize, however, that although locally administered estrogens escape the first-pass effect (so that some undesirable hepatic effects are reduced), they are almost completely absorbed into the circulation, and these preparations should be given cyclically.

As noted below, the administration of estrogen is associated with an increased risk of endometrial carcinoma. The administration of a progestational agent with the estrogen prevents endometrial hyperplasia and markedly reduces the risk of this cancer. When estrogen is given for the first 25 days of the month and the progestin medroxyprogesterone (10 mg/d) is added during the last 10 to 14 days, the risk is only half of that in women not receiving hormone replacement therapy. On this regimen, some women will experience a return of symptoms during the period off estrogen administration. In these patients, the estrogen can be given continuously. If the progestin produces sedation or other undesirable effects, its dose can be reduced to 2.5 to 5 mg for the last 10 days of the cycle with a slight increase in the risk for endometrial hyperplasia. These regimens are usually accompanied by bleeding at the end of each cycle. Some women experience migraine headaches during the last few days of the cycle. The use of a continuous estrogen regimen will often prevent their occurrence. Women who object to the cyclic bleeding associated with sequential therapy can also consider continuous therapy. Daily therapy with 0.625 mg of conjugated equine estrogens and 2.5 to 5 mg of medroxyprogesterone will eliminate cyclic bleeding, control vasomotor symptoms, prevent genital atrophy, maintain bone density, and show a favorable lipid profile with a small decrease in LDL and an increase in HDL concentrations. These women have endometrial atrophy on biopsy. About half of these patients experience breakthrough bleeding during the first few months of therapy. Seventy to 80 percent become amenorrheic after the first 4 months, and most remain so. The main disadvantage of continuous therapy is the need for uterine biopsy if bleeding occurs after the first few months.

As noted above, estrogens may also be administered vaginally or transdermally. When estrogens are given by these routes, the liver is bypassed on the first circulation, and the ratio of the liver effects to peripheral effects is reduced.

In patients in whom estrogen replacement therapy is contraindicated, such as those with estrogen-sensitive tumors, relief of vasomotor symptoms may be obtained by the use of clonidine.

#### **OTHER USES**

Estrogens combined with progestins can be used to suppress ovulation in patients with intractable dysmenorrhea or when suppression of ovarian function is used in the treatment of hirsutism and amenorrhea due to excessive secretion of androgens by the ovary. Under these circumstances, greater suppression may be needed, and oral contraceptives containing 50 mcg of estrogen or a combination of a low estrogen pill with GnRH suppression may be required.

#### **Adverse Effects**

Adverse effects of variable severity have been reported with the therapeutic use of estrogens. Many other effects reported in conjunction with hormonal contraceptives may be related to their estrogen content. These are discussed below.

#### **UTERINE BLEEDING**

Estrogen therapy is a major cause of postmenopausal uterine bleeding. Unfortunately, vaginal bleeding at this time of life may also be due to carcinoma of the endometrium. In order to avoid confusion, patients should be treated with the smallest amount of estrogen possible. It should be given cyclically so that bleeding, if it occurs, will be more likely to occur during the withdrawal period. As noted above, endometrial hyperplasia can be prevented by administration of a progestational agent with estrogen in each cycle.

#### **CANCER**

The relation of estrogen therapy to cancer continues to be the subject of active investigation. Although no adverse effect of short-term estrogen therapy on the incidence of breast cancer has been demonstrated, a small increase in the incidence of this tumor may occur with prolonged therapy. Although the risk factor is small (1.25), the impact may be great since this tumor occurs in 10% of women, and addition of progesterone does not confer a protective effect. Studies indicate that following unilateral excision of breast cancer, women receiving tamoxifen (an estrogen partial agonist, see below) show a 35% decrease in contralateral breast cancer compared with controls. These studies also demonstrate that tamoxifen is well tolerated by most patients, produces estrogen-like alterations in plasma lipid levels, and stabilizes bone mineral loss. Studies bearing on the possible efficacy of tamoxifen in postmenopausal women at high risk for breast cancer are under way. A recent study shows that postmenopausal hormone replacement therapy with estrogens plus progestins was

associated with greater breast epithelial cell proliferation and breast epithelial cell density than estrogens alone or no replacement therapy. Furthermore, with estrogens plus progestins, breast proliferation was localized to the terminal duct-lobular unit of the breast, which is the main site of development of breast cancer. Thus, further studies are needed to conclusively assess the possible association between progestins and breast cancer risk.

Many studies show an increased risk of endometrial carcinoma in patients taking estrogens alone. The risk seems to vary with the dose and duration of treatment: 15 times greater in patients taking large doses of estrogen for 5 or more years, in contrast with two to four times greater in patients receiving lower doses for short periods. However, as noted above, the concomitant use of a progestin prevents this increased risk and may in fact reduce the incidence of endometrial cancer to less than that in the general population.

There have been a number of reports of adenocarcinoma of the vagina in young women whose mothers were treated with large doses of diethylstilbestrol early in pregnancy. These cancers are most common in young women (ages 14-44). The incidence is less than 1 per 1000 women exposed—too low to establish a cause-and-effect relationship with certainty. However, the risks for infertility, ectopic pregnancy, and premature delivery are also increased. It is now recognized that there is no indication for the use of diethylstilbestrol during pregnancy, and it should be avoided. It is not known whether other estrogens have a similar effect or whether the observed phenomena are peculiar to diethylstilbestrol. This agent should be used only in the treatment of cancer (eg, of the prostate) or as a "morning after" contraceptive (see below).

#### **OTHER EFFECTS**

Nausea and breast tenderness are common and can be minimized by using the smallest effective dose of estrogen. Hyperpigmentation also occurs. Estrogen therapy is associated with an increase in frequency of migraine headaches as well as cholestasis, gallbladder disease, and hypertension.

#### **Contraindications**

Estrogens should not be used in patients with estrogen-dependent neoplasms such as carcinoma of the endometrium or in those with or at high risk for carcinoma of the breast. They should be avoided in patients with undiagnosed genital bleeding, liver disease, or a history of thromboembolic disorder. In addition, the use of estrogens should be avoided by heavy smokers.

#### **Preparations & Dosages**

The dosages of commonly used natural and synthetic preparations are listed in Table 40-1. Although all of the estrogens produce almost the same hormonal effects, their potencies vary both between agents and depending on the route of administration. As noted above, estradiol is the most active endogenous estrogen, and it has the highest affinity for the estrogen receptor. However, its metabolites estrone and estriol have weak uterine effects.

For a given level of gonadotropin suppression, oral estrogen preparations have more effect on the circulating levels of CBG, SHBG, and a host of other liver proteins, including angiotensinogen, than do transdermal preparations. The oral route of administration allows greater concentrations of hormone to reach the liver, thus increasing the synthesis of these proteins. Transdermal preparations were developed to avoid this effect. When administered transdermally, 50-100 mcg of estradiol has effects similar to those of 0.625-1.25 mg of conjugated oral estrogens on gonadotropin concentrations, endometrium, and vaginal epithelium. Furthermore, the transdermal estrogen preparations do not significantly increase the concentrations of renin substrate, CBG, and TBG and do not produce the characteristic changes in serum lipids. Combined oral preparations containing 0.625 mg of conjugated estrogens and 2.5 mg of medroxyprogesterone acetate are available for menopausal replacement therapy. Tablets containing 0.625 mg of conjugated estrogens and 5 mg of medroxyprogesterone acetate are available to be used in conjunction with conjugated estrogens in a sequential fashion. Estrogens alone are taken on days 1-14 and the combination on days 15-28.

### **The Progestins**

#### **Natural Progestins: Progesterone**

Progesterone is the most important progestin in humans. In addition to having important hormonal effects, it serves as a precursor to the estrogens, androgens, and adrenocortical steroids. It is synthesized in the ovary, testis, and adrenal from circulating cholesterol. Large amounts are also synthesized and released by the placenta during pregnancy.

In the ovary, progesterone is produced primarily by the corpus luteum. Normal males appear to secrete 5 mg of progesterone daily, resulting in plasma levels of about 0.03 mcg/dL. The level is only slightly higher in the female during the follicular phase of the cycle, when only a few milligrams per day of progesterone are secreted. During the luteal phase, plasma levels range from 0.5 mcg/dL to more than 2 mcg/dL (Figure 40-1). Plasma levels of progesterone are further elevated and reach their peak levels in the third trimester of pregnancy.

#### **Synthetic Progestins**

A variety of progestational compounds have been synthesized. Some are active when given by mouth. They are not a uniform group of compounds, and all of them differ from progesterone in one or more respects. Table 40-2 lists some of these compounds and their effects. In general, the 21-carbon compounds (hydroxyprogesterone, medroxyprogesterone, megestrol, and dimethisterone) are the most closely related, pharmacologically as well as chemically, to progesterone. A new group of third-generation synthetic progestins has been introduced, principally as components of oral contraceptives. These "19-nor, 13-ethyl" steroid compounds include desogestrel (Figure 40-4), gestodene, and norgestimate. They are claimed to have lower androgenic activity than older synthetic progestins.

#### **Table 40-2 Properties of Some Progestational Agents.**

	Route Duration of Action		Activities <sup>1</sup>				
			Estrogenic	Androgenic	Antiestrogenic	Antiandrogenic	Anabolic
<b>Progesterone and derivatives</b>							
Progesterone	IM	1 day	â€”	â€”	+	â€”	â€”

Progesterone and some progestational agents in clinical use.

## Pharmacokinetics

Progesterone is rapidly absorbed following administration by any route. Its half-life in the plasma is approximately 5 minutes, and small amounts are stored temporarily in body fat. It is almost completely metabolized in one passage through the liver, and for that reason it is quite ineffective when the usual formulation is administered orally. However, high-dose oral micronized progesterone preparations have been developed that provide adequate progestational effect.

In the liver, progesterone is metabolized to pregnanediol and conjugated with glucuronic acid. It is excreted into the urine as pregnanediol glucuronide. The amount of pregnanediol in the urine has been used as an index of progesterone secretion. This measure has been very useful in spite of the fact that the proportion of secreted progesterone converted to this compound varies from day to day and from individual to individual. In addition to progesterone, 20 $\alpha$ - and 20 $\beta$ -hydroxyprogesterone (20 $\alpha$ - and 20 $\beta$ -hydroxy-4-pregnene-3-one) are also found. These compounds have about one fifth the progestational activity of progesterone in humans and other species. Little is known of their physiologic role, but 20 $\alpha$ -hydroxyprogesterone is produced in large amounts in some species and may be of some importance biologically.

The usual routes of administration and durations of action of the synthetic progestins are listed in Table 40â€²2. Most of these agents are extensively metabolized to inactive products that are excreted mainly in the urine.

## Physiologic Effects

### MECHANISM

The mechanism of action of progesteroneâ€²described in more detail aboveâ€²is similar to that of other steroid hormones. Progestins enter the cell and bind to progesterone receptors that are distributed between the nucleus and the cytoplasm. The ligand-receptor complex binds to a progesterone response element (PRE) to activate gene transcription. The response element for progesterone appears to be similar to the corticosteroid response element, and the specificity of the response depends upon which receptor is present in the cell as well as upon other cell-specific receptor coregulators and interacting transcription factors. The progesterone-receptor complex forms a dimer before binding to DNA. Like the estrogen receptor, it can form heterodimers as well as homodimers between two isoforms: A and B. These isoforms are produced by alternative splicing of the same gene.

### EFFECTS OF PROGESTERONE

Progesterone has little effect on protein metabolism. It stimulates lipoprotein lipase activity and seems to favor fat deposition. The effects on carbohydrate metabolism are more marked. Progesterone increases basal insulin levels and the insulin response to glucose. There is usually no manifest change in carbohydrate tolerance. In the liver, progesterone promotes glycogen storage, possibly by facilitating the effect of insulin. Progesterone also promotes ketogenesis.

Progesterone can compete with aldosterone for the mineralocorticoid receptor of the renal tubule, causing a decrease in Na<sup>+</sup> reabsorption. This leads to an increased secretion of aldosterone by the adrenal cortex (eg, in pregnancy). Proges-terone increases body temperature in humans. The mechanism of this effect is not known, but an alteration of the temperature-regulating centers in the hypothalamus has been suggested. Progesterone also alters the function of the respiratory centers. The ventilatory response to CO<sub>2</sub> is increased by progesterone but synthetic progestins with an ethinyl group do not have respiratory effects. This leads to a measurable reduction in arterial and alveolar

PCO<sub>2</sub> during pregnancy and in the luteal phase of the menstrual cycle. Progesterone and related steroids also have depressant and hypnotic effects on the brain.

Progesterone is responsible for the alveolobular development of the secretory apparatus in the breast. It also participates in the preovulatory LH surge and causes the maturation and secretory changes in the endometrium that are seen following ovulation (Figure 40â€"1).

Progesterone decreases the plasma levels of many amino acids and leads to increased urinary nitrogen excretion. It induces changes in the structure and function of smooth endoplasmic reticulum in experimental animals.

Other effects of progesterone and its analogs are noted below in the section, Hormonal Contraception.

#### SYNTHETIC PROGESTINS

The 21-carbon progesterone analogs antagonize aldosterone-induced sodium retention (see above). The remaining compounds ("19-nortestosterone" third-generation agents) produce a decidual change in the endometrial stroma, do not support pregnancy in test animals, are more effective gonadotropin inhibitors, and may have minimal estrogenic and androgenic or anabolic activity (Table 40â€"2; Figure 40â€"4). They are sometimes referred to as "impeded androgens." Progestins without androgenic activity include desogestrel, norgestimate, and gestodene. The first two of these compounds are dispensed in combination with ethinyl estradiol for oral contraception (Table 40â€"3) in the USA. Oral contraceptives containing the progestins cyproterone acetate (also an antiandrogen) in combination with ethinyl estradiol are investigational in the USA.

**Table 40â€"3 Some Oral and Implantable Contraceptive Agents in Use.<sup>1</sup>**

	Estrogen (mg)	Progestin (mg)
<b>Monophasic combination tablets</b>		
Alesse, Aviane, Lessinea, Levlite	Ethinyl estradiol 0.02	L-Norgestrel 0.1

### Implantable progestin preparation

Implanon	. . .	Etonogestrel (one tube of 68 mg)	
----------	-------	----------------------------------	--

<sup>1</sup>The estrogen-containing compounds are arranged in order of increasing content of estrogen. Other preparations are available. (Ethinyl estradiol and mestranol have similar potencies.)

## Clinical Uses of Progestins

### THERAPEUTIC APPLICATIONS

The major uses of progestational hormones are for hormone replacement therapy (see above) and hormonal contraception (see below). In addition, they are useful in producing long-term ovarian suppression for other purposes. When used alone in large doses parenterally (eg, medroxyprogesterone acetate, 150 mg intramuscularly every 90 days), prolonged anovulation and amenorrhea result. This therapy has been employed in the treatment of dysmenorrhea, endometriosis, and bleeding disorders when estrogens are contraindicated, and for contraception. The major problem with this regimen is the prolonged time required in some patients for ovulatory function to return after cessation of therapy. It should not be used for patients planning a pregnancy in the near future. Similar regimens will relieve hot flashes in some menopausal women and can be used if estrogen therapy is contraindicated.

Medroxyprogesterone acetate, 10–20 mg orally twice weekly<sup>1</sup> or intramuscularly in doses of 100 mg/m<sup>2</sup> every 1–2 weeks<sup>2</sup> will prevent menstruation, but it will not arrest accelerated bone maturation in children with precocious puberty.

Progestins do not appear to have any place in the therapy of threatened or habitual abortion. Early reports of the usefulness of these agents resulted from the unwarranted assumption that after several abortions the likelihood of repeated abortions was over 90%. When progestational agents were administered to patients with previous abortions, a salvage rate of 80% was achieved. It is now recognized that similar patients abort only 20% of the time even when untreated. On the other hand, progesterone was given experimentally to delay premature labor with encouraging results.

Progesterone and medroxyprogesterone have been used in the treatment of women who have difficulty in conceiving and who demonstrate a slow rise in basal body temperature. There is no convincing evidence that this treatment is effective.

Preparations of progesterone and medroxyprogesterone have been used to treat premenstrual syndrome. Controlled studies have not confirmed the effectiveness of such therapy except when doses sufficient to suppress ovulation have been used.

### DIAGNOSTIC USES

Progesterone can be used as a test of estrogen secretion. The administration of progesterone, 150 mg/d, or medroxyprogesterone, 10 mg/d, for 5–7 days, is followed by withdrawal bleeding in amenorrheic patients only when the endometrium has been stimulated by estrogens. A combination of estrogen and progestin can be given to test the responsiveness of the endometrium in patients with amenorrhea.

### Contraindications, Cautions, & Adverse Effects

Studies of progestational compounds alone and with combination oral contraceptives indicate that the progestin in these agents may increase blood pressure in some patients. The more androgenic progestins also reduce plasma HDL levels in women. (See Hormonal Contraception, below.) Two recent studies suggest that combined progestin plus estrogen replacement therapy in postmenopausal women may increase breast cancer risk significantly compared with the risk in women taking estrogen alone. These findings require careful examination and if confirmed will lead to important changes in postmenopausal hormone replacement practice.

### Other Ovarian Hormones

The normal ovary produces small amounts of **androgens**, including testosterone, androstenedione, and dehydroepiandrosterone. Of these, only testosterone has a significant amount of biologic activity, although androstenedione can be converted to testosterone or estrone in peripheral tissues. The normal woman produces less than 200 mcg of testosterone in 24 hours, and about one third of this is probably formed in the ovary directly. The physiologic significance of these small amounts of androgens is not established, but they may be partly responsible for normal hair growth at puberty, for stimulation of female libido, and, possibly, for metabolic effects. Androgen production by the ovary may be markedly increased in some abnormal states, usually in association with hirsutism and amenorrhea as noted above.

The ovary also produces **inhibin** and **activin**. These peptides consist of several combinations of  $\alpha$  and  $\beta$  subunits and are described in greater detail later. The  $\alpha\beta$  dimer (inhibin) inhibits FSH secretion while the  $\beta\beta$  dimer (activin) increases FSH secretion. Studies in primates indicate that inhibin has no direct effect on ovarian steroidogenesis but that activin modulates the response to LH and FSH. For example, simultaneous treatment with activin and human FSH enhances FSH stimulation of progesterone synthesis and aromatase activity in granulosa cells. When combined with LH, activin suppressed the LH-induced progesterone response by 50% but markedly enhanced basal and LH-stimulated aromatase activity. Activin may also act as a growth factor in other tissues. The physiologic roles of these modulators are not fully understood.

**Relaxin** is another peptide that can be extracted from the ovary. The three-dimensional structure of relaxin is related to that of growth-

promoting peptides and is similar to that of insulin. Although the amino acid sequence differs from that of insulin, this hormone, like insulin, consists of two chains linked by disulfide bonds, cleaved from a prohormone. It is found in the ovary, placenta, uterus, and blood. Relaxin synthesis has been demonstrated in luteinized granulosa cells of the corpus luteum. It has been shown to increase glycogen synthesis and water uptake by the myometrium and decreases uterine contractility. In some species, it changes the mechanical properties of the cervix and pubic ligaments, facilitating delivery.

In women, relaxin has been measured by immunoassay. Levels were highest immediately after the LH surge and during menstruation. A physiologic role for this peptide has not been established.

Clinical trials with relaxin have been conducted in patients with dysmenorrhea. Relaxin has also been administered to patients in premature labor and during prolonged labor. When applied to the cervix of a woman at term, it facilitates dilation and shortens labor.

Several other nonsteroidal substances such as corticotropin-releasing hormone, follistatin, and prostaglandins are produced by the ovary. These probably have paracrine effects within the ovary.

## **Hormonal Contraception (Oral, Parenteral, & Implanted Contraceptives)**

A large number of oral contraceptives containing estrogens or progestins (or both) are now available for clinical use (Table 40-3). These preparations vary chemically and pharmacologically and have many properties in common as well as definite differences important for the correct selection of the optimum agent.

Two types of preparations are used for oral contraception: (1) combinations of estrogens and progestins and (2) continuous progestin therapy without concomitant administration of estrogens. The combination agents are further divided into **monophasic** forms (constant dosage of both components during the cycle) and **biphasic** or **triphasic** forms (dosage of one or both components is changed once or twice during the cycle). The preparations for oral use are all adequately absorbed, and in combination preparations the pharmacokinetics of neither drug is significantly altered by the other.

Only one implantable contraceptive preparation is available at present in the USA. Etonogestrel, also used in some oral contraceptives, is available in the subcutaneous implant form listed in Table 40-3. Several hormonal contraceptives are available as vaginal rings or intrauterine devices. Intramuscular injection of large doses of medroxyprogesterone also provides contraception of long duration.

### **Pharmacologic Effects**

#### **MECHANISM OF ACTION**

The combinations of estrogens and progestins exert their contraceptive effect largely through selective inhibition of pituitary function that results in inhibition of ovulation. The combination agents also produce a change in the cervical mucus, in the uterine endometrium, and in motility and secretion in the uterine tubes, all of which decrease the likelihood of conception and implantation. The continuous use of progestins alone does not always inhibit ovulation. The other factors mentioned, therefore, play a major role in the prevention of pregnancy when these agents are used.

#### **EFFECTS ON THE OVARY**

Chronic use of combination agents depresses ovarian function. Follicular development is minimal, and corpora lutea, larger follicles, stromal edema, and other morphologic features normally seen in ovulating women are absent. The ovaries usually become smaller even when enlarged before therapy.

The great majority of patients return to normal menstrual patterns when these drugs are discontinued. About 75% will ovulate in the first posttreatment cycle and 97% by the third posttreatment cycle. About 2% of patients remain amenorrheic for periods of up to several years after administration is stopped.

The cytologic findings on vaginal smears vary depending on the preparation used. However, with almost all of the combined drugs, a low maturation index is found because of the presence of progestational agents.

#### **EFFECTS ON THE UTERUS**

After prolonged use, the cervix may show some hypertrophy and polyp formation. There are also important effects on the cervical mucus, making it more like postovulation mucus, ie, thicker and less copious.

Agents containing both estrogens and progestins produce further morphologic and biochemical changes of the endometrial stroma under the influence of the progestin, which also stimulates glandular secretion throughout the luteal phase. The agents containing "19-nor" progestins—particularly those with the smaller amounts of estrogen—tend to produce more glandular atrophy and usually less bleeding.

#### **EFFECTS ON THE BREAST**

Stimulation of the breasts occurs in most patients receiving estrogen-containing agents. Some enlargement is generally noted. The administration of estrogens and combinations of estrogens and progestins tends to suppress lactation. When the doses are small, the effects on breast-feeding are not appreciable. Studies of the transport of the oral contraceptives into breast milk suggest that only small amounts of these compounds cross into the milk, and they have not been considered to be of importance.

#### **OTHER EFFECTS OF ORAL CONTRACEPTIVES**

##### **Effects on the Central Nervous System**

The central nervous system effects of the oral contraceptives have not been well studied in humans. A variety of effects of estrogen and progesterone have been noted in animals. Estrogens tend to increase excitability in the brain, whereas progesterone tends to decrease it. The thermogenic action of progesterone and some of the synthetic progestins is also thought to occur in the central nervous system.

It is very difficult to evaluate any behavioral or emotional effects of these compounds in humans. Although the incidence of pronounced changes in mood, affect, and behavior appears to be low, milder changes are commonly reported, and estrogens are being successfully employed in the therapy of premenstrual tension syndrome, postpartum depression, and climacteric depression.

#### **Effects on Endocrine Function**

The inhibition of pituitary gonadotropin secretion has been mentioned. Estrogens also alter adrenal structure and function. Estrogens given orally or at high doses increase the plasma concentration of the  $\alpha_2$  globulin that binds cortisol (corticosteroid-binding globulin). Plasma concentrations may be more than double the levels found in untreated individuals, and urinary excretion of free cortisol is elevated.

These preparations cause alterations in the renin-angiotensin-aldosterone system. Plasma renin activity has been found to increase, and there is an increase in aldosterone secretion.

Thyroxine-binding globulin is increased. As a result, total plasma thyroxine (T4) levels are increased to those commonly seen during pregnancy. Since more of the thyroxine is bound, the free thyroxine level in these patients is normal. Estrogens also increase the plasma level of SHBG and decrease plasma levels of free androgens by increasing their binding; large amounts of estrogen may decrease androgens by gonadotropin suppression.

#### **Effects on Blood**

Serious thromboembolic phenomena occurring in women taking oral contraceptives gave rise to a great many studies of the effects of these compounds on blood coagulation. A clear picture of such effects has not yet emerged. The oral contraceptives do not consistently alter bleeding or clotting times. The changes that have been observed are similar to those reported in pregnancy. There is an increase in factors VII, VIII, IX, and X and a decrease in antithrombin III. Increased amounts of coumarin anticoagulants may be required to prolong prothrombin time in patients taking oral contraceptives.

There is an increase in serum iron and total iron-binding capacity similar to that reported in patients with hepatitis.

Significant alterations in the cellular components of blood have not been reported with any consistency. A number of patients have been reported to develop folic acid deficiency anemias.

#### **Effects on the Liver**

These hormones also have profound effects on the function of the liver. Some of these effects are deleterious and will be considered below in the section on adverse effects. The effects on serum proteins result from the effects of the estrogens on the synthesis of the various  $\alpha_2$  globulins and fibrinogen. Serum haptoglobins produced in the liver are depressed rather than increased by estrogen. Some of the effects on carbohydrate and lipid metabolism are probably influenced by changes in liver metabolism (see below).

Important alterations in hepatic drug excretion and metabolism also occur. Estrogens in the amounts seen during pregnancy or used in oral contraceptive agents delay the clearance of sulfobromophthalein and reduce the flow of bile. The proportion of cholic acid in bile acids is increased while the proportion of chenodeoxycholic acid is decreased. These changes may be responsible for the observed increase in cholelithiasis associated with the use of these agents.

#### **Effects on Lipid Metabolism**

As noted above, estrogens increase serum triglycerides and free and esterified cholesterol. Phospholipids are also increased, as are HDL; levels of LDL usually decrease. Although the effects are marked with doses of 100 mcg of mestranol or ethinyl estradiol, doses of 50 mcg or less have minimal effects. The progestins (particularly the "19-nortestosterone" derivatives) tend to antagonize these effects of estrogen. Preparations containing small amounts of estrogen and a progestin may slightly decrease triglycerides and HDL.

#### **Effects on Carbohydrate Metabolism**

The administration of oral contraceptives produces alterations in carbohydrate metabolism similar to those observed in pregnancy. There is a reduction in the rate of absorption of carbohydrates from the gastrointestinal tract. Progesterone increases the basal insulin level and the rise in insulin induced by carbohydrate ingestion. Preparations with more potent progestins such as norgestrel may cause progressive decreases in carbohydrate tolerance over several years. However, the changes in glucose tolerance are reversible on discontinuing medication.

#### **Effects on the Cardiovascular System**

These agents cause small increases in cardiac output associated with higher systolic and diastolic blood pressure and heart rate. The pressure returns to normal when treatment is terminated. Although the magnitude of the pressure change is small in most patients, it is marked in a few. It is important that blood pressure be followed in each patient. An increase in blood pressure has been reported to occur in a few postmenopausal women treated with estrogens alone.

#### **Effects on the Skin**

The oral contraceptives have been noted to increase pigmentation of the skin (chloasma). This effect seems to be enhanced in women with dark complexions and by exposure to ultraviolet light. Some of the androgen-like progestins might increase the production of sebum, causing acne in some patients. However, since ovarian androgen is suppressed, many patients note decreased sebum production, acne, and terminal hair growth. The sequential oral contraceptive preparations as well as estrogens alone often decrease sebum production.

#### **Clinical Uses**

The most important use of combined estrogens and progestins is for oral contraception. A large number of preparations are available for this specific purpose, some of which are listed in Table 40-3. They are specially packaged for ease of administration. In general, they

are very effective; when these agents are taken according to directions, the risk of conception is extremely small. The pregnancy rate with combination agents is estimated to be about 0.5% per 100 woman years at risk. Contraceptive failure has been observed in some patients when one or more doses are missed, if phenytoin is also being used (which may increase catabolism of the compounds), or if antibiotics are taken that alter enterohepatic cycling of metabolites.

Progestins and estrogens are also useful in the treatment of endometriosis. When severe dysmenorrhea is the major symptom, the suppression of ovulation with estrogen alone may be followed by painless periods. However, in most patients this approach to therapy is inadequate. The long-term administration of large doses of progestins or combinations of progestins and estrogens prevents the periodic breakdown of the endometrial tissue and in some cases will lead to endometrial fibrosis and prevent the reactivation of implants for prolonged periods.

As is true with most hormonal preparations, many of the undesired effects are physiologic or pharmacologic actions that are objectionable only because they are not pertinent to the situation for which they are being used. Therefore, the product containing the smallest effective amounts of hormones should be selected for use.

### **Adverse Effects**

The incidence of serious known toxicities associated with the use of these drugs is low—far lower than the risks associated with pregnancy. There are a number of reversible changes in intermediary metabolism. Minor adverse effects are frequent, but most are mild and many are transient. Continuing problems may respond to simple changes in pill formulation. Although it is not often necessary to discontinue medication for these reasons, as many as one third of all patients started on oral contraception discontinue use for reasons other than a desire to become pregnant.

#### **MILD ADVERSE EFFECTS**

1. Nausea, mastalgia, breakthrough bleeding, and edema are related to the amount of estrogen in the preparation. These effects can often be alleviated by a shift to a preparation containing smaller amounts of estrogen or to agents containing progestins with more androgenic effects.
2. Changes in serum proteins and other effects on endocrine function (see above) must be taken into account when thyroid, adrenal, or pituitary function is being evaluated. Increases in sedimentation rate are thought to be due to increased levels of fibrinogen.
3. Headache is mild and often transient. However, migraine is often made worse and has been reported to be associated with an increased frequency of cerebrovascular accidents. When this occurs or when migraine has its onset during therapy with these agents, treatment should be discontinued.
4. Withdrawal bleeding sometimes fails to occur—most often with combination preparations—and may cause confusion with regard to pregnancy. If this is disturbing to the patient, a different preparation may be tried or other methods of contraception used.

#### **MODERATE ADVERSE EFFECTS**

Any of the following may require discontinuance of oral contraceptives:

1. Breakthrough bleeding is the most common problem in using progestational agents alone for contraception. It occurs in as many as 25% of patients. It is more frequently encountered in patients taking low-dose preparations than in those taking combination pills with higher levels of progestin and estrogen. The biphasic and triphasic oral contraceptives (Table 40-3) decrease breakthrough bleeding without increasing the total hormone content.
2. Weight gain is more common with the combination agents containing androgen-like progestins. It can usually be controlled by shifting to preparations with less progestin effect or by dieting.
3. Increased skin pigmentation may occur, especially in dark-skinned women. It tends to increase with time, the incidence being about 5% at the end of the first year and about 40% after 8 years. It is thought to be exacerbated by vitamin B deficiency. It is often reversible upon discontinuance of medication but may disappear very slowly.
4. Acne may be exacerbated by agents containing androgen-like progestins (Table 40-2), whereas agents containing large amounts of estrogen usually cause marked improvement in acne.
5. Hirsutism may also be aggravated by the "19-nortestosterone" derivatives, and combinations containing nonandrogenic progestins are preferred in these patients.
6. Ureteral dilation similar to that observed in pregnancy has been reported, and bacteriuria is more frequent.
7. Vaginal infections are more common and more difficult to treat in patients who are receiving oral contraceptives.
8. Amenorrhea occurs in some patients. Following cessation of administration of oral contraceptives, 95% of patients with normal menstrual histories resume normal periods and all but a few resume normal cycles during the next few months. However, some patients remain amenorrheic for several years. Many of these patients also have galactorrhea. Patients who have had menstrual irregularities before taking oral contraceptives are particularly susceptible to prolonged amenorrhea when the agents are discontinued. Prolactin levels should be measured in these patients, since many have prolactinomas.

#### **SEVERE ADVERSE EFFECTS**

##### **Vascular Disorders**

Thromboembolism was one of the earliest of the serious unanticipated effects to be reported and has been the most thoroughly studied.

##### **VENOUS THROMBOEMBOLIC DISEASE**

Superficial or deep thromboembolic disease in women not taking oral contraceptives occurs in about one patient per 1000 woman years. The overall incidence of these disorders in patients taking low-dose oral contraceptives is about three-fold higher. The risk for this disorder is increased during the first month of contraceptive use and remains constant for several years or more. The risk returns to normal within a month when use is discontinued. The risk of venous thrombosis or pulmonary embolism is increased among women with predisposing conditions such as stasis, altered clotting factors such as antithrombin III, increased levels of homocysteine, or injury. Genetic disorders, including mutations in the genes governing the production of protein C (factor V Leiden), protein S, hepatic cofactor II, and others, markedly increase the risk of venous thromboembolism. The incidence of these disorders is too low for cost-effective screening by current methods, but prior episodes or a family history may be helpful in identifying patients with increased risk.

The incidence of venous thromboembolism appears to be related to the estrogen but not the progestin content of oral contraceptives and is not related to age, parity, mild obesity, or cigarette smoking. Decreased venous blood flow, endothelial proliferation in veins and arteries, and increased coagulability of blood resulting from changes in platelet functions and fibrinolytic systems contribute to the increased incidence of thrombosis. The major plasma inhibitor of thrombin, antithrombin III, is substantially decreased during oral contraceptive use. This change occurs in the first month of treatment and lasts as long as treatment persists, reversing within a month thereafter.

#### **MYOCARDIAL INFARCTION**

The use of oral contraceptives is associated with a slightly higher risk of myocardial infarction in women who are obese, have a history of preeclampsia or hypertension, or have hyperlipoproteinemia or diabetes. There is a much higher risk in women who smoke. The risk attributable to oral contraceptives in women 30-40 years of age who do not smoke is about 4 cases per 100,000 users per year, as compared with 185 cases per 100,000 among women 40-44 who smoke heavily. The association with myocardial infarction is thought to involve acceleration of atherogenesis because of decreased glucose tolerance, decreased levels of HDL, increased levels of LDL, and increased platelet aggregation. In addition, facilitation of coronary arterial spasm may play a role in some of these patients. The progestational component of oral contraceptives decreases HDL cholesterol levels, in proportion to the androgenic activity of the progestin. The net effect, therefore, will depend on the specific composition of the pill used and the patient's susceptibility to the particular effects. Recent studies suggest that risk of infarction is not increased in past users who have discontinued oral contraceptives.

#### **CEREBROVASCULAR DISEASE**

The risk of stroke is concentrated in women over age 35. It is increased in current users of oral contraceptives but not in past users. However, subarachnoid hemorrhages have been found to be increased among both current and past users and may increase with time. The risk of thrombotic or hemorrhagic stroke attributable to oral contraceptives (based on older, higher-dose preparations) has been estimated to about 37 cases per 100,000 users per year.

In summary, available data indicate that oral contraceptives increase the risk of various cardiovascular disorders at all ages and among both smokers and nonsmokers. However, this risk appears to be concentrated in women 35 years of age or older who are heavy smokers. It is clear that these risk factors must be considered in each individual patient for whom oral contraceptives are being considered. Some experts have suggested that screening for coagulopathy should be performed before starting oral contraception.

#### **Gastrointestinal Disorders**

Many cases of cholestatic jaundice have been reported in patients taking progestin-containing drugs. The differences in incidence of these disorders from one population to another suggest that genetic factors may be involved. The jaundice caused by these agents is similar to that produced by other 17-alkyl-substituted steroids. It is most often observed in the first three cycles and is particularly common in women with a history of cholestatic jaundice during pregnancy. Jaundice and pruritus disappear 1-8 weeks after the drug is discontinued.

These agents have also been found to increase the incidence of symptomatic gallbladder disease, including cholecystitis and cholangitis. This is probably the result of the alterations responsible for jaundice and bile acid changes described above.

It also appears that the incidence of hepatic adenomas is increased in women taking oral contraceptives. Ischemic bowel disease secondary to thrombosis of the celiac and superior and inferior mesenteric arteries and veins has also been reported in women using these drugs.

#### **Depression**

Depression of sufficient degree to require cessation of therapy occurs in about 6% of patients treated with some preparations.

#### **Cancer**

The occurrence of malignant tumors in patients taking oral contraceptives has been studied extensively. It is now clear that these compounds *reduce* the risk of endometrial and ovarian cancer. The lifetime risk of breast cancer in the population as a whole does not seem to be affected by oral contraceptive use. Some studies have shown an increased risk in younger women, and it is possible that tumors that develop in younger women become clinically apparent sooner. The relation of risk of cervical cancer to oral contraceptive use is still controversial. It should be noted that a number of recent studies associate the use of oral contraceptives by women who are infected with human papillomavirus with an increased risk of cervical cancer.

#### **Other**

In addition to the above effects, a number of other adverse reactions have been reported for which a causal relation has not been established. These include alopecia, erythema multiforme, erythema nodosum, and other skin disorders.

#### **Contraindications & Cautions**

These drugs are contraindicated in patients with thrombophlebitis, thromboembolic phenomena, and cardiovascular and cerebrovascular

disorders or a past history of these conditions. They should not be used to treat vaginal bleeding when the cause is unknown. They should be avoided in patients with known or suspected tumors of the breast or other estrogen-dependent neoplasms. Since these preparations have caused aggravation of preexisting disorders, they should be avoided or used with caution in patients with liver disease, asthma, eczema, migraine, diabetes, hypertension, optic neuritis, retrobulbar neuritis, or convulsive disorders.

The oral contraceptives may produce edema, and for that reason they should be used with great caution in patients in heart failure or in whom edema is otherwise undesirable or dangerous.

Estrogens may increase the rate of growth of fibroids. Therefore, for women with these tumors, agents with the smallest amounts of estrogen and the most androgenic progestins should be selected. The use of progestational agents alone for contraception might be especially useful in such patients (see below).

These agents are contraindicated in adolescents in whom epiphysial closure has not yet been completed.

Women using oral contraceptives must be made aware of an important interaction that occurs with antimicrobial drugs. Because the normal gastrointestinal flora increase the enterohepatic cycling (and bioavailability) of estrogens, antimicrobial drugs that interfere with these organisms may reduce the efficacy of oral contraceptives. Additionally, coadministration with potent inducers of the hepatic microsomal metabolizing enzymes, such as rifampin, may increase liver catabolism of estrogens or progestins and diminish the efficacy of oral contraceptives.

### Contraception with Progestins Alone

Small doses of progestins administered orally or by implantation under the skin can be used for contraception. They are particularly suited for use in patients for whom estrogen administration is undesirable. They are about as effective as intrauterine devices or combination pills containing 20-30 mcg of ethinyl estradiol. There is a high incidence of abnormal bleeding.

Effective contraception can also be achieved by injecting 150 mg of depot medroxyprogesterone acetate (DMPA) every 3 months. After a 150 mg dose, ovulation is inhibited for at least 14 weeks. Almost all users experience episodes of unpredictable spotting and bleeding, particularly during the first year of use. Spotting and bleeding decrease with time, and amenorrhea is common. This preparation is not desirable for women planning a pregnancy soon after cessation of therapy because ovulation suppression can sometimes persist for as long as 18 months after the last injection. Long-term DMPA use reduces menstrual blood loss and is associated with a decreased risk of endometrial cancer. Suppression of endogenous estrogen secretion may be associated with a reversible reduction in bone density, and changes in plasma lipids are associated with an increased risk of atherosclerosis.

The progestin implant method utilizes the subcutaneous implantation of capsules containing etonogestrel. These capsules release one fifth to one third as much steroid as oral agents, are extremely effective, and last for 2-4 years. The low levels of hormone have little effect on lipoprotein and carbohydrate metabolism or blood pressure. The disadvantages include the need for surgical insertion and removal of capsules and some irregular bleeding rather than predictable menses. An association of intracranial hypertension with an earlier type of implant utilizing norgestrel was observed in a small number of women. Patients experiencing headache or visual disturbances should be checked for papilledema.

Contraception with progestins is useful in patients with hepatic disease, hypertension, psychosis or mental retardation, or prior thromboembolism. The side effects include headache, dizziness, bloating and weight gain of 1-2 kg, and a reversible reduction of glucose tolerance.

### Postcoital Contraceptives

Pregnancy can be prevented following coitus by the administration of estrogens alone, progestin alone, or in combination ("morning after" contraception). When treatment is begun within 72 hours, it is effective 99% of the time. Some effective schedules are shown in Table 40-4. The hormones are often administered with antiemetics, since 40% of the patients have nausea or vomiting. Other adverse effects include headache, dizziness, breast tenderness, and abdominal and leg cramps.

#### Table 40-4 Schedules for Use of Postcoital Contraceptives.

Conjugated estrogens: 10 mg three times daily for 5 days

Ethinyl estradiol: 2.5 mg twice daily for 5 days

Diethylstilbestrol: 50 mg daily for 5 days

Mifepristone: 600 mg once with misoprostol, 400 mcg once<sup>1</sup>

L-Norgestrel: 0.75 mg twice daily for 1 day (eg, Plan B<sup>2</sup>)

Norgestrel, 0.5 mg, with ethinyl estradiol, 0.05 mg (eg, Ovral, Preven<sup>2</sup>): Two tablets and then two in 12 hours

<sup>1</sup>Mifepristone given on day 1, misoprostol on day 3.

<sup>2</sup>Sold as emergency contraceptive kits.

Mifepristone, an antagonist at progesterone and glucocorticoid receptors, has a luteolytic effect and is effective as a postcoital contraceptive. When combined with a prostaglandin it is also an effective abortifacient.

### **Beneficial Effects of Oral Contraceptives**

It has become apparent that reduction in the dose of the constituents of oral contraceptives has markedly reduced mild and severe adverse effects, providing a relatively safe and convenient method of contraception for many young women. Treatment with oral contraceptives has also been shown to be associated with many benefits unrelated to contraception. These include a reduced risk of ovarian cysts, ovarian and endometrial cancer, and benign breast disease. There is a lower incidence of ectopic pregnancy. Iron deficiency and rheumatoid arthritis are less common, and premenstrual symptoms, dysmenorrhea, endometriosis, acne, and hirsutism may be ameliorated with their use.

## **ESTROGEN & PROGESTERONE INHIBITORS & ANTAGONISTS**

### **TAMOXIFEN & RELATED PARTIAL AGONIST ESTROGENS**

Tamoxifen, a competitive partial agonist inhibitor of estradiol at the estrogen receptor (Figure 40â€5), was the first **selective estrogen receptor modulator (SERM)** to be introduced. It is extensively used in the palliative treatment of breast cancer in postmenopausal women and is approved for chemoprevention of breast cancer in high-risk women (see Chapter 54). It is a nonsteroidal agent (see structure below) that is given orally. Peak plasma levels are reached in a few hours. Tamoxifen has an initial half-life of 7â€14 hours in the circulation and is predominantly excreted by the liver. It is used in doses of 10â€20 mg twice daily. Hot flushes and nausea and vomiting occur in 25% of patients, and many other minor adverse effects are observed. Studies of patients treated with tamoxifen as adjuvant therapy for early breast cancer have shown a 35% decrease in contralateral breast cancer. However, adjuvant therapy extended beyond 5 years in patients with breast cancer has shown no further improvement in outcome. **Toremifene** is a structurally similar compound with very similar properties, indications, and toxicities.

Control of ovarian secretion and the actions of its hormones. In the follicular phase the ovary produces mainly estrogens; in the luteal phase it produces estrogens and progesterone. SERMs, selective estrogen receptor modulators. See text.

Tamoxifen

Prevention of the expected loss of lumbar spine bone density and plasma lipid changes consistent with a reduction in the risk for atherosclerosis have also been reported in tamoxifen-treated patients following spontaneous or surgical menopause. However, this agonist activity also affects the uterus and may increase the risk of endometrial cancer.

**Raloxifene** is another partial estrogen agonist-antagonist (SERM) at some but not all target tissues. It has similar effects on lipids and bone but appears not to stimulate the endometrium or breast. Although subject to a high first-pass effect, raloxifene has a very large volume of distribution and a long half-life (> 24 hours), so it can be taken once a day. Raloxifene has been approved in the USA for the prevention of postmenopausal osteoporosis and prophylaxis of breast cancer in women with risk factors.

**Clomiphene** is an older partial agonist, a weak estrogen that also acts as a competitive inhibitor of endogenous estrogens (Figure 40â€5). It has found use as an ovulation-inducing agent (see below).

### MIFEPRISTONE

Mifepristone is a "19-norsteroid" that binds strongly to the progesterone receptor and inhibits the activity of progesterone. The drug has luteolytic properties in 80% of women when given in the midluteal period. The mechanism of this effect is unknown, but it may provide the basis for using mifepristone as a contraceptive (as opposed to an abortifacient). However, because the compound has a long half-life, large doses may prolong the follicular phase of the subsequent cycle and so make it difficult to use continuously for this purpose. A single dose of 600 mg is an effective emergency postcoital contraceptive, though it may result in delayed ovulation in the following cycle. As noted in Chapter 39, the drug also binds to and acts as an antagonist at the glucocorticoid receptor. Limited clinical studies suggest that mifepristone or other analogs with similar properties may be useful in the treatment of endometriosis, Cushing's syndrome, breast cancer, and possibly other neoplasms such as meningiomas that contain glucocorticoid or progesterone receptors.

Mifepristone

Mifepristone's major use thus far has been to terminate early pregnancies. Doses of 400â€600 mg/d for 4 days or 800 mg/d for 2 days successfully terminated pregnancy in over 85% of the women studied. The major adverse effect was prolonged bleeding that on most occasions did not require treatment. The combination of a single oral dose of 600 mg of mifepristone and a vaginal pessary containing 1 mg of prostaglandin E1 or oral misoprostol has been found to effectively terminate pregnancy in over 95% of patients treated during the first 7 weeks after conception. The adverse effects of the medications included vomiting, diarrhea, and abdominal or pelvic pain. As many as 5% of patients have vaginal bleeding requiring intervention. Because of these adverse effects, mifepristone is administered only by physicians at family planning centers. **Note:** In a very small number of cases, use of a vaginal tablet for the prostaglandin dose has been associated with sepsis, so it is recommended that *both* drugs be given by mouth in all patients.

ZK 98734 (lilopristone) is a potent experimental progesterone inhibitor and abortifacient in doses of 25 mg twice daily. Like mifepristone, it also appears to have antiglucocorticoid activity.

## DANAZOL

Danazol, an isoxazole derivative of ethisterone (17 $\alpha$ -ethinyltestosterone) with weak progestational, androgenic, and glucocorticoid activities, is used to suppress ovarian function. Danazol inhibits the midcycle surge of LH and FSH and can prevent the compensatory increase in LH and FSH following castration in animals, but it does not significantly lower or suppress basal LH or FSH levels in normal women (Figure 40 $\hat{c}$ 5). Danazol binds to androgen, progesterone, and glucocorticoid receptors and can translocate the androgen receptor into the nucleus to initiate androgen-specific RNA synthesis. It does not bind to intracellular estrogen receptors, but it does bind to sex hormone-binding and corticosteroid-binding globulins. It inhibits P450<sub>scc</sub> (the cholesterol side chain-cleaving enzyme), 3 $\beta$ -hydroxysteroid dehydrogenase, 17 $\alpha$ -hydroxysteroid dehydrogenase, P450<sub>c17</sub> (17 $\alpha$ -hydroxylase), P450<sub>c11</sub> (11 $\beta$ -hydroxylase), and P450<sub>c21</sub> (21 $\beta$ -hydroxylase). However, it does not inhibit aromatase, the enzyme required for estrogen synthesis. It increases the mean clearance of progesterone, probably by competing with the hormone for binding proteins, and may have similar effects on other active steroid hormones. Ethisterone, a major metabolite of danazol, has both progestational and mild androgenic effects.

Danazol is slowly metabolized in humans, having a half-life of over 15 hours. This results in stable circulating levels when the drug is administered twice daily. It is highly concentrated in the liver, adrenals, and kidneys and is excreted in both feces and urine.

Danazol has been employed as an inhibitor of gonadal function and has found its major use in the treatment of endometriosis. For this purpose, it can be given in a dosage of 600 mg/d. The dosage is reduced to 400 mg/d after 1 month and to 200 mg/d in 2 months. About 85% of patients show marked improvement in 3 $\hat{c}$ 12 months.

Danazol has also been used in the treatment of fibrocystic disease of the breast and hematologic or allergic disorders, including hemophilia, Christmas disease, idiopathic thrombocytopenic purpura, and angioneurotic edema.

The major adverse effects are weight gain, edema, decreased breast size, acne and oily skin, increased hair growth, deepening of the voice, headache, hot flushes, changes in libido, and muscle cramps. Although mild adverse effects are very common, it is seldom necessary to discontinue the drug because of them. Occasionally, because of its inherent glucocorticoid activity, danazol may cause adrenal suppression.

Danazol should be used with great caution in patients with hepatic dysfunction, since it has been reported to produce mild to moderate hepatocellular damage in some patients, as evidenced by enzyme changes. It is also contraindicated during pregnancy and breast-feeding, as it may produce urogenital abnormalities in the offspring.

## OTHER INHIBITORS

**Anastrozole**, a selective nonsteroidal inhibitor of aromatase (the enzyme required for estrogen synthesis, Figures 40 $\hat{c}$ 2 and 40 $\hat{c}$ 5), is effective in some women whose breast tumors have become resistant to tamoxifen (see Chapter 54). **Letrozole** is similar. **Exemestane**, a steroid molecule, is an irreversible inhibitor of aromatase. Like anastrozole and letrozole, it is approved for use in women with advanced breast cancer (see Chapter 54).

Several other aromatase inhibitors are undergoing clinical trials in patients with breast cancer. **Fadrozole** is an oral nonsteroidal (triazole) inhibitor of aromatase activity. These compounds appear to be as effective as tamoxifen. In addition to their use in breast cancer, aromatase inhibitors have been successfully employed as adjuncts to androgen antagonists in the treatment of precocious puberty and as primary treatment in the excessive aromatase syndrome.

**Fulvestrant** is a pure estrogen receptor antagonist that has been somewhat more effective than those with partial agonist effects in some patients who have become resistant to tamoxifen. ICI 164,384 is a newer antagonist; it inhibits dimerization of the occupied estrogen receptor and interferes with its binding to DNA. It has also been used experimentally in breast cancer patients who have become resistant to tamoxifen.

**GnRH** and its analogs (**nafarelin**, **buserelin**, etc) have become important in both stimulating and inhibiting ovarian function. They are discussed in Chapter 37.

## Ovulation-Inducing Agents

### CLOMIPHENE

Clomiphene citrate, a partial estrogen agonist, is closely related to the estrogen chlorotrianisene (Figure 40 $\hat{c}$ 3). This compound is well absorbed when taken orally. It has a half-life of 5 $\hat{c}$ 7 days and is excreted primarily in the urine. It exhibits significant protein binding and enterohepatic circulation and is distributed to adipose tissues.

### Pharmacologic Effects

#### MECHANISMS OF ACTION

Clomiphene is a partial agonist at estrogen receptors. The estrogenic agonist effects are best demonstrated in animals with marked gonadal deficiency. Clomiphene has also been shown to effectively inhibit the action of stronger estrogens. In humans it leads to an increase in the secretion of gonadotropins and estrogens by inhibiting estradiol's negative feedback effect on the gonadotropins (Figure 40 $\hat{c}$ 5).

#### EFFECTS

The pharmacologic importance of this compound rests on its ability to stimulate ovulation in women with oligomenorrhea or amenorrhea and ovulatory dysfunction. The majority of patients suffer from polycystic ovary syndrome, a common disorder affecting about 7% of women of reproductive age. The syndrome is characterized by gonadotropin-dependent ovarian hyperandrogenism associated with

anovulation and infertility. The disorder is frequently accompanied by adrenal hyperandrogenism. Clomiphene probably blocks the feedback inhibitory influence of estrogens on the hypothalamus, causing a surge of gonadotropins, which leads to ovulation.

### **Clinical Use**

Clomiphene is used in the treatment of disorders of ovulation in patients who wish to become pregnant. Usually, a single ovulation is induced by a single course of therapy, and the patient must be treated repeatedly until pregnancy is achieved, since normal ovulatory function does not usually resume. The compound is of no value in patients with ovarian or pituitary failure.

When clomiphene is administered in doses of 100 mg/d for 5 days, a rise in plasma LH and FSH is observed after several days. In patients who ovulate, the initial rise is followed by a second rise of gonadotropin levels just prior to ovulation.

### **Adverse Effects**

The most common adverse effects in patients treated with this drug are hot flushes, which resemble those experienced by menopausal patients. They tend to be mild, and disappear when the drug is discontinued. There have been occasional reports of eye symptoms due to intensification and prolongation of afterimages. These are generally of short duration. Headache, constipation, allergic skin reactions, and reversible hair loss have been reported occasionally.

The effective use of clomiphene is associated with some stimulation of the ovaries and usually with ovarian enlargement. The degree of enlargement tends to be greater and its incidence higher in patients who have enlarged ovaries at the beginning of therapy.

A variety of other symptoms such as nausea and vomiting, increased nervous tension, depression, fatigue, breast soreness, weight gain, urinary frequency, and heavy menses have also been reported. However, these appear to result from the hormonal changes associated with an ovulatory menstrual cycle rather than from the medication. The incidence of multiple pregnancy is approximately 10%. Clomiphene has not been shown to have an adverse effect when inadvertently given to women who are already pregnant.

### **Contraindications & Cautions**

Special precautions should be observed in patients with enlarged ovaries. These women are thought to be more sensitive to this drug and should receive small doses. Any patient who complains of abdominal symptoms should be examined carefully. Maximum ovarian enlargement occurs after the 5-day course has been completed, and many patients can be shown to have a palpable increase in ovarian size by the seventh to tenth days. Treatment with clomiphene for more than a year may be associated with an increased risk of low-grade ovarian cancer; however, the evidence for this effect is not conclusive.

Special precautions must also be taken in patients who have visual symptoms associated with clomiphene therapy, since these symptoms may make activities such as driving more hazardous.

### **Other Drugs Used in Ovulatory Disorders**

In addition to clomiphene, a variety of other hormonal and nonhormonal agents are used in treating anovulatory disorders. They are discussed in Chapter 37.

## **THE TESTIS (ANDROGENS & ANABOLIC STEROIDS, ANTIANDROGENS, & MALE CONTRACEPTION)**

The testis, like the ovary, has both gametogenic and endocrine functions. The onset of gametogenic function of the testes is controlled largely by the secretion of FSH by the pituitary. High concentrations of testosterone locally are also required for continuing sperm production in the seminiferous tubules. The Sertoli cells in the seminiferous tubules may be the source of the estradiol produced in the testes via aromatization of locally produced testosterone. With LH stimulation, testosterone is produced by the interstitial or Leydig cells found in the spaces between the seminiferous tubules.

The Sertoli cells in the testis synthesize and secrete a variety of active proteins, including Müllerian duct inhibitory factor, inhibin, and activin. As in the ovary, inhibin and activin appear to be the product of three genes that produce a common  $\alpha$  subunit and two  $\beta$  subunits, A and B. Activin is composed of the two  $\beta$  subunits ( $\beta_A\beta_B$ ). There are two inhibins (A and B), which contain the  $\alpha$  subunit and one of the  $\beta$  subunits. Activin stimulates pituitary FSH release and is structurally similar to transforming growth factor- $\beta$ , which also increases FSH. The inhibins in conjunction with testosterone and dihydrotestosterone are responsible for the feedback inhibition of pituitary FSH secretion.

### **Androgens & Anabolic Steroids**

In humans, the most important androgen secreted by the testis is testosterone. The pathways of synthesis of testosterone in the testes are similar to those previously described for the adrenal and ovary (Figures 39 and 40).

In men, approximately 8 mg of testosterone is produced daily. About 95% is produced by the Leydig cells and only 5% by the adrenals. The testis also secretes small amounts of another potent androgen, dihydrotestosterone, as well as androstenedione and dehydroepiandrosterone, which are weak androgens. Pregnenolone and progesterone and their 17-hydroxylated derivatives are also released in small amounts. Plasma levels of testosterone in males are about 0.6 mcg/dL after puberty and appear to decline after age 50. Testosterone is also present in the plasma of women in concentrations of approximately 0.03 mcg/dL and is derived in approximately equal parts from the ovaries and adrenals and by the peripheral conversion of other hormones.

About 65% of circulating testosterone is bound to sex hormone-binding globulin. SHBG is increased in plasma by estrogen, by thyroid

hormone, and in patients with cirrhosis of the liver. It is decreased by androgen and growth hormone and is lower in obese individuals. Most of the remaining testosterone is bound to albumin. Approximately 2% remains free and available to enter cells and bind to intracellular receptors.

### Metabolism

In many target tissues, testosterone is converted to dihydrotestosterone by 5 $\alpha$ -reductase. In these tissues, dihydrotestosterone is the major active androgen. The conversion of testosterone to estradiol by P450 aromatase also occurs in some tissues, including adipose tissue, liver, and the hypothalamus, where it may be of importance in regulating gonadal function.

The major pathway for the degradation of testosterone in humans occurs in the liver, with the reduction of the double bond and ketone in the A ring, as is seen in other steroids with a  $\Delta^4$ -ketone configuration in the A ring. This leads to the production of inactive substances such as androsterone and etiocholanolone that are then conjugated and excreted in the urine.

Androstenedione, dehydroepiandrosterone (DHEA), and dehydroepiandrosterone sulfate (DHEAS) are also produced in significant amounts in humans, although largely in the adrenal rather than in the testes. They contribute slightly to the normal maturation process supporting other androgen-dependent pubertal changes in the human, primarily development of pubic and axillary hair and bone maturation. As noted in Chapter 39, some studies suggest that DHEA and DHEAS may have other central nervous system and metabolic effects and may prolong life in rabbits. In men they may improve the sense of well-being and inhibit atherosclerosis. In a placebo-controlled clinical trial in patients with systemic lupus erythematosus, DHEA demonstrated some beneficial effects (see Adrenal Androgens, Chapter 39). Adrenal androgens are to a large extent metabolized in the same fashion as testosterone. Both steroids can be converted by peripheral tissues to estrone in very small amounts (1 $\alpha$ 5%). The P450 aromatase enzyme responsible for this conversion is also found in the brain and is thought to play an important role in development.

### Physiologic Effects

In the normal male, testosterone or its active metabolite 5 $\alpha$ -dihydrotestosterone is responsible for the many changes that occur in puberty. In addition to the general growth-promoting properties of androgens on body tissues, these hormones are responsible for penile and scrotal growth. Changes in the skin include the appearance of pubic, axillary, and beard hair. The sebaceous glands become more active, and the skin tends to become thicker and oilier. The larynx grows and the vocal cords become thicker, leading to a lower-pitched voice. Skeletal growth is stimulated and epiphyseal closure accelerated. Other effects include growth of the prostate and seminal vesicles, darkening of the skin, and increased skin circulation. Androgens play an important role in stimulating and maintaining sexual function in men. Androgens increase lean body mass and stimulate body hair growth and sebum secretion. Metabolic effects include the reduction of hormone binding and other carrier proteins and increased liver synthesis of clotting factors, triglyceride lipase,  $\alpha_1$ -antitrypsin, haptoglobin, and sialic acid. They also stimulate renal erythropoietin secretion and decrease HDL levels.

### Synthetic Steroids with Androgenic & Anabolic Action

Testosterone, when administered by mouth, is rapidly absorbed. However, it is largely converted to inactive metabolites, and only about one sixth of the dose administered is available in active form. Testosterone can be administered parenterally, but it has a more prolonged absorption time and greater activity in the propionate, enanthate, undecanoate, or cypionate ester forms. These derivatives are hydrolyzed to release free testosterone at the site of injection. Testosterone derivatives alkylated at the 17 position, eg, methyltestosterone and fluoxymesterone, are active when given by mouth.

Testosterone and its derivatives have been used for their anabolic effects as well as in the treatment of testosterone deficiency. Although testosterone and other known active steroids can be isolated in pure form and measured by weight, biologic assays are still used in the investigation of new compounds. In some of these studies in animals, the anabolic effects of the compound as measured by trophic effects on muscles or the reduction of nitrogen excretion may be dissociated from the other androgenic effects. This has led to the marketing of compounds claimed to have anabolic activity associated with only weak androgenic effects. Unfortunately, this dissociation is less marked in humans than in the animals used for testing (Table 40-5), and all are potent androgens.

**Table 40-5 Androgens: Preparations Available and Relative Androgenic:Anabolic Activity in Animals.**

Drug	Androgenic: Anabolic Activity
Testosterone	1:1
Testosterone cypionate	1:1
Testosterone enanthate	1:1
Methyltestosterone	1:1
Fluoxymesterone	1:2
Oxymetholone	1:3
Oxandrolone	1:3 $\alpha$ 1:13
Nandrolone decanoate	1:2.5 $\alpha$ 1:4

### Pharmacologic Effects

## MECHANISMS OF ACTION

Like other steroids, testosterone acts intracellularly in target cells. In skin, prostate, seminal vesicles, and epididymis, it is converted to  $5\alpha$ -dihydrotestosterone by  $5\alpha$ -reductase. In these tissues, dihydrotestosterone is the dominant androgen. The distribution of this enzyme in the fetus is different and has important developmental implications.

Testosterone and dihydrotestosterone bind to the intracellular androgen receptor, initiating a series of events similar to those described above for estradiol and progesterone, leading to growth, differentiation, and synthesis of a variety of enzymes and other functional proteins.

## EFFECTS

In the male at puberty, androgens cause development of the secondary sex characteristics (see above). In the adult male, large doses of testosterone—when given alone—or its derivatives suppress the secretion of gonadotropins and result in some atrophy of the interstitial tissue and the tubules of the testes. Since fairly large doses of androgens are required to suppress gonadotropin secretion, it has been postulated that inhibin, in combination with androgens, is responsible for the feedback control of secretion. In women, androgens are capable of producing changes similar to those observed in the prepubertal male. These include growth of facial and body hair, deepening of the voice, enlargement of the clitoris, frontal baldness, and prominent musculature. The natural androgens stimulate erythrocyte production.

The administration of androgens reduces the excretion of nitrogen into the urine, indicating an increase in protein synthesis or a decrease in protein breakdown within the body. This effect is much more pronounced in women and children than in normal men.

## Clinical Uses

### ANDROGEN REPLACEMENT THERAPY IN MEN

Androgens are used to replace or augment endogenous androgen secretion in hypogonadal men (Table 40-6). Even in the presence of pituitary deficiency, androgens are used rather than gonadotropin except when normal spermatogenesis is to be achieved. In patients with hypopituitarism, androgens are not added to the treatment regimen until puberty, at which time they are instituted in gradually increasing doses to achieve the growth spurt and the development of secondary sex characteristics. In these patients, therapy should be started with long-acting agents such as testosterone enanthate or cypionate in doses of 50 mg intramuscularly, initially every 4, then every 3, and finally every 2 weeks, with each change taking place at 3-month intervals. The dose is then doubled to 100 mg every 2 weeks until maturation is complete. Finally, it is changed to the adult replacement dose of 200 mg at 2-week intervals.

**Table 40-6 Androgen Preparations for Replacement Therapy.**

Drug	Route of Administration	Dosage
Methyltestosterone	Oral	25–50 mg/d
	Sublingual (buccal)	5–10 mg/d
Fluoxymesterone	Oral	2–10 mg/d
Testosterone enanthate	Intramuscular	See text
Testosterone cypionate	Intramuscular	See text
Testosterone	Transdermal	2.5–10 mg/d
	Topical gel (1%)	5–10 g/d

Testosterone propionate, though potent, has a short duration of action and is not practical for long-term use. Testosterone undecanoate can be given orally, administering large amounts of the steroid twice daily (eg, 40 mg/d); however, this is not recommended because oral testosterone administration has been associated with liver tumors. Testosterone can also be administered transdermally; skin patches or gels are available for scrotal or other skin area application. Two applications daily are usually required for replacement therapy. Implanted pellets and other longer-acting preparations are under study. The development of polycythemia or hypertension may require some reduction in dose.

### GYNECOLOGIC DISORDERS

Androgens are used occasionally in the treatment of certain gynecologic disorders, but the undesirable effects in women are such that they must be used with great caution. Androgens have been used to reduce breast engorgement during the postpartum period, usually in conjunction with estrogens. The weak androgen danazol is used in the treatment of endometriosis (see above).

Androgens are sometimes given in combination with estrogens for replacement therapy in the postmenopausal period in an attempt to eliminate the endometrial bleeding that may occur when only estrogens are used and to enhance libido. They have been used for chemotherapy of breast tumors in premenopausal women.

### USE AS PROTEIN ANABOLIC AGENTS

Androgens and anabolic steroids have been used in conjunction with dietary measures and exercises in an attempt to reverse protein loss after trauma, surgery, or prolonged immobilization and in patients with debilitating diseases.

### ANEMIA

In the past, large doses of androgens were employed in the treatment of refractory anemias such as aplastic anemia, Fanconi's anemia,

sickle cell anemia, myelofibrosis, and hemolytic anemias. Recombinant erythropoietin has largely replaced androgens for this purpose.

#### **OSTEOPOROSIS**

Androgens and anabolic agents have been used in the treatment of osteoporosis, either alone or in conjunction with estrogens. With the exception of substitution therapy in hypogonadism, bisphosphonates have largely replaced androgen use for this purpose.

#### **USE AS GROWTH STIMULATORS**

These agents have been used to stimulate growth in boys with delayed puberty. If the drugs are used carefully, these children will probably achieve their expected adult height. If treatment is too vigorous, the patient may grow rapidly at first but will not achieve full predicted final stature because of the accelerated epiphyseal closure that occurs. It is difficult to control this type of therapy adequately even with frequent x-ray examination of the epiphyses, since the action of the hormones on epiphyseal centers may continue for many months after therapy is discontinued.

#### **ANABOLIC STEROID AND ANDROGEN ABUSE IN SPORTS**

The use of anabolic steroids by athletes has received worldwide attention. Many athletes and their coaches believe that anabolic steroids in doses 10–200 times larger than the daily normal production increase strength and aggressiveness, thereby improving competitive performance. Such effects have been unequivocally demonstrated only in women. Furthermore, the adverse effects of these drugs clearly make their use inadvisable.

#### **AGING**

Androgen production falls with age in men and may contribute to the decline in muscle mass, strength, and libido. Preliminary studies of androgen replacement in aging males with low androgen levels show an increase in lean body mass and hematocrit and a decrease in bone turnover. Longer studies will be required to assess the usefulness of this therapy.

#### **Adverse Effects**

The adverse effects of these compounds are due largely to their masculinizing actions and are most noticeable in women and prepubertal children. In women, the administration of more than 200–300 mg of testosterone per month is usually associated with hirsutism, acne, amenorrhea, clitoral enlargement, and deepening of the voice. These effects may occur with even smaller doses in some women. Some of the androgenic steroids exert progestational activity, leading to endometrial bleeding upon discontinuation. These hormones also alter serum lipids and could conceivably increase susceptibility to atherosclerotic disease in women.

Except under the most unusual circumstances, androgens should not be used in infants. Recent studies in animals suggest that administration of androgens in early life may have profound effects on maturation of central nervous system centers governing sexual development, particularly in the female. Administration of these drugs to pregnant women may lead to masculinization or undermasculinization of the external genitalia in the female and male fetus, respectively. Although the above-mentioned effects may be less marked with the anabolic agents, they do occur.

Sodium retention and edema are not common but must be carefully watched for in patients with heart and kidney disease.

Most of the synthetic androgens and anabolic agents are 17-alkyl-substituted steroids. Administration of drugs with this structure is often associated with evidence of hepatic dysfunction. Hepatic dysfunction usually occurs early in the course of treatment, and the degree is proportionate to the dose. Bilirubin levels may increase until clinical jaundice is apparent. The cholestatic jaundice is reversible upon cessation of therapy, and permanent changes do not occur. In older males, prostatic hyperplasia may develop, causing urinary retention.

Replacement therapy in men may cause acne, sleep apnea, erythrocytosis, gynecomastia, and azoospermia. Supraphysiologic doses of androgens produce azoospermia and decrease in testicular size, both of which may take months to recover after cessation of therapy. The alkylated androgens in high doses can produce peliosis hepatica, cholestasis, and hepatic failure. They lower plasma HDL<sub>2</sub> and may increase LDL. Hepatic adenomas and carcinomas have also been reported. Behavioral effects include psychologic dependence, increased aggressiveness, and psychotic symptoms.

#### **Contraindications & Cautions**

The use of androgenic steroids is contraindicated in pregnant women or women who may become pregnant during the course of therapy.

Androgens should not be administered to male patients with carcinoma of the prostate or breast. Until more is known about the effects of these hormones on the central nervous system in developing children, they should be avoided in infants and young children.

Special caution is required in giving these drugs to children to produce a growth spurt. In most patients, the use of somatotropin is more appropriate (see Chapter 37).

Care should be exercised in the administration of these drugs to patients with renal or cardiac disease predisposed to edema. If sodium and water retention occurs, it will respond to diuretic therapy.

Methyltestosterone therapy is associated with creatinuria, but the significance of this finding is not known.

**Caution:** Several cases of hepatocellular carcinoma have been reported in patients with aplastic anemia treated with androgen anabolic therapy. Erythropoietin and colony-stimulating factors (see Chapter 33) should be used instead.

### **Androgen Suppression & Antiandrogens**

#### **ANDROGEN SUPPRESSION**

The treatment of advanced prostatic carcinoma often requires orchiectomy or large doses of estrogens to reduce available endogenous androgen. The psychologic effects of the former and gynecomastia produced by the latter make these approaches undesirable. As noted in Chapter 37, the GnRH analogs such as goserelin, nafarelin, buserelin, and leuprolide acetate produce effective gonadal suppression when blood levels are continuous rather than pulsatile (see Chapter 37 and Figure 40â€6).

**Figure 40â€6**

Control of androgen secretion and activity and some sites of action of antiandrogens: **(1)**, competitive inhibition of GnRH receptors; **(2)**, stimulation (+, pulsatile administration) or inhibition via desensitization of GnRH receptors ( $\hat{\text{C}}$ , continuous administration); **(3)**, decreased synthesis of testosterone in the testis; **(4)**, decreased synthesis of dihydrotestosterone by inhibition of  $5\alpha$ -reductase; **(5)**, competition for binding to cytosol androgen receptors.

## ANTIANDROGENS

The potential usefulness of antiandrogens in the treatment of patients producing excessive amounts of testosterone has led to the search for effective drugs that can be used for this purpose. Several approaches to the problem, especially inhibition of synthesis and receptor antagonism, have met with some success.

### Steroid Synthesis Inhibitors

**Ketoconazole**, used primarily in the treatment of fungal disease, is an inhibitor of adrenal and gonadal steroid synthesis, as described in Chapter 39. It does not affect ovarian aromatase, but it reduces human placental aromatase activity. It displaces estradiol and dihydrotestosterone from sex hormone-binding protein in vitro and increases the estradiol:testosterone ratio in plasma in vivo by a different mechanism. However, it does not appear to be clinically useful in women with increased androgens because of the toxicity associated with prolonged use of the 400–800 mg/d required. The drug has also been used experimentally to treat prostatic carcinoma, but the results have not been encouraging. Men treated with ketoconazole often develop reversible gynecomastia during therapy; this may be due to the demonstrated increase in the estradiol:testosterone ratio.

### Conversion of Steroid Precursors to Androgens

Several compounds have been developed that inhibit the 17-hydroxylation of progesterone or pregnenolone, thereby preventing the action of the side chain-splitting enzyme and the further transformation of these steroid precursors to active androgens. A few of these compounds have been tested clinically but have been too toxic for prolonged use. As noted in Chapter 39, **abiraterone**, a newer 17-hydroxylase inhibitor, may prove to be clinically successful.

Since dihydrotestosterone “not testosterone” appears to be the essential androgen in the prostate, androgen effects in this and similar dihydrotestosterone-dependent tissues can be reduced by an inhibitor of  $5\alpha$ -reductase (Figure 40–6). **Finasteride**, a steroid-like inhibitor of this enzyme, is orally active and causes a reduction in dihydrotestosterone levels that begins within 8 hours after administration and lasts for about 24 hours. The half-life is about 8 hours (longer in elderly individuals). Forty to 50 percent of the dose is metabolized; more than half is excreted in the feces. Finasteride has been reported to be moderately effective in reducing prostate size in men with benign prostatic hyperplasia and is approved for this use in the USA. The dosage is 5 mg/d. **Dutasteride** is a similar orally active steroid derivative with a slow onset of action and a much longer half-life than finasteride. The dose is 0.5 mg daily. These drugs are not approved for use in women or children, although finasteride has been used successfully in the treatment of hirsutism in women and early male pattern baldness in men (1 mg/d).

### Receptor Inhibitors

**Cyproterone** and **cyproterone acetate** are effective antiandrogens that inhibit the action of androgens at the target organ. The acetate form has a marked progestational effect that suppresses the feedback enhancement of LH and FSH, leading to a more effective antiandrogen effect. These compounds have been used in women to treat hirsutism and in men to decrease excessive sexual drive and are being studied in other conditions in which the reduction of androgenic effects would be useful. Cyproterone acetate in a dosage of 2 mg/d administered concurrently with an estrogen is used in the treatment of hirsutism in women, doubling as a contraceptive pill; it has orphan drug status in the USA.

**Flutamide**, a substituted anilide, is a potent antiandrogen that has been used in the treatment of prostatic carcinoma. Although not a steroid, it behaves like a competitive antagonist at the androgen receptor. It is rapidly metabolized in humans. It frequently causes mild gynecomastia (probably by increasing testicular estrogen production) and occasionally causes mild reversible hepatic toxicity. Administration of this compound causes some improvement in most patients with prostatic carcinoma who have not had prior endocrine therapy. Preliminary studies indicate that flutamide is also useful in the management of excess androgen effect in women.

Flutamide

**Bicalutamide** and **nilutamide** are potent orally active antiandrogens that can be administered as a single daily dose and are used in patients with metastatic carcinoma of the prostate. Studies in patients with carcinoma of the prostate indicate that these agents are well tolerated. Bicalutamide is recommended for use in combination with a GnRH analog (to reduce tumor flare) and may have fewer gastrointestinal side effects than flutamide. A dosage of 150–200 mg/d (when used alone) is required to reduce prostate-specific antigen levels to those achieved by castration, but, in combination with a GnRH analog, 50 mg/d may be adequate. Nilutamide is approved for use following surgical castration in a dosage of 300 mg/d for 30 days followed by 150 mg/d.

**Spirolactone**, a competitive inhibitor of aldosterone (see Chapter 15), also competes with dihydrotestosterone for the androgen receptors in target tissues. It also reduces 17 $\alpha$ -hydroxylase activity, lowering plasma levels of testosterone and androstenedione. It is used in dosages of 50–200 mg/d in the treatment of hirsutism in women and appears to be as effective as finasteride, flutamide, or cyproterone in this condition.

### Chemical Contraception in Men

Although many studies have been conducted, an effective oral contraceptive for men has not yet been found. For example, various androgens, including testosterone and testosterone enanthate, in a dosage of 400 mg per month, produced azoospermia in less than half the men treated. Minor adverse reactions, including gynecomastia and acne, were encountered. Testosterone in combination with danazol was well tolerated but no more effective than testosterone alone. Androgens in combination with a progestin such as medroxyprogesterone acetate were no more effective. However, preliminary studies indicate that the intramuscular administration of 100 mg of testosterone enanthate weekly together with 500 mg of levonorgestrel daily orally can produce azoospermia in 94% of men.

Cyproterone acetate, a very potent progestin and antiandrogen, also produces oligospermia; however, it does not cause reliable contraception.

At present, pituitary hormones and potent antagonist analogs of GnRH are receiving increased attention. A GnRH antagonist in combination with testosterone has been shown to produce reversible azoospermia in nonhuman primates.

### GOSSYPOL

Extensive trials of this cottonseed derivative have been conducted in China. This compound destroys elements of the seminiferous epithelium but does not significantly alter the endocrine function of the testis.

In Chinese studies, large numbers of men were treated with 20 mg/d of gossypol or gossypol acetic acid for 2 months, followed by a maintenance dosage of 60 mg/wk. On this regimen, 99% of men developed sperm counts below 4 million/mL. Preliminary data indicate that recovery (return of normal sperm count) following discontinuance of gossypol administration is more apt to occur in men whose counts do not fall to extremely low levels and when administration is not continued for more than 2 years. Hypokalemia is the major adverse effect and may lead to transient paralysis. Because of low efficacy and significant toxicity, gossypol has been abandoned as a candidate male contraceptive.

## PREPARATIONS AVAILABLE<sup>1</sup>

### ESTROGENS

#### Conjugated estrogens (Premarin)

Oral: 0.3, 0.45, 0.625, 0.9, 1.25 mg tablets

Parenteral: 25 mg/5 mL for IM, IV injection

Vaginal: 0.625 mg/g cream base

#### Diethylstilbestrol (Stilphostrol)

Oral: 50 mg tablets

Parenteral: 0.25 g

#### Esterified estrogens (Cenestin, Enjuvia, Menest)

Oral: 0.3, 0.45, 0.625, 0.9, 1.25, 2.5 mg tablets

#### Estradiol cypionate in oil (Depo-Estradiol)

Parenteral: 5 mg/mL for IM injection

**Estradiol** (generic, Estrace, others)

Oral: 0.45, 0.5, 0.9, 1, 1.5, 1.8, 2 mg tablets

Vaginal: 0.1 mg/g cream, 2 mg ring, 25 mcg tablets

**Estradiol transdermal** (generic, Estraderm, many others)

Transdermal patch: 0.014, 0.025, 0.0375, 0.05, 0.06, 0.075, 0.1 mg/d release rates

Topical: 2.5 mg/g emulsion (Estrasorb); 0.75 mg/1.25 g unit dose (Estrogel)

**Estradiol valerate in oil** (generic)

Parenteral: 10, 20, 40 mg/mL for IM injection

**Estrone** (Menest)

Oral: 0.3, 0.625, 1.25, 2.5 mg tablets

**Estropipate** (generic, Ogen)

Oral: 0.625, 1.25, 2.5, 5 mg tablets

Vaginal: 1.5 mg/g cream base

## PROGESTINS

**Levonorgestrel** (Norplant)

Kit for subcutaneous implant: 6 capsules of 36 mg each

Intrauterine system: 52 mg

**Medroxyprogesterone acetate** (generic, Provera)

Oral: 2.5, 5, 10 mg tablets

Parenteral (Depo-Provera): 150, 400 mg/mL for IM injection

**Megestrol acetate** (generic, Megace)

Oral: 20, 40 mg tablets; 40, 125 mg/mL suspension

**Norethindrone acetate** (generic, Aygestin)

Oral: 5 mg tablets

**Progesterone** (generic)

Oral: 100, 200 mg capsules

Topical: 4, 8% vaginal gel, 100 mg insert

Parenteral: 50 mg/mL in oil for IM injection

Intrauterine contraceptive system: 38 mg in silicone

## ANDROGENS & ANABOLIC STEROIDS

**Fluoxymesterone** (generic)

Oral: 10 mg tablets

**Methyltestosterone** (generic)

Oral: 10, 25 mg tablets; 10 mg capsules; 10 mg buccal tablets

**Nandrolone decanoate** (generic)

Parenteral: 100, 200 mg/mL in oil for injection

**Oxandrolone** (Oxandrin)

Oral: 2.5, 10 mg tablets

**Oxymetholone** (Androl-50)

Oral: 50 mg tablets

**Testosterone**

Buccal system: 30 mg

**Testosterone cypionate in oil** (generic, Depo-testosterone)

Parenteral: 100, 200 mg/mL for IM injection

**Testosterone enanthate in oil** (generic, Delatestryl)

Parenteral: 200 mg/mL for IM injection

**Testosterone transdermal system**

Patch (Androderm): 2.5, 5 mg/24 h release rate

Gel (AndroGel): 1%

**Testosterone pellets** (Testopel)

Parenteral: 75 mg/pellet for parenteral injection (not IV)

**ANTAGONISTS & INHIBITORS**

See also Chapter 37

**Anastrozole** (Arimidex)

Oral: 1 mg tablets

**Bicalutamide** (Casodex)

Oral: 50 mg tablets

**Clomiphene** (generic, Clomid, Serophene, Milophene)

Oral: 50 mg tablets

**Danazol** (generic, Danocrine)

Oral: 50, 100, 200 mg capsules

**Dutasteride** (Avodart)

Oral: 0.5 mg tablets

**Exemestane** (Aromasin)

Oral: 25 mg tablets

**Finasteride**

Oral: 1 mg tablets (Propecia); 5 mg tablets (Proscar)

**Flutamide** (Eulexin)

Oral: 125 mg capsules

**Fulvestrant** (Faslodex)

Parenteral: 50 mg/mL for IM injection

**Letrozole** (Femara)

Oral: 2.5 mg tablets

**Mifepristone** (Mifeprex)

Oral: 200 mg tablets

**Nilutamide** (Nilandron)

Oral: 50, 150 mg tablets

**Raloxifene** (Evista)

Oral: 60 mg tablets

**Tamoxifen** (generic, Nolvadex)

Oral: 10, 20 mg tablets; 10 mg/5 mL oral solution

**Toremifene** (Fareston)

Oral: 60 mg tablets

<sup>1</sup>Oral contraceptives are listed in Table 40â€³.

Basic and Clinical Pharmacology > Chapter 41. Pancreatic Hormones & Antidiabetic Drugs >

## CASE STUDY

A 56-year-old Hispanic woman presents to her medical practitioner with symptoms of fatigue, increased thirst, frequent urination, and exercise intolerance with shortness of breath for many months. She does not get regular medical care and is unaware of any medical problems. Her family history is significant for obesity, diabetes, high blood pressure, and coronary artery disease in both parents and several siblings. She is not treated with any medications. Five of her six children had a birthweight of over 9 pounds. Physical examination reveals a BMI (body mass index) of 34, blood pressure of 150/90 mm Hg, and evidence of mild peripheral neuropathy. Laboratory tests reveal a random blood sugar of 261 mg/dL. This is confirmed with a fasting plasma glucose of 192 mg/dL; a fasting lipid panel reveals total cholesterol 264 mg/dL, triglycerides 255 mg/dL, high-density lipoproteins 43 mg/dL, and low-density lipoproteins 170 mg/dL. What kind of diabetes does this woman have? What further evaluations should be obtained? How would you treat her diabetes?

## THE ENDOCRINE PANCREAS

The endocrine pancreas in the adult human consists of approximately 1 million islets of Langerhans interspersed throughout the pancreatic gland. Within the islets, at least four hormone-producing cells are present (Table 41-1). Their hormone products include **insulin**, the storage and anabolic hormone of the body; **islet amyloid polypeptide (IAPP, or amylin)**, which modulates appetite, gastric emptying, and glucagon and insulin secretion; **glucagon**, the hyperglycemic factor that mobilizes glycogen stores; **somatostatin**, a universal inhibitor of secretory cells; **gastrin**, which stimulates gastric acid secretion; and **pancreatic peptide**, a small protein that facilitates digestive processes by a mechanism not yet clarified.

**Table 41-1 Pancreatic Islet Cells and Their Secretory Products.**

Cell Types	Approximate Percent of Islet Mass	Secretory Products
Alpha (A) cell	20	Glucagon, proglucagon
Beta (B) cell	75	Insulin, C-peptide, proinsulin, amylin
Delta (D) cell	3-5	Somatostatin
G cell	1	Gastrin
F cell (PP cell) <sup>1</sup>	1	Pancreatic polypeptide (PP)

<sup>1</sup>Within pancreatic polypeptide-rich lobules of adult islets, located only in the posterior portion of the head of the human pancreas, glucagon cells are scarce (< 0.5%) and F cells make up as much as 80% of the cells.

**Diabetes mellitus** is defined as an elevated blood glucose associated with absent or inadequate pancreatic insulin secretion, with or without concurrent impairment of insulin action. The disease states underlying the diagnosis of diabetes mellitus are now classified into four categories: type 1, *insulin-dependent diabetes*; type 2, *non-insulin-dependent diabetes*; type 3, *other*; and type 4, *gestational diabetes mellitus* (Expert Committee, 2003).

### Type 1 Diabetes Mellitus

The hallmark of type 1 diabetes is selective beta cell (B cell) destruction and *severe* or *absolute* insulin deficiency. Type 1 diabetes is further subdivided into immune and idiopathic causes. The immune form is the most common form of type 1 diabetes. Although most patients are younger than 30 years of age at the time of diagnosis, the onset can occur at any age. Type 1 diabetes is found in all ethnic groups, but the highest incidence is in people from northern Europe and from Sardinia. Susceptibility appears to involve a multifactorial genetic linkage, but only 10-15% of patients have a positive family history.

For persons with type 1 diabetes, insulin replacement therapy is necessary to sustain life. Pharmacologic insulin is administered by injection into the subcutaneous tissue using a manual injection device or an insulin pump that continuously infuses insulin under the skin. Interruption of the insulin replacement therapy can be life-threatening and can result in **diabetic ketoacidosis** or death. Diabetic ketoacidosis is caused by insufficient or absent insulin and results from excess release of fatty acids and subsequent formation of toxic levels of ketoacids.

### Type 2 Diabetes Mellitus

Type 2 diabetes is characterized by tissue resistance to the action of insulin combined with a *relative* deficiency in insulin secretion. A given individual may have more resistance or more beta-cell deficiency, and the abnormalities may be mild or severe. Although insulin is produced by the beta cells in these patients, it is inadequate to overcome the resistance, and the blood glucose rises. The impaired insulin action also affects fat metabolism, resulting in increased free fatty acid flux and triglyceride levels and reciprocally low levels of high-density lipoprotein (HDL).

Individuals with type 2 diabetes may not require insulin to survive, but 30% or more will benefit from insulin therapy to control blood glucose. It is likely that 10-20% of individuals in whom type 2 diabetes was initially diagnosed actually have both type 1 and type 2 or a slowly progressing type 1 called latent autoimmune diabetes of adults (LADA), and they will ultimately require full insulin replacement. Although persons with type 2 diabetes ordinarily do not develop ketosis, ketoacidosis may occur as the result of stress such as infection or the use of medication that enhances resistance, eg,

corticosteroids. Dehydration in untreated and poorly controlled individuals with type 2 diabetes can lead to a life-threatening condition called *nonketotic hyperosmolar coma*. In this condition, the blood glucose may rise to 6â€20 times the normal range and an altered mental state develops or the person loses consciousness. Urgent medical care and rehydration is required.

### Type 3 Diabetes Mellitus

The type 3 designation refers to multiple *other* specific causes of an elevated blood glucose: pancreatectomy, pancreatitis, nonpancreatic diseases, drug therapy, etc. For a detailed list the reader is referred to Expert Committee, 2003.

### Type 4 Diabetes Mellitus

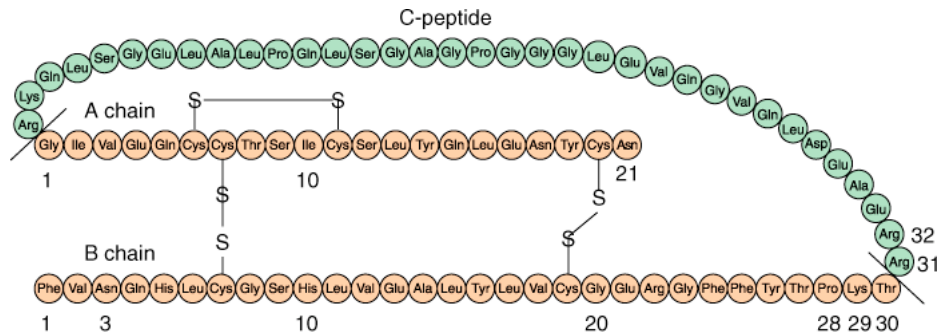

Gestational diabetes (GDM) is defined as any abnormality in glucose levels noted for the first time during pregnancy. Gestational diabetes is diagnosed in approximately 4% of all pregnancies in the USA. During pregnancy, the placenta and placental hormones create an insulin resistance that is most pronounced in the last trimester. Risk assessment for diabetes is suggested starting at the first prenatal visit. High-risk women should be screened immediately. Screening may be deferred in lower-risk women until the 24th to 28th week of gestation.

## INSULIN

### Chemistry

Insulin is a small protein with a molecular weight in humans of 5808. It contains 51 amino acids arranged in two chains (A and B) linked by disulfide bridges; there are species differences in the amino acids of both chains. Proinsulin, a long single-chain protein molecule, is processed within the Golgi apparatus of beta cells and packaged into granules, where it is hydrolyzed into insulin and a residual connecting segment called C-peptide by removal of four amino acids (Figure 41â€1).

**Figure 41â€1**

Structure of human proinsulin and insulin. Insulin is shown as the shaded (green color) peptide chains, A and B. Differences in the A and B chains and amino acid modifications for the rapid-acting insulin analogs (aspart, lispro, and glulisine) and long-acting insulin analogs (glargine and detemir) are discussed in the text.

Insulin and C-peptide are secreted in equimolar amounts in response to all insulin secretagogues; a small quantity of unprocessed or partially hydrolyzed proinsulin is released as well. Although proinsulin may have some mild hypoglycemic action, C-peptide has no known physiologic function. Granules within the beta cells store the insulin in the form of crystals consisting of two atoms of zinc and six molecules of insulin. The entire human pancreas contains up to 8 mg of insulin, representing approximately 200 biologic units. Originally, the unit was defined on the basis of the hypoglycemic activity of insulin in rabbits. With improved purification techniques, the unit is presently defined on the basis of weight, and present insulin standards used for assay purposes contain 28 units per milligram.

### Insulin Secretion

Insulin is released from pancreatic beta cells at a low basal rate and at a much higher stimulated rate in response to a variety of stimuli, especially glucose. Other stimulants such as other sugars (eg, mannose), certain amino acids (eg, leucine, arginine), hormones such as glucagon-like polypeptide-1 (GLP-1), glucose-dependent insulinotropic polypeptide (GIP), glucagon, cholecystokinin, and vagal activity are recognized. Inhibitory signals include somatostatin, leptin, and chronically elevated glucose and fatty acid levels.

One mechanism of stimulated insulin release is diagrammed in Figure 41â€2. As shown in the figure, hyperglycemia results in increased intracellular ATP levels, which close the ATP-dependent potassium channels. Decreased outward potassium efflux results in depolarization of the beta cell and opening of voltage-gated calcium channels. The resulting increased intracellular calcium triggers secretion of the hormone. The insulin secretagogue drug group (sulfonylureas, meglitinides, and D-phenylalanine) exploits parts of this mechanism.

**Figure 41â€2**

One model of control of insulin release from the pancreatic beta cell by glucose and by sulfonylurea drugs. In the resting cell with normal (low) ATP levels, potassium diffuses down its concentration gradient through ATP-gated potassium channels, maintaining the intracellular potential at a fully polarized, negative level. Insulin release is minimal. If glucose concentration rises, ATP production increases, potassium channels close, and depolarization of the cell results. As in muscle and nerve, voltage-gated calcium channels open in response to depolarization, allowing more calcium to enter the cell. Increased intracellular calcium results in increased insulin secretion. Insulin secretagogues close the ATP-dependent potassium channel, thereby depolarizing the membrane and causing increased insulin release by the same mechanism.

### Insulin Degradation

The liver and kidney are the two main organs that remove insulin from the circulation. The liver normally clears the blood of approximately 60% of the insulin released from the pancreas by virtue of its location as the terminal site of portal vein blood flow, with the kidney removing 35%–40% of the endogenous hormone. However, in insulin-treated diabetics receiving subcutaneous insulin injections, this ratio is reversed, with as much as 60% of exogenous insulin being cleared by the kidney and the liver removing no more than 30%–40%. The half-life of circulating insulin is 3–5 minutes.

### Circulating Insulin

Basal insulin values of 5–15  $\mu\text{U/mL}$  (30–90 pmol/L) are found in normal humans, with a peak rise to 60–90  $\mu\text{U/mL}$  (360–540 pmol/L) during meals.

### The Insulin Receptor

After insulin has entered the circulation, it diffuses into tissues, where it is bound by specialized receptors that are found on the membranes of most tissues. The biologic responses promoted by these insulin-receptor complexes have been identified in the primary target tissues, ie, liver, muscle, and adipose tissue. The receptors bind insulin with high specificity and affinity in the picomolar range. The full insulin receptor consists of two covalently linked heterodimers, each containing an  $\alpha$  subunit, which is entirely extracellular and constitutes the recognition site, and a  $\beta$  subunit that spans the membrane (Figure 41-3). The  $\beta$  subunit contains a tyrosine kinase. The binding of an insulin molecule to the  $\alpha$  subunits at the outside surface of the cell activates the receptor and through a conformational change brings the catalytic loops of the opposing cytoplasmic  $\beta$  subunits into closer proximity. This facilitates mutual phosphorylation of tyrosine residues on the  $\beta$  subunits and tyrosine kinase activity directed at cytoplasmic proteins.

Schematic diagram of the insulin receptor heterodimer in the activated state. IRS, insulin receptor substrate; MAP, mitogen-activated protein; P, phosphate; tyr, tyrosine.

The first proteins to be phosphorylated by the activated receptor tyrosine kinases are the docking proteins, insulin receptor substrates (IRS). After tyrosine phosphorylation at several critical sites, the IRS molecules bind to and activate other kinases—most significantly phosphatidylinositol-3-kinase—which produce further phosphorylations. Alternatively, they may bind to an adaptor protein such as growth factor receptor-binding protein 2, which translates the insulin signal to a guanine nucleotide-releasing factor that ultimately activates the GTP binding protein, ras, and the mitogen-activated protein kinase (MAPK) system. The particular IRS-phosphorylated tyrosine kinases have binding specificity with downstream molecules based on their surrounding 4–5 amino acid sequences or motifs that recognize specific Src homology 2 (SH2) domains on the other protein. This network of phosphorylations within the cell represents insulin's second message and results in multiple effects, including translocation of glucose transporters (especially GLUT 4, Table 41–2) to the cell membrane with a resultant increase in glucose uptake; increased glycogen synthase activity and increased glycogen formation; multiple effects on protein synthesis, lipolysis, and lipogenesis; and activation of transcription factors that enhance DNA synthesis and cell growth and division.

**Table 41–2 Glucose Transporters.**

Transporter	Tissues	Glucose $K_m$ (mmol/L)	Function
GLUT 1	All tissues, especially red cells, brain	1–2	Basal uptake of glucose; transport across the blood-brain barrier
GLUT 2	Beta cells of pancreas; liver, kidney; gut	15–20	Regulation of insulin release, other aspects of glucose homeostasis
GLUT 3	Brain, kidney, placenta, other tissues	< 1	Uptake into neurons, other tissues
GLUT 4	Muscle, adipose	~5	Insulin-mediated uptake of glucose
GLUT 5	Gut, kidney	1–2	Absorption of fructose

Various hormonal agents (eg, glucocorticoids) lower the affinity of insulin receptors for insulin; growth hormone in excess increases this affinity slightly. Aberrant serine and threonine phosphorylation of the insulin receptor  $\beta$  subunits or IRS molecules may result in insulin resistance and functional receptor down-regulation.

### Effects of Insulin on Its Targets

Insulin promotes the storage of fat as well as glucose (both sources of energy) within specialized target cells (Figure 41â€³4) and influences cell growth and the metabolic functions of a wide variety of tissues (Table 41â€³3).

**Figure 41â€³4**

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 11th Edition: <http://www.accessmedicine.com>  
 Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

Insulin promotes synthesis (from circulating nutrients) and storage of glycogen, triglycerides, and protein in its major target tissues: liver, fat, and muscle. The release of insulin from the pancreas is stimulated by increased blood glucose, incretins, vagal nerve stimulation, and other factors (see text).

**Table 41â€³3 Endocrine Effects of Insulin.**

#### Effect on liver:

Reversal of catabolic features of insulin deficiency

Inhibits glycogenolysis

Inhibits conversion of fatty acids and amino acids to keto acids

Inhibits conversion of amino acids to glucose

Anabolic action

Promotes glucose storage as glycogen (induces glucokinase and glycogen synthase, inhibits phosphorylase)

Increases triglyceride synthesis and very-low-density lipoprotein formation

#### Effect on muscle:

Increased protein synthesis

Increases amino acid transport

Increases ribosomal protein synthesis

Increased glycogen synthesis

Increases glucose transport

Induces glycogen synthase and inhibits phosphorylase

#### Effect on adipose tissue:

Increased triglyceride storage

Lipoprotein lipase is induced and activated by insulin to hydrolyze triglycerides from lipoproteins

Glucose transport into cell provides glycerol phosphate to permit esterification of fatty acids supplied by lipoprotein transport

Intracellular lipase is inhibited by insulin

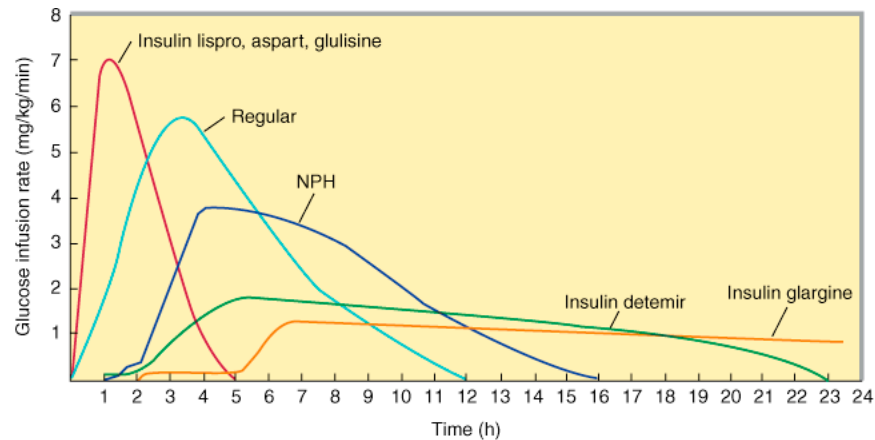

## Characteristics of Available Insulin Preparations

Commercial insulin preparations differ in a number of ways, such as differences in the recombinant DNA production techniques, amino acid sequence, concentration, solubility, and the time of onset and duration of their biologic action.

### PRINCIPAL TYPES AND DURATION OF ACTION OF INSULIN PREPARATIONS

Four principal types of injected insulins are available: (1) rapid-acting, with very fast onset and short duration; (2) short-acting, with rapid onset of action; (3) intermediate-acting; and (4) long-acting, with slow onset of action (Figure 41â€5, Table 41â€4). Injected rapid-acting and short-acting insulins are dispensed as clear solutions at neutral pH and contain small amounts of zinc to improve their stability and shelf life. Injected intermediate-acting NPH insulins have been modified to provide prolonged action and are dispensed as a turbid suspension at neutral pH with protamine in phosphate buffer (neutral protamine Hagedorn [NPH] insulin). Insulin glargine and insulin detemir are clear, soluble long-acting insulins.

**Figure 41â€5**

Extent and duration of action of various types of insulin as indicated by the glucose infusion rates (mg/kg/min) required to maintain a constant glucose concentration. The durations of action shown are typical of an average dose of 0.2â€0.3 U/kg. The durations of regular and NPH insulin increase considerably when dosage is increased.

**Table 41â€4 Some Insulin Preparations Available in the USA.<sup>1</sup>**

Preparation	Species Source	Concentration
<b>Rapid-acting insulins</b>		
Insulin Lispro, Humalog (Lilly)	Human analog	U100
Insulin Aspart, Novolog (Novo Nordisk)	Human analog	U100
Insulin Glulisine, Apidra (Aventis)	Human analog	U100
<b>Short-acting insulins</b>		
Regular Novolin R (Novo Nordisk)	Human	U100
Regular Humulin R (Lilly)	Human	U100, U500
<b>Intermediate-acting insulins</b>		
NPH Humulin N (Lilly)	Human	U100
NPH Novolin N (Novo Nordisk)	Human	U100
<b>Premixed insulins</b>		
Novolin 70 NPH/30 regular (Novo Nordisk)	Human	U100
Humulin 70 NPH/30 regular and 50/50 (Lilly)	Human	U100
50/50 NPL, Lispro (Lilly)	Human analog	U100
75/25 NPL, Lispro (Lilly)	Human analog	U100
70/30 NPA, Aspart (Novo Nordisk)	Human analog	U100
<b>Long-acting insulins</b>		
Insulin detemir, Levemir (Novo Nordisk)	Human analog	U100

Insulin glargine, Lantus (Aventis/Hoechst Marion Roussel)

Human analog

U100

<sup>1</sup>These agents (except insulin lispro, insulin aspart, insulin detemir, insulin glulisine, and U500 regular Humulin) are available without a prescription. All insulins should be refrigerated and brought to room temperature just before injection.

NPL, neutral protamine lispro; NPA, neutral protamine aspart.

The goal of subcutaneous insulin therapy is to replicate normal physiologic insulin secretion and replace the background or basal overnight, fasting, and between meal) as well as bolus or prandial (mealtime) insulin. An exact reproduction of the normal glycemic profile is not technically possible because of the limitations inherent in subcutaneous administration of insulin. Current regimens generally use insulin analogs because of their more predictable action. Intensive therapy ("tight control") attempts to restore near-normal glucose patterns throughout the day while minimizing the risk of hypoglycemia.

Intensive regimens involving multiple daily injections (MDI) use long-acting insulin analogs to provide basal or background coverage, and rapid-acting insulin analogs to meet the mealtime requirements. The latter insulins are given as supplemental doses to correct transient hyperglycemia. The most sophisticated insulin regimen delivers rapid-acting insulin analogs through a continuous subcutaneous insulin infusion device. Conventional therapy consists of split-dose injections of mixtures of rapid- or short-acting and intermediate-acting insulins.

#### **Rapid-Acting Insulin**

Three injected rapid-acting insulin analogs—**insulin lispro**, **insulin aspart**, and **insulin glulisine**—are commercially available. The rapid-acting insulins permit more physiologic prandial insulin replacement because their rapid onset and early peak action more closely mimic normal endogenous prandial insulin secretion than does regular insulin, and they have the additional benefit of allowing insulin to be taken immediately before the meal without sacrificing glucose control. Their duration of action is rarely more than 4–5 hours, which decreases the risk of late postmeal hypoglycemia. The injected rapid-acting insulins have the lowest variability of absorption (approximately 5%) of all available commercial insulins (compared with 25% for regular insulin and 25% to over 50% for long-acting analog formulations and intermediate insulin, respectively). They are the preferred insulins for use in continuous subcutaneous insulin infusion devices.

Insulin lispro, the first monomeric insulin analog to be marketed, is produced by recombinant technology wherein two amino acids near the carboxyl terminal of the B chain have been reversed in position: Proline at position B28 has been moved to B29, and lysine at position B29 has been moved to B28 (Figure 41–1). Reversing these two amino acids does not interfere in any way with insulin lispro's binding to the insulin receptor, its circulating half-life, or its immunogenicity, which are similar to those of human regular insulin. However, the advantage of this analog is its very low propensity to self-associate in antiparallel fashion and form dimers. To enhance the shelf life of insulin in vials, insulin lispro is stabilized into hexamers by a cresol preservative. When injected subcutaneously, the drug quickly dissociates into monomers and is rapidly absorbed with onset of action within 5–15 minutes and peak activity as early as 1 hour. The time to peak action is relatively constant, regardless of the dose.

Insulin aspart is created by the substitution of the B28 proline with a negatively charged aspartic acid (Figure 41–1). This modification reduces the normal ProB28 and GlyB23 monomer-monomer interaction, thereby inhibiting insulin self-aggregation. Its absorption and activity profile is similar to that of insulin lispro, and it is more reproducible than regular insulin, but has binding properties, activity, and mitogenicity characteristic similar to those of regular insulin in addition to equivalent immunogenicity.

Insulin glulisine is formulated by substituting an asparagine for lysine at B3 and glutamic acid for lysine at B29. Its absorption, action, and immunologic characteristics are similar to those of other injected rapid-acting insulins. After high-dose insulin glulisine interaction with the insulin receptor, there may be downstream differences in IRS-2 pathway activation relative to human insulin. The clinical significance of such differences is unclear.

#### **Short-Acting Insulin**

Regular insulin is a short-acting soluble crystalline zinc insulin that is now made by recombinant DNA techniques to produce a molecule identical to that of human insulin. Its effect appears within 30 minutes and peaks between 2 and 3 hours after subcutaneous injection and generally lasts 5–8 hours. In high concentrations, eg, in the vial, regular insulin molecules self-aggregate in antiparallel fashion to form dimers that stabilize around zinc ions to create insulin hexamers. The hexameric nature of regular insulin causes a delayed onset and prolongs the time to peak action. After subcutaneous injection, the insulin hexamers are too large and bulky to be transported across the vascular endothelium into the bloodstream. As the insulin depot is diluted by interstitial fluid and the concentration begins to fall, the hexamers break down into dimers and finally monomers. This results in three rates of absorption of the injected insulin, with the final monomeric phase having the fastest uptake out of the injection site.

The clinical consequence is that when regular insulin is administered at mealtime, the blood glucose rises faster than the insulin with resultant early postprandial hyperglycemia and an increased risk of late postprandial hypoglycemia. Therefore, regular insulin should be injected 30–45 or more minutes before the meal to minimize the mismatching. As with all older insulin formulations, the duration of action as well as the time of onset and the intensity of peak action increase with the size of the dose. Clinically, this is a critical issue because the pharmacokinetics and pharmacodynamics of small doses of regular and NPH insulins differ greatly from those of large doses. The delayed absorption, dose-dependent duration of action, and variability of absorption (~ 25%) of regular human insulin frequently results in a mismatching of insulin availability with need, and its use is declining.

However, short-acting, regular soluble insulin is the only type that should be administered intravenously because the dilution causes the hexameric insulin to immediately dissociate into monomers. It is particularly useful for intravenous therapy in the management of diabetic ketoacidosis and when the insulin requirement is changing rapidly, such as after surgery or during acute infections.

#### **Intermediate-Acting and Long-Acting Insulins**

##### **NPH (NEUTRAL PROTAMINE HAGEDORN, OR ISOPHANE) INSULIN**

NPH insulin is an intermediate-acting insulin whose absorption and the onset of action are delayed by combining appropriate amounts of insulin and protamine so that neither is present in an uncomplexed form ("isophane"). After subcutaneous injection, proteolytic tissue enzymes degrade the protamine to permit absorption of insulin. NPH insulin has an onset of approximately 2–5 hours and duration of 4–12 hours (Figure 41–5); it is usually mixed with regular, lispro, aspart, or glulisine insulin and given two to four times daily for insulin replacement. The dose regulates the action profile; specifically, small doses have lower, earlier peaks and a short duration of action with the converse true for large doses. The action of NPH is

highly unpredictable, and its variability of absorption is over 50%. The clinical use of NPH is waning because of its adverse pharmacokinetics combined with the availability of long-acting insulin analogs that have a more predictable and physiologic action.

#### **INSULIN GLARGINE**

Insulin glargine is a soluble, "peakless" (ie, having a broad plasma concentration plateau), long-acting insulin analog. This product was designed to provide reproducible, convenient, background insulin replacement. The attachment of two arginine molecules to the B-chain carboxyl terminal and substitution of a glycine for asparagine at the A21 position created an analog that is soluble in an acidic solution but precipitates in the more neutral body pH after subcutaneous injection. Individual insulin molecules slowly dissolve away from the crystalline depot and provide a low, continuous level of circulating insulin. Insulin glargine has a slow onset of action (1â€”1.5 hours) and achieves a maximum effect after 4â€”6 hours. This maximum activity is maintained for 11â€”24 hours or longer. Glargine is usually given once daily, although some very insulin-sensitive or insulin-resistant individuals benefit from split (twice a day) dosing. To maintain solubility, the formulation is unusually acidic (pH 4.0), and insulin glargine should not be mixed with other insulins. Separate syringes must be used to minimize the risk of contamination and subsequent loss of efficacy. The absorption pattern of insulin glargine appears to be independent of the anatomic site of injection, and this drug is associated with less immunogenicity than human insulin in animal studies. Glargine's interaction with the insulin receptor is similar to that of native insulin and shows no increase in mitogenic activity in vitro. It has sixfold to sevenfold greater binding than native insulin to the insulin-like growth factor-1 (IGF-1) receptor, but the clinical significance of this is unclear.

#### **INSULIN DETEMIR**

This insulin is the most recently developed long-acting insulin analog. The terminal threonine is dropped from the B30 position and myristic acid (a C-14 fatty acid chain) is attached to the terminal B29 lysine. These modifications prolong the availability of the injected analog by increasing both self-aggregation in subcutaneous tissue and reversible albumin binding. Insulin detemir has the most reproducible effect of the intermediate- and long-acting insulins, and its use is associated with less hypoglycemia than NPH insulin. Insulin detemir has a dose-dependent onset of action of 1â€”2 hours and duration of action of more than 24 hours. It is given twice daily to obtain a smooth background insulin level.

#### **Mixtures of Insulins**

Because intermediate-acting NPH insulins require several hours to reach adequate therapeutic levels, their use in diabetic patients usually requires supplements of rapid- or short-acting insulin before meals. For convenience, these are often mixed together in the same syringe before injection. Insulin lispro, aspart, and glulisine can be *acutely* mixed (ie, just before injection) with NPH insulin without affecting their rapid absorption. However, *premixed* preparations have thus far been unstable. To remedy this, intermediate insulins composed of isophane complexes of protamine with insulin lispro and insulin aspart have been developed. These intermediate insulins have been designated as "NPL" (neutral protamine lispro) and "NPA" (neutral protamine aspart) and have the same duration of action as NPH insulin. They have the advantage of permitting formulation as premixed combinations of NPL and insulin lispro, and as NPA and insulin aspart, and they have been shown to be safe and effective in clinical trials. The FDA has approved 50%/50% and 75%/25% NPL/insulin lispro and 70%/30% NPA/insulin aspart premixed formulations. Additional ratios are available abroad. Insulin glargine and detemir must be given as separate injections. They are not miscible acutely or in a premixed preparation with any other insulin formulation.

#### **INSULIN PRODUCTION**

##### **Human Insulins**

Mass production of human insulin and insulin analogs by recombinant DNA techniques is carried out by inserting the human or a modified human proinsulin gene into *Escherichia coli* or yeast and treating the extracted proinsulin to form the insulin or insulin analog molecules.

#### **CONCENTRATION**

All insulins in the USA and Canada are available in a concentration of 100 U/mL (U100). A limited supply of U500 regular human insulin is available for use in rare cases of severe insulin resistance in which larger doses of insulin are required.

#### **Insulin Delivery Systems**

The standard mode of insulin therapy is subcutaneous injection using conventional disposable needles and syringes.

#### **PORTABLE PEN INJECTORS**

To facilitate multiple subcutaneous injections of insulin, particularly during intensive insulin therapy, portable pen-sized injectors have been developed. These contain cartridges of insulin and replaceable needles.

Disposable insulin pens are also available for selected formulations. These are regular insulin, insulin lispro, insulin aspart, insulin glulisine, insulin glargine, insulin detemir, and several mixtures of NPH with regular, lispro, or aspart insulin (Table 41â€”4). They have been well accepted by patients because they eliminate the need to carry syringes and bottles of insulin to the workplace and while traveling.

#### **CONTINUOUS SUBCUTANEOUS INSULIN INFUSION DEVICES (CSII, INSULIN PUMPS)**

Continuous subcutaneous insulin infusion devices are external open-loop pumps for insulin delivery. The devices have a user-programmable pump that delivers individualized basal and bolus insulin replacement doses based on blood glucose self-monitoring results. Normally, the 24-hour background basal rates are relatively constant from day to day, although temporarily altered rates can be superimposed to adjust for a short-term change in requirement. For example, the basal delivery rate might need to be decreased for several hours because of the increased insulin sensitivity associated with strenuous activity. In contrast, the bolus amounts have to be dynamically programmed as the bolus timing and dose varies. The boluses are used to correct high blood glucose levels and to cover mealtime insulin requirements based on the carbohydrate content of the food and concurrent activity. The pumpâ€”which contains an insulin reservoir, the program chip, the keypad, and the display screenâ€”is about the size of a pager. It is usually placed on a belt or in a pocket, and the insulin is infused through thin plastic tubing that is connected to the subcutaneously inserted infusion set. The abdomen is the favored site for the infusion set, although flanks and thighs are also used. The insulin reservoir, tubing, and infusion set need to be changed using sterile techniques every 2 or 3 days. Currently, only one pump does not require tubing. In this model, the pump is attached directly to the infusion set. Programming is done through a hand-held unit that communicates wirelessly with the pump. CSII delivery is regarded as the most physiologic method of insulin replacement.

Use of these continuous infusion devices is encouraged for people who are unable to obtain target control while on multiple injection regimens and in circumstances in which excellent glycemic control is desired, such as during pregnancy. Optimal use of these devices requires responsible involvement

and commitment by the patient. Velosulin (a regular insulin) and insulin aspart, lispro, and glulisine all are specifically approved for pump use. Insulins aspart, lispro, and glulisine are preferred pump insulins because their favorable pharmacokinetic attributes allow glycemic control without increasing the risk of hypoglycemia.

### **Treatment with Insulin**

The current classification of diabetes mellitus identifies a group of patients who have virtually no insulin secretion and whose survival depends on administration of exogenous insulin. This insulin-dependent group (type 1) represents 5%–10% of the diabetic population in the USA. Most type 2 diabetics do not require exogenous insulin for survival, but many need exogenous supplementation of their endogenous secretion to achieve optimum health.

### **Benefit of Glycemic Control in Diabetes Mellitus**

The consensus of the American Diabetes Association is that intensive glycemic control and targeting normal or near-normal glucose control associated with comprehensive self-management training should become standard therapy in diabetic patients (see Benefits of Tight Glycemic Control in Diabetes). Exceptions include patients with advanced renal disease and the elderly, because the risks of hypoglycemia may outweigh the benefit of normal or near-normal glycemic control in these groups. In children under 7 years, the extreme susceptibility of the developing brain to incur damage from hypoglycemia contraindicates attempts at intensive glycemic control.

#### **Benefits of Tight Glycemic Control in Diabetes**

A long-term randomized prospective study involving 1441 type 1 patients in 29 medical centers reported in 1993 that "near normalization" of blood glucose resulted in a delay in onset and a major slowing of progression of microvascular and neuropathic complications of diabetes during follow-up periods of up to 10 years (Diabetes Control And Complications Trial [DCCT] Research Group, 1993). In the intensively treated group, a mean glycosylated hemoglobin HbA<sub>1c</sub> of 7.2% (normal < 6%) and a mean blood glucose of 155 mg/dL were achieved, whereas in the conventionally treated group, HbA<sub>1c</sub> averaged 8.9% with an average blood glucose of 225 mg/dL. Over the study period, which averaged 7 years, approximately a 60% reduction in risk of diabetic retinopathy, nephropathy, and neuropathy was noted in the tight control group compared with the standard control group.

The DCCT study, in addition, introduced the concept of *glycemic memory*, which comprises the long-term benefits of any significant period of glycemic control. During a 6-year follow-up period, both the intensively and the conventionally treated groups had similar levels of glycemic control, and both had progression of carotid intimal-medial thickness. However, the intensively treated cohort had significantly less progression of intimal thickness.

The United Kingdom Prospective Diabetes Study (UKPDS) was a very large randomized prospective study carried out to study the effects of intensive glycemic control with several types of therapies and the effects of blood pressure control in type 2 diabetic patients. A total of 3867 newly diagnosed type 2 diabetic patients were studied over 10 years. A significant fraction of these were overweight and hypertensive. Patients were given dietary treatment alone or intensive therapy with insulin, chlorpropamide, glyburide, or glipizide. Metformin was an option for patients with inadequate response to other therapies. Tight control of blood pressure was added as a variable, with an angiotensin-converting enzyme inhibitor,  $\beta$  blocker or, in some cases, a calcium channel blocker available for this purpose.

Tight control of diabetes, with reduction of HbA<sub>1c</sub> from 9.1% to 7%, was shown to reduce the risk of microvascular complications overall compared with that achieved with conventional therapy (mostly diet alone, which decreased HbA<sub>1c</sub> to 7.9%). Cardiovascular complications were not noted for any particular therapy; metformin treatment alone reduced the risk of macrovascular disease (myocardial infarction, stroke). Epidemiologic analysis of the study suggested that every 1% decrease in the A<sub>1c</sub> achieved an estimated risk reduction of 37% for microvascular complications, 21% for any diabetes-related endpoint and death related to diabetes, and 14% for myocardial infarction.

Tight control of hypertension also had a surprisingly significant effect on microvascular disease (as well as more conventional hypertension-related sequelae) in these diabetic patients. Epidemiologic analysis of the results suggested that every 10 mm Hg decrease in the systolic pressure achieved an estimated risk reduction of 13% for diabetic microvascular complications, and 12% for any diabetes related complication, 15% for death related to diabetes, and 11% for myocardial infarction.

Post-study monitoring showed that 5 years after the closure of the UKPDS, the benefits of intensive management on diabetic endpoints was maintained and the risk reduction for a myocardial infarction became significant. The benefits of metformin therapy were maintained.

These studies show that tight glycemic control benefits both type 1 and type 2 patients.

The STOP-NIDDM trial followed 1429 patients with impaired glucose tolerance who were randomized to treatment with acarbose or placebo over 3 years. This trial demonstrated that normalization of glycemic control in subjects with impaired glucose tolerance significantly diminished cardiovascular risk. The acarbose-treated group had a significant reduction in the development of major cardiovascular events and hypertension. A prospective placebo-controlled subgroup analysis has shown a marked decrease in the progression of intimal-medial thickness.

### **Insulin Regimens**

#### **INTENSIVE INSULIN THERAPY**

Intensive insulin regimens are prescribed for almost everyone with type 1 diabetes—diabetes associated with a severe deficiency or absence of endogenous insulin production—as well as many with type 2 diabetes.

Generally, the total daily insulin requirement in units is equal to the weight in pounds divided by four, or 0.55 times the person's weight in kilograms. Approximately half the total daily insulin dose covers the background or basal insulin requirements, and the remainder covers meal and snack requirement and high blood sugar corrections. This is an approximate calculation and has to be individualized. Examples of reduced insulin requirement include newly diagnosed persons and those with ongoing endogenous insulin production, longstanding diabetes with insulin sensitivity, significant renal insufficiency, or other endocrine deficiencies. Increased insulin requirements typically occur with obesity, during adolescence, during the latter trimesters

of pregnancy, and in individuals with type 2 diabetes.

In intensive insulin regimens, the meal or snack and high blood sugar correction boluses are prescribed by formulas. The patient uses the formulas to calculate the rapid-acting insulin bolus dose by considering how much carbohydrate is in the meal or snack, the current plasma glucose, and the target glucose. The formula for the meal or snack bolus is expressed as an insulin-to-carbohydrate ratio, which refers to how many grams of carbohydrate will be disposed of by 1 unit of rapid-acting insulin. The high blood sugar correction formula is expressed as the predicted fall in plasma glucose (in mg/dL) after 1 unit of rapid-acting insulin. Diurnal variations in insulin sensitivity can be accommodated by prescribing different basal rates and bolus insulin doses throughout the day. Continuous subcutaneous insulin infusion devices provide the most sophisticated and physiologic insulin replacement.

#### **CONVENTIONAL INSULIN THERAPY**

Conventional insulin therapy is usually prescribed only for certain people with type 2 diabetes who are felt not to benefit from intensive glucose control. The insulin regimen ranges from one injection per day to many injections per day, using intermediate- or long-acting insulin alone or with short- or rapid-acting insulin or premixed insulins. Referred to as sliding-scale regimens, conventional insulin regimens customarily fix the dose of the intermediate- or long-acting insulin, but vary the short- or rapid-acting insulin based on the plasma glucose level before the injection.

### **Insulin Treatment of Special Circumstances**

#### **DIABETIC KETOACIDOSIS**

Diabetic ketoacidosis (DKA) is a life-threatening medical emergency caused by inadequate or absent insulin replacement, which occurs in people with type 1 diabetes and infrequently in those with type 2 diabetes. It typically occurs in newly diagnosed type 1 patients or in those who have experienced interrupted insulin replacement, and rarely in people with type 2 diabetes who have concurrent unusually stressful conditions such as sepsis or pancreatitis or are on high-dose steroid therapy. Signs and symptoms include nausea, vomiting, abdominal pain, deep slow (Kussmaul) breathing, change in mental status, elevated blood and urinary ketones and glucose, and an arterial blood pH higher than 7.3 and low bicarbonate ( $< 15$  mmol/L).

The fundamental treatment for DKA includes aggressive intravenous hydration and insulin therapy and maintenance of potassium and other electrolyte levels. Fluid and insulin therapy is based on the patient's individual needs and requires frequent reevaluation and modification. Close attention has to be given to hydration and renal status, the sodium and potassium levels, and the rate of correction of plasma glucose and plasma osmolality. Fluid therapy generally begins with normal saline. Regular human insulin should be used for intravenous therapy with a usual starting dose of about 0.1 IU/kg/h.

#### **HYPEROSMOLAR HYPERGLYCEMIC SYNDROME**

Hyperosmolar, hyperglycemic syndrome (HHS) is diagnosed in persons with type 2 diabetes and is characterized by profound hyperglycemia and dehydration. It is associated with inadequate oral hydration, especially in elderly patients, with other illnesses, the use of medication that elevates the blood sugar or causes dehydration, such as phenytoin, steroids, diuretics, and  $\beta$  blockers, and with peritoneal dialysis and hemodialysis. The diagnostic hallmarks are declining mental status and even seizures, a plasma glucose of over 600 mg/dL, and a calculated serum osmolality higher than 320 mmol/L. Persons with HHS are not acidotic, (except with a combined DKA and HHS.)

The treatment of HHS centers around aggressive rehydration and restoration of glucose and electrolyte homeostasis; the rate of correction of these variables must be monitored closely. Low-dose insulin therapy may be required.

### **Complications of Insulin Therapy**

#### **HYPOGLYCEMIA**

##### **Mechanisms and Diagnosis**

Hypoglycemic reactions are the most common complication of insulin therapy. They commonly result from inadequate carbohydrate consumption, unusual physical exertion, and too large a dose of insulin.

Rapid development of hypoglycemia in persons with intact hypoglycemic awareness causes signs of autonomic hyperactivity—both sympathetic (tachycardia, palpitations, sweating, tremulousness) and parasympathetic (nausea, hunger)—and may progress to convulsions and coma if untreated.

In persons exposed to frequent hypoglycemic episodes during tight glycemic control, autonomic warning signals of hypoglycemia are less common or even absent. This dangerous acquired condition is termed "hypoglycemic unawareness." When patients lack the early warning signs of low blood glucose, they may not take corrective measures in time. In patients with persistent, untreated hypoglycemia, the manifestations of insulin excess may develop—confusion, weakness, bizarre behavior, coma, seizures—at which point they may not be able to procure or safely swallow glucose-containing foods.

Hypoglycemic awareness may be restored by preventing frequent hypoglycemic episodes. An identification bracelet, necklace, or card in the wallet or purse, as well as some form of rapidly absorbed glucose, should be carried by every diabetic who is receiving hypoglycemic drug therapy.

##### **Treatment of Hypoglycemia**

All the manifestations of hypoglycemia are relieved by glucose administration. To expedite absorption, simple sugar or glucose should be given, preferably in liquid form. To treat mild hypoglycemia in a patient who is conscious and able to swallow, dextrose tablets, glucose gel, or any sugar-containing beverage or food may be given. If more severe hypoglycemia has produced unconsciousness or stupor, the treatment of choice is to give 20â€”50 mL of 50% glucose solution by intravenous infusion over a period of 2â€”3 minutes. If intravenous therapy is not available, 1 mg of glucagon injected either subcutaneously or intramuscularly may restore consciousness within 15 minutes to permit ingestion of sugar. If the patient is stuporous and glucagon is not available, small amounts of honey or syrup can be inserted into the buccal pouch. In general, however, oral feeding is contraindicated in unconscious patients. Emergency medical services should be called immediately for all episodes of severely impaired consciousness.

#### **IMMUNOPATHOLOGY OF INSULIN THERAPY**

At least five molecular classes of insulin antibodies may be produced in diabetics during the course of insulin therapy: IgA, IgD, IgE, IgG, and IgM. There are two major types of immune disorders in these patients:

##### **Insulin Allergy**

Insulin allergy, an immediate type hypersensitivity, is a rare condition in which local or systemic urticaria results from histamine release from tissue mast cells sensitized by anti-insulin IgE antibodies. In severe cases, anaphylaxis results. Because sensitivity is often to noninsulin protein contaminants, the human and analog insulins have markedly reduced the incidence of insulin allergy, especially local reactions.

### **Immune Insulin Resistance**

A low titer of circulating IgG anti-insulin antibodies that neutralize the action of insulin to a negligible extent develops in most insulin-treated patients. Rarely, the titer of insulin antibodies leads to insulin resistance and may be associated with other systemic autoimmune processes such as lupus erythematosus.

### **LIPODYSTROPHY AT INJECTION SITES**

Injection of animal insulin preparations sometimes led to atrophy of subcutaneous fatty tissue at the site of injection. This type of immune complication is almost never seen ever since the development of human and analog insulin preparations of neutral pH. Injection of these newer preparations directly into the atrophic area often results in restoration of normal contours.

Hypertrophy of subcutaneous fatty tissue remains a problem if injected repeatedly at the same site. However, this may be corrected by avoiding the specific injection site or by liposuction.

## **ORAL ANTIDIABETIC AGENTS**

Six categories of oral antidiabetic agents are now available in the USA for the treatment of persons with type 2 diabetes: insulin secretagogues (sulfonylureas, meglitinides, D-phenylalanine derivatives), biguanides, thiazolidinediones,  $\alpha$ -glucosidase inhibitors, incretin-based therapies, and an amylin analog. The sulfonylureas and biguanides have been available the longest and are the traditional treatment choice for type 2 diabetes. Novel classes of rapid-acting insulin secretagogues, the meglitinides and D-phenylalanine derivatives, are alternatives to the short-acting sulfonylureas. Insulin secretagogues increase insulin secretion from beta cells. Biguanides decrease hepatic glucose production. The thiazolidinediones reduce insulin resistance. The incretin-based therapies control post-meal glucose excursions by increasing insulin release and decreasing glucagon secretion. The amylin analog also decreases post-meal glucose levels and reduces appetite. Alpha-glucosidase inhibitors slow the digestion and absorption of starch and disaccharides.

### **Insulin Secretagogues: Sulfonylureas**

#### **Mechanism of Action**

The major action of sulfonylureas is to increase insulin release from the pancreas (Table 41-5). Two additional mechanisms of action have been proposed—a reduction of serum glucagon levels and closure of potassium channels in extrapancreatic tissue (which are of unknown but probably minimal significance).

#### **Table 41-5 Regulation of Insulin Release in Humans.**

##### Stimulants of insulin release

Glucose, mannose

Leucine

Vagal stimulation

Sulfonylureas

##### Amplifiers of glucose-induced insulin release

Hormones:

Glucagon-like peptide 1(7-37)

Gastrin inhibitory peptide

Cholecystokinin

Secretin, gastrin, glucagon

Neural amplifiers:

$\beta$ -Adrenoceptor stimulation

Amino acids:

Arginine

##### Inhibitors of insulin release

Neural:  $\alpha$ -Sympathomimetic effect of catecholamines

Humoral: Somatostatin, leptin

Drugs: Diazoxide, phenytoin, vinblastine, colchicine

Modified and reproduced, with permission, from Greenspan FS, Strewler GJ (editors): *Basic & Clinical Endocrinology*, 5th ed. Originally published by Appleton & Lange. Copyright © 1997 by The McGraw-Hill Companies, Inc.

### **INSULIN RELEASE FROM PANCREATIC BETA CELLS**

Sulfonylureas bind to a 140-kDa high-affinity sulfonylurea receptor (Figure 41-2) that is associated with a beta-cell inward rectifier ATP-sensitive potassium channel. Binding of a sulfonylurea inhibits the efflux of potassium ions through the channel and results in depolarization. Depolarization opens a voltage-gated calcium channel and results in calcium influx and the release of preformed insulin.

### **REDUCTION OF SERUM GLUCAGON CONCENTRATIONS**

Long-term administration of sulfonylureas to type 2 diabetics reduces serum glucagon levels, which may contribute to the hypoglycemic effect of the

drugs. The mechanism for this suppressive effect of sulfonylureas on glucagon levels is unclear but appears to involve indirect inhibition due to enhanced release of both insulin and somatostatin, which inhibit alpha-cell secretion.

### Efficacy & Safety of the Sulfonylureas

In 1970, the University Group Diabetes Program (UGDP) in the USA reported that the number of deaths due to cardiovascular disease in diabetic patients treated with tolbutamide was excessive compared with either insulin-treated patients or those receiving placebos. Owing to design flaws, this study and its conclusions were not generally accepted. A study in the United Kingdom, the UKPDS, did not find an untoward cardiovascular effect of sulfonylurea usage in their large, long-term study.

The sulfonylureas continue to be widely prescribed, and six are available in the USA (Table 41â€6). They are conventionally divided into first-generation and second-generation agents, which differ primarily in their potency and adverse effects. The first-generation sulfonylureas are increasingly difficult to procure, and as the second-generation agents become generic and less expensive, the older compounds probably will be discontinued.

**Table 41â€6 Sulfonylureas.**

Sulfonylureas	Chemical Structure	Daily Dose	Duration of Action (hours)
Tolbutamide (Orinase)		0.5–2 g in divided doses	6–12
Tolazamide (Tolinase)		0.1–1 g as single dose or in divided doses	10–14
Chlorpropamide (Diabinese)		0.1–0.5 g as single dose	Up to 60
Glyburide (glibenclamide <sup>1</sup> ) (DiaBeta, Micronase, Glynase, PresTab)		0.00125–0.02 g	10–24
Glipizide (glydiazinamide <sup>1</sup> ) (Glucotrol, Glucotrol XL)		0.005–0.03 g (0.02 g in Glucotrol XL)	10–24 <sup>2</sup>
Glimepiride		0.001–	12–24

<sup>1</sup>Outside USA.

<sup>2</sup>Elimination half-life considerably shorter (see text).

### FIRST-GENERATION SULFONYLUREAS

**Tolbutamide** is well absorbed but rapidly metabolized in the liver. Its duration of effect is relatively short, with an elimination half-life of 4â€5 hours, and it is best administered in divided doses. Because of its short half-life, it is the safest sulfonylurea for elderly diabetics. Prolonged hypoglycemia has been reported rarely, mostly in patients receiving certain drugs (eg, dicumarol, phenylbutazone, some sulfonamides) that inhibit the metabolism of tolbutamide.

**Chlorpropamide** has a half-life of 32 hours and is slowly metabolized in the liver to products that retain some biologic activity; approximately 20â€30% is excreted unchanged in the urine. Chlorpropamide also interacts with the drugs mentioned above that depend on hepatic oxidative catabolism,

and it is contraindicated in patients with hepatic or renal insufficiency. Dosages higher than 500 mg daily increase the risk of jaundice. The average maintenance dosage is 250 mg daily, given as a single dose in the morning. Prolonged hypoglycemic reactions are more common in elderly patients, and the drug is contraindicated in this group. Other adverse effects include a hyperemic flush after alcohol ingestion in genetically predisposed patients and dilutional hyponatremia. Hematologic toxicity (transient leukopenia, thrombocytopenia) occurs in less than 1% of patients.

**Tolazamide** is comparable to chlorpropamide in potency but has a shorter duration of action. Tolazamide is more slowly absorbed than the other sulfonylureas, and its effect on blood glucose does not appear for several hours. Its half-life is about 7 hours. Tolazamide is metabolized to several compounds that retain hypoglycemic effects. If more than 500 mg/d are required, the dose should be divided and given twice daily.

## SECOND-GENERATION SULFONYLUREAS

The second-generation sulfonylureas are prescribed more frequently in the USA than are the first-generation agents because they have fewer adverse effects and drug interactions. These potent sulfonylurea compounds—glyburide, glipizide, and glimepiride—should be used with caution in patients with cardiovascular disease or in elderly patients, in whom hypoglycemia would be especially dangerous.

**Glyburide** is metabolized in the liver into products with very low hypoglycemic activity. The usual starting dosage is 2.5 mg/d or less, and the average maintenance dosage is 5–10 mg/d given as a single morning dose; maintenance dosages higher than 20 mg/d are not recommended. A formulation of "micronized" glyburide (Glynase PresTab) is available in a variety of tablet sizes. However, there is some question as to its bioequivalence with nonmicronized formulations, and the FDA recommends careful monitoring to retitrate dosage when switching from standard glyburide doses or from other sulfonylurea drugs.

Glyburide has few adverse effects other than its potential for causing hypoglycemia. Flushing has rarely been reported after ethanol ingestion, and the compound slightly enhances free water clearance. Glyburide is contraindicated in the presence of hepatic impairment and in patients with renal insufficiency.

**Glipizide** has the shortest half-life (2–4 hours) of the more potent agents. For maximum effect in reducing postprandial hyperglycemia, this agent should be ingested 30 minutes before breakfast because absorption is delayed when the drug is taken with food. The recommended starting dosage is 5 mg/d, with up to 15 mg/d given as a single dose. When higher daily dosages are required, they should be divided and given before meals. The maximum total daily dosage recommended by the manufacturer is 40 mg/d, although some studies indicate that the maximum therapeutic effect is achieved by 15–20 mg of the drug. An extended-release preparation (Glucotrol XL) provides 24-hour action after a once-daily morning dose (maximum of 20 mg/d). However, this formulation appears to have sacrificed its lower propensity for severe hypoglycemia compared with longer-acting glyburide without showing any demonstrable therapeutic advantages over the latter (which can be obtained as a generic drug).

Because of its shorter half-life, the regular formulation of glipizide is much less likely than glyburide to produce serious hypoglycemia. At least 90% of glipizide is metabolized in the liver to inactive products, and 10% is excreted unchanged in the urine. Glipizide therapy is therefore contraindicated in patients with significant hepatic or renal impairment, who would be at high risk for hypoglycemia.

**Glimepiride** is approved for once-daily use as monotherapy or in combination with insulin. Glimepiride achieves blood glucose lowering with the lowest dose of any sulfonylurea compound. A single daily dose of 1 mg has been shown to be effective, and the recommended maximal daily dose is 8 mg. Glimepiride has a long duration of effect with a half-life of 5 hours, allowing once-daily dosing and thereby improving compliance. It is completely metabolized by the liver to inactive products.

## Insulin Secretagogue: Meglitinide

**Repaglinide** is the first member of the meglitinide group of insulin secretagogues (Table 41–7). These drugs modulate beta-cell insulin release by regulating potassium efflux through the potassium channels previously discussed. There is overlap with the sulfonylureas in their molecular sites of action because the meglitinides have two binding sites in common with the sulfonylureas and one unique binding site.

**Table 41–7 Other Insulin Secretagogues.**

Drug	Chemical Structure	Oral Dose	t <sub>1/2</sub>	Duration of Action (hours)
Repaglinide (Prandin)		0.25–4 mg before meals	1 hour	4–5

Repaglinide has a very fast onset of action, with a peak concentration and peak effect within approximately 1 hour after ingestion, but the duration of action is 5–8 hours. It is hepatically cleared by CYP3A4 with a plasma half-life of 1 hour. Because of its rapid onset, repaglinide is indicated for use in controlling postprandial glucose excursions. The drug should be taken just before each meal in doses of 0.25–4 mg (maximum 16 mg/d); hypoglycemia is a risk if the meal is delayed or skipped or contains inadequate carbohydrate. This drug should be used cautiously in individuals with renal and hepatic impairment. Repaglinide is approved as monotherapy or in combination with biguanides. There is no sulfur in its structure, so repaglinide may be used in type 2 diabetics with sulfur or sulfonylurea allergy.

### Insulin Secretagogue: D-Phenylalanine Derivative

**Nateglinide**, a D-phenylalanine derivative, is the latest insulin secretagogue to become clinically available. Nateglinide stimulates very rapid and transient release of insulin from beta cells through closure of the ATP-sensitive  $K^+$  channel. It also partially restores initial insulin release in response to an intravenous glucose tolerance test. This may be a significant advantage of the drug because type 2 diabetes is associated with loss of this initial insulin response. The restoration of more normal insulin secretion may suppress glucagon release early in the meal and result in less endogenous or hepatic glucose production. Nateglinide may have a special role in the treatment of individuals with isolated postprandial hyperglycemia, but it has minimal effect on overnight or fasting glucose levels. Nateglinide is efficacious when given alone or in combination with nonsecretagogue oral agents (such as metformin). In contrast to other insulin secretagogues, dose titration is not required.

Nateglinide is ingested just before meals. It is absorbed within 20 minutes after oral administration with a time to peak concentration of less than 1 hour and is metabolized in the liver by CYP2C9 and CYP3A4 with a half-life of 1.5 hours. The overall duration of action is less than 4 hours.

Nateglinide amplifies the insulin secretory response to a glucose load, but it has a markedly diminished effect in the presence of normoglycemia. The incidence of hypoglycemia with nateglinide may be the lowest of all the secretagogues, and nateglinide has the advantage of being safe in those with very reduced renal function.

### Biguanides

The structure of **metformin** is shown below. Phenformin (an older biguanide) was discontinued in the USA because of its association with lactic acidosis and because there was no documentation of any long-term benefit from its use.

Metformin

### Mechanisms of Action

A full explanation of the mechanism of action of the biguanides remains elusive, but their primary effect is to reduce hepatic glucose production through activation of the enzyme AMP-activated protein kinase (AMPK). Possible minor mechanisms of action include impairment of renal gluconeogenesis, slowing of glucose absorption from the gastrointestinal tract, with increased glucose to lactate conversion by enterocytes, direct stimulation of glycolysis in tissues, increased glucose removal from blood, and reduction of plasma glucagon levels. The biguanide blood glucose-lowering action does not depend on functioning pancreatic beta cells. Patients with type 2 diabetes have considerably less fasting hyperglycemia as well as lower postprandial hyperglycemia after biguanides; however, hypoglycemia during biguanide therapy is essentially unknown. These agents are therefore more appropriately termed "euglycemic" agents.

### Metabolism & Excretion

Metformin has a half-life of 1.5–3 hours, is not bound to plasma proteins, is not metabolized, and is excreted by the kidneys as the active compound. As a consequence of metformin's blockade of gluconeogenesis, the drug may impair the hepatic metabolism of lactic acid. In patients with renal insufficiency, biguanides accumulate and thereby increase the risk of lactic acidosis, which appears to be a dose-related complication.

### Clinical Use

Biguanides are recommended as first-line therapy for type 2 diabetes. Because metformin is an insulin-sparing agent and does not increase weight or provoke hypoglycemia, it offers obvious advantages over insulin or sulfonylureas in treating hyperglycemia in such persons. The UKPDS reported that metformin therapy decreases the risk of macrovascular as well as microvascular disease; this is in contrast to the other therapies, which only modified microvascular morbidity. Biguanides are also indicated for use in combination with insulin secretagogues or thiazolidinediones in type 2 diabetics in whom oral monotherapy is inadequate. Metformin is useful in the prevention of type 2 diabetes; the landmark Diabetes Prevention Program concluded that metformin is efficacious in preventing the new onset of type 2 diabetes in middle-aged, obese persons with impaired glucose tolerance and fasting hyperglycemia. It is interesting that metformin did not prevent diabetes in older, leaner prediabetics.

The dosage of metformin is from 500 mg to a maximum of 2.55 g daily, with the lowest effective dose being recommended. Depending on whether the

primary abnormality is fasting hyperglycemia or postprandial hyperglycemia, metformin therapy can be initiated as a once-daily dose at bedtime or before a meal. A common schedule for fasting hyperglycemia would be to begin with a single 500-mg tablet at bedtime for a week or more. If this is tolerated without gastrointestinal discomfort and if hyperglycemia persists, a second 500-mg tablet may be added with the evening meal. If further dose increases are required, an additional 500-mg tablet can be added to be taken with breakfast or the midday meal, or the larger (850-mg) tablet can be prescribed twice daily or even three times daily (the maximum recommended dosage) if needed. Dosage should always be divided because ingestion of more than 1000 mg at any one time usually provokes significant gastrointestinal adverse effects.

### Toxicities

The most common toxic effects of metformin are gastrointestinal (anorexia, nausea, vomiting, abdominal discomfort, and diarrhea), which occur in up to 20% of patients. They are dose-related, tend to occur at the onset of therapy, and are often transient. However, metformin may have to be discontinued in 3%–5% of patients because of persistent diarrhea. Absorption of vitamin B<sub>12</sub> appears to be reduced during long-term metformin therapy, and annual screening of serum vitamin B<sub>12</sub> levels and red blood cell parameters has been encouraged by the manufacturer to determine the need for vitamin B<sub>12</sub> injections. In the absence of hypoxia or renal or hepatic insufficiency, lactic acidosis is less common with metformin therapy than with phenformin therapy.

Biguanide drugs are contraindicated in patients with renal disease, alcoholism, hepatic disease, or conditions predisposing to tissue anoxia (eg, chronic cardiopulmonary dysfunction) because of an increased risk of lactic acidosis induced by biguanide drugs.

### Thiazolidinediones

Thiazolidinediones (TZDs) act to decrease insulin resistance. TZDs are ligands of **peroxisome proliferator-activated receptor-gamma (PPAR- $\gamma$ )**, part of the steroid and thyroid superfamily of nuclear receptors. These PPAR receptors are found in muscle, fat, and liver. PPAR- $\gamma$  receptors modulate the expression of the genes involved in lipid and glucose metabolism, insulin signal transduction, and adipocyte and other tissue differentiation. The available TZDs do not have identical clinical effects, and new drug development will focus on defining PPAR effects and designing ligands that have selective action—much like the selective estrogen receptor modulators (see Chapter 40).

In addition to targeting adipocytes, myocytes, and hepatocytes, TZDs also have significant effects on vascular endothelium, the immune system, the ovaries, and tumor cells. Some of these responses may be independent of the PPAR- $\gamma$  pathway.

In persons with diabetes, a major site of TZd action is adipose tissue, where the drug promotes glucose uptake and utilization and modulates synthesis of lipid hormones or cytokines and other proteins involved in energy regulation. TZDs also regulate adipocyte apoptosis and differentiation. Numerous other effects have been documented in animal studies, but applicability to human tissues has yet to be determined.

Two thiazolidinediones are currently available: pioglitazone and rosiglitazone (Table 41-8). Their distinct side chains create differences in therapeutic action, metabolism, metabolite profile, and adverse effects. An earlier compound, troglitazone, was withdrawn from the market because of hepatic toxicity thought to be related to its side chain.

**Table 41-8 Thiazolidinediones.**

#### Thiazolidinedione

#### Chemical Structure

#### Oral Dose

Pioglitazone (Actos)

15–45 mg once daily

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 11th Edition: <http://www.accessmedicine.com>

Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

Rosiglitazone (Avandia)

2–8 mg once daily

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 11th Edition: <http://www.accessmedicine.com>

Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

**Pioglitazone** has PPAR- $\alpha$  as well as PPAR- $\gamma$  activity. It is absorbed within 2 hours of ingestion; although food may delay uptake, total bioavailability is not affected. Pioglitazone is metabolized by CYP2C8 and CYP3A4 to active metabolites. The bioavailability of numerous other drugs also degraded by these enzymes may be affected by pioglitazone therapy, including estrogen-containing oral contraceptives; additional methods of contraception are advised. Pioglitazone may be taken once daily; the usual starting dose is 15–30 mg/d, and the maximum is 45 mg/d. The triglyceride-lowering effect is more significant than that observed with rosiglitazone, presumably because of its PPAR- $\alpha$ -binding characteristics. Pio-glitazone therapy reduces mortality and macrovascular events (myocardial infarction and stroke). Pioglitazone is approved as a monotherapy and in combination with metformin, sulfonyleureas, and insulin for the treatment of type 2 diabetes.

**Rosiglitazone** is rapidly absorbed and highly protein-bound. It is metabolized in the liver to minimally active metabolites, predominantly by CYP2C8 and

to a lesser extent by CYP2C9. It is administered once or twice daily; 4â€¸8 mg is the usual total dose. There are reports that rosiglitazone increases the risk of cardiovascular disease; this controversy remains unresolved. Rosiglitazone shares the common Tzd adverse effects but does not seem to have any significant drug interactions. The drug is approved for use in type 2 diabetes as monotherapy, in double combination therapy with a biguanide or sulfonylurea, or in quadruple combination with a biguanide, sulfonylurea, and insulin.

Tzds are considered euglycemics and are efficacious in about 70% of new users. The overall response is similar to sulfonylurea and biguanide monotherapy. Individuals experiencing secondary failure with other oral agents should benefit from the addition (rather than substitution) of a Tzd. Because their mechanism of action involves gene regulation, the Tzds have a slow onset and offset of activity over weeks or even months. Combination therapy with sulfonylureas and insulin can lead to hypoglycemia and may require dosage adjustment.

An adverse effect common to both Tzds is fluid retention, which presents as a mild anemia and peripheral edema, especially when used in combination with insulin or insulin secretagogues. Both drugs increase the risk of heart failure. Many users have a dose-related weight gain (average 1â€¸3 kg), which may be fluid-related. Rarely, new or worsening macular edema has been reported in association with treatment. Increased bone fractures in women are described for both compounds, which is postulated to be due to decreased osteoblast formation. Studies are ongoing to determine whether the fracture risk is also increased in men. Long-term therapy is associated with a drop in triglyceride levels and a slight rise in high-density lipoprotein (HDL) and low-density lipoprotein (LDL) cholesterol values. These agents should not be used during pregnancy or in the presence of significant liver disease (ALT more than 2.5 times upper limit of normal) or with a concurrent diagnosis of heart failure. Because of the hepatotoxicity observed with troglitazone, a discontinued Tzd, the FDA continues to require monitoring of liver function tests before initiation of Tzd therapy and periodically afterward. To date, hepatotoxicity has not been associated with rosiglitazone or pioglitazone. Anovulatory women may resume ovulation and should be counseled on the increased risk of pregnancy.

Thiazolidinediones have benefit in the *prevention* of type 2 diabetes. The Diabetes Prevention Trial reported a 75% reduction in diabetes incidence rate when troglitazone was administered to patients with prediabetes. Another study reported that troglitazone therapy significantly decreased the recurrence of diabetes mellitus in high-risk Hispanic women with a history of gestational diabetes.

Although these medications are highly efficacious, the adverse effects of weight gain, congestive heart failure, increased bone fracture risk in women, and possible (for rosiglitazone) worsening of cardiovascular risk potentially limit their popularity and future use.

## Alpha-Glucosidase Inhibitors

**Acarbose** and **miglitol** are competitive inhibitors of the intestinal  $\alpha$ -glucosidases and reduce post-meal glucose excursions by delaying the digestion and absorption of starch and disaccharides (Table 41â€¸9). Only monosaccharides, such as glucose and fructose, can be transported out of the intestinal lumen and into the bloodstream. Complex starches, oligosaccharides, and disaccharides must be broken down into individual monosaccharides before being absorbed in the duodenum and upper jejunum. This digestion is facilitated by enteric enzymes, including pancreatic  $\alpha$ -amylase and  $\alpha$ -glucosidases that are attached to the brush border of the intestinal cells. Miglitol differs structurally from acarbose and is six times more potent in inhibiting sucrase. Although the binding affinity of the two compounds differs, acarbose and miglitol both target the  $\alpha$ -glucosidases: sucrase, maltase, glucoamylase, and dextranase. Miglitol alone has effects on isomaltase and on  $\beta$ -glucosidases, which split  $\beta$ -linked sugars such as lactose. Acarbose alone has a small effect on  $\alpha$ -amylase. The consequence of enzyme inhibition is to minimize upper intestinal digestion and defer digestion (and thus absorption) of the ingested starch and disaccharides to the distal small intestine, thereby lowering postmeal glycemic excursions as much as 45â€¸60 mg/dL and creating an insulin-sparing effect.

**Table 41â€¸9 Alpha-Glucosidase Inhibitors.**

### Alpha-Glucosidase Inhibitor Chemical Structure

Acarbose (Precose)

### Oral Dose

25â€¸100 mg before meals

Miglitol (Glyset)

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 11th Edition: <http://www.accessmedicine.com>  
Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

25â€¸100 mg before meals

Monotherapy with these drugs is associated with a modest drop (0.5â€¸1%) in glycohemoglobin levels and a 20â€¸25 mg/dL fall in fasting glucose levels. They are FDA-approved for persons with type 2 diabetes as monotherapy and in combination with sulfonylureas, in which the glycemic effect is additive. Both acarbose and miglitol are taken in doses of 25â€¸100 mg just before ingesting the first portion of each meal; therapy should be initiated with the lowest dose and slowly titrated upward, and a similar amount of starch and disaccharides should be ingested at each meal.

Prominent adverse effects include flatulence, diarrhea, and abdominal pain and result from the appearance of undigested carbohydrate in the colon that is then fermented into short-chain fatty acids, releasing gas. These adverse effects tend to diminish with ongoing use because chronic exposure to

carbohydrate induces the expression of  $\alpha$ -glucosidase in the jejunum and ileum, increasing distal small intestine glucose absorption and minimizing the passage of carbohydrate into the colon. Although not a problem with monotherapy or combination therapy with a biguanide, hypoglycemia may occur with concurrent sulfonylurea treatment. Hypoglycemia should be treated with glucose (dextrose) and not sucrose, whose breakdown may be blocked. These drugs are contraindicated in patients with inflammatory bowel disease or any intestinal condition that could be worsened by gas and distention. Because both miglitol and acarbose are excreted by the kidneys, these medications should not be prescribed in individuals with renal impairment. Acarbose has been associated with reversible hepatic enzyme elevation and should be used with caution in the presence of hepatic disease.

The STOP-NIDDM trial demonstrated that  $\alpha$ -glucosidase therapy in prediabetic persons successfully prevented a significant number of new cases of type 2 diabetes and helped restore beta-cell function, in addition to reducing cardiovascular disease and hypertension. Intervention with acarbose also reduced cardiovascular events in persons with diabetes. Diabetes and cardiovascular disease prevention may become a further indication for this class of medications.

Alpha-glucosidase inhibitors are infrequently prescribed in the United States because of their prominent gastrointestinal adverse effects and relatively minor glucose-lowering benefit.

## **PRAMLINTIDE**

Pramlintide, a synthetic analog of amylin, is an injectable antihyperglycemic agent that modulates postprandial glucose levels and is approved for preprandial use in persons with type 1 and type 2 diabetes. It is administered in addition to insulin in those who are unable to achieve their target postprandial blood sugars. Pramlintide suppresses glucagon release via undetermined mechanisms, delays gastric emptying, and has central nervous system-mediated anorectic effects. It is rapidly absorbed after subcutaneous administration; levels peak within 20 minutes, and the duration of action is not more than 150 minutes. Pramlintide is renally metabolized and excreted, but even at low creatinine clearance there is no significant change in bioavailability. It has not been evaluated in dialysis patients. The most reliable absorption is from the abdomen and thigh; arm administration is less reliable. Pramlintide should be injected immediately before eating; doses range from 15 to 60 mcg subcutaneously for individuals with type 1 diabetes and from 60 to 120 mcg subcutaneously for individuals with type 2 diabetes. Therapy with this agent should be initiated with the lowest dose and titrated upward. Because of the risk of hypoglycemia, concurrent rapid- or short-acting mealtime insulin doses should be decreased by 50% or more. Concurrent insulin secretagogue doses also may need to be decreased in persons with type 2 diabetes. Pramlintide should always be injected by itself with a separate syringe; it cannot be mixed with insulin. The major adverse effects of pramlintide are hypoglycemia and gastrointestinal symptoms including nausea, vomiting, and anorexia.

## **EXENATIDE**

As a synthetic analog of glucagon-like-polypeptide 1 (GLP-1), exenatide is the first incretin therapy to become available for the treatment of diabetes. Exenatide is approved as an injectable, adjunctive therapy in persons with type 2 diabetes treated with metformin or metformin plus sulfonylureas who still have suboptimal glycemic control. In clinical studies, exenatide therapy was shown to have multiple actions such as potentiation of glucose-mediated insulin secretion, suppression of postprandial glucagon release through as-yet unknown mechanisms, slowed gastric emptying, and a central loss of appetite. The increased insulin secretion is speculated to be due in part to an increase in beta-cell mass. It is not known whether the increased beta-cell mass results from decreased beta-cell apoptosis, increased beta-cell formation, or both.

Exenatide is absorbed equally from arm, abdomen, or thigh injection sites, reaching a peak concentration in approximately 2 hours with a duration of action of up to 10 hours. It undergoes glomerular filtration, and dosage adjustment is required only when the creatinine clearance is less than 30 mL/min. Exenatide is injected subcutaneously within 60 minutes before a meal; therapy is initiated at 5 mcg twice daily, with a maximum dosage of 10 mcg twice daily. When exenatide is added to preexisting sulfonylurea therapy, the oral hypoglycemic dosage may need to be decreased to prevent hypoglycemia. The major adverse effects are nausea (about 44% of users) and vomiting and diarrhea. The nausea decreases with ongoing exenatide usage. Weight loss is reported in some users, presumably because of the nausea and anorectic effects. A serious and, in some cases, fatal adverse effect of exenatide is necrotizing and hemorrhagic pancreatitis.

Although an injectable, exenatide has gained popularity because of the improved glucose control and associated anorexia and weight loss in some users. Safety issues, however, may deter future use.

## **SITAGLIPTIN**

Sitagliptin is an inhibitor of dipeptidyl peptidase-4 (DPP-4), the enzyme that degrades incretin and other GLP-1-like molecules. Its major action is to increase circulating levels of GLP-1 and GIP. This ultimately decreases postprandial glucose excursions by increasing glucose-mediated insulin secretion and decreasing glucagon levels. Sitagliptin has an oral bioavailability of over 85% and a half-life of approximately 12 hours; the dosage is 100 mg orally once daily. Common adverse effects include nasopharyngitis, upper respiratory infections, and headaches. Rarely, severe allergic reactions have been reported. Dosage should be reduced in patients with renal impairment. Sitagliptin can be given as monotherapy or combined with metformin or Tzds.

## **Combination Therapy—“Oral Antidiabetic Agents & Injectable Medication**

### **Combination Therapy in Type 2 Diabetes Mellitus**

Failure to maintain a good response to therapy over the long term owing to a progressive decrease in beta-cell mass, reduction in physical activity, decline in lean body mass, or increase in ectopic fat deposition, remains a disconcerting problem in the management of type 2 diabetes. Multiple medications may be required to achieve glycemic control. Unless there is a contraindication, medical therapy should be initiated with a biguanide. If clinical failure occurs with biguanide monotherapy, a second agent or insulin is added. The second-line drug can be an insulin secretagogue, Tzd, incretin-based therapy, amylin analog, or a glucosidase inhibitor; preference is given to sulfonylureas or insulin because of cost, adverse effects, and safety concerns. Third-line therapy can include a biguanide, multiple other oral medications, or a noninsulin injectable and a biguanide and intensified insulin therapy. Recommended fourth-line therapy is intensified insulin management with or without a biguanide or Tzd.

### **COMBINATION THERAPY WITH EXENATIDE**

Exenatide is approved for use in individuals who fail to achieve desired glycemic control on biguanides, or biguanides plus sulfonylureas. Hypoglycemia is a risk when exenatide is used with an insulin secretagogue or with insulin. The doses of the latter drugs have to be reduced at the initiation of exena-

time therapy and subsequently titrated.

#### **COMBINATION THERAPY WITH PRAMLINTIDE**

Pramlintide is approved for concurrent mealtime administration in individuals with type 2 diabetes treated with insulin, metformin, or a sulfonylurea who are unable to achieve their postprandial glucose targets. Combination therapy results in a significant reduction in early postprandial glucose excursions; mealtime insulin or sulfonylurea doses usually have to be reduced to prevent hypoglycemia.

#### **COMBINATION THERAPY WITH INSULIN**

Bedtime insulin has been suggested as an adjunct to oral antidiabetic therapy in patients with type 2 diabetes who have not responded to maximal oral therapy. Clinical practice has evolved to include sulfonylureas, meglitinides, D-phenylalanine derivatives, biguanides, thiazolidinediones, or  $\alpha$ -glucosidase inhibitors given in conjunction with insulin.

Persons unable to achieve glycemic control with bedtime insulin as described generally require full insulin replacement and multiple daily injections of insulin. Insulin secretagogues are redundant when a person is receiving multiple daily insulin injections, but persons with severe insulin resistance may benefit from the addition of a biguanide or Tzd. When a biguanide or Tzd is added to the regimen of a person already taking insulin, the blood glucose should be closely monitored and the insulin dosage decreased as needed to avoid hypoglycemia.

#### **Combination Therapy in Type 1 Diabetes Mellitus**

Insulin secretagogues (sulfonylureas, meglitinides, or D-phenylalanine derivatives), Tzds, biguanides,  $\alpha$ -glucosidase inhibitors, and incretin-based agents are *not* approved for use in type 1 diabetes.

#### **COMBINATION THERAPY WITH PRAMLINTIDE**

Pramlintide is approved for concurrent mealtime administration in individuals with type 1 diabetes who have poor glucose control after eating despite optimal insulin therapy. The addition of pramlintide leads to a significant reduction in early postprandial glucose excursions; mealtime insulin doses usually have to be reduced to prevent hypoglycemia.

## **GLUCAGON**

### **Chemistry & Metabolism**

Glucagon is synthesized in the alpha cells of the pancreatic islets of Langerhans (Table 41-1). Glucagon is a peptide—identical in all mammals—consisting of a single chain of 29 amino acids, with a molecular weight of 3485. Selective proteolytic cleavage converts a large precursor molecule of approximately 18,000 MW to glucagon. One of the precursor intermediates consists of a 69-amino-acid peptide called **glicentin**, which contains the glucagon sequence interposed between peptide extensions.

Glucagon is extensively degraded in the liver and kidney as well as in plasma and at its tissue receptor sites. Because of its rapid inactivation by plasma, chilling of the collecting tubes and addition of inhibitors of proteolytic enzymes are necessary when samples of blood are collected for immunoassay of circulating glucagon. Its half-life in plasma is between 3 and 6 minutes, which is similar to that of insulin.

### **"Gut Glucagon"**

Glicentin immunoreactivity has been found in cells of the small intestine as well as in pancreatic alpha cells and in effluents of perfused pancreas. The intestinal cells secrete **enteroglucagon**, a family of glucagon-like peptides, of which glicentin is a member, along with glucagon-like peptides 1 and 2 (GLP-1 and GLP-2). Unlike the pancreatic alpha cell, these intestinal cells lack the enzymes to convert glucagon precursors to true glucagon by removing the carboxyl terminal extension from the molecule.

### **Glucagon-Like Peptide 1 (Glp-1)**

The function of the enteroglucagons has not been clarified, although smaller peptides can bind hepatic glucagon receptors where they exert partial activity. A derivative of the 37-amino-acid form of GLP-1 that lacks the first six amino acids (GLP-1[7-37]) is a potent stimulant of insulin synthesis and release and beta-cell mass. In addition, it inhibits glucagon secretion, slows gastric emptying, and has an anorectic effect. After oral glucose ingestion, GLP-1 along with another gut hormone, glucose-dependent insulinotropic polypeptide (GIP), accounts for as much as 70% of the induced insulin secretion. GLP-1 represents the predominant form of GLP in the human intestine and has been termed *insulinotropin*. It has been considered as a potential therapeutic agent in type 2 diabetes. However, GLP-1 requires continuous subcutaneous infusion to produce a sustained lowering of both fasting and postprandial hyperglycemia in type 2 diabetic patients; therefore, its clinical usefulness is limited. Exenatide (see previous text) is an analog of GLP-1.

## **Pharmacologic Effects of Glucagon**

### **METABOLIC EFFECTS**

The first six amino acids at the amino terminal of the glucagon molecule bind to specific  $G_s$  protein-coupled receptors on liver cells. This leads to an increase in cAMP, which facilitates catabolism of stored glycogen and increases gluconeogenesis and ketogenesis. The immediate pharmacologic result of glucagon infusion is to raise blood glucose at the expense of stored hepatic glycogen. There is no effect on skeletal muscle glycogen, presumably because of the lack of glucagon receptors on skeletal muscle. Pharmacologic amounts of glucagon cause release of insulin from normal pancreatic beta cells, catecholamines from pheochromocytoma, and calcitonin from medullary carcinoma cells.

### **CARDIAC EFFECTS**

Glucagon has a potent inotropic and chronotropic effect on the heart, mediated by the cAMP mechanism described above. Thus, it produces an effect very similar to that of  $\beta$ -adrenoceptor agonists without requiring functioning  $\beta$  receptors.

### **EFFECTS ON SMOOTH MUSCLE**

Large doses of glucagon produce profound relaxation of the intestine. In contrast to the above effects of the peptide, this action on the intestine may be due to mechanisms other than adenylyl cyclase activation.

## Clinical Uses

### SEVERE HYPOGLYCEMIA

The major use of glucagon is for emergency treatment of severe hypoglycemic reactions in patients with type 1 diabetes when unconsciousness precludes oral feedings and intravenous glucose treatment is not possible. Recombinant glucagon is currently available in 1-mg vials for parenteral use (Glucagon Emergency Kit). Nasal sprays have been developed for this purpose but have not yet received FDA approval.

### ENDOCRINE DIAGNOSIS

Several tests use glucagon to diagnose endocrine disorders. In patients with type 1 diabetes mellitus, a classic research test of pancreatic beta-cell secretory reserve uses 1 mg of glucagon administered as an intravenous bolus. Because insulin-treated patients develop circulating anti-insulin antibodies that interfere with radioimmunoassays of insulin, measurements of C-peptide are used to indicate beta-cell secretion.

### BETA-ADRENOCEPTOR BLOCKER OVERDOSE

Glucagon is sometimes useful for reversing the cardiac effects of an overdose of  $\beta$ -blocking agents because of its ability to increase cAMP production in the heart. However, it is not clinically useful in the treatment of cardiac failure.

### RADIOLOGY OF THE BOWEL

Glucagon has been used extensively in radiology as an aid to x-ray visualization of the bowel because of its ability to relax the intestine.

### Adverse Reactions

Transient nausea and occasional vomiting can result from glucagon administration. These are generally mild, and glucagon is relatively free of severe adverse reactions.

## ISLET AMYLOID POLYPEPTIDE (IAPP, AMYLIN)

Amylin is a 37-amino-acid peptide originally derived from islet amyloid deposits in pancreas material from patients with long-standing type 2 diabetes or insulinomas. It is produced by pancreatic beta cells, packaged within beta-cell granules in a concentration 1% that of insulin and co-secreted with insulin in a pulsatile manner and in response to physiologic secretory stimuli. Approximately 1 molecule of amylin is released for every 10 molecules of insulin. It circulates in a glycosylated (active) and nonglycosylated (inactive) form with physiologic concentrations ranging from 4 to 25 pmol/L and is primarily excreted by the kidney. Amylin appears to be a member of the superfamily of neuroregulatory peptides, with 46% homology with the calcitonin gene-related peptide CGRP (see Chapter 17). The physiologic effect of amylin may be to modulate insulin release by acting as a negative feedback on insulin secretion. At pharmacologic doses, amylin reduces glucagon secretion, slows gastric emptying by a vagally mediated mechanism, and centrally decreases appetite. An analog of amylin, **pramlintide** (see in previous section), differs from amylin by the substitution of proline at positions 25, 28, and 29. These modifications make pramlintide soluble and nonself-aggregating and suitable for pharmacologic use.

## SUMMARY: DRUGS USED FOR DIABETES<sup>1</sup>

Drugs Used for Diabetes				
Subclass	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>Insulins</b>				
Rapid-acting: Lispro, aspart, glulisine	Activate insulin receptor	Reduce circulating glucose • promote glucose transport and oxidation, glycogen, lipid, protein synthesis, and regulation of gene expression	Type 1 and type 2 diabetes	Parenteral (subcutaneous or intravenous) • duration varies (see text) • <i>Toxicity</i> : Hypoglycemia, weight gain, lipodystrophy (rare)
Short-acting: Regular				
Intermediate-acting: NPH				
Long-acting: Detemir, glargine				
<b>Sulfonylureas</b>				
Glipizide	Insulin secretagogue:	In patients with functioning beta cells, reduce circulating glucose • increase glycogen, fat, and protein formation • gene regulation	Type 2 diabetes	Orally active • duration 10–24 h • <i>Toxicity</i> : Hypoglycemia, weight gain
Glyburide	Close K <sup>+</sup> channels in beta cells • increase insulin release			
Glimepiride				
<i>Tolazamide, tolbutamide, chlorpropamide: Older sulfonylureas, lower potency, greater toxicity; rarely used</i>				
<b>Glitinides</b>				
Repaglinide	Insulin secretagogue: Similar to sulfonylureas with some overlap in binding sites	In patients with functioning beta cells, reduces circulating glucose • increases glycogen, fat, and protein formation • gene regulation	Type 2 diabetes	Oral • very fast onset of action • duration 5–8 h • <i>Toxicity</i> : Hypoglycemia
Nateglinide	Insulin secretagogue:	In patients with functioning beta cells,	Type 2	Oral • very fast onset and short duration (< 4 h) •

	Similar to sulfonylureas with some overlap in binding sites	reduces circulating glucose • increases glycogen, fat, and protein formation • gene regulation	diabetes	<i>Toxicity:</i> Hypoglycemia
<b>Biguanides</b>				
Metformin	Obscure: Reduced hepatic and renal gluconeogenesis	Decreased endogenous glucose production	Type 2 diabetes	Oral • maximal plasma concentration in 2-3 h • <i>Toxicity:</i> Gastrointestinal symptoms, lactic acidosis (rare) • cannot use if impaired renal/hepatic function • congestive heart failure (CHF), hypoxic/acidotic states, alcoholism
<b>Alpha-Glucosidase inhibitors</b>				
Acarbose, miglitol	Inhibit intestinal $\alpha$ -glucosidases	Reduce conversion of starch and disaccharides to monosaccharides • reduce postprandial hyperglycemia	Type 2 diabetes	Oral • rapid onset • <i>Toxicity:</i> Gastrointestinal symptoms • cannot use if impaired renal/hepatic function, intestinal disorders
<b>Thiazolidinediones</b>				
Rosiglitazone	Regulates gene expression by binding to PPAR- $\gamma$	Reduces insulin resistance	Type 2 diabetes	Oral • long-acting (> 24 h) • <i>Toxicity:</i> Fluid retention, edema, anemia, weight gain, macular edema, bone fractures in women • cannot use if CHF, hepatic disease • may worsen heart disease
Pioglitazone	Regulates gene expression by binding to PPAR- $\gamma$ and PPAR- $\alpha$	Reduces insulin resistance	Type 2 diabetes	Oral • long-acting (> 24 h) • <i>Toxicity:</i> Fluid retention, edema, anemia, weight gain, macular edema, bone fractures in women • cannot use if CHF, hepatic disease
<b>Incretin-based drugs</b>				
Exenatide	Analog of GLP-1: Binds to GLP-1 receptors	Reduces post-meal glucose excursions: increases glucose-mediated insulin release, lowers glucagon levels, slows gastric emptying, decreases appetite	Type 2 diabetes	Parenteral (subcutaneous) • half-life ~2.4 h • <i>Toxicity:</i> Nausea, headache, vomiting, anorexia, mild weight loss, pancreatitis
Sitagliptin	DPP-4 inhibitor: Blocks degradation of GLP-1, raises circulating GLP-1 levels	Reduces post-meal glucose excursions: Increases glucose mediated insulin release, lowers glucagon levels, slows gastric emptying, decreases appetite	Type 2 diabetes	Oral • half-life ~12 h • 24-h duration of action • <i>Toxicity:</i> Rhinitis, upper respiratory infections, rare allergic reactions
<b>Amylin analog</b>				
Pramlintide	Analog of amylin: Binds to amylin receptors	Reduces post-meal glucose excursions: Lowers glucagons levels, slows gastric emptying, decreases appetite	Type 1 and type 2 diabetes	Parenteral (subcutaneous) • rapid onset • half-life ~48 min • <i>Toxicity:</i> Nausea, anorexia, hypoglycemia, headache

<sup>1</sup>See text for acronyms.

## PREPARATIONS AVAILABLE<sup>1</sup>

### SULFONYLUREAS

#### **Chlorpropamide** (generic, Diabinese)

Oral: 100, 250 mg tablets

#### **Glimepiride** (generic, Amaryl)

Oral: 1, 2, 4 mg tablets

#### **Glipizide** (generic, Glucotrol, Glucotrol XL)

Oral: 5, 10 mg tablets; 2.5, 5, 10 mg extended-release tablets

#### **Glyburide** (generic, DiaBeta, Micronase, Glynase PresTab)

Oral: 1.25, 2.5, 5 mg tablets; 1.5, 3, 4.5, 6 mg Glynase PresTab, micronized tablets

#### **Tolazamide** (generic, Tolinase)

Oral: 100, 250, 500 mg tablets

#### **Tolbutamide** (generic, Orinase)

Oral: 500 mg tablets

## MEGLITINIDE & RELATED DRUGS

### Repaglinide (Prandin)

Oral: 0.5, 1, 2 mg tablets

### Nateglinide (Starlix)

Oral: 60, 120 mg tablets

## BIGUANIDE

### Metformin (generic, Glucophage, Glucophage XR)

Oral: 500, 850, 1000 mg tablets; extended-release (XR): 500, 750, 1000 mg tablets; 500 mg/5 mL solution

## METFORMIN COMBINATIONS<sup>2</sup>

### Glipizide plus metformin (generic, Metaglip)

Oral: 2.5/250, 2.5/500, 5/500 mg tablets

### Glyburide plus metformin (generic, Glucovance)

Oral: 1.25/250, 2.5/500, 5/500 mg tablets

### Rosiglitazone plus metformin (Avandamet)

Oral: 1/500, 2/500, 4/500; 2/1000, 4/1000 mg tablets

## THIAZOLIDINEDIONE DERIVATIVES

### Pioglitazone (Actos)

Oral: 15, 30, 45 mg tablets

### Rosiglitazone (Avandia)

Oral: 2, 4, 8 mg tablets

## THIAZOLIDINEDIONE COMBINATION

### Rosiglitazone plus glimepiride (Avandaryl)

Oral: 4/1, 4/2, 4/4, 8/2, 8/4 mg rosiglitazone/mg glimepiride tablets

## ALPHA-GLUCOSIDASE INHIBITORS

### Acarbose (Precose)

Oral: 25, 50, 100 mg tablets

### Miglitol (Glyset)

Oral: 25, 50, 100 mg tablets

## AMYLIN ANALOGS

### Pramlintide (Symlin)

Parenteral: vial: 0.6, 1 mg/mL

## GLUCAGON-LIKE POLYPEPTIDE-1 ANALOGS

### Exenatide (Byetta)

Parenteral: 250 mcg/mL

## DIPEPTIDYL PEPTIDASE 4 INHIBITOR

### Sitagliptin (Januvia)

Oral: 25, 50, 100 mg tablets

## GLUCAGON

### Glucagon (generic)

Parenteral: 1 mg lyophilized powder to reconstitute for injection

<sup>1</sup>See Table 41â€4 for insulin preparations.

<sup>2</sup>Other combinations are available.

Basic and Clinical Pharmacology > Chapter 42. Agents that Affect Bone Mineral Homeostasis >

## Case Study

A 65-year-old man is referred to you from his primary care physician (PCP) for evaluation and management of possible osteoporosis. He saw his PCP for evaluation of low back pain. X-rays of the spine showed some degenerative changes in the lumbar spine plus several wedge deformities in the thoracic spine. The patient is a long-time smoker (up to two packs per day) and has two to four glasses of wine with dinner, more on the weekends. He has chronic bronchitis, presumably from smoking and has been treated many times with oral prednisone for exacerbations of bronchitis. He is currently on 10 mg/d prednisone. Examination shows kyphosis of the thoracic spine, with some tenderness to fist percussion over the thoracic spine. The DEXA (dual-energy x-ray absorptiometry) measurement of the lumbar spine is "within the normal limits," but the radiologist noted that the reading may be misleading because of the degenerative changes. The hip measurement shows a T score (number of standard deviations that the patient's measured bone density is from normal young adult bone density) in the femoral neck of  $-2.2$ . What further workup should be considered, and what therapy should be initiated?

## BASIC PHARMACOLOGY

Calcium and phosphate, the major mineral constituents of bone, are also two of the most important minerals for general cellular function. Accordingly, the body has evolved a complex set of mechanisms by which calcium and phosphate homeostasis are carefully maintained (Figure 42-1). Approximately 98% of the  $1.2$  kg of calcium and 85% of the 1 kg of phosphorus in the human adult are found in bone, the principal reservoir for these minerals. These functions are dynamic, with constant remodeling of bone and ready exchange of bone mineral with that in the extracellular fluid. Bone also serves as the principal structural support for the body and provides the space for hematopoiesis. Thus, abnormalities in bone mineral homeostasis can lead not only to a wide variety of cellular dysfunctions (eg, tetany, coma, muscle weakness) but also to disturbances in structural support of the body (eg, osteoporosis with fractures) and loss of hematopoietic capacity (eg, infantile osteopetrosis).

Some mechanisms contributing to bone mineral homeostasis. Direct actions are shown and feedback may alter the net effect. Calcium (Ca) and phosphorus (P) concentrations in the serum are controlled principally by three hormones, 1,25(OH)<sub>2</sub>D<sub>3</sub> (D), fibroblast growth factor 23 (FGF23), and parathyroid hormone (PTH), through their action on absorption from the gut and from bone and on excretion in the urine. PTH and 1,25(OH)<sub>2</sub>D<sub>3</sub> increase input of calcium and phosphorus from bone into the serum and stimulate bone formation. 1,25(OH)<sub>2</sub>D<sub>3</sub> also increases calcium and phosphate absorption from the gut. 1,25(OH)<sub>2</sub>D<sub>3</sub> decreases urinary excretion of both calcium and phosphorus, whereas PTH reduces calcium but increases phosphorus excretion. FGF23 stimulates renal excretion of phosphate. Calcitonin (CT) is a less critical hormone for calcium homeostasis, but in pharmacologic concentrations can reduce serum calcium and phosphorus by inhibiting bone resorption and stimulating their renal excretion. Feedback may alter the effects shown; for example, vitamin D usually increases urinary calcium excretion because of effects on calcium absorption from the gut and effects on PTH.

Calcium and phosphate enter the body from the intestine. The average American diet provides 600–1000 mg of calcium per day, of which approximately 100–250 mg is absorbed. This figure represents net absorption, because both absorption (principally in the duodenum and upper jejunum) and secretion (principally in the ileum) occur. The amount of phosphorus in the American diet is about the same as that of calcium. However, the efficiency of absorption (principally in the jejunum) is greater, ranging from 70% to 90%, depending on intake. In the steady state, renal excretion of calcium and phosphate balances intestinal absorption. In general, over 98% of filtered calcium and 85% of filtered phosphate is reabsorbed by the kidney. The movement of calcium and phosphate across the intestinal and renal epithelia is closely regulated. Intrinsic disease of the intestine (eg, nontropical sprue) or kidney (eg, chronic renal failure) disrupts bone mineral homeostasis.

Three hormones serve as the principal regulators of calcium and phosphate homeostasis: parathyroid hormone (PTH), fibroblast growth factor 23 (FGF23), and the steroid vitamin D (Figure 42–2). Vitamin D is a prohormone rather than a true hormone, because it must be further metabolized to gain biologic activity. PTH stimulates the production of the active metabolite of vitamin D, 1,25(OH)<sub>2</sub>D. 1,25(OH)<sub>2</sub>D, on the other hand, suppresses the production of PTH.

1,25(OH)<sub>2</sub>D stimulates the intestinal absorption of calcium and phosphate. 1,25(OH)<sub>2</sub>D and PTH promote both bone formation and resorption in part by stimulating the proliferation and differentiation of osteoblasts and osteoclasts. Both PTH and 1,25(OH)<sub>2</sub>D enhance renal retention of calcium, but PTH promotes renal phosphate excretion. FGF23 is a

recently discovered hormone that stimulates renal phosphate excretion and inhibits renal production of  $1,25(\text{OH})_2\text{D}$ . Other hormones—calcitonin, prolactin, growth hormone, insulin, thyroid hormone, glucocorticoids, and sex steroids— influence calcium and phosphate homeostasis under certain physiologic circumstances and can be considered secondary regulators. Deficiency or excess of these secondary regulators within a physiologic range does not produce the disturbance of calcium and phosphate homeostasis that is observed in situations of deficiency or excess of PTH, FGF23, and vitamin D. However, certain of these secondary regulators—especially calcitonin, glucocorticoids, and estrogens—are useful therapeutically and are discussed in subsequent sections.

**Figure 42-2**

The hormonal interactions controlling bone mineral homeostasis. In the body (A),  $1,25(\text{OH})_2\text{D}$  is produced by the kidney under the control of parathyroid hormone (PTH), which stimulates its production, and fibroblast growth factor 23 (FGF23), which

inhibits its production.  $1,25(\text{OH})_2\text{D}$  in turn inhibits the production of PTH by the parathyroid glands and stimulates FGF23 release from bone.  $1,25(\text{OH})_2\text{D}$  is the principal regulator of intestinal calcium and phosphate absorption. At the level of the bone (**B**), both PTH and  $1,25(\text{OH})_2\text{D}$  regulate bone formation and resorption, with each capable of stimulating both processes. This is accomplished by their stimulation of preosteoblast proliferation and differentiation into osteoblasts, the bone forming cell. PTH and  $1,25(\text{OH})_2\text{D}$  stimulate the expression of RANKL by the osteoblast, which, with MCSF, stimulates the differentiation and subsequent activation of osteoclasts, the bone resorbing cell. FGF23 in excess leads to osteomalacia by inhibiting  $1,25(\text{OH})_2\text{D}$  production and lowering phosphate levels. MCSF, macrophage colony-stimulating factor; OPG, osteoprotegerin; RANKL, ligand for receptor for activation of nuclear factor- $\kappa\text{B}$ .

In addition to these hormonal regulators, calcium and phosphate themselves, other ions such as sodium and fluoride, and a variety of drugs (bisphosphonates, plicamycin, and diuretics) also alter calcium and phosphate homeostasis.

## Principal Hormonal Regulators of Bone Mineral Homeostasis

### PARATHYROID HORMONE

Parathyroid hormone (PTH) is a single-chain peptide hormone composed of 84 amino acids. It is produced in the parathyroid gland in a precursor form of 115 amino acids, the remaining 31 amino terminal amino acids being cleaved off before secretion. Within the gland is a calcium-sensitive protease capable of cleaving the intact hormone into fragments. Biologic activity resides in the amino terminal region such that synthetic PTH 1-34 is fully active. Loss of the first two amino terminal amino acids eliminates most biologic activity.

The metabolic clearance of intact PTH is rapid, with a half-time of disappearance measured in minutes. Most of the clearance occurs in the liver and kidney. The biologically inactive carboxyl terminal fragments produced during metabolism of the intact hormone have a much lower clearance, especially in current renal failure. This accounts in part for the very high PTH values often observed in the past in patients with renal failure when measured by radioimmunoassays directed against the carboxyl terminal region of the molecule. However, most PTH assays in current use measure the intact hormone by a double antibody method, so that this circumstance is less frequently encountered in clinical practice. PTH regulates calcium and phosphate flux across cellular membranes in bone and kidney, resulting in increased serum calcium and decreased serum phosphate. In bone, PTH increases the activity and number of osteoclasts, the cells responsible for bone resorption. However, this stimulation of osteoclasts is not a direct effect. Rather, PTH acts on the osteoblast (the bone-forming cell) to induce a membrane-bound protein called **RANK ligand (RANKL)**. This factor acts on osteoclasts and osteoclast precursors to increase both the numbers and the activity of osteoclasts. This action increases bone turnover or bone remodeling, a specific sequence of cellular events initiated by osteoclastic bone resorption and followed by osteoblastic bone formation. Although both bone resorption and bone formation are enhanced by PTH, the net effect of excess PTH is to increase bone resorption. However, PTH in low and intermittent doses increases bone formation without first stimulating bone resorption. This action may be indirect, involving other growth factors such as insulin-like growth factor 1 (IGF-1). This has led to the recent approval of recombinant PTH 1-34 (**teriparatide**) for the treatment of osteoporosis. In the kidney, PTH increases the ability of the nephron to reabsorb calcium and magnesium but reduces its ability to reabsorb phosphate, amino acids, bicarbonate, sodium, chloride, and sulfate. Another important action of PTH on the kidney is its stimulation of  $1,25$ -dihydroxyvitamin D ( $1,25[\text{OH}]_2\text{D}$ ) production.

### VITAMIN D

Vitamin D is a secosteroid produced in the skin from 7-dehydrocholesterol under the influence of ultraviolet radiation. Vitamin D is also found in certain foods and is used to supplement dairy products. Both the natural form (vitamin D<sub>3</sub>, cholecalciferol) and the plant-derived form (vitamin D<sub>2</sub>, ergocalciferol) are present in the diet. These forms differ in that ergocalciferol contains a double bond (C<sub>22</sub>=C<sub>23</sub>) and an additional methyl group in the side chain (Figure 42-3). In humans, this difference apparently is of limited physiologic consequence (although ergocalciferol is less potent), and the following comments apply equally well to both forms of vitamin D.

### Figure 42-3

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 11th Edition: <http://www.accessmedicine.com>

Conversion of 7-dehydrocholesterol to vitamin D<sub>3</sub> and metabolism of D<sub>3</sub> to 1,25(OH)<sub>2</sub>D<sub>3</sub> and 24,25(OH)<sub>2</sub>D<sub>3</sub>. Control of the latter step is exerted primarily at the level of the kidney, where low serum phosphorus, low serum calcium, and high parathyroid hormone favor the production of 1,25(OH)<sub>2</sub>D<sub>3</sub>, whereas fibroblast growth factor 23 inhibits its production. The inset shows the side chain for ergosterol. Ergosterol undergoes similar transformation to vitamin D<sub>2</sub> (ergocalciferol), which, in turn, is metabolized to 25(OH)D<sub>2</sub>, 1,25(OH)<sub>2</sub>D<sub>2</sub>, and 24,25(OH)<sub>2</sub>D<sub>2</sub>. In humans, corresponding D<sub>2</sub> and D<sub>3</sub> derivatives have equivalent effects and potency. They are therefore referred to in the text without a subscript.

Vitamin D is a prohormone that serves as precursor to a number of biologically active metabolites (Figure 42â€³3). Vitamin D is first hydroxylated in the liver to form 25-hydroxyvitamin D (25[OH]D). This metabolite is further converted in the kidney to a number of other forms, the best studied of which are 1,25-dihydroxyvitamin D (1,25[OH]<sub>2</sub>D) and 24,25-dihydroxyvitamin D (24,25[OH]<sub>2</sub>D). Of the natural metabolites, only vitamin D and 1,25(OH)<sub>2</sub>D (as calcitriol) are available for clinical use (Table 42â€³1). Moreover, a number of analogs of 1,25(OH)<sub>2</sub>D are being synthesized to extend the usefulness of this metabolite to a variety of nonclassic conditions. Calcipotriene (calcipotriol), for example, is being used to treat psoriasis, a hyperproliferative skin disorder. Doxercalciferol and paricalcitol have recently been approved for the treatment of secondary hyperparathyroidism in patients with chronic kidney disease. Other analogs are being investigated for the treatment of various malignancies. The regulation of vitamin D metabolism is complex, involving calcium, phosphate, and a variety of hormones, the most important of which is PTH, which stimulates, and FGF23, which inhibits the production of 1,25(OH)<sub>2</sub>D by the kidney.

**Table 42-1 Vitamin D and Its Major Metabolites and Analogs.**

<b>Chemical and Generic Names</b>	<b>Abbreviation</b>
Vitamin D3; cholecalciferol	D3
Vitamin D2; ergocalciferol	D <sub>2</sub>
25-Hydroxyvitamin D3; calcifediol	25(OH)D3
1,25-Dihydroxyvitamin D3; calcitriol	1,25(OH) <sub>2</sub> D3
24,25-Dihydroxyvitamin D3; secalcifediol	24,25(OH) <sub>2</sub> D3
Dihydrotachysterol	DHT
Calcipotriene (calcipotriol)	None
1 $\alpha$ -Hydroxyvitamin D <sub>2</sub> ; doxercalciferol	1 $\alpha$ (OH)D <sub>2</sub>
19-nor-1,25-Dihydroxyvitamin D <sub>2</sub> ; paricalcitol	19-nor-1,25(OH) <sub>2</sub> D <sub>2</sub>

Vitamin D and its metabolites circulate in plasma tightly bound to a carrier protein, the vitamin D-binding protein. This  $\alpha_2$ -globulin binds 25(OH)D and 24,25(OH)<sub>2</sub>D with comparable high affinity and vitamin D and 1,25(OH)<sub>2</sub>D with lower affinity. In normal subjects, the terminal half-life of injected calcifediol is 23 days, whereas in anephric subjects it is 42 days. The half-life of 24,25(OH)<sub>2</sub>D is probably similar. Tracer studies with vitamin D have shown a rapid clearance from the blood. The liver appears to be the principal organ for clearance. Excess vitamin D is stored in adipose tissue. The metabolic clearance of calcitriol in humans indicates a rapid turnover, with a terminal half-life measured in hours. Several of the 1,25(OH)<sub>2</sub>D analogs are bound poorly by the vitamin D-binding protein. As a result, their clearance is very rapid, with a terminal half-life of minutes. Such analogs have little of the hypercalcemic, hypercalciuric effects of calcitriol, an important aspect of their use for the management of conditions such as psoriasis and hyperparathyroidism.

The mechanism of action of the vitamin D metabolites remains under active investigation. However, calcitriol is well established as the most potent agent with respect to stimulation of intestinal calcium and phosphate transport and bone resorption. Calcitriol appears to act on the intestine both by induction of new protein synthesis (eg, calcium-binding protein and TRPV6, an intestinal calcium channel) and by modulation of calcium flux across the brush border and basolateral membranes by a means that does not require new protein synthesis. The molecular action of calcitriol on bone has received less attention. However, like PTH, calcitriol can induce RANK ligand in osteoblasts and proteins such as osteocalcin, which may regulate the mineralization process. The metabolites 25(OH)D and 24,25(OH)<sub>2</sub>D are far less potent stimulators of intestinal calcium and phosphate transport or bone resorption. However, 25(OH)D appears to be more potent than 1,25(OH)<sub>2</sub>D in stimulating renal reabsorption of calcium and phosphate and may be the major metabolite regulating calcium flux and contractility in muscle. Specific receptors for 1,25(OH)<sub>2</sub>D exist in target tissues. However, the role and even the existence of separate receptors for 25(OH)D and 24,25(OH)<sub>2</sub>D remain controversial.

The receptor for 1,25(OH)<sub>2</sub>D exists in a wide variety of tissues—“not just bone, gut, and kidney. In these “nonclassic” tissues, 1,25(OH)<sub>2</sub>D exerts a number of actions including regulation of parathyroid hormone secretion from the parathyroid gland, insulin secretion from the pancreas, cytokine production by macrophages and T cells, and proliferation and differentiation of a large number of cells, including cancer cells. Thus, the clinical utility of 1,25(OH)<sub>2</sub>D and its analogs is likely to expand.

## FIBROBLAST GROWTH FACTOR 23

Fibroblast growth factor 23 (FGF23) is a single-chain protein with 251 amino acids including a 24-amino-acid leader sequence. It inhibits  $1,25(\text{OH})_2\text{D}_3$  production and phosphate reabsorption (via the sodium phosphate co-transporters NaPi 2a and 2c) in the kidney, leading to both hypophosphatemia and inappropriately low levels of circulating  $1,25(\text{OH})_2\text{D}_3$ . Although FGF23 was originally identified in certain mesenchymal tumors, osteoblasts and osteocytes in bone appear to be its primary site of production. However, other tissues can produce FGF23, though at lower levels. FGF23 requires O-glycosylation for its secretion, a glycosylation mediated by the glycosyl transferase GALNT3. Mutations in GALNT3 result in tumoral calcinosis with elevated phosphate and  $1,25(\text{OH})_2\text{D}_3$ . FGF23 is inactivated by cleavage at an RXXR site (amino acids 176–179) by subtilisin-like proprotein convertases such as furin. Mutations in this site lead to excess FGF23, the underlying problem in autosomal dominant hypophosphatemic rickets. The similar disease, X-linked hypophosphatemic rickets is due to mutations in PHEX, an endopeptidase, which initially was thought to cleave FGF23. However, this concept has been shown to be invalid. FGF23 binds to the FGF receptors 1 and IIIc in the presence of the accessory receptor Klotho. Both Klotho and the FGF receptor must be present for signaling. Mutations in Klotho disrupt FGF23 signaling resulting in elevated phosphate and  $1,25(\text{OH})_2\text{D}_3$  levels with what has been characterized as premature aging. FGF23 production is stimulated by  $1,25(\text{OH})_2\text{D}_3$  and directly or indirectly inhibited by the dentin matrix protein DMP1 found in osteocytes. Mutations in DMP1 lead to increased FGF23 levels and osteomalacia.

## INTERACTION OF PTH, FGF23, & VITAMIN D

A summary of the principal actions of PTH, FGF23, and vitamin D on the three main target tissues—intestine, kidney, and bone—is presented in Table 42–2. The net effect of PTH is to raise serum calcium and reduce serum phosphate; the net effect of FGF23 is to decrease serum phosphate; the net effect of vitamin D is to raise both. Regulation of calcium and phosphate homeostasis is achieved through a variety of feedback loops. Calcium is the principal regulator of PTH secretion. It binds to a novel ion recognition site that is part of a  $G_q$  protein-coupled receptor called the calcium sensing receptor (CaR) and links changes in intracellular free calcium concentration to changes in extracellular calcium. As serum calcium levels rise and bind to this receptor, intracellular calcium levels increase and inhibit PTH secretion. Phosphate regulates PTH secretion directly and indirectly by forming complexes with calcium in the serum. Because it is the ionized free concentration of calcium that is detected by the parathyroid gland, increases in serum phosphate levels reduce the ionized calcium and lead to enhanced PTH secretion. Such feedback regulation is appropriate to the net effect of PTH to raise serum calcium and reduce serum phosphate levels. Likewise, both calcium and phosphate at high levels reduce the amount of  $1,25(\text{OH})_2\text{D}$  produced by the kidney and increase the amount of  $24,25(\text{OH})_2\text{D}$  produced.

**Table 42–2 Actions of Parathyroid Hormone (PTH), Vitamin D, and FGF23 on Gut, Bone, and Kidney.**

	<b>PTH</b>	<b>Vitamin D</b>	<b>FGF23</b>
Intestine	Increased calcium and phosphate absorption (by increased $1,25(\text{OH})_2\text{D}$ production)	Increased calcium and phosphate absorption by $1,25(\text{OH})_2\text{D}$	Decreased calcium and phosphate absorption by decreased $1,25(\text{OH})_2$ production
Kidney	Decreased calcium excretion, increased phosphate excretion	Calcium and phosphate excretion may be decreased by $25(\text{OH})\text{D}$ and $1,25(\text{OH})_2\text{D}$ <sup>1</sup>	Increased phosphate excretion
Bone	Calcium and phosphate resorption increased by high doses. Low doses may increase bone formation.	Increased calcium and phosphate resorption by $1,25(\text{OH})_2\text{D}$ ; bone formation may be increased by $1,25(\text{OH})_2\text{D}$ and $24,25(\text{OH})_2\text{D}$	Decreased mineralization due to hypophosphatemia

Net effect on serum levels	Serum calcium increased, serum phosphate decreased	Serum calcium and phosphate both increased	Decreased serum phosphate
----------------------------	--	--	---------------------------

<sup>1</sup>Direct effect. Vitamin D often increases urine calcium owing to increased calcium absorption from the intestine and resulting decreased PTH.

The high calcium works directly and indirectly by reducing PTH secretion. The high phosphate works directly and indirectly by increasing FGF23 levels. Since 1,25(OH)<sub>2</sub>D raises serum calcium and phosphate, whereas 24,25(OH)<sub>2</sub>D has less effect, such feedback regulation is again appropriate. 1,25(OH)<sub>2</sub>D itself directly inhibits PTH secretion (independently of its effect on serum calcium) by a direct action on PTH gene transcription. This provides yet another negative feedback loop. The ability of 1,25(OH)<sub>2</sub>D to inhibit PTH secretion directly is being exploited using calcitriol analogs that have less effect on serum calcium because of their lesser effect on intestinal calcium absorption. Such drugs are proving useful in the management of secondary hyperparathyroidism accompanying chronic kidney disease and may be useful in selected cases of primary hyperparathyroidism. 1,25(OH)<sub>2</sub>D<sub>3</sub> also stimulates the production of FGF23. This completes the negative feedback loop in that FGF23 inhibits 1,25(OH)<sub>2</sub>D<sub>3</sub> production while promoting hypophosphatemia, which in turn inhibits FGF23 production and stimulates that of 1,25(OH)<sub>2</sub>D<sub>3</sub>.

## Secondary Hormonal Regulators of Bone Mineral Homeostasis

A number of hormones modulate the actions of PTH, FGF23, and vitamin D in regulating bone mineral homeostasis. Compared with that of PTH, FGF23, and vitamin D, the physiologic impact of such secondary regulation on bone mineral homeostasis is minor. However, in pharmacologic amounts, a number of these hormones have actions on the bone mineral homeostatic mechanisms that can be exploited therapeutically.

### CALCITONIN

The calcitonin secreted by the parafollicular cells of the mammalian thyroid is a single-chain peptide hormone with 32 amino acids and a molecular weight of 3600. A disulfide bond between positions 1 and 7 is essential for biologic activity. Calcitonin is produced from a precursor with MW 15,000. The circulating forms of calcitonin are multiple, ranging in size from the monomer (MW 3600) to forms with an apparent MW of 60,000. Whether such heterogeneity includes precursor forms or covalently linked oligomers is not known. Because of its heterogeneity, calcitonin is standardized by bioassay in rats. Activity is compared to a standard maintained by the British Medical Research Council (MRC) and expressed as MRC units.

Human calcitonin monomer has a half-life of about 10 minutes with a metabolic clearance of 8â€”9 mL/kg/min. Salmon calcitonin has a longer half-life and a reduced metabolic clearance (3 mL/kg/min), making it more attractive as a therapeutic agent. Much of the clearance occurs in the kidney, although little intact calcitonin appears in the urine.

The principal effects of calcitonin are to lower serum calcium and phosphate by actions on bone and kidney. Calcitonin inhibits osteoclastic bone resorption. Although bone formation is not impaired at first after calcitonin administration, with time both formation and resorption of bone are reduced. In the kidney, calcitonin reduces both calcium and phosphate reabsorption as well as reabsorption of other ions, including sodium, potassium, and magnesium. Tissues other than bone and kidney are also affected by calcitonin. Calcitonin in pharmacologic amounts decreases gastrin secretion and reduces gastric acid output while increasing secretion of sodium, potassium, chloride, and water in the gut. Pentagastrin is a potent stimulator of calcitonin secretion (as is hypercalcemia), suggesting a possible physiologic relation between gastrin and calcitonin. In the adult human, no readily demonstrable problem develops in cases of calcitonin deficiency (thyroidectomy) or excess (medullary carcinoma of the thyroid). However, the ability of calcitonin to block bone resorption and lower serum calcium makes it a useful drug for the treatment of Paget's disease, hypercalcemia, and osteoporosis.

### GLUCOCORTICOIDS

Glucocorticoid hormones alter bone mineral homeostasis by antagonizing vitamin D-stimulated intestinal calcium transport, by stimulating renal calcium excretion, and by blocking bone formation. Although these observations underscore the negative impact of glucocorticoids on bone mineral homeostasis, these hormones have proved useful in reversing the hypercalcemia associated with lymphomas and granulomatous diseases such as sarcoidosis (in which production of  $1,25[\text{OH}]_2\text{D}$  is increased) or in cases of vitamin D intoxication. Prolonged administration of glucocorticoids is a common cause of osteoporosis in adults and stunted skeletal development in children.

## **ESTROGENS**

Estrogens can prevent accelerated bone loss during the immediate postmenopausal period and at least transiently increase bone in the postmenopausal woman.

The prevailing hypothesis advanced to explain these observations is that estrogens reduce the bone-resorbing action of PTH. Estrogen administration leads to an increased  $1,25(\text{OH})_2\text{D}$  level in blood, but estrogens have no direct effect on  $1,25(\text{OH})_2\text{D}$  production in vitro. The increased  $1,25(\text{OH})_2\text{D}$  levels in vivo following estrogen treatment may result from decreased serum calcium and phosphate and increased PTH. Estrogen receptors have been found in bone, and estrogen has direct effects on bone remodeling. Recent case reports of men who lack the estrogen receptor or who are unable to produce estrogen because of aromatase deficiency noted marked osteopenia and failure to close epiphyses. This further substantiates the role of estrogen in bone development, even in men. The principal therapeutic application for estrogen administration in disorders of bone mineral homeostasis is the treatment or prevention of postmenopausal osteoporosis. However, long-term use of estrogen is being discouraged because of its deleterious adverse effects. Rather, selective estrogen receptor modulators (SERMs) have been developed to retain the beneficial effects on bone while minimizing these deleterious adverse effects on breast, uterus, and the cardiovascular system (see Newer Therapies for Osteoporosis).

### **Newer Therapies for Osteoporosis**

Bone undergoes a continuous remodeling process involving bone resorption and formation. Any process that disrupts this balance by increasing resorption relative to formation results in osteoporosis. Inadequate sex hormone production is a major cause of osteoporosis in men and women. Estrogen replacement therapy at menopause is a well-established means of preventing osteoporosis in the female, but many women fear its adverse effects, particularly the increased risk of breast cancer from continued estrogen use (the well-demonstrated increased risk of endometrial cancer is prevented by cycling with a progestin) and do not like the persistence of menstrual bleeding that often accompanies this form of therapy. Medical enthusiasm for this treatment has waned with the demonstration that it does not protect against heart disease. Raloxifene is the first of the selective estrogen receptor modulators (SERMs; see Chapter 40) to be approved for the prevention of osteoporosis. Raloxifene shares some of the beneficial effects of estrogen on bone without increasing the risk of breast or endometrial cancer (it may actually reduce the risk of breast cancer). Although not as effective as estrogen in increasing bone density, raloxifene has been shown to reduce vertebral fractures.

Nonhormonal forms of therapy for osteoporosis with proven efficacy in reducing fracture risk have also been developed. Bisphosphonates such as alendronate, risedronate, and ibandronate have been conclusively shown to increase bone density and reduce fractures over at least 5 years when used continuously at a dosage of 10 mg/d or 70 mg/wk for alendronate; 5 mg/d or 35 mg/wk for risedronate; or 2.5 mg/d or 150 mg/mo for ibandronate. Side-by-side trials between alendronate and calcitonin (another approved nonestrogen drug for osteoporosis) indicated a greater efficacy of alendronate. Bisphosphonates are poorly absorbed and must be given on an empty stomach or infused intravenously. At the higher oral doses used in the treatment of Paget's disease, alendronate causes gastric irritation, but this is not a significant problem at the doses recommended for osteoporosis when patients are instructed to take the drug with a glass of water and remain upright. The most recently approved drug for osteoporosis is teriparatide, the recombinant form of PTH 1-34. Unlike other approved drugs for osteoporosis, teriparatide stimulates bone formation rather than inhibiting bone resorption. However, teriparatide must be given daily by subcutaneous injection. Its efficacy in preventing fractures appears to be at least as great as that of the bisphosphonates. In all cases, adequate intake of calcium and vitamin D needs to be maintained.

Thus, we now have several well-validated, efficacious forms of treatment for this common debilitating disease.

In Europe, strontium ranelate has been used for several years with favorable results in large clinical trials; approval for use in the USA is expected.

## Nonhormonal Agents Affecting Bone Mineral Homeostasis

### BISPHOSPHONATES

The bisphosphonates are analogs of pyrophosphate in which the P-O-P bond has been replaced with a nonhydrolyzable P-C-P bond (Figure 42-4). **Etidronate**, **pamidronate**, and **alendronate** have now been joined by **risedronate**, **tiludronate**, **ibandronate**, and **zoledronate** for clinical use. The bisphosphonates owe at least part of their clinical usefulness and toxicity to their ability to retard formation and dissolution of hydroxyapatite crystals within and outside the skeletal system. They localize to regions of bone resorption and so exert their greatest effects on osteoclasts. However, the exact mechanism by which they selectively inhibit bone resorption is not clear.

**Figure 42-4**

The structure of pyrophosphate and of the first three bisphosphonates—etidronate, pamidronate, and alendronate—that were approved for use in the USA.

The results from animal and clinical studies indicate that less than 10% of an oral dose of these drugs is absorbed. Food reduces absorption even further, necessitating their administration on an empty stomach. Because it causes gastric irritation, pamidronate is not available as an oral preparation. However, with the possible exception of etidronate, all currently available bisphosphonates have this complication. Nearly half of the absorbed drug accumulates in bone; the remainder is excreted unchanged in the urine. Decreased renal function, esophageal motility disorders, and peptic ulcer disease are the main contraindications to the use of these drugs, although the latter two

complications can be circumvented using intravenous administration of pamidronate, zoledronate, and ibandronate. The portion bound to bone is retained for months, depending on the turnover of bone itself.

Etidronate and the other bisphosphonates exert a variety of effects on bone mineral homeostasis. In particular, bisphosphonates are useful for the treatment of hypercalcemia associated with malignancy, for Paget's disease, and for osteoporosis (see Newer Therapies for Osteoporosis). Contrary to expectations, some of the newer bisphosphonates appear to increase bone mineral density well beyond the 2-year period predicted for a drug whose effects are limited to blocking bone resorption. The bisphosphonates exert a variety of other cellular effects, including inhibition of  $1,25(\text{OH})_2\text{D}$  production, inhibition of intestinal calcium transport, metabolic changes in bone cells such as inhibition of glycolysis, inhibition of cell growth, and changes in acid and alkaline phosphatase.

Amino bisphosphonates such as alendronate and risedronate have been found to block farnesyl pyrophosphate synthase, an enzyme in the mevalonate pathway that appears to be critical for osteoclast survival. Statins, which block mevalonate synthesis, stimulate bone formation at least in animal studies. Thus, the mevalonate pathway appears to be important in bone cell function and provides new targets for drug development. These effects vary depending on the bisphosphonate being studied (ie, only amino bisphosphonates have this property) and may account for some of the clinical differences observed in the effects of the various bisphosphonates on bone mineral homeostasis. However, with the exceptions of the induction of a mineralization defect by higher than approved doses of etidronate and gastric and esophageal irritation by pamidronate and by high doses of alendronate, these drugs have proved to be remarkably free of adverse effects when used at the doses recommended for the treatment of osteoporosis. Esophageal irritation can be minimized by taking the drug with a full glass of water and remaining upright for 30 minutes. Of the other complications, osteonecrosis of the jaw (ONJ) has received considerable attention, but is rare in patients receiving the usual doses of bisphosphonates (perhaps 1/100,000 patient-years), although this complication is more frequent when high intravenous doses of zoledronate are used to control bone metastases and cancer-induced hypercalcemia.

## **CALCIMIMETICS**

**Cinacalcet** is the first representative of a new class of drugs that activates the calcium sensing receptor (CaR). CaR is widely distributed but has its greatest concentration in the parathyroid gland. Cinacalcet blocks PTH secretion by this mechanism and is approved for the treatment of secondary hyperparathyroidism in chronic kidney disease and for the treatment of parathyroid carcinoma.

## **PLICAMYCIN (MITHRAMYCIN)**

Plicamycin is a cytotoxic antibiotic (see Chapter 54) that has been used clinically for two disorders of bone mineral metabolism: Paget's disease and hypercalcemia. The cytotoxic properties of the drug appear to involve its binding to DNA and interruption of DNA directed RNA synthesis. The reasons for its usefulness in the treatment of Paget's disease and hypercalcemia are unclear but may relate to the need for protein synthesis to sustain bone resorption. The doses required to treat Paget's disease and hypercalcemia are about one tenth the amounts required to achieve cytotoxic effects.

## **THIAZIDES**

The chemistry and pharmacology of the thiazide family of drugs are covered in Chapter 15. The principal application of thiazides in the treatment of bone mineral disorders is in reducing renal calcium excretion. Thiazides may increase the effectiveness of PTH in stimulating reabsorption of calcium by the renal tubules or may act on calcium reabsorption secondarily by increasing sodium reabsorption in the proximal tubule. In the distal tubule, thiazides block sodium reabsorption at the luminal surface, increasing the calcium-sodium exchange at the basolateral membrane and thus enhancing calcium reabsorption into the blood at this site. Thiazides have proved to be useful in reducing the hypercalciuria and incidence of stone formation in subjects with idiopathic hypercalciuria. Part of their efficacy in reducing stone formation may lie in their ability to decrease urine oxalate excretion and increase urine magnesium and zinc levels (both of which inhibit calcium oxalate stone formation).

## **FLUORIDE**

Fluoride is well established as effective for the prophylaxis of dental caries and has been under investigation for the treatment of osteoporosis. Both therapeutic applications originated from epidemiologic observations that subjects living in areas with naturally fluoridated water ( $1\text{--}2$  ppm) had less dental caries and fewer vertebral compression

fractures than subjects living in nonfluoridated water areas. Fluoride is accumulated by bones and teeth, where it may stabilize the hydroxyapatite crystal. Such a mechanism may explain the effectiveness of fluoride in increasing the resistance of teeth to dental caries, but it does not explain new bone growth.

Fluoride in drinking water appears to be most effective in preventing dental caries if consumed before the eruption of the permanent teeth. The optimum concentration in drinking water supplies is 0.5–1 ppm. Topical application is most effective if done just as the teeth erupt. There is little further benefit to giving fluoride after the permanent teeth are fully formed. Excess fluoride in drinking water leads to mottling of the enamel proportionate to the concentration above 1 ppm.

Because of the paucity of agents that stimulate new bone growth in patients with osteoporosis, fluoride for this disorder has been examined (see Osteoporosis, below). Results of earlier studies indicated that fluoride alone without adequate calcium supplementation produced osteomalacia. More recent studies, in which calcium supplementation has been adequate, have demonstrated an improvement in calcium balance, an increase in bone mineral, and an increase in trabecular bone volume. However, studies of the ability of fluoride to reduce fractures reach opposite conclusions. Adverse effects observed at the doses used for testing fluoride's effect on bone include nausea and vomiting, gastrointestinal blood loss, arthralgias, and arthritis in a substantial proportion of patients. Such effects are usually responsive to reduction of the dose or giving fluoride with meals (or both). At present, fluoride is not approved by the Food and Drug Administration (FDA) for use in osteoporosis.

## **STRONTIUM RANELATE**

Strontium ranelate is composed of an organic ion, ranelic acid, bound to two atoms of strontium. Although not yet approved for use in the United States, this drug is being used in Europe for the treatment of osteoporosis. Strontium ranelate appears to block osteoclast differentiation while promoting their apoptosis and thus inhibiting bone resorption. At the same time, strontium ranelate appears to promote bone formation. Unlike bisphosphonates or teriparatide, this drug increases bone formation markers while inhibiting bone resorption markers. Large clinical trials have demonstrated its efficacy in increasing bone mineral density and decreasing fractures in the spine and hip. Toxicities reported thus far are similar to placebo.

## **CLINICAL PHARMACOLOGY**

Persons with disorders of bone mineral homeostasis generally present with abnormalities in serum or urine calcium levels (or both), often accompanied by abnormal serum phosphate levels. These abnormal mineral concentrations may themselves cause symptoms requiring immediate treatment (eg, coma in malignant hypercalcemia, tetany in hypocalcemia). More commonly, they serve as clues to an underlying disorder in hormonal regulators (eg, primary hyperparathyroidism), target tissue response (eg, chronic kidney disease), or drug misuse (eg, vitamin D intoxication). In such cases, treatment of the underlying disorder is of prime importance.

Since bone and kidney play central roles in bone mineral homeostasis, conditions that alter bone mineral homeostasis usually affect one or both of these tissues secondarily. Effects on bone can result in osteoporosis (abnormal loss of bone; remaining bone histologically normal), osteomalacia (abnormal bone formation due to inadequate mineralization), or osteitis fibrosa (excessive bone resorption with fibrotic replacement of resorption cavities and marrow). Biochemical markers of skeletal involvement include changes in serum levels of the skeletal isoenzyme of alkaline phosphatase and osteocalcin (reflecting osteoblastic activity) and urine levels of hydroxyproline and pyridinoline cross-links (reflecting osteoclastic activity). The kidney becomes involved when the calcium x phosphate product in serum exceeds the point at which ectopic calcification occurs (nephrocalcinosis) or when the calcium x oxalate (or phosphate) product in urine exceeds saturation, leading to nephrolithiasis. Subtle early indicators of such renal involvement include polyuria, nocturia, and hyposthenuria. Radiologic evidence of nephrocalcinosis and stones is not generally observed until later. The degree of the ensuing renal failure is best followed by monitoring the decline in creatinine clearance. On the other hand, chronic kidney disease can be a primary cause of bone disease because of altered handling of calcium and phosphate, decreased 1,25(OH)<sub>2</sub>D production, and secondary hyperparathyroidism.

## **Abnormal Serum Calcium & Phosphate Levels**

### **HYPERCALCEMIA**

Hypercalcemia causes central nervous system depression, including coma, and is potentially lethal. Its major causes

(other than thiazide therapy) are hyperparathyroidism and cancer with or without bone metastases. Less common causes are hypervitaminosis D, sarcoidosis, thyrotoxicosis, milk-alkali syndrome, adrenal insufficiency, and immobilization. With the possible exception of hypervitaminosis D, the latter disorders seldom require emergency lowering of serum calcium. A number of approaches are used to manage the hypercalcemic crisis.

### **Saline Diuresis**

In hypercalcemia of sufficient severity to produce symptoms, rapid reduction of serum calcium is required. The first steps include rehydration with saline and diuresis with furosemide, although the efficacy of furosemide in this setting has not been proved and the drug appears to be falling out of favor. Most patients presenting with severe hypercalcemia have a substantial component of prerenal azotemia owing to dehydration, which prevents the kidney from compensating for the rise in serum calcium by excreting more calcium in the urine. Therefore, the initial infusion of 500–1000 mL/h of saline to reverse the dehydration and restore urine flow can by itself substantially lower serum calcium. The addition of a loop diuretic such as furosemide following rehydration not only enhances urine flow but also inhibits calcium reabsorption in the ascending limb of the loop of Henle (see Chapter 15). Monitoring central venous pressure is important to forestall the development of heart failure and pulmonary edema in predisposed subjects. In many subjects, saline diuresis suffices to reduce serum calcium levels to a point at which more definitive diagnosis and treatment of the underlying condition can be achieved. If this is not the case or if more prolonged medical treatment of hypercalcemia is required, the following agents are available (discussed in order of preference).

### **Bisphosphonates**

Pamidronate, 60–90 mg, infused over 2–4 hours, and zoledronate, 4 mg, infused over at least 15 minutes, have been approved for the treatment of hypercalcemia of malignancy and have largely replaced the less effective etidronate for this indication. The effects generally persist for weeks, but treatment can be repeated after a 7-day interval if necessary and if renal function is not impaired. Some patients experience a self-limited flu-like syndrome after the infusion. Repeated doses of these drugs have been linked to renal deterioration and osteonecrosis of the jaw, but this adverse effect is rare.

### **Calcitonin**

Calcitonin has proved useful as ancillary treatment in a large number of patients. Calcitonin by itself seldom restores serum calcium to normal, and refractoriness frequently develops. However, its lack of toxicity permits frequent administration at high doses (200 MRC units or more). An effect on serum calcium is observed within 4–6 hours and lasts for 6–10 hours. Calcimar (salmon calcitonin) is available for parenteral and nasal administration.

### **Gallium Nitrate**

Gallium nitrate is approved by the FDA for the management of hypercalcemia of malignancy. This drug acts by inhibiting bone resorption. At a dosage of 200 mg/m<sup>2</sup> body surface area per day given as a continuous intravenous infusion in 5% dextrose for 5 days, gallium nitrate proved superior to calcitonin in reducing serum calcium in cancer patients. Because of potential nephrotoxicity, patients should be well hydrated and have good renal output before starting the infusion.

### **Plicamycin (Mithramycin)**

Because of its toxicity, plicamycin (mithramycin) is not the drug of first choice for the treatment of hypercalcemia. However, when other forms of therapy fail, 25–50 mcg/kg given intravenously usually lowers serum calcium substantially within 24–48 hours. This effect can last several days. This dose can be repeated as necessary. The most dangerous toxic effect is sudden thrombocytopenia followed by hemorrhage. Hepatic and renal toxicity can also occur. Hypocalcemia, nausea, and vomiting may limit therapy. Use of this drug must be accompanied by careful monitoring of platelet counts, liver and kidney function, and serum calcium levels.

### **Phosphate**

Giving intravenous phosphate is probably the fastest and surest way to reduce serum calcium, but it is a hazardous procedure if not done properly. Intravenous phosphate should be used only after other methods of treatment (bisphosphonates, calcitonin, and saline diuresis) have failed to control symptomatic hypercalcemia. Phosphate must be given slowly (50 mmol or 1.5 g elemental phosphorus over 6–8 hours) and the patient switched to oral phosphate (1–2 g/d elemental phosphorus, as one of the salts indicated below) as soon as symptoms of

hypercalcemia have cleared. The risks of intravenous phosphate therapy include sudden hypocalcemia, ectopic calcification, acute renal failure, and hypotension. Oral phosphate can also lead to ectopic calcification and renal failure if serum calcium and phosphate levels are not carefully monitored, but the risk is less and the time of onset much longer. Phosphate is available in oral and intravenous forms as sodium or potassium salt. Amounts required to provide 1 g of elemental phosphorus are as follows:

**Intravenous:**

In-Phos: 40 mL

Hyper-Phos-K: 15 mL

**Oral:**

Fleet Phospho-Soda: 6.2 mL

Neutra-Phos: 300 mL

K-Phos-Neutral: 4 tablets

### **Glucocorticoids**

Glucocorticoids have no clear role in the immediate treatment of hypercalcemia. However, the chronic hypercalcemia of sarcoidosis, vitamin D intoxication, and certain cancers may respond within several days to glucocorticoid therapy. Prednisone in oral doses of 30–60 mg daily is generally used, although equivalent doses of other glucocorticoids are effective. The rationale for the use of glucocorticoids in these diseases differs, however. The hypercalcemia of sarcoidosis is secondary to increased production of 1,25(OH)<sub>2</sub>D, possibly by the sarcoid tissue itself. Glucocorticoid therapy directed at the reduction of sarcoid tissue results in restoration of normal serum calcium and 1,25(OH)<sub>2</sub>D levels. The treatment of hypervitaminosis D with glucocorticoids probably does not alter vitamin D metabolism significantly but is thought to reduce vitamin D-mediated intestinal calcium transport. An action of glucocorticoids to reduce vitamin D-mediated bone resorption has not been excluded, however. The effect of glucocorticoids on the hypercalcemia of cancer is probably twofold. The malignancies responding best to glucocorticoids (ie, multiple myeloma and related lymphoproliferative diseases) are sensitive to the lytic action of glucocorticoids. Therefore part of the effect may be related to decreased tumor mass and activity. Glucocorticoids have also been shown to inhibit the secretion or effectiveness of cytokines elaborated by multiple myeloma and related cancers that stimulate osteoclastic bone resorption. Other causes of hypercalcemia—particularly primary hyperparathyroidism—do not respond to glucocorticoid therapy.

### **HYPOCALCEMIA**

The main features of hypocalcemia are neuromuscular—tetany, paresthesias, laryngospasm, muscle cramps, and convulsions. The major causes of hypocalcemia in the adult are hypoparathyroidism, vitamin D deficiency, chronic kidney disease, and malabsorption. Neonatal hypocalcemia is a common disorder that usually resolves without therapy. The roles of PTH, vitamin D, and calcitonin in the neonatal syndrome are under active investigation. Large infusions of citrated blood can produce hypocalcemia by the formation of citrate-calcium complexes. Calcium and vitamin D (or its metabolites) form the mainstay of treatment of hypocalcemia.

### **Calcium**

A number of calcium preparations are available for intravenous, intramuscular, and oral use. Calcium gluceptate (0.9 mEq calcium/mL), calcium gluconate (0.45 mEq calcium/mL), and calcium chloride (0.68–1.36 mEq calcium/mL) are available for intravenous therapy. Calcium gluconate is the preferred form because it is less irritating to veins. Oral preparations include calcium carbonate (40% calcium), calcium lactate (13% calcium), calcium phosphate (25% calcium), and calcium citrate (21% calcium). Calcium carbonate is often the preparation of choice because of its high percentage of calcium, ready availability (eg, Tums), low cost, and antacid properties. In achlorhydric patients, calcium carbonate should be given with meals to increase absorption, or the patient should be switched to calcium citrate, which is somewhat better absorbed. Combinations of vitamin D and calcium are available, but treatment must be tailored to the individual patient and the individual disease, a flexibility lost by fixed-dosage combinations.

Treatment of severe symptomatic hypocalcemia can be accomplished with slow infusion of 5–20 mL of 10% calcium gluconate. Rapid infusion can lead to cardiac arrhythmias. Less severe hypocalcemia is best treated with oral forms

sufficient to provide approximately 400–1200 mg of elemental calcium (1–3 g calcium carbonate) per day. Dosage must be adjusted to avoid hypercalcemia and hypercalciuria.

## Vitamin D

When rapidity of action is required, 1,25(OH)<sub>2</sub>D<sub>3</sub> (calcitriol), 0.25–1 mcg daily, is the vitamin D metabolite of choice, because it is capable of raising serum calcium within 24–48 hours. Calcitriol also raises serum phosphate, although this action is usually not observed early in treatment. The combined effects of calcitriol and all other vitamin D metabolites and analogs on both calcium and phosphate make careful monitoring of these mineral levels especially important to prevent ectopic calcification secondary to an abnormally high serum calcium × phosphate product. Since the choice of the appropriate vitamin D metabolite or analog for long-term treatment of hypocalcemia depends on the nature of the underlying disease, further discussion of vitamin D treatment is found under the headings of the specific diseases.

## HYPERPHOSPHATEMIA

Hyperphosphatemia is a common complication of renal failure but is also found in all types of hypoparathyroidism (idiopathic, surgical, and pseudohypoparathyroidism), vitamin D intoxication, and the rare syndrome of tumoral calcinosis. Emergency treatment of hyperphosphatemia is seldom necessary but can be achieved by dialysis or glucose and insulin infusions. In general, control of hyperphosphatemia involves restriction of dietary phosphate plus the use of phosphate-binding gels such as **sevelamer** and of calcium supplements. Because of their potential to induce aluminum-associated bone disease, aluminum-containing antacids should be used sparingly and only when other measures fail to control the hyperphosphatemia.

## HYPOPHOSPHATEMIA

A variety of conditions are associated with hypophosphatemia, including primary hyperparathyroidism, vitamin D deficiency, idiopathic hypercalciuria, X-linked and autosomal dominant hypophosphatemic rickets, tumor-induced osteomalacia, various other forms of renal phosphate wasting (eg, Fanconi's syndrome), overzealous use of phosphate binders, and parenteral nutrition with inadequate phosphate content. Acute hypophosphatemia may lead to a reduction in the intracellular levels of high-energy organic phosphates (eg, ATP), interfere with normal hemoglobin-to-tissue oxygen transfer by decreasing red cell 2,3-diphosphoglycerate levels, and lead to rhabdomyolysis. However, clinically significant acute effects of hypophosphatemia are seldom seen, and emergency treatment is generally not indicated. The long-term effects of hypophosphatemia include proximal muscle weakness and abnormal bone mineralization (osteomalacia). Therefore, hypophosphatemia should be avoided during other forms of therapy and treated in conditions such as the various forms of hypophosphatemic rickets, of which hypophosphatemia is a cardinal feature. Oral forms of phosphate available for use are listed above in latter section on hypercalcemia.

## Specific Disorders Involving the Bone Mineral-Regulating Hormones

### PRIMARY HYPERPARATHYROIDISM

This rather common disease, if associated with symptoms and significant hypercalcemia, is best treated surgically. Oral phosphate and bisphosphonates have been tried but cannot be recommended. Asymptomatic patients with mild disease often do not get worse and may be left untreated. The calcimimetic agent **cinacalcet**, discussed previously, has been approved for secondary hyperparathyroidism and is in clinical trials for the treatment of primary hyperparathyroidism. If such drugs prove efficacious, medical management of this disease will need to be reconsidered.

### HYPOPARATHYROIDISM

In the absence of PTH (idiopathic or surgical hypoparathyroidism) or an abnormal target tissue response to PTH (pseudohypoparathyroidism), serum calcium falls and serum phosphate rises. In such patients, 1,25(OH)<sub>2</sub>D levels are usually low, presumably reflecting the lack of stimulation by PTH of 1,25(OH)<sub>2</sub>D production. The skeletons of patients with idiopathic or surgical hypoparathyroidism are normal except for a slow turnover rate. A number of patients with pseudohypoparathyroidism appear to have osteitis fibrosa, suggesting that the normal or high PTH levels found in such patients are capable of acting on bone but not on the kidney. The distinction between pseudohypoparathyroidism and idiopathic hypoparathyroidism is made on the basis of normal or high PTH levels but deficient renal response (ie, diminished excretion of cAMP or phosphate) in patients with pseudohypoparathyroidism.

The principal therapeutic concern is to restore normocalcemia and normophosphatemia. Under most circumstances, vitamin D (25,000–100,000 units three times per week) and dietary calcium supplements suffice. More rapid increments in serum calcium can be achieved with calcitriol, although it is not clear whether this metabolite offers a substantial advantage over vitamin D itself for long-term therapy. Many patients treated with vitamin D develop episodes of hypercalcemia. This complication is more rapidly reversible with cessation of therapy using calcitriol rather than vitamin D. This would be of importance to the patient in whom such hypercalcemic crises are common. Although teriparatide (PTH 1-34) is not approved for the treatment of hypoparathyroidism, it can be effective in patients who respond poorly to calcium and vitamin D.

## **NUTRITIONAL VITAMIN D DEFICIENCY OR INSUFFICIENCY**

The level of vitamin D thought to be necessary for good health is undergoing reexamination with the appreciation that vitamin D acts on a large number of cell types, not just those responsible for bone and mineral metabolism. Maintaining a level of 25(OH)D above 10 ng/mL is necessary for preventing rickets or osteomalacia. However, substantial epidemiologic and some prospective trial data indicate that a higher level, such as 30 ng/mL, is required to optimize intestinal calcium absorption, optimize the accrual and maintenance of bone mass, reduce falls and fractures, and prevent a wide variety of diseases including diabetes mellitus, hyperparathyroidism, autoimmune diseases, and cancer. Current recommendations are for a daily intake of 800–1200 units of vitamin D. Vitamin D deficiency or insufficiency can be treated by higher dosages (4000 units per day or 50,000 units per week for several weeks). No other metabolite is indicated. The diet should also contain adequate amounts of calcium and phosphate.

## **CHRONIC KIDNEY DISEASE**

The major problems of chronic kidney disease that impact bone mineral homeostasis are the loss of 1,25(OH)<sub>2</sub>D production, the retention of phosphate that reduces ionized calcium levels, and the secondary hyperparathyroidism that results. With the loss of 1,25(OH)<sub>2</sub>D production, less calcium is absorbed from the intestine and less bone is resorbed under the influence of PTH. As a result hypocalcemia usually develops, furthering the development of hyperparathyroidism. The bones show a mixture of osteomalacia and osteitis fibrosa.

In contrast to the hypocalcemia that is more often associated with chronic kidney disease, some patients may become hypercalcemic from two other possible causes (in addition to overzealous treatment with calcium). The most common cause of hypercalcemia is the development of severe secondary (sometimes referred to as tertiary) hyperparathyroidism. In such cases, the PTH level in blood is very high. Serum alkaline phosphatase levels also tend to be high. Treatment often requires parathyroidectomy.

A less common circumstance leading to hypercalcemia is development of a form of bone disease characterized by a profound decrease in bone cell activity and loss of the calcium buffering action of bone (adynamic bone disease). In the absence of kidney function, any calcium absorbed from the intestine accumulates in the blood. Therefore, such patients are very sensitive to the hypercalcemic action of 1,25(OH)<sub>2</sub>D. These individuals generally have a high serum calcium but nearly normal alkaline phosphatase and PTH levels. The bone in such patients may have a high aluminum content, especially in the mineralization front, which blocks normal bone mineralization. These patients do not respond favorably to parathyroidectomy. Deferoxamine, an agent used to chelate iron (see Chapter 57), also binds aluminum and is being used as therapy for this disorder. However, with less use of aluminum-containing phosphate binders, most cases of adynamic bone disease are not associated with aluminum deposition but are attributed to overzealous suppression of PTH secretion.

## **Vitamin D Preparations**

The choice of vitamin D preparation to be used in the setting of chronic kidney disease depends on the type and extent of bone disease and hyperparathyroidism. Individuals with vitamin D deficiency or insufficiency should first have their 25(OH)D levels restored to normal (above 30 ng/mL) with vitamin D. 1,25(OH)<sub>2</sub>D<sub>3</sub> (calcitriol) rapidly corrects hypocalcemia and at least partially reverses the secondary hyperparathyroidism and osteitis fibrosa. Many patients with muscle weakness and bone pain gain an improved sense of well-being.

Two analogs of calcitriol—doxercalciferol and paricalcitol—are approved for the treatment of secondary hyperparathyroidism of chronic kidney disease. Their principal advantage is that they are less likely than calcitriol to induce hypercalcemia for any given reduction in PTH. Their greatest impact is in patients in whom the use of calcitriol

may lead to unacceptably high serum calcium levels.

Regardless of the drug used, careful attention to serum calcium and phosphate levels is required. A calcium  $\times$  phosphate product (in mg/dL units) less than 55 is desired with both calcium and phosphate in the normal range. Calcium adjustments in the diet and dialysis bath and phosphate restriction (dietary and with oral ingestion of phosphate binders) should be used along with vitamin D metabolites. Monitoring serum PTH and alkaline phosphatase levels is useful in determining whether therapy is correcting or preventing secondary hyperparathyroidism. Although not generally available, percutaneous bone biopsies for quantitative histomorphometry may help in choosing appropriate therapy and following the effectiveness of such therapy, especially in cases suspected of having adynamic bone disease. Unlike the rapid changes in serum values, changes in bone morphology require months to years. Monitoring serum levels of the vitamin D metabolites is useful for determining compliance, absorption, and metabolism.

### **INTESTINAL OSTEODYSTROPHY**

A number of gastrointestinal and hepatic diseases result in disordered calcium and phosphate homeostasis, which ultimately leads to bone disease. The bones in such patients show a combination of osteoporosis and osteomalacia. Osteitis fibrosa does not occur, as in renal osteodystrophy. The common features that appear to be important in this group of diseases are malabsorption of calcium and malabsorption of vitamin D. Liver disease may, in addition, reduce the production of 25(OH)D from vitamin D, although its importance in all but patients with terminal liver failure remains in dispute. The malabsorption of vitamin D is probably not limited to exogenous vitamin D. The liver secretes into bile a substantial number of vitamin D metabolites and conjugates that are reabsorbed in (presumably) the distal jejunum and ileum. Interference with this process could deplete the body of endogenous vitamin D metabolites as well as limit absorption of dietary vitamin D.

In mild forms of malabsorption, vitamin D (25,000–50,000 units three times per week) should suffice to raise serum levels of 25(OH)D into the normal range. Many patients with severe disease do not respond to vitamin D. Clinical experience with the other metabolites is limited, but both calcitriol and calcifediol have been used successfully in doses similar to those recommended for treatment of renal osteodystrophy. Theoretically, calcifediol should be the drug of choice under these conditions, because no impairment of the renal metabolism of 25(OH)D to 1,25(OH)<sub>2</sub>D and 24,25(OH)<sub>2</sub>D exists in these patients. Both calcitriol and 24,25(OH)<sub>2</sub>D may be of importance in reversing the bone disease. However, calcifediol is no longer available.

As in the other diseases discussed, treatment of intestinal osteodystrophy with vitamin D and its metabolites should be accompanied by appropriate dietary calcium supplementation and monitoring of serum calcium and phosphate levels.

### **OSTEOPOROSIS**

Osteoporosis is defined as abnormal loss of bone predisposing to fractures. It is most common in postmenopausal women but also occurs in men. The annual cost of fractures in older women and men in the USA was estimated at \$13.8 billion in 1996 and would be much higher today. It may occur as an adverse effect of long-term administration of glucocorticoids or other drugs; as a manifestation of endocrine disease such as thyrotoxicosis or hyperparathyroidism; as a feature of malabsorption syndrome; as a consequence of alcohol abuse and cigarette smoking; or without obvious cause (idiopathic). The ability of some agents to reverse the bone loss of osteoporosis is shown in Figure 42–5. The postmenopausal form of osteoporosis may be accompanied by lower 1,25(OH)<sub>2</sub>D levels and reduced intestinal calcium transport. This form of osteoporosis is due to estrogen deficiency and can be treated with estrogen (cycled with a progestin in women with a uterus to prevent endometrial carcinoma). However, concern that estrogen increases the risk of breast cancer and fails to reduce the development of heart disease has reduced enthusiasm for this form of therapy.

Typical changes in bone mineral density with time after the onset of menopause, with and without treatment. In the untreated condition, bone is lost during aging in both men and women. Fluoride, strontium (Sr<sup>2+</sup>), and parathyroid hormone (PTH) promote new bone formation and can increase bone mineral density in subjects who respond to it throughout the period of treatment, although PTH also activates bone resorption. In contrast, estrogen, calcitonin, and bisphosphonates block bone resorption. This leads to a transient increase in bone mineral density because bone formation is not initially decreased. However, with time, both bone formation and bone resorption are decreased with these pure antiresorptive agents, and bone mineral density reaches a new plateau.

As previously noted, estrogen-like SERMs (selective estrogen receptor modulators, Chapter 40) have been developed that prevent the increased risk of breast and uterine cancer associated with estrogen while maintaining the benefit to bone. **Raloxifene** is such a drug approved for treatment of osteoporosis. Like tamoxifen, it appears to reduce the risk of breast cancer. Raloxifene protects against spine fractures but not hip fractures—unlike bisphosphonates and teriparatide, which protect against both. Raloxifene does not prevent hot flashes and imposes the same increased risk of thrombophlebitis as estrogen. To counter the reduced intestinal calcium transport associated with osteoporosis, vitamin D therapy is often used in addition to dietary calcium supplementation. There is no clear evidence that pharmacologic doses of vitamin D are of much additional benefit beyond cyclic estrogens and calcium supplementation. However, in several large studies, vitamin D supplementation (800 IU/d) has been shown to be useful. In addition, calcitriol and its analog 1 $\alpha$ .(OH)D<sub>3</sub> have been shown to increase bone mass and reduce fractures in several recent studies. Use of these agents for osteoporosis is not FDA-approved, although they are used in other countries.

Despite early promise that **fluoride** might be useful in the prevention or treatment of postmenopausal osteoporosis, this form of therapy remains controversial. A new formulation of fluoride (slow release, lower dose) appears to avoid much of the toxicity of earlier formulations and may reduce fracture rates. However, this formulation has not been approved by the FDA.

**Teriparatide**, the recombinant form of PTH 1-34, is approved for treatment of osteoporosis. Teriparatide is given in a dosage of 20 mcg subcutaneously daily. Like fluoride, teriparatide stimulates new bone formation, but unlike fluoride, this new bone appears structurally normal and is associated with a substantial reduction in the incidence of fractures. Teriparatide is approved for use for only 2 years. Trials examining the sequential use of teriparatide followed by a bisphosphonate after 1 or 2 years are in progress and look promising. Giving teriparatide with a bisphosphonate has not shown greater efficacy than the bisphosphonate alone.

**Calcitonin** is approved for use in the treatment of postmenopausal osteoporosis. It has been shown to increase bone mass and reduce fractures, but only in the spine. It does not appear to be as effective as bisphosphonates or teriparatide.

Bisphosphonates are potent inhibitors of bone resorption. They increase bone density and reduce the risk of fractures

in the hip, spine, and other locations. **Alendronate, risedronate, ibandronate, and zoledronate** are approved for the treatment of osteoporosis, using daily dosing schedules of alendronate 10 mg/d, risedronate 5 mg/d, ibandronate 2.5 mg/d; or weekly schedules of alendronate 70 mg/wk, risedronate 35 mg/wk; or monthly schedules of ibandronate 150 mg/mo; or quarterly (every 3 months) injections of 3 mg ibandronate; or annual infusions of zoledronate 5 mg. These drugs are effective in men as well as women and for various causes of osteoporosis.

**Strontium ranelate** has not been approved in the United States for the treatment of osteoporosis but is being used in Europe, generally at a dose of 2 g/d. **Denosumab**, an antibody to RANKL that suppresses bone resorption by interfering with RANKL/RANK induction of osteoclast differentiation and function, has shown good efficacy in phase 3 trials and may be approved for clinical use in the near future.

## **X-LINKED & AUTOSOMAL DOMINANT HYPOPHOSPHATEMIA**

These disorders are manifested by the appearance of rickets and hypophosphatemia in children, although they may first present in adults. X-linked hypophosphatemia is caused by mutations in a gene encoding the PHEX protein, which appears to be an endopeptidase. Mutations in the gene responsible for the autosomal dominant form target FGF23 (fibroblast growth factor 23). The current concept is that FGF23 blocks the renal uptake of phosphate and blocks 1,25(OH)<sub>2</sub>D<sub>3</sub> production. Mutations in PHEX inactivate it, and FGF23 levels increase. Similarly, mutations in FGF23 that resist hydrolysis, as seen in patients with the autosomal form of hypophosphatemic rickets, also result in elevated FGF23 levels.

Initially, it was thought that FGF23 was a direct substrate for PHEX, but this no longer appears to be the case. In either disease, intact and biologically active FGF23 accumulates, leading to phosphate wasting in the urine and hypophosphatemia.

Phosphate is critical to normal bone mineralization; when phosphate stores are deficient, a clinical and pathologic picture resembling vitamin D-deficient rickets develops. However, affected children fail to respond to the usual doses of vitamin D used in the treatment of nutritional rickets. A defect in 1,25(OH)<sub>2</sub>D production by the kidney has also been noted, because the serum 1,25(OH)<sub>2</sub>D levels tend to be low in comparison with the degree of hypophosphatemia observed. This combination of low serum phosphate and low or low-normal serum 1,25(OH)<sub>2</sub>D provides the rationale for treating such patients with oral phosphate (1–3 g daily) and calcitriol (0.25–0.5 mcg daily). Reports of such combination therapy are encouraging in this otherwise debilitating disease.

## **VITAMIN D-DEPENDENT RICKETS TYPES I & II**

These distinctly different autosomal recessive diseases present as childhood rickets that do not respond to conventional doses of vitamin D. Type I vitamin D-dependent rickets, now known as pseudovitamin D deficiency rickets, is due to an isolated deficiency of 1,25(OH)<sub>2</sub>D production caused by mutations in 25(OH)D-1 $\alpha$ -hydroxylase (CYP27B1). This condition can be treated with vitamin D (4000 units daily) or calcitriol (0.25–0.5 mcg daily). Type II vitamin D-dependent rickets, now known as hereditary vitamin D resistant rickets, is caused by mutations in the gene for the vitamin D receptor, which disrupt the functions of this receptor and lead to this syndrome. The serum levels of 1,25(OH)<sub>2</sub>D are very high in type II but not in type I vitamin D-dependent rickets. Treatment with large doses of calcitriol has been claimed to be effective in restoring normocalcemia in some patients, presumably those with a partially functional vitamin D receptor, although many patients are completely resistant to all forms of vitamin D. Calcium and phosphate infusions have been shown to correct the osteomalacia in some children, similar to studies in mice in which the *VDR* gene has been deleted. These diseases are rare.

## **NEPHROTIC SYNDROME**

Patients with nephrotic syndrome can lose vitamin D metabolites in the urine, presumably by loss of the vitamin D-binding protein. Such patients may have very low 25(OH)D levels. Some of them develop bone disease. It is not yet clear what value vitamin D therapy has in such patients, because therapeutic trials with vitamin D (or any other vitamin D metabolite) have not yet been carried out. Because the problem is not related to vitamin D metabolism, one would not anticipate any advantage in using the more expensive vitamin D metabolites in place of vitamin D itself.

## **IDIOPATHIC HYPERCALCIURIA**

People with idiopathic hypercalciuria, characterized by hypercalciuria and nephrolithiasis with normal serum calcium

and PTH levels, have been divided into three groups: (1) hyperabsorbers, patients with increased intestinal absorption of calcium, resulting in high-normal serum calcium, low-normal PTH, and a secondary increase in urine calcium; (2) renal calcium leakers, patients with a primary decrease in renal reabsorption of filtered calcium, leading to low-normal serum calcium and high-normal serum PTH; and (3) renal phosphate leakers, patients with a primary decrease in renal reabsorption of phosphate, leading to stimulation of  $1,25(\text{OH})_2\text{D}$  production, increased intestinal calcium absorption, increased ionized serum calcium, low-normal PTH levels, and a secondary increase in urine calcium. There is some disagreement about this classification, and many patients are not readily categorized. Many such patients present with mild hypophosphatemia, and oral phosphate has been used with some success in reducing stone formation. However, a clear role for phosphate in the treatment of this disorder has not been established.

Therapy with hydrochlorothiazide, up to 50 mg twice daily, or chlorthalidone, 50–100 mg daily, is recommended. Loop diuretics such as furosemide and ethacrynic acid should not be used because they increase urinary calcium excretion. The major toxicity of thiazide diuretics, besides hypokalemia, hypomagnesemia, and hyperglycemia, is hypercalcemia. This is seldom more than a biochemical observation unless the patient has a disease such as hyperparathyroidism in which bone turnover is accelerated. Accordingly, one should screen patients for such disorders before starting thiazide therapy and monitor serum and urine calcium when therapy has begun.

An alternative to thiazides is allopurinol. Some studies indicate that hyperuricosuria is associated with idiopathic hypercalcemia and that a small nidus of urate crystals could lead to the calcium oxalate stone formation characteristic of idiopathic hypercalcemia. Allopurinol, 300 mg daily, may reduce stone formation by reducing uric acid excretion.

## **Other Disorders of Bone Mineral Homeostasis**

### **PAGET'S DISEASE OF BONE**

Paget's disease is a localized bone disease characterized by uncontrolled osteoclastic bone resorption with secondary increases in bone formation. This new bone is poorly organized, however. The cause of Paget's disease is obscure, although some studies suggest that a slow virus may be involved. The disease is fairly common, although symptomatic bone disease is less common. The biochemical parameters of elevated serum alkaline phosphatase and urinary hydroxyproline are useful for diagnosis. Along with the characteristic radiologic and bone scan findings, these biochemical determinations provide good markers by which to follow therapy.

The goal of treatment is to reduce bone pain and stabilize or prevent other problems such as progressive deformity, hearing loss, high-output cardiac failure, and immobilization hypercalcemia. Calcitonin and bisphosphonates are the first-line agents for this disease. Treatment failures may respond to plicamycin. Calcitonin is administered subcutaneously or intramuscularly in doses of 50–100 MRC (Medical Research Council) units every day or every other day. Nasal inhalation at 200–400 units per day is also effective. Higher or more frequent doses have been advocated when this initial regimen is ineffective. Improvement in bone pain and reduction in serum alkaline phosphatase and urine hydroxyproline levels require weeks to months. Often a patient who responds well initially loses the response to calcitonin. This refractoriness is not correlated with the development of antibodies.

Sodium etidronate, alendronate, risedronate, and tiludronate are the bisphosphonates currently approved for clinical use in Paget's disease of bone in the USA. However, other bisphosphonates, including pamidronate, are being used in other countries. The recommended dosages of bisphosphonates are etidronate, 5 mg/kg/d; alendronate, 40 mg/d; risedronate, 30 mg/d; and tiludronate, 400 mg/d. Long-term (months to years) remission may be expected in patients who respond to these agents. Treatment should not exceed 6 months per course but can be repeated after 6 months if necessary. The principal toxicity of etidronate is the development of osteomalacia and an increased incidence of fractures when the dosage is raised substantially above 5 mg/kg/d. The newer bisphosphonates such as risedronate and alendronate do not share this adverse effect. Some patients treated with etidronate develop bone pain similar in nature to the bone pain of osteomalacia. This subsides after stopping the drug. The principal adverse effect of alendronate and the newer bisphosphonates is gastric irritation when used at these high doses. This is reversible on cessation of the drug.

The use of a potentially lethal cytotoxic drug such as plicamycin in a generally benign disorder such as Paget's disease is recommended only when other less toxic agents (calcitonin, alendronate) have failed and the symptoms are debilitating. Clinical data on long-term use of plicamycin are insufficient to determine its usefulness for extended therapy. However, short courses involving 15–25 mcg/kg/d intravenously for 5–10 days followed by 15 mcg/kg

intravenously each week have been used to control the disease.

## ENTERIC OXALURIA

Patients with short bowel syndromes associated with fat malabsorption can present with renal stones composed of calcium and oxalate. Such patients characteristically have normal or low urine calcium levels but elevated urine oxalate levels. The reasons for the development of oxaluria in such patients are thought to be two-fold: first, in the intestinal lumen, calcium (which is now bound to fat) fails to bind oxalate and no longer prevents its absorption; second, enteric flora, acting on the increased supply of nutrients reaching the colon, produce larger amounts of oxalate. Although one would ordinarily avoid treating a patient with calcium oxalate stones with calcium supplementation, this is precisely what is done in patients with enteric oxaluria. The increased intestinal calcium binds the excess oxalate and prevents its absorption. One to 2 g of calcium carbonate can be given daily in divided doses, with careful monitoring of urinary calcium and oxalate to be certain that urinary oxalate falls without a dangerous increase in urinary calcium.

## SUMMARY: MAJOR DRUGS USED IN DISEASES OF BONE MINERAL HOMEOSTASIS

### Major Drugs Used in Diseases of Bone Mineral Homeostasis

Subclass	Mechanism of Action	Effects	Clinical Applications	Toxicities
<b>Vitamin D, metabolites, analogs</b>				
Cholecalciferol	Regulate gene transcription via the vitamin D receptor	Stimulate intestinal calcium absorption, bone resorption, renal calcium and phosphate reabsorption • decrease parathyroid hormone (PTH) • promote innate immunity • inhibit adaptive immunity	Osteoporosis, osteomalacia, renal failure, malabsorption	Hypercalcemia, hypercalciuria • the vitamin D preparations have much longer half-life than the metabolites and analogs
Ergocalciferol				
Calcitriol				
Doxercalciferol				
Paricalcitol				
<b>Bisphosphonates</b>				
Alendronate	Suppress the activity of osteoclasts in part via inhibition of farnesyl pyrophosphate synthesis	Inhibit bone resorption and secondarily bone formation	Osteoporosis, bone metastases, hypercalcemia	Adynamic bone, possible renal failure, rare osteonecrosis of the jaw
Risedronate				
Ibandronate				
Pamidronate				
Zoledronate				
<b>Hormones</b>				
Teriparatide	These hormones act on their cognate receptors coupled to G protein signaling pathways	Teriparatide stimulates bone turnover, calcitonin suppresses bone resorption	Both are used in osteoporosis • calcitonin is used for hypercalcemia	Teriparatide may cause hypercalcemia and hypercalciuria
Calcitonin				
<b>Selective estrogen-receptor modulators</b>				
Raloxifene	Interacts selectively with estrogen receptors	Inhibits bone resorption without stimulating breast or uterus	Osteoporosis	Does not prevent hot flashes • increased risk of thrombophlebitis
<b>Calcium receptor agonists</b>				

Cinacalcet	Activates the calcium sensing receptor	Inhibits PTH secretion	Hyperparathyroidism	Nausea
<b>Minerals</b>				
Calcium	Multiple physiologic actions through regulation of multiple enzymatic pathways	Strontium suppresses bone resorption and increases bone formation, calcium and phosphate required for bone mineralization	Osteoporosis, osteomalacia, deficiencies in calcium or phosphate	Ectopic calcification

## PREPARATIONS AVAILABLE

### VITAMIN D, METABOLITES, AND ANALOGS

#### Calcitriol

Oral (generic, Rocaltrol): 0.25, 0.5 mcg capsules, 1 mcg/mL solution

Parenteral (generic, Calcijex): 1, 2 mcg/mL for injection

#### Cholecalciferol [D<sub>3</sub>] (vitamin D<sub>3</sub>, Delta-D)

Oral: 400, 1000 IU tablets

#### Doxercalciferol (Hectoral)

Oral: 0.5, 2.5 mcg capsules

Parenteral: 2 mcg/mL

#### Ergocalciferol [D<sub>2</sub>] (vitamin D<sub>2</sub>, Calciferol, Drisdol)

Oral: 50,000 IU capsules; 8000 IU/mL drops

#### Paricalcitol (Zemplar)

Oral: 1, 2, 4 mcg capsules

Parenteral: 2, 5 mcg/mL for injection

## CALCIUM

#### Calcium acetate [25% calcium] (PhosLo)

Oral: 668 mg (167 mg calcium) tablets; 333.5 mg (84.5 mg calcium), 667 mg (169 mg calcium) capsules

#### Calcium carbonate [40% calcium] (generic, Tums, Cal-Sup, Os-Cal 500, others)

Oral: Numerous forms available containing 260–600 mg calcium per unit

#### Calcium chloride [27% calcium] (generic)

Parenteral: 10% solution for IV injection only

#### Calcium citrate [21% calcium] (generic, Citracal)

Oral: 950 mg (200 mg calcium), 2376 mg (500 mg calcium)

**Calcium glubionate [6.5% calcium]** (Calcionate, Calciquid)

Oral: 1.8 g (115 mg calcium)/5 mL syrup

**Calcium gluceptate [8% calcium]** (Calcium Gluceptate)

Parenteral: 1.1 g/5 mL solution for IM or IV injection

**Calcium gluconate [9% calcium]** (generic)

Oral: 500 mg (45 mg calcium), 650 mg (58.5 mg calcium), 975 mg (87.75 mg calcium), 1 g (90 mg calcium) tablets

Parenteral: 10% solution for IV or IM injection

**Calcium lactate [13% calcium]** (generic)

Oral: 650 mg (84.5 mg calcium), 770 mg (100 mg calcium) tablets

**Tricalcium phosphate [39% calcium]** (Posture)

Oral: 1565 mg (600 mg calcium) tablets (as phosphate)

## PHOSPHATE AND PHOSPHATE BINDER

### Phosphate

Oral (Fleet Phospho-soda): solution containing 2.5 g phosphate/5 mL (816 mg phosphorus/5 mL; 751 mg sodium/5 mL)

Oral (K-Phos-Neutral): tablets containing 250 mg phosphorus, 298 mg sodium, 45 mg phosphorus

Oral (Neutra-Phos): For reconstitution in 75 mL water, packet containing 250 mg phosphorus; 164 mg sodium; 278 mg potassium

Oral (Neutra-Phos-K): For reconstitution in 75 mL water, packet containing 250 mg phosphorus; 556 mg potassium; 0 mg sodium

Parenteral (potassium or sodium phosphate): 3 mmol/mL

### Sevelamer (Renagel, Renvela)

Oral: 400, 800 mg capsules

## OTHER DRUGS

### Alendronate (Fosamax)

Oral: 5, 10, 35, 40, 70 mg tablets; 70 mg/75 mL oral solution

### Calcitonin-Salmon

Nasal spray (Miacalcin): 200 IU/puff

Parenteral (Calcimar, Miacalcin, Salmonine): 200 IU/mL for injection

### Cinacalcet (Sensipar)

Oral: 30, 60, 90 mg tablets

### Etidronate (Didronel)

Oral: 200, 400 mg tablets

**Gallium nitrate** (Ganite)

Parenteral: 500 mg/20 mL vial

**Ibandronate** (Boniva)

Oral: 2.5, 150 mg tablets

Parenteral: 1 mg/mL

**Pamidronate** (generic, Aredia)

Parenteral: 30, 60, 90 mg/vial

**Plicamycin** (mithramycin) (Mithracin)

Parenteral: 2.5 mg per vial powder to reconstitute for injection

**Risedronate** (Actonel)

Oral: 5, 30, 35, 75, 150 mg tablets

**Sodium fluoride** (generic)

Oral: 0.55 mg (0.25 mg F), 1.1 mg (0.5 mg F), 2.2 mg (1.0 mg F) tablets; drops

**Teriparatide** (Forteo)

Subcutaneous: 250 mcg/mL from prefilled pen (3 mL)

**Tiludronate** (Skelid)

Oral: 200 mg tablets (as tiludronic acid)

**Zoledronic acid** (Zometa)

Parenteral: 4 mg/vial

## INTRODUCTION TO ANTIMICROBIAL AGENTS

Antimicrobial agents provide the most dramatic examples of the advances of modern medicine. Many infectious diseases once considered incurable and lethal are now amenable to treatment with a few pills. The remarkably powerful and specific activity of antimicrobial drugs is due to their selectivity for targets that are either unique to prokaryote and fungal microorganisms or much more important in them than in humans. Among these targets are bacterial and fungal cell wall-synthesizing enzymes (Chapters 43 and 48), the bacterial ribosome (Chapters 44 and 45), the enzymes required for nucleotide synthesis and DNA replication (Chapter 46), and the machinery of viral replication (Chapter 49). The special group of drugs used in mycobacterial infections is discussed in Chapter 47. The much older and less selective cytotoxic antiseptics and disinfectants are discussed in Chapter 50. The clinical uses of all these agents are presented in Chapter 51.

Microorganisms can adapt to environmental pressures in a variety of effective ways, and their response to antibiotic pressure is no exception. An inevitable consequence of antimicrobial usage is the selection of resistant microorganisms, perhaps the most obvious example of evolution in action. Overuse and inappropriate use of antibiotics has fueled a major increase in prevalence of multidrug-resistant pathogens, leading some to speculate that we are nearing the end of the antibiotic era. Unfortunately, as the need has grown in recent years, development of novel drugs has slowed. The most vulnerable molecular targets of antimicrobial drugs have been identified, and in many cases crystallized and characterized. Pending the identification of new targets and compounds, it seems likely that over the next decade we will have to rely on currently available families of drugs. In the face of continuing development of resistance, considerable effort will be required to maintain the effectiveness of these drug groups.

Basic and Clinical Pharmacology > Chapter 43. Beta-Lactam & Other Cell Wall- & Membrane-Active Antibiotics >

## CASE STUDY

A 69-year-old man is brought to the local hospital emergency department by ambulance. His wife reports that he had been in his normal state of health until 3 days ago when he developed a fever and a productive cough. During the last 24 hours he has complained of a headache and is increasingly confused. His wife reports that his medical history is significant only for hypertension, for which he takes hydrochlorothiazide and lisinopril, and that he is allergic to amoxicillin. She says that he developed a rash many years ago when prescribed amoxicillin for bronchitis. In the emergency department, the man is febrile (38.7°C [101.7°F]), hypotensive (90/54 mm Hg), tachypneic (36/min), and tachycardic (110/min). He has no signs of meningismus but is oriented only to person. A stat chest x-ray shows a left lower lung consolidation consistent with pneumonia. The plan is to start empiric antibiotics and perform a lumbar puncture to rule out bacterial meningitis. What antibiotic regimen should be started to treat both pneumonia and meningitis? Does the history of amoxicillin rash affect the antibiotic choice? Why or why not?

## BETA-LACTAM COMPOUNDS

### PENICILLINS

The penicillins share features of chemistry, mechanism of action, pharmacology, and immunologic characteristics with cephalosporins, monobactams, carbapenems, and  $\beta$ -lactamase inhibitors. All are  $\beta$ -lactam compounds, so named because of their unique four-membered lactam ring.

#### Chemistry

All penicillins have the basic structure shown in Figure 43-1. A thiazolidine ring (A) is attached to a  $\beta$ -lactam ring (B) that carries a secondary amino group (RNH<sub>2</sub>). Substituents (R; examples shown in Figure 43-2) can be attached to the amino group. Structural integrity of the 6-aminopenicillanic acid nucleus (rings A plus B) is essential for the biologic activity of these compounds. Hydrolysis of the  $\beta$ -lactam ring by bacterial  $\beta$  lactamases yields penicilloic acid, which lacks antibacterial activity.

**Figure 43-1**

Core structures of four  $\beta$ -lactam antibiotic families. The ring marked B in each structure is the  $\beta$ -lactam ring. The penicillins are susceptible to bacterial metabolism and inactivation by amidases and lactamases at the points shown. Note that the carbapenems have a different stereochemical configuration in the lactam ring that apparently imparts resistance to  $\beta$  lactamases. Substituents for the penicillin and cephalosporin families are shown in Figures 43â€²2 and 43â€²6, respectively.

**Figure 43â€²2**

### 6-Aminopenicillanic acid

The following structures can each be substituted at the R to produce a new penicillin.

#### Penicillin G (benzylpenicillin):

High activity against gram-positive bacteria. Low activity against gram-negative bacteria. Acid-labile. Destroyed by  $\beta$  lactamase. 60% protein-bound.

#### Oxacillin (no Cl atoms); cloxacillin (one Cl in structure); dicloxacillin (2 Cls in structure); flucloxacillin (one Cl and one F in structure) (isoxazolyl penicillins):

Similar to methicillin in  $\beta$  lactamase resistance, but acid-stable. Can be taken orally. Highly protein-bound (95–98%).

#### Nafcillin (ethoxynaphthamidopenicillin):

Similar to isoxazolyl penicillins. Less strongly protein-bound (90%). Resistant to staphylococcal  $\beta$  lactamase.

#### Ampicillin (alpha-aminobenzylpenicillin):

Similar to Penicillin G (destroyed by  $\beta$  lactamase) but acid-stable and more active against gram-negative bacteria. Carbenicillin has  $-\text{COONa}$  instead of  $\text{NH}_2$  group.

#### Ticarcillin:

Similar to carbenicillin but gives higher blood levels. Piperacillin, azlocillin, and mezlocillin resemble ticarcillin in action against gram-negative aerobes.

#### Amoxicillin:

Similar to ampicillin but better absorbed, gives higher blood levels.

Side chains of some penicillins (R groups of Figure 43â€1).

### CLASSIFICATION

Substituents of the 6-aminopenicillanic acid moiety determine the essential pharmacologic and antibacterial properties of the resulting molecules. Penicillins can be assigned to one of three groups (below). Within each of these groups are compounds that are relatively stable to gastric acid and suitable for oral administration, eg, penicillin V, dicloxacillin, and amoxicillin. The side chains of some representatives of each group are shown in Figure 43â€2, with a few distinguishing characteristics.

#### Penicillins (Eg, Penicillin G)

These have greatest activity against gram-positive organisms, gram-negative cocci, and nonâ€ $\beta$ -lactamase producing anaerobes. However, they have little activity against gram-negative rods, and they are susceptible to hydrolysis by  $\beta$  lactamases.

#### Antistaphylococcal Penicillins (Eg, Nafcillin)

These penicillins are resistant to staphylococcal  $\beta$  lactamases. They are active against staphylococci and streptococci but not against enterococci, anaerobic bacteria, and gram-negative cocci and rods.

#### Extended-Spectrum Penicillins (Ampicillin and the Antipseudomonal Penicillins)

These drugs retain the antibacterial spectrum of penicillin and have improved activity against gram-negative organisms. Like penicillin, however, they are relatively susceptible to hydrolysis by  $\beta$  lactamases.

### PENICILLIN UNITS AND FORMULATIONS

The activity of penicillin G was originally defined in units. Crystalline sodium penicillin G contains approximately 1600 units per mg (1 unit = 0.6 mcg; 1

million units of penicillin = 0.6 g). Semisynthetic penicillins are prescribed by weight rather than units. The **minimum inhibitory concentration (MIC)** of any penicillin (or other antimicrobial) is usually given in mcg/mL. Most penicillins are dispensed as the sodium or potassium salt of the free acid. Potassium penicillin G contains about 1.7 mEq of  $K^+$  per million units of penicillin (2.8 mEq/g). Nafcillin contains  $Na^+$ , 2.8 mEq/g. Procaine salts and benzathine salts of penicillin G provide repository forms for intramuscular injection. In dry crystalline form, penicillin salts are stable for years at 4°C. Solutions lose their activity rapidly (eg, 24 hours at 20°C) and must be prepared fresh for administration.

### Mechanism of Action

Penicillins, like all  $\beta$ -lactam antibiotics, inhibit bacterial growth by interfering with the transpeptidation reaction of bacterial cell wall synthesis. The cell wall is a rigid outer layer unique to bacterial species. It completely surrounds the cytoplasmic membrane (Figure 43-3), maintains cell shape and integrity, and prevents cell lysis from high osmotic pressure. The cell wall is composed of a complex cross-linked polymer of polysaccharides and polypeptides, peptidoglycan (murein, mucopeptide). The polysaccharide contains alternating amino sugars, *N*-acetylglucosamine and *N*-acetylmuramic acid (Figure 43-4). A five-amino-acid peptide is linked to the *N*-acetylmuramic acid sugar. This peptide terminates in D-alanyl-D-alanine. Penicillin-binding protein (PBP, an enzyme) removes the terminal alanine in the process of forming a cross-link with a nearby peptide. Cross-links give the cell wall its structural rigidity.  $\beta$ -Lactam antibiotics, structural analogs of the natural D-Ala-D-Ala substrate, covalently bind to the active site of PBPs. This inhibits the transpeptidation reaction (Figure 43-5), halting peptidoglycan synthesis, and the cell dies. The exact mechanism of cell death is not completely understood, but autolysins and disruption of cell wall morphogenesis are involved.  $\beta$ -Lactam antibiotics kill bacterial cells only when they are actively growing and synthesizing cell wall.

Figure 43-3

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 11th Edition: <http://www.accessmedicine.com>

A highly simplified diagram of the cell envelope of a gram-negative bacterium. The outer membrane, a lipid bilayer, is present in gram-negative but not gram-positive organisms. It is penetrated by porins, proteins that form channels providing hydrophilic access to the cytoplasmic membrane. The peptidoglycan layer is unique to bacteria and is much thicker in gram-positive organisms than in gram-negative ones. Together, the outer membrane and the peptidoglycan layer constitute the cell wall. Penicillin-binding proteins (PBPs) are membrane proteins that cross-link peptidoglycan.  $\beta$  Lactamases, if present, reside in the periplasmic space or on the outer surface of the cytoplasmic membrane, where they may destroy  $\beta$ -lactam antibiotics that penetrate the outer membrane.

Figure 43-4

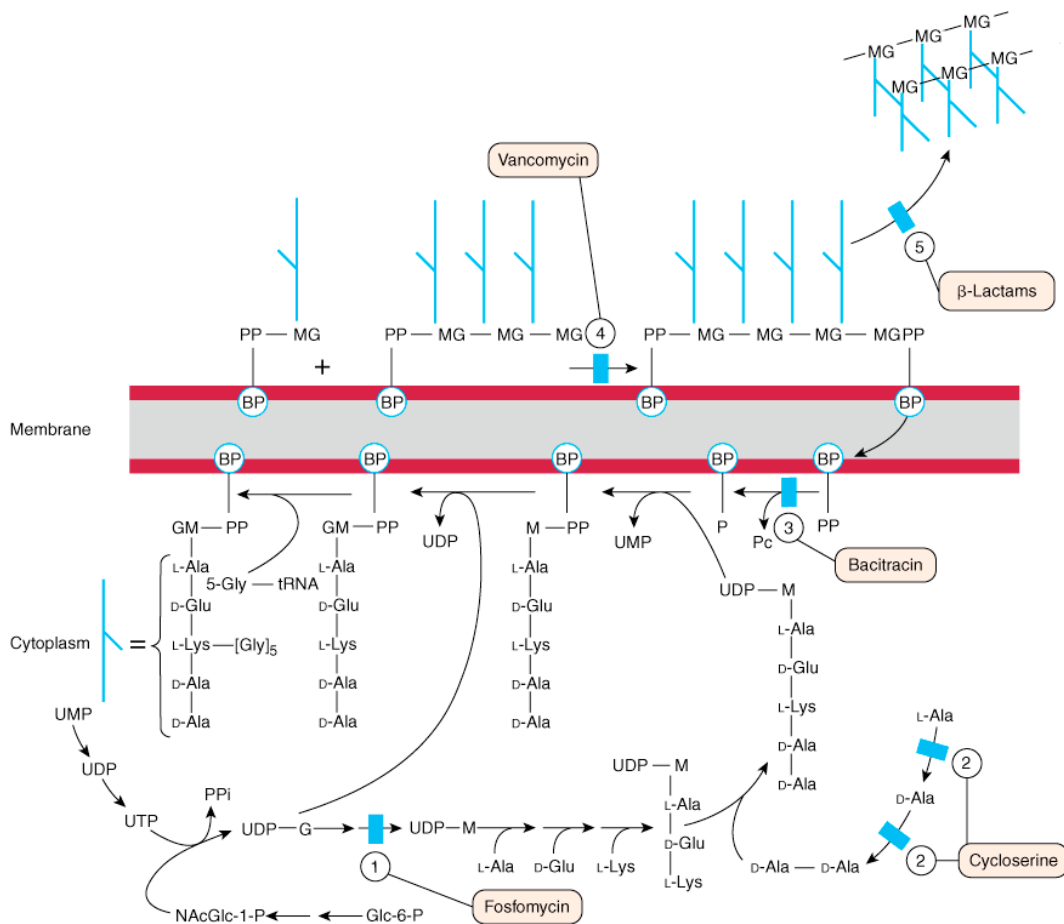

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 12th Edition: <http://www.accessmedicine.com>

The transpeptidation reaction in *Staphylococcus aureus* that is inhibited by  $\beta$ -lactam antibiotics. The cell wall of gram-positive bacteria is made up of long peptidoglycan polymer chains consisting of the alternating aminohexoses *N*-acetylglucosamine (G) and *N*-acetylmuramic acid (M) with pentapeptide side chains linked (in *S aureus*) by pentaglycine bridges. The exact composition of the side chains varies among species. The diagram illustrates small segments of two such polymer chains and their amino acid side chains. These linear polymers must be cross-linked by transpeptidation of the side chains at the points indicated by the asterisk to achieve the strength necessary for cell viability.

**Figure 43â€5**

The biosynthesis of cell wall peptidoglycan, showing the sites of action of five antibiotics (shaded bars; 1 = fosfomycin, 2 = cycloserine, 3 = bacitracin, 4 = vancomycin, 5 =  $\beta$ -lactam antibiotics). Bactoprenin (BP) is the lipid membrane carrier that transports building blocks across the cytoplasmic membrane; M, *N*-acetylmuramic acid; Glc, glucose; NAcGlc or G, *N*-acetylglucosamine.

## Resistance

Resistance to penicillins and other  $\beta$  lactams is due to one of four general mechanisms: (1) inactivation of antibiotic by  $\beta$  lactamase, (2) modification of target PBPs, (3) impaired penetration of drug to target PBPs, and (4) efflux.  $\beta$ -Lactamase production is the most common mechanism of resistance. Many hundreds of different  $\beta$  lactamases have been identified. Some, such as those produced by *Staphylococcus aureus*, *Haemophilus sp*, and *Escherichia coli*, are relatively narrow in substrate specificity, preferring penicillins to cephalosporins. Other  $\beta$  lactamases, eg, AmpC  $\beta$  lactamase produced by *Pseudomonas aeruginosa* and *Enterobacter sp*, and extended-spectrum  $\beta$  lactamases (ESBLs), hydrolyze both cephalosporins and penicillins. Carbapenems are highly resistant to hydrolysis by penicillinases and cephalosporinases, but they are hydrolyzed by metallo- $\beta$  lactamase and carbapenemases.

Altered target PBPs are the basis of methicillin resistance in staphylococci and of penicillin resistance in pneumococci and enterococci. These resistant organisms produce PBPs that have low affinity for binding  $\beta$ -lactam antibiotics, and consequently they are not inhibited except at relatively high, often clinically unachievable, drug concentrations.

Resistance due to impaired penetration of antibiotic to target PBPs occurs only in gram-negative species because of their impermeable outer cell wall membrane, which is absent in gram-positive bacteria.  $\beta$ -Lactam antibiotics cross the outer membrane and enter gram-negative organisms via outer membrane protein channels (porins). Absence of the proper channel or down-regulation of its production can greatly impair drug entry into the cell. Poor penetration alone is usually not sufficient to confer resistance, because enough antibiotic eventually enters the cell to inhibit growth. However, this barrier can become important in the presence of a  $\beta$  lactamase, even a relatively inactive one, as long as it can hydrolyze drug faster than it enters the cell. Gram-negative organisms also may produce an efflux pump, which consists of cytoplasmic and periplasmic protein components that efficiently transport some  $\beta$ -lactam antibiotics from the periplasm back across the outer membrane.

## Pharmacokinetics

Absorption of orally administered drug differs greatly for different penicillins, depending in part on their acid stability and protein binding. Gastrointestinal absorption of nafcillin is erratic, so it is not suitable for oral administration. Dicloxacillin, ampicillin, and amoxicillin are acid-stable and relatively well absorbed, producing serum concentrations in the range of 4-8 mcg/mL after a 500-mg oral dose. Absorption of most oral penicillins (amoxicillin being an exception) is impaired by food, and the drugs should be administered at least 1-2 hours before or after a meal.

After parenteral administration, absorption of most penicillins is complete and rapid. Intravenous administration is preferred to the intramuscular route because of irritation and local pain from intramuscular injection of large doses. Serum concentrations 30 minutes after an intravenous injection of 1 g of a penicillin (equivalent to approximately 1.6 million units of penicillin G) are 20–50 mcg/mL. Only a small amount of the total drug in serum is present as free drug, the concentration of which is determined by protein binding. Highly protein-bound penicillins (eg, nafcillin) generally achieve lower free-drug concentrations in serum than less protein-bound penicillins (eg, penicillin G, ampicillin). Protein binding becomes clinically relevant when the protein-bound percentage is approximately 95% or more. Penicillins are widely distributed in body fluids and tissues with a few exceptions. They are polar molecules, so intracellular concentrations are well below those found in extracellular fluids.

Benzathine and procaine penicillins are formulated to delay absorption, resulting in prolonged blood and tissue concentrations. A single intramuscular injection of 1.2 million units of benzathine penicillin maintains serum levels above 0.02 mcg/mL for 10 days, sufficient to treat  $\beta$ -hemolytic streptococcal infection. After 3 weeks, levels still exceed 0.003 mcg/mL, which is enough to prevent  $\beta$ -hemolytic streptococcal infection. A 600,000 unit dose of procaine penicillin yields peak concentrations of 1–2 mcg/mL and clinically useful concentrations for 12–24 hours after a single intramuscular injection.

Penicillin concentrations in most tissues are equal to those in serum. Penicillin is also excreted into sputum and milk to levels 3–15% of those in the serum. Penetration into the eye, the prostate, and the central nervous system is poor. However, with active inflammation of the meninges, as in bacterial meningitis, penicillin concentrations of 1–5 mcg/mL can be achieved with a daily parenteral dose of 18–24 million units. These concentrations are sufficient to kill susceptible strains of pneumococci and meningococci.

Penicillin is rapidly excreted by the kidneys; small amounts are excreted by other routes. About 10% of renal excretion is by glomerular filtration and 90% by tubular secretion. The normal half-life of penicillin G is approximately 30 minutes; in renal failure, it may be as long as 10 hours. Ampicillin and the extended-spectrum penicillins are secreted more slowly than penicillin G and have half-lives of 1 hour. For penicillins that are cleared by the kidney, the dose must be adjusted according to renal function, with approximately one fourth to one third the normal dose being administered if creatinine clearance is 10 mL/min or less (Table 43–1).

**Table 43–1 Guidelines for Dosing of Some Commonly Used Penicillins.**

Antibiotic (Route of Administration)	Adult Dose	Pediatric Dose <sup>1</sup>	Neonatal Dose <sup>2</sup>	Adjusted Dose as a Percentage of Normal Dose for Renal Failure Based on Creatinine Clearance ( $Cl_{cr}$ )	
				$Cl_{cr}$ Approx 50 mL/min	$Cl_{cr}$ Approx 10 mL/min
<b>Penicillins</b>					
Penicillin G (IV)	1–4 × 10 <sup>6</sup> Units q4–6h	25,000–400,000 units/kg/d in 4–6 doses	75,000–150,000 units/kg/d in 2 or 3 doses	50–75%	25%
Penicillin V (PO)	0.25–0.5 g qid	25–50 mg/kg/d in 4 doses		None	None
<b>Antistaphylococcal penicillins</b>					
Cloxacillin, dicloxacillin (PO)	0.25–0.5 g qid	25–50 mg/kg/d in 4 doses		100%	100%
Nafcillin (IV)	1–2 g q4–6h	1–2 g q4–6h	50–75 mg/kg/d in 2 or 3 doses	100%	100%
Oxacillin (IV)	1–2 g q4–6h	50–100 mg/kg/d in 4–6 doses	50–75 mg/kg/d in 2 or 3 doses	100%	100%
<b>Extended-spectrum penicillins</b>					
Amoxicillin (PO)	0.25–0.5 g tid	20–40 mg/kg/d in 3 doses		66%	33%
Amoxicillin/potassium clavulanate (PO)	500/125 tid or 875/125 mg bid	20–40 mg/kg/d in 3 doses		66%	33%
Piperacillin (IV)	3–4 g q4–6h	300 mg/kg/d in 4–6 doses	150 mg/kg/d in 2 doses	50–75%	25–33%
Ticarcillin (IV)	3 g q4–6h	200–300 mg/kg/d in 4–6 doses	150–200 mg/kg/d in 2 or 3 doses	50–75%	25–33%

<sup>1</sup>The total dose should not exceed the adult dose.

<sup>2</sup>The dose shown is during the first week of life. The daily dose should be increased by approximately 33–50% after the first week of life. The lower dosage range should be used for neonates weighing less than 2 kg. After the first month of life, pediatric doses may be used.

Nafcillin is primarily cleared by biliary excretion. Oxacillin, dicloxacillin, and cloxacillin are eliminated by both the kidney and biliary excretion; no dosage adjustment is required for these drugs in renal failure. Because clearance of penicillins is less efficient in the newborn, doses adjusted for weight alone result in higher systemic concentrations for longer periods than in the adult.

### Clinical Uses

Except for oral amoxicillin, penicillins should be given 1–2 hours before or after a meal; they should not be given with food to minimize binding to food proteins and acid inactivation. Blood levels of all penicillins can be raised by simultaneous administration of probenecid, 0.5 g (10 mg/kg in children) every 6 hours orally, which impairs renal tubular secretion of weak acids such as  $\beta$ -lactam compounds.

### PENICILLIN

Penicillin G is a drug of choice for infections caused by streptococci, meningococci, enterococci, penicillin-susceptible pneumococci, non- $\beta$ -lactamase producing staphylococci, *Treponema pallidum* and many other spirochetes, clostridium species, actinomyces, and other gram-positive rods and non- $\beta$ -

lactamase producing gram-negative anaerobic organisms. Depending on the organism, the site, and the severity of infection, effective doses range between 4 and 24 million units per day administered intravenously in four to six divided doses. High-dose penicillin G can also be given as a continuous intravenous infusion.

Penicillin V, the oral form of penicillin, is indicated only in minor infections because of its relatively poor bioavailability, the need for dosing four times a day, and its narrow antibacterial spectrum. Amoxicillin (see below) is often used instead.

Benzathine penicillin and procaine penicillin G for intramuscular injection yield low but prolonged drug levels. A single intramuscular injection of benzathine penicillin, 1.2 million units, is effective treatment for  $\beta$ -hemolytic streptococcal pharyngitis; given intramuscularly once every 3 $\times$ 4 weeks, it prevents reinfection. Benzathine penicillin G, 2.4 million units intramuscularly once a week for 1 $\times$ 3 weeks, is effective in the treatment of syphilis. Procaine penicillin G, formerly a work horse for treating uncomplicated pneumococcal pneumonia or gonorrhea, is rarely used now because many strains are penicillin-resistant.

#### **PENICILLINS RESISTANT TO STAPHYLOCOCCAL BETA LACTAMASE (METHICILLIN, NAFICILLIN, AND ISOXAZOLYL PENICILLINS)**

These semisynthetic penicillins are indicated for infection by  $\beta$ -lactamase-producing staphylococci, although penicillin-susceptible strains of streptococci and pneumococci are also susceptible. *Listeria*, enterococci, and methicillin-resistant strains of staphylococci are resistant. In recent years the empirical use of these drugs has decreased substantially given increasing rates of methicillin-resistance in staphylococci. However, for infections caused by methicillin-susceptible strains of staphylococci these are considered the drugs of choice.

An isoxazolyl penicillin such as oxacillin, cloxacillin, or dicloxacillin, 0.25 $\times$ 0.5 g orally every 4 $\times$ 6 hours (15 $\times$ 25 mg/kg/d for children), is suitable for treatment of mild to moderate localized staphylococcal infections. All are relatively acid-stable and have reasonable bioavailability. However, food interferes with absorption, and the drugs should be administered 1 hour before or after meals.

For serious systemic staphylococcal infections, oxacillin or nafcillin, 8 $\times$ 12 g/d, is given by intermittent intravenous infusion of 1 $\times$ 2 g every 4 $\times$ 6 hours (50 $\times$ 100 mg/kg/d for children).

#### **EXTENDED-SPECTRUM PENICILLINS (AMINOPENICILLINS, CARBOXPENICILLINS, AND UREIDOPENICILLINS)**

These drugs have greater activity than penicillin against gram-negative bacteria because of their enhanced ability to penetrate the gram-negative outer membrane. Like penicillin G, they are inactivated by many  $\beta$  lactamases.

The aminopenicillins, ampicillin and amoxicillin, have identical spectrums and activity, but amoxicillin is better absorbed orally. Amoxicillin, 250 $\times$ 500 mg three times daily, is equivalent to the same amount of ampicillin given four times daily. These drugs are given orally to treat urinary tract infections, sinusitis, otitis, and lower respiratory tract infections. Ampicillin and amoxicillin are the most active of the oral  $\beta$ -lactam antibiotics against penicillin-resistant pneumococci and are the preferred  $\beta$ -lactam antibiotics for treating infections suspected to be caused by these resistant strains. Ampicillin (but not amoxicillin) is effective for shigellosis. Its use to treat uncomplicated salmonella gastroenteritis is controversial because it may prolong the carrier state.

Ampicillin, at dosages of 4 $\times$ 12 g/d intravenously, is useful for treating serious infections caused by penicillin-susceptible organisms, including anaerobes, enterococci, *Listeria monocytogenes*, and  $\beta$ -lactamase-negative strains of gram-negative cocci and bacilli such as *E coli*, and salmonella species. Non- $\beta$ -lactamase producing strains of *H influenzae* are generally susceptible, but strains that are resistant because of altered PBPs are emerging. Many gram-negative species produce  $\beta$  lactamases and are resistant, precluding use of ampicillin for empirical therapy of urinary tract infections, meningitis, and typhoid fever. Ampicillin is not active against klebsiella, enterobacter, *Pseudomonas aeruginosa*, citrobacter, serrata, indole-positive proteus species, and other gram-negative aerobes that are commonly encountered in hospital-acquired infections.

Carbenicillin, the very first antipseudomonal carboxypenicillin, is obsolete. A derivative, carbenicillin indanyl sodium, can be given orally for urinary tract infections. There are more active, better tolerated alternatives. A carboxypenicillin with activity similar to that of carbenicillin is ticarcillin. It is less active than ampicillin against enterococci. The ureidopenicillins, piperacillin, mezlocillin, and azlocillin, are also active against selected gram-negative bacilli, such as *Klebsiella pneumoniae*. Although supportive clinical data are lacking for superiority of combination therapy over single-drug therapy, because of the propensity of *P aeruginosa* to develop resistance during treatment, an antipseudomonal penicillin is frequently used in combination with an aminoglycoside or fluoroquinolone for pseudomonal infections outside the urinary tract.

Ampicillin, amoxicillin, ticarcillin, and piperacillin are also available in combination with one of several  $\beta$ -lactamase inhibitors: clavulanic acid, sulbactam, or tazobactam. The addition of a  $\beta$ -lactamase inhibitor extends the activity of these penicillins to include  $\beta$ -lactamase-producing strains of *S aureus* as well as some  $\beta$ -lactamase-producing gram-negative bacteria (see Beta-Lactamase Inhibitors).

#### **Adverse Reactions**

The penicillins are remarkably nontoxic. Most of the serious adverse effects are due to hypersensitivity. All penicillins are cross-sensitizing and cross-reacting. The antigenic determinants are degradation products of penicillins, particularly penicilloic acid and products of alkaline hydrolysis bound to host protein. A history of a penicillin reaction is not reliable; about 5 $\times$ 8% of people claim such a history, but only a small number of these will have an allergic reaction when given penicillin. Less than 1% of persons who previously received penicillin without incident will have an allergic reaction when given penicillin. Because of the potential for anaphylaxis, however, penicillin should be administered with caution or a substitute drug given if the person is a history of penicillin allergy. The incidence of allergic reactions in small children is negligible.

Allergic reactions include anaphylactic shock (very rare $\times$ 0.05% of recipients); serum sickness-type reactions (now rare $\times$ urticaria, fever, joint swelling, angioneurotic edema, intense pruritus, and respiratory embarrassment occurring 7 $\times$ 12 days after exposure); and a variety of skin rashes. Oral lesions, fever, interstitial nephritis (an autoimmune reaction to a penicillin-protein complex), eosinophilia, hemolytic anemia and other hematologic disturbances, and vasculitis may also occur. Most patients allergic to penicillins can be treated with alternative drugs. However, if necessary (eg, treatment of enterococcal endocarditis or neurosyphilis in a highly penicillin-allergic patient), desensitization can be accomplished with gradually increasing doses of penicillin.

In patients with renal failure, penicillin in high doses can cause seizures. Nafcillin is associated with neutropenia; oxacillin can cause hepatitis; and methicillin causes interstitial nephritis (and is no longer used for this reason). Large doses of penicillins given orally may lead to gastrointestinal upset, particularly nausea, vomiting, and diarrhea. Ampicillin has been associated with pseudomembranous colitis. Secondary infections such as vaginal candidiasis may occur. Ampicillin and amoxicillin can cause skin rashes that are not allergic in nature. These rashes frequently occur when aminopenicillins are inappropriately prescribed for a viral illness.

#### **CEPHALOSPORINS & CEPHAMYCINS**

Cephalosporins are similar to penicillins, but more stable to many bacterial  $\beta$  lactamases and therefore have a broader spectrum of activity. However, strains of *E coli* and *Klebsiella* species expressing extended-spectrum  $\beta$  lactamases that can hydrolyze most cephalosporins are becoming a problem.

Cephalosporins are not active against enterococci and *L. monocytogenes*.

### **Chemistry**

The nucleus of the cephalosporins, 7-aminocephalosporanic acid (Figure 43â€6), bears a close resemblance to 6-aminopenicillanic acid (Figure 43â€1). The intrinsic antimicrobial activity of natural cephalosporins is low, but the attachment of various R<sub>1</sub> and R<sub>2</sub> groups has yielded hundreds of potent compounds of low toxicity (Figure 43â€6). Cephalosporins can be classified into four major groups or generations, depending mainly on the spectrum of antimicrobial activity.

**Figure 43â€6**

7-Aminocephalosporanic acid nucleus. The following structures can each be substituted at  $R_1$  and  $R_2$  to produce the named derivatives.

**Cefoxitin (a cephamycin)**

Structures of some cephalosporins.  $R_1$  and  $R_2$  structures are substituents on the 7-aminocephalosporanic acid nucleus pictured at the top. Other structures (cefoxitin and below) are complete in themselves.

## FIRST-GENERATION CEPHALOSPORINS

First-generation cephalosporins include **cefazolin**, **cefadroxil**, **cephalexin**, **cephalothin**, **cephapirin**, and **cephradine**. These drugs are very active against gram-positive cocci, such as pneumococci, streptococci, and staphylococci. Traditional cephalosporins are not active against methicillin-resistant strains of staphylococci; however, new compounds have been developed that have activity against methicillin-resistant strains (see below). *E coli*, *K pneumoniae*, and *Proteus mirabilis* are often sensitive, but activity against *P aeruginosa*, indole-positive proteus, enterobacter, *Serratia marcescens*, citrobacter, and acinetobacter is poor. Anaerobic cocci (eg, peptococcus, peptostreptococcus) are usually sensitive, but *Bacteroides fragilis* is not.

### Pharmacokinetics & Dosage

#### ORAL

Cephalexin, cephradine, and cefadroxil are absorbed from the gut to a variable extent. After oral doses of 500 mg, serum levels are 15â€”20 mcg/mL. Urine concentration is usually very high, but in most tissues levels are variable and generally lower than in serum. Cephalexin and cephradine are given orally in dosages of 0.25â€”0.5 g four times daily (15â€”30 mg/kg/d) and cefadroxil in dosages of 0.5â€”1 g twice daily. Excretion is mainly by glomerular filtration and tubular secretion into the urine. Drugs that block tubular secretion, eg, probenecid, may increase serum levels substantially. In patients with impaired renal function, dosage must be reduced (Table 43â€”2).

**Table 43â€”2 Guidelines for Dosing of Some Commonly Used Cephalosporins and Other Cell-Wall Inhibitor Antibiotics.**

Antibiotic (Route of Administration)	Adult Dose	Pediatric Dose <sup>1</sup>	Neonatal Dose <sup>2</sup>	Adjusted Dose as a Percentage of Normal Dose for Renal Failure Based on Creatinine Clearance (Cl <sub>cr</sub> )	
				Cl <sub>cr</sub> Approx 50 mL/min	Cl <sub>cr</sub> Approx 10 mL/min
<b>First-generation cephalosporins</b>					
Cefadroxil (PO)	0.5â€”1 g qdâ€”bid	30 mg/kg/d in 2 doses		50%	25%
Cephalexin, cephradine (PO)	0.25â€”0.5 g qid	25â€”50 mg/kg/d in 4 doses		50%	25%
Cefazolin (IV)	0.5â€”2 g q8h	25â€”100 mg/kg/d in 3 or 4 doses		50%	25%
<b>Second-generation cephalosporins</b>					
Cefoxitin (IV)	1â€”2 g q6â€”8h	75â€”150 mg/kg/d in 3 or 4 doses		50â€”75%	25%
Cefotetan (IV)	1â€”2 g q12h			50%	25%
Cefuroxime (IV)	0.75â€”1.5 g q8h	50â€”100 mg/kg/d in 3 or 4 doses		66%	25â€”33%
<b>Third- and fourth-generation cephalosporins</b>					
Cefotaxime (IV)	1â€”2 g q6â€”12h	50â€”200 mg/kg/d in 4â€”6 doses	100 mg/kg/d in 2 doses	50%	25%
Ceftazidime (IV)	1â€”2 g q8â€”12h	75â€”150 mg/kg/d in 3 doses	100â€”150 mg/kg/d in 2 or 3 doses	50%	25%
Ceftriaxone (IV)	1â€”4 g q24h	50â€”100 mg/kg/d in 1 or 2 doses	50 mg/kg/d qd	None	None
Cefepime (IV)	0.5â€”2 g q12h	75â€”120 mg/kg/d in 2 or 3 divided doses		50%	25%
<b>Carbapenems</b>					
Ertapenem (IM or IV)	1 g			100% <sup>3</sup>	50%
Doripenem	500 mg q8h			50%	33%
Imipenem (IV)	0.25â€”0.5 g q6â€”8h			75%	50%
Meropenem (IV)	1 g q8h (2 g q8h for meningitis)	60â€”120 mg/kg/d in 3 doses (maximum of 2 g q8h)		66%	50%
<b>Glycopeptides</b>					
Vancomycin (IV)	30 mg/kg/d in 2â€”3 doses	40 mg/kg/d in 3 or 4 doses	15 mg/kg load, then 20 mg/kg/d in 2 doses	40%	10%

<sup>1</sup>The total dose should not exceed the adult dose.

<sup>2</sup>The dose shown is during the first week of life. The daily dose should be increased by approximately 33â€”50% after the first week of life. The lower dosage range should be used for neonates weighing less than 2 kg. After the first month of life, pediatric doses may be used.

<sup>3</sup>50% of dose for Cl<sub>cr</sub> < 30 mL/min.

#### PARENTERAL

Cefazolin is the only first-generation parenteral cephalosporin still in general use. After an intravenous infusion of 1 g, the peak level of cefazolin is 90â€”120 mcg/mL. The usual intravenous dosage of cefazolin for adults is 0.5â€”2 g intravenously every 8 hours. Cefazolin can also be administered intramuscularly. Excretion is via the kidney, and dose adjustments must be made for impaired renal function.

## Clinical Uses

Although the first-generation cephalosporins are broad spectrum and relatively nontoxic, they are rarely the drug of choice for any infection. Oral drugs may be used for the treatment of urinary tract infections, for staphylococcal, or for streptococcal infections including cellulitis or soft tissue abscess. However, oral cephalosporins should not be relied on in serious systemic infections.

Cefazolin penetrates well into most tissues. It is a drug of choice for surgical prophylaxis. Cefazolin may be a choice in infections for which it is the least toxic drug (eg, penicillinase-producing *E coli* or *K pneumoniae*) and in persons with staphylococcal or streptococcal infections who have a history of penicillin allergy other than immediate hypersensitivity. Cefazolin does not penetrate the central nervous system and cannot be used to treat meningitis. Cefazolin is an alternative to an antistaphylococcal penicillin for patients who are allergic to penicillin.

## SECOND-GENERATION CEPHALOSPORINS

Members of the second-generation cephalosporins include **cefaclor**, **cefamandole**, **cefonicid**, **cefuroxime**, **cefprozil**, **loracarbef**, and **ceforanide**; and the structurally related cephamecins **cefoxitin**, **cefmetazole**, and **cefotetan**, which have activity against anaerobes. This is a heterogeneous group of drugs with marked individual differences in activity, pharmacokinetics, and toxicity. In general, they are active against organisms inhibited by first-generation drugs, but in addition they have extended gram-negative coverage. Klebsiellae (including those resistant to cephalothin) are usually sensitive. Cefamandole, cefuroxime, cefonicid, ceforanide, and cefaclor are active against *H influenzae* but not against *Serratia* or *B fragilis*. In contrast, cefoxitin, cefmetazole, and cefotetan are active against *B fragilis* and some *Serratia* strains but are less active against *H influenzae*. As with first-generation agents, none is active against enterococci or *P aeruginosa*. Second-generation cephalosporins may exhibit in vitro activity against enterobacter species, but resistant mutants that constitutively express a chromosomal  $\beta$  lactamase that hydrolyzes these compounds (and third-generation cephalosporins) are readily selected, and they should not be used to treat enterobacter infections.

## Pharmacokinetics & Dosage

### ORAL

Cefaclor, cefuroxime axetil, cefprozil, and loracarbef can be given orally. The usual dosage for adults is 10-15 mg/kg/d in two to four divided doses; children should be given 20-40 mg/kg/d up to a maximum of 1 g/d. Except for cefuroxime axetil, these drugs are not predictably active against penicillin-resistant pneumococci and should be used cautiously, if at all, to treat suspected or proved pneumococcal infections. Cefaclor is more susceptible to  $\beta$ -lactamase hydrolysis compared with the other agents, and its usefulness is correspondingly diminished.

### PARENTERAL

After a 1-g intravenous infusion, serum levels are 75-125 mcg/mL for most second-generation cephalosporins. Intramuscular administration is painful and should be avoided. Doses and dosing intervals vary depending on the specific agent (Table 43-2). There are marked differences in half-life, protein binding, and interval between doses. All are renally cleared and require dosage adjustment in renal failure.

## Clinical Uses

The oral second-generation cephalosporins are active against  $\beta$ -lactamase-producing *H influenzae* or *Moraxella catarrhalis* and have been primarily used to treat sinusitis, otitis, and lower respiratory tract infections, in which these organisms have an important role. Because of their activity against anaerobes (including *B fragilis*), cefoxitin, cefotetan, or cefmetazole can be used to treat mixed anaerobic infections such as peritonitis or diverticulitis. Cefuroxime is used to treat community-acquired pneumonia because it is active against  $\beta$ -lactamase-producing *H influenzae* or *K pneumoniae* and penicillin-resistant pneumococci. Although cefuroxime crosses the blood-brain barrier, it is less effective in treatment of meningitis than ceftriaxone or cefotaxime and should not be used.

## THIRD-GENERATION CEPHALOSPORINS

Third-generation agents include **cefoperazone**, **cefotaxime**, **ceftazidime**, **ceftizoxime**, **ceftriaxone**, **cefixime**, **cefpodoxime proxetil**, **cefdinir**, **cefditoren pivoxil**, **ceftibuten**, and **moxalactam**.

## Antimicrobial Activity

Compared with second-generation agents, these drugs have expanded gram-negative coverage, and some are able to cross the blood-brain barrier. Third-generation drugs are active against *Citrobacter*, *S marcescens*, and *Providencia* (although resistance can emerge during treatment of infections caused by these species due to selection of mutants that constitutively produce cephalosporinase). They are also effective against  $\beta$ -lactamase-producing strains of *Haemophilus* and *Neisseria*. Ceftazidime and cefoperazone are the only two drugs with useful activity against *P aeruginosa*. Like the second-generation drugs, third-generation cephalosporins are hydrolyzable by constitutively produced AmpC  $\beta$  lactamase, and they are not reliably active against enterobacter species. *Serratia*, *Providencia*, and *Citrobacter* also produce a chromosomally encoded cephalosporinase that, when constitutively expressed, can confer resistance to third-generation cephalosporins. Ceftizoxime and moxalactam are active against *B fragilis*. Cefixime, cefdinir, ceftibuten, and cefpodoxime proxetil are oral agents possessing similar activity except that cefixime and ceftibuten are much less active against pneumococci (and completely inactive against penicillin-resistant strains) and have poor activity against *S aureus*.

## Pharmacokinetics & Dosage

Intravenous infusion of 1 g of a parenteral cephalosporin produces serum levels of 60-140 mcg/mL. Third-generation cephalosporins penetrate body fluids and tissues well and, with the exception of cefoperazone and all oral cephalosporins, achieve levels in the cerebrospinal fluid sufficient to inhibit most pathogens, including gram-negative rods, except *Pseudomonas*.

The half-lives of these drugs and the necessary dosing intervals vary greatly: Ceftriaxone (half-life 7-8 hours) can be injected once every 24 hours at a dosage of 15-50 mg/kg/d. A single daily 1-g dose is sufficient for most serious infections, with 2 g every 12 hours recommended for treatment of meningitis. Cefoperazone (half-life 2 hours) can be injected every 8-12 hours in a dosage of 25-100 mg/kg/d. The remaining drugs in the group (half-life 1-1.7 hours) can be injected every 6-8 hours in dosages between 2 and 12 g/d, depending on the severity of infection. Cefixime can be given orally (200 mg twice daily or 400 mg once daily) for respiratory or urinary tract infections. The adult dose for cefpodoxime proxetil or cefditoren pivoxil is 200-400 mg twice daily; for ceftibuten, 400 mg once daily; and for cefdinir, 300 mg/12 h. The excretion of cefoperazone and ceftriaxone is mainly through the biliary tract, and no dosage adjustment is required in renal insufficiency. The others are excreted by the kidney and therefore require dosage adjustment in renal insufficiency.

## Clinical Uses

Third-generation cephalosporins are used to treat a wide variety of serious infections caused by organisms that are resistant to most other drugs. Strains expressing extended-spectrum  $\beta$  lactamases, however, are not susceptible. Third-generation cephalosporins should be avoided in treatment of enterobacter infections even if the clinical isolate appears susceptible in vitro because of emergence of resistance. Ceftriaxone and cefotaxime are approved for

treatment of meningitis, including meningitis caused by pneumococci, meningococci, *H influenzae*, and susceptible enteric gram-negative rods, but not by *L monocytogenes*. Ceftriaxone and cefotaxime are the most active cephalosporins against penicillin-resistant strains of pneumococci and are recommended for empirical therapy of serious infections that may be caused by these strains. Meningitis caused by highly penicillin-resistant strains of pneumococci (ie, those susceptible only to penicillin MICs > 1 mcg/mL) may not respond even to these agents, and addition of vancomycin is recommended. Other potential indications include empirical therapy of sepsis of unknown cause in both the immunocompetent and the immunocompromised patient and treatment of infections for which a cephalosporin is the least toxic drug available. In neutropenic, febrile immunocompromised patients, third-generation cephalosporins are often used in combination with an aminoglycoside.

#### FOURTH-GENERATION CEPHALOSPORINS

Cefepime is an example of a so-called fourth-generation cephalosporin. It is more resistant to hydrolysis by chromosomal  $\beta$  lactamases (eg, those produced by enterobacter). However, like the third-generation compounds, it may be hydrolyzed by extended-spectrum  $\beta$  lactamases. Cefepime has good activity against *P aeruginosa*, Enterobacteriaceae, *S aureus*, and *S pneumoniae*. It is highly active against haemophilus and neisseria. It penetrates well into cerebrospinal fluid. It is cleared by the kidneys and has a half-life of 2 hours, and its pharmacokinetic properties are very similar to those of ceftazidime. Unlike ceftazidime, however, cefepime has good activity against most penicillin-resistant strains of streptococci, and it may be useful in treatment of enterobacter infections. Otherwise, its clinical role is similar to that of third-generation cephalosporins.

#### Cephalosporins Active Against Methicillin-Resistant Staphylococci

$\beta$ -Lactam antibiotics with activity against methicillin-resistant staphylococci are currently under development. Ceftaroline fosamil, the prodrug of ceftaroline, and ceftobiprole medocaril, the prodrug of ceftobiprole, are furthest along in development. Both have increased binding to penicillin-binding protein 2a, which mediates methicillin-resistance in staphylococci, resulting in bactericidal activity against these strains. Both have some activity against enterococci and broad gram-negative spectrum, although neither is active against extended-spectrum  $\beta$ -lactamase-producing strains. Since clinical experience with these drugs is limited, their role in therapy is not yet defined.

#### Adverse Effects of Cephalosporins

##### ALLERGY

Cephalosporins are sensitizing and may elicit a variety of hypersensitivity reactions that are identical to those of penicillins, including anaphylaxis, fever, skin rashes, nephritis, granulocytopenia, and hemolytic anemia. However, the chemical nucleus of cephalosporins is sufficiently different from that of penicillins so that some individuals with a history of penicillin allergy may tolerate cephalosporins. The frequency of cross-allergenicity between the two groups of drugs is uncertain but is probably around 5%–10%. However, patients with a history of anaphylaxis to penicillins should not receive cephalosporins.

##### TOXICITY

Local irritation can produce severe pain after intramuscular injection and thrombophlebitis after intravenous injection. Renal toxicity, including interstitial nephritis and even tubular necrosis, has been demonstrated and has caused the withdrawal of cephaloridine from clinical use.

Cephalosporins that contain a methylthiotetrazole group (eg, cefamandole, cefmetazole, cefotetan, cefoperazone) frequently cause hypoprothrombinemia and bleeding disorders. Administration of vitamin K<sub>1</sub>, 10 mg twice weekly, can prevent this. Drugs with the methylthiotetrazole ring can also cause severe disulfiram-like reactions; consequently, alcohol and alcohol-containing medications must be avoided.

#### OTHER BETA-LACTAM DRUGS

##### MONOBACTAMS

Monobactams are drugs with a monocyclic  $\beta$ -lactam ring (Figure 43-1). Their spectrum of activity is limited to aerobic gram-negative rods (including pseudomonas). Unlike other  $\beta$ -lactam antibiotics, they have no activity against gram-positive bacteria or anaerobes. **Aztreonam** is the only monobactam available in the USA. It has structural similarities to ceftazidime; hence its gram-negative spectrum is similar to that of the third generation cephalosporins. It is stable to many  $\beta$  lactamases with the notable exceptions being AmpC  $\beta$  lactamases and extended-spectrum  $\beta$  lactamases. It penetrates well into the cerebrospinal fluid. Aztreonam is given intravenously every 8 hours in a dose of 1g, providing peak serum levels of 100 mcg/mL. The half-life is 12 hours and is greatly prolonged in renal failure.

Penicillin-allergic patients tolerate aztreonam without reaction. Occasional skin rashes and elevations of serum aminotransferases occur during administration of aztreonam, but major toxicity has not yet been reported. In patients with a history of penicillin anaphylaxis, aztreonam may be used to treat serious infections such as pneumonia, meningitis, and sepsis caused by susceptible gram-negative pathogens.

##### BETA-LACTAMASE INHIBITORS (CLAVULANIC ACID, SULBACTAM, & TAZOBACTAM)

These substances resemble  $\beta$ -lactam molecules (Figure 43-7) but they have very weak antibacterial action. They are potent inhibitors of many but not all bacterial  $\beta$  lactamases and can protect hydrolyzable penicillins from inactivation by these enzymes.  $\beta$ -Lactamase inhibitors are most active against Ambler class A  $\beta$  lactamases (plasmid-encoded transposable element [TEM]  $\beta$  lactamases in particular), such as those produced by staphylococci, *H influenzae*, *N gonorrhoeae*, salmonella, shigella, *E coli*, and *K pneumoniae*. They are not good inhibitors of class C  $\beta$  lactamases, which typically are chromosomally encoded and inducible, produced by enterobacter, citrobacter, serratia, and pseudomonas, but they do inhibit chromosomal  $\beta$  lactamases of bacteroides and moraxella.

Figure 43-7

## $\beta$ -Lactamase inhibitors.

The three inhibitors differ slightly with respect to pharmacology, stability, potency, and activity, but these differences usually are of little therapeutic significance.  $\beta$ -Lactamase inhibitors are available only in fixed combinations with specific penicillins. The antibacterial spectrum of the combination is determined by the companion penicillin, not the  $\beta$ -lactamase inhibitor. (The fixed combinations available in the USA are listed in Preparations Available.) An inhibitor extends the spectrum of a penicillin provided that the inactivity of the penicillin is due to destruction by  $\beta$  lactamase and that the inhibitor is active against the  $\beta$  lactamase that is produced. Thus, ampicillin-sulbactam is active against  $\beta$ -lactamase-producing *S aureus* and *H influenzae* but not against *Serratia*, which produces a  $\beta$  lactamase that is not inhibited by sulbactam. Similarly, if a strain of *P aeruginosa* is resistant to piperacillin, it is also resistant to piperacillin-tazobactam because tazobactam does not inhibit the chromosomal  $\beta$  lactamase.

The indications for penicillin- $\beta$ -lactamase inhibitor combinations are empirical therapy for infections caused by a wide range of potential pathogens in both immunocompromised and immunocompetent patients and treatment of mixed aerobic and anaerobic infections, such as intra-abdominal infections. Doses are the same as those used for the single agents except that the recommended dosage of piperacillin in the piperacillin-tazobactam combination is 3 g every 6 hours. Adjustments for renal insufficiency are made based on the penicillin component.

## CARBAPENEMS

The carbapenems are structurally related to  $\beta$ -lactam antibiotics (Figure 43â€1). **Doripenem, ertapenem, imipenem, and meropenem** are licensed for use in the USA. Imipenem has a wide spectrum with good activity against many gram-negative rods, including *P aeruginosa*, gram-positive organisms, and anaerobes. It is resistant to most  $\beta$  lactamases but not metallo- $\beta$ -lactamases. *Enterococcus faecium*, methicillin-resistant strains of staphylococci, *Clostridium difficile*, *Burkholderia cepacia*, and *Stenotrophomonas maltophilia* are resistant. Imipenem is inactivated by dehydropeptidases in renal tubules, resulting in low urinary concentrations. Consequently, it is administered together with an inhibitor of renal dehydropeptidase, **cilastatin**, for clinical use. Doripenem and meropenem are similar to imipenem but have slightly greater activity against gram-negative aerobes and slightly less activity against gram-positives. They are not significantly degraded by renal dehydropeptidase and do not require an inhibitor. Ertapenem is less active than the other carbapenems against *P aeruginosa* and acinetobacter species. It is not degraded by renal dehydropeptidase.

Carbapenems penetrate body tissues and fluids well, including the cerebrospinal fluid. All are cleared renally, and the dose must be reduced in patients with renal insufficiency. The usual dosage of imipenem is 0.25â€0.5 g given intravenously every 6â€8 hours (half-life 1 hour). The usual adult dosage of meropenem is 0.5â€1 g intravenously every 8 hours. The usual adult dosage of doripenem is 0.5 g administered as a 4-hour infusion every 8 hours. Ertapenem has the longest half-life (4 hours) and is administered as a once-daily dose of 1 g intravenously or intramuscularly. Intramuscular ertapenem is irritating, and for that reason the drug is formulated with 1% lidocaine for administration by this route.

A carbapenem is indicated for infections caused by susceptible organisms that are resistant to other available drugs, eg, *P aeruginosa*, and for treatment of mixed aerobic and anaerobic infections. Carbapenems are active against many highly penicillin-resistant strains of pneumococci. A carbapenem is the  $\beta$ -lactam antibiotic of choice for treatment of enterobacter infections because it is resistant to destruction by the  $\beta$  lactamase produced by these organisms; it is also the treatment of choice for infections caused by extended-spectrum  $\beta$ -lactamase-producing gram-negatives. Ertapenem is insufficiently active against *P aeruginosa* and should not be used to treat infections caused by that organism. Imipenem or meropenem with or without an aminoglycoside may be effective treatment for febrile neutropenic patients.

The most common adverse effects of carbapenemsâ€which tend to be more common with imipenemâ€are nausea, vomiting, diarrhea, skin rashes, and reactions at the infusion sites. Excessive levels of imipenem in patients with renal failure may lead to seizures. Meropenem, doripenem, and ertapenem are much less likely to cause seizures than imipenem. Patients allergic to penicillins may be allergic to carbapenems as well.

## GLYCOPEPTIDE ANTIBIOTICS

### VANCOMYCIN

Vancomycin is an antibiotic produced by *Streptococcus orientalis* and *Amycolatopsis orientalis*. With the single exception of flavobacterium, it is active only against gram-positive bacteria, particularly staphylococci. Vancomycin is a glycopeptide of molecular weight 1500. It is water soluble and quite stable.

### Mechanisms of Action & Basis of Resistance

Vancomycin inhibits cell wall synthesis by binding firmly to the D-Ala-D-Ala terminus of nascent peptidoglycan pentapeptide (Figure 43â€5). This inhibits the transglycosylase, preventing further elongation of peptidoglycan and cross-linking. The peptidoglycan is thus weakened, and the cell becomes susceptible to lysis. The cell membrane is also damaged, which contributes to the antibacterial effect.

Resistance to vancomycin in enterococci is due to modification of the D-Ala-D-Ala binding site of the peptidoglycan building block in which the terminal D-Ala is replaced by D-lactate. This results in the loss of a critical hydrogen bond that facilitates high-affinity binding of vancomycin to its target and loss of activity. This mechanism is also present in vancomycin-resistant *S aureus* strains (MIC  $\geq$  16 mcg/mL), which have acquired the enterococcal resistance determinants. The underlying mechanism for reduced vancomycin susceptibility in vancomycin-intermediate strains (MICs  $\geq$  4â€8 mcg/mL) of *S aureus* is not known. However these strains have altered cell wall metabolism that results in a thickened cell wall with increased numbers of D-Ala-D-Ala residues, which serve as dead-end binding sites for vancomycin. Vancomycin is sequestered within the cell wall by these false targets and is unable to reach its site of action.

### Antibacterial Activity

Vancomycin is bactericidal for gram-positive bacteria in concentrations of 0.5â€10 mcg/mL. Most pathogenic staphylococci, including those producing  $\beta$  lactamase and those resistant to nafcillin and methicillin, are killed by 2 mcg/mL or less. Vancomycin kills staphylococci relatively slowly and only if cells are actively dividing; the rate is less than that of the penicillins both in vitro and in vivo. Vancomycin is synergistic in vitro with gentamicin and streptomycin against *Enterococcus faecium* and *Enterococcus faecalis* strains that do not exhibit high levels of aminoglycoside resistance.

### Pharmacokinetics

Vancomycin is poorly absorbed from the intestinal tract and is administered orally only for the treatment of antibiotic-associated enterocolitis caused by *C difficile*. Parenteral doses must be administered intravenously. A 1-hour intravenous infusion of 1 g produces blood levels of 15â€30 mcg/mL for 1â€2 hours. The drug is widely distributed in the body. Cerebrospinal fluid levels 7â€30% of simultaneous serum concentrations are achieved if there is meningeal inflammation. Ninety percent of the drug is excreted by glomerular filtration. In the presence of renal insufficiency, striking accumulation may occur (Table 43â€2). In functionally anephric patients, the half-life of vancomycin is 6â€10 days. A significant amount (roughly 50%) of vancomycin is removed during a standard hemodialysis run when a modern, high-flux membrane is used.

### Clinical Uses

The main indication for parenteral vancomycin is sepsis or endocarditis caused by methicillin-resistant staphylococci. However, vancomycin is not as effective as an antistaphylococcal penicillin for treatment of serious infections such as endocarditis caused by methicillin-susceptible strains. Vancomycin in combination with gentamicin is an alternative regimen for treatment of enterococcal endocarditis in a patient with serious penicillin allergy. Vancomycin (in combination with cefotaxime, ceftriaxone, or rifampin) is also recommended for treatment of meningitis suspected or known to be caused by a highly penicillin-resistant strain of pneumococcus (ie, MIC > 1 mcg/mL). The recommended dosage is 30 mg/kg/d in two or three divided doses. A typical dosing regimen for most infections in adults with normal renal function is 1 g every 12 hours. The dosage in children is 40 mg/kg/d in three or four divided doses. Clearance of vancomycin is directly proportional to creatinine clearance, and the dosage is reduced accordingly in patients with renal insufficiency. For functionally anephric adult patients, a 1-g dose administered once a week is usually sufficient. Patients receiving a prolonged course of therapy should have serum concentrations checked. Recommended trough concentrations are 10–15 mcg/mL.

Oral vancomycin, 0.125–0.25 g every 6 hours, is used to treat antibiotic-associated enterocolitis caused by *C difficile*. Because of the emergence of vancomycin-resistant enterococci and the selective pressure of oral vancomycin for these resistant organisms, metronidazole had been preferred as initial therapy over the last two decades. However, recent clinical data suggest that vancomycin is associated with a better clinical response than metronidazole for more severe cases of *C difficile* enterocolitis. Therefore, oral vancomycin may be used as a first line treatment for severe cases or for cases that fail to respond to metronidazole.

### Adverse Reactions

Adverse reactions are encountered in about 10% of cases. Most reactions are minor. Vancomycin is irritating to tissue, resulting in phlebitis at the site of injection. Chills and fever may occur. Ototoxicity is rare and nephrotoxicity uncommon with current preparations. However, administration with another ototoxic or nephrotoxic drug, such as an aminoglycoside, increases the risk of these toxicities. Ototoxicity can be minimized by maintaining peak serum concentrations below 60 mcg/mL. Among the more common reactions is the so-called "red man" or "red neck" syndrome. This infusion-related flushing is caused by release of histamine. It can be largely prevented by prolonging the infusion period to 1–2 hours.

### TEICOPLANIN

Teicoplanin is a glycopeptide antibiotic that is very similar to vancomycin in mechanism of action and antibacterial spectrum. Unlike vancomycin, it can be given intramuscularly as well as intravenously. Teicoplanin has a long half-life (45–70 hours), permitting once-daily dosing. This drug is available in Europe but has not been approved for use in the United States.

### DALBAVANCIN

Dalbavancin is a semisynthetic lipoglycopeptide derived from teicoplanin. Dalbavancin shares the same mechanism of action as vancomycin and teicoplanin but has improved activity against many gram-positive bacteria including methicillin-resistant and vancomycin-intermediate *S aureus*. It is not active against most strains of vancomycin-resistant enterococci. Dalbavancin has an extremely long half-life of 6–11 days, which allows for once-weekly intravenous administration. Development of dalbavancin has been put on hold pending additional clinical trials.

### TELAVANCIN

Telavancin is a semisynthetic lipoglycopeptide derived from vancomycin. Telavancin is active versus gram-positive bacteria, including strains with reduced susceptibility to vancomycin. Telavancin exerts its antibacterial activity through two mechanisms of action. Like vancomycin, telavancin inhibits cell wall synthesis by binding to the D-Ala-D-Ala terminus of peptidoglycan in the growing cell wall. In addition, it targets the bacterial cell membrane and causes disruption of membrane potential and increases membrane permeability. The half-life of telavancin is approximately 8 hours, which supports once-daily intravenous dosing. Phase III clinical studies with telavancin have been completed, and the drug is awaiting approval for use in the United States.

### OTHER CELL WALL- OR MEMBRANE-ACTIVE AGENTS

#### DAPTOMYCIN

Daptomycin is a novel cyclic lipopeptide fermentation product of *Streptomyces roseosporus* (Figure 43–8). It was discovered decades ago but has only recently been developed as the need for drugs active against resistant organisms has become more acute. Its spectrum of activity is similar to that of vancomycin except that it is more rapidly bactericidal in vitro and it is active against vancomycin-resistant strains of enterococci and *S aureus*. The precise mechanism of action is not fully understood, but it is known to bind to the cell membrane via calcium-dependent insertion of its lipid tail. This results in depolarization of the cell membrane with potassium efflux and rapid cell death (Figure 43–9). Daptomycin is cleared renally. The recommended doses are 4 mg/kg/dose for treatment of skin and soft tissue infections and 6 mg/kg/dose for treatment of bacteremia and endocarditis once daily in patients with normal renal function and every other day in patients with creatinine clearance of less than 30 mL/min. In clinical trials powered for noninferiority, daptomycin was equivalent in efficacy to vancomycin. It can cause myopathy, and creatine phosphokinase levels should be monitored. Pulmonary surfactant antagonizes daptomycin, and it should not be used to treat pneumonia. Treatment failures have been reported in association with an increase in daptomycin MIC for clinical isolates obtained during therapy. The relation between an increase in MIC and treatment failure is unclear at this point. Daptomycin is an effective alternative to vancomycin, and its ultimate role continues to unfold.

#### Figure 43–8

indicated for the suppression of mixed bacterial flora in surface lesions of the skin, in wounds, or on mucous membranes. Solutions of bacitracin containing 100â€³200 units/mL in saline can be used for irrigation of joints, wounds, or the pleural cavity.

## CYCLOSERINE

Cycloserine is an antibiotic produced by *Streptomyces orchidaceus*. It is water soluble and very unstable at acid pH. Cycloserine inhibits many gram-positive and gram-negative organisms, but it is used almost exclusively to treat tuberculosis caused by strains of *Mycobacterium tuberculosis* resistant to first-line agents. Cycloserine is a structural analog of D-alanine and inhibits the incorporation of D-alanine into peptidoglycan pentapeptide by inhibiting alanine racemase, which converts L-alanine to D-alanine, and D-alanyl-D-alanine ligase (Figure 43â€³5). After ingestion of 0.25 g of cycloserine blood levels reach 20â€³30 mcg/mLâ€³sufficient to inhibit many strains of mycobacteria and gram-negative bacteria. The drug is widely distributed in tissues. Most of the drug is excreted in active form into the urine. The dosage for treating tuberculosis is 0.5 to 1 g/d in two or three divided doses.

Cycloserine causes serious dose-related central nervous system toxicity with headaches, tremors, acute psychosis, and convulsions. If oral dosages are maintained below 0.75 g/d, such effects can usually be avoided.

## SUMMARY: BETA-LACTAM & OTHER CELL WALL- & MEMBRANE-ACTIVE ANTIBIOTICS

### Beta-Lactam & Other Cell Wall- & Membrane-Active Antibiotics

Subclass	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>Penicillins</b>				
Penicillin G	Prevents bacterial cell wall synthesis by binding to and inhibiting cell wall transpeptidases	Rapid bactericidal activity against susceptible bacteria	Streptococcal infections, meningococcal infections, neurosyphilis	IV administration • rapid renal clearance (half-life 30 min, so requires frequent dosing (every 4 h) • <i>Toxicity:</i> Immediate hypersensitivity, rash, seizures
<i>Penicillin V: Oral, low systemic levels limit widespread use</i>				
<i>Benzathine penicillin, procaine penicillin: Intramuscular, long-acting formulations</i>				
<i>Nafcillin, oxacillin: Intravenous, added stability to staphylococcal <math>\beta</math> lactamase, biliary clearance</i>				
<i>Ampicillin, amoxicillin, ticarcillin, piperacillin: Greater activity versus gram-negative bacteria; addition of <math>\beta</math>-lactamase inhibitor restores activity against many <math>\beta</math>-lactamaseâ€³producing bacteria</i>				
<b>Cephalosporins</b>				
Cefazolin	Prevents bacterial cell wall synthesis by binding to and inhibiting cell wall transpeptidases	Rapid bactericidal activity against susceptible bacteria	Skin and soft tissue infections, urinary tract infections, surgical prophylaxis	IV administration • renal clearance (half-life 1.5 h) • dosed every 8 h • poor penetration into the central nervous system (CNS) • <i>Toxicity:</i> Rash, drug fever
<i>Cephalexin: Oral, first-generation drug, used for treating skin and soft tissue infections and urinary tract infections</i>				
<i>Cefuroxime: Oral and intravenous, second generation drug, improved activity versus Pneumococcus and Haemophilus influenzae</i>				
<i>Cefotetan, cefoxitin: Intravenous, second-generation drugs, activity versus Bacteroides fragilis allows for use in abdominal/pelvic infections</i>				
<i>Ceftriaxone: Intravenous, third-generation drug, mixed clearance with long half-life (6 hours), good CNS penetration, many uses including pneumonia, meningitis, pyelonephritis, and gonorrhea</i>				
<i>Cefotaxime: Intravenous, third-generation, similar to ceftriaxone; however, clearance is renal and half-life is 1 hour</i>				
<i>Ceftazidime: Intravenous, third-generation drug, poor gram-positive activity, good activity versus Pseudomonas</i>				
<i>Cefepime: Intravenous, fourth-generation drug, broad activity with improved stability to chromosomal <math>\beta</math> lactamase</i>				
<i>Ceftobiprole<sup>1</sup>, ceftaroline<sup>1</sup>: Intravenous, active against methicillin-resistant staphylococci, broad gram-negative activity</i>				
<b>Carbapenems</b>				
Imipenem-cilastatin	Prevents bacterial cell wall synthesis by binding to and inhibiting cell wall transpeptidases	Rapid bactericidal activity against susceptible bacteria	Serious infections such as pneumonia and sepsis	IV administration • renal clearance (half-life 1 h), dosed every 6â€³8 h, cilastatin added to prevent hydrolysis by renal dehydropeptidase • <i>Toxicity:</i> Seizures especially in renal failure or with high doses (> 2 g/d)
<i>Meropenem, doripenem: Intravenous, similar activity to imipenem; stable to renal dehydropeptidase, lower incidence of seizures</i>				
<i>Ertapenem: Intravenous, longer half-life allows for once-daily dosing, lacks activity versus pseudomonas and acinetobacter</i>				
<b>Monobactams</b>				
Aztreonam	Prevents bacterial cell wall synthesis by binding to and inhibiting cell wall transpeptidases	Rapid bactericidal activity against susceptible bacteria	Infections caused by aerobic, gram-negative bacteria in patients with immediate hypersensitivity to penicillins	IV administration • renal clearance half-life 1.5 h • dosed every 8 h • <i>Toxicity:</i> No cross-allergenicity with penicillins
<b>Glycopeptide</b>				
Vancomycin	Inhibits cell wall synthesis by binding to the D-Ala-D-Ala terminus of nascent peptidoglycan	Bactericidal activity against susceptible bacteria, slower kill than $\beta$ -lactam antibiotics	Infections caused by gram-positive bacteria including sepsis, endocarditis, and meningitis • <i>Clostridium difficile</i> colitis (oral formulation)	Oral, IV administration • renal clearance (half-life 6 h) • starting dose of 30 mg/kg/d in two or three divided doses in patients with normal renal function • trough concentrations of 10â€³15 mcg/mL sufficient for most infections • <i>Toxicity:</i> "Red-man" syndrome • nephrotoxicity uncommon

*Teicoplanin: Intravenous, similar to vancomycin except that long half-life (45-75 h) permits once-daily dosing*

*Dalbavancin<sup>1</sup>: Intravenous, very long half-life (6-11 days) permits once-weekly dosing, more active than vancomycin*

*Telavancin<sup>1</sup>: Intravenous, dual mechanism of action results in improved activity against bacteria with reduced susceptibility to vancomycin*

#### **Lipopeptide**

Daptomycin	Binds to cell membrane, causing depolarization and rapid cell death	Bactericidal activity against susceptible bacteria • more rapidly bactericidal than vancomycin	Infections caused by gram-positive bacteria including sepsis and endocarditis	IV administration • renal clearance (half-life 8 h) • dosed once daily • inactivated by pulmonary surfactant so cannot be used to treat pneumonia • <i>Toxicity</i> : Myopathy • monitoring of weekly creatine phosphokinase levels recommended

<sup>1</sup>Investigational.

## **PREPARATIONS AVAILABLE**

### **PENICILLINS**

**Amoxicillin** (generic, Amoxil, others)

Oral: 125, 200, 250, 400 mg chewable tablets; 500, 875 mg tablets; 250, 500 mg capsules; powder to reconstitute for 50, 125, 200, 250, 400 mg/mL solution

**Amoxicillin/potassium clavulanate** (generic, Augmentin)<sup>1</sup>

Oral: 250, 500, 875 mg tablets; 125, 200, 250, 400 mg chewable tablets; 1000 mg extended-release tablet powder to reconstitute for 125, 200, 250 mg/5 mL suspension

**Ampicillin** (generic)

Oral: 250, 500 mg capsules; powder to reconstitute for 125, 250 mg suspensions

Parenteral: powder to reconstitute for injection (125, 250, 500 mg, 1, 2 g per vial)

**Ampicillin/sulbactam sodium** (generic, Unasyn)<sup>2</sup>

Parenteral: 1, 2 g ampicillin powder to reconstitute for IV or IM injection

**Carbenicillin** (Geocillin)

Oral: 382 mg tablets

**Dicloxacillin** (generic)

Oral: 250, 500 mg capsules

**Nafcillin** (generic)

Parenteral: 1, 2 g per IV piggyback units

**Oxacillin** (generic)

Parenteral: powder to reconstitute for injection (0.5, 1, 2, 10 g per vial)

**Penicillin G** (generic, Pentids, Pfizerpen)

Parenteral: powder to reconstitute for injection (1, 2, 3, 5, 10, 20 million units)

**Penicillin G benzathine** (Permapen, Bicillin)

Parenteral: 0.6, 1.2, 2.4 million units per dose

**Penicillin G procaine** (generic)

Parenteral: 0.6, 1.2 million units/mL for IM injection only

**Penicillin V** (generic, V-Cillin, Pen-Vee K, others)

Oral: 250, 500 mg tablets; powder to reconstitute for 125, 250 mg/5 mL solution

**Piperacillin** (Pipracil)

Parenteral: powder to reconstitute for injection (2, 3, 4 g per vial)

**Piperacillin and tazobactam sodium** (Zosyn)<sup>3</sup>

Parenteral: 2, 3, 4 g powder to reconstitute for IV injection

**Ticarcillin** (Ticar)

Parenteral: powder to reconstitute for injection (1, 3, 6 g per vial)

**Ticarcillin/clavulanate potassium** (Timentin)<sup>4</sup>

Parenteral: 3 g powder to reconstitute for injection

**CEPHALOSPORINS & OTHER BETA-LACTAM DRUGS**

**NARROW-SPECTRUM (FIRST-GENERATION) CEPHALOSPORINS**

**Cefadroxil** (generic, Duricef)

Oral: 500 mg capsules; 1 g tablets; 125, 250, 500 mg/5 mL suspension

**Cefazolin** (generic, Ancef, Kefzol)

Parenteral: powder to reconstitute for injection (0.25, 0.5, 1 g per vial or IV piggyback unit)

**Cephalexin** (generic, Keflex, others)

Oral: 250, 500 mg capsules and tablets; 1 g tablets; 125, 250 mg/5 mL suspension

**INTERMEDIATE-SPECTRUM (SECOND-GENERATION) CEPHALOSPORINS**

**Cefaclor** (generic, Ceclor)

Oral: 250, 500 mg capsules; 375, 500 mg extended-release tablets; powder to reconstitute for 125, 187, 250, 375 mg/5 mL suspension

**Cefmetazole (Zefazone)**

Parenteral: 1, 2 g powder for IV injection

**Cefotetan** (Cefotan)

Parenteral: powder to reconstitute for injection (1, 2, 10 g per vial)

**Cefoxitin** (Mefoxin)

Parenteral: powder to reconstitute for injection (1, 2, 10 g per vial)

**Cefprozil** (Cefzil)

Oral: 250, 500 mg tablets; powder to reconstitute 125, 250 mg/5 mL suspension

**Cefuroxime** (generic, Ceftin, Kefurox, Zinacef)

Oral: 125, 250, 500 mg tablets; 125, 250 mg/5 mL suspension

Parenteral: powder to reconstitute for injection (0.75, 1.5, 7.5 g per vial or infusion pack)

**Loracarbef** (Lorabid)

Oral: 200, 400 mg capsules; powder for 100, 200 mg/5 mL suspension

**BROAD-SPECTRUM (THIRD- & FOURTH-GENERATION) CEPHALOSPORINS**

**Cefdinir** (Omnicef)

Oral: 300 mg capsules; 125 mg/5 mL suspension

**Cefditoren** (Spectracef)

Oral: 200 mg tablets

**Cefepime** (Maxipime)

Parenteral: powder for injection 0.5, 1, 2 g

**Cefixime** (Suprax)

Oral: 200, 400 mg tablets; powder for oral suspension, 100 mg/5 mL

**Cefotaxime** (Claforan)

Parenteral: powder to reconstitute for injection (0.5, 1, 2 g per vial)

**Cefpodoxime proxetil** (Vantin)

Oral: 100, 200 mg tablets; 50, 100 mg granules for suspension in 5 mL

**Ceftazidime** (generic, Fortaz, Tazidime)

Parenteral: powder to reconstitute for injection (0.5, 1, 2 g per vial)

**Ceftibuten** (Cedax)

Oral: 400 mg capsules; 90, 180 mg/5 mL powder for oral suspension

**Ceftizoxime** (Cefizox)

Parenteral: powder to reconstitute for injection and solution for injection (0.5, 1, 2 g per vial)

**Ceftriaxone** (Rocephin)

Parenteral: powder to reconstitute for injection (0.25, 0.5, 1, 2, 10 g per vial)

**CARBAPENEMS & MONOBACTAM**

**Aztreonam** (Azactam)

Parenteral: powder to reconstitute for injection (0.5, 1, 2 g)

**Doripenem** (Doribax)

Parenteral: powder to reconstitute for injection (500 mg per vial)

**Ertapenem** (Invanz)

Parenteral: 1 g powder to reconstitute for IV (0.9% diluent) or IM (1% lidocaine diluent) injection

**Imipenem/cilastatin** (Primaxin)

Parenteral: powder to reconstitute for injection (250, 500, 750 mg imipenem per vial)

**Meropenem (Merrem IV)**

Parenteral: powder for injection (0.5, 1 g per vial)

**OTHER DRUGS DISCUSSED IN THIS CHAPTER**

**Cycloserine** (Seromycin Pulvules)

Oral: 250 mg capsules

**Daptomycin** (Cubicin)

Parenteral: 0.25 or 0.5 g lyophilized powder to reconstitute for IV injection

**Fosfomycin** (Monurol)

Oral: 3 g packet

**Vancomycin** (generic, Vancocin, Vancoled)

Oral: 125, 250 mg pulvules; powder to reconstitute for 250 mg/5 mL, 500 mg/6 mL solution

Parenteral: 0.5, 1, 5, 10 g powder to reconstitute for IV injection

<sup>1</sup>Clavulanate content varies with the formulation; see package insert.

<sup>2</sup>Sulbactam content is half the ampicillin content.

<sup>3</sup>Tazobactam content is 12.5% of the piperacillin content.

<sup>4</sup>Clavulanate content 0.1 g.

Basic and Clinical Pharmacology > Chapter 44. Tetracyclines, Macrolides, Clindamycin, Chloramphenicol, Streptogramins, & Oxazolidinones >

## CASE STUDY

A 19-year-old woman with no significant past medical history presents to her college medical clinic complaining of a 2-week history of foul-smelling vaginal discharge. She denies any fever or abdominal pain but does report vaginal bleeding after sexual intercourse. When questioned about her sexual activity she reports having vaginal intercourse, at times unprotected, with two men in the last 6 months. A pelvic examination is performed and is positive for mucopurulent discharge from the endocervical canal. No cervical motion tenderness is present. A first-catch urine specimen is obtained to be tested for chlamydia and gonococcus. A pregnancy test is also ordered as the patient reports she "missed her last period." Pending these results the decision is made to treat her empirically for gonococcal and chlamydial cervicitis. What are the potential treatment options? How does her potential pregnancy affect the treatment decision?

## TETRACYCLINES, MACROLIDES, CLINDAMYCIN, CHLORAMPHENICOL, STREPTOGRAMINS, & OXAZOLIDINONES: INTRODUCTION

The drugs described in this chapter inhibit bacterial protein synthesis by binding to and interfering with ribosomes. They are active against a wide variety of organisms (broad spectrum). Most are bacteriostatic but a few are bactericidal against certain organisms. Because of overuse, resistance is common. Except for tigecycline and the streptogramins, they are usually given orally.

### TETRACYCLINES

All of the tetracyclines have the basic structure shown below:

	R <sub>7</sub>	R <sub>6</sub>	R <sub>5</sub>	Renal Clearance (mL/min)
Chlortetracycline	—Cl	—CH <sub>3</sub>	—H	35
Oxytetracycline	—H	—CH <sub>3</sub>	—OH	90
Tetracycline	—H	—CH <sub>3</sub>	—H	65
Demeclocycline	—Cl	—H	—H	35
Methacycline	—H	≡CH <sub>2</sub> *	—OH	31
Doxycycline	—H	—CH <sub>3</sub> *	—OH	16
Minocycline	—N(CH <sub>3</sub> ) <sub>2</sub>	—H	—H	10

\*There is no —OH at position 6 on methacycline and doxycycline.

Free tetracyclines are crystalline amphoteric substances of low solubility. They are available as hydrochlorides, which are more soluble. Such solutions are acid and, with the exception of chlortetracycline, fairly stable. Tetracyclines chelate divalent metal ions, which can interfere with their absorption and activity. A newly approved tetracycline analog, tigecycline, is a glycylcycline and a semisynthetic derivative of minocycline.

### Antimicrobial Activity

Tetracyclines are broad-spectrum bacteriostatic antibiotics that inhibit protein synthesis. They are active against many gram-positive and gram-negative bacteria, including anaerobes, rickettsiae, chlamydiae, mycoplasmas, and L forms; and against some protozoa (eg, amebas). The antibacterial activities of most tetracyclines are similar except that tetracycline-resistant strains may be susceptible to doxycycline, minocycline, and tigecycline, all of which are poor substrates for the efflux pump that mediates resistance. Differences in clinical efficacy for susceptible organisms are minor and attributable largely to features of absorption, distribution, and excretion of individual drugs.

Tetracyclines enter microorganisms in part by passive diffusion and in part by an energy-dependent process of active transport. Susceptible cells concentrate the drug intracellularly. Once inside the cell, tetracyclines bind reversibly to the 30S subunit of the bacterial ribosome, blocking the binding of aminoacyl-tRNA to the acceptor site on the mRNA-ribosome complex (Figure 44-1). This prevents addition of amino acids to the growing peptide.

**Figure 44-1**

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 11th Edition: <http://www.accessmedicine.com>

Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

Steps in bacterial protein synthesis and targets of several antibiotics. Amino acids are shown as numbered circles. The 70S ribosomal

mRNA complex is shown with its 50S and 30S subunits. In step 1, the charged tRNA unit carrying amino acid 6 binds to the acceptor site on the 70S ribosome. The peptidyl tRNA at the donor site, with amino acids 1 through 5, then binds the growing amino acid chain to amino acid 6 (transpeptidation, step 2). The uncharged tRNA left at the donor site is released (step 3), and the new 6-amino acid chain with its tRNA shifts to the peptidyl site (translocation, step 4). The antibiotic binding sites are shown schematically as triangles. Chloramphenicol (C) and macrolides (M) bind to the 50S subunit and block transpeptidation (step 2). The tetracyclines (T) bind to the 30S subunit and prevent binding of the incoming charged tRNA unit (step 1).

## Resistance

Three mechanisms of resistance to tetracycline analogs have been described: (1) impaired influx or increased efflux by an active transport protein pump; (2) ribosome protection due to production of proteins that interfere with tetracycline binding to the ribosome; and (3) enzymatic inactivation. The most important of these are production of an efflux pump and ribosomal protection. Tet(AE) efflux pump-expressing gram-negative species are resistant to the older tetracyclines, doxycycline, and minocycline. They are susceptible, however, to tigecycline, which is not a substrate of these pumps. Similarly, the Tet(K) efflux pump of staphylococci confers resistance to tetracycline, but not to doxycycline, minocycline, or tigecycline, none of which are pump substrates. The Tet(M) ribosomal protection protein expressed by gram-positives produces resistance to tetracycline, doxycycline, and minocycline, but not to tigecycline, which because of its bulky *t*-butylglycylamido substituent, has a steric hindrance effect on Tet(M) binding to the ribosome. Tigecycline is a substrate of the chromosomally encoded multidrug efflux pumps of *Proteus* species, and *Pseudomonas aeruginosa*, accounting for their intrinsic resistance to all tetracyclines including tigecycline.

## Pharmacokinetics

Tetracyclines mainly differ in their absorption after oral administration and their elimination. Absorption after oral administration is approximately 30% for chlortetracycline; 60%–70% for tetracycline, oxytetracycline, demeclocycline, and methacycline; and 95%–100% for doxycycline and minocycline. Tigecycline is poorly absorbed orally and must be administered intravenously. A portion of an orally administered dose of tetracycline remains in the gut lumen, modifies intestinal flora, and is excreted in the feces. Absorption occurs mainly in the upper small intestine and is impaired by food (except doxycycline and minocycline); by divalent cations ( $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Fe}^{2+}$ ) or  $\text{Al}^{3+}$ ; by dairy products and antacids, which contain multivalent cations; and by alkaline pH. Specially buffered tetracycline solutions are formulated for intravenous administration.

Tetracyclines are 40%–80% bound by serum proteins. Oral dosages of 500 mg every 6 hours of tetracycline hydrochloride or oxytetracycline produce peak blood levels of 4–6 mcg/mL. Intravenously injected tetracyclines give somewhat higher levels, but only temporarily. Peak levels of 2–4 mcg/mL are achieved with a 200-mg dose of doxycycline or minocycline. Steady-state peak serum concentrations of tigecycline are 0.6 mcg/mL at the usual dosage. Tetracyclines are distributed widely to tissues and body fluids except for cerebrospinal fluid, where concentrations are 10%–25% of those in serum. Minocycline reaches very high concentrations in tears and saliva, which makes it useful for eradication of the meningococcal carrier state. Tetracyclines cross the placenta to reach the fetus and are also excreted in milk. As a result of chelation with calcium, tetracyclines are bound to and damage growing bones and teeth. Carbamazepine, phenytoin, barbiturates, and chronic alcohol ingestion may shorten the half-life of doxycycline 50% by induction of hepatic enzymes that metabolize the drug.

Tetracyclines are excreted mainly in bile and urine. Concentrations in bile exceed those in serum tenfold. Some of the drug excreted in bile is reabsorbed from the intestine (enterohepatic circulation) and may contribute to maintenance of serum levels. Ten to 50 percent of various tetracyclines is excreted into the urine, mainly by glomerular filtration. Ten to 40 percent of the drug is excreted in feces. Doxycycline and tigecycline, in contrast to other tetracyclines, are eliminated by nonrenal mechanisms, do not accumulate significantly and require no dosage adjustment in renal failure.

Tetracyclines are classified as short-acting (chlortetracycline, tetracycline, oxytetracycline), intermediate-acting (demeclocycline and methacycline), or long-acting (doxycycline and minocycline) based on serum half-lives of 6–8 hours, 12 hours, and 16–18 hours, respectively. Tigecycline has a half-life of 36 hours. The almost complete absorption and slow excretion of doxycycline and minocycline allow for once-daily dosing.

## Clinical Uses

A tetracycline is the drug of choice in infections with *Mycoplasma pneumoniae*, chlamydiae, rickettsiae, and some spirochetes. They are used in combination regimens to treat gastric and duodenal ulcer disease caused by *Helicobacter pylori*. They may be used in various gram-positive and gram-negative bacterial infections, including vibrio infections, provided the organism is not resistant. In cholera, tetracyclines rapidly stop the shedding of vibrios, but tetracycline resistance has appeared during epidemics. Tetracyclines remain effective in most chlamydial infections, including sexually transmitted diseases. Tetracyclines are no longer recommended for treatment of gonococcal disease because of resistance. A tetracycline—usually in combination with an aminoglycoside—is indicated for plague, tularemia, and brucellosis. Tetracyclines are sometimes used in the treatment of protozoal infections, eg, those due to *Entamoeba histolytica* or *Plasmodium falciparum* (see Chapter 52). Other

uses include treatment of acne, exacerbations of bronchitis, community-acquired pneumonia, Lyme disease, relapsing fever, leptospirosis, and some nontuberculous mycobacterial infections (eg, *Mycobacterium marinum*). Tetracyclines formerly were used for a variety of common infections, including bacterial gastroenteritis, pneumonia (other than mycoplasmal or chlamydial pneumonia), and urinary tract infections. However, many strains of bacteria causing these infections now are resistant, and other agents have largely supplanted tetracyclines.

**Minocycline**, 200 mg orally daily for 5 days, can eradicate the meningococcal carrier state, but because of side effects and resistance of many meningococcal strains, rifampin is preferred. **Demeclocycline** inhibits the action of antidiuretic hormone in the renal tubule and has been used in the treatment of inappropriate secretion of antidiuretic hormone or similar peptides by certain tumors (see Chapter 15).

**Tigecycline**, the first glycycline to reach the clinic, has several unique features that warrant its consideration apart from the older tetracyclines. Many tetracycline-resistant strains are susceptible to tigecycline because the common resistance determinants have no activity against it. Its spectrum is very broad. Coagulase-negative staphylococci and *Staphylococcus aureus*, including methicillin-resistant, vancomycin-intermediate, and vancomycin-resistant strains; streptococci, penicillin-susceptible and resistant; enterococci, including vancomycin-resistant strains; gram-positive rods; Enterobacteriaceae; multi-drug-resistant strains of *Acinetobacter* sp; anaerobes, both gram-positive and gram-negative; atypical agents, rickettsiae, chlamydia, and legionella; and rapidly growing mycobacteria all are susceptible. *Proteus* and *P aeruginosa*, however, are intrinsically resistant.

Tigecycline, formulated for intravenous administration only, is given as a 100-mg loading dose; then 50 mg every 12 hours. As with all tetracyclines, tissue and intracellular penetration is excellent; consequently, the volume of distribution is quite large and peak serum concentrations are somewhat blunted. Elimination is primarily biliary, and no dosage adjustment is needed for patients with renal insufficiency. In addition to the tetracycline class effects, the chief adverse effect of tigecycline is nausea, which occurs in up to one third of patients, and occasionally vomiting. Neither nausea nor vomiting usually requires discontinuation of the drug.

Tigecycline is FDA-approved for treatment of skin and skin-structure infection and intra-abdominal infections. Because active drug concentrations in the urine are relatively low, tigecycline may not be effective for urinary tract infections and has no indication for this use. Because it is active against a wide variety of multidrug-resistant nosocomial pathogens (eg, methicillin-resistant *S aureus*, extended-spectrum  $\beta$ -lactamase-producing gram-negatives, and *Acinetobacter* species), tigecycline is a welcome addition to the antimicrobial drug group.

#### **ORAL DOSAGE**

The oral dosage for rapidly excreted tetracyclines, equivalent to tetracycline hydrochloride, is 0.25–0.5 g four times daily for adults and 20–40 mg/kg/d for children (8 years of age and older). For severe systemic infections, the higher dosage is indicated, at least for the first few days. The daily dose is 600 mg for demeclocycline or methacycline, 100 mg once or twice daily for doxycycline, and 100 mg twice daily for minocycline. Doxycycline is the oral tetracycline of choice because it can be given as a once-daily dose and its absorption is not significantly affected by food. All tetracyclines chelate with metals, and none should be orally administered with milk, antacids, or ferrous sulfate. To avoid deposition in growing bones or teeth, tetracyclines should be avoided in pregnant women and children less than 8 years of age.

#### **PARENTERAL DOSAGE**

Several tetracyclines are available for intravenous injection in doses of 0.1–0.5 g every 6–12 hours (similar to oral doses) but doxycycline is the usual preferred agent, at a dosage of 100 mg every 12–24 hours. Intramuscular injection is not recommended because of pain and inflammation at the injection site.

#### **Adverse Reactions**

Hypersensitivity reactions (drug fever, skin rashes) to tetracyclines are uncommon. Most adverse effects are due to direct toxicity of the drug or to alteration of microbial flora.

#### **GASTROINTESTINAL ADVERSE EFFECTS**

Nausea, vomiting, and diarrhea are the most common reasons for discontinuing tetracycline medication. These effects are attributable to direct local irritation of the intestinal tract. Nausea, anorexia, and diarrhea can usually be controlled by administering the drug with food or carboxymethylcellulose, reducing drug dosage, or discontinuing the drug.

Tetracyclines modify the normal flora, with suppression of susceptible coliform organisms and overgrowth of pseudomonas, proteus, staphylococci, resistant coliforms, clostridia, and candida. This can result in intestinal functional disturbances, anal pruritus, vaginal or oral candidiasis, or enterocolitis with shock and death.

#### **BONY STRUCTURES AND TEETH**

Tetracyclines are readily bound to calcium deposited in newly formed bone or teeth in young children. When a tetracycline is

given during pregnancy, it can be deposited in the fetal teeth, leading to fluorescence, discoloration, and enamel dysplasia; it can also be deposited in bone, where it may cause deformity or growth inhibition. Because of these effects tetracyclines are generally avoided in pregnancy. If the drug is given for long periods to children under 8 years of age, similar changes can result.

#### LIVER TOXICITY

Tetracyclines can probably impair hepatic function, especially during pregnancy, in patients with preexisting hepatic insufficiency and when high doses are given intravenously. Hepatic necrosis has been reported with daily doses of 4 g or more intravenously.

#### KIDNEY TOXICITY

Renal tubular acidosis and other renal injury resulting in nitrogen retention have been attributed to the administration of outdated tetracycline preparations. Tetracyclines given along with diuretics may produce nitrogen retention. Tetracyclines other than doxycycline may accumulate to toxic levels in patients with impaired kidney function.

#### LOCAL TISSUE TOXICITY

Intravenous injection can lead to venous thrombosis. Intramuscular injection produces painful local irritation and should be avoided.

#### PHOTOSENSITIZATION

Systemically administered tetracycline, especially demeclocycline, can induce sensitivity to sunlight or ultraviolet light, particularly in fair-skinned persons.

#### VESTIBULAR REACTIONS

Dizziness, vertigo, nausea, and vomiting have been noted particularly with doxycycline at doses above 100 mg. With dosages of 200–400 mg/d of minocycline, 35–70% of patients will have these reactions.

## MACROLIDES

The macrolides are a group of closely related compounds characterized by a macrocyclic lactone ring (usually containing 14 or 16 atoms) to which deoxy sugars are attached. The prototype drug, erythromycin, which consists of two sugar moieties attached to a 14-atom lactone ring, was obtained in 1952 from *Streptomyces erythreus*. Clarithromycin and azithromycin are semisynthetic derivatives of erythromycin.

## ERYTHROMYCIN

### Chemistry

The general structure of erythromycin is shown with the macrolide ring and the sugars desosamine and cladinose. It is poorly soluble in water (0.1%) but dissolves readily in organic solvents. Solutions are fairly stable at 4°C but lose activity rapidly at 20°C and at acid pH. Erythromycins are usually dispensed as various esters and salts.

## Antimicrobial Activity

Erythromycin is effective against gram-positive organisms, especially pneumococci, streptococci, staphylococci, and corynebacteria, in plasma concentrations of 0.02–2 mcg/mL. *Mycoplasma*, legionella, *Chlamydia trachomatis*, *C psittaci*, *C pneumoniae*, helicobacter, listeria, and certain mycobacteria (*Mycobacterium kansasii*, *M scrofulaceum*) are also susceptible. Gram-negative organisms such as *Neisseria*, *Bordetella pertussis*, *Bartonella henselae*, and *B quintana* (etiologic agents of cat-scratch disease and bacillary angiomatosis), some *Rickettsia* species, *Treponema pallidum*, and *Campylobacter* species are susceptible. *Haemophilus influenzae* is somewhat less susceptible.

The antibacterial action of erythromycin may be inhibitory or bactericidal, particularly at higher concentrations, for susceptible organisms. Activity is enhanced at alkaline pH. Inhibition of protein synthesis occurs via binding to the 50S ribosomal RNA, which blocks the aminoacyl translocation reaction and formation of initiation complexes (Figure 44–1).

## Resistance

Resistance to erythromycin is usually plasmid-encoded. Three mechanisms have been identified: (1) reduced permeability of the cell membrane or active efflux; (2) production (by Enterobacteriaceae) of esterases that hydrolyze macrolides; and (3) modification of the ribosomal binding site (so-called ribosomal protection) by chromosomal mutation or by a macrolide-inducible or constitutive methylase. Efflux and methylase production are by far the most important resistance mechanisms in gram-positive organisms. Cross-resistance is complete between erythromycin and the other macrolides. Constitutive methylase production also confers resistance to structurally unrelated but mechanistically similar compounds such as clindamycin and streptogramin B (so-called macrolide-lincosamide-streptogramin, or MLS-type B, resistance), which share the same ribosomal binding site. Because nonmacrolides are poor inducers of the methylase, strains expressing an inducible methylase will appear susceptible in vitro. However, constitutive mutants that are resistant can be selected out and emerge during therapy with clindamycin.

## Pharmacokinetics

Erythromycin base is destroyed by stomach acid and must be administered with enteric coating. Food interferes with absorption. Stearates and esters are fairly acid-resistant and somewhat better absorbed. The lauryl salt of the propionyl ester of erythromycin (erythromycin estolate) is the best-absorbed oral preparation. Oral dosage of 2 g/d results in serum erythromycin base and ester concentrations of approximately 2 mcg/mL. However, only the base is microbiologically active, and its concentration tends to be similar regardless of the formulation. A 500-mg intravenous dose of erythromycin lactobionate produces serum concentrations of 10 mcg/mL 1 hour after dosing. The serum half-life is approximately 1.5 hours normally and 5 hours in patients with anuria. Adjustment for renal failure is not necessary. Erythromycin is not removed by dialysis. Large amounts of an administered dose are excreted in the bile and lost in feces, and only 5% is excreted in the urine. Absorbed drug is distributed widely except to the brain and cerebrospinal fluid. Erythromycin is taken up by polymorphonuclear leukocytes and macrophages. It traverses the placenta and reaches the fetus.

## Clinical Uses

An erythromycin is a drug of choice in corynebacterial infections (diphtheria, corynebacterial sepsis, erythrasma); in respiratory, neonatal, ocular, or genital chlamydial infections; and in treatment of community-acquired pneumonia because its spectrum of activity includes pneumococcus, mycoplasma, and legionella. Erythromycin is also useful as a penicillin substitute in penicillin-allergic individuals with infections caused by staphylococci (assuming that the isolate is susceptible), streptococci, or pneumococci. Emergence of erythromycin resistance in strains of group A streptococci and pneumococci (penicillin-resistant pneumococci in particular) has made macrolides less attractive as first-line agents for treatment of pharyngitis, skin and soft tissue infections, and pneumonia. Erythromycin has been recommended as prophylaxis against endocarditis during dental procedures in individuals with valvular heart disease, although clindamycin, which is better tolerated, has largely replaced it. Although erythromycin estolate is the best-absorbed salt, it imposes the greatest risk of adverse reactions. Therefore, the stearate or succinate salt may be preferred.

The oral dosage of erythromycin base, stearate, or estolate is 0.25–0.5 g every 6 hours (for children, 40 mg/kg/d). The dosage of erythromycin ethylsuccinate is 0.4–0.6 g every 6 hours. Oral erythromycin base (1 g) is sometimes combined with oral neomycin or kanamycin for preoperative preparation of the colon. The intravenous dosage of erythromycin gluceptate or lactobionate is 0.5–1.0 g every 6 hours for adults and 20–40 mg/kg/d for children. The higher dosage is recommended when treating pneumonia caused by *Legionella* species.

## Adverse Reactions

### GASTROINTESTINAL EFFECTS

Anorexia, nausea, vomiting, and diarrhea occasionally accompany oral administration. Gastrointestinal intolerance, which is due to a direct stimulation of gut motility, is the most common reason for discontinuing erythromycin and substituting another

antibiotic.

### **LIVER TOXICITY**

Erythromycins, particularly the estolate, can produce acute cholestatic hepatitis (fever, jaundice, impaired liver function), probably as a hypersensitivity reaction. Most patients recover from this, but hepatitis recurs if the drug is readministered. Other allergic reactions include fever, eosinophilia, and rashes.

### **DRUG INTERACTIONS**

Erythromycin metabolites can inhibit cytochrome P450 enzymes and thus increase the serum concentrations of numerous drugs, including theophylline, oral anticoagulants, cyclosporine, and methylprednisolone. Erythromycin increases serum concentrations of oral digoxin by increasing its bioavailability.

## **CLARITHROMYCIN**

Clarithromycin is derived from erythromycin by addition of a methyl group and has improved acid stability and oral absorption compared with erythromycin. Its mechanism of action is the same as that of erythromycin. Clarithromycin and erythromycin are virtually identical with respect to antibacterial activity except that clarithromycin is more active against *Mycobacterium avium* complex (see Chapter 47). Clarithromycin also has activity against *M leprae* and *Toxoplasma gondii*. Erythromycin-resistant streptococci and staphylococci are also resistant to clarithromycin.

A 500-mg dose of clarithromycin produces serum concentrations of  $2 \times 10^3$  mcg/mL. The longer half-life of clarithromycin (6 hours) compared with erythromycin permits twice-daily dosing. The recommended dosage is 250–500 mg twice daily or 1000 mg of the extended release formulation once daily. Clarithromycin penetrates most tissues well, with concentrations equal to or exceeding serum concentrations.

Clarithromycin is metabolized in the liver. The major metabolite is 14-hydroxycarithromycin, which also has antibacterial activity. A portion of active drug and this major metabolite is eliminated in the urine, and dosage reduction (eg, a 500-mg loading dose, then 250 mg once or twice daily) is recommended for patients with creatinine clearances less than 30 mL/min. Clarithromycin has drug interactions similar to those described for erythromycin.

The advantages of clarithromycin compared with erythromycin are lower incidence of gastrointestinal intolerance and less frequent dosing. Except for the specific organisms noted above, the two drugs are otherwise therapeutically very similar, and the choice of one over the other usually turns out to be cost and tolerability.

## **AZITHROMYCIN**

Azithromycin, a 15-atom lactone macrolide ring compound, is derived from erythromycin by addition of a methylated nitrogen into the lactone ring. Its spectrum of activity and clinical uses are virtually identical to those of clarithromycin. Azithromycin is active against *M avium* complex and *T gondii*. Azithromycin is slightly less active than erythromycin and clarithromycin against staphylococci and streptococci and slightly more active against *H influenzae*. Azithromycin is highly active against chlamydia.

Azithromycin differs from erythromycin and clarithromycin mainly in pharmacokinetic properties. A 500-mg dose of azithromycin produces relatively low serum concentrations of approximately 0.4 mcg/mL. However, azithromycin penetrates into most tissues (except cerebrospinal fluid) and phagocytic cells extremely well, with tissue concentrations exceeding serum concentrations by 10- to 100-fold. The drug is slowly released from tissues (tissue half-life of  $2 \times 10^4$  days) to produce an elimination half-life approaching 3 days. These unique properties permit once-daily dosing and shortening of the duration of treatment in many cases. For example, a single 1-g dose of azithromycin is as effective as a 7-day course of doxycycline for chlamydial cervicitis and urethritis. Community-acquired pneumonia can be treated with azithromycin given as a 500-mg loading dose, followed by a 250-mg single daily dose for the next 4 days.

Azithromycin is rapidly absorbed and well tolerated orally. It should be administered 1 hour before or 2 hours after meals. Aluminum and magnesium antacids do not alter bioavailability but delay absorption and reduce peak serum concentrations. Because it has a 15-member (not 14-member) lactone ring, azithromycin does not inactivate cytochrome P450 enzymes and therefore is free of the drug interactions that occur with erythromycin and clarithromycin.

## **KETOLIDES**

Ketolides are semisynthetic 14-membered-ring macrolides, differing from erythromycin by substitution of a 3-keto group for the neutral sugar l-cladinose. **Telithromycin** is approved for clinical use. It is active in vitro against *Streptococcus pyogenes*, *S pneumoniae*, *S aureus*, *H influenzae*, *Moraxella catarrhalis*, mycoplasmas, *Legionella*, *Chlamydia*, *H pylori*, *N gonorrhoeae*, *B fragilis*, *T gondii*, and nontuberculosis mycobacteria. Many macrolide-resistant strains are susceptible to ketolides because the structural modification of these compounds renders them poor substrates for efflux pump-mediated resistance and they bind to ribosomes of some bacterial species with higher affinity than macrolides.

Oral bioavailability of telithromycin is 57%, and tissue and intracellular penetration is generally good. Telithromycin is metabolized in the liver and eliminated by a combination of biliary and urinary routes of excretion. It is administered as a once-daily dose of 800 mg, which results in peak serum concentrations of approximately 2 mcg/mL. Telithromycin is indicated for treatment of respiratory tract infections, including community-acquired bacterial pneumonia, acute exacerbations of chronic bronchitis, sinusitis, and streptococcal pharyngitis. It is a reversible inhibitor of the CYP3A4 enzyme system and may slightly prolong the QT<sub>c</sub> interval. Rare cases of hepatitis and liver failure have been reported.

## CLINDAMYCIN

Clindamycin is a chlorine-substituted derivative of **lincomycin**, an antibiotic that is elaborated by *Streptomyces lincolnensis*.

Clindamycin

### Antibacterial Activity

Streptococci, staphylococci, and pneumococci are inhibited by clindamycin, 0.5–5 mcg/mL. Enterococci and gram-negative aerobic organisms are resistant. *Bacteroides* species and other anaerobes, both gram-positive and gram-negative, are usually susceptible. Clindamycin, like erythromycin, inhibits protein synthesis by interfering with the formation of initiation complexes and with aminoacyl translocation reactions. The binding site for clindamycin on the 50S subunit of the bacterial ribosome is identical with that for erythromycin. Resistance to clindamycin, which generally confers cross-resistance to macrolides, is due to (1) mutation of the ribosomal receptor site; (2) modification of the receptor by a constitutively expressed methylase (see section on erythromycin resistance, above); and (3) enzymatic inactivation of clindamycin. Gram-negative aerobic species are intrinsically resistant because of poor permeability of the outer membrane.

### Pharmacokinetics

Oral dosages of clindamycin, 0.15–0.3 g every 8 hours (10–20 mg/kg/d for children), yield serum levels of 2–3 mcg/mL. When administered intravenously, 600 mg of clindamycin every 8 hours gives levels of 5–15 mcg/mL. The drug is about 90% protein-bound. Clindamycin penetrates well into most tissues, with brain and cerebrospinal fluid being important exceptions. It penetrates well into abscesses and is actively taken up and concentrated by phagocytic cells. Clindamycin is metabolized by the liver, and both active drug and active metabolites are excreted in bile and urine. The half-life is about 2.5 hours in normal individuals, increasing to 6 hours in patients with anuria. No dosage adjustment is required for renal failure.

### Clinical Uses

Clindamycin is indicated for the treatment of skin and soft-tissue infections caused by streptococci and staphylococci. It is often active against community-acquired strains of methicillin-resistant *S aureus*, an increasingly common cause of skin and soft tissue infections. Clindamycin is also indicated for treatment of anaerobic infection caused by bacteroides and other anaerobes that often participate in mixed infections. Clindamycin, sometimes in combination with an aminoglycoside or cephalosporin, is used to treat penetrating wounds of the abdomen and the gut; infections originating in the female genital tract, eg, septic abortion and pelvic abscesses; and aspiration pneumonia. Clindamycin is now recommended rather than erythromycin for prophylaxis of endocarditis in patients with valvular heart disease who are undergoing certain dental procedures. Clindamycin plus primaquine is an effective alternative to trimethoprim-sulfamethoxazole for moderate to moderately severe *Pneumocystis jiroveci* pneumonia in AIDS patients. It is also used in combination with pyrimethamine for AIDS-related toxoplasmosis of the brain.

### Adverse Effects

Common adverse effects are diarrhea, nausea, and skin rashes. Impaired liver function (with or without jaundice) and neutropenia sometimes occur. Severe diarrhea and enterocolitis have followed clindamycin administration. Administration of clindamycin is a risk factor for diarrhea and colitis due to *Clostridium difficile*.

## CHLORAMPHENICOL

Crystalline chloramphenicol is a neutral, stable compound with the following structure:

**Chloramphenicol**

It is soluble in alcohol but poorly soluble in water. Chloramphenicol succinate, which is used for parenteral administration, is highly water-soluble. It is hydrolyzed in vivo with liberation of free chloramphenicol.

### Antimicrobial Activity

Chloramphenicol is a potent inhibitor of microbial protein synthesis. It binds reversibly to the 50S subunit of the bacterial ribosome (Figure 44€¹) and inhibits the peptidyl transferase step of protein synthesis. Chloramphenicol is a bacteriostatic broad-spectrum antibiotic that is active against both aerobic and anaerobic gram-positive and gram-negative organisms. It is active also against rickettsiae but not chlamydiae. Most gram-positive bacteria are inhibited at concentrations of 1€¹10 mcg/mL, and many gram-negative bacteria are inhibited by concentrations of 0.2€¹5 mcg/mL. *H influenzae*, *N meningitidis*, and some strains of bacteroides are highly susceptible, and for them chloramphenicol may be bactericidal.

Low-level resistance to chloramphenicol may emerge from large populations of chloramphenicol-susceptible cells by selection of mutants that are less permeable to the drug. Clinically significant resistance is due to production of chloramphenicol acetyltransferase, a plasmid-encoded enzyme that inactivates the drug.

### Pharmacokinetics

The usual dosage of chloramphenicol is 50€¹100 mg/kg/d. After oral administration, crystalline chloramphenicol is rapidly and completely absorbed. A 1-g oral dose produces blood levels between 10 and 15 mcg/mL. Chloramphenicol palmitate is a prodrug that is hydrolyzed in the intestine to yield free chloramphenicol. The parenteral formulation is a prodrug, chloramphenicol succinate, which hydrolyzes to yield free chloramphenicol, giving blood levels somewhat lower than those achieved with orally administered drug. Chloramphenicol is widely distributed to virtually all tissues and body fluids, including the central nervous system and cerebrospinal fluid, such that the concentration of chloramphenicol in brain tissue may be equal to that in serum. The drug penetrates cell membranes readily.

Most of the drug is inactivated either by conjugation with glucuronic acid (principally in the liver) or by reduction to inactive aryl amines. Active chloramphenicol (about 10% of the total dose administered) and its inactive degradation products (about 90% of the total) are eliminated in the urine. A small amount of active drug is excreted into bile and feces. The systemic dosage of chloramphenicol need not be altered in renal insufficiency, but it must be reduced markedly in hepatic failure. Newborns less than a week old and premature infants also clear chloramphenicol less well, and the dosage should be reduced to 25 mg/kg/d.

### Clinical Uses

Because of potential toxicity, bacterial resistance, and the availability of many other effective alternatives, chloramphenicol is rarely used. It may be considered for treatment of serious rickettsial infections such as typhus and Rocky Mountain spotted fever. It is an alternative to a  $\beta$ -lactam antibiotic for treatment of meningococcal meningitis occurring in patients who have major hypersensitivity reactions to penicillin or bacterial meningitis caused by penicillin-resistant strains of pneumococci. The dosage is 50€¹100 mg/kg/d in four divided doses.

Chloramphenicol is used topically in the treatment of eye infections because of its broad spectrum and its penetration of ocular tissues and the aqueous humor. It is ineffective for chlamydial infections.

### Adverse Reactions

#### GASTROINTESTINAL DISTURBANCES

Adults occasionally develop nausea, vomiting, and diarrhea. This is rare in children. Oral or vaginal candidiasis may occur as a result of alteration of normal microbial flora.

#### BONE MARROW DISTURBANCES

Chloramphenicol commonly causes a dose-related reversible suppression of red cell production at dosages exceeding 50 mg/kg/d after 1€¹2 weeks. Aplastic anemia, a rare consequence (1 in 24,000 to 40,000 courses of therapy) of chloramphenicol administration by any route, is an idiosyncratic reaction unrelated to dose, although it occurs more frequently with prolonged use. It tends to be irreversible and can be fatal.

### TOXICITY FOR NEWBORN INFANTS

Newborn infants lack an effective glucuronic acid conjugation mechanism for the degradation and detoxification of chloramphenicol. Consequently, when infants are given dosages above 50 mg/kg/d, the drug may accumulate, resulting in the **gray baby syndrome**, with vomiting, flaccidity, hypothermia, gray color, shock, and collapse. To avoid this toxic effect, chloramphenicol should be used with caution in infants and the dosage limited to 50 mg/kg/d or less (during the first week of life) in full-term infants more than 1 week old and 25 mg/kg/d in premature infants.

### INTERACTION WITH OTHER DRUGS

Chloramphenicol inhibits hepatic microsomal enzymes that metabolize several drugs. Half-lives are prolonged, and the serum concentrations of phenytoin, tolbutamide, chlorpropamide, and warfarin are increased. Like other bacteriostatic inhibitors of microbial protein synthesis, chloramphenicol can antagonize bactericidal drugs such as penicillins or aminoglycosides.

## STREPTOGRAMINS

**Quinupristin-dalfopristin** is a combination of two streptogramins—quinupristin, a streptogramin B, and dalfopristin, a streptogramin A—in a 30:70 ratio. It is rapidly bactericidal for most organisms except *Enterococcus faecium*, which is killed slowly. Quinupristin-dalfopristin is active against gram-positive cocci, including multidrug-resistant strains of streptococci, penicillin-resistant strains of *S pneumoniae*, methicillin-susceptible and resistant strains of staphylococci, and *E faecium* (but not *E faecalis*). Resistance is due to modification of the quinupristin binding site (MLS-B type), enzymatic inactivation of dalfopristin, or efflux.

Quinupristin-dalfopristin is administered intravenously at a dosage of 7.5 mg/kg every 8–12 hours. Peak serum concentrations following an infusion of 7.5 mg/kg over 60 minutes are 3 mcg/mL for quinupristin and 7 mcg/mL for dalfopristin. Quinupristin and dalfopristin are rapidly metabolized, with half-lives of 0.85 and 0.7 hours, respectively. Elimination is principally by the fecal route. Dose adjustment is not necessary for renal failure, peritoneal dialysis, or hemodialysis. Patients with hepatic insufficiency may not tolerate the drug at usual doses, however, because of increased area under the concentration curve of both parent drugs and metabolites. This may necessitate a dose reduction to 7.5 mg/kg every 12 hours or 5 mg/kg every 8 hours. Quinupristin and dalfopristin significantly inhibit CYP3A4, which metabolizes warfarin, diazepam, astemizole, terfenadine, cisapride, nonnucleoside reverse transcriptase inhibitors, and cyclosporine, among others. Dosage reduction of cyclosporine may be necessary.

Quinupristin-dalfopristin is approved for treatment of infections caused by staphylococci or by vancomycin-resistant strains of *E faecium*, but not *E faecalis*, which is intrinsically resistant probably because of an efflux-type resistance mechanism. The principal toxicities are infusion-related events, such as pain at the infusion site, and an arthralgia-myalgia syndrome.

## OXAZOLIDINONES

**Linezolid** is a member of the oxazolidinones, a new class of synthetic antimicrobials. It is active against gram-positive organisms including staphylococci, streptococci, enterococci, gram-positive anaerobic cocci, and gram-positive rods such as corynebacteria and *Listeria monocytogenes*. It is primarily a bacteriostatic agent except for streptococci, for which it is bactericidal. It is active in vitro against *Mycobacterium tuberculosis*.

Linezolid inhibits protein synthesis by preventing formation of the ribosome complex that initiates protein synthesis. Its unique binding site, located on 23S ribosomal RNA of the 50S subunit, results in no cross-resistance with other drug classes. Resistance is caused by mutation of the linezolid binding site on 23S ribosomal RNA.

The principal toxicity of linezolid is hematologic—reversible and generally mild. Thrombocytopenia is the most common manifestation (seen in approximately 3% of treatment courses), particularly when the drug is administered for longer than 2 weeks. Anemia and neutropenia may also occur, most commonly in patients with a predisposition to or underlying bone marrow suppression. Cases of optic and peripheral neuropathy and lactic acidosis have been reported with prolonged courses of linezolid. These side effects are thought to be related to linezolid-induced inhibition of mitochondrial protein synthesis.

Linezolid is 100% bioavailable after oral administration and has a half-life of 4–6 hours. It is metabolized by oxidative metabolism, yielding two inactive metabolites. It is neither an inducer nor an inhibitor of cytochrome P450 enzymes. Linezolid is a weak, reversible monoamine oxidation inhibitor. There are case reports of serotonin syndrome occurring when linezolid is co-administered with serotonergic drugs, most frequently selective serotonin reuptake inhibitor antidepressants. Peak serum concentrations average 18 mcg/mL following a 600-mg oral dose. The recommended dosage for most indications is 600 mg twice daily, either orally or intravenously. Linezolid is approved for vancomycin-resistant *E faecium* infections; nosocomial pneumonia; community-acquired pneumonia; and skin infections, complicated or uncomplicated. It should be reserved for treatment of infections caused by multidrug-resistant gram-positive bacteria.

## SUMMARY: TETRACYCLINES, MACROLIDES, CLINDAMYCIN, CHLORAMPHENICOL, STREPTOGRAMINS, & OXAZOLIDINONES

### Tetracyclines, Macrolides, Clindamycin, Chloramphenicol, Streptogramins, & Oxazolidinones

Subclass	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics , Toxicities, Interactions
<b>Tetracyclines</b>				
Tetracycline	Prevents bacterial protein synthesis by binding to the 30S ribosomal subunit	Bacteriostatic activity against susceptible bacteria	Infections caused by mycoplasma, chlamydiae, rickettsiae, some spirochetes • malaria • <i>H pylori</i> • acne	Oral • mixed clearance (half-life 8 h) • dosed every 6 h • divalent cations impair oral absorption • <i>Toxicity</i> : Gastrointestinal upset, hepatotoxicity, photosensitivity, deposition in bone and teeth
<i>Doxycycline: Oral and IV; longer half-life (18 h) so dosed twice daily; nonrenal elimination; absorption is minimally effected by divalent cations; used to treat community-acquired pneumonia and exacerbations of bronchitis</i>				
<i>Minocycline: Oral; longer half-life (16 h) so dosed twice daily; frequently causes reversible vestibular toxicity</i>				
<i>Tigecycline: IV; unaffected by common tetracycline resistance mechanisms; very broad spectrum of activity against gram-positive, gram-negative, and anaerobic bacteria; nausea and vomiting are the primary toxicities</i>				
<b>Macrolides</b>				
Erythromycin	Prevents bacterial protein synthesis by binding to the 50S ribosomal subunit	Bacteriostatic activity against susceptible bacteria	Community-acquired pneumonia • pertussis • corynebacterial, and chlamydial infections	Oral, IV • hepatic clearance (half-life 1.5 h) dosed every 6 h • cytochrome P450 inhibitor • <i>Toxicity</i> : Gastrointestinal upset, hepatotoxicity, QT <sub>c</sub> prolongation
<i>Clarithromycin: Oral; longer half-life (4 h) so dosed twice daily; added activity versus Mycobacterium avium complex, toxoplasma, and M leprae</i>				
<i>Azithromycin: Oral, IV; very long half-life (68 h) allows for once-daily dosing and 5-day course of therapy of community-acquired pneumonia; does not inhibit cytochrome P450 enzymes</i>				
<i>Telithromycin: Oral; unaffected by efflux-mediated resistance so is active versus many erythromycin-resistant strains of pneumococci; rare cases of fulminant hepatic failure</i>				
<b>Lincosamide</b>				
Clindamycin	Prevents bacterial protein synthesis by binding to the 50S ribosomal subunit	Bacteriostatic activity against susceptible bacteria	Skin and soft tissue infections • anaerobic infections	Oral, IV • hepatic clearance (half-life 2.5 h) • dosed every 6-8 hours • <i>Toxicity</i> : Gastrointestinal upset, <i>difficile</i> colitis
<b>Streptogramins</b>				
Quinupristin-dalfopristin	Prevents bacterial protein synthesis by binding to the 50S ribosomal subunit	Rapid bactericidal activity against most susceptible bacteria	Infections caused by staphylococci or vancomycin-resistant strains of <i>faecium</i>	IV • hepatic clearance • dosed every 8-12 h • cytochrome P450 inhibitor • <i>Toxicity</i> : Severe infusion-related myalgias and arthralgias
<b>Chloramphenicol</b>	Prevents bacterial protein synthesis by binding to the 50S ribosomal subunit	Bacteriostatic activity against susceptible bacteria	Use is rare in the developed world because of serious toxicities	Oral, IV • hepatic clearance (half-life 2.5 h) • dosage is 50-100 mg/kg/d in four divided doses • <i>Toxicity</i> : Dose-related anemia, idiosyncratic aplastic anemia, gray baby syndrome

## Oxazolidinones

Linezolid	Prevents bacterial protein synthesis by binding to the 23S ribosomal RNA of 50S subunit	Bacteriostatic activity against susceptible bacteria	Infections caused by methicillin-resistant staphylococci and vancomycin-resistant enterococci	Oral, IV • hepatic clearance (half-life 6 h) • dosed twice-daily • <i>Toxicity</i> : Duration-dependent bone marrow suppression, neuropathy, and optic neuritis • serotonin-syndrome may occur when coadministered with other serotonergic drugs (eg, selective serotonin reuptake inhibitors)
-----------	---	--	---	--

## PREPARATIONS AVAILABLE

### CHLORAMPHENICOL

**Chloramphenicol** (generic, Chloromycetin)

Parenteral: 100 mg powder to reconstitute for injection

### TETRACYCLINES

**Demeclocycline** (Declomycin)

Oral: 150, 300 mg tablets

**Doxycycline** (generic, Vibramycin, others)

Oral: 20, 50, 75, 100 mg tablets and capsules; powder to reconstitute for 25 mg/5 mL suspension; 50 mg/5 mL syrup

Parenteral: 100, 200 mg powder to reconstitute for injection

**Minocycline** (generic, Minocin, various)

Oral: 20, 50, 75, 100 mg tablets and capsules; 50 mg/5 mL suspension

**Tetracycline** (generic, others)

Oral: 250, 500 mg capsules; 125 mg/5 mL suspension

**Tigecycline** (Tygacil)

Parenteral: 50 mg powder to reconstitute for IV administration

### MACROLIDES

**Azithromycin** (Zithromax)

Oral: 250, 500, 600 mg capsules; powder for 100, 200 mg/5 mL oral suspension

Parenteral: 500 mg powder for injection

**Clarithromycin** (generic, Biaxin)

Oral: 250, 500 mg tablets, 500, 1000 mg extended-release tablets; granules for 125, 250 mg/5 mL oral suspension

**Erythromycin** (generic, others)

Oral (base): 250, 333, 500 mg enteric-coated tablets

Oral (base) delayed-release: 250 mg capsules, 500 mg tablets

Oral (estolate): 125, 250 mg/5 mL suspension

Oral (ethylsuccinate): 400 mg tablets; 200, 400 mg/5 mL suspension

Oral (stearate): 250, 500 mg film-coated tablets

Parenteral: lactobionate, 0.5, 1 g powder to reconstitute for IV injection

## **KETOLIDES**

**Telithromycin** (Keteck)

Oral: 300, 400 mg tablets

## **LINCOMYCIN**

**Clindamycin** (generic, Cleocin)

Oral: 75, 150, 300 mg capsules; 75 mg/5 mL granules to reconstitute for solution

Parenteral: 150 mg/mL in 2, 4, 6, 60 mL vials for injection

## **STREPTOGRAMINS**

**Quinupristin and dalfopristin** (Synercid)

Parenteral: 30:70 formulation in 500 mg vial for reconstitution for IV injection

## **OXAZOLIDINONE**

**Linezolid** (Zyvox)

Oral: 600 mg tablets; 100 mg powder for 5 mL suspension

Parenteral: 2 mg/mL for IV infusion

Basic and Clinical Pharmacology > Chapter 45. Aminoglycosides & Spectinomycin >

## Case Study

A 45 year-old man with no medical history was admitted to the intensive care unit (ICU) 10 days ago after suffering third-degree burns over 40% of his body. He had been relatively stable until the last 24 hours. Now he is febrile ( $39.5^{\circ}\text{C}$  [ $103.1^{\circ}\text{F}$ ]), and his white blood cell count has risen from 8,500 to 20,000/mm<sup>3</sup>. He has also had an episode of hypotension (86/50 mm Hg) that responded to a fluid bolus. Blood cultures were obtained at the time of his fever and results are pending. The ICU attending physician is concerned about sepsis and wants to prescribe empiric combination therapy directed against *Pseudomonas* that includes tobramycin. The patient weighs 70 kg (154 lb) and has an estimated creatinine clearance of 90 mL/min. How should tobramycin be dosed using once-daily and conventional dosing strategies? How should each regimen be monitored for efficacy and toxicity?

## AMINOGLYCOSIDES & SPECTINOMYCIN: INTRODUCTION

The drugs described in this chapter are bactericidal inhibitors of protein synthesis that interfere with ribosomal function. These agents are useful mainly against aerobic gram-negative microorganisms.

### AMINOGLYCOSIDES

The aminoglycosides include **streptomycin, neomycin, kanamycin, amikacin, gentamicin, tobramycin, sisomicin, netilmicin**, and others. They are used most widely against gram-negative enteric bacteria, especially in bacteremia and sepsis, in combination with vancomycin or a penicillin for endocarditis, and for treatment of tuberculosis.

### General Properties of Aminoglycosides

#### PHYSICAL AND CHEMICAL PROPERTIES

Aminoglycosides have a hexose ring, either streptidine (in streptomycin) or 2-deoxystreptamine (in other aminoglycosides), to which various amino sugars are attached by glycosidic linkages (Figures 45-1 and 45-2). They are water-soluble, stable in solution, and more active at alkaline than at acid pH.

Structures of several important aminoglycoside antibiotics. Ring II is 2-deoxystreptamine. The resemblance between kanamycin and amikacin and between gentamicin, netilmicin, and tobramycin can be seen. The circled numerals on the kanamycin molecule indicate points of attack of plasmid-mediated bacterial transferase enzymes that can inactivate this drug. ①, ②, and ③, acetyltransferase; ④, phosphotransferase; ⑤, adenylyltransferase. Amikacin is resistant to modification at ②, ③, ④, and ⑤.

### **MECHANISM OF ACTION**

The mode of action of streptomycin has been studied far more closely than that of other aminoglycosides, but they probably all act similarly. Aminoglycosides are irreversible inhibitors of protein synthesis, but the precise mechanism for bactericidal activity is not known. The initial event is passive diffusion via porin channels across the outer membrane (see Figure 43â€³). Drug is then actively transported across the cell membrane into the cytoplasm by an oxygen-dependent process. The transmembrane electrochemical gradient supplies the energy for this process, and transport is coupled to a proton pump. Low extracellular pH and anaerobic conditions inhibit transport by reducing the gradient. Transport may be enhanced by cell wall-active drugs such as penicillin or vancomycin; this enhancement may be the basis of the synergism of these antibiotics with aminoglycosides.

Inside the cell, aminoglycosides bind to specific 30S-subunit ribosomal proteins (S12 in the case of streptomycin). Protein synthesis is inhibited by aminoglycosides in at least three ways (Figure 45â€³): (1) interference with the initiation complex of peptide formation; (2) misreading of mRNA, which causes incorporation of incorrect amino acids into the peptide and results in a nonfunctional or toxic protein; and (3) breakup of polysomes into nonfunctional monosomes. These activities occur more or less simultaneously, and the overall effect is irreversible and lethal for the cell.

Putative mechanisms of action of the aminoglycosides in bacteria. Normal protein synthesis is shown in the top panel. At least three aminoglycoside effects have been described, as shown in the bottom panel: block of formation of the initiation complex; miscoding of amino acids in the emerging peptide chain due to misreading of the mRNA; and block of translocation on mRNA. Block of movement of the ribosome may occur after the formation of a single initiation complex, resulting in an mRNA chain with only a single ribosome on it, a so-called monosome.

### MECHANISMS OF RESISTANCE

Three principal mechanisms have been established: (1) production of a transferase enzyme or enzymes inactivates the aminoglycoside by adenylation, acetylation, or phosphorylation. This is the principal type of resistance encountered clinically. (Specific transferase enzymes are discussed below.) (2) There is impaired entry of aminoglycoside into the cell. This may be genotypic, ie, resulting from mutation or deletion of a porin protein or proteins involved in transport and maintenance of the electrochemical

gradient; or phenotypic, eg, resulting from growth conditions under which the oxygen-dependent transport process described above is not functional. (3) The receptor protein on the 30S ribosomal subunit may be deleted or altered as a result of a mutation.

### **PHARMACOKINETICS AND ONCE-DAILY DOSING**

Aminoglycosides are absorbed very poorly from the intact gastrointestinal tract; almost the entire oral dose is excreted in feces after oral administration. However, the drugs may be absorbed if ulcerations are present. After intramuscular injection, aminoglycosides are well absorbed, giving peak concentrations in blood within 30–90 minutes. Aminoglycosides are usually administered intravenously as a 30- to 60-minute infusion; after a brief distribution phase, this results in serum concentrations that are identical with those following intramuscular injection.

Traditionally, aminoglycosides have been administered in two or three equally divided daily doses for patients with normal renal function. However, once-daily aminoglycoside dosing may be preferred in certain clinical situations. Aminoglycosides have **concentration-dependent killing**; that is, increasing concentrations kill an increasing proportion of bacteria and at a more rapid rate. They also have a significant **postantibiotic effect**, such that the antibacterial activity persists beyond the time during which measurable drug is present. The postantibiotic effect of aminoglycosides can last several hours. Because of these properties, a given total amount of aminoglycoside may have better efficacy when administered as a single large dose than when administered as multiple smaller doses.

Adverse effects from aminoglycoside are both time- and concentration-dependent. Toxicity is unlikely to occur until a certain threshold concentration is reached, but once that concentration is achieved the time beyond this threshold becomes critical. This threshold is not precisely defined, but a trough concentration above 2 mcg/mL is predictive of toxicity. At clinically relevant doses, the total time above this threshold is greater with multiple smaller doses of drug than with a single large dose.

Numerous clinical studies demonstrate that a single daily dose of aminoglycoside is just as effective—and no more (and often less) toxic—than multiple smaller doses. Therefore, many authorities now recommend that aminoglycosides be administered as a single daily dose in many clinical situations. The efficacy of once-daily aminoglycoside dosing in combination therapy of enterococcal, and staphylococcal endocarditis remains to be defined, and the standard low-dose, thrice-daily administration is still recommended. In contrast, there is limited data supporting once-daily dosing in streptococcal endocarditis. The role of once-daily dosing in pregnancy and in neonates also is not well defined.

Once-daily dosing has potential practical advantages. For example, repeated determinations of serum concentrations are probably unnecessary unless aminoglycoside

is given for more than 3 days. A drug administered once a day rather than three times a day saves time. And once-a-day dosing lends itself to outpatient therapy.

Once-daily dosing, however, does not eliminate responsibility for careful monitoring and dosage adjustment to minimize toxicity. Selection of the appropriate dose is particularly critical if renal function is impaired. Aminoglycosides are cleared by the kidney, and excretion is directly proportional to creatinine clearance. Rapidly changing renal function, which may occur with acute renal failure in the patient with septic shock, must be anticipated to avoid overdose. Provided these pitfalls are avoided, once-daily aminoglycoside dosing is safe and effective. If the creatinine clearance is 100 mL/min, gentamicin is given as a 5 mg/kg dose (15 mg/kg for amikacin) over 30–60 minutes. If the creatinine clearance is 80 mL/min, the dose is 4 mg/kg (12 mg/kg for amikacin); if creatinine clearance is 50 mL/min, the dose is 3 mg/kg (9 mg/kg for amikacin). If the creatinine clearance is less than 50 mL/min, a 2 mg/kg gentamicin loading dose is given, and subsequent doses are adjusted as would normally be done.

Serum concentrations need not be routinely checked until the second or third day of therapy, depending on the stability of renal function and the anticipated duration of therapy. It is probably unnecessary to check peak concentrations because they will be high. The goal is to administer drug so that concentrations of less than 1 mcg/mL are present between 18 and 24 hours after dosing. This provides a sufficient period of time for washout of drug to occur before the next dose is given. This is most easily determined either by measuring serum concentrations in samples obtained 2 hours and 12 hours after dosing and then adjusting the dose based on the actual clearance of drug or by measuring the concentration in a sample obtained 8 hours after a dose. If the 8-hour concentration is between 1.5 mcg and 6 mcg/mL, the target trough can be achieved at 18 hours.

Aminoglycosides are highly polar compounds that do not enter cells readily. They are largely excluded from the central nervous system and the eye. In the presence of active inflammation, however, cerebrospinal fluid levels reach 20% of plasma levels, and in neonatal meningitis the levels may be higher. Intrathecal or intraventricular injection is required for high levels in cerebrospinal fluid. Even after parenteral administration, concentrations of aminoglycosides are not high in most tissues except the renal cortex. Concentration in most secretions is also modest; in the bile, it may reach 30% of the blood level. With prolonged therapy, diffusion into pleural or synovial fluid may result in concentrations 50–90% of that of plasma.

The normal half-life of aminoglycosides in serum is 2–3 hours, increasing to 24–48 hours in patients with significant impairment of renal function. Aminoglycosides are only partially and irregularly removed by hemodialysis—eg, 40–60% for gentamicin—and even less effectively by peritoneal dialysis.

Dosage adjustments must be made to prevent accumulation of drug and toxicity in patients with renal insufficiency. Either the dose of drug is kept constant and the interval between doses is increased, or the interval is kept constant and the dose is reduced. Nomograms and formulas have been constructed relating serum creatinine levels to adjustments in treatment regimens. The simplest formula divides the dose (calculated on the basis of normal renal function) by the serum creatinine value (mg/dL). Thus, a 60-kg patient with normal renal function might receive 300 mg/d of gentamicin (maximum daily dose of 5 mg/kg), whereas a 60-kg patient with a serum creatinine of 3 mg/dL would receive 100 mg/d. However, this approach fails to take into account the age and gender of the patient, both of which significantly affect creatinine clearance without necessarily being reflected as a change in serum creatinine. Because aminoglycoside clearance is directly proportional to the creatinine clearance, a better method for determining the aminoglycoside dose is to estimate creatinine clearance using the Cockcroft-Gault formula described in Chapter 60.

The daily dosage of aminoglycoside is calculated by multiplying the maximum daily dosage by the ratio of estimated creatinine clearance to normal creatinine clearance, ie, 120 mL/min, which is a typical value for a 70-kg young adult male. For a 60-year-old woman weighing 60 kg with a serum creatinine of 3 mg/dL, the corrected dosage of gentamicin would be approximately 50 mg/d, half the dose calculated by the simplest formula. There is considerable individual variation in aminoglycoside serum levels among patients with similar estimated creatinine clearance values. Therefore, it is mandatory, especially when using higher dosages for more than a few days or when renal function is rapidly changing, to measure serum drug levels to avoid severe toxicity. For a traditional twice- or thrice-daily dosing regimen, peak serum concentrations should be determined from a blood sample obtained 30–60 minutes after a dose, and trough concentrations from a sample obtained just before the next dose.

### **ADVERSE EFFECTS**

All aminoglycosides are ototoxic and nephrotoxic. Ototoxicity and nephrotoxicity are more likely to be encountered when therapy is continued for more than 5 days, at higher doses, in the elderly, and in the setting of renal insufficiency. Concurrent use with loop diuretics (eg, furosemide, ethacrynic acid) or other nephrotoxic antimicrobial agents (eg, vancomycin or amphotericin) can potentiate nephrotoxicity and should be avoided if possible. Ototoxicity can manifest either as auditory damage, resulting in tinnitus and high-frequency hearing loss initially, or as vestibular damage, evident by vertigo, ataxia, and loss of balance. Nephrotoxicity results in rising serum creatinine levels or reduced creatinine clearance, although the earliest indication often is an increase in trough serum aminoglycoside concentrations. Neomycin, kanamycin, and amikacin are the most ototoxic agents. Streptomycin and gentamicin are the most vestibulotoxic. Neomycin, tobramycin, and gentamicin are the most nephrotoxic.

In very high doses, aminoglycosides can produce a curare-like effect with neuromuscular blockade that results in respiratory paralysis. This paralysis is usually reversible by calcium gluconate (given promptly) or neostigmine. Hypersensitivity occurs infrequently.

### **CLINICAL USES**

Aminoglycosides are mostly used against gram-negative enteric bacteria, especially when the isolate may be drug-resistant and when there is suspicion of sepsis. They are almost always used in combination with a  $\beta$ -lactam antibiotic to extend coverage to include potential gram-positive pathogens and to take advantage of the synergism between these two classes of drugs. Penicillin-aminoglycoside combinations also are used to achieve bactericidal activity in treatment of enterococcal endocarditis and to shorten duration of therapy for viridans streptococcal and staphylococcal endocarditis. Which aminoglycoside and what dose should be used depend on the infection being treated and the susceptibility of the isolate.

### **STREPTOMYCIN**

Streptomycin (Figure 45-1) was isolated from a strain of *Streptomyces griseus*. The antimicrobial activity of streptomycin is typical of that of other aminoglycosides, as are the mechanisms of resistance. Resistance has emerged in most species, severely limiting the current usefulness of streptomycin, with the exceptions listed below. Ribosomal resistance to streptomycin develops readily, limiting its role as a single agent.

### **Clinical Uses**

#### **MYCOBACTERIAL INFECTIONS**

Streptomycin is mainly used as a second-line agent for treatment of tuberculosis. The dosage is 0.5-1 g/d (7.5-15 mg/kg/d for children), which is given intramuscularly or intravenously. It should be used only in combination with other agents to prevent emergence of resistance. See Chapter 47 for additional information regarding the use of streptomycin in mycobacterial infections.

#### **NONTUBERCULOUS INFECTIONS**

In plague, tularemia, and sometimes brucellosis, streptomycin, 1 g/d (15 mg/kg/d for children), is given intramuscularly in combination with an oral tetracycline.

Penicillin plus streptomycin is effective for enterococcal endocarditis and 2-week therapy of viridans streptococcal endocarditis. Gentamicin has largely replaced streptomycin for these indications. Streptomycin remains a useful agent for treating enterococcal infections, however, because approximately 15% of enterococcal isolates that are resistant to gentamicin (and therefore to netilmicin, tobramycin, and amikacin) will be susceptible to streptomycin.

### **Adverse Reactions**

Fever, skin rashes, and other allergic manifestations may result from hypersensitivity to

streptomycin. This occurs most frequently with prolonged contact with the drug either in patients who receive a prolonged course of treatment (eg, for tuberculosis) or in medical personnel who handle the drug. Desensitization is occasionally successful.

Pain at the injection site is common but usually not severe. The most serious toxic effect with streptomycin is disturbance of vestibular function—vertigo and loss of balance. The frequency and severity of this disturbance are in proportion to the age of the patient, the blood levels of the drug, and the duration of administration. Vestibular dysfunction may follow a few weeks of unusually high blood levels (eg, in individuals with impaired renal function) or months of relatively low blood levels. Vestibular toxicity tends to be irreversible. Streptomycin given during pregnancy can cause deafness in the newborn and therefore is relatively contraindicated.

## **GENTAMICIN**

Gentamicin is an aminoglycoside (Figure 45-2) isolated from *Micromonospora purpurea*. It is effective against both gram-positive and gram-negative organisms, and many of its properties resemble those of other aminoglycosides. **Sisomicin** is very similar to the C<sub>1a</sub> component of gentamicin.

### **Antimicrobial Activity**

Gentamicin sulfate, 2-10 mcg/mL, inhibits in vitro many strains of staphylococci and coliforms and other gram-negative bacteria. It is active alone, but also as a synergistic companion with  $\beta$ -lactam antibiotics, against pseudomonas, proteus, enterobacter, klebsiella, serratia, stenotrophomonas, and other gram-negative rods that may be resistant to multiple other antibiotics. Like all aminoglycosides, it has no activity against anaerobes.

### **Resistance**

Streptococci and enterococci are relatively resistant to gentamicin owing to failure of the drug to penetrate into the cell. However, gentamicin in combination with vancomycin or a penicillin produces a potent bactericidal effect, which in part is due to enhanced uptake of drug that occurs with inhibition of cell wall synthesis. Resistance to gentamicin rapidly emerges in staphylococci owing to selection of permeability mutants. Ribosomal resistance is rare. Among gram-negative bacteria, resistance is most commonly due to plasmid-encoded aminoglycoside-modifying enzymes. Gram-negative bacteria that are gentamicin-resistant usually are susceptible to amikacin, which is much more resistant to modifying enzyme activity. The enterococcal enzyme that modifies gentamicin is a bifunctional enzyme that also inactivates amikacin, netilmicin, and tobramycin, but not streptomycin; the latter is modified by a different enzyme. This is why some gentamicin-resistant enterococci are susceptible to streptomycin.

### **Clinical Uses**

## **INTRAMUSCULAR OR INTRAVENOUS ADMINISTRATION**

Gentamicin is used mainly in severe infections (eg, sepsis and pneumonia) caused by gram-negative bacteria that are likely to be resistant to other drugs, especially pseudomonas, enterobacter, serratia, proteus, acinetobacter, and klebsiella. It usually is used in combination with a second agent, because an aminoglycoside alone may not be effective for infections outside the urinary tract. For example, gentamicin should not be used as a single agent to treat staphylococcal infections because resistance develops rapidly. Aminoglycosides should not be used for single-agent therapy of pneumonia because penetration of infected lung tissue is poor and local conditions of low pH and low oxygen tension contribute to poor activity. Gentamicin 5â€”6 mg/kg/d traditionally is given intravenously in three equal doses, but once-daily administration is just as effective for some organisms and less toxic.

Serum gentamicin concentrations and renal function should be monitored if gentamicin is administered for more than a few days or if renal function is changing (eg, in sepsis, which often is complicated by acute renal failure). For patients receiving dosing every 8 hours, target peak concentrations are 5â€”10 mcg/mL, and trough concentrations should be less than 1â€”2 mcg/mL. Trough concentrations above 2 mcg/mL indicate accumulation of drug and are associated with toxicity; in this case, the dose should be lowered or the interval extended to achieve the target range.

## **TOPICAL ADMINISTRATION**

Creams, ointments, and solutions containing 0.1â€”0.3% gentamicin sulfate have been used for the treatment of infected burns, wounds, or skin lesions and the prevention of intravenous catheter infections. Topical gentamicin is partly inactivated by purulent exudates. Ten mg can be injected subconjunctivally for treatment of ocular infections.

## **INTRATHECAL ADMINISTRATION**

Meningitis caused by gram-negative bacteria has been treated by the intrathecal injection of gentamicin sulfate, 1â€”10 mg/d. However, neither intrathecal nor intraventricular gentamicin was beneficial in neonates with meningitis, and intraventricular gentamicin was toxic, raising questions about the usefulness of this form of therapy. Moreover, the availability of third-generation cephalosporins for gram-negative meningitis has rendered this therapy obsolete in most cases.

## **Adverse Reactions**

Nephrotoxicity is usually reversible and mild. It occurs in 5â€”25% of patients receiving gentamicin for longer than 3â€”5 days. Such toxicity requires, at the very least, adjustment of the dosing regimen and should prompt reconsideration of the need for the drug, particularly if there is a less toxic alternative agent. Measurement of gentamicin serum levels is essential. Ototoxicity, which tends to be irreversible, manifests itself mainly as vestibular dysfunction. Loss of hearing can also occur. The incidence of

ototoxicity is in part genetically determined, having been linked to point mutations in mitochondrial DNA, and occurs in 1â€”5% for patients receiving gentamicin for more than 5 days. Hypersensitivity reactions to gentamicin are uncommon.

## **TOBRAMYCIN**

This aminoglycoside (Figure 45â€”2) has an antibacterial spectrum similar to that of gentamicin. Although there is some cross-resistance between gentamicin and tobramycin, it is unpredictable in individual strains. Separate laboratory susceptibility tests are therefore necessary.

The pharmacokinetic properties of tobramycin are virtually identical with those of gentamicin. The daily dose of tobramycin is 5â€”6 mg/kg intramuscularly or intravenously, traditionally divided into three equal amounts and given every 8 hours. Monitoring blood levels in renal insufficiency is an essential guide to proper dosing.

Tobramycin has almost the same antibacterial spectrum as gentamicin with a few exceptions. Gentamicin is slightly more active against *Serratia*, whereas tobramycin is slightly more active against *Pseudomonas*; *Enterococcus faecalis* is susceptible to both gentamicin and tobramycin, but *E. faecium* is resistant to tobramycin. Gentamicin and tobramycin are otherwise interchangeable clinically.

Like other aminoglycosides, tobramycin is ototoxic and nephrotoxic. Nephrotoxicity of tobramycin may be slightly less than that of gentamicin, but the difference is clinically inconsequential.

Tobramycin is also formulated in solution (300 mg in 5 mL) for inhalation for treatment of *Pseudomonas aeruginosa* lower respiratory tract infections complicating cystic fibrosis. The drug is recommended as a 300-mg dose regardless of the patient's age or weight for administration twice daily in repeated cycles of 28 days on therapy, followed by 28 days off therapy. Serum concentrations 1 hour after inhalation average 1 mcg/mL; consequently, nephrotoxicity and ototoxicity rarely occur. Caution should be used when administering tobramycin to patients with preexisting renal, vestibular, or hearing disorders.

## **AMIKACIN**

Amikacin is a semisynthetic derivative of kanamycin; it is less toxic than the parent molecule (Figure 45â€”2). It is resistant to many enzymes that inactivate gentamicin and tobramycin, and it therefore can be used against some microorganisms resistant to the latter drugs. Many gram-negative enteric bacteria, including many strains of *Proteus*, *Pseudomonas*, *Enterobacter*, and *Serratia*, are inhibited by 1â€”20 mcg/mL amikacin in vitro. After injection of 500 mg of amikacin every 12 hours (15 mg/kg/d) intramuscularly, peak levels in serum are 10â€”30 mcg/mL.

Strains of multidrug-resistant *Mycobacterium tuberculosis*, including streptomycin-resistant strains, are usually susceptible to amikacin. Kanamycin-resistant strains may be cross-resistant to amikacin. The dosage of amikacin for tuberculosis is 7.5–15 mg/kg/d as a once-daily or two to three times weekly injection and always in combination with other drugs to which the isolate is susceptible.

Like all aminoglycosides, amikacin is nephrotoxic and ototoxic (particularly for the auditory portion of the eighth nerve). Serum concentrations should be monitored. Target peak serum concentrations for an every-12-hours dosing regimen are 20–40 mcg/mL, and troughs should be maintained between 4 and 8 mcg/mL.

## **NETILMICIN**

Netilmicin shares many characteristics with gentamicin and tobramycin. However, the addition of an ethyl group to the 1-amino position of the 2-deoxystreptamine ring (ring II, Figure 45–2) sterically protects the netilmicin molecule from enzymatic degradation at the 3-amino (ring II) and 2-hydroxyl (ring III) positions. Consequently, netilmicin may be active against some gentamicin-resistant and tobramycin-resistant bacteria.

The dosage (5–7 mg/kg/d) and the routes of administration are the same as for gentamicin. Netilmicin is completely interchangeable with gentamicin or tobramycin but is no longer available in the USA.

## **NEOMYCIN & KANAMYCIN**

Neomycin and kanamycin are closely related. **Paromomycin** is also a member of this group. All have similar properties.

### **Antimicrobial Activity & Resistance**

Drugs of the neomycin group are active against gram-positive and gram-negative bacteria and some mycobacteria. *Pseudomonas* and streptococci are generally resistant. Mechanisms of antibacterial action and resistance are the same as with other aminoglycosides. The widespread use of these drugs in bowel preparation for elective surgery has resulted in the selection of resistant organisms and some outbreaks of enterocolitis in hospitals. Cross-resistance between kanamycin and neomycin is complete.

### **Pharmacokinetics**

Drugs of the neomycin group are poorly absorbed from the gastrointestinal tract. After oral administration, the intestinal flora is suppressed or modified, and the drug is excreted in the feces. Excretion of any absorbed drug is mainly through glomerular filtration into the urine.

### **Clinical Uses**

Neomycin and kanamycin are now limited to topical and oral use. Neomycin is too toxic

for parenteral use. With the advent of more potent and less toxic aminoglycosides, parenteral administration of kanamycin has also been largely abandoned. Paromomycin has recently been shown to be effective against visceral leishmaniasis when given parenterally (see Chapter 52), and this serious infection may represent an important new use for this drug.

### **TOPICAL ADMINISTRATION**

Solutions containing 1–5 mg/mL are used on infected surfaces or injected into joints, the pleural cavity, tissue spaces, or abscess cavities where infection is present. The total amount of drug given in this fashion must be limited to 15 mg/kg/d because at higher doses enough drug may be absorbed to produce systemic toxicity. Whether topical application for active infection adds anything to appropriate systemic therapy is questionable. Ointments, often formulated as a neomycin-polymyxin-bacitracin combination, can be applied to infected skin lesions or in the nares for suppression of staphylococci but they are largely ineffective.

### **ORAL ADMINISTRATION**

In preparation for elective bowel surgery, 1 g of neomycin is given orally every 6–8 hours for 1–2 days, often combined with 1 g of erythromycin base. This reduces the aerobic bowel flora with little effect on anaerobes. In hepatic coma, coliform flora can be suppressed by giving 1 g every 6–8 hours together with reduced protein intake, thus reducing ammonia intoxication. Use of neomycin for hepatic coma has been almost entirely supplanted by lactulose, which is much less toxic. Use of paromomycin is discussed in Chapter 52.

### **Adverse Reactions**

All members of the neomycin group have significant nephrotoxicity and ototoxicity. Auditory function is affected more than vestibular function. Deafness has occurred, especially in adults with impaired renal function and prolonged elevation of drug levels.

The sudden absorption of postoperatively instilled kanamycin from the peritoneal cavity (3–5 g) has resulted in curare-like neuromuscular blockade and respiratory arrest. Calcium gluconate and neostigmine can act as antidotes.

Although hypersensitivity is not common, prolonged application of neomycin-containing ointments to skin and eyes has resulted in severe allergic reactions.

### **SPECTINOMYCIN**

Spectinomycin is an aminocyclitol antibiotic that is structurally related to aminoglycosides. It lacks amino sugars and glycosidic bonds.

**Spectinomycin**

Spectinomycin is active in vitro against many gram-positive and gram-negative organisms, but it is used almost solely as an alternative treatment for drug-resistant gonorrhea or gonorrhea in penicillin-allergic patients. The majority of gonococcal isolates are inhibited by 6 mcg/mL of spectinomycin. Strains of gonococci may be resistant to spectinomycin, but there is no cross-resistance with other drugs used in gonorrhea. Spectinomycin is rapidly absorbed after intramuscular injection. A single dose of 40 mg/kg up to a maximum of 2 g is given. There is pain at the injection site and occasionally fever and nausea. Nephrotoxicity and anemia have been observed rarely.

## SUMMARY: AMINOGLYCOSIDES

### Aminoglycosides

Subclass	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>Aminoglycosides &amp; Spectinomycin</b>				
Gentamicin	Prevents bacterial protein synthesis by binding to the 30S ribosomal subunit	Bactericidal activity against susceptible bacteria • synergistic effects against gram-positive bacteria when combined with $\beta$ lactams or vancomycin • demonstrate concentration-dependent killing and a significant	Sepsis caused by aerobic gram-negative bacteria • synergistic activity in endocarditis caused by streptococci, staphylococci, and enterococci	IV • renal clearance (half-life 2.5 h) • conventional dosing 1.3â€”1.7 mg/kg q8h with goal peak levels 5â€”8 mcg/mL • trough levels < 2 mcg/mL • once-daily dosing at 5â€”7 mg/kg as effective and may have less toxicity than conventional dosing • <i>Toxicity:</i> Nephrotoxicity (reversible), ototoxicity (irreversible),

postantibiotic  
effect

neuromuscular blockade

*Tobramycin: Intravenous; more active than gentamicin versus pseudomonas; may also have less nephrotoxicity*

*Amikacin: Intravenous; resistant to many enzymes that inactivate gentamicin and tobramycin; higher doses and target peaks and troughs than gentamicin and tobramycin*

*Streptomycin: Intramuscular, widespread resistance limits use to specific indications such as tuberculosis and enterococcal endocarditis*

*Neomycin: Oral or topical, poor bioavailability; used before bowel surgery to decrease aerobic flora; also used to treat hepatic encephalopathy*

*Spectinomycin: Intramuscular; sole use is for treatment of antibiotic-resistant gonococcal infections or gonococcal infections in penicillin-allergic patients*

## PREPARATIONS AVAILABLE

### **Amikacin** (generic, Amikin)

Parenteral: 50, 250 mg (in vials) for IM, IV injection

### **Gentamicin** (generic, Garamycin)

Parenteral: 10, 40 mg/mL vials for IM, IV injection

### **Kanamycin** (Kantrex)

Parenteral: 500, 1000 mg for IM, IV injection; 75 mg for pediatric injection

### **Neomycin** (generic, Mycifradin)

Oral: 500 mg tablets

### **Paromomycin** (Humatin)

Oral: 250 mg capsules

### **Spectinomycin** (Trobicin)

Parenteral: 2 g powder to reconstitute for 400 mg/mL IM injection

### **Streptomycin** (generic)

Parenteral: 400 mg/mL for IM injection

**Tobramycin** (generic, Nebcin)

Parenteral: 10, 40 mg/mL for IM, IV injection; powder to reconstitute for injection

Solution for inhalation (TOBI): 300 mg in 5 mL sodium chloride solution

Basic and Clinical Pharmacology > Chapter 46. Sulfonamides, Trimethoprim, & Quinolones >

## CASE STUDY

A 59-year-old woman presents to an urgent care clinic with a 4-day history of frequent and painful urination. She has had fevers, chills, and flank pain for the last 2 days. Her physician advised her to immediately come to the clinic for evaluation. In the clinic she is febrile (38.5°C [101.3°F]) but otherwise stable and states she is not experiencing any nausea or vomiting. Her urine dipstick test is positive for leukocyte esterase. Urinalysis and urine culture are also ordered. Her past medical history is significant for three urinary tract infections in the past year. Each of these episodes was uncomplicated, treated with trimethoprim-sulfamethoxazole, and promptly resolved. She also has osteoporosis for which she takes a daily calcium supplement. The decision is made to treat her with oral antibiotics for a complicated urinary tract infection with close follow-up. Given her history what would be a reasonable empiric antibiotic choice? Depending on the antibiotic choice are there potential drug interactions she should be counseled on?

## ANTIFOLATE DRUGS

### SULFONAMIDES

#### Chemistry

The basic formulas of the sulfonamides and their structural similarity to *p*-aminobenzoic acid (PABA) are shown in Figure 46-1. Sulfonamides with varying physical, chemical, pharmacologic, and antibacterial properties are produced by attaching substituents to the amido group ( $\text{-SO}_2\text{-NH-R}$ ) or the amino group ( $\text{-NH}_2$ ) of the sulfanilamide nucleus. Sulfonamides tend to be much more soluble at alkaline than at acid pH. Most can be prepared as sodium salts, which are used for intravenous administration.

Structures of some sulfonamides and p-aminobenzoic acid.

## Antimicrobial Activity

Sulfonamide-susceptible organisms, unlike mammals, cannot use exogenous folate but must synthesize it from PABA. This pathway (Figure 46-2) is thus essential for production of purines and nucleic acid synthesis. Because sulfonamides are structural analogs of PABA, they inhibit dihydropteroate synthase and folate production. Sulfonamides inhibit both gram-positive and gram-negative bacteria, nocardia, *Chlamydia trachomatis*,

and some protozoa. Some enteric bacteria, such as *Escherichia coli*, klebsiella, salmonella, shigella, and enterobacter, are also inhibited. It is interesting that rickettsiae are not inhibited by sulfonamides but are actually stimulated in their growth. Activity is poor against anaerobes.

**Figure 46â€"2**

Actions of sulfonamides and trimethoprim.

Combination of a sulfonamide with an inhibitor of dihydrofolate reductase (trimethoprim or pyrimethamine) provides synergistic activity because of sequential inhibition of folate synthesis (Figure 46â€"2).

## Resistance

Mammalian cells (and some bacteria) lack the enzymes required for folate synthesis from PABA and depend on exogenous sources of folate; therefore, they are not susceptible to sulfonamides. Sulfonamide resistance may occur as a result of mutations that (1) cause

overproduction of PABA, (2) cause production of a folic acid-synthesizing enzyme that has low affinity for sulfonamides, or (3) impair permeability to the sulfonamide.

Dihydropteroate synthase with low sulfonamide affinity is often encoded on a plasmid that is transmissible and can disseminate rapidly and widely. Sulfonamide-resistant dihydropteroate synthase mutants also can emerge under selective pressure.

## Pharmacokinetics

Sulfonamides can be divided into three major groups: (1) oral, absorbable; (2) oral, nonabsorbable; and (3) topical. The oral, absorbable sulfonamides can be classified as short-, intermediate-, or long-acting on the basis of their half-lives (Table 46-1). They are absorbed from the stomach and small intestine and distributed widely to tissues and body fluids (including the central nervous system and cerebrospinal fluid), placenta, and fetus. Protein binding varies from 20% to over 90%. Therapeutic concentrations are in the range of 40-100 mcg/mL of blood. Blood levels generally peak 2-6 hours after oral administration.

**Table 46-1 Pharmacokinetic Properties of Some Sulfonamides and Trimethoprim**

Drug	Half-Life	Oral Absorption
<b>Sulfonamides</b>		
Sulfacytine	Short	Prompt (peak levels in 1-4 hours)
Sulfisoxazole	Short (6 hours)	Prompt
Sulfamethizole	Short (9 hours)	Prompt
Sulfadiazine	Intermediate (10-17 hours)	Slow (peak levels in 4-8 hours)
Sulfamethoxazole	Intermediate (10-12 hours)	Slow
Sulfapyridine	Intermediate (17 hours)	Slow
Sulfadoxine	Long (7-9 days)	Intermediate
<b>Pyrimidines</b>		
Trimethoprim	Intermediate (11 hours)	Prompt

A portion of absorbed drug is acetylated or glucuronidated in the liver. Sulfonamides and inactive metabolites are then excreted into the urine, mainly by glomerular filtration. In significant renal failure, the dosage of sulfonamide must be reduced.

## Clinical Uses

Sulfonamides are infrequently used as single agents. Many strains of formerly susceptible species, including meningococci, pneumococci, streptococci, staphylococci, and gonococci, are now resistant. The fixed-drug combination of trimethoprim-sulfamethoxazole is the

drug of choice for infections such as *Pneumocystis jiroveci* (formerly *P. carinii*) pneumonia, toxoplasmosis, nocardiosis, and occasionally other bacterial infections.

### **ORAL ABSORBABLE AGENTS**

Sulfisoxazole and sulfamethoxazole are short- to medium-acting agents used almost exclusively to treat urinary tract infections. The usual adult dosage is 1 g of sulfisoxazole four times daily or 1 g of sulfamethoxazole two or three times daily.

Sulfadiazine in combination with pyrimethamine is first-line therapy for treatment of acute toxoplasmosis. The combination of sulfadiazine with pyrimethamine, a potent inhibitor of dihydrofolate reductase, is synergistic because these drugs block sequential steps in the folate synthetic pathway blockade (Figure 46â€²). The dosage of sulfadiazine is 1 g four times daily, with pyrimethamine given as a 75-mg loading dose followed by a 25-mg once-daily dose. Folinic acid, 10 mg orally each day, should also be administered to minimize bone marrow suppression.

Sulfadoxine is the only long-acting sulfonamide currently available in the USA and only as a combination formulation with pyrimethamine (Fansidar), a second-line agent in treatment for malaria (see Chapter 52).

### **ORAL NONABSORBABLE AGENTS**

Sulfasalazine (salicylazosulfapyridine) is widely used in ulcerative colitis, enteritis, and other inflammatory bowel disease (see Chapter 62).

### **TOPICAL AGENTS**

Sodium sulfacetamide ophthalmic solution or ointment is effective in the treatment of bacterial conjunctivitis and as adjunctive therapy for trachoma. Another sulfonamide, mafenide acetate, is used topically but can be absorbed from burn sites. The drug and its primary metabolite inhibit carbonic anhydrase and can cause metabolic acidosis, a side effect that limits its usefulness. Silver sulfadiazine is a much less toxic topical sulfonamide and is preferred to mafenide for prevention of infection of burn wounds.

### **Adverse Reactions**

All sulfonamides, including antimicrobial sulfas, diuretics, diazoxide, and the sulfonylurea hypoglycemic agents, have been considered to be partially cross-allergenic. However, evidence for this is not extensive. The most common adverse effects are fever, skin rashes, exfoliative dermatitis, photosensitivity, urticaria, nausea, vomiting, diarrhea, and difficulties referable to the urinary tract (see below). Stevens-Johnson syndrome, although relatively uncommon (ie, < 1% of treatment courses), is a particularly serious and potentially fatal type of skin and mucous membrane eruption associated with sulfonamide use. Other unwanted effects include stomatitis, conjunctivitis, arthritis, hematopoietic disturbances (see below), hepatitis, and, rarely, polyarteritis nodosa and psychosis.

### **URINARY TRACT DISTURBANCES**

Sulfonamides may precipitate in urine, especially at neutral or acid pH, producing

crystalluria, hematuria, or even obstruction. This is rarely a problem with the more soluble sulfonamides (eg, sulfisoxazole). Sulfadiazine when given in large doses, particularly if fluid intake is poor, can cause crystalluria. Crystalluria is treated by administration of sodium bicarbonate to alkalinize the urine and fluids to maintain adequate hydration. Sulfonamides have also been implicated in various types of nephrosis and in allergic nephritis.

### HEMATOPOIETIC DISTURBANCES

Sulfonamides can cause hemolytic or aplastic anemia, granulocytopenia, thrombocytopenia, or leukemoid reactions. Sulfonamides may provoke hemolytic reactions in patients with glucose-6-phosphate dehydrogenase deficiency. Sulfonamides taken near the end of pregnancy increase the risk of kernicterus in newborns.

### TRIMETHOPRIM & TRIMETHOPRIM-SULFAMETHOXAZOLE MIXTURES

Trimethoprim, a trimethoxybenzylpyrimidine, selectively inhibits bacterial dihydrofolic acid reductase, which converts dihydrofolic acid to tetrahydrofolic acid, a step leading to the synthesis of purines and ultimately to DNA (Figure 46-2). Trimethoprim is about 50,000 times less efficient in inhibition of *mammalian* dihydrofolic acid reductase. Pyrimethamine, another benzylpyrimidine, selectively inhibits dihydrofolic acid reductase of protozoa compared with that of mammalian cells. As noted above, trimethoprim or pyrimethamine in combination with a sulfonamide blocks sequential steps in folate synthesis, resulting in marked enhancement (synergism) of the activity of both drugs. The combination often is bactericidal, compared with the bacteriostatic activity of a sulfonamide alone.

**Trimethoprim**

**Pyrimethamine**

## Resistance

Resistance to trimethoprim can result from reduced cell permeability, overproduction of dihydrofolate reductase, or production of an altered reductase with reduced drug binding. Resistance can emerge by mutation, although more commonly it is due to plasmid-encoded trimethoprim-resistant dihydrofolate reductases. These resistant enzymes may be coded within transposons on conjugative plasmids that exhibit a broad host range, accounting for rapid and widespread dissemination of trimethoprim resistance among numerous bacterial species.

## Pharmacokinetics

Trimethoprim is usually given orally, alone, or in combination with sulfamethoxazole, which has a similar half-life. Trimethoprim-sulfamethoxazole can also be given intravenously. Trimethoprim is well absorbed from the gut and distributed widely in body fluids and tissues, including cerebrospinal fluid. Because trimethoprim is more lipid-soluble than sulfamethoxazole, it has a larger volume of distribution than the latter drug.

Therefore, when 1 part of trimethoprim is given with 5 parts of sulfamethoxazole (the ratio in the formulation), the peak plasma concentrations are in the ratio of 1:20, which is optimal for the combined effects of these drugs *in vitro*. About 30%–50% of the sulfonamide and 50%–60% of the trimethoprim (or their respective metabolites) are excreted in the urine within 24 hours. The dose should be reduced by half for patients with creatinine clearances of 15–30 mL/min.

Trimethoprim (a weak base) concentrates in prostatic fluid and in vaginal fluid, which are more acidic than plasma. Therefore, it has more antibacterial activity in prostatic and vaginal fluids than many other antimicrobial drugs.

## Clinical Uses

### ORAL TRIMETHOPRIM

Trimethoprim can be given alone (100 mg twice daily) in acute urinary tract infections. Most community-acquired organisms tend to be susceptible to the high concentrations that are found in the urine (200–600 mcg/mL).

### ORAL TRIMETHOPRIM-SULFAMETHOXAZOLE (TMP-SMZ)

A combination of trimethoprim-sulfamethoxazole is effective treatment for a wide variety of infections including *P jiroveci* pneumonia, shigellosis, systemic salmonella infections, urinary tract infections, prostatitis, and some nontuberculous mycobacterial infections. It is active against most *Staphylococcus aureus* strains, both methicillin-susceptible and methicillin-resistant, and against respiratory tract pathogens such as the pneumococcus, *Haemophilus* sp, *Moraxella catarrhalis*, and *Klebsiella pneumoniae* (but not *Mycoplasma pneumoniae*). However, the increasing prevalence of strains of *E coli* (up to 30% or more) and pneumococci that are resistant to trimethoprim-sulfamethoxazole must be considered before using this combination for empirical therapy of upper urinary tract infections or

pneumonia.

One double-strength tablet (each tablet contains trimethoprim 160 mg plus sulfamethoxazole 800 mg) given every 12 hours is effective treatment for urinary tract infections and prostatitis. One half of the regular (single-strength) tablet given three times weekly for many months may serve as prophylaxis in recurrent urinary tract infections of some women. One double-strength tablet every 12 hours is effective treatment for infections caused by susceptible strains of shigella and salmonella. The dosage for children treated for shigellosis, urinary tract infection, or otitis media is 8 mg/kg trimethoprim and 40 mg/kg sulfamethoxazole every 12 hours.

Infections with *P jiroveci* and some other pathogens can be treated orally with high doses of the combination (dosed on the basis of the trimethoprim component at 15–20 mg/kg) or can be prevented in immunosuppressed patients by one double-strength tablet daily or three times weekly.

### **INTRAVENOUS TRIMETHOPRIM-SULFAMETHOXAZOLE**

A solution of the mixture containing 80 mg trimethoprim plus 400 mg sulfamethoxazole per 5 mL diluted in 125 mL of 5% dextrose in water can be administered by intravenous infusion over 60–90 minutes. It is the agent of choice for moderately severe to severe pneumocystis pneumonia. It may be used for gram-negative bacterial sepsis, including that caused by some multidrug-resistant species such as enterobacter and serratia; shigellosis; typhoid fever; or urinary tract infection caused by a susceptible organism when the patient is unable to take the drug by mouth. The dosage is 10–20 mg/kg/d of the trimethoprim component.

### **ORAL PYRIMETHAMINE WITH SULFONAMIDE**

Pyrimethamine and sulfadiazine have been used for treatment of leishmaniasis and toxoplasmosis. In falciparum malaria, the combination of pyrimethamine with sulfadoxine (Fansidar) has been used (see Chapter 52).

### **Adverse Effects**

Trimethoprim produces the predictable adverse effects of an antifolate drug, especially megaloblastic anemia, leukopenia, and granulocytopenia. The combination trimethoprim-sulfamethoxazole may cause all of the untoward reactions associated with sulfonamides. Nausea and vomiting, drug fever, vasculitis, renal damage, and central nervous system disturbances occasionally occur also. Patients with AIDS and pneumocystis pneumonia have a particularly high frequency of untoward reactions to trimethoprim-sulfamethoxazole, especially fever, rashes, leukopenia, diarrhea, elevations of hepatic aminotransferases, hyperkalemia, and hyponatremia.

## **DNA GYRASE INHIBITORS**

### **FLUOROQUINOLONES**

The important quinolones are synthetic fluorinated analogs of nalidixic acid (Figure 46â€³). They are active against a variety of gram-positive and gram-negative bacteria. Quinolones block bacterial DNA synthesis by inhibiting bacterial topoisomerase II (DNA gyrase) and topoisomerase IV. Inhibition of DNA gyrase prevents the relaxation of positively supercoiled DNA that is required for normal transcription and replication. Inhibition of topoisomerase IV interferes with separation of replicated chromosomal DNA into the respective daughter cells during cell division.

**Gatifloxacin**

**Moxifloxacin**

Structures of nalidixic acid and some fluoroquinolones.

Earlier quinolones such as nalidixic acid did not achieve systemic antibacterial levels and were useful only for treatment of lower urinary tract infections. Fluorinated derivatives (ciprofloxacin, levofloxacin, and others; Figure 46â€³ and Table 46â€²) have greatly improved antibacterial activity compared with nalidixic acid and achieve bactericidal levels in blood and tissues.

**Table 46â€² Pharmacokinetic Properties of Fluoroquinolones.**

<b>Drug</b>	<b>Half-Life (h)</b>	<b>Oral Bioavailability (%)</b>	<b>Peak Serum Concentration (mcg/mL)</b>	<b>Oral Dose (mg)</b>	<b>Primary Route of Excretion</b>
Ciprofloxacin	3â€³5	70	2.4	500	Renal
Gatifloxacin	8	98	3.4	400	Renal
Gemifloxacin	8	70	1.6	320	Renal & nonrenal
Levofloxacin	5â€³7	95	5.7	500	Renal
Lomefloxacin	8	95	2.8	400	Renal
Moxifloxacin	9â€³10	> 85	3.1	400	Nonrenal
Norfloxacin	3.5â€³5	80	1.5	400	Renal
Ofloxacin	5â€³7	95	2.9	400	Renal

### **Antibacterial Activity**

Fluoroquinolones were originally developed because of their excellent activity against gram-negative aerobic bacteria; they had limited activity against gram-positive organisms. Several newer agents have improved activity against gram-positive cocci. This relative

activity against gram-negative versus gram-positive species is useful for classification of these agents. Norfloxacin is the least active of the fluoroquinolones against both gram-negative and gram-positive organisms, with minimum inhibitory concentrations (MICs) four-fold to eight-fold higher than those of ciprofloxacin. Ciprofloxacin, enoxacin, lomefloxacin, levofloxacin, ofloxacin, and pefloxacin make up a second group of similar agents possessing excellent gram-negative activity and moderate to good activity against gram-positive bacteria. MICs for gram-negative cocci and bacilli, including enterobacter, pseudomonas, neisseria, haemophilus, and campylobacter, are  $1 \times 10^{-2}$  mcg/mL and often less. Methicillin-susceptible strains of *S aureus* are generally susceptible to these fluoroquinolones, but methicillin-resistant strains of staphylococci are often resistant. Streptococci and enterococci tend to be less susceptible than staphylococci, and efficacy in infections caused by these organisms is limited. Ciprofloxacin is the most active agent of this group against gram-negatives, *Pseudomonas aeruginosa* in particular. Levofloxacin, the L-isomer of ofloxacin, has superior activity against gram-positive organisms, including *Streptococcus pneumoniae*.

Gatifloxacin, gemifloxacin, and moxifloxacin make up a third group of fluoroquinolones with improved activity against gram-positive organisms, particularly *S pneumoniae* and some staphylococci. Gemifloxacin is active in vitro against ciprofloxacin-resistant strains of *S pneumoniae*, but in vivo efficacy is unproven. Although MICs of these agents for staphylococci are lower than those of ciprofloxacin (and the other compounds mentioned in the paragraph above) and may fall within the susceptible range, it is not known whether the enhanced activity is sufficient to permit use of these agents for treatment of infections caused by ciprofloxacin-resistant strains. In general, none of these agents is as active as ciprofloxacin against gram-negative organisms. Fluoroquinolones also are active against agents of atypical pneumonia (eg, mycoplasmas and chlamydiae) and against intracellular pathogens such as *Legionella* species and some mycobacteria, including *Mycobacterium tuberculosis* and *M avium* complex. Moxifloxacin also has modest activity against anaerobic bacteria. Because of toxicity, gatifloxacin is no longer available in the USA.

## Resistance

During fluoroquinolone therapy, resistant organisms emerge about once in  $10^7$  to  $10^9$ , especially among staphylococci, pseudomonas, and serratia. Resistance is due to one or more point mutations in the quinolone binding region of the target enzyme or to a change in the permeability of the organism. However, this does not account for the relative ease with which resistance develops in exquisitely susceptible bacteria. More recently two types of plasmid-mediated resistance have been described. The first type utilizes Qnr proteins, which protect DNA gyrase from the fluoroquinolones. The second is a variant of an aminoglycoside acetyltransferase capable of modifying ciprofloxacin. Both mechanisms confer low-level resistance that may facilitate the point mutations that confer high-level resistance. Resistance to one fluoroquinolone, particularly if it is of high level, generally confers cross-resistance to all other members of this class.

## Pharmacokinetics

After oral administration, the fluoroquinolones are well absorbed (bioavailability of 80–95%) and distributed widely in body fluids and tissues (Table 46–2). Serum half-lives range from 3 to 10 hours. The relatively long half-lives of levofloxacin, gemifloxacin, gatifloxacin, and moxifloxacin permit once-daily dosing. Oral absorption is impaired by di- and trivalent cations, including those in antacids. Therefore, oral fluoroquinolones should be taken 2 hours before or 4 hours after any products containing these cations. Serum concentrations of intravenously administered drug are similar to those of orally administered drug. Most fluoroquinolones are eliminated by renal mechanisms, either tubular secretion or glomerular filtration (Table 46–2). Dose adjustment is required for patients with creatinine clearances less than 50 mL/min, the exact adjustment depending on the degree of renal impairment and the specific fluoroquinolone being used. Dose adjustment for renal failure is not necessary for moxifloxacin. Nonrenally cleared fluoroquinolones are relatively contraindicated in patients with hepatic failure.

## Clinical Uses

Fluoroquinolones (other than moxifloxacin, which achieves relatively low urinary levels) are effective in urinary tract infections even when caused by multidrug-resistant bacteria, eg, pseudomonas. These agents are also effective for bacterial diarrhea caused by shigella, salmonella, toxigenic *E coli*, and campylobacter. Fluoroquinolones (except norfloxacin, which does not achieve adequate systemic concentrations) have been used in infections of soft tissues, bones, and joints and in intra-abdominal and respiratory tract infections, including those caused by multidrug-resistant organisms such as pseudomonas and enterobacter. Ciprofloxacin is a drug of choice for prophylaxis and treatment of anthrax, although the newer fluoroquinolones are active in vitro and very likely in vivo as well.

Ciprofloxacin and levofloxacin are no longer recommended for the treatment of gonococcal infection in the USA as resistance is now common. However, both drugs are effective in treating chlamydial urethritis or cervicitis. Ciprofloxacin, levofloxacin, or moxifloxacin is occasionally used for treatment of tuberculosis and atypical mycobacterial infections. These agents may be suitable for eradication of meningococci from carriers or for prophylaxis of infection in neutropenic patients.

Levofloxacin, gatifloxacin, gemifloxacin, and moxifloxacin, so-called respiratory fluoroquinolones, with their enhanced gram-positive activity and activity against atypical pneumonia agents (eg, chlamydia, mycoplasma, and legionella), are effective and used increasingly for treatment of upper and lower respiratory tract infections.

## Adverse Effects

Fluoroquinolones are extremely well tolerated. The most common effects are nausea, vomiting, and diarrhea. Occasionally, headache, dizziness, insomnia, skin rash, or abnormal liver function tests develop. Photosensitivity has been reported with lomefloxacin and

pefloxacin. QT<sub>c</sub> prolongation may occur with gatifloxacin, levofloxacin, gemifloxacin, and moxifloxacin, which should be avoided or used with caution in patients with known QT<sub>c</sub> interval prolongation or uncorrected hypokalemia; in those receiving class IA (eg, quinidine or procainamide) or class III antiarrhythmic agents (sotalol, ibutilide, amiodarone); and in patients receiving other agents known to increase the QT<sub>c</sub> interval (eg, erythromycin, tricyclic antidepressants). Gatifloxacin has been associated with hyperglycemia in diabetic patients and with hypoglycemia in patients also receiving oral hypoglycemic agents. Because of these serious effects (including some fatalities), gatifloxacin was withdrawn from sales in the USA in 2006; it may be available elsewhere.

Fluoroquinolones may damage growing cartilage and cause an arthropathy. Thus, these drugs are not routinely recommended for patients under 18 years of age. However, the arthropathy is reversible, and there is a growing consensus that fluoroquinolones may be used in children in some cases (eg, for treatment of pseudomonas infections in patients with cystic fibrosis). Tendinitis, a rare complication that has been reported in adults, is potentially more serious because of the risk of tendon rupture. Risk factors for tendonitis include advanced age, renal insufficiency, and concurrent steroid use. Fluoroquinolones should be avoided during pregnancy in the absence of specific data documenting their safety.

## SUMMARY: SULFONAMIDES, TRIMETHOPRIM, AND FLUOROQUINOLONES

### Sulfonamides, Trimethoprim, and Fluoroquinolones

Subclass	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics , Toxicities, Interactions
<b>Folate antagonists</b>				
Trimethoprim-sulfamethoxazole	Synergistic combination of folate antagonists blocks purine production and nucleic acid synthesis	Bactericidal activity against susceptible bacteria	Urinary tract infections • <i>Pneumocystis jiroveci</i> pneumonia • toxoplasmosis • nocardiosis	Oral, IV • renal clearance (half-life 8 h) • dosed every 8-12 h • formulated in a 5:1 ratio of sulfamethoxazole to trimethoprim • <b>Toxicity:</b> Rash, fever, bone marrow suppression, hyperkalemia

*Sulfisoxazole: Oral; used only for lower urinary tract infections*

*Sulfadiazine: Oral; first-line therapy for toxoplasmosis when combined with pyrimethamine*

*Trimethoprim: Oral; used only for lower urinary tract infections; may be safely prescribed to patients with sulfonamide allergy*

*Pyrimethamine: Oral; first-line therapy for toxoplasmosis when combined with sulfadiazine; coadminister with leucovorin to limit bone marrow toxicity*

*Pyrimethamine-sulfadoxine: Oral; second-line malaria treatment*

### **Fluoroquinolones**

Ciprofloxacin	Inhibits DNA replication by binding to DNA gyrase and topoisomerase IV	Bactericidal activity against susceptible bacteria	Urinary tract infections • gastroenteritis • osteomyelitis • anthrax	Oral, IV • mixed clearance (half-life 4 h) • dosed every 12 h • di- and trivalent cations impair oral absorption • <i>Toxicity:</i> Gastrointestinal upset, neurotoxicity, tendonitis
---------------	--	--	--	--

*Ofloxacin: Oral; levofloxacin has improved pharmacokinetics and pharmacodynamics; use is limited to urinary tract infections and nongonococcal urethritis and cervicitis*

*Levofloxacin: Oral, IV; L -isomer of ofloxacin; once-daily dosing; renal clearance; "respiratory" fluoroquinolone with improved activity versus pneumococcus*

*Moxifloxacin: Oral, IV; "respiratory" fluoroquinolone; once-daily dosing; improved activity versus anaerobes and Mycobacterium tuberculosis; hepatic clearance results in lower urinary levels so use in urinary tract infections is not recommended*

*Gemifloxacin: Oral; "respiratory" fluoroquinolone*

## **PREPARATIONS AVAILABLE**

### **GENERAL-PURPOSE SULFONAMIDES**

**Sulfadiazine** (generic)

Oral: 500 mg tablets

**Sulfisoxazole** (generic)

Oral: 500 mg tablets; 500 mg/5 mL syrup

### **SULFONAMIDES FOR SPECIAL APPLICATIONS**

**Mafenide** (Sulfamylon)

Topical: 85 mg/g cream; 5% solution

**Silver sulfadiazine** (generic, Silvadene)

Topical: 10 mg/g cream

**Sulfacetamide sodium** (generic)

Ophthalmic: 1, 10, 15, 30% solutions; 10% ointment

## TRIMETHOPRIM

**Trimethoprim** (generic, Proloprim, Trimpex)

Oral: 100, 200 mg tablets

**Trimethoprim-sulfamethoxazole [co-trimoxazole, TMP-SMZ]** (generic, Bactrim, Septra, others)

Oral: 80 mg trimethoprim + 400 mg sulfamethoxazole per single-strength tablet; 160 mg trimethoprim + 800 mg sulfamethoxazole per double-strength tablet; 40 mg trimethoprim + 200 mg sulfamethoxazole per 5 mL suspension

Parenteral: 80 mg trimethoprim + 400 mg sulfamethoxazole per 5 mL for infusion (in 5 mL ampules and 5, 10, 20 mL vials)

## PYRIMETHAMINE

**Pyrimethamine** (generic, Daraprim)

Oral: 25 mg tablets

**Pyrimethamine-sulfadoxine** (Fansidar)

Oral: 25 mg pyrimethamine + 500 mg sulfadoxine per tablet

## QUINOLONES & FLUOROQUINOLONES

**Ciprofloxacin** (generic, Cipro, Cipro I.V.)

Oral: 100, 250, 500, 750 mg tablets; 500, 1000 mg extended-release tablet; 50, 100 mg/mL suspension

Parenteral: 10 mg/mL for IV infusion

Ophthalmic (Ciloxan): 3 mg/mL solution; 3.3 mg/g ointment

**Gemifloxacin** (Factive)

Oral: 320 mg tablet

**Levofloxacin** (Levaquin)

Oral: 250, 500, 750 mg tablets; 25 mg/mL solution

Parenteral: 5, 25 mg/mL for IV injection

Ophthalmic (Quixin): 5 mg/mL solution

**Lomefloxacin** (Maxaquin)

Oral: 400 mg tablets

**Moxifloxacin** (Avelox, Avelox I.V.)

Oral: 400 mg tablets

Parenteral: 400 mg in IV bag

**Norfloxacin** (Noroxin)

Oral: 400 mg tablets

**Ofloxacin** (Floxin)

Oral: 200, 300, 400 mg tablets

Ophthalmic (Ocuflox): 3 mg/mL solution

Otic (Floxin Otic): 0.3% solution

Basic and Clinical Pharmacology > Chapter 47. Antimycobacterial Drugs >

## CASE STUDY

A 45-year-old homeless man presents to the emergency department complaining of a 2-month history of fatigue, weight loss (10 kg), fevers, night sweats, and a productive cough. He is currently living on the street but has spent time in homeless shelters and prison in the last several years. He reports drinking 2–3 pints of hard alcohol per day for the last 15 years, and he also reports a history of intravenous drug use. In the emergency department, a chest x-ray is obtained that shows a right apical infiltrate. Given the high suspicion for pulmonary tuberculosis, the patient is placed in respiratory isolation. His first sputum smear shows many acid-fast bacilli, and a rapid HIV antibody test returns with a positive result. What drugs should be started for presumptive pulmonary tuberculosis? Does the patient have a heightened risk of developing medication toxicity? Which medication would be likely to cause toxicity?

## ANTIMYCOBACTERIAL DRUGS: INTRODUCTION

Mycobacteria are intrinsically resistant to most antibiotics. Because they grow slowly compared with other bacteria, antibiotics that are most active against growing cells are relatively ineffective. Mycobacterial cells can also be dormant and thus completely resistant to many drugs or killed only very slowly. The lipid-rich mycobacterial cell wall is impermeable to many agents. Mycobacterial species are intracellular pathogens, and organisms residing within macrophages are inaccessible to drugs that penetrate these cells poorly. Finally, mycobacteria are notorious for their ability to develop resistance. Combinations of two or more drugs are required to overcome these obstacles and to prevent emergence of resistance during the course of therapy. The response of mycobacterial infections to chemotherapy is slow, and treatment must be administered for months to years, depending on which drugs are used. The drugs used to treat tuberculosis, atypical mycobacterial infections, and leprosy are described in this chapter.

## DRUGS USED IN TUBERCULOSIS

**Isoniazid (INH), rifampin (or other rifamycin), pyrazinamide, ethambutol, and streptomycin** are the five first-line agents for treatment of tuberculosis (Table 47-1). Isoniazid and rifampin are the two most active drugs. An isoniazid-rifampin combination administered for 9 months will cure 95–98% of cases of tuberculosis caused by susceptible strains. The addition of pyrazinamide to an isoniazid-rifampin combination for the first 2 months allows the total duration of therapy to be reduced to 6 months without loss of efficacy (Table 47-2). In practice, therapy is initiated with a four-drug regimen

of isoniazid, rifampin, pyrazinamide, and either ethambutol or streptomycin until susceptibility of the clinical isolate has been determined. Neither ethambutol nor streptomycin adds substantially to the overall activity of the regimen (ie, the duration of treatment cannot be further reduced if either drug is used), but they provide additional coverage if the isolate proves to be resistant to isoniazid, rifampin, or both. The prevalence of isoniazid resistance among US clinical isolates is approximately 10%. Prevalence of resistance to both isoniazid and rifampin (ie, multiple drug resistance) is about 3%.

**Table 47â€“1 Antimicrobials Used in the Treatment of Tuberculosis.**

<b>Drug</b>	<b>Typical Adult Dosage<sup>1</sup></b>
<b>First-line agents (in approximate order of preference)</b>	
Isoniazid	300 mg/d
Rifampin	600 mg/d
Pyrazinamide	25 mg/kg/d
Ethambutol	15â€“25 mg/kg/d
Streptomycin	15 mg/kg/d
<b>Second-line agents</b>	
Amikacin	15 mg/kg/d
Aminosalicylic acid	8â€“12 g/d
Capreomycin	15 mg/kg/d
Ciprofloxacin	1500 mg/d, divided
Clofazimine	200 mg/d
Cycloserine	500â€“1000 mg/d, divided
Ethionamide	500â€“750 mg/d
Levofloxacin	500 mg/d
Rifabutin	300 mg/d <sup>2</sup>
Rifapentine	600 mg once or twice weekly

<sup>1</sup>Assuming normal renal function.

<sup>2</sup>150 mg/d if used concurrently with a protease inhibitor.

**Table 47â€“2 Recommended Duration of Therapy for Tuberculosis.**

<b>Regimen (in Approximate Order of Preference)</b>	<b>Duration in Months</b>
---	---------------------------

Isoniazid, rifampin, pyrazinamide	6
Isoniazid, rifampin	9
Rifampin, ethambutol, pyrazinamide	6
Rifampin, ethambutol	12
Isoniazid, ethambutol	18
All others	≥ 24

## ISONIAZID

Isoniazid is the most active drug for the treatment of tuberculosis caused by susceptible strains. It is small (MW 137) and freely soluble in water. The structural similarity to pyridoxine is shown below.

**Isoniazid**

**Pyridoxine**

In vitro, isoniazid inhibits most tubercle bacilli in a concentration of 0.2 mcg/mL or less and is bactericidal for actively growing tubercle bacilli. It is less effective against atypical mycobacterial species. Isoniazid penetrates into macrophages and is active against both extracellular and intracellular organisms.

### Mechanism of Action & Basis of Resistance

Isoniazid inhibits synthesis of mycolic acids, which are essential components of mycobacterial cell walls. Isoniazid is a prodrug that is activated by KatG, the mycobacterial catalase-peroxidase. The activated form of isoniazid forms a covalent complex with an acyl carrier protein (AcpM) and KasA, a beta-ketoacyl carrier protein synthetase, which blocks mycolic acid synthesis and kills the cell. Resistance to isoniazid is associated with mutations resulting in overexpression of *inhA*, which encodes an NADH-dependent acyl carrier protein reductase; mutation or deletion of the *katG* gene; promoter mutations resulting in overexpression of *ahpC*, a putative virulence gene

involved in protection of the cell from oxidative stress; and mutations in *kasA*. Overproducers of *inhA* express low-level isoniazid resistance and cross-resistance to ethionamide. *KatG* mutants express high-level isoniazid resistance and often are not cross-resistant to ethionamide.

Drug-resistant mutants are normally present in susceptible mycobacterial populations at about 1 bacillus in  $10^6$ . Since tuberculous lesions often contain more than  $10^8$  tubercle bacilli, resistant mutants are readily selected out if isoniazid or any other drug is given as a single agent. The use of two independently acting drugs in combination is much more effective. The probability that a bacillus is resistant to both drugs is approximately  $1$  in  $10^6 \times 10^6$ , or  $1$  in  $10^{12}$ , several orders of magnitude greater than the number of infecting organisms. Thus, at least two (or more in certain cases) active agents should always be used to treat active tuberculosis to prevent emergence of resistance during therapy.

### **Pharmacokinetics**

Isoniazid is readily absorbed from the gastrointestinal tract. A 300-mg oral dose (5 mg/kg in children) achieves peak plasma concentrations of  $3\text{--}5$  mcg/mL within  $1\text{--}2$  hours. Isoniazid diffuses readily into all body fluids and tissues. The concentration in the central nervous system and cerebrospinal fluid ranges between 20% and 100% of simultaneous serum concentrations.

Metabolism of isoniazid, especially acetylation by liver *N*-acetyltransferase, is genetically determined (see Chapter 4). The average plasma concentration of isoniazid in rapid acetylators is about one third to one half of that in slow acetylators, and average half-lives are less than 1 hour and 3 hours, respectively. More rapid clearance of isoniazid by rapid acetylators is usually of no therapeutic consequence when appropriate doses are administered daily, but subtherapeutic concentrations may occur if drug is administered as a once-weekly dose or if there is malabsorption.

Isoniazid metabolites and a small amount of unchanged drug are excreted, mainly in the urine. The dose need not be adjusted in renal failure. Dose adjustment is not well defined in patients with severe preexisting hepatic insufficiency (isoniazid is contraindicated if it is the cause of the hepatitis) and should be guided by serum concentrations if a reduction in dose is contemplated.

### **Clinical Uses**

The typical dosage of isoniazid is 5 mg/kg/d; a typical adult dose is 300 mg given once daily. Up to 10 mg/kg/d may be used for serious infections or if malabsorption is a problem. A 15 mg/kg dose, or 900 mg, may be used in a twice-weekly dosing regimen in combination with a second antituberculous agent (eg, rifampin 600 mg). Pyridoxine, 25–50 mg/d, is recommended for those with conditions predisposing to neuropathy, an adverse effect of isoniazid. Isoniazid is usually given by mouth but can be given parenterally in the same dosage.

Isoniazid as a single agent is also indicated for treatment of latent tuberculosis. The dosage is 300 mg/d (5 mg/kg/d) or 900 mg twice weekly for 9 months.

## **Adverse Reactions**

The incidence and severity of untoward reactions to isoniazid are related to dosage and duration of administration.

### **IMMUNOLOGIC REACTIONS**

Fever and skin rashes are occasionally seen. Drug-induced systemic lupus erythematosus has been reported.

### **DIRECT TOXICITY**

Isoniazid-induced hepatitis is the most common major toxic effect of isoniazid. This is distinct from the minor increases in liver aminotransferases (up to three or four times normal), which do not require cessation of the drug and which are seen in 10%–20% of patients, who usually are asymptomatic. Clinical hepatitis with loss of appetite, nausea, vomiting, jaundice, and right upper quadrant pain occurs in 1% of isoniazid recipients and can be fatal, particularly if the drug is not discontinued promptly. There is histologic evidence of hepatocellular damage and necrosis. The risk of hepatitis depends on age. It occurs rarely under age 20, in 0.3% of those aged 21–35, 1.2% of those aged 36–50, and 2.3% for those aged 50 and above. The risk of hepatitis is greater in alcoholics and possibly during pregnancy and the postpartum period. Development of isoniazid hepatitis contraindicates further use of the drug.

Peripheral neuropathy is observed in 10%–20% of patients given dosages greater than 5 mg/kg/d, but it is infrequently seen with the standard 300-mg adult dose. Peripheral neuropathy is more likely to occur in slow acetylators and patients with predisposing conditions such as malnutrition, alcoholism, diabetes, AIDS, and uremia. Neuropathy is due to a relative pyridoxine deficiency. Isoniazid promotes excretion of pyridoxine, and this toxicity is readily reversed by administration of pyridoxine in a dosage as low as 10 mg/d. Central nervous system toxicity, which is less common, includes memory loss, psychosis, and seizures. These may also respond to pyridoxine.

Miscellaneous other reactions include hematologic abnormalities, provocation of pyridoxine deficiency anemia, tinnitus, and gastrointestinal discomfort. Isoniazid can reduce the metabolism of phenytoin, increasing its blood level and toxicity.

## **RIFAMPIN**

Rifampin is a semisynthetic derivative of rifamycin, an antibiotic produced by *Streptomyces mediterranei*. It is active in vitro against gram-positive and gram-negative cocci, some enteric bacteria, mycobacteria, and chlamydia. Susceptible organisms are inhibited by less than 1 mcg/mL. Resistant mutants are present in all microbial populations at approximately 1 in 10<sup>6</sup> and are rapidly selected out if rifampin is used as a single drug, especially in a patient with active infection. There is no cross-resistance to other classes of antimicrobial drugs, but there is cross-resistance to other rifamycin derivatives, eg, rifabutin and rifapentine.

### **Antimycobacterial Activity, Resistance, & Pharmacokinetics**

Rifampin binds to the  $\beta$  subunit of bacterial DNA-dependent RNA polymerase and thereby

inhibits RNA synthesis. Resistance results from any one of several possible point mutations in *rpoB*, the gene for the  $\beta$  subunit of RNA polymerase. These mutations result in reduced binding of rifampin to RNA polymerase. Human RNA polymerase does not bind rifampin and is not inhibited by it. Rifampin is bactericidal for mycobacteria. It readily penetrates most tissues and penetrates into phagocytic cells. It can kill organisms that are poorly accessible to many other drugs, such as intracellular organisms and those sequestered in abscesses and lung cavities.

Rifampin is well absorbed after oral administration and excreted mainly through the liver into bile. It then undergoes enterohepatic recirculation, with the bulk excreted as a deacylated metabolite in feces and a small amount in the urine. Dosage adjustment for renal or hepatic insufficiency is not necessary. Usual doses result in serum levels of 5–7 mcg/mL. Rifampin is distributed widely in body fluids and tissues. Rifampin is relatively highly protein-bound, and adequate cerebrospinal fluid concentrations are achieved only in the presence of meningeal inflammation.

## **Clinical Uses**

### **MYCOBACTERIAL INFECTIONS**

Rifampin, usually 600 mg/d (10 mg/kg/d) orally, must be administered with isoniazid or other antituberculous drugs to patients with active tuberculosis to prevent emergence of drug-resistant mycobacteria. In some short-course therapies, 600 mg of rifampin are given twice weekly. Rifampin 600 mg daily or twice weekly for 6 months also is effective in combination with other agents in some atypical mycobacterial infections and in leprosy. Rifampin, 600 mg daily for 4 months as a single drug, is an alternative to isoniazid prophylaxis for patients with latent tuberculosis only, who are unable to take isoniazid or who have had exposure to a case of active tuberculosis caused by an isoniazid-resistant, rifampin-susceptible strain.

### **OTHER INDICATIONS**

Rifampin has other uses. An oral dosage of 600 mg twice daily for 2 days can eliminate meningococcal carriage. Rifampin, 20 mg/kg/d for 4 days, is used as prophylaxis in contacts of children with *Haemophilus influenzae* type b disease. Rifampin combined with a second agent is used to eradicate staphylococcal carriage. Rifampin combination therapy is also indicated for treatment of serious staphylococcal infections such as osteomyelitis and prosthetic valve endocarditis.

### **Adverse Reactions**

Rifampin imparts a harmless orange color to urine, sweat, tears, and contact lenses (soft lenses may be permanently stained). Occasional adverse effects include rashes, thrombocytopenia, and nephritis. It may cause cholestatic jaundice and occasionally hepatitis. Rifampin commonly causes light-chain proteinuria. If administered less often than twice weekly, rifampin causes a flu-like syndrome characterized by fever, chills, myalgias, anemia, and thrombocytopenia and sometimes is associated with acute tubular necrosis. Rifampin strongly induces most cytochrome P450 isoforms (CYPs 1A2, 2C9, 2C19, 2D6, and 3A4), which increases the elimination of numerous other drugs including methadone, anticoagulants, cyclosporine, some anticonvulsants, protease inhibitors,

some nonnucleoside reverse transcriptase inhibitors, contraceptives, and a host of others. Administration of rifampin results in significantly lower serum levels of these drugs.

## ETHAMBUTOL

Ethambutol is a synthetic, water-soluble, heat-stable compound, the dextro-isomer of the structure shown below, dispensed as the dihydrochloride salt.

**Ethambutol**

Susceptible strains of *Mycobacterium tuberculosis* and other mycobacteria are inhibited in vitro by ethambutol, 1 µg/mL. Ethambutol inhibits mycobacterial arabinosyl transferases, which are encoded by the *embCAB* operon. Arabinosyl transferases are involved in the polymerization reaction of arabinoglycan, an essential component of the mycobacterial cell wall. Resistance to ethambutol is due to mutations resulting in overexpression of *emb* gene products or within the *embB* structural gene.

Ethambutol is well absorbed from the gut. After ingestion of 25 mg/kg, a blood level peak of 5 µg/mL is reached in 4 hours. About 20% of the drug is excreted in feces and 50% in urine in unchanged form. Ethambutol accumulates in renal failure, and the dose should be reduced by half if creatinine clearance is less than 10 mL/min. Ethambutol crosses the blood-brain barrier only when the meninges are inflamed. Concentrations in cerebrospinal fluid are highly variable, ranging from 4% to 64% of serum levels in the setting of meningeal inflammation.

As with all antituberculous drugs, resistance to ethambutol emerges rapidly when the drug is used alone. Therefore, ethambutol is always given in combination with other antituberculous drugs.

## Clinical Use

Ethambutol hydrochloride, 15–25 mg/kg, is usually given as a single daily dose in combination with isoniazid or rifampin. The higher dose is recommended for treatment of tuberculous meningitis. The dose of ethambutol is 50 mg/kg when a twice-weekly dosing schedule is used.

## Adverse Reactions

Hypersensitivity to ethambutol is rare. The most common serious adverse event is retrobulbar neuritis, resulting in loss of visual acuity and red-green color blindness. This dose-related adverse effect is more likely to occur at dosages of 25 mg/kg/d continued for several months. At 15 mg/kg/d or less, visual disturbances are very rare. Periodic visual acuity testing is desirable if the 25 mg/kg/d dosage is used. Ethambutol is relatively contraindicated in children too young to permit assessment of visual acuity and red-green color discrimination.

## PYRAZINAMIDE

Pyrazinamide (PZA) is a relative of nicotinamide, stable, and slightly soluble in water. It is inactive at neutral pH, but at pH 5.5 it inhibits tubercle bacilli and some other mycobacteria at concentrations of approximately 20 mcg/mL. The drug is taken up by macrophages and exerts its activity against mycobacteria residing within the acidic environment of lysosomes.

Pyrazinamide is converted to pyrazinoic acid—the active form of the drug—by mycobacterial pyrazinamidase, which is encoded by *pncA*. The drug target and mechanism of action are unknown. Resistance may be due to impaired uptake of pyrazinamide or mutations in *pncA* that impair conversion of pyrazinamide to its active form.

### Pyrazinamide (PZA)

#### Clinical Use

Serum concentrations of 30–50 mcg/mL at 1–2 hours after oral administration are achieved with dosages of 25 mg/kg/d. Pyrazinamide is well absorbed from the gastrointestinal tract and widely distributed in body tissues, including inflamed meninges. The half-life is 8–11 hours. The parent compound is metabolized by the liver, but metabolites are renally cleared; therefore, pyrazinamide should be administered at 25–35 mg/kg three times weekly (not daily) in hemodialysis patients and those in whom the creatinine clearance is less than 30 mL/min. In patients with normal renal function, a dose of 40–50 mg/kg is used for thrice-weekly or twice-weekly treatment regimens. Pyrazinamide is an important front-line drug used in conjunction with isoniazid and rifampin in short-course (ie, 6-month) regimens as a "sterilizing" agent active against residual intracellular organisms that may cause relapse. Tubercle bacilli develop resistance to pyrazinamide fairly readily, but there is no cross-resistance with isoniazid or other antimycobacterial drugs.

#### Adverse Reactions

Major adverse effects of pyrazinamide include hepatotoxicity (in 1–5% of patients), nausea, vomiting, drug fever, and hyperuricemia. The latter occurs uniformly and is not a reason to halt therapy. Hyperuricemia may provoke acute gouty arthritis.

## STREPTOMYCIN

The mechanism of action and other pharmacologic features of streptomycin are discussed in Chapter 45. The typical adult dose is 1 g/d (15 mg/kg/d). If the creatinine clearance is less than 30 mL/min or the patient is on hemodialysis, the dose is 15 mg/kg two or three

times per week. Most tubercle bacilli are inhibited by streptomycin, 10–100 mcg/mL, in vitro. Nontuberculosis species of mycobacteria other than *Mycobacterium avium* complex (MAC) and *Mycobacterium kansasii* are resistant. All large populations of tubercle bacilli contain some streptomycin-resistant mutants. On average, 1 in 10<sup>8</sup> tubercle bacilli can be expected to be resistant to streptomycin at levels of 10–100 mcg/mL. Resistance is due to a point mutation in either the *rpsL* gene encoding the S12 ribosomal protein gene or the *rrs* gene encoding 16S ribosomal rRNA, which alters the ribosomal binding site.

Streptomycin penetrates into cells poorly and is active mainly against extracellular tubercle bacilli. Streptomycin crosses the blood-brain barrier and achieves therapeutic concentrations with inflamed meninges.

### **Clinical Use in Tuberculosis**

Streptomycin sulfate is used when an injectable drug is needed or desirable, principally in individuals with severe, possibly life-threatening forms of tuberculosis, eg, meningitis and disseminated disease, and in the treatment of infections resistant to other drugs. The usual dosage is 15 mg/kg/d intramuscularly or intravenously daily for adults (20–40 mg/kg/d, not to exceed 1.5 g for children) for several weeks, followed by 1.5 g two or three times weekly for several months. Serum concentrations of approximately 40 mcg/mL are achieved 30–60 minutes after intramuscular injection of a 15 mg/kg dose. Other drugs are always given in combination to prevent emergence of resistance.

### **Adverse Reactions**

Streptomycin is ototoxic and nephrotoxic. Vertigo and hearing loss are the most common adverse effects and may be permanent. Toxicity is dose-related, and the risk is increased in the elderly. As with all aminoglycosides, the dose must be adjusted according to renal function (see Chapter 45). Toxicity can be reduced by limiting therapy to no more than 6 months whenever possible.

### **ALTERNATIVE SECOND-LINE DRUGS FOR TUBERCULOSIS**

The alternative drugs listed below are usually considered only (1) in case of resistance to first-line agents; (2) in case of failure of clinical response to conventional therapy; (3) in case of serious treatment-limiting adverse drug reactions; and (4) when expert guidance is available to deal with the toxic effects. For many of the second-line drugs listed in the following text, the dosage, emergence of resistance, and long-term toxicity have not been fully established.

#### **Ethionamide**

Ethionamide is chemically related to isoniazid and also blocks the synthesis of mycolic acids. It is poorly water soluble and available only in oral form. It is metabolized by the liver.

### **Ethionamide**

Most tubercle bacilli are inhibited in vitro by ethionamide, 2.5 mcg/mL or less. Some other species of mycobacteria also are inhibited by ethionamide, 10 mcg/mL. Serum concentrations in plasma and tissues of approximately 20 mcg/mL are achieved by a dosage of 1 g/d. Cerebrospinal fluid concentrations are equal to those in serum.

Ethionamide is administered at an initial dose of 250 mg once daily, which is increased in 250-mg increments to the recommended dosage of 1 g/d (or 15 mg/kg/d), if possible. The 1 g/d dosage, though theoretically desirable, is poorly tolerated because of the intense gastric irritation and neurologic symptoms that commonly occur, and one often must settle for a total daily dose of 500–750 mg. Ethionamide is also hepatotoxic. Neurologic symptoms may be alleviated by pyridoxine.

Resistance to ethionamide as a single agent develops rapidly in vitro and in vivo. There can be low-level cross-resistance between isoniazid and ethionamide.

### **Capreomycin**

Capreomycin is a peptide protein synthesis inhibitor antibiotic obtained from *Streptomyces capreolus*. Daily injection of 1 g intramuscularly results in blood levels of 10 mcg/mL or more. Such concentrations in vitro are inhibitory for many mycobacteria, including multidrug-resistant strains of *M tuberculosis*.

Capreomycin (15 mg/kg/d) is an important injectable agent for treatment of drug-resistant tuberculosis. Strains of *M tuberculosis* that are resistant to streptomycin or amikacin (eg, the multidrug-resistant W strain) usually are susceptible to capreomycin. Resistance to capreomycin, when it occurs, may be due to an *rrs* mutation.

Capreomycin is nephrotoxic and ototoxic. Tinnitus, deafness, and vestibular disturbances occur. The injection causes significant local pain, and sterile abscesses may occur.

Dosing of capreomycin is the same as that of streptomycin. Toxicity is reduced if 1 g is given two or three times weekly after an initial response has been achieved with a daily dosing schedule.

### **Cycloserine**

Cycloserine is an inhibitor of cell wall synthesis and is discussed in Chapter 43. Concentrations of 15–20 mcg/mL inhibit many strains of *M tuberculosis*. The dosage of cycloserine in tuberculosis is 0.5–1 g/d in two divided doses. Cycloserine is cleared renally, and the dose should be reduced by half if creatinine clearance is less than 50 mL/min.

The most serious toxic effects are peripheral neuropathy and central nervous system dysfunction, including depression and psychotic reactions. Pyridoxine 150 mg/d should be given with cycloserine because this ameliorates neurologic toxicity. Adverse effects, which are most common during the first 2 weeks of therapy, occur in 25% or more of patients, especially at higher doses. Adverse effects can be minimized by monitoring peak serum concentrations. The peak concentration is reached 2–4 hours after dosing. The recommended range of peak concentrations is 20–40 mcg/mL.

### **Aminosalicylic Acid (PAS)**

Aminosalicylic acid is a folate synthesis antagonist that is active almost exclusively against *M tuberculosis*. It is structurally similar to *p*-aminobenzoic acid (PABA) and to the sulfonamides (see Chapter 46).

### **Aminosalicylic acid (PAS)**

Tubercle bacilli are usually inhibited in vitro by aminosalicylic acid, 1–5 mcg/mL. Aminosalicylic acid is readily absorbed from the gastrointestinal tract. Serum levels are 50 mcg/mL or more after a 4-g oral dose. The dosage is 8–12 g/d orally for adults and 300 mg/kg/d for children. The drug is widely distributed in tissues and body fluids except the cerebrospinal fluid. Aminosalicylic acid is rapidly excreted in the urine, in part as active aminosalicylic acid and in part as the acetylated compound and other metabolic products. Very high concentrations of aminosalicylic acid are reached in the urine, which can result in crystalluria.

Aminosalicylic acid is used infrequently now because other oral drugs are better tolerated. Gastrointestinal symptoms are common and may be diminished by giving the drug with meals and with antacids. Peptic ulceration and hemorrhage may occur. Hypersensitivity reactions manifested by fever, joint pains, skin rashes, hepatosplenomegaly, hepatitis, adenopathy, and granulocytopenia often occur after 3–8 weeks of aminosalicylic acid therapy, making it necessary to stop aminosalicylic acid administration temporarily or permanently.

### **Kanamycin & Amikacin**

The aminoglycoside antibiotics are discussed in Chapter 45. Kanamycin has been used for treatment of tuberculosis caused by streptomycin-resistant strains, but the availability of less toxic alternatives (eg, capreomycin and amikacin) has rendered it obsolete.

The role of amikacin in treatment of tuberculosis has increased with the increasing incidence and prevalence of multidrug-resistant tuberculosis. Prevalence of amikacin-

resistant strains is low (less than 5%), and most multidrug-resistant strains remain amikacin-susceptible. *M tuberculosis* is inhibited at concentrations of 1 mcg/mL or less. Amikacin is also active against atypical mycobacteria. There is no cross-resistance between streptomycin and amikacin, but kanamycin resistance often indicates resistance to amikacin as well. Serum concentrations of 30–50 mcg/mL are achieved 30–60 minutes after a 15 mg/kg intravenous infusion. Amikacin is indicated for treatment of tuberculosis suspected or known to be caused by streptomycin-resistant or multidrug-resistant strains. Amikacin must be used in combination with at least one and preferably two or three other drugs to which the isolate is susceptible for treatment of drug-resistant cases. The recommended dosages are the same as that for streptomycin.

### **Fluoroquinolones**

In addition to their activity against many gram-positive and gram-negative bacteria (discussed in Chapter 46), ciprofloxacin, levofloxacin, gatifloxacin, and moxifloxacin inhibit strains of *M tuberculosis* at concentrations less than 2 mcg/mL. They are also active against atypical mycobacteria. Moxifloxacin is the most active against *M tuberculosis* by weight in vitro. Levofloxacin tends to be slightly more active than ciprofloxacin against *M tuberculosis*, whereas ciprofloxacin is slightly more active against atypical mycobacteria.

Fluoroquinolones are an important addition to the drugs available for tuberculosis, especially for strains that are resistant to first-line agents. Resistance, which may result from any one of several single point mutations in the gyrase A subunit, develops rapidly if a fluoroquinolone is used as a single agent; thus, the drug must be used in combination with two or more other active agents. The standard dosage of ciprofloxacin is 750 mg orally twice a day. The dosage of levofloxacin is 500–750 mg once a day. The dosage of moxifloxacin is 400 mg once a day.

### **Linezolid**

Linezolid (discussed in Chapter 44) inhibits strains of *M tuberculosis* in vitro at concentrations of 4–8 mcg/mL. It achieves good intracellular concentrations, and it is active in murine models of tuberculosis. Linezolid has been used in combination with other second- and third-line drugs to treat patients with tuberculosis caused by multidrug-resistant strains. Conversion of sputum cultures to negative was associated with linezolid use in these cases, and some may have been cured. Significant and at times treatment-limiting adverse effects, including bone marrow suppression and irreversible peripheral and optic neuropathy, have been reported with the prolonged courses of therapy that are necessary for treatment of tuberculosis. A 600-mg (adult) dose administered once a day (half of that used for treatment of other bacterial infections) seems to be sufficient and may limit the occurrence of these adverse effects. Although linezolid may eventually prove to be an important new agent for treatment of tuberculosis, at this point it should be considered a drug of last resort for infection caused by multidrug-resistant strains that also are resistant to several other first- and second-line agents.

### **Rifabutin (Ansamycin)**

Rifabutin is derived from rifamycin and is related to rifampin. It has significant activity against *M tuberculosis*, *M avium-intracellulare*, and *M fortuitum* (see below). Its activity is similar to that of rifampin, and cross-resistance with rifampin is virtually complete. Some rifampin-resistant strains may appear susceptible to rifabutin in vitro, but a clinical response is unlikely because the molecular basis of resistance, *rpoB* mutation, is the same. Rifabutin is both substrate and inducer of cytochrome P450 enzymes. Because it is a less potent inducer, rifabutin is indicated in place of rifampin for treatment of tuberculosis in HIV-infected patients who are receiving concurrent antiretroviral therapy with a protease inhibitor or nonnucleoside reverse transcriptase inhibitor (eg, efavirenz) and drugs that also are cytochrome P450 substrates.

The typical dose of rifabutin is 300 mg/d unless the patient is receiving a protease inhibitor, in which case the dose should be reduced to 150 mg/d. If efavirenz (also a P450 inducer) is used, the recommended dose of rifabutin is 450 mg/d.

Rifabutin is effective in prevention and treatment of disseminated atypical mycobacterial infection in AIDS patients with CD4 counts below 50/μL. It is also effective for preventive therapy of tuberculosis, either alone in a 3–4 month regimen or with pyrazinamide in a 2-month regimen.

### **Rifapentine**

Rifapentine is an analog of rifampin. It is active against both *M tuberculosis* and *M avium*. As with all rifamycins, it is a bacterial RNA polymerase inhibitor, and cross-resistance between rifampin and rifapentine is complete. Like rifampin, rifapentine is a potent inducer of cytochrome P450 enzymes, and it has the same drug interaction profile. Toxicity is similar to that of rifampin. Rifapentine and its microbiologically active metabolite, 25-desacetyl-rifapentine, have an elimination half-life of 13 hours. Rifapentine 600 mg (10 mg/kg) once weekly is indicated for treatment of tuberculosis caused by rifampin-susceptible strains during the continuation phase only (ie, after the first 2 months of therapy and ideally after conversion of sputum cultures to negative).

Rifapentine should not be used to treat HIV-infected patients because of an unacceptably high relapse rate with rifampin-resistant organisms.

## **DRUGS ACTIVE AGAINST ATYPICAL MYCOBACTERIA**

About 10% of mycobacterial infections seen in clinical practice in the USA are caused not by *M tuberculosis* or *M tuberculosis* complex organisms, but by nontuberculous or "atypical" mycobacteria. These organisms have distinctive laboratory characteristics, are present in the environment, and are not communicable from person to person. As a rule, these mycobacterial species are less susceptible than *M tuberculosis* to antituberculous drugs. On the other hand, agents such as erythromycin, sulfonamides, or tetracycline, which are not active against *M tuberculosis*, may be effective for infections caused by atypical strains. Emergence of resistance during therapy is also a problem with these mycobacterial species, and active infection should be treated with combinations of drugs. *M kansasii* is susceptible to rifampin and ethambutol, partially resistant to isoniazid, and completely resistant to pyrazinamide. A three-drug combination of isoniazid, rifampin,

and ethambutol is the conventional treatment for *M kansasii* infection. A few representative pathogens, with the clinical presentation and the drugs to which they are often susceptible, are given in Table 47â€³.

**Table 47â€³ Clinical Features and Treatment Options for Infections with Atypical Mycobacteria.**

<b>Species</b>	<b>Clinical Features</b>	<b>Treatment Options</b>
<i>M kansasii</i>	Resembles tuberculosis	Ciprofloxacin, clarithromycin, ethambutol, isoniazid, rifampin, trimethoprim-sulfamethoxazole
<i>M marinum</i>	Granulomatous cutaneous disease	Amikacin, clarithromycin, ethambutol, doxycycline, minocycline, rifampin, trimethoprim-sulfamethoxazole
<i>M scrofulaceum</i>	Cervical adenitis in children	Amikacin, erythromycin (or other macrolide), rifampin, streptomycin (Surgical excision is often curative and the treatment of choice.)
<i>M avium</i> complex	Pulmonary disease in patients with chronic lung disease; disseminated infection in AIDS	Amikacin, azithromycin, clarithromycin, ciprofloxacin, ethambutol, rifabutin
<i>M chelonae</i>	Abscess, sinus tract, ulcer; bone, joint, tendon infection	Amikacin, doxycycline, imipenem, macrolides, tobramycin
<i>M fortuitum</i>	Abscess, sinus tract, ulcer; bone, joint, tendon infection	Amikacin, ceftazidime, ciprofloxacin, doxycycline, ofloxacin, trimethoprim-sulfamethoxazole
<i>M ulcerans</i>	Skin ulcers	Isoniazid, streptomycin, rifampin, minocycline (Surgical excision may be effective.)

*M avium* complex, which includes both *M avium* and *M intracellulare*, is an important and common cause of disseminated disease in late stages of AIDS (CD4 counts < 50/µL). *M avium* complex is much less susceptible than *M tuberculosis* to most antituberculous drugs. Combinations of agents are required to suppress the disease. Azithromycin, 500 mg once daily, or clarithromycin, 500 mg twice daily, plus ethambutol, 15â€³25 mg/kg/d, is an effective and well-tolerated regimen for treatment of disseminated disease. Some authorities recommend use of a third agent, such as ciprofloxacin, 750 mg twice daily, or rifabutin, 300 mg once daily. Other agents that may be useful are listed in Table 47â€³. Rifabutin in a single daily dose of 300 mg has been shown to reduce the incidence of *M avium* complex bacteremia in AIDS patients with CD4 less than 100/µL. Clarithromycin also effectively prevents MAC bacteremia in AIDS patients, but if breakthrough bacteremia occurs, the isolate often is resistant to both clarithromycin and azithromycin, precluding the use of the most effective drugs for treatment.

## DRUGS USED IN LEPROSY

*Mycobacterium leprae* has never been grown in vitro, but animal models, such as growth in injected mouse footpads, have permitted laboratory evaluation of drugs. Only those drugs that have the widest clinical use are presented here. Because of increasing reports of dapsone resistance, treatment of leprosy with combinations of the drugs listed below is recommended.

### DAPSONE & OTHER SULFONES

Several drugs closely related to the sulfonamides have been used effectively in the long-term treatment of leprosy. The most widely used is dapsone (diaminodiphenylsulfone). Like the sulfonamides, it inhibits folate synthesis. Resistance can emerge in large populations of *M leprae*, eg, in lepromatous leprosy, if very low doses are given. Therefore, the combination of dapsone, rifampin, and clofazimine is recommended for initial therapy. Dapsone may also be used to prevent and treat *Pneumocystis jiroveci* pneumonia in AIDS patients.

**Dapsone**

Sulfones are well absorbed from the gut and widely distributed throughout body fluids and tissues. Dapsone's half-life is 12 days, and drug tends to be retained in skin, muscle, liver, and kidney. Skin heavily infected with *M leprae* may contain several times more drug than normal skin. Sulfones are excreted into bile and reabsorbed in the intestine. Excretion into urine is variable, and most excreted drug is acetylated. In renal failure, the dose may have to be adjusted. The usual adult dosage in leprosy is 100 mg daily. For children, the dose is proportionately less, depending on weight.

Dapsone is usually well tolerated. Many patients develop some hemolysis, particularly if they have glucose-6-phosphate dehydrogenase deficiency. Methemoglobinemia is common, but usually is not a problem clinically. Gastrointestinal intolerance, fever, pruritus, and various rashes occur. During dapsone therapy of lepromatous leprosy, erythema nodosum leprosum often develops. It is sometimes difficult to distinguish reactions to dapsone from manifestations of the underlying illness. Erythema nodosum leprosum may be suppressed by **corticosteroids** or by **thalidomide**.

### RIFAMPIN

Rifampin (see earlier discussion) in a dosage of 600 mg daily is highly effective in lepromatous leprosy. Because of the probable risk of emergence of rifampin-resistant *M leprae*, the drug is given in combination with dapsone or another antileprosy drug. A single monthly dose of 600 mg may be beneficial in combination therapy.

### CLOFAZIMINE

Clofazimine is a phenazine dye that can be used as an alternative to dapsone. Its mechanism of action is unknown but may involve DNA binding.

Absorption of clofazimine from the gut is variable, and a major portion of the drug is excreted in feces. Clofazimine is stored widely in reticuloendothelial tissues and skin, and its crystals can be seen inside phagocytic reticuloendothelial cells. It is slowly released from these deposits, so that the serum half-life may be 2 months.

Clofazimine is given for sulfone-resistant leprosy or when patients are intolerant to sulfones. A common dosage is 100 mg/d orally. The most prominent untoward effect is skin discoloration ranging from red-brown to nearly black. Gastrointestinal intolerance occurs occasionally.

## SUMMARY: FIRST-LINE ANTIMYCOBACTERIAL DRUGS

### First-Line Antimycobacterial Drugs

Subclass	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics , Toxicities, Interactions
<b>Rifamycins</b>				
Rifampin	Inhibits DNA-dependent RNA polymerase, thereby blocking production of RNA	Bactericidal activity against susceptible bacteria and mycobacteria • resistance rapidly emerges when used as a single drug in the treatment of active infection	First-line agent for tuberculosis • atypical mycobacterial infections • eradication of meningococcal colonization, staphylococcal infections	Oral, IV • hepatic clearance (half-life 3.5 h) • potent cytochrome P450 inducer • turns body fluids an orange color • <i>Toxicity:</i> Rash, nephritis, thrombocytopenia, cholestasis, flu-like syndrome with intermittent dosing
<i>Rifabutin: Oral; similar to rifampin but less cytochrome P450 induction and fewer drug interactions</i>				
<i>Rifapentine: Oral; long-acting analog of rifampin that may given once weekly in the continuation phase of tuberculosis treatment</i>				
<b>Isoniazid</b>	Inhibits synthesis of mycolic acids, an essential component of mycobacterial	Bactericidal activity against susceptible strains of <i>M tuberculosis</i>	First-line agent for tuberculosis • treatment of latent infection • less	Oral, IV • hepatic clearance (half-life 1 h) • reduces levels of phenytoin • <i>Toxicity:</i> Hepatotoxic, peripheral neuropathy (give

	cell walls		active against other mycobacteria	pyridoxine to prevent)
<b>Pyrazinamide</b>	Not fully understood ● pyrazinamide is converted to the active pyrazinoic acid under acidic conditions of macrophage lysosomes	Bacteriostatic activity against susceptible strains of <i>M tuberculosis</i> ● may be bactericidal against actively dividing organisms	"Sterilizing" agent used during first 2 months of therapy ● allows total duration of therapy to be shortened to 6 months	Oral ● hepatic clearance (half-life 9 h), but metabolites are renally cleared so use doses 3 x weekly if creatinine clearance < 30 mL/min ● <i>Toxicity</i> : Hepatotoxicity, hyperuricemia
<b>Ethambutol</b>	Inhibits mycobacterial arabinosyl transferases, which are involved in the polymerization reaction of arabinoglycan ● an essential component of the mycobacterial cell wall	Bacteriostatic activity against susceptible mycobacteria	Given as four-drug initial combination therapy for tuberculosis until drug sensitivities are known ● also used for atypical mycobacterial infections	Oral ● mixed clearance (half-life 4 h) ● dose must be reduced in renal failure ● <i>Toxicity</i> : Retrobulbar neuritis
<b>Streptomycin</b>	Prevents bacterial protein synthesis by binding to the S12 ribosomal subunit (see also Chapter 45)	Bactericidal activity against susceptible mycobacteria	Used in tuberculosis when an injectable drug is needed or desirable and in treatment of drug-resistant strains	IM, IV ● renal clearance (half-life 2.5 h) ● administered daily initially, then 2 x week ● <i>Toxicity</i> : Nephrotoxicity, ototoxicity

## PREPARATIONS AVAILABLE<sup>1</sup>

### DRUGS USED IN TUBERCULOSIS

**Aminosalicylate sodium** (Paser)

Oral: 4 g delayed-release granules

**Capreomycin** (Capastat Sulfate)

Parenteral: 1 g powder to reconstitute for injection

**Cycloserine** (Seromycin Pulvules)

Oral: 250 mg capsules

**Ethambutol** (Myambutol)

Oral: 100, 400 mg tablets

**Ethionamide** (Trecator-SC)

Oral: 250 mg tablets

**Isoniazid** (generic)

Oral: 100, 300 mg tablets; syrup, 50 mg/5 mL

Parenteral: 100 mg/mL for injection

**Pyrazinamide** (generic)

Oral: 500 mg tablets

**Rifabutin** (Mycobutin)

Oral: 150 mg capsules

**Rifampin** (generic, Rifadin, Rimactane)

Oral: 150, 300 mg capsules

Parenteral: 600 mg powder for IV injection

**Rifapentine** (Priftin)

Oral: 150 mg tablets

**Streptomycin** (generic)

Parenteral: 1 g lyophilized for IM injection

## **DRUGS USED IN LEPROSY**

**Clofazimine** (Lamprene)

Oral: 50 mg capsules

## **Dapsone** (generic)

Oral: 25, 100 mg tablets

<sup>1</sup>Drugs used against atypical mycobacteria are listed in Chapters 43, 44, 45, and 46.

Basic and Clinical Pharmacology > Chapter 48. Antifungal Agents >

## CASE STUDY

A 55-year-old man presents to the emergency department with a 2-week history of an expanding ulcer on his left lower leg. He has a history of chronic neutropenia and transfusion-dependent anemia secondary to myelodysplastic syndrome requiring chronic therapy with deferoxamine for hepatic iron overload. He first noticed a red bump on his leg while fishing at his cabin in the woods and thought it was a bug bite. It rapidly enlarged, first as a red swollen area, and then began to ulcerate. He was given dicloxacillin orally, but with no improvement. In the emergency department he is febrile to 39.2°C (102.2°F), and looks unwell. On his left leg he has a 6 by 12 cm black ulcer with surrounding swelling and erythema that is quite tender. His complete blood count demonstrates an absolute neutrophil count of 300 and a total white blood cell count of 1000. An immediate operative debridement yields pathologic specimens demonstrating broad club-like nonseptate hyphae and extensive tissue necrosis. What initial medical therapy would be most appropriate?\*

## ANTIFUNGAL AGENTS: INTRODUCTION

Human fungal infections have increased dramatically in incidence and severity in recent years, owing mainly to advances in surgery, cancer treatment, treatment of patients with solid organ and bone marrow transplantation, the HIV epidemic, and increasing use of broad-spectrum antimicrobial therapy in critically ill patients. These changes have resulted in increased numbers of patients at risk for fungal infections.

For many years, **amphotericin B** was the only efficacious antifungal drug available for systemic use. While highly effective in many serious infections, it is also quite toxic. In the last several decades, pharmacotherapy of fungal disease has been revolutionized by the introduction of the relatively nontoxic **azole** drugs (both oral and parenteral formulations) and the **echinocandins** (only available for parenteral administration). The new agents in these classes offer more targeted, less toxic therapy than older agents such as amphotericin B for patients with serious systemic fungal infections. Combination therapy is being reconsidered, and new formulations of old agents are becoming available. Unfortunately, the appearance of azole-resistant organisms, as well as the rise in the number of patients at risk for mycotic infections, has created new challenges.

The antifungal drugs presently available fall into several categories: systemic drugs (oral or parenteral) for systemic infections, oral drugs for mucocutaneous infections, and topical drugs for mucocutaneous infections.

\*Treatment of this patient is described at the end of the chapter.

## SYSTEMIC ANTIFUNGAL DRUGS FOR SYSTEMIC INFECTIONS

### AMPHOTERICIN B

Amphotericin A and B are antifungal antibiotics produced by *Streptomyces nodosus*. Amphotericin A is not in clinical use.

#### Chemistry

Amphotericin B is an amphoteric polyene macrolide (polyene = containing many double bonds; macrolide = containing a large lactone ring of 12 or more atoms). It is nearly insoluble in water and is therefore prepared as a colloidal suspension of amphotericin B and sodium desoxycholate for intravenous injection. Several new formulations have been developed in which amphotericin B is packaged in a lipid-associated delivery system (Table 48-1 and Liposomal Amphotericin B).

Amphotericin B

**Table 48-1 Properties of Conventional Amphotericin B and Some Lipid Formulations.<sup>1</sup>**

Drug	Physical Form	Dosing (mg/kg/d)	C <sub>max</sub>	Clearance	Nephrotoxicity	Infusional Toxicity	Daily Cost (\$)
<b>Conventional formulation</b>							
Fungizone	Micelles	1	...	...	...	...	24
<b>Lipid formulations</b>

<sup>1</sup>Changes in C<sub>max</sub> (peak plasma concentration), clearance, nephrotoxicity, and infusional toxicity are relative to conventional amphotericin B.

#### LIPOSOMAL AMPHOTERICIN B

Therapy with amphotericin B is often limited by toxicity, especially drug-induced renal impairment. This has led to the development of lipid drug formulations on the assumption that lipid-packaged drug binds to the mammalian membrane less readily, permitting the use of effective doses of the drug with lower toxicity. Liposomal amphotericin preparations package the active drug in lipid delivery vehicles, in contrast to the colloidal suspensions, which were previously the only available forms. Amphotericin binds to the lipids in these vehicles with an affinity between that for fungal ergosterol and that for human cholesterol. The lipid vehicle then serves as an amphotericin reservoir, reducing nonspecific binding to human cell membranes. This preferential binding allows for a reduction of toxicity without sacrificing efficacy and permits use of larger doses. Furthermore, some fungi contain lipases that may liberate free amphotericin B directly at the site of infection.

Three such formulations are now available and have differing pharmacologic properties as summarized in Table 48-1. Although clinical trials have demonstrated different renal and infusion-related toxicities for these preparations compared with regular amphotericin B, there are no trials comparing the different formulations with each other. Limited studies have suggested at best a moderate improvement in the clinical efficacy of the lipid formulations compared with conventional amphotericin B. Because the lipid preparations are much more expensive, their use is usually restricted to patients intolerant to, or not responding to, conventional amphotericin treatment.

#### Pharmacokinetics

Amphotericin B is poorly absorbed from the gastrointestinal tract. Oral amphotericin B is thus effective only on fungi within the lumen of the tract and cannot be used for treatment of systemic disease. The intravenous injection of 0.6 mg/kg/d of amphotericin B results in average blood levels of 0.3-1 mcg/mL; the drug is more than 90% bound by serum proteins. Although it is mostly metabolized, some amphotericin B is excreted slowly in the urine over a period of several days. The serum  $t_{1/2}$  is approximately 15 days. Hepatic impairment, renal impairment, and dialysis have little impact on drug concentrations, and therefore no dose adjustment is required. The drug is widely distributed in most tissues, but only 2-3% of the blood level is reached in cerebrospinal fluid, thus occasionally necessitating intrathecal therapy for certain types of fungal meningitis.

#### Mechanism of Action

Amphotericin B is selective in its fungicidal effect because it exploits the difference in lipid composition of fungal and mammalian cell membranes. **Ergosterol**, a cell membrane sterol, is found in the cell membrane of fungi, whereas the predominant sterol of bacteria and human cells is **cholesterol**. Amphotericin B binds to ergosterol and alters the permeability of the cell by forming amphotericin B-associated pores in the cell membrane (Figure 48-1). As suggested by its chemistry, amphotericin B combines avidly with lipids (ergosterol) along the double bond-rich side of its structure and associates with water molecules along the hydroxyl-rich side. This amphipathic characteristic facilitates pore formation by multiple amphotericin molecules, with the lipophilic portions around the outside of the pore and the hydrophilic regions lining the inside. The pore allows the leakage of intracellular ions and macromolecules, eventually leading to cell death. Some binding to human membrane sterols does occur, probably accounting for the drug's prominent toxicity.

#### Figure 48-1

Targets of antifungal drugs. Except for flucytosine (and possibly griseofulvin, not shown), all currently available antifungals target the fungal cell membrane or cell wall.

Resistance to amphotericin B occurs if ergosterol binding is impaired, either by decreasing the membrane concentration of ergosterol or by modifying the sterol target molecule to reduce its affinity for the drug.

### Antifungal Activity

Amphotericin B remains the antifungal agent with the broadest spectrum of action. It has activity against the clinically significant yeasts, including *Candida albicans* and *Cryptococcus neoformans*; the organisms causing endemic mycoses, including *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis*; and the pathogenic molds, such as *Aspergillus fumigatus* and mucor. Some fungal organisms such as *Candida lusitanae* and *Pseudallescheria boydii* display intrinsic amphotericin B resistance.

### Clinical Use

Owing to its broad spectrum of activity and fungicidal action, amphotericin B remains a useful agent for nearly all life-threatening mycotic infections, although newer less toxic agents have largely replaced amphotericin B for most conditions. It is often used as the initial induction regimen in order to rapidly reduce fungal burden and is then replaced by one of the newer azole drugs (described below) for chronic therapy or prevention of relapse. Such induction therapy is especially important for immunosuppressed patients and those with severe fungal pneumonia, severe cryptococcal meningitis, or disseminated infections with one of the endemic mycoses such as histoplasmosis or coccidioidomycosis. Once a clinical response has been elicited, these patients then often continue maintenance therapy with an azole; therapy may be lifelong in patients at high risk for disease relapse. For treatment of systemic fungal disease, amphotericin B is given by slow intravenous infusion at a dosage of 0.5–1 mg/kg/d. It is usually continued to a defined total dose (eg, 1–2 g), rather than a defined time span, as used with other antimicrobial drugs.

Intrathecal therapy for fungal meningitis is poorly tolerated and fraught with difficulties related to maintaining cerebrospinal fluid access. Thus, intrathecal therapy with amphotericin B is being increasingly supplanted by other therapies but remains an option in cases of fungal central nervous system infections that have not responded to other agents.

Local or topical administration of amphotericin B has been used with success. Mycotic corneal ulcers and keratitis can be cured with topical drops as well as by direct subconjunctival injection. Fungal arthritis has been treated with adjunctive local injection directly into the joint. Candiduria responds to bladder irrigation with amphotericin B, and this route has been shown to produce no significant systemic toxicity.

### Adverse Effects

The toxicity of amphotericin B can be divided into two broad categories: immediate reactions, related to the infusion of the drug, and those occurring more slowly.

#### INFUSION-RELATED TOXICITY

Infusion-related reactions are nearly universal and consist of fever, chills, muscle spasms, vomiting, headache, and hypotension. They can be ameliorated by slowing the infusion rate or decreasing the daily dose. Premedication with antipyretics, antihistamines, meperidine, or corticosteroids can be helpful. When starting therapy, many clinicians administer a test dose of 1 mg intravenously to gauge the severity of the reaction. This can serve as a guide to an initial dosing regimen and premedication strategy.

#### **CUMULATIVE TOXICITY**

Renal damage is the most significant toxic reaction. Renal impairment occurs in nearly all patients treated with clinically significant doses of amphotericin. The degree of azotemia is variable and often stabilizes during therapy, but it can be serious enough to necessitate dialysis. A reversible component is associated with decreased renal perfusion and represents a form of prerenal renal failure. An irreversible component results from renal tubular injury and subsequent dysfunction. The irreversible form of amphotericin nephrotoxicity usually occurs in the setting of prolonged administration (> 4 g cumulative dose). Renal toxicity commonly manifests as renal tubular acidosis and severe potassium and magnesium wasting. There is some evidence that the prerenal component can be attenuated with sodium loading, and it is common practice to administer normal saline infusions with the daily doses of amphotericin B.

Abnormalities of liver function tests are occasionally seen, as is a varying degree of anemia due to reduced erythropoietin production by damaged renal tubular cells. After intrathecal therapy with amphotericin, seizures and a chemical arachnoiditis may develop, often with serious neurologic sequelae.

#### **FLUCYTOSINE**

Flucytosine (5-FU) was discovered in 1957 during a search for novel antineoplastic agents. Though devoid of anticancer properties, it became apparent that it was a potent antifungal agent. Flucytosine is a water-soluble pyrimidine analog related to the chemotherapeutic agent fluorouracil (5-FU). Its spectrum of action is much narrower than that of amphotericin B.

**Flucytosine**

#### **Pharmacokinetics**

Flucytosine is currently available in North America only in an oral formulation. The dosage is 100–150 mg/kg/d in patients with normal renal function. It is well absorbed (> 90%), with serum concentrations peaking 1–2 hours after an oral dose. It is poorly protein-bound and penetrates well into all body fluid compartments, including the cerebrospinal fluid. It is eliminated by glomerular filtration with a half-life of 3–4 hours and is removed by hemodialysis. Levels rise rapidly with renal impairment and can lead to toxicity. Toxicity is more likely to occur in AIDS patients and those with renal insufficiency. Peak serum concentrations should be measured periodically in patients with renal insufficiency and maintained between 50 and 100 mcg/mL.

#### **Mechanism of Action**

Flucytosine is taken up by fungal cells via the enzyme cytosine permease. It is converted intracellularly first to 5-FU and then to 5-fluorodeoxyuridine monophosphate (FdUMP) and fluorouridine triphosphate (FUTP), which inhibit DNA and RNA synthesis, respectively (Figure 48–1). Human cells are unable to convert the parent drug to its active metabolites, resulting in selective toxicity.

Synergy with amphotericin B has been demonstrated in vitro and in vivo. It may be related to enhanced penetration of the flucytosine through amphotericin-damaged fungal cell membranes. In vitro synergy with azole drugs has also been seen, although the mechanism is unclear.

Resistance is thought to be mediated through altered metabolism of flucytosine, and, though uncommon in primary isolates, it develops rapidly in the course of flucytosine monotherapy.

#### **Clinical Use**

The spectrum of activity of flucytosine is restricted to *C neoformans*, some candida species, and the dematiaceous molds that cause chromoblastomycosis. Flucytosine is not used as a single agent because of its demonstrated synergy with other agents and to avoid the development of secondary resistance. Clinical use at present is confined to combination therapy, either with amphotericin B for cryptococcal meningitis or with itraconazole for chromoblastomycosis.

#### **Adverse Effects**

The adverse effects of flucytosine result from metabolism (possibly by intestinal flora) to the toxic antineoplastic compound fluorouracil. Bone marrow toxicity with anemia, leukopenia, and thrombocytopenia are the most common adverse effects, with derangement of liver enzymes occurring less frequently. A form of toxic enterocolitis can occur. There seems to be a narrow therapeutic window, with an increased risk of toxicity at higher drug levels and resistance developing rapidly at subtherapeutic concentrations. The use of drug

concentration measurements may be helpful in reducing the incidence of toxic reactions, especially when flucytosine is combined with nephrotoxic agents such as amphotericin B.

## AZOLES

Azoles are synthetic compounds that can be classified as either imidazoles or triazoles according to the number of nitrogen atoms in the five-membered azole ring, as indicated below. The imidazoles consist of ketoconazole, miconazole, and clotrimazole (Figure 48â€²2). The latter two drugs are now used only in topical therapy. The triazoles include itraconazole, fluconazole, voriconazole, and posaconazole.

### Azole nucleus

### Pharmacokinetics

The pharmacology of each of the azoles is unique and accounts for some of the variations in clinical use. Table 48â€²2 summarizes the differences among five of the azoles.

**Table 48â€²2 Pharmacologic properties of five systemic azole drugs**

	Water Solubility	Absorption	CSF: Serum Concentration Ratio	t <sub>1/2</sub> (Hours)	Elimination	Formulations
Ketoconazole	Low	Variable	< 0.1	7â€²10	Hepatic	Oral
Itraconazole	Low	Variable	< 0.01	24â€²42	Hepatic	Oral, IV
Fluconazole	High	High	> 0.7	22â€²31	Renal	Oral, IV
Voriconazole	High	High	. . .	6	Hepatic	Oral, IV
Posaconazole	Low	High	. . .	25	Hepatic	Oral

### Mechanism of Action

The antifungal activity of azole drugs results from the reduction of ergosterol synthesis by inhibition of fungal cytochrome P450 enzymes (Figure 48â€²1). The selective toxicity of azole drugs results from their greater affinity for fungal than for human cytochrome P450 enzymes. Imidazoles exhibit a lesser degree of selectivity than the triazoles, accounting for their higher incidence of drug interactions and side effects.

Resistance to azoles occurs via multiple mechanisms. Once rare, increasing numbers of resistant strains are being reported, suggesting that increasing use of these agents for prophylaxis and therapy may be selecting for clinical drug resistance in certain settings.

### Clinical Use

The spectrum of action of azole medications is broad, including many candida species, *C neoformans*, the endemic mycoses (blastomycosis, coccidioidomycosis, histoplasmosis), the dermatophytes, and, in the case of itraconazole and voriconazole, even aspergillus infections. They are also useful in the treatment of intrinsically amphotericin-resistant organisms such as *P boydii*.

### Adverse Effects

As a group, the azoles are relatively nontoxic. The most common adverse reaction is relatively minor gastrointestinal upset. All azoles have been reported to cause abnormalities in liver enzymes and, very rarely, clinical hepatitis. Adverse effects specific to individual agents are discussed below.

### Drug Interactions

All azole drugs affect the mammalian cytochrome P450 system of enzymes to some extent, and consequently they are prone to drug interactions. The most significant reactions are indicated below.

### KETOCONAZOLE

Ketoconazole was the first oral azole introduced into clinical use. It is distinguished from triazoles by its greater propensity to inhibit mammalian cytochrome P450 enzymes; that is, it is less selective for fungal P450 than are the newer azoles. As a result, systemic ketoconazole has fallen out of clinical use in the USA and is not discussed in any detail here. Its dermatologic use is discussed in Chapter 61.

### ITRACONAZOLE

Itraconazole is available in oral and intravenous formulations and is used at a dosage of 100â€²400 mg/d. Drug absorption is increased by food and by low gastric pH. Like other lipid-soluble azoles, it interacts with hepatic microsomal enzymes, though to a lesser degree

than ketoconazole. An important drug interaction is reduced bioavailability of itraconazole when taken with rifamycins (rifampin, rifabutin, rifapentine). It does not affect mammalian steroid synthesis, and its effects on the metabolism of other hepatically cleared medications are much less than those of ketoconazole. While itraconazole displays potent antifungal activity, effectiveness can be limited by reduced bioavailability. Newer formulations, including an oral liquid and an intravenous preparation, have utilized cyclodextran as a carrier molecule to enhance solubility and bioavailability. Like ketoconazole, it penetrates poorly into the cerebrospinal fluid. Itraconazole is the azole of choice for treatment of disease due to the dimorphic fungi histoplasma, *Blastomyces*, and sporothrix. Itraconazole has activity against *Aspergillus* sp, but it has been replaced by voriconazole as the azole of choice for aspergillosis. Itraconazole is used extensively in the treatment of dermatophytoses and onychomycosis.

## FLUCONAZOLE

Fluconazole displays a high degree of water solubility and good cerebrospinal fluid penetration. Unlike ketoconazole and itraconazole, its oral bioavailability is high. Drug interactions are also less common because fluconazole has the least effect of all the azoles on hepatic microsomal enzymes. Because of fewer hepatic enzyme interactions and better gastrointestinal tolerance, fluconazole has the widest therapeutic index of the azoles, permitting more aggressive dosing in a variety of fungal infections. The drug is available in oral and intravenous formulations and is used at a dosage of 100–800 mg/d.

Fluconazole is the azole of choice in the treatment and secondary prophylaxis of cryptococcal meningitis. Intravenous fluconazole has been shown to be equivalent to amphotericin B in treatment of candidemia in ICU patients with normal white blood cell counts.

Fluconazole is the agent most commonly used for the treatment of mucocutaneous candidiasis. Activity against the dimorphic fungi is limited to coccidioidal disease, and in particular for meningitis, where high doses of fluconazole often obviate the need for intrathecal amphotericin B. Fluconazole displays no activity against aspergillus or other filamentous fungi.

Prophylactic use of fluconazole has been demonstrated to reduce fungal disease in bone marrow transplant recipients and AIDS patients, but the emergence of fluconazole-resistant fungi has raised concerns about this indication.

## Voriconazole

Voriconazole is available in intravenous and oral formulations. The recommended dosage is 400 mg/d. The drug is well absorbed orally, with a bioavailability exceeding 90%, and it exhibits less protein binding than itraconazole. Metabolism is predominantly hepatic.

Voriconazole is a clinically relevant inhibitor of mammalian CYP3A4. As a result, dose reduction of a number of medications is required when voriconazole is started, including cyclosporine, tacrolimus, and HMG-CoA reductase inhibitors. Observed toxicities include rash and elevated hepatic enzymes. Visual disturbances are common, occurring in up to 30% of patients receiving intravenous voriconazole, and include blurring and changes in color vision or brightness. These visual changes usually occur immediately after a dose of voriconazole and resolve within 30 minutes. Photosensitivity dermatitis is commonly observed in patients receiving chronic oral therapy.

Voriconazole is similar to itraconazole in its spectrum of action, having excellent activity against *Candida* sp (including fluconazole-resistant species such as *C. krusei*) and the dimorphic fungi. Voriconazole is less toxic than amphotericin B and is the treatment of choice for invasive aspergillosis.

## Posaconazole

Posaconazole is the newest triazole to be licensed in the USA. It is available only in a liquid oral formulation and is used at a dosage of 800 mg/d, divided into two or three doses. Absorption is improved when taken with meals high in fat. Posaconazole is rapidly distributed to the tissues, resulting in high tissue levels but relatively low blood levels. Visual changes have not been reported, but drug interactions with increased levels of CYP3A4 substrates such as tacrolimus and cyclosporine have been documented.

Posaconazole is the broadest spectrum member of the azole family, with activity against most species of candida and aspergillus. It is the only azole with significant activity against the agents of zygomycosis and mucormycosis. It is currently licensed for salvage therapy in invasive aspergillosis, as well as prophylaxis of fungal infections during induction chemotherapy for leukemia, and for allogeneic bone marrow transplant patients with graft-versus-host disease.

## ECHINOCANDINS

Echinocandins are the newest class of antifungal agents to be developed. They are large cyclic peptides linked to a long-chain fatty acid.

**Caspofungin, micafungin, and anidulafungin** are the only licensed agents in this category of antifungals, although other drugs are under active investigation. These agents are active against candida and aspergillus, but not *C. neoformans* or the agents of zygomycosis and mucormycosis.

## Pharmacokinetics

Echinocandins are available only in intravenous formulations. Caspofungin is administered as a single loading dose of 70 mg, followed by a daily dose of 50 mg. Caspofungin is water-soluble and highly protein-bound. The half-life is 9–11 hours, and the metabolites are excreted by the kidneys and gastrointestinal tract. Dosage adjustments are required only in the presence of severe hepatic insufficiency. Micafungin displays similar properties with a half-life of 11–15 hours and is used at a dose of 150 mg/d for treatment of candida esophagitis, 100 mg/d for treatment of candidemia, and 50 mg/d for prophylaxis of fungal infections. Anidulafungin has a half-life of 24–48 hours. For esophageal candidiasis, it is administered intravenously at 100 mg on the first day and 50 mg/d thereafter for 14 days. For candidemia, a loading dose of 200 mg is recommended with 100 mg/d thereafter for at least 14 days after the last positive blood culture.

## Mechanism of Action

Echinocandins act at the level of the fungal cell wall by inhibiting the synthesis of  $\beta(1\rightarrow3)$ -glucan (Figure 48â€1). This results in disruption of the fungal cell wall and cell death.

## Adverse Effects

Echinocandin agents are extremely well tolerated, with minor gastrointestinal side effects and flushing reported infrequently. Elevated liver enzymes have been noted in several patients receiving caspofungin in combination with cyclosporine, and this combination should be avoided. Micafungin has been shown to increase levels of nifedipine, cyclosporine, and sirolimus. Anidulafungin does not seem to have significant drug interactions, but histamine release may occur during intravenous infusion.

## Clinical Use

Caspofungin is currently licensed for disseminated and mucocutaneous candida infections, as well as for empiric antifungal therapy during febrile neutropenia and has largely replaced amphotericin B for the latter indication. Note that caspofungin is licensed for use in invasive aspergillosis only as salvage therapy in patients who have failed to respond to amphotericin B, and not as primary therapy. Micafungin is licensed for mucocutaneous candidiasis, candidemia, and prophylaxis of candida infections in bone marrow transplant patients. Anidulafungin is approved for use in esophageal candidiasis and invasive candidiasis, including candidemia.

## SYSTEMIC ANTIFUNGAL DRUGS FOR MUCOCUTANEOUS INFECTIONS

### GRISEOFULVIN

Griseofulvin is a very insoluble fungistatic drug derived from a species of penicillium. Its only use is in the systemic treatment of dermatophytosis (see Chapter 61). It is administered in a microcrystalline form at a dosage of 1 g/d. Absorption is improved when it is given with fatty foods. Griseofulvin's mechanism of action at the cellular level is unclear, but it is deposited in newly forming skin where it binds to keratin, protecting the skin from new infection. Because its action is to prevent infection of these new skin structures, griseofulvin must be administered for 2â€6 weeks for skin and hair infections to allow the replacement of infected keratin by the resistant structures. Nail infections may require therapy for months to allow regrowth of the new protected nail and is often followed by relapse. Adverse effects include an allergic syndrome much like serum sickness, hepatitis, and drug interactions with warfarin and phenobarbital. Griseofulvin has been largely replaced by newer antifungal medications such as itraconazole and terbinafine.

### TERBINAFINE

Terbinafine is a synthetic allylamine that is available in an oral formulation and is used at a dosage of 250 mg/d. It is used in the treatment of dermatophytoses, especially onychomycosis (see Chapter 61). Like griseofulvin, terbinafine is a keratophilic medication, but unlike griseofulvin, it is fungicidal. Like the azole drugs, it interferes with ergosterol biosynthesis, but rather than interacting with the P450 system, terbinafine inhibits the fungal enzyme squalene epoxidase (Figure 48â€1). This leads to the accumulation of the sterol squalene, which is toxic to the organism. One tablet given daily for 12 weeks achieves a cure rate of up to 90% for onychomycosis and is more effective than griseofulvin or itraconazole. Adverse effects are rare, consisting primarily of gastrointestinal upset and headache. Terbinafine does not seem to affect the P450 system and has demonstrated no significant drug interactions to date.

## TOPICAL ANTIFUNGAL THERAPY

### NYSTATIN

Nystatin is a polyene macrolide much like amphotericin B. It is too toxic for parenteral administration and is only used topically. Nystatin is currently available in creams, ointments, suppositories, and other forms for application to skin and mucous membranes. It is not absorbed to a significant degree from skin, mucous membranes, or the gastrointestinal tract. As a result, nystatin has little toxicity, although oral use is often limited by the unpleasant taste.

Nystatin is active against most *Candida* sp and is most commonly used for suppression of local candidal infections. Some common indications include oropharyngeal thrush, vaginal candidiasis, and intertriginous candidal infections.

### TOPICAL AZOLES

The two azoles most commonly used topically are clotrimazole and miconazole; several others are available (see Preparations Available). Both are available over-the-counter and are often used for vulvovaginal candidiasis. Oral clotrimazole troches are available for treatment of oral thrush and are a pleasant-tasting alternative to nystatin. In cream form, both agents are useful for dermatophytic infections, including tinea corporis, tinea pedis, and tinea cruris. Absorption is negligible, and adverse effects are rare.

Topical and shampoo forms of ketoconazole are also available and useful in the treatment of seborrheic dermatitis and pityriasis versicolor. Several other azoles are available for topical use (see Preparations Available).

### TOPICAL ALLYLAMINES

Terbinafine and naftifine are allylamines available as topical creams (see Chapter 61). Both are effective for treatment of tinea cruris and tinea corporis. These are prescription drugs in the USA.

## SUMMARY: ANTIFUNGAL DRUGS

## Antifungal Drugs

Subclass	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
<b>Polyene macrolide</b>				
Amphotericin B	Forms pores in fungal membranes (which contain ergosterol) but not in mammalian (cholesterol-containing) membranes	Loss of intracellular contents through pores is fungicidal • broad spectrum of action	Localized and systemic candidemia • <i>Cryptococcus</i> • <i>Histoplasma</i> • <i>Blastomyces</i> • <i>Coccidioides</i> • <i>Aspergillus</i>	Oral but not absorbed • IV for systemic use • intrathecal for fungal meningitis • topical for ocular and bladder infections • duration, days • <b>Toxicity:</b> Infusion reactions • renal impairment • <b>Interactions:</b> Additive with other renal toxic drugs
<i>Lipid formulations: Lower toxicity, higher doses can be used</i>				
<b>Pyrimidine Analog</b>				
Flucytosine	Interferes with DNA and RNA synthesis selectively in fungi	Synergistic with amphotericin • systemic toxicity in host due to DNA and RNA effects	<i>Cryptococcus</i> and chromoblastomycosis infections	Oral • duration, hours • renal excretion • <b>Toxicity:</b> Myelosuppression
<b>Azoles</b>				
Ketoconazole	Blocks fungal P450 enzymes and interferes with ergosterol synthesis	Poorly selective • interferes with mammalian P450 function	Broad spectrum but toxicity restricts use to topical therapy	Oral, topical • <b>Toxicity and interactions:</b> Interferes with steroid hormone synthesis and phase I drug metabolism
Itraconazole	Same as for ketoconazole	Much more selective than ketoconazole	Broad spectrum: <i>Candida</i> , <i>Cryptococcus</i> , blastomycosis, coccidioidomycosis, histoplasmosis	Oral and IV • duration, 1-2 d • poor entry into central nervous system (CNS) • <b>Toxicity and interactions:</b> Low toxicity
<i>Fluconazole, voriconazole, posaconazole: Fluconazole has excellent CNS penetration, used in fungal meningitis</i>				
<b>Echinocandins</b>				
Caspofungin	Blocks $\beta$ -glucan synthase	Prevents synthesis of fungal cell wall	Fungicidal <i>Candida</i> sp • also used in aspergillosis	IV only • duration, 11-15 h • <b>Toxicity:</b> Minor gastrointestinal effects, flushing • <b>Interactions:</b> Increases cyclosporine levels (avoid combination)
<i>Micafungin, anidulafungin: Micafungin increases levels of nifedipine, cyclosporine, sirolimus; anidulafungin is relatively free of this interaction</i>				
<b>Allylamine</b>				
Terbinafine	Inhibits epoxidation of squalene in fungi • increased levels are toxic to them	Reduces ergosterol • prevents synthesis of fungal cell membrane	Mucocutaneous fungal infections	Oral • duration, days • <b>Toxicity:</b> Gastrointestinal upset, headache, hepatotoxicity • <b>Interactions:</b> None reported

## PREPARATIONS AVAILABLE

### Anidulafungin (Eraxis)

Parenteral: 50 mg powder for injection

### Amphotericin B

Parenteral:

Conventional formulation (Amphotericin B, Fungizone): 50 mg powder for injection

Lipid formulations:

(Abelcet): 100 mg/20 mL suspension for injection

(AmBisome): 50 mg powder for injection

(Amphotec): 50, 100 mg powder for injection

Topical: 3% cream, lotion, ointment

**Butoconazole** (Gynazole-1, Mycelex-3)

Topical: 2% vaginal cream

**Butenafine** (Lotrimin Ultra, Mentax)

Topical: 1% cream

**Caspofungin** (Cancidas)

Parenteral: 50, 70 mg powder for injection

**Clotrimazole** (generic, Lotrimin)

Topical: 1% cream, solution, lotion; 100, 200 mg vaginal suppositories

**Econazole** (generic, Spectazole)

Topical: 1% cream

**Fluconazole** (Diflucan)

Oral: 50, 100, 150, 200 mg tablets; powder for 10, 40 mg/mL suspension

Parenteral: 2 mg/mL in 100 and 200 mL vials

**Flucytosine** (Ancobon)

Oral: 250, 500 mg capsules

**Griseofulvin** (Grifulvin, Grisactin, Fulvicin P/G)

Oral microsize: 125, 250 mg tablets; 250 mg capsule, 125 mg/5 mL suspension

Oral ultramicrosize:<sup>1</sup> 125, 165, 250, 330 mg tablets

**Itraconazole** (Sporanox)

Oral: 100 mg capsules; 10 mg/mL solution

Parenteral: 10 mg/mL for IV infusion

**Ketoconazole** (generic, Nizoral)

Oral: 200 mg tablets

Topical: 2% cream, shampoo

**Miconazole** (generic, Micatin)

Topical: 2% cream, powder, spray; 100, 200 mg vaginal suppositories

**Micafungin** (Mycamine)

Parenteral: 50 mg powder for injection

**Naftifine** (Naftin)

Topical: 1% cream, gel

**Natamycin** (Natacyn)

Topical: 5% ophthalmic suspension

**Nystatin** (generic, Mycostatin)

Oral: 500,000 unit tablets

Topical: 100,000 units/g cream, ointment, powder; 100,000 units vaginal tablets

**Oxiconazole** (Oxistat)

Topical: 1% cream, lotion

**Posaconazole** (Noxafil)

Oral: suspension 40 mg/mL

**Sulconazole** (Exelderm)

Topical: 1% cream, solution

**Terbinafine** (Lamisil)

Oral: 250 mg tablets

Topical: 1% cream, gel

**Terconazole** (Terazol 3, Terazol 7)

Topical: 0.4%, 0.8% vaginal cream; 80 mg vaginal suppositories

**Tioconazole** (Vagistat-1, Monistat 1)

Topical: 6.5% vaginal ointment

**Tolnaftate** (generic, Aftate, Tinactin)

Topical: 1% cream, gel, solution, aerosol powder

**Voriconazole** (Vfend)

Oral: 50, 200 mg tablets; oral suspension 40 mg/mL

Parenteral: 200 mg vials, reconstituted to a 5 mg/mL solution

<sup>1</sup>Ultramicrosize formulations of griseofulvin are approximately 1.5 times more potent, milligram for milligram, than the microsize preparations.

## CASE STUDY

The patient described in the case study underwent extensive surgical debridement, and fungal culture of intraoperative specimens were positive for *Rhizopus* sp, one of the agents of mucormycosis. The patient was subsequently treated with a prolonged course of therapy with liposomal amphotericin B and caspofungin and subsequent chronic suppressive therapy with posaconazole.

Basic and Clinical Pharmacology > Chapter 49. Antiviral Agents >

## ACRONYMS & OTHER NAMES

**3TC** Lamivudine

**AZT** Zidovudine (previously azidothymidine)

**CMV** Cytomegalovirus

**CYP** Cytochrome P450

**d4T** Stavudine

**ddC** Zalcitabine

**ddI** Didanosine

**EBV** Epstein-Barr virus

**FTC** Emtricitabine

**HAART** Highly active antiretroviral therapy

**HBV** Hepatitis B virus

**HCV** Hepatitis C virus

**HHV-6** Human herpesvirus-6

**HIV** Human immunodeficiency virus

**HPV** Human papillomavirus

**HSV** Herpes simplex virus

**IFN** Interferon

**NNRTI** Nonnucleoside reverse transcriptase inhibitor

**NRTI** Nucleoside reverse transcriptase inhibitor

**PI** Protease inhibitor

**RSV** Respiratory syncytial virus

**SVR** Sustained antiviral response

**VZV** Varicella-zoster virus

## CASE STUDY

A 35-year-old white woman who recently tested seropositive for both HIV and hepatitis B virus surface antigen is referred for evaluation. She is feeling well overall but reports a 25-pack-year smoking history. She drinks 3–4 beers per week and has no known medication allergies. She has a history of heroin use and is currently receiving methadone. Physical examination reveals normal vital signs and no abnormalities. White blood cell count is 5800 cells/mm<sup>3</sup> with a normal differential, hemoglobin is 11.8 g/dL, all liver function tests are within normal limits, CD4 cell count is 278 cells/mm<sup>3</sup>, and viral load (HIV RNA) is 110,000 copies/mL. What other laboratory tests should be ordered? Which antiretroviral medications would you begin?

## ANTIVIRAL AGENTS: INTRODUCTION

Viruses are obligate intracellular parasites; their replication depends primarily on synthetic processes of the host cell. Therefore, to be effective, antiviral agents must either block viral entry into or exit from the cell or be active inside the host cell. As a corollary, nonselective inhibitors of virus replication may interfere with host cell function and result in toxicity.

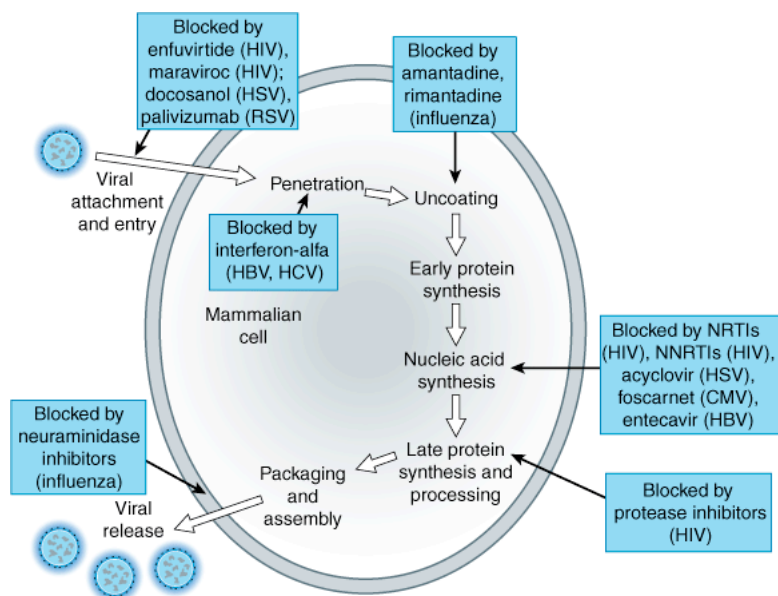

Progress in antiviral chemotherapy began in the early 1950s, when the search for anticancer drugs generated several new compounds capable of inhibiting viral DNA synthesis. The two first-generation antiviral agents, 5-iododeoxyuridine and trifluorothymidine, had poor specificity (ie, they inhibited host cell DNA as well as viral DNA) that rendered them too toxic for systemic use. However, both agents are effective when used topically for the treatment of herpes keratitis.

Knowledge of the mechanisms of viral replication has provided insights into critical steps in the viral life cycle that can serve as potential targets for antiviral therapy. Recent research has focused on the identification of agents with greater selectivity, higher potency, in vivo stability, and reduced toxicity. Antiviral therapy is now available for herpesviruses, hepatitis C virus (HCV), hepatitis B virus (HBV), papillomavirus, influenza, and human immunodeficiency virus (HIV). Antiviral drugs share the common property of being virustatic; they are active only against replicating viruses and do not affect latent virus. Whereas some infections require monotherapy for very brief periods of time (eg, acyclovir for herpes simplex virus), others require dual therapy for prolonged periods of time (interferon alfa/ribavirin for HCV), whereas still others

require multiple drug therapy for indefinite periods of time (HIV). In chronic illnesses such as viral hepatitis and HIV infection, potent inhibition of viral replication is crucial in limiting the extent of systemic damage.

Viral replication consists of several steps (Figure 49â€1): (1) attachment of the virus to receptors on the host cell surface; (2) entry of the virus through the host cell membrane; (3) uncoating of viral nucleic acid; (4) synthesis of early regulatory proteins, eg, nucleic acid polymerases; (5) synthesis of new viral RNA or DNA; (6) synthesis of late, structural proteins; (7) assembly (maturation) of viral particles; and (8) release from the cell. Antiviral agents can potentially target any of these steps.

## AGENTS TO TREAT HERPES SIMPLEX VIRUS (HSV) & VARICELLA-ZOSTER VIRUS (VZV) INFECTIONS

Three oral nucleoside analogs are licensed for the treatment of HSV and VZV infections: acyclovir, valacyclovir, and famciclovir. They have similar mechanisms of action and similar indications for clinical use; all are well tolerated. Acyclovir has been the most extensively studied; it was licensed first and is the only one of the three that is available for intravenous use in the United States. Comparative trials have demonstrated similar efficacies of these three agents for the treatment of HSV but modest superiority of famciclovir and valacyclovir for the treatment of herpes zoster. Neither valacyclovir nor famciclovir has been fully evaluated in pediatric patients; thus, neither is indicated for the treatment of varicella infection.

### ACYCLOVIR

Acyclovir (Figure 49â€2) is an acyclic guanosine derivative with clinical activity against HSV-1, HSV-2, and VZV, but it is approximately 10 times more potent against HSV-1 and HSV-2 than against VZV. In vitro activity against Epstein-Barr virus (EBV), cytomegalovirus (CMV), and human herpesvirus-6 (HHV-6) is present but weaker.

Chemical structures of some antiviral nucleoside and nucleotide analogs.

Acyclovir requires three phosphorylation steps for activation. It is converted first to the monophosphate derivative by the virus-specified thymidine kinase and then to the di- and triphosphate compounds by host cell enzymes (Figure 49â€³3). Because it requires the viral kinase for initial phosphorylation, acyclovir is selectively activatedâ€³and the active metabolite accumulatesâ€³only in infected cells. Acyclovir triphosphate inhibits viral DNA synthesis by two mechanisms: competition with deoxyGTP for the viral DNA polymerase, resulting in binding to the DNA template as an irreversible complex; and chain termination following incorporation into the viral DNA.

Mechanism of action of antiherpes agents.

The bioavailability of oral acyclovir is low (15%–20%) and is unaffected by food. An intravenous formulation is available. Topical formulations produce high concentrations in herpetic lesions, but systemic concentrations are undetectable by this route.

Acyclovir is cleared primarily by glomerular filtration and tubular secretion. The half-life is 2.5–3 hours in patients with normal renal function and 20 hours in patients with anuria. Acyclovir diffuses readily into most tissues and body fluids. Cerebrospinal fluid concentrations are 20%–50% of serum values.

Oral acyclovir has multiple uses. In first episodes of genital herpes, oral acyclovir shortens the duration of symptoms by approximately 2 days, the time to lesion healing by 4 days, and the duration of viral shedding by 7 days. In recurrent genital herpes, the time course is shortened by 1–2 days. Treatment of first-episode genital herpes does not alter the frequency or severity of recurrent outbreaks. Long-term suppression with oral acyclovir in patients with frequent recurrences of genital herpes decreases the frequency of symptomatic recurrences and of asymptomatic viral shedding, thus decreasing the rate of sexual transmission. However, outbreaks may resume upon discontinuation of suppressive acyclovir. Oral acyclovir is only modestly beneficial in recurrent herpes labialis. In contrast, acyclovir therapy significantly decreases the total number of lesions, duration of symptoms, and viral shedding in patients with varicella (if begun within 24 hours after the onset of rash) or cutaneous zoster (if begun within 72 hours). However, because VZV is less susceptible to acyclovir than HSV, higher doses are required (Table 49–1). When given prophylactically to patients undergoing organ transplantation, oral or intravenous acyclovir prevents reactivation of HSV infection.

**Table 49–1 Agents to Treat or Prevent Herpes Simplex Virus (HSV) and Varicella-Zoster Virus (VZV) Infections.**

	Route of Administration	Use	Recommended Adult Dosage and Regimen
Acyclovir <sup>1</sup>	Oral	First episode genital herpes	400 mg tid or 200 mg 5 times daily × 7–10 days
		Recurrent genital herpes	400 mg tid or 200 mg 5 times daily or 800 mg bid × 3–5 days or 800 mg tid × 2 days
		Genital herpes suppression	400 mg bid
		Herpes proctitis	400 mg 5 times daily until healed
		Orolabial herpes	400 mg 5 times daily × 5 days
		Orolabial or genital herpes suppression	400 mg bid
		Mucocutaneous herpes in the immunocompromised host	400 mg 5 times daily × 7–10 days
		Varicella	20 mg/kg (maximum 800 mg) qid × 5 days
		Zoster	800 mg 5 times daily × 7–10 days
		Intravenous	
Mucocutaneous herpes in the immunocompromised host	10 mg/kg q8h × 7–14 days		
Herpes encephalitis	10–15 mg/kg q8h × 14–21 days		

		Neonatal HSV infection	10â€”20 mg/kg q8h x 14â€”21 days
		Varicella or zoster in the immunosuppressed host	10 mg/kg q8h x 7 days
	Topical	Herpes labialis	Thin film covering lesion 5 times daily x 4 days
	Topical (5% cream)	Recurrent herpes labialis	Thin film covering lesion 5 times daily x 4 days
Famciclovir <sup>1</sup>	Oral	First episode genital herpes	250 mg tid x 7â€”10 days
		Recurrent genital herpes	125 mg bid x 3â€”5 days or 1000 mg bid x 2 doses
		Genital herpes suppression	250 mg bid
		Orolabial herpes	500 mg bid x 7 days (primary); 1500 mg once (recurrent)
		Orolabial or genital herpes in the immunosuppressed host	500 mg bid x 7â€”10 days
		Orolabial or genital herpes suppression	250â€”500 mg bid
		Zoster	500 mg tid x 7 days
Valacyclovir <sup>1</sup>	Oral	First episode genital herpes	1 g bid x 10 days
		Recurrent genital herpes	500 mg bid x 3 days
		Genital herpes suppression	500â€”1000 mg daily
		Orolabial herpes	2 g bid x 2 doses
		Orolabial or genital herpes in the immunosuppressed host	1 g bid x 7â€”10 days
		Orolabial or genital herpes suppression	500â€”1000 mg daily
		Zoster	1 g tid x 7 days
Foscarnet <sup>1</sup>	Intravenous	Acyclovir-resistant HSV and VZV infections	40 mg/kg q8h until healed
Docosanol	Topical	Herpes labialis	Thin film covering lesion 5 times daily until healed
Penciclovir	Topical (1% cream)	Recurrent herpes labialis	Thin film covering lesion every 2 hours x 4 days
Trifluridine	Topical	Herpes keratitis	1 drop 9 times daily for 7 days
		Acyclovir-resistant HSV infection	Thin film covering lesion 5 times daily until healed

<sup>1</sup>Dosage must be reduced in patients with renal insufficiency.

Intravenous acyclovir is the treatment of choice for herpes simplex encephalitis, neonatal HSV infection, and serious HSV or VZV infections (Table 49â€”1). In immunocompromised patients with VZV infection, intravenous acyclovir reduces the incidence of cutaneous and visceral dissemination.

Topical acyclovir is substantially less effective than oral therapy for primary HSV infection. It is of no benefit in treating recurrent genital herpes.

Resistance to acyclovir can develop in HSV or VZV through alteration in either the viral thymidine kinase or the DNA polymerase, and clinically resistant infections have been reported in immunocompromised hosts. Most clinical isolates are resistant on the basis of deficient thymidine kinase activity and thus are cross-resistant to valacyclovir, famciclovir, and ganciclovir. Agents such as foscarnet, cidofovir, and trifluridine do not require activation by viral thymidine kinase and thus have preserved activity against the most prevalent acyclovir-resistant strains (Figure 49â€”3).

Acyclovir is generally well tolerated. Nausea, diarrhea, and headache have occasionally been reported. Intravenous infusion may be associated with reversible renal (ie, crystalline nephropathy or interstitial nephritis) or neurologic (eg, tremors, delirium, seizures) toxicity. However, these are uncommon with adequate hydration and avoidance of rapid infusion rates. High doses of acyclovir cause chromosomal damage and testicular atrophy in rats, but there has been no evidence of teratogenicity, reduction in sperm production, or cytogenetic alterations in peripheral blood lymphocytes in patients receiving long-term daily suppression of genital herpes for more than 10 years.

Concurrent use of nephrotoxic agents may enhance the potential for nephrotoxicity. Probenecid and cimetidine decrease acyclovir clearance and increase exposure. Somnolence and lethargy may occur in patients receiving zidovudine and acyclovir.

## VALACYCLOVIR

Valacyclovir is the L-valyl ester of acyclovir (Figure 49â€”2). It is rapidly converted to acyclovir after oral administration via first-pass enzymatic hydrolysis in the liver and intestine, resulting in serum levels that are three to five times greater than those achieved with oral acyclovir and approximate those achieved with intravenous acyclovir. Oral bioavailability is 54â€”70%, and cerebrospinal fluid levels are about 50% of those in serum. Elimination half-life is 2.5â€”3.3 hours.

Approved uses of valacyclovir include treatment of first or recurrent genital herpes, suppression of frequently recurring genital herpes, as a 1-day treatment for orolabial herpes, and as treatment for herpes zoster (Table 49â€”1). Once-daily dosing of valacyclovir for chronic suppression in persons with recurrent genital herpes has been shown to markedly decrease the risk of sexual transmission. In comparative trials with acyclovir for the treatment of patients with zoster, rates of cutaneous healing were similar, but valacyclovir was associated with a shorter duration of zoster-associated pain. Valacyclovir has also been shown to be effective in preventing cytomegalovirus (CMV) disease after organ transplantation when compared with placebo.

Valacyclovir is generally well tolerated, although nausea, vomiting, or rash occasionally occur. At high doses, confusion, hallucinations, and seizures have been reported. AIDS patients who received high-dosage valacyclovir chronically (ie, 8 g/d) had an increased incidence of gastrointestinal intolerance as well as thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome; this dose was associated with confusion and hallucinations in transplant patients.

## FAMCICLOVIR

Famciclovir is the diacetyl ester prodrug of 6-deoxypenciclovir, an acyclic guanosine analog (Figure 49â€²2). After oral administration, famciclovir is rapidly deacetylated and oxidized by first-pass metabolism to penciclovir. It is active in vitro against HSV-1, HSV-2, VZV, EBV, and HBV. As with acyclovir, activation by phosphorylation is catalyzed by the virus-specified thymidine kinase in infected cells, followed by competitive inhibition of the viral DNA polymerase to block DNA synthesis. Unlike acyclovir, however, penciclovir does not cause chain termination. Penciclovir triphosphate has lower affinity for the viral DNA polymerase than acyclovir triphosphate, but it achieves higher intracellular concentrations. The most commonly encountered clinical mutants of HSV are thymidine kinase-deficient; these are cross-resistant to acyclovir and famciclovir.

The bioavailability of penciclovir from orally administered famciclovir is 70%. The intracellular half-life of penciclovir triphosphate is prolonged, at 7â€²20 hours. Penciclovir is excreted primarily in the urine.

Oral famciclovir is effective for the treatment of first and recurrent genital herpes, for chronic daily suppression of genital herpes, for treatment of herpes labialis, and for the treatment of acute zoster (Table 49â€²1). One-day usage of famciclovir significantly accelerates time to healing of recurrent genital herpes and of herpes labialis. Comparison of famciclovir to valacyclovir for treatment of herpes zoster in immunocompetent patients showed similar rates of cutaneous healing and pain resolution; both agents shortened the duration of zoster-associated pain compared with acyclovir.

Oral famciclovir is generally well tolerated, although headache, diarrhea, and nausea may occur. As with acyclovir, testicular toxicity has been demonstrated in animals receiving repeated doses. However, men receiving daily famciclovir (250 mg every 12 hours) for 18 weeks had no changes in sperm morphology or motility. The incidence of mammary adenocarcinoma was increased in female rats receiving famciclovir for 2 years.

## PENCICLOVIR

The guanosine analog penciclovir, the active metabolite of famciclovir, is available for topical use. Penciclovir cream (1%) is effective for the treatment of recurrent herpes labialis (Table 49â€²1). When applied within 1 hour of the onset of prodromal symptoms and continued every 2 hours during waking hours for 4 days, median time until healing was shortened by 17 hours compared with placebo. Adverse effects are uncommon, although application site reactions occur in about 1%.

## DOCOSANOL

Docosanol is a saturated 22-carbon aliphatic alcohol that inhibits fusion between the plasma membrane and the HSV envelope, thereby preventing viral entry into cells and subsequent viral replication. Topical docosanol 10% cream is available without a prescription; application site reactions occur in approximately 2%. When applied within 12 hours of the onset of prodromal symptoms, five times daily, median healing time was shortened by 18 hours compared with placebo in recurrent orolabial herpes.

## TRIFLURIDINE

Trifluridine (trifluorothymidine) is a fluorinated pyrimidine nucleoside that inhibits viral DNA synthesis in HSV-1, HSV-2, CMV, vaccinia, and some adenoviruses. It is phosphorylated intracellularly by host cell enzymes, and then competes with thymidine triphosphate for incorporation by the viral DNA polymerase (Figure 49â€²3). Incorporation of trifluridine triphosphate into both viral and host DNA prevents its systemic use. Application of a 1% solution is effective in treating keratoconjunctivitis and recurrent epithelial keratitis due to HSV-1 or HSV-2. Cutaneous application of trifluridine solution, alone or in combination with interferon alfa, has been used successfully in the treatment of acyclovir-resistant HSV infections.

## AGENTS TO TREAT CYTOMEGALOVIRUS (CMV) INFECTIONS

CMV infections occur primarily in the setting of advanced immunosuppression and are typically due to reactivation of latent infection. Dissemination of infection results in end-organ disease, including retinitis, colitis, esophagitis, central nervous system disease, and pneumonitis. Although the incidence in HIV-infected patients has markedly decreased with the advent of potent antiretroviral therapy, reactivation of CMV infection after organ transplantation is still clinically prevalent.

The availability of oral valganciclovir and the ganciclovir intraocular implant has decreased the usage of intravenous ganciclovir, intravenous foscarnet, and intravenous cidofovir for the treatment of end-organ CMV disease (Table 49â€²2). Oral valganciclovir has largely replaced oral ganciclovir because of its lower pill burden.

**Table 49â€²2 Agents to Treat Cytomegalovirus (CMV) Infection.**

Agent	Route of Administration	Use	Recommended Adult Dosage <sup>1</sup>
Valganciclovir	Oral	CMV retinitis treatment	Induction: 900 mg bid Maintenance: 900 mg daily
	Oral	CMV prophylaxis (transplant patients)	900 mg daily
Ganciclovir	Intravenous	CMV retinitis treatment	Induction: 5 mg/kg q12h Maintenance: 5 mg/kg/d or 6 mg/kg five times per week
		CMV prophylaxis	1 g tid
	Intraocular implant	CMV retinitis treatment	1 g tid
		CMV retinitis treatment	4.5 mg every 5â€²8 months
Foscarnet	Intravenous	CMV retinitis treatment Induction: 60 mg/kg q8h or 90 mg/kg q12h Maintenance: 90â€²120 mg/kg/d	
Cidofovir	Intravenous	CMV retinitis treatment Induction: 5 mg/kg every 7 days Maintenance: 5 mg/kg every 14 days	

<sup>1</sup>Dosage must be reduced in patients with renal insufficiency.

## **GANCICLOVIR**

Ganciclovir is an acyclic guanosine analog (Figure 49â€²2) that requires activation by triphosphorylation before inhibiting the viral DNA polymerase. Initial phosphorylation is catalyzed by the virus-specified protein kinase phosphotransferase UL97 in CMV-infected cells. The activated compound competitively inhibits viral DNA polymerase and causes termination of viral DNA elongation (Figure 49â€²3). Ganciclovir has in vitro activity against CMV, HSV, VZV, EBV, HHV-6, and HHV-8. Its activity against CMV is up to 100 times greater than that of acyclovir.

Ganciclovir may be administered intravenously, orally, or via intraocular implant. The bioavailability of oral ganciclovir is poor. Cerebrospinal fluid concentrations are approximately 50% of those in serum. The elimination half-life is 4 hours, and the intracellular half-life is prolonged at 16â€²24 hours. Clearance of the drug is linearly related to creatinine clearance. Ganciclovir is readily cleared by hemodialysis.

Intravenous ganciclovir has been shown to delay progression of CMV retinitis in patients with AIDS. Dual therapy with foscarnet and ganciclovir has been shown to be more effective in delaying progression of retinitis than either drug administered alone (see Foscarnet), although adverse effects are compounded. Intravenous ganciclovir is also used to treat CMV colitis, esophagitis, and pneumonitis (the latter often treated with ganciclovir in combination with intravenous cytomegalovirus immunoglobulin) in immunocompromised patients. Intravenous ganciclovir, followed by either oral ganciclovir or high-dose oral acyclovir, reduces the risk of CMV infection in transplant recipients. Oral ganciclovir is indicated for prevention of end-organ CMV disease in AIDS patients and as maintenance therapy of CMV retinitis after induction. Although less effective than intravenous ganciclovir, the risk of myelosuppression and of catheter-related complications is diminished. The risk of Kaposi's sarcoma is reduced in AIDS patients receiving long-term ganciclovir, presumably because of in vitro activity against HHV-8.

Ganciclovir may also be administered intraocularly to treat CMV retinitis, either by direct intravitreal injection or by intraocular implant. The implant has been shown to delay progression of retinitis to a greater degree than systemic ganciclovir therapy. Surgical replacement is required at intervals of 5â€²8 months. Concurrent therapy with a systemic anti-CMV agent is recommended to prevent other sites of end-organ CMV disease.

Resistance to ganciclovir increases with duration of usage. The more common mutation, in UL97, results in decreased levels of the triphosphorylated (ie, active) form of ganciclovir. The less common UL54 mutation in DNA polymerase results in higher levels of resistance and potential cross-resistance with cidofovir and foscarnet. Antiviral susceptibility testing is recommended in patients in whom resistance is suspected clinically, as is the substitution of alternative therapies and concomitant reduction in immunosuppressive therapies, if possible. The addition of CMV hyperimmune globulin may also be considered.

The most common adverse effect of systemic ganciclovir treatment, particularly after intravenous administration, is myelosuppression. Myelosuppression may be additive in patients receiving concurrent zidovudine, azathioprine, or mycophenolate mofetil. Other potential adverse effects are nausea, diarrhea, fever, rash, headache, insomnia, and peripheral neuropathy. Central nervous system toxicity (confusion, seizures, psychiatric disturbance) and hepatotoxicity have been rarely reported. Ganciclovir is mutagenic in mammalian cells and carcinogenic and embryotoxic at high doses in animals and causes aspermatogenesis; the clinical significance of these preclinical data is unclear.

Levels of ganciclovir may rise in patients concurrently taking probenecid or trimethoprim. Concurrent use of ganciclovir with didanosine may result in increased levels of didanosine.

## **VALGANCICLOVIR**

Valganciclovir is an L-valyl ester prodrug of ganciclovir that exists as a mixture of two diastereomers (Figure 49â€²2). After oral administration, both diastereomers are rapidly hydrolyzed to ganciclovir by intestinal and hepatic esterases.

Valganciclovir is well absorbed and rapidly metabolized in the intestinal wall and liver to ganciclovir; no other metabolites have been detected. The absolute bioavailability of oral valganciclovir is 60%; it is recommended that the drug be taken with food. The AUC<sub>0â€²24h</sub> resulting from valganciclovir (900 mg once daily) is similar to that after 5 mg/kg once daily of intravenous ganciclovir and approximately 1.65 times that of oral ganciclovir. The major route of elimination is renal, through glomerular filtration and active tubular secretion. Plasma concentrations of valganciclovir are reduced approximately 50% by hemodialysis.

Valganciclovir is indicated for the treatment of CMV retinitis in patients with AIDS and for the prevention of CMV disease in high-risk kidney, heart, and kidney-pancreas transplant patients. Adverse effects, drug interactions, and resistance patterns are the same as those associated with ganciclovir.

## **FOSCARNET**

Foscarnet (phosphonoformic acid) is an inorganic pyrophosphate analog (Figure 49â€²2) that inhibits viral DNA polymerase, RNA polymerase, and HIV reverse transcriptase directly without requiring activation by phosphorylation. Foscarnet blocks the pyrophosphate binding site of these enzymes and inhibits cleavage of pyrophosphate from deoxynucleotide triphosphates. It has in vitro activity against HSV, VZV, CMV, EBV, HHV-6, HHV-8, and HIV-1.

Foscarnet is available in an intravenous formulation only; poor oral bioavailability and gastrointestinal intolerance preclude oral use. Cerebrospinal fluid concentrations are 43â€²67% of steady-state serum concentrations. Although the mean plasma half-life is 3â€²6.8 hours, up to 30% of foscarnet may be deposited in bone, with a half-life of several months. The clinical repercussions of this are unknown. Clearance of foscarnet is primarily renal and is directly proportional to creatinine clearance. Serum drug concentrations are reduced approximately 50% by hemodialysis.

Foscarnet is effective in the treatment of CMV retinitis, CMV colitis, CMV esophagitis, acyclovir-resistant HSV infection, and acyclovir-resistant VZV infection. The dosage of foscarnet must be titrated according to the patient's calculated creatinine clearance before each infusion. Use of an infusion pump to control the rate of infusion is important to prevent toxicity, and large volumes of fluid are required because of the drug's poor solubility. The combination of ganciclovir and foscarnet is synergistic in vitro against CMV and has been shown to be superior to either agent alone in delaying progression of retinitis; however, toxicity is also increased when these agents are administered concurrently. As with ganciclovir, a decrease in the incidence of Kaposi's sarcoma has been observed in patients who have received long-term foscarnet.

Foscarnet has been administered intravitreally for the treatment of CMV retinitis in patients with AIDS, but data regarding efficacy and safety are incomplete.

Resistance to foscarnet in HSV and CMV isolates is due to point mutations in the DNA polymerase gene and is typically associated with prolonged or repeated exposure to the drug. Mutations in the HIV-1 reverse transcriptase gene have also been described. Although foscarnet-resistant CMV isolates are typically cross-resistant to ganciclovir, foscarnet activity is usually maintained against ganciclovir- and cidofovir-resistant isolates of CMV.

Potential adverse effects of foscarnet include renal impairment, hypo- or hypercalcemia, hypo- or hyperphosphatemia, hypokalemia, and hypomagnesemia. Saline preloading helps to prevent nephrotoxicity, as does avoidance of concomitant administration of drugs with nephrotoxic potential (eg, amphotericin B, pentamidine, aminoglycosides). The risk of severe hypocalcemia, caused by chelation of divalent cations, is increased with concomitant use of pentamidine. Penile ulcerations associated with foscarnet therapy may be due to high levels of ionized drug in the urine. Nausea, vomiting, anemia, elevation of liver enzymes, and fatigue have been reported; the risk of anemia may be additive in patients receiving concurrent zidovudine. Central nervous system toxicities include headache, hallucinations, and seizures; seizures may be increased with concurrent use of imipenem. Foscarnet caused chromosomal damage in preclinical studies.

## CIDOFOVIR

Cidofovir (Figure 49â€³2) is an acyclic cytosine nucleotide analog with in vitro activity against CMV, HSV-1, HSV-2, VZV, EBV, HHV-6, HHV-8, adenovirus, poxviruses, polyomaviruses, and human papillomavirus. In contrast to ganciclovir, phosphorylation of cidofovir to the active diphosphate is independent of viral enzymes (Figure 49â€³3); thus activity is maintained against thymidine kinase-deficient or -altered strains of CMV or HSV. Cidofovir diphosphate acts both as a potent inhibitor of and as an alternative substrate for viral DNA polymerase, competitively inhibiting DNA synthesis and becoming incorporated into the viral DNA chain. Cidofovir-resistant isolates tend to be cross-resistant with ganciclovir but retain susceptibility to foscarnet.

Although the terminal half-life of cidofovir is ~ 2.6 hours, the active metabolite, cidofovir diphosphate, has a prolonged intracellular half-life of 17â€³65 hours, thus allowing infrequent dosing. A separate metabolite, cidofovir phosphocholine, has a half-life of at least 87 hours and may serve as an intracellular reservoir of active drug. Cerebrospinal fluid penetration is poor. Elimination is by active renal tubular secretion. High-flux hemodialysis has been shown to reduce the serum levels of cidofovir by approximately 75%.

Intravenous cidofovir is effective for the treatment of CMV retinitis and is used experimentally to treat adenovirus infections. Intravenous cidofovir must be administered with high-dose probenecid (2 g at 3 hours before the infusion and 1 g at 2 and 8 hours after), which blocks active tubular secretion and decreases nephrotoxicity. Cidofovir dosage must be adjusted for alterations in the calculated creatinine clearance or for the presence of urine protein before each infusion, and aggressive adjunctive hydration is required. Initiation of cidofovir therapy is contraindicated in patients with existing renal insufficiency. Direct intravitreal administration of cidofovir is not recommended because of ocular toxicity.

The primary adverse effect of intravenous cidofovir is a dose-dependent proximal tubular nephrotoxicity, which may be reduced with prehydration using normal saline. Proteinuria, azotemia, metabolic acidosis, and Fanconi's syndrome may occur. Concurrent administration of other potentially nephrotoxic agents (eg, amphotericin B, aminoglycosides, nonsteroidal anti-inflammatory drugs, pentamidine, foscarnet) should be avoided. Prior administration of foscarnet may increase the risk of nephrotoxicity. Other potential adverse effects include uveitis, ocular hypotony, and neutropenia (15â€³24%). Concurrent probenecid use may result in other toxicities or drug-drug interactions (see Chapter 36). Cidofovir is mutagenic, gonadotoxic, and embryotoxic and caused mammary adenocarcinomas in rats.

## INVESTIGATIONAL AGENTS

The benzimidazole riboside **maribavir** is under active clinical investigation as an anti-CMV agent. Unlike currently available agents that inhibit CMV DNA polymerase, this agent inhibits viral DNA assembly as well as egress of the viral capsid from the nucleus of infected cells.

## ANTIRETROVIRAL AGENTS

Substantial advances have been made in antiretroviral therapy since the introduction of the first agent, zidovudine, in 1987 (Table 49â€³3). Greater knowledge of viral dynamics through the use of viral load and resistance testing has made clear that combination therapy with maximally potent agents will reduce viral replication to the lowest possible level and decrease the likelihood of emergence of resistance. Thus, administration of highly active antiretroviral therapy (HAART), typically comprising a combination of three to four antiretroviral agents, has become the standard of care. Viral susceptibility to specific agents varies among patients and may change with time, owing to development of resistance. Therefore, such combinations must be chosen with care and tailored to the individual, as must changes to a given regimen. In addition to potency and susceptibility, important factors in the selection of agents for any given patient are tolerability, convenience, and optimization of adherence.

**Table 49â€³3 Currently Available Antiretroviral Agents.**

Agent	Class of Agent	Recommended Adult Dosage	Administration Recommendation	Characteristic Adverse Effects	Comments
Abacavir	NRTI <sup>1</sup>	300 mg bid	Testing to rule out the presence of the HLA-B*5701 allele is recommended prior to the initiation of therapy	Rash, hypersensitivity reaction, nausea. Possible increase in myocardial infarction	Avoid alcohol
Atazanavir	PI <sup>2</sup>	400 mg daily or 300 mg daily with ritonavir 100 daily. Adjust dose in hepatic insufficiency	Take with food. Separate dosing from ddI or antacids by 1 h. Separate dosing from cimetidine and other acid-reducing agents by 12 h	Nausea, vomiting, diarrhea, abdominal pain, headache, peripheral neuropathy, skin rash, indirect hyperbilirubinemia, prolonged PR and/or QT <sub>c</sub> interval	See footnote 4 for contraindicated medications. Also avoid indinavir, irinotecan, and omeprazole. Avoid in severe hepatic insufficiency
Darunavir	PI <sup>2</sup>	600 mg bid with ritonavir 100 mg bid	Take with food	Diarrhea, headache, nausea, rash, hyperlipidemia, ↑ liver enzymes, ↑ serum amylase	Avoid in patients with sulfa allergy. See footnote 4 for contraindicated medications
Delavirdine	NNRTI	400 mg tid	Separate dosing from ddI or antacids by 1 h	Rash, ↑ liver enzymes, headache, nausea, diarrhea	See footnote 4 for contraindicated medications. Also avoid concurrent fosamprenavir and rifabutin. Teratogenic in rats
Didanosine (ddI)	NRTI <sup>1</sup>	Tablets, 400 mg daily, <sup>3</sup>	30 min before or 2 h after	Peripheral neuropathy,	Avoid concurrent neuropathic drugs (eg,

		adjusted for weight. Buffered powder, 250 mg bid <sup>3</sup>	meals. Separate dosing from fluoroquinolones and tetracyclines by 2 h	pancreatitis, diarrhea, nausea, hyperuricemia. Possible increase in myocardial infarction	stavudine, zalcitabine, isoniazid), ribavirin, and alcohol. Do not administer with tenofovir
Efavirenz	NNRTI	600 mg daily	Take on empty stomach. Bedtime dosing recommended initially to minimize central nervous system side effects	Central nervous system effects, rash, ↑ liver enzymes, headache, nausea	See footnote 4 for contraindicated medications. Teratogenic in primates
Emtricitabine	NRTI <sup>1</sup>	200 mg daily <sup>3</sup>	Oral solution should be refrigerated	Headache, diarrhea, nausea, asthenia, skin hyperpigmentation	Do not administer concurrent lamivudine. Avoid disulfiram and metronidazole with oral solution
Enfuvirtide	Fusion inhibitor	90 mg subcutaneously bid	Store at room temperature as a powder; refrigerate once reconstituted	Local injection site reactions, hypersensitivity reaction	
Etravirine	NNRTI	200 mg bid	Take after a meal; do not take on an empty stomach.	Rash, nausea, diarrhea	See footnote 4 for contraindicated medications. Do not administer with other NNRTIs, indinavir, atazanavir-ritonavir, fosamprenavir-ritonavir, tipranavir-ritonavir, or any unboosted PI
Fosamprenavir	pI <sup>2</sup>	1400 mg bid or 700 mg bid with ritonavir 100 mg bid or 1400 mg daily with ritonavir 100 mg daily. Adjust dose in hepatic insufficiency	Separate dosing from antacids by 2 h. Avoid concurrent high-fat meals	Diarrhea, nausea, vomiting, hypertriglyceridemia, rash, headache, perioral paresthesias, ↑ liver enzymes	See footnote 4 for contraindicated medications. Do not administer with lopinavir/ritonavir or in severe hepatic insufficiency. Also avoid cimetidine, disulfiram, metronidazole, vitamin E, ritonavir oral solution, and alcohol when using the oral solution
Indinavir	pI <sup>2</sup>	800 mg tid or 800 mg bid with ritonavir 100 mg bid. Adjust dose in hepatic insufficiency	Best on an empty stomach. Drink at least 48 oz liquid daily. Separate dosing from ddI by 1 h. Store in original container, which contains desiccant	Nephrolithiasis, nausea, indirect hyperbilirubinemia, headache, asthenia, blurred vision	See footnote 4 for contraindicated medications. Also avoid efavirenz
Lamivudine	NRTI <sup>1</sup>	150 mg bid or 300 mg daily <sup>3</sup>		Nausea, headache, dizziness, fatigue	Do not administer with zalcitabine
Lopinavir/ritonavir	pI/pI <sup>2</sup>	400 mg/100 mg bid or 800 mg/200 mg daily. May need dose adjustment in hepatic insufficiency	Take with food. Separate dosing from ddI by 1 h. Store capsules and solution in refrigerator	Diarrhea, abdominal pain, nausea, hypertriglyceridemia, headache, ↑ liver enzymes,	See footnote 4 for contraindicated medications. Also avoid fosamprenavir. Avoid disulfiram and metronidazole with oral solution
Maraviroc	CCR5 inhibitor	300 mg bid		Muscle and joint pain, diarrhea, sleep disturbance, ↑ liver enzymes	See footnote 4 for medications that must be co-administered with caution. Decrease dose to 150 mg bid with CYP3A inhibitors and increase to 600 mg bid with CYP3A inducers. Avoid rifampin
Nelfinavir	pI <sup>2</sup>	750 mg tid or 1250 mg bid	Take with food	Diarrhea, nausea, flatulence	See footnote 4 for contraindicated medications
Nevirapine	NNRTI	200 mg bid. Adjust dose in hepatic insufficiency	Dose-escalate from 200 mg daily over 14 days to decrease frequency of rash	Rash, hepatitis (occasionally fulminant), nausea, headache	See footnote 4 for contraindicated medications
Raltegravir	Integrase inhibitor	400 mg bid	Separate dosing from antacids	Diarrhea, nausea, fatigue, headache, dizziness, muscle aches, ↑ creatine kinase	Avoid rifampin
Ritonavir	pI <sup>2</sup>	600 mg bid	Take with food. Separate dosing with ddI by 2 h. Dose-escalate from 300 mg bid over 1-2 weeks to improve tolerance. Refrigerate capsules but not oral solution	Nausea, diarrhea, paresthesias, hepatitis	See footnote 4 for contraindicated medications
Saquinavir	pI <sup>2</sup>	Tablets and hard gel capsules: 600 mg tid or 1000 mg bid with ritonavir 100 mg bid	Take within 2 h of a full meal. Refrigeration recommended	Nausea, diarrhea, rhinitis, abdominal pain, dyspepsia, rash	See footnote 4 for contraindicated medications. Avoid in severe hepatic insufficiency. Use sunscreen owing to an increase in photosensitivity. Avoid concomitant garlic capsules
Stavudine	NRTI <sup>1</sup>	Immediate release: 30-40 mg bid, depending on weight <sup>3</sup>		Peripheral neuropathy, lipodystrophy, hyperlipidemia, rapidly	Avoid concurrent zidovudine and neuropathic drugs (eg, ddI, zalcitabine, isoniazid)

		Extended-release: 75â€”100 mg/d, depending on weight <sup>3</sup>		progressive ascending neuromuscular weakness (rare), pancreatitis	
Tenofovir	NRTI <sup>1</sup>	300 mg qd <sup>3</sup>	Take with food.	Nausea, diarrhea, vomiting, flatulence, headache, renal insufficiency	Avoid concurrent atazanavir, probenecid, didanosine
Tipranavir	PI <sup>2</sup>	Must be taken with ritonavir to achieve effective levels: tipranavir 500 mg bid/ritonavir 200 mg bid. Avoid use in hepatic insufficiency. Approved for pediatric usage	Take with food. Separate from ddI by at least 2 h. Avoid antacids. Avoid in patients with sulfa allergy. Refrigeration required	Diarrhea, nausea, vomiting, abdominal pain, rash, $\uparrow$ liver enzymes, hypercholesterolemia, hypertriglyceridemia	See footnote 4 for contraindicated medications. Avoid concurrent fosamprenavir, saquinavir. Do not administer to patients at risk for bleeding
Zalcitabine	NRTI <sup>1</sup>	0.75 mg tid <sup>3</sup>	Administer 1 h before or 2 h after an antacid	Peripheral neuropathy; oral ulcerations, pancreatitis, headache, nausea, rash, arthralgias	Avoid concurrent cimetidine; avoid concurrent neuropathic drugs (eg, ddI, zalcitabine, isoniazid). Do not administer with lamivudine
Zidovudine	NRTI <sup>1</sup>	200 mg tid or 300 mg bid <sup>3</sup>		Macrocytic anemia, neutropenia, nausea, headache, insomnia, asthenia	Avoid concurrent stavudine and myelosuppressive drugs (eg, ganciclovir, ribavirin)

<sup>1</sup>All NRTI agents, as well as tenofovir, carry the risk of lactic acidosis with hepatic steatosis as a potential adverse event.

<sup>2</sup>All PI agents, with the possible exception of fosamprenavir, carry the risk of hyperlipidemia, fat maldistribution, hyperglycemia, and insulin resistance as a potential adverse event.

<sup>3</sup>Adjust dose in renal insufficiency.

<sup>4</sup>Because of altered systemic exposures, contraindicated concurrent drugs generally include anti-arrhythmics (flecainide, propafenone), antihistamines (astemizole, terfenadine), sedative-hypnotics (alprazolam, diazepam, flurazepam, midazolam, triazolam, trazodone, clorazepate), neuroleptics (pimozide), ergot alkaloid derivatives, HMG CoA reductase inhibitors (atorvastatin, simvastatin, lovastatin, rosuvastatin), anticonvulsants (phenobarbital, phenytoin), oral contraceptives (ethinyl estradiol/norethidrone acetate), cisapride, rifampin, rifapentine, and St. John's wort. Drugs that should be used with caution owing to altered levels include amiodarone, bepridil, quinidine, lidocaine, nifedipine, nicardipine, felodipine, sildenafil, vardenafil, tadalafil, warfarin, levodopa, tacrolimus, cyclosporine, rapamycin, voriconazole, itraconazole, ketoconazole, astemizole, carbamazepine, desipramine, bupropion, dofetilide, fluticasone, atovaquone, dapson, dexamethasone, methadone, omeprazole, and lansoprazole. The dosages of rifabutin and clarithromycin should be decreased when administered concurrently.

NNRTI, nonnucleoside reverse transcriptase inhibitor; NRTI, nucleoside reverse transcriptase inhibitor; PI, protease inhibitor; RTI, reverse transcriptase inhibitor.

The retroviral genomic RNA serves as the template for synthesis of a double-stranded DNA copy, the provirus (Figure 49â€”4). Synthesis of the provirus is mediated by a virus-encoded RNA-dependent DNA polymerase, or "reverse transcriptase." The provirus is translocated to the nucleus and is integrated into host DNA. Transcription of this integrated DNA is regulated primarily by cellular transcriptional machinery.

Life cycle of HIV. Binding of viral glycoproteins to host cell CD4 and chemokine receptors precedes fusion and entry into the cell. After uncoating, reverse transcription copies the single-stranded HIV RNA genome into double-stranded DNA, which is integrated into the host cell genome. Gene transcription by host cell enzymes produces messenger RNA, which is translated into proteins that assemble into immature noninfectious virions that bud from the host cell membrane. Maturation into fully infectious virions is through proteolytic cleavage. NNRTIs, nonnucleoside reverse transcriptase inhibitors; NRTIs, nucleoside/nucleotide reverse transcriptase inhibitors.

Six classes of antiretroviral agents are currently available for use: nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), fusion inhibitors, CCR5 receptor antagonists, and integrase inhibitors. As new agents have become available, several older ones have had diminished usage, because of either suboptimal safety profile or inferior antiviral potency. It is important to recognize that the high rate of mutation of HIV-1 per replication cycle results in a great potential for genotypic variation. Genotypic resistance has been reported for each of the antiretroviral agents currently in use. Treatment that slows or stops replication is critical in reducing the number of cumulative mutations, as is the use of combinations of agents with differing susceptibility patterns.

### Nucleoside & Nucleotide Reverse Transcriptase Inhibitors

The NRTIs act by competitive inhibition of HIV-1 reverse transcriptase; incorporation into the growing viral DNA chain results in premature chain termination due to inhibition of binding with the incoming nucleotide (Figure 49â€4). Each requires intracytoplasmic activation via phosphorylation by cellular enzymes to the triphosphate form. Most have activity against HIV-2 as well as HIV-1.

Typical resistance mutations include M184V, L74V, D67N, and M41L. Lamivudine or emtricitabine therapy tends to select rapidly for the M184V mutation in regimens that are not fully suppressive; however, although this mutation confers reduced susceptibility to abacavir, didanosine, and zalcitabine, its presence may restore phenotypic susceptibility to zidovudine. The K65R mutation is associated with reduced susceptibility to tenofovir, abacavir, lamivudine, and emtricitabine.

All NRTIs may be associated with mitochondrial toxicity, probably owing to inhibition of mitochondrial DNA polymerase gamma. Less commonly, lactic acidosis with hepatic steatosis may occur, which can be fatal. NRTI treatment should be suspended in the setting of rapidly rising aminotransferase levels, progressive hepatomegaly, or metabolic acidosis of unknown cause. The thymidine analogues zidovudine and stavudine may be particularly associated with dyslipidemia and insulin resistance. Also, recent evidence suggests an increased risk of myocardial infarction in patients receiving abacavir or didanosine; this bears further investigation.

## ABACAVIR

Abacavir is a guanosine analog (Figure 49â€²2) that is well absorbed following oral administration (83%) and is unaffected by food. The serum half-life is 1.5 hours; the intracellular half-life of 3.3 hours necessitates twice-daily dosing. The drug undergoes hepatic glucuronidation and carboxylation. Cerebrospinal fluid levels are approximately one third those of plasma.

Abacavir is often co-administered with lamivudine, and a combination formulation is available.

High-level resistance to abacavir appears to require at least two or three concomitant mutations and thus tends to develop slowly.

Hypersensitivity reactions, occasionally fatal, have been reported in 3â€²5% of patients receiving abacavir. Symptoms, which generally occur within the first 6 weeks of therapy, include fever, malaise, nausea, vomiting, diarrhea, and anorexia. Respiratory symptoms such as dyspnea, pharyngitis, and cough may also be present, and skin rash occurs in about 50% of patients. Laboratory abnormalities such as mildly elevated serum aminotransferase or creatine kinase levels may be present but are nonspecific. Although the syndrome tends to resolve quickly with discontinuation of medication, rechallenge with abacavir results in return of symptoms within hours and may be fatal. Testing for the HLA-B\*5701 allele before initiation of abacavir therapy is recommended to identify patients with an increased risk for an abacavir-associated hypersensitivity reaction.

Other potential adverse events are rash, fever, nausea, vomiting, diarrhea, headache, dyspnea, fatigue, and pancreatitis (rare). Abacavir should be used cautiously in patients with existing cardiac risk factors due to a possible increased risk of myocardial events.

## DIDANOSINE

Didanosine (ddI) is a synthetic analog of deoxyadenosine (Figure 49â€²2). Oral bioavailability is approximately 40%; dosing on an empty stomach is optimal, but buffered formulations are necessary to prevent inactivation by gastric acid (Table 49â€²3). Cerebrospinal fluid concentrations of the drug are approximately 20% of serum concentrations. Serum half-life is 1.5 hours, but the intracellular half-life of the activated compound is as long as 20â€²24 hours. The drug is eliminated by both cellular metabolism and renal excretion.

The major clinical toxicity associated with didanosine therapy is dose-dependent pancreatitis. Other risk factors for pancreatitis (eg, alcoholism, hypertriglyceridemia) are relative contraindications, and other drugs with the potential to cause pancreatitis, including zalcitabine, stavudine, and hydroxyurea, should be avoided (Table 49â€²3). Other reported adverse effects include peripheral distal sensory neuropathy, diarrhea (particularly with the buffered formulation), hepatitis, esophageal ulceration, cardiomyopathy, central nervous system toxicity (headache, irritability, insomnia), and hypertriglyceridemia. Asymptomatic hyperuricemia may precipitate attacks of gout in susceptible individuals. Reports of retinal changes and optic neuritis in patients receiving didanosine, particularly in adults receiving high doses and in children, mandate periodic retinal examinations. As with abacavir, didanosine should be used cautiously in patients with cardiac risk factors.

The buffer in didanosine tablets and powder interferes with absorption of indinavir, delavirdine, atazanavir, dapsone, itraconazole, and fluoroquinolone agents; therefore, administration should be separated in time. Serum levels of didanosine are increased when co-administered with tenofovir or ganciclovir, and are decreased by atazanavir, delavirdine, ritonavir, tipranavir, and methadone (Table 49â€²4).

**Table 49â€²4 Clinically Significant Drug-Drug Interactions Pertaining to Two-Drug Antiretroviral Combinations.<sup>1</sup>**

Agent	Drugs That Increase Its Serum Levels	Drugs That Decrease Its Serum Levels
Abacavir		Tipranavir
Atazanavir	Ritonavir	Fosamprenavir, didanosine, efavirenz, etravirine, stavudine, tenofovir
Darunavir	Indinavir	Lopinavir, ritonavir, saquinavir
Delavirdine		Fosamprenavir, didanosine, lopinavir, nelfinavir, ritonavir
Didanosine	Tenofovir, ganciclovir	Atazanavir, delavirdine, ritonavir, tipranavir
Efavirenz	Ritonavir	Lopinavir, nelfinavir, nevirapine
Enfuvirtide	Ritonavir	
Etravirine	Delavirdine, efavirenz, lopinavir/ritonavir, nevirapine, ritonavir, tipranavir	Darunavir, saquinavir, tenofovir
Fosamprenavir	Abacavir, atazanavir, delavirdine, etravirine, indinavir, lopinavir, ritonavir, tipranavir, zidovudine	Didanosine, efavirenz, nevirapine, saquinavir
Indinavir	Delavirdine, nelfinavir, ritonavir, zidovudine, darunavir	Fosamprenavir, didanosine, efavirenz, etravirine, nevirapine
Lamivudine	Nelfinavir	Abacavir, tenofovir, tipranavir
Lopinavir	Delavirdine, indinavir, ritonavir, darunavir	Fosamprenavir, efavirenz, nelfinavir, nevirapine, tenofovir
Maraviroc	Atazanavir, lopinavir/ritonavir, nevirapine, saquinavir	Efavirenz, etravirine
Nelfinavir	Fosamprenavir, delavirdine, efavirenz, indinavir, ritonavir, saquinavir	
Nevirapine	Fosamprenavir, lopinavir	
Raltegravir		Etravirine
Ritonavir	Fosamprenavir, delavirdine, efavirenz, indinavir	Didanosine, tenofovir, zidovudine

Saquinavir	Atazanavir, delavirdine, indinavir, lopinavir, nelfinavir, tenofovir	Efavirenz, nevirapine, tipranavir
Stavudine	Indinavir	
Tenofovir	Atazanavir, lopinavir/ritonavir	
Tipranavir	Didanosine, efavirenz	
Zidovudine	Fosamprenavir, indinavir, lamivudine	Didanosine, nelfinavir, ritonavir

<sup>1</sup>Dose adjustment is likely to be necessary if co-administered.

## EMTRICITABINE

Emtricitabine (FTC) is a fluorinated analog of lamivudine with a long intracellular half-life (> 24 hours), allowing for once-daily dosing (Figure 49â€²2). Oral bioavailability of the capsules is 93% and is unaffected by food, but penetration into the cerebrospinal fluid is low. Elimination is by both glomerular filtration and active tubular secretion. The serum half-life is about 10 hours.

The oral solution, which contains propylene glycol, is contraindicated in young children, pregnant women, patients with renal or hepatic failure, and those using metronidazole or disulfiram. Also, because of its in vitro activity against HBV, patients co-infected with HIV and HBV should be closely monitored if treatment with emtricitabine is interrupted or discontinued, owing to the likelihood of hepatitis flare.

Like lamivudine, the M184V/I mutation is most frequently associated with emtricitabine use and may emerge rapidly in patients receiving HAART regimens that are not fully suppressive. Because of their similar mechanisms of action and resistance profiles, the combination of lamivudine and emtricitabine is not recommended.

The most common adverse effects observed in patients receiving emtricitabine are headache, diarrhea, nausea, and asthenia. In addition, hyperpigmentation of the palms and/or soles may be observed (~ 3%), particularly in blacks (up to 13%). No drug-drug interactions of note have been reported to date.

## LAMIVUDINE

Lamivudine (3TC) is a cytosine analog (Figure 49â€²2) with in vitro activity against HIV-1 that is synergistic with a variety of antiretroviral nucleoside analogsâ€”including zidovudine and stavudineâ€”against both zidovudine-sensitive and zidovudine-resistant HIV-1 strains. Activity against HBV is described below.

Oral bioavailability exceeds 80% and is not food-dependent. In children, the mean cerebrospinal fluid:plasma ratio of lamivudine was 0.2. Serum half-life is 2.5 hours, whereas the intracellular half-life of the triphosphorylated compound is 11â€”14 hours. Most of lamivudine is eliminated unchanged in the urine (Table 49â€²3).

Lamivudine therapy rapidly selects for the M184V mutation in regimens that are not fully suppressive.

Potential adverse effects are headache, dizziness, insomnia, fatigue, and gastrointestinal discomfort, although these are typically mild. Lamivudine's bioavailability increases when it is co-administered with trimethoprim-sulfamethoxazole. Lamivudine and zalcitabine may inhibit the intracellular phosphorylation of one another; therefore, their concurrent use should be avoided if possible. Short-term safety of lamivudine has been demonstrated for both mother and infant.

## STAVUDINE

The thymidine analog stavudine (d4T) (Figure 49â€²2) has high oral bioavailability (86%) that is not food-dependent. The serum half-life is 1.1 hours, the intracellular half-life is 3.0â€”3.5 hours, and mean cerebrospinal fluid concentrations are 55% of those of plasma. Excretion is by active tubular secretion and glomerular filtration (Table 49â€²3).

The major dose-limiting toxicity is a dose-related peripheral sensory neuropathy. The incidence of neuropathy may be increased when stavudine is administered with other neuropathy-inducing drugs such as didanosine and zalcitabine, or in patients with advanced immunosuppression. Symptoms typically resolve completely upon discontinuation of stavudine; in such cases, a reduced dosage may be cautiously restarted. Other potential adverse effects are pancreatitis, arthralgias, and elevation in serum aminotransferases. Lactic acidosis with hepatic steatosis, as well as lipodystrophy, appear to occur more frequently in patients receiving stavudine than in those receiving other NRTI agents. Moreover, because the co-administration of stavudine and didanosine may increase the incidence of lactic acidosis and pancreatitis, concurrent use should be avoided. This combination has been implicated in several deaths in HIV-infected pregnant women. A rare adverse effect is a rapidly progressive ascending neuromuscular weakness. Since zidovudine may reduce the phosphorylation of stavudine, these two drugs should not be used together. There is no evidence of human teratogenicity in those taking stavudine.

## TENOFOVIR

Tenofovir is an acyclic nucleoside phosphonate (ie, nucleotide) analog of adenosine (Figure 49â€²2). Like the nucleoside analogs, tenofovir competitively inhibits HIV reverse transcriptase and causes chain termination after incorporation into DNA. However, only two rather than three intracellular phosphorylations are required for active inhibition of DNA synthesis.

Tenofovir disoproxilfumarate is a water-soluble prodrug of active tenofovir. The oral bioavailability in fasted patients is approximately 25% and increases to 39% after a high-fat meal. The prolonged serum (12â€”17 hours) and intracellular half-lives allow once-daily dosing. Elimination occurs by both glomerular filtration and active tubular secretion.

Tenofovir is often co-administered with emtricitabine, and a combination formulation is available.

The primary mutation associated with resistance to tenofovir is K65R.

Gastrointestinal complaints (eg, nausea, diarrhea, vomiting, flatulence) are the most common adverse effects but rarely require discontinuation of therapy. Other potential adverse effects include headache and asthenia. Tenofovir-associated proximal renal tubulopathy causes excessive renal phosphate and calcium losses and 1-hydroxylation defects of vitamin D, and preclinical studies in several animal species have demonstrated bone toxicity (eg, osteomalacia). Monitoring of bone mineral density should be considered with long-term use in those with risk factors for or with known osteoporosis, as well as in children. Reduction of renal function over time, as well as cases of acute renal failure and Fanconi's syndrome, have been reported in patients receiving tenofovir alone or in combination with emtricitabine. For this reason, tenofovir should be used with caution in patients at risk for renal dysfunction. Tenofovir may compete with other drugs that are actively secreted by the kidneys, such as cidofovir, acyclovir, and ganciclovir.

Tenofovir is associated with decreased fetal growth and reduction in fetal bone porosity in monkeys. There is significant placental passage in humans.

## ZALCITABINE

Zalcitabine (ddC) is a cytosine analog with high oral bioavailability (87%) and a serum half-life of 1.2 hours. Intracellular half-life of 2.6 hours necessitates thrice-daily dosing, which limits its usefulness (Figure 49.2). Plasma levels decrease by 25–39% when the drug is administered with food or antacids. The drug is excreted renally. Cerebrospinal fluid concentrations are approximately 20% of those in the plasma.

Although a variety of mutations associated with in vitro resistance to zalcitabine have been described, phenotypic resistance appears to be rare.

Zalcitabine therapy is associated with a dose-dependent peripheral neuropathy that can be treatment-limiting in 10–20% of patients but appears to be slowly reversible if treatment is stopped promptly. The potential for causing peripheral neuropathy constitutes a relative contraindication to use with other drugs that may cause neuropathy, including stavudine, didanosine, and zalcitabine. Decreased creatinine clearance or concurrent use of potential nephrotoxins (eg, amphotericin B, foscarnet, and aminoglycosides) may increase the risk of zalcitabine neuropathy, as does more advanced immunosuppression. The other major reported toxicity consists of oral and esophageal ulcerations. Pancreatitis occurs less frequently than with didanosine administration, but co-administration of other drugs that cause pancreatitis may increase the frequency of this adverse effect. Headache, nausea, rash, and arthralgias may occur but tend to be mild or resolve during therapy. Zalcitabine causes thymic lymphomas in rodents, as well as hydrocephalus at high doses; clinical relevance is unclear. The AUC of zalcitabine increases when co-administered with probenecid or cimetidine, and bioavailability decreases with concurrent antacids or metoclopramide. Lamivudine inhibits the phosphorylation of zalcitabine in vitro, potentially interfering with its efficacy.

## ZIDOVUDINE

Zidovudine (azidothymidine; AZT) is a deoxythymidine analog (Figure 49.2) that is well absorbed (63%) and distributed to most body tissues and fluids, including the cerebrospinal fluid, where drug levels are 60–65% of those in serum. Although the serum half-life averages 1.1 hours, the intracellular half-life of the phosphorylated compound is 3–4 hours, allowing twice-daily dosing. Zidovudine is eliminated primarily by renal excretion following glucuronidation in the liver.

Zidovudine is often co-administered with lamivudine, and a combination formulation is available.

Zidovudine was the first antiretroviral agent to be approved and has been well studied. The drug has been shown to decrease the rate of clinical disease progression and prolong survival in HIV-infected individuals. Efficacy has also been demonstrated in the treatment of HIV-associated dementia and thrombocytopenia. In pregnancy (Table 49.5), a regimen of oral zidovudine beginning between 14 and 34 weeks of gestation, intravenous zidovudine during labor, and zidovudine syrup to the neonate from birth through 6 weeks of age has been shown to reduce the rate of vertical (mother-to-newborn) transmission of HIV by up to 23%.

**Table 49.5 The Use of Antiretroviral Agents in Pregnancy.<sup>1</sup>**

Recommended Agents	Alternate Agents
<b>Nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs)</b>	
Zidovudine, lamivudine	Didanosine, emtricitabine, stavudine, abacavir
<b>Nonnucleoside reverse transcriptase inhibitors (NNRTIs)</b>	
Nevirapine	
<b>Protease inhibitors (PIs)</b>	
Lopinavir/ritonavir	Indinavir, nelfinavir, ritonavir, saquinavir

<sup>1</sup>Data are insufficient to recommend the use of entry inhibitors or integrase inhibitors in pregnancy at the present time.

High-level zidovudine resistance is generally seen in strains with three or more of the five most common mutations: M41L, D67N, K70R, T215F, and K219Q. However, the emergence of certain mutations that confer decreased susceptibility to one drug (eg, L74V for didanosine and M184V for lamivudine) may enhance zidovudine susceptibility in previously zidovudine-resistant strains. Withdrawal of zidovudine exposure may permit the reversion of zidovudine-resistant HIV-1 isolates to the susceptible wild-type phenotype.

The most common adverse effect of zidovudine is myelosuppression, resulting in macrocytic anemia (1–4%) or neutropenia (2–8%). Gastrointestinal intolerance, headaches, and insomnia may occur but tend to resolve during therapy. Extremity fat loss may be more common with zidovudine than with other agents. Less common toxicities include thrombocytopenia, hyperpigmentation of the nails, and myopathy. High doses can cause anxiety, confusion, and tremulousness. Zidovudine causes vaginal neoplasms in mice; however, no human cases of genital neoplasms have been reported to date. Short-term safety has been demonstrated for both mother and infant.

Increased serum levels of zidovudine may occur with concomitant administration of probenecid, phenytoin, methadone, fluconazole, atovaquone, valproic acid, and lamivudine, either through inhibition of first-pass metabolism or through decreased clearance. Zidovudine may decrease phenytoin levels. Hematologic toxicity may be increased during co-administration of other myelosuppressive drugs such as ganciclovir, ribavirin, and cytotoxic agents. Combination regimens containing zidovudine and stavudine should be avoided due to in vitro antagonism.

## Nonnucleoside Reverse Transcriptase Inhibitors

The NNRTIs bind directly to HIV-1 reverse transcriptase (Figure 49.4), resulting in allosteric inhibition of RNA- and DNA-dependent DNA polymerase. The binding site of NNRTIs is near to but distinct from that of NRTIs. Unlike the NRTI agents, NNRTIs neither compete with nucleoside triphosphates nor require phosphorylation to be active. In addition, they lack in vitro activity against HIV-2.

NNRTI resistance occurs rapidly with monotherapy and can be due to a single mutation. The K103N and Y181C mutations confer resistance across the entire class of NNRTIs, with the exception of the newest agent etravirine; other mutations (eg, L100I, Y188C, G190A) may confer cross-resistance among the NNRTI class. However, there is no cross-resistance between the NNRTIs and the NRTIs; in fact, some nucleoside-resistant viruses display hypersusceptibility to NNRTIs.

As a class, NNRTI agents tend to be associated with varying levels of gastrointestinal intolerance and skin rash, the latter of which may infrequently be serious (eg, Stevens-Johnson syndrome). A further limitation to use of NNRTI agents as a component of HAART is their metabolism by the CYP450 system, leading to innumerable

potential drug-drug interactions (Tables 49â€³ and 49â€´4). All NNRTI agents are substrates for CYP3A4 and can act as inducers (nevirapine), inhibitors (delavirdine), or mixed inducers and inhibitors (efavirenz, etravirine). Given the large number of non-HIV medications that are also metabolized by this pathway (see Chapter 4); drug-drug interactions must be expected and looked for.

## **DELAVIRDINE**

Delavirdine has an oral bioavailability of about 85%, but this is reduced by antacids or H<sub>2</sub>-blockers. It is extensively bound (~ 98%) to plasma proteins and has correspondingly low cerebrospinal fluid levels. Serum half-life is approximately 6 hours.

Skin rash occurs in up to 38% of patients receiving delavirdine; it typically occurs during the first 1â€³ weeks of therapy and does not preclude rechallenge. However, severe rash such as erythema multiforme and Stevens-Johnson syndrome have rarely been reported. Other possible adverse effects are headache, fatigue, nausea, diarrhea, and increased serum aminotransferase levels. Delavirdine has been shown to be teratogenic in rats, causing ventricular septal defects and other malformations at dosages not unlike those achieved in humans. Thus, pregnancy should be avoided when taking delavirdine.

Delavirdine is extensively metabolized to inactive metabolites by the CYP3A and CYP2D6 enzymes and also inhibits CYP3A4 and 2C9. Therefore, there are numerous potential drug-drug interactions to consider (Tables 49â€³ and 49â€´4). The concurrent use of delavirdine with fosamprenavir and rifabutin is not recommended because of decreased delavirdine levels.

## **EFAVIRENZ**

Efavirenz can be given once daily because of its long half-life (40â€³55 hours). It is moderately well absorbed following oral administration (45%). Since toxicity may increase owing to increased bioavailability after a high-fat meal, efavirenz should be taken on an empty stomach. Efavirenz is principally metabolized by CYP3A4 and CYP2B6 to inactive hydroxylated metabolites; the remainder is eliminated in the feces as unchanged drug. It is highly bound to albumin (~ 99%), and cerebrospinal fluid levels range from 0.3% to 1.2% of plasma levels.

The principal adverse effects of efavirenz involve the central nervous system. Dizziness, drowsiness, insomnia, and headache tend to diminish with continued therapy; dosing at bedtime may also be helpful. Psychiatric symptoms such as depression, mania, and psychosis have been observed and may necessitate discontinuation. Skin rash has also been reported early in therapy in up to 28% of patients, is usually mild to moderate in severity, and typically resolves despite continuation. Other potential adverse reactions are nausea, vomiting, diarrhea, crystalluria, elevated liver enzymes, and an increase in total serum cholesterol by 10â€³20%. High rates of fetal abnormalities occurred in pregnant monkeys exposed to efavirenz in doses roughly equivalent to the human dosage; several cases of congenital anomalies have been reported in humans. Therefore, efavirenz should be avoided in pregnant women, particularly in the first trimester.

As both an inducer and an inhibitor of CYP3A4, efavirenz induces its own metabolism and interacts with the metabolism of many other drugs (Tables 49â€³ and 49â€´4).

## **ETRAVIRINE**

Etravirine has in vitro activity against a wide variety of wild-type and NNRTI-resistant HIV-1, and it was approved in the USA for use in treatment-experienced patients with HIV infection in early 2008. Etravirine may be effective against strains of HIV that have developed resistance to first-generation NNRTIs, depending on the number of mutations present. Although etravirine has a higher genetic barrier to resistance than the other NNRTIs, mutations selected by etravirine usually are associated with resistance to efavirenz, nevirapine, and delavirdine.

The most common symptomatic adverse effects of etravirine are rash, nausea, and diarrhea. The rash is typically mild and usually resolves after 1â€² weeks without discontinuation of therapy. Rarely, rash has been severe or life-threatening. Laboratory abnormalities include elevations in serum cholesterol, triglyceride, glucose, and hepatic transaminase levels. Transaminase elevations are more common in patients with HBV or HCV co-infection.

Etravirine is a substrate as well as an inducer of CYP3A4 and an inhibitor of CYP2C9 and CYP2C19; it has many therapeutically significant drug-drug interactions (Tables 49â€³ and 49â€´4). Some of the interactions are difficult to predict. For example, etravirine may decrease itraconazole and ketoconazole concentrations but increase voriconazole concentrations.

## **NEVIRAPINE**

The oral bioavailability of nevirapine is excellent (> 90%) and is not food-dependent. The drug is highly lipophilic and achieves cerebrospinal fluid levels that are 45% of those in plasma. Serum half-life is 25â€³30 hours. It is extensively metabolized by the CYP3A isoform to hydroxylated metabolites and then excreted, primarily in the urine.

A single dose of nevirapine (200 mg) is effective in the prevention of transmission of HIV from mother to newborn when administered to women at the onset of labor and followed by a 2-mg/kg oral dose to the neonate within 3 days after delivery. There is no evidence of human teratogenicity. However, resistance has been documented after this single dose.

Rash, usually a maculopapular eruption that spares the palms and soles, occurs in up to 20% of patients, usually in the first 4â€³6 weeks of therapy. Although typically mild and self-limited, rash is dose-limiting in about 7% of patients. Women appear to have an increased incidence of rash. When initiating therapy, gradual dose escalation over 14 days is recommended to decrease the incidence of rash. Severe and life-threatening skin rashes have been rarely reported, including Stevens-Johnson syndrome and toxic epidermal necrolysis. Nevirapine therapy should be immediately discontinued in patients with severe rash and in those with accompanying constitutional symptoms. Elevated hepatic enzyme levels may occur in up to 20% of patients and are more frequent in those with higher pre-therapy CD4 cell counts (ie, > 250 cells/mm<sup>3</sup> in women and > 400 cells/mm<sup>3</sup> in men), in women, and in those with HBV or HCV co-infection. Fulminant, life-threatening hepatitis may rarely occur, typically within the first 18 weeks of therapy. Other adverse effects associated with nevirapine therapy are fever, nausea, headache, and somnolence.

Nevirapine is a moderate inducer of CYP3A metabolism, resulting in decreased levels of amprenavir, indinavir, lopinavir, saquinavir, efavirenz, and methadone (Table 49â€´4). Drugs that induce the CYP3A system, such as tipranavir, rifampin, rifabutin, and St. John's wort, can decrease levels of nevirapine, whereas those that inhibit CYP3A activity, such as fluconazole, ketoconazole, and clarithromycin, can increase nevirapine levels.

## **PROTEASE INHIBITORS**

During the later stages of the HIV growth cycle, the Gag and Gag-Pol gene products are translated into polyproteins, and these become immature budding particles. Protease is responsible for cleaving these precursor molecules to produce the final structural proteins of the mature virion core. By preventing post-translational cleavage of

the Gag-Pol polyprotein, protease inhibitors (PIs) prevent the processing of viral proteins into functional conformations, resulting in the production of immature, noninfectious viral particles (Figure 49â€4). Protease inhibitors are active against both HIV-1 and HIV-2; unlike the NRTIs, however, they do not need intracellular activation.

Specific genotypic alterations that confer phenotypic resistance are fairly common with these agents, thus contraindicating monotherapy. Some of the most common mutations conferring broad resistance to PIs are substitutions at the 10, 46, 54, 82, 84, and 90 codons; the number of mutations may predict the level of phenotypic resistance. The I50L substitution emerging during atazanavir therapy has been associated with *increased* susceptibility to other PIs. Darunavir and tipranavir appear to have improved virologic activity in patients harboring PI-resistant HIV-1.

A syndrome of redistribution and accumulation of body fat that results in central obesity, dorsocervical fat enlargement (buffalo hump), peripheral and facial wasting, breast enlargement, and a cushingoid appearance has been observed in patients receiving antiretroviral therapy. These abnormalities may be particularly associated with the use of PIs, although the recently licensed atazanavir appears to be an exception (see below). Concurrent increases in triglyceride and LDL levels, along with hyperglycemia and insulin resistance, have also been noted. The cause is not yet known.

Whether PI agents are associated with bone loss and osteoporosis after long-term use is controversial and under active investigation. PIs have been associated with increased spontaneous bleeding in patients with hemophilia A or B.

All the antiretroviral PIs are extensively metabolized by CYP3A4, with ritonavir having the most pronounced inhibitory effect and saquinavir the least. Some PI agents such as amprenavir and ritonavir are also inducers of specific CYP isoforms. As a result, there is enormous potential for drug-drug interactions with other antiretroviral agents and other commonly used medications (Tables 49â€3 and 49â€4). It is noteworthy that the potent CYP3A4 inhibitory properties of ritonavir have been used to clinical advantage by having it "boost" the levels of other PI agents when given in combination, thus acting as a pharmacokinetic enhancer rather than an antiretroviral agent. Ritonavir boosting increases drug exposure, thereby prolonging the drug's half-life and allowing reduction in frequency; in addition, the genetic barrier to resistance is raised.

## ATAZANAVIR

Atazanavir is an azapeptide PI with a pharmacokinetic profile that allows once-daily dosing. It should be taken with a light meal to enhance bioavailability. Atazanavir requires an acidic medium for absorption and exhibits pH-dependent aqueous solubility; therefore, separation of ingestion from acid-reducing agents by at least 12 hours is recommended. Atazanavir is able to penetrate both the cerebrospinal and seminal fluids. The plasma half-life is 6â€7 hours, which increases to approximately 11 hours when co-administered with ritonavir. The primary route of elimination is biliary; atazanavir should not be given to patients with severe hepatic insufficiency.

The most common adverse effects in patients receiving atazanavir are diarrhea and nausea; vomiting, abdominal pain, headache, peripheral neuropathy, and skin rash may also occur. As with indinavir, indirect hyperbilirubinemia with overt jaundice may occur (7â€8%) owing to inhibition of the UGT1A1 glucuronidation enzyme. Elevation of hepatic enzymes has also been observed, usually in patients with underlying HBV or HCV co-infection. In contrast to the other PIs, atazanavir does not appear to be associated with dyslipidemia, fat redistribution, or the metabolic syndrome. Atazanavir may be associated with electrocardiographic PR-interval prolongation, which is usually inconsequential but may be exacerbated by other causative agents such as calcium channel blockers. Also, a possible concentration-dependent increase in the QT<sub>c</sub> interval may occur in patients receiving atazanavir in dosages higher than 400 mg/d or in conjunction with a CYP3A4 inhibitor such as clarithromycin.

As an inhibitor of CYP3A4 and CYP2C9, the potential for drug-drug interactions with atazanavir is great (Tables 49â€3 and 49â€4). Atazanavir AUC is reduced by 76% when combined with omeprazole; thus, the combination is to be avoided. In addition, co-administration of atazanavir with other drugs that inhibit UGT1A1, such as indinavir and irinotecan, is contraindicated because of enhanced toxicity. Tenofovir and efavirenz should not be co-administered with atazanavir unless ritonavir is added to boost levels.

## DARUNAVIR

Darunavir is licensed as a PI to be co-administered with ritonavir in treatment-experienced patients with resistance to other PIs.

Symptomatic adverse effects of darunavir include diarrhea, nausea, headache, and rash. Laboratory abnormalities include dyslipidemia (though possibly less frequent than with other boosted PI regimens) and increases in amylase and hepatic transaminase levels. Liver toxicity, including severe hepatitis, has been reported in some patients taking darunavir; the risk of hepatotoxicity may be higher for persons with HBV, HCV, or other chronic liver disease.

Darunavir contains a sulfonamide moiety and should be used cautiously in patients with sulfonamide allergy.

Darunavir both inhibits and is metabolized by the CYP3A enzyme system, conferring many possible drug-drug interactions (Table 49â€3). In addition, the co-administered ritonavir is a potent inhibitor of CYP3A and CYP2D6, and an inducer of other hepatic enzyme systems.

## FOSAMPRENAVIR

Fosamprenavir is a prodrug of amprenavir that is rapidly hydrolyzed by enzymes in the intestinal epithelium. Because of its significantly lower daily pill burden, fosamprenavir tablets have replaced amprenavir capsules for adults. Fosamprenavir is most often administered in combination with low-dose ritonavir.

Amprenavir is rapidly absorbed from the gastrointestinal tract, and its prodrug can be taken with or without food. However, high-fat meals decrease absorption and thus should be avoided. The plasma half-life is relatively long (7â€11 hours). Amprenavir is metabolized in the liver by CYP3A4 and should be used with caution in the setting of hepatic insufficiency.

The most common adverse effects of fosamprenavir are headache, nausea, diarrhea, perioral paresthesias, depression, and rash. Up to 3% of patients may experience rashes (including Stevens-Johnson syndrome) severe enough to warrant drug discontinuation.

Amprenavir is both an inducer and an inhibitor of CYP3A4 and is contraindicated with numerous drugs (Tables 49â€3 and 49â€4). The oral solution, which contains propylene glycol, is contraindicated in young children, pregnant women, patients with renal or hepatic failure, and those using metronidazole or disulfiram. Also, the oral solutions of amprenavir and ritonavir should not be co-administered because the propylene glycol in one and the ethanol in the other may compete for the same metabolic pathway, leading to accumulation of either. Because the oral solution also contains vitamin E at several times the recommended daily dosage, supplemental vitamin E should be avoided. Amprenavir is contraindicated in patients with a history of sulfa allergy because it is itself a sulfonamide. Lopinavir/ritonavir should not be co-administered with amprenavir owing to decreased amprenavir and increased lopinavir exposures. An increased dosage of amprenavir is recommended when co-administered with efavirenz (with or without the addition of ritonavir to boost levels).

## INDINAVIR

Indinavir requires an acidic environment for optimum solubility and therefore must be consumed on an empty stomach or with a small, low-fat, low-protein meal for maximal absorption (60%–65%). The serum half-life is 1.5–2 hours, protein binding is approximately 60%, and the drug has a high level of cerebrospinal fluid penetration (up to 76% of serum levels). Excretion is primarily fecal. An increase in AUC by 60% and in half-life to 2.8 hours in the setting of hepatic insufficiency necessitates dose reduction.

The most common adverse effects of indinavir are indirect hyperbilirubinemia and nephrolithiasis due to crystallization of the drug. Nephrolithiasis can occur within days after initiating therapy, with an estimated incidence of approximately 10%. Consumption of at least 48 ounces of water daily is important to maintain adequate hydration. Thrombocytopenia, elevations of serum aminotransferase levels, nausea, diarrhea, insomnia, dry throat, dry skin, and indirect hyperbilirubinemia have also been reported. Insulin resistance may be more common with indinavir than with the other PIs, occurring in 3%–5% of patients. There have also been rare cases of acute hemolytic anemia. In rats, high doses of indinavir are associated with development of thyroid adenomas.

Since indinavir is an inhibitor of CYP3A4, numerous and complex drug interactions can occur (Tables 49–3 and 49–4). Combination with ritonavir (boosting) allows for twice-daily rather than thrice-daily dosing and eliminates the food restriction associated with use of indinavir. However, there is potential for an increase in nephrolithiasis with this combination compared with indinavir alone; thus, a high fluid intake (1.5–2 L/d) is advised.

## LOPINAVIR

Lopinavir is currently formulated with ritonavir, which inhibits the CYP3A-mediated metabolism of lopinavir, thereby resulting in increased exposure to this drug. In addition to improved patient compliance due to reduced pill burden, lopinavir/ritonavir is generally well tolerated.

Lopinavir should be taken with food to enhance bioavailability. The drug is highly protein bound (98%–99%), and its half-life is 5–6 hours. Lopinavir is extensively metabolized by CYP3A, which is inhibited by ritonavir. Serum levels of lopinavir may be increased in patients with hepatic impairment.

The most common adverse effects of lopinavir are diarrhea, abdominal pain, nausea, vomiting, and asthenia. Elevations in serum cholesterol and triglycerides are common. Potential drug-drug interactions are extensive (Tables 49–3 and 49–4). Increased dosage of lopinavir/ritonavir is recommended when co-administered with efavirenz or nevirapine, which induce lopinavir metabolism. Concurrent use of fosamprenavir should be avoided owing to increased exposure to lopinavir with decreased levels of amprenavir. Also, concomitant use of lopinavir/ritonavir and rifampin is contraindicated due to an increased risk for hepatotoxicity. Since the oral solution contains alcohol, concurrent disulfiram and metronidazole are contraindicated. There is no evidence of human teratogenicity of lopinavir/ritonavir; short-term safety in pregnant women has been demonstrated for mother and infant.

## NELFINAVIR

Nelfinavir has high absorption in the fed state (70%–80%), undergoes metabolism by CYP3A, and is excreted primarily in the feces. The plasma half-life in humans is 3.5–5 hours, and the drug is more than 98% protein-bound.

The most common adverse effects associated with nelfinavir are diarrhea and flatulence. Diarrhea often responds to antidiarrheal medications but can be dose-limiting. Nelfinavir is an inhibitor of the CYP3A system, and multiple drug interactions may occur (Tables 49–3 and 49–4). An increased dosage of nelfinavir is recommended when co-administered with rifabutin (with a decreased dose of rifabutin), whereas a decrease in saquinavir dose is suggested with concurrent nelfinavir. Co-administration with efavirenz should be avoided due to decreased indinavir levels. Nelfinavir has a favorable safety and pharmacokinetic profile for pregnant women compared with that of other PIs (Table 49–5); there is no evidence of human teratogenicity.

## RITONAVIR

Ritonavir has a high bioavailability (about 75%) that increases with food. It is 98% protein-bound and has a serum half-life of 3–5 hours. Metabolism to an active metabolite occurs via the CYP3A and CYP2D6 isoforms; excretion is primarily in the feces. Caution is advised when administering the drug to persons with impaired hepatic function.

Potential adverse effects of ritonavir, particularly when administered at full dosage, are gastrointestinal disturbances, paresthesias (circumoral or peripheral), elevated serum aminotransferase levels, altered taste, headache, hypertriglyceridemia, hypercholesterolemia, and elevations in serum creatine kinase. Nausea, vomiting, diarrhea, or abdominal pain typically occur during the first few weeks of therapy but may diminish over time or if the drug is taken with meals. Dose escalation over 1–2 weeks is recommended to decrease the dose-limiting side effects. Liver adenomas and carcinomas have been induced in male mice receiving ritonavir; no similar effects have been observed to date in humans.

Ritonavir is a potent inhibitor of CYP3A4, resulting in many potential drug interactions (Tables 49–3 and 49–4). However, this characteristic has been used to great advantage when ritonavir is administered in low doses (100–200 mg twice daily) in combination with any of the other PI agents, in that increased blood levels of the latter agents permit lower or less frequent dosing (or both) with greater tolerability as well as the potential for greater potency against resistant virus. Therapeutic levels of digoxin and theophylline should be monitored when co-administered with ritonavir owing to likely increase in their concentrations. There is limited experience with full-dose ritonavir during pregnancy to date; however, low-dose ritonavir as a "booster" has appeared to be well tolerated in mother and infant.

## SAQUINAVIR

In its original formulation as a hard gel capsule (saquinavir-H; Invirase), oral saquinavir is poorly bioavailable (only about 4% after food). However, reformulation of saquinavir-H for once-daily dosing in combination with low-dose ritonavir has both improved antiviral efficacy and decreased gastrointestinal adverse effects.

Saquinavir should be taken within 2 hours after a fatty meal for enhanced absorption. Saquinavir is 97% protein-bound, and serum half-life is approximately 2 hours. Saquinavir has a large volume of distribution, but penetration into the cerebrospinal fluid is negligible. Excretion is primarily in the feces. Reported adverse effects include gastrointestinal discomfort (nausea, diarrhea, abdominal discomfort, dyspepsia) and rhinitis. When administered in combination with low-dose ritonavir, there appears to be less dyslipidemia or gastrointestinal toxicity than with some of the other boosted PI regimens.

Saquinavir is subject to extensive first-pass metabolism by CYP3A4 and functions as a CYP3A4 inhibitor as well as a substrate; thus, there are many potential drug-drug interactions (Table 49–4). A decreased dose of saquinavir is recommended when co-administered with nelfinavir. Increased saquinavir levels when co-administered with omeprazole necessitate close monitoring for toxicities. Digoxin levels may increase if co-administered with saquinavir and should therefore be monitored. Liver function tests

should be monitored if saquinavir is co-administered with delavirdine or rifampin. There is no evidence of human teratogenicity from saquinavir; there is short-term safety data for both mother and infant.

## **TIPRANAVIR**

Tipranavir is a newer PI for treating patients with resistance to other PI agents. Bioavailability is poor but is increased when taken with a high-fat meal. The drug is metabolized by the liver microsomal system. Tipranavir must be taken in combination with ritonavir to achieve effective serum levels. It is contraindicated in patients with hepatic insufficiency. Tipranavir contains a sulfonamide moiety and should not be administered to patients with known sulfa allergy.

The most common adverse effects from tipranavir are diarrhea, nausea, vomiting, abdominal pain, and rash (urticarial or maculopapular); the latter may be accompanied by systemic symptoms or desquamation. Liver toxicity, including life-threatening hepatic decompensation, has been observed and is more common in patients with chronic HBV or HCV. Tipranavir should be discontinued in patients with increased serum transaminase levels to more than 10 times the upper limit of normal. Because of an increased risk for intracranial hemorrhage in patients receiving tipranavir, the drug should be avoided in patients with head trauma or bleeding diathesis. Other potential adverse effects include depression; elevations in total cholesterol, triglycerides, and amylase; and decreased white blood cell count.

Tipranavir both inhibits and induces the CYP3A4 system. When used in combination with ritonavir, its net effect is inhibition. Tipranavir also induces P-glycoprotein transporter and thus may alter the disposition of many other drugs (Table 49â€4). Concurrent administration of tipranavir with fosamprenavir or saquinavir should be avoided owing to decreased blood levels of the latter drugs. Tipranavir/ritonavir may also decrease serum levels of valproic acid and omeprazole. Levels of lovastatin, simvastatin, atorvastatin, and rosuvastatin may be increased, increasing the risk for rhabdomyolysis and myopathy.

## **Entry Inhibitors**

The process of HIV-1 entry into host cells is complex; each step forms a potential target for inhibition. Viral attachment to the host cell entails binding of the viral envelope glycoprotein complex gp160 (consisting of gp120 and gp41) to its cellular receptor CD4. This binding induces conformational changes in gp120 that enable access to the chemokine coreceptors CCR5 or CXCR4. Coreceptor binding induces further conformational changes in gp120, allowing exposure to gp41 and leading to fusion of the viral envelope with the host cell membrane and subsequent entry of the viral core into the cellular cytoplasm.

## **ENFUVIRTIDE**

Enfuvirtide is a synthetic 36-amino-acid peptide fusion inhibitor that blocks entry into the cell (Figure 49â€4). Enfuvirtide, binds to the gp41 subunit of the viral envelope glycoprotein, preventing the conformational changes required for the fusion of the viral and cellular membranes. It has no activity against HIV-2. Enfuvirtide must be administered by subcutaneous injection. Metabolism appears to be by proteolytic hydrolysis without involvement of the CYP450 system. Elimination half-life is 3.8 hours.

Resistance to enfuvirtide can occur as a result of mutations in gp41 codons; the frequency and significance of this phenomenon are being investigated. However, enfuvirtide lacks cross-resistance to the other currently approved antiretroviral drug classes.

The most common adverse effects associated with enfuvirtide therapy are local injection site reactions. Hypersensitivity reactions may rarely occur, are of varying severity, and may recur on rechallenge. Eosinophilia has also been noted. In one prospective clinical trial, an increased rate of bacterial pneumonia was noted in patients receiving enfuvirtide. No interactions have been identified that would require the alteration of the dosage of other antiretroviral drugs.

## **MARAVIROC**

Maraviroc binds specifically and selectively to CCR5, one of two coreceptors necessary for entrance of HIV into CD4+ cells, thus blocking entry of CCR5-tropic HIV into these cells. Maraviroc is to be used in adults with CCR5-tropic (also known as R5) HIV-1 infection that are experiencing virologic failure due to resistance to other antiretroviral agents. Studies have shown that 52â€60% of patients in whom at least two antiviral regimens had failed were infected with R5 HIV. Since maraviroc is active against HIV that uses the CCR5 coreceptor exclusively, and not against HIV strains with CXCR4, dual, or mixed tropism, tropism testing should be performed before initiating treatment with maraviroc.

The absorption of maraviroc is rapid but variable, with the time to maximum absorption generally being 1â€4 hours after ingestion of the drug. Most of the drug (â‰¥ 75%) is excreted in the feces, whereas approximately 20% is excreted in urine. No dose adjustment is necessary for renal or hepatic impairment. Maraviroc has been shown to have excellent penetration into the cervicovaginal fluid, with levels almost four times higher than the corresponding concentrations in blood plasma.

Resistance to maraviroc is associated with one or more mutations in the V3 loop of gp120. There appears to be no cross-resistance with drugs from any other class, including the fusion inhibitor enfuvirtide. However, virologic failure of regimens containing maraviroc may potentially be caused not only by resistance but also by emergence of nonâ€CCR5-tropic virus (eg, CXCR4-tropic virus) or by changes in viral tropism, owing to the development of multiple mutations throughout gp160.

Maraviroc is a substrate for CYP3A4 and therefore requires adjustment in the presence of drugs that interact with these enzymes (Tables 49â€3 and 49â€4). It is also a substrate for P-glycoprotein, which limits intracellular concentrations of the drug. The dosage of maraviroc must be decreased if it is co-administered with other strong CYP3A inhibitors (eg, delavirdine, ketoconazole, itraconazole, or clarithromycin) and must be increased if co-administered with CYP3A inducers (eg, efavirenz, etravirine, rifampin, carbamazepine, phenytoin, or St. John's wort).

Maraviroc has been well tolerated in studies to date; potential adverse effects include cough, upper respiratory tract infections, muscle and joint pain, diarrhea, sleep disturbance, and increases in hepatic transaminase levels. Clinical trials of another CCR5 inhibitor, aplaviroc, were discontinued because of serious hepatotoxicity; therefore, caution is advised when administering maraviroc to those with preexisting liver dysfunction (eg, those with HBV or HCV co-infection). There has been some concern that blockade of CCR5â€a human protein rather than a viral enzymeâ€may result in decreased immune surveillance, with a subsequent increased risk of development of malignancies (eg, lymphomas) or infection. To date, however, there has been no evidence of an increased risk of either malignancy or infection in patients receiving maraviroc.

## **Integrase Inhibitors**

### **RALTEGRAVIR**

Raltegravir is a pyrimidinone analog that binds integrase, a viral enzyme essential to the replication of both HIV-1 and HIV-2. By doing so, it inhibits strand transfer, the third and final step of the provirus integration, thus interfering with the integration of reverse-transcribed HIV DNA into the chromosomes of host cells. It is licensed for use in treatment-experienced adult patients infected with strains of HIV-1 resistant to multiple other agents.

Absolute bioavailability of raltegravir has not been established but does not appear to be food-dependent. The drug is metabolized by glucuronidation and does not interact with the cytochrome P450 system; therefore, it is expected to have fewer drug-drug interactions than many of the other available antiretroviral agents. However, there is potential for drug-drug interactions with agents that are strong inducers (eg, rifampin, efavirenz, etravirine, tipranavir/ritonavir) or inhibitors (atazanavir, tipranavir) of UGT1A1; the clinical relevance of these interactions is under investigation. It is recommended, however, that rifampin not be co-administered with raltegravir owing to a decrease in raltegravir levels. Since polyvalent cations (eg, magnesium, calcium, and iron) may bind integrase inhibitors and interfere with their activity against integrase, antacids should be used cautiously and taken separately from raltegravir.

Although virologic failures have been uncommon in clinical trials of raltegravir to date, in vitro resistance requires only a single point mutation (eg, at codons 148 or 155). The low genetic barrier to resistance emphasizes the importance of combination therapies and of adherence. Integrase mutations are not expected to affect sensitivity to other classes of antiretroviral agents.

Potential adverse effects of raltegravir include diarrhea, nausea, dizziness, and headache. Laboratory abnormalities include increases in creatine phosphokinase, but there is minimal effect on serum lipids.

## Investigational Antiretroviral Agents

New therapies are continually being sought that exploit new viral targets, have activity against resistant viral strains, have a lower incidence of adverse effects, and offer convenient dosing. New agents of existing classes that are currently in advanced stages of clinical development include the NRTI agent **elvucitabine**, the NNRTI agents TMC-278 and IDN899, the PI agent bracanavir, entry inhibitors such as the CCR5 receptor antagonists **vicriviroc** and PRO 140, and integrase inhibitors such as **elvitegravir**. In addition, new drug classes such as maturation inhibitors (**bevrimat**) and the CD4 receptor inhibitor TNX-355 are under investigation.

## ANTIHEPATITIS AGENTS

Several agents effective against HBV and HCV are now available (Table 49â€6). Current treatment is suppressive rather than curative and the high prevalence of these infections worldwide, with their concomitant morbidity and mortality, reflect a critical need for improved therapeutics.

**Table 49â€6 Drugs Used to Treat Viral Hepatitis.**

Agent	Indication	Recommended Adult Dosage	Route of Administration
<b>Hepatitis B</b>			
Lamivudine <sup>1</sup>	Chronic hepatitis B	100 mg once daily (150 mg once daily if co-infection with HIV is present)	Oral
Adefovir <sup>1</sup>	Chronic hepatitis B	10 mg once daily	Oral
Entecavir <sup>1</sup>	Chronic hepatitis B	0.5â€1 mg once daily	Oral
Tenofovir <sup>1</sup>	Chronic hepatitis B	300 mg once daily	Oral
Telbivudine <sup>1</sup>	Chronic hepatitis B	600 mg once daily	Oral
Interferon alfa-2b	Chronic hepatitis B	5 million units once daily or 10 million units three times weekly	Subcutaneous or intramuscular
Pegylated interferon alfa-2a <sup>1</sup>	Chronic hepatitis B	180 mcg once weekly	Subcutaneous
<b>Hepatitis C</b>			
Pegylated interferon alfa-2a <sup>1</sup>	Chronic hepatitis C	180 mcg once weekly with or without ribavirin (800 mg/d)	Subcutaneous
Pegylated interferon alfa-2b <sup>1</sup>	Chronic hepatitis C	1.5 mcg/kg once weekly with ribavirin (800 mg/d) or 1.0 mcg/kg once weekly as monotherapy	Subcutaneous
Ribavirin <sup>2</sup>	Chronic hepatitis C	800â€1200 mg daily, according to weight and prognosis	Oral
Interferon alfa-2b <sup>1</sup>	Acute hepatitis C	5 million units once daily for 3â€4 weeks, then 5 million units three times weekly	Subcutaneous or intramuscular
Interferon alfa-2a <sup>1</sup>	Chronic hepatitis C	3 million units three times weekly	Subcutaneous or intramuscular
Interferon alfa-2b <sup>1</sup>	Chronic hepatitis C	3 million units three times weekly	Subcutaneous or intramuscular

Interferon alfacon-1      Chronic hepatitis C      9â€³15 mcg three times weekly as monotherapy

Subcutaneous

<sup>1</sup>Dose must be reduced in patients with renal insufficiency.

<sup>2</sup>Not recommended as monotherapy.

## INTERFERON ALFA

Interferons are host cytokines that exert complex antiviral, immunomodulatory, and antiproliferative actions (see Chapter 55). Interferon alfa appears to function by induction of intracellular signals following binding to specific cell membrane receptors, resulting in inhibition of viral penetration, translation, transcription, protein processing, maturation, and release, as well as increased expression of major histocompatibility complex antigens, enhanced phagocytic activity of macrophages, and augmentation of the proliferation and survival of cytotoxic T cells.

Injectable preparations of interferon alfa are available for treatment of both HBV and HCV infections (Table 49â€³6). Interferon alfa-2a and interferon alfa-2b may be administered subcutaneously or intramuscularly, whereas interferon alfacon-1 is administered subcutaneously. Elimination half-life is 2â€³5 hours for interferon alfa-2a and -2b, depending on the route of administration. The half-life of interferon alfacon-1 in patients with chronic HCV ranges from 6 to 10 hours. Alfa interferons are filtered at the glomerulus and undergo rapid proteolytic degradation during tubular reabsorption, such that detection in the systemic circulation is negligible. Liver metabolism and subsequent biliary excretion are considered minor pathways.

A recent meta-analysis of clinical trials in patients with chronic HBV infection showed that treatment with interferon alfa is associated with a higher incidence of hepatitis e antigen (HBeAg) seroconversion and undetectable HBV DNA levels than placebo. The addition of the pegylated moiety results in further increases in the proportion of patients with HBeAg seroconversion (~ 30%) and a decline by approximately 4 log copies/mL (99.99%) in HBV DNA after 1 year.

The use of pegylated interferon alfa-2a and pegylated interferon alfa-2b, as a result of slower clearance resulting in substantially longer terminal half-lives and steadier drug concentrations, allows for less frequent dosing in patients with chronic HCV infection. Renal elimination accounts for about 30% of clearance, and clearance is approximately halved in subjects with impaired renal function; dosage must therefore be adjusted.

Typical adverse effects of interferon alfa include a flu-like syndrome (ie, headache, fevers, chills, myalgias, and malaise) that occurs within 6 hours after dosing in more than 30% of patients during the first week of therapy and tends to resolve upon continued administration. Transient hepatic enzyme elevations may occur in the first 8â€³12 weeks of therapy and appear to be more common in responders. Potential adverse effects during chronic therapy include neurotoxicities (mood disorders, depression, somnolence, confusion, seizures), myelosuppression, profound fatigue, weight loss, rash, cough, myalgia, alopecia, tinnitus, reversible hearing loss, retinopathy, pneumonitis, and possibly cardiotoxicity. Induction of autoantibodies may occur, causing exacerbation or unmasking of autoimmune disease (particularly thyroiditis). The polyethylene glycol molecule is a nontoxic polymer that is readily excreted in the urine.

Contraindications to interferon alfa therapy include hepatic decompensation, autoimmune disease, and history of cardiac arrhythmia. Caution is advised in the setting of psychiatric disease, epilepsy, thyroid disease, ischemic cardiac disease, severe renal insufficiency, and cytopenia. Alfa interferons are abortifacient in primates and should not be administered in pregnancy. Potential drug-drug interactions include increased theophylline levels and increased methadone levels. Co-administration with didanosine is not recommended because of a risk of hepatic failure, and co-administration with zidovudine may exacerbate cytopenias.

## Treatment of Hepatitis B Virus Infection

The goals of chronic HBV therapy are to sustain suppression of HBV replication, resulting in slowing of progression of hepatic disease (with retardation of hepatic fibrosis and even reversal of cirrhosis), prevention of complications (ie, cirrhosis, hepatic failure, and hepatocellular carcinoma), and reduction of the need for liver transplantation. The goals of antiviral therapy in patients with chronic HBV infection therefore are suppression of HBV DNA to undetectable levels, seroconversion from HBeAg (or more rarely, HBsAg) from positive to negative, and reduction in elevated hepatic transaminase levels. These end points are correlated with improvement in necroinflammatory disease, a decreased risk of hepatocellular carcinoma and cirrhosis, and a decreased need for liver transplantation. All the currently licensed therapies achieve these goals. However, because current therapies suppress HBV replication rather than eradicate the virus, initial responses may not be durable. The covalently closed circular (ccc) DNA exists in stable form indefinitely within the cell, serving as a reservoir for HBV throughout the life of the cell and resulting in the capacity to reactivate. Relapse is more common in patients co-infected with HBV and hepatitis D virus.

As of 2008 seven drugs were approved for treatment of chronic HBV infection in the USA: five oral nucleoside/nucleotide analogs (lamivudine, adefovir dipivoxil, tenofovir, entecavir, telbivudine) and two injectable interferon drugs (interferon alfa-2b, pegylated interferon alfa-2a) (Table 49â€³6). The use of interferon has been supplanted by long-acting pegylated interferon, owing to once-weekly rather than daily or thrice weekly dosing. In general, nucleoside/nucleotide analog therapies have better tolerability and incur an ultimately higher response rate than the interferons (though less rapid); however, response may be less sustained after discontinuation of the nucleoside/nucleotide therapies, and emergence of resistance may be problematic. The nucleotides are effective in nucleoside resistance and vice versa. In addition, oral agents may be used in patients with decompensated liver disease, and the therapy is chronic rather than finite as with interferon therapy.

Several anti-HBV agents have anti-HIV activity as well, including lamivudine, adefovir dipivoxil, and tenofovir. Emtricitabine, an antiretroviral NRTI, is under clinical evaluation for HBV treatment. Because NRTI agents may be used in patients co-infected with HBV and HIV, it is important to note that acute exacerbation of hepatitis may occur upon discontinuation or interruption of these agents.

## ADEFOVIR DIPIVOXIL

Although initially and abortively developed for treatment of HIV infection, adefovir dipivoxil gained approval, at lower and less toxic doses, for treatment of HBV infection. Adefovir dipivoxil is the diester prodrug of adefovir, an acyclic phosphonated adenine nucleotide analog (Figure 49â€³2). It is phosphorylated by cellular kinases to the active diphosphate metabolite and then competitively inhibits HBV DNA polymerase to result in chain termination after incorporation into the viral DNA. Adefovir is active in vitro against a wide range of DNA and RNA viruses, including HBV, HIV, and herpesviruses.

Oral bioavailability of adefovir dipivoxil is about 59% and is unaffected by meals; it is rapidly and completely hydrolyzed to the parent compound by intestinal and blood esterases. Protein binding is low (< 5%). The intracellular half-life of the diphosphate is prolonged, ranging from 5 to 18 hours in various cells; this makes once-daily dosing feasible. Adefovir is excreted by a combination of glomerular filtration and active tubular secretion and requires dose adjustment for renal dysfunction; however, it may be administered to patients with decompensated liver disease.

Of the oral agents, adefovir may be slower to suppress HBV DNA levels and the least likely to induce HBeAg seroconversion. Although emergence of resistance is rare during the first year of therapy, it approaches 30% at the end of 4 years. Naturally occurring (ie, primary) adefovir-resistant rt233 HBV mutants have recently been described. There is no cross-resistance between adefovir and lamivudine.

Adefovir dipivoxil is well tolerated. A dose-dependent nephrotoxicity has been observed in clinical trials, manifested by increased serum creatinine with decreased serum phosphorous and more common in patients with baseline renal insufficiency and those receiving high doses (60 mg/d). Other potential adverse effects are headache, diarrhea, asthenia, and abdominal pain. As with other NRTI agents, lactic acidosis and hepatic steatosis are considered a risk owing to mitochondrial dysfunction. No clinically important drug-drug interactions have been recognized to date. Pivalic acid, a by-product of adefovir dipivoxil metabolism, can esterify free carnitine and result in decreased carnitine levels. However, it is not felt necessary to administer carnitine supplementation with the low doses used to treat patients with HBV (10 mg/d).

Adefovir is embryotoxic in rats at high doses and is genotoxic in preclinical studies.

## ENTECAVIR

Entecavir is an orally administered guanosine nucleoside analog (Figure 49) that competitively inhibits all three functions of HBV DNA polymerase, including base priming, reverse transcription of the negative strand, and synthesis of the positive strand of HBV DNA. Oral bioavailability approaches 100% but is decreased by food; therefore, entecavir should be taken on an empty stomach. The intracellular half-life of the active phosphorylated compound is 15 hours. It is excreted by the kidney, undergoing both glomerular filtration and net tubular secretion.

Comparison with lamivudine in patients with chronic HBV infection demonstrated similar rates of HBeAg seroconversion but significantly higher rates of HBV DNA viral suppression with entecavir, normalization of serum alanine aminotransferase levels, and histologic improvement in the liver. Entecavir appears to have a higher barrier to the emergence of resistance than lamivudine. Although selection of resistant isolates with the S202G mutation has been documented during therapy, clinical resistance is rare (< 1% at 4 years). Also, decreased susceptibility to entecavir may occur in association with lamivudine resistance. Entecavir is well tolerated. The most frequently reported adverse events are headache, fatigue, dizziness, and nausea. Lung adenomas and carcinomas in mice, hepatic adenomas and carcinomas in rats and mice, vascular tumors in mice, and brain gliomas and skin fibromas in rats have been observed at varying exposures. Co-administration of entecavir with drugs that reduce renal function or compete for active tubular secretion may increase serum concentrations of either entecavir or the co-administered drug.

## LAMIVUDINE

The pharmacokinetics of lamivudine are described earlier in this chapter (see section, Nucleoside and Nucleotide Reverse Transcriptase Inhibitors). The more prolonged intracellular half-life in HBV cell lines (17–19 hours) than in HIV-infected cell lines (10.5–15.5 hours) allows for lower doses and less frequent administration. Lamivudine can be safely administered to patients with decompensated liver disease.

Lamivudine inhibits HBV DNA polymerase and HIV reverse transcriptase by competing with deoxycytidine triphosphate for incorporation into the viral DNA, resulting in chain termination. Lamivudine achieves 3–4 log decreases in viral replication in most patients and suppression of HBV DNA to undetectable levels in about 44% of patients. Seroconversion of HBeAg from positive to negative occurs in about 17% of patients and is durable at 3 years in about 70% of responders. Continuation of treatment for 4–8 months after seroconversion may improve the durability of response. Response in HBeAg-negative patients is initially high but less durable.

Although lamivudine results in rapid and potent virus suppression, chronic therapy may ultimately be limited by the emergence of lamivudine-resistant HBV isolates (eg, L180M or M204I/V), estimated at 15–30% at 1 year and 70% at 5 years of therapy. Resistance has been associated with flares of hepatitis and progressive liver disease. Cross-resistance between lamivudine and emtricitabine or entecavir may occur; however, adefovir maintains activity against lamivudine-resistant strains of HBV.

In the doses used for HBV infection, lamivudine has an excellent safety profile. Headache, nausea, and dizziness are rare. Co-infection with HIV may increase the risk of pancreatitis. No evidence of mitochondrial toxicity has been reported.

## TELBIVUDINE

Telbivudine is a thymidine nucleoside analog with activity against HBV DNA polymerase. It is phosphorylated by cellular kinases to the active triphosphate form, which has an intracellular half-life of 14 hours. The phosphorylated compound competitively inhibits HBV DNA polymerase, resulting in incorporation into viral DNA and chain termination. It is not active in vitro against HIV-1.

Oral bioavailability is unaffected by food. Plasma protein-binding is low (3%) and distribution wide. The serum half-life is approximately 15 hours and excretion is renal. There are no known metabolites and no known interactions with the CYP450 system or other drugs.

In a comparative trial against lamivudine in patients with chronic HBV infection, significantly more patients receiving telbivudine achieved the combined end point of suppression of HBV DNA to less than 5 log copies/mL plus loss of serum HBeAg. The mean reduction in HBV DNA from baseline, the proportion with ALT normalization, and HBeAg seroconversion all were greater in those receiving telbivudine. Liver biopsies performed 1 year later showed less scarring. However, emergence of resistance, typically due to the M204I mutation, may occur in up to 22% with durations of therapy exceeding 1 year, and may result in virologic rebound.

Adverse effects in clinical trials were mild, including fatigue, headache, abdominal pain, upper respiratory infection, increased creatine phosphokinase levels, and nausea and vomiting. A potential association with peripheral neuropathy is under evaluation. As with other nucleoside analogs, lactic acidosis and severe hepatomegaly with steatosis may occur during therapy as well as flares of hepatitis after discontinuation.

## TENOFOVIR

Tenofovir, a nucleotide analog of adenosine in use as an antiretroviral agent, has recently gained licensure for the treatment of patients with chronic HBV infection. The characteristics of tenofovir are described earlier in this chapter. Tenofovir maintains activity against lamivudine- and entecavir-resistant isolates but has reduced activity against adefovir-resistant strains. Although similar in structure to adefovir dipivoxil, recent comparative trials showed a significantly higher rate of complete response, defined as serum HBV DNA levels less than 400 copies/mL, as well as of histologic improvement, in patients with chronic HBV infection receiving tenofovir than in those receiving adefovir dipivoxil. The emergence of resistance appears to be substantially less frequent during therapy with tenofovir than with adefovir.

## INVESTIGATIONAL AGENTS

Compounds in clinical development for the treatment of patients with HBV infection include the nucleoside analogs **emtricitabine**, **clevudine**, **valtorcitabine**, **pradefovir**, and **alamifovir**, as well as the immunologic modulator **thymosin alpha-1**, agents that facilitate uptake by the liver using conjugation to ligands, and RNA interference

compounds.

## Treatment of Hepatitis C Infection

In contrast to the treatment of patients with chronic HBV infection, the primary goal of treatment in patients with HCV infection is viral eradication. In clinical trials, the primary efficacy end point is typically achievement of sustained viral response (SVR), defined as the absence of detectable viremia for 6 months after completion of therapy. SVR is associated with improvement in liver histology and reduction in risk of hepatocellular carcinoma and occasionally with regression of cirrhosis as well. Late relapse occurs in less than 5% of patients who achieve SVR.

In acute hepatitis C, the rate of clearance of the virus without therapy is estimated at 15%–30%. In one (uncontrolled) study, treatment of acute infection with interferon alfa-2b, in doses higher than those used for chronic hepatitis C (Table 49–6), resulted in a sustained rate of clearance of 95% at 6 months. Therefore, if HCV RNA testing documents persistent viremia 12 weeks after initial seroconversion, antiviral therapy is recommended.

Treatment of patients with chronic HCV infection is recommended for those with an increased risk for progression to cirrhosis. The parameters for selection are complex. In those who are to be treated, however, the current standard of treatment is once-weekly pegylated interferon alfa in combination with daily oral ribavirin. Pegylated interferon alfa-2a and -2b have replaced their unmodified interferon alfa counterparts because of superior efficacy in combination with ribavirin, regardless of genotype. It is also clear that combination therapy with oral ribavirin is more effective than monotherapy with either interferon or ribavirin alone. Therefore, monotherapy with pegylated interferon alfa is recommended only in patients who cannot tolerate ribavirin. Factors associated with a favorable response to therapy include HCV genotype 2 or 3, absence of cirrhosis on liver biopsy, and low pretreatment HCV RNA levels.

## RIBAVIRIN

Ribavirin is a guanosine analog that is phosphorylated intracellularly by host cell enzymes. Although its mechanism of action has not been fully elucidated, it appears to interfere with the synthesis of guanosine triphosphate, to inhibit capping of viral messenger RNA, and to inhibit the viral RNA-dependent polymerase of certain viruses. Ribavirin triphosphate inhibits the replication of a wide range of DNA and RNA viruses, including influenza A and B, parainfluenza, respiratory syncytial virus, paramyxoviruses, HCV, and HIV-1.

The absolute oral bioavailability of ribavirin is 45%–64%, increases with high-fat meals, and decreases with co-administration of antacids. Plasma protein binding is negligible, volume of distribution is large, and cerebrospinal fluid levels are about 70% of those in plasma. Ribavirin elimination is primarily through the urine; therefore, clearance is decreased in patients with creatinine clearances less than 30 mL/min.

Higher doses of ribavirin (ie, 1000–1200 mg/d, according to weight, rather than 800 mg/d) or a longer duration of therapy or both may be more efficacious in those with a lower likelihood of response to therapy (eg, those with genotype 1 or 4) or in those who have relapsed. This must be balanced with an increased likelihood of toxicity. A dose-dependent hemolytic anemia occurs in 10%–20% of patients. Other potential adverse effects are depression, fatigue, irritability, rash, cough, insomnia, nausea, and pruritus. Contraindications to ribavirin therapy include uncorrected anemia, end-stage renal failure, ischemic vascular disease, and pregnancy. Ribavirin is teratogenic and embryotoxic in animals as well as mutagenic in mammalian cells. Patients exposed to the drug should not conceive children for at least 6 months thereafter.

## INVESTIGATIONAL AGENTS

Investigational agents for the treatment of HCV infection are multiple and include inhibitors of the HCV RNA polymerase such as **valopicitabine**, PIs such as **telaprevir**, the ribavirin analogs **merimepodib** and **viramidine**, an anti-aminophospholipid antibody, a caspase inhibitor, and the immunomodulator thymosin alpha-1.

## ANTI-INFLUENZA AGENTS

Influenza virus strains are classified by their core proteins (ie, A, B, or C), species of origin (eg, avian, swine), and geographic site of isolation. Influenza A, the only strain that causes pandemics, is classified into 16 H (hemagglutinin) and 9 N (neuraminidase) known subtypes based on surface proteins. Although influenza B viruses usually infect only people, influenza A viruses can infect a variety of animal hosts. Current influenza A subtypes that are circulating among people worldwide include H1N1, H1N2, and H3N2. Fifteen subtypes are known to infect birds, providing an extensive reservoir. Although avian influenza subtypes are typically highly species-specific, they have on rare occasions crossed the species barrier to infect humans and cats. Viruses of the H5 and H7 subtypes (eg, H5N1, H7N7, and H7N3) may rapidly mutate within poultry flocks from a low to high pathogenic form and have recently expanded their host range to cause both avian and human disease. Of particular concern is the H5N1 virus, which first caused human infection (including severe disease and death) in 1997 and has become endemic in Southeast Asia poultry since 2003. It is feared that the virus will become transmissible from person to person rather than solely from poultry to human, thus initiating the potential for a global outbreak (ie, pandemic).

Although antiviral drugs available for influenza have activity against influenza A, many or most of the circulating strains of avian H5N1, as well as the H1 and H3 strains causing seasonal influenza in the United States, are resistant to the adamantane agents. Resistance to oseltamivir has also increased dramatically.

## AMANTADINE & RIMANTADINE

Amantadine (1-aminoadamantane hydrochloride) and its  $\alpha$ -methyl derivative, rimantadine, are tricyclic amines of the adamantane family that block the M2 proton ion channel of the virus particle and inhibit uncoating of the viral RNA within infected host cells, thus preventing its replication. They are active against influenza A only. Rimantadine is four to ten times more active than amantadine in vitro. Amantadine is well absorbed and 67% protein-bound. Its plasma half-life is 12–18 hours and varies by creatinine clearance. Rimantadine is about 40% protein-bound and has a half-life of 24–36 hours. Nasal secretion and salivary levels approximate those in the serum, and cerebrospinal fluid levels are 52%–96% of those in the serum; nasal mucus concentrations of rimantadine average 50% higher than those in plasma. Amantadine is excreted unchanged in the urine, whereas rimantadine undergoes extensive metabolism by hydroxylation, conjugation, and glucuronidation before urinary excretion. Dose reductions are required for both agents in the elderly and in patients with renal insufficiency and for rimantadine in patients with marked hepatic insufficiency.

In the absence of resistance, both amantadine and rimantadine, at 100 mg twice daily or 200 mg once daily, are 70%–90% protective in the prevention of clinical illness when initiated before exposure. When begun within 1–2 days after the onset of illness, the duration of fever and systemic symptoms is reduced by 1–2 days.

The primary target for both agents is the M2 protein within the viral membrane, incurring both influenza A specificity and a mutation-prone site that results in the rapid development of resistance in up to 50% of treated individuals. Resistant isolates with single-point mutations are genetically stable, retain pathogenicity, can be transmitted to close contacts, and may be shed chronically by immunocompromised patients. The marked increase in the prevalence of resistance to both agents in clinical isolates over the last decade, in influenza A H1N1 as well as H3N2, has limited the usefulness of these agents for either the treatment or the prevention of influenza. Cross-resistance to

zanamivir and oseltamivir does not occur.

The most common adverse effects are gastrointestinal (nausea, anorexia) and central nervous system (nervousness, difficulty in concentrating, insomnia, light-headedness); these are dose-related. Central nervous system toxicity may be due to alteration of dopamine neurotransmission (see Chapter 28), is less frequent with rimantadine than with amantadine, tends to diminish after the first week of use, and may increase with concomitant antihistamines, anticholinergic drugs, hydrochlorothiazide, and trimethoprim-sulfamethoxazole. Serious neurotoxic reactions, occasionally fatal, may occur in association with high amantadine plasma concentrations and are more likely in the elderly or those with renal insufficiency. Clinical manifestations of anticholinergic activity tend to be present in acute amantadine overdose. Both agents are teratogenic in rodents, and birth defects have been reported after exposure during pregnancy.

## **OSELTAMIVIR & ZANAMIVIR**

The neuraminidase inhibitors oseltamivir and zanamivir, analogs of sialic acid, interfere with release of progeny influenza virus from infected to new host cells, thus halting the spread of infection within the respiratory tract. These agents competitively and reversibly interact with the active enzyme site to inhibit neuraminidase activity at low nanomolar concentrations and destroy the receptors recognized by viral hemagglutinin on cells, newly released virions, and respiratory tract mucins. Unlike amantadine and rimantadine, oseltamivir and zanamivir have activity against both influenza A and influenza B viruses. Early administration is crucial because replication of influenza virus peaks at 24–72 hours after the onset of illness. When a 5-day course of therapy is initiated within 36–48 hours after the onset of symptoms, the duration of illness is decreased by 1–2 days compared with those on placebo, severity is diminished, and the incidence of secondary complications in children and adults decreases. Once-daily prophylaxis is 70–90% effective in preventing disease after exposure. Oseltamivir is FDA-approved for patients 1 year and older, whereas zanamivir is approved in patients 7 years or older.

Oseltamivir is an orally administered prodrug that is activated by hepatic esterases and widely distributed throughout the body. The dosage is 75 mg twice daily for 5 days for treatment and 75 mg once daily for prevention; dosage must be modified in patients with renal insufficiency. Oral bioavailability is approximately 80%, plasma protein binding is low, and concentrations in the middle ear and sinus fluid are similar to those in plasma. The half-life of oseltamivir is 6–10 hours, and excretion is by glomerular filtration and tubular secretion in the urine. Probenecid reduces renal clearance of oseltamivir by 50%. Serum concentrations of oseltamivir carboxylate, the active metabolite of oseltamivir, increase with declining renal function; therefore, dosage should be adjusted in such patients. Potential adverse effects include nausea, vomiting, and abdominal pain, which occur in 5–10% of patients early in therapy but tend to resolve spontaneously. Taking oseltamivir with food does not interfere with absorption and may decrease nausea and vomiting. Headache, fatigue, and diarrhea have also been reported and appear to be more common with prophylactic use. Rash is rare.

Zanamivir is delivered directly to the respiratory tract via inhalation. Ten to twenty percent of the active compound reaches the lungs, and the remainder is deposited in the oropharynx. The concentration of the drug in the respiratory tract is estimated to be more than 1000 times the 50% inhibitory concentration for neuraminidase, and the pulmonary half-life is 2.8 hours. Five to fifteen percent of the total dose (10 mg twice daily for 5 days for treatment and 10 mg once daily for prevention) is absorbed and excreted in the urine with minimal metabolism. Potential adverse effects include cough, bronchospasm (occasionally severe), reversible decrease in pulmonary function, and transient nasal and throat discomfort.

In adults, resistance to oseltamivir may be associated with point mutations in the viral hemagglutinin or neuraminidase genes. Rates of resistance to oseltamivir among H1N1 viruses have risen abruptly and dramatically worldwide, reaching 97.4% in tested strains in the USA from 2008 to 2009. No tested H1N1 viruses were resistant to zanamivir, and all A (H3N2) and influenza B viruses were susceptible to both oseltamivir and zanamivir.

## **OTHER ANTIVIRAL AGENTS**

### **INTERFERONS**

Interferons have been studied for numerous clinical indications. In addition to HBV and HCV infections (see Antihepatitis Agents), intravesical injection of interferon alfa-2b or alfa-n3 may be used for treatment of condylomata acuminata (see Chapter 61).

### **RIBAVIRIN**

In addition to oral administration for hepatitis C infection in combination with interferon alfa, aerosolized ribavirin is administered by nebulizer (20 mg/mL for 12–18 hours per day) to children and infants with severe respiratory syncytial virus (RSV) bronchiolitis or pneumonia to reduce the severity and duration of illness. Aerosolized ribavirin has also been used to treat influenza A and B infections but has not gained widespread use. Systemic absorption is low (< 1%). Aerosolized ribavirin is generally well tolerated but may cause conjunctival or bronchial irritation. Health care workers should be protected against extended inhalation exposure. The aerosolized drug may precipitate on contact lenses.

Intravenous ribavirin decreases mortality in patients with Lassa fever and other viral hemorrhagic fevers if started early. High concentrations inhibit West Nile virus in vitro, but clinical data are lacking. Clinical benefit has been reported in cases of severe measles pneumonitis and certain encephalitides, and continuous infusion of ribavirin has decreased virus shedding in several patients with severe lower respiratory tract influenza or parainfluenza infections. At steady state, cerebrospinal fluid levels are about 70% of those in plasma.

### **PALIVIZUMAB**

Palivizumab is a humanized monoclonal antibody directed against an epitope in the A antigen site on the F surface protein of RSV. It is licensed for the prevention of RSV infection in high-risk infants and children, such as premature infants and those with bronchopulmonary dysplasia or congenital heart disease. A placebo-controlled trial using once-monthly intramuscular injections (15 mg/kg) for 5 months beginning at the start of the RSV season demonstrated a 55% reduction in the risk of hospitalization for RSV in treated patients, as well as decreases in the need for supplemental oxygen, illness severity score, and need for intensive care. Although resistant strains have been isolated in the laboratory, no resistant clinical isolates have yet been identified. Potential adverse effects include upper respiratory tract infection, fever, rhinitis, rash, diarrhea, vomiting, cough, otitis media, and elevation in serum aminotransferase levels.

### **IMIQUIMOD**

Imiquimod is an immune response modifier shown to be effective in the topical treatment of external genital and perianal warts (ie, condyloma acuminatum; see Chapter 61). The 5% cream is applied three times weekly and washed off 6–10 hours after each application. Recurrences appear to be less common than after ablative therapies. Imiquimod is also effective against actinic keratoses, and possibly, molluscum contagiosum. Local skin reactions are the most common side effect; these tend to resolve

within weeks after therapy. However, pigmentary skin changes may persist. Systemic adverse effects such as fatigue and influenza-like syndrome have occasionally been reported.

## PREPARATIONS AVAILABLE

### **Abacavir**

Oral (Ziagen): 300 mg tablets; 20 mg/mL solution

Oral (Epzicom): 600 mg plus 300 mg lamivudine

Oral (Trizivir): 300 mg tablets in combination with 150 mg lamivudine and 300 mg zidovudine

### **Acyclovir** (generic, Zovirax)

Oral: 200 mg capsules; 400, 800 mg tablets; 200 mg/5 mL suspension

Parenteral: 50 mg/mL; powder to reconstitute for injection (500, 1000 mg/vial)

Topical: 5% ointment

### **Adefovir** (Hepsera)

Oral: 10 mg tablets

### **Amantadine** (generic, Symmetrel)

Oral: 100 mg capsules, tablets; 50 mg/5 mL syrup

### **Amprenavir** (Agenerase)

Oral: 50 mg capsules; 15 mg/mL solution

### **Atazanavir** (Reyataz)

Oral: 100, 150, 200 mg capsules

### **Cidofovir** (Vistide)

Parenteral: 375 mg/vial (75 mg/mL) for IV injection

### **Darunavir** (Prezista)

Oral: 300 mg tablets (must be taken with ritonavir)

### **Delavirdine** (Rescriptor)

Oral: 100, 200 mg tablets

### **Didanosine** (dideoxyinosine, ddI)

Oral (Videx): 25, 50, 100, 150, 200 mg tablets; 100, 167, 250 mg powder for oral solution; 2, 4 g powder for pediatric solution

Oral (Videx-EC): 125, 200, 250, 400 mg delayed-release capsules

### **Docosanol** (Abreva) (over-the-counter)

Topical: 10% cream

### **Efavirenz** (Sustiva)

Oral: 50, 100, 200 mg capsules; 600 mg tablets

### **Emtricitabine**

Oral (Emtriva): 200 mg tablets

Oral (Truvada): 200 mg plus 300 mg tenofovir tablets

### **Enfuvirtide** (Fuzeon)

Parenteral: 90 mg/mL for injection

### **Entecavir** (Baraclude)

Oral: 0.5, 1 mg tablets; 0.05 mg/mL oral solution

**Etravirine** (Intelence)

Oral: 100 mg tablets

**Famciclovir** (Famvir)

Oral: 125, 250, 500 mg tablets

**Fomivirsen** (Vitravene)

Intraocular injection: 6.6 mg/mL

**Fosamprenavir** (Lexiva)

Oral: 700 mg tablets

**Foscarnet** (Foscavir)

Parenteral: 24 mg/mL for IV injection

**Ganciclovir** (Cytovene)

Oral: 250, 500 mg capsules

Parenteral: 500 mg/vial for IV injection

Intraocular implant (Vitrasert): 4.5 mg ganciclovir/implant

**Idoxuridine** (Herplex)

Ophthalmic: 0.1% solution

**Imiquimod** (Aldera)

Topical: 5% cream

**Indinavir** (Crixivan)

Oral: 100, 200, 333, 400 mg capsules

**Interferon alfa-2a** (Roferon-A)

Parenteral: 3, 6, 9, 36 million IU vials

**Interferon alfa-2b** (Intron A)

Parenteral: 3, 5, 10, 18, 25, and 50 million IU vials

**Interferon alfa-2b** (Rebetron)

Parenteral: 3 million IU vials (supplied with oral ribavirin, 200 mg capsules)

**Interferon alfa-n3** (Alferon N)

Parenteral: 5 million IU/vial

**Interferon alfacon-1** (Infergen)

Parenteral: 9 and 15 mcg vials

**Lamivudine**

Oral (Epivir): 150, 300 mg tablets; 10 mg/mL oral solution

Oral (Epivir-HBV): 100 mg tablets; 5 mg/mL solution

Oral (Combivir): 150 mg tablets in combination with 300 mg zidovudine

Oral (Trizivir): 150 mg tablets in combination with 300 mg abacavir and 300 mg zidovudine

**Lopinavir/ritonavir** (Kaletra)

Oral: 133.3 mg/33.3 mg capsules; 80 mg/20 mg per mL solution

**Maraviroc** (Selzentry)

Oral: 150, 300 mg tablets

**Nelfinavir** (Viracept)

Oral: 250, 625 mg tablets; 50 mg/g powder

**Nevirapine** (Viramune)

Oral: 200 mg tablets; 50 mg/5 mL suspension

**Oseltamivir** (Tamiflu)

Oral: 75 mg capsules; powder to reconstitute as suspension (12 mg/mL)

**Palivizumab** (Synagis)

Parenteral: 50, 100 mg/vial

**Peginterferon alfa-2a** (pegylated interferon alfa-2a, Pegasys)

Parenteral: 180 mcg/mL

**Peginterferon alfa-2b** (pegylated interferon alfa-2b, PEG-Intron)

Parenteral: powder to reconstitute as 100, 160, 240, 300 mcg/mL injection

**Penciclovir** (Denavir)

Topical: 1% cream

**Raltegravir** (Isentress)

Oral: 400 mg tablets

**Ribavirin**

Aerosol (Virazole): powder to reconstitute for aerosol; 6 g/100 mL vial

Oral (Rebetol, generic): 200 mg capsules, tablets; 40 mg/mL oral solution

Oral (Rebetron): 200 mg in combination with 3 million units interferon alfa-2b (Intron-A)

**Rifabutin** (Mycobutin)

Oral: 150 mg capsules

**Rimantadine** (Flumadine)

Oral: 100 mg tablets; 50 mg/5 mL syrup

**Ritonavir** (Norvir)

Oral: 100 mg capsules; 80 mg/mL oral solution

**Saquinavir**

Oral (Invirase): 200 mg hard gel capsules, 500 mg tablets

Oral (Fortovase): 200 mg soft gel capsules

**Stavudine**

Oral (Zerit): 15, 20, 30, 40 mg capsules; powder for 1 mg/mL oral solution

Oral extended-release (Zerit XR): 37.5, 50, 75, 100 mg capsules

**Telbivudine** (Tyzeka)

Oral: 600 mg tablets

**Tenofovir** (Viread)

Oral: 300 mg tablets

**Tipranavir** (Aptivus)

Oral: 250 mg capsules

**Trifluridine** (Viroptic)

Topical: 1% ophthalmic solution

**Valacyclovir** (Valtrex)

Oral: 500, 1000 mg tablets

**Valganciclovir** (Valcyte)

Oral: 450 mg capsules

**Vidarabine** (Vira-A)

Topical: 3% ointment

**Zalcitabine** (dideoxycytidine, ddC) (Hivid)

Oral: 0.375, 0.75 mg tablets

**Zanamivir** (Relenza)

Inhalational: 5 mg/blister

**Zidovudine** (azidothymidine, AZT) (Retrovir)

Oral: 100 mg capsules, 300 mg tablets, 50 mg/5 mL syrup

Oral (Combivir): 300 mg tablets in combination with 150 mg lamivudine

Oral (Trizivir): 300 mg tablets in combination with 150 mg lamivudine and 300 mg zidovudine

Parenteral: 10 mg/mL

**Basic and Clinical Pharmacology** > Chapter 50. Miscellaneous Antimicrobial Agents; Disinfectants, Antiseptics, & Sterilants >

## CASE STUDY

A 66-year-old man is admitted to the intensive care unit of a hospital for treatment of community-acquired pneumonia. He receives ceftriaxone and azithromycin upon admission, rapidly improves, and is transferred to a semiprivate ward room. On day 7 of his hospitalization, he develops copious diarrhea with eight bowel movements that day but is otherwise clinically stable. *Clostridium difficile*-associated colitis is suspected and a toxin assay is sent to confirm this diagnosis. What is an acceptable treatment for the patient's diarrhea? The patient is transferred to a single-bed room the following day. The housekeeping staff asks if the old room should be cleaned with alcohol or bleach. Which product should be chosen? Why?

## METRONIDAZOLE, MUPIROCIN, POLYMYXINS, & URINARY ANTISEPTICS

### METRONIDAZOLE

Metronidazole is a nitroimidazole antiprotozoal drug (see Chapter 52) that also has potent antibacterial activity against anaerobes, including bacteroides and *Clostridium* species. It is well absorbed after oral administration, is widely distributed in tissues, and reaches serum levels of 4–6 mcg/mL after a 250-mg oral dose. Metronidazole can also be given intravenously or by rectal suppository. The drug penetrates well into the cerebrospinal fluid and brain, reaching levels similar to those in serum. Metronidazole is metabolized in the liver and may accumulate in hepatic insufficiency.

Metronidazole is indicated for treatment of anaerobic or mixed intra-abdominal infections, vaginitis (trichomonas infection, bacterial vaginosis), *C difficile* colitis, and brain abscess. The typical dosage is 500 mg three times daily orally or intravenously (30 mg/kg/d). Vaginitis may respond to a single 2-g dose. A vaginal gel is available for topical use.

Adverse effects include nausea, diarrhea, stomatitis, and peripheral neuropathy with prolonged use. Metronidazole has a disulfiram-like effect, and patients should be instructed to avoid alcohol. Although teratogenic in some animals, metronidazole has not been associated with this effect in humans. Other properties of metronidazole are discussed in Chapter 52.

A structurally similar agent, tinidazole, is a once-daily drug approved for treatment of trichomonas infection, giardiasis, and amebiasis. It also is active against anaerobic bacteria, but is not FDA-approved for treatment of anaerobic infections.

### MUPIROCIN

Mupirocin (pseudomonic acid) is a natural product produced by *Pseudomonas fluorescens*. It is rapidly inactivated after absorption, and systemic levels are undetectable. It is available as an ointment for

topical application.

Mupirocin is active against gram-positive cocci, including methicillin-susceptible and methicillin-resistant strains of *Staphylococcus aureus*. Mupirocin inhibits staphylococcal isoleucyl tRNA synthetase. Low-level resistance, defined as a minimum inhibitory concentration (MIC) of up to 100 mcg/mL, is due to point mutation in the gene of the target enzyme. Low-level resistance has been observed after prolonged use. However, local concentrations achieved with topical application are well above this MIC, and this level of resistance appears not to result in clinical failure. High-level resistance, with MICs exceeding 1000 mcg/mL, is due to the presence of a second isoleucyl tRNA synthetase gene, which is plasmid-encoded. High-level resistance results in complete loss of activity. Strains with high-level resistance have caused nosocomial (hospital) outbreaks of staphylococcal infection and colonization. Although higher rates of resistance are encountered with intensive use of mupirocin, more than 95% of staphylococcal isolates are still susceptible.

Mupirocin is indicated for topical treatment of minor skin infections, such as impetigo (see Chapter 61). Topical application over large infected areas, such as decubitus ulcers or open surgical wounds, has been identified as an important factor leading to emergence of mupirocin-resistant strains and is not recommended. Mupirocin effectively eliminates *S aureus* nasal carriage by patients or health care workers, but results are mixed with respect to its ability to prevent subsequent staphylococcal infection.

## **POLYMYXINS**

The polymyxins are a group of basic peptides active against gram-negative bacteria and include **polymyxin B** and **polymyxin E (colistin)**. Polymyxins act like cationic detergents. They attach to and disrupt bacterial cell membranes. They also bind and inactivate endotoxin. Gram-positive organisms, proteus, and neisseria are resistant.

Owing to their significant toxicity with systemic administration, polymyxins have been largely restricted to topical use. Ointments containing polymyxin B, 0.5 mg/g, in mixtures with bacitracin or neomycin (or both) are commonly applied to infected superficial skin lesions. Emergence of strains of *Acinetobacter baumannii* and *Pseudomonas aeruginosa* that are resistant to all other agents has led to renewed interest in polymyxins, eg, colistin as a parenteral agent for salvage therapy of infections caused by these organisms.

## **URINARY ANTISEPTICS**

Urinary antiseptics are oral agents that exert antibacterial activity in the urine but have little or no systemic antibacterial effect. Their usefulness is limited to lower urinary tract infections. Prolonged suppression of bacteriuria by means of urinary antiseptics may be desirable in chronic urinary tract infections in which eradication of infection by short-term systemic therapy has not been possible.

### **Nitrofurantoin**

Nitrofurantoin is bacteriostatic and bactericidal for many gram-positive and gram-negative bacteria but *P aeruginosa* and many strains of proteus are resistant. There is no cross-resistance between nitrofurantoin and other antimicrobial agents and resistance emerges slowly. As *Escherichia coli* resistant to trimethoprim-sulfamethoxazole and fluoroquinolones has become more common, nitrofurantoin has become an important alternative oral agent for treatment of uncomplicated urinary tract infection.

Nitrofurantoin is well absorbed after ingestion. It is metabolized and excreted so rapidly that no systemic antibacterial action is achieved. The drug is excreted into the urine by both glomerular filtration and tubular secretion. With average daily doses, concentrations of 200 mcg/mL are reached in urine. In renal

failure, urine levels are insufficient for antibacterial action, but high blood levels may cause toxicity. Nitrofurantoin is contraindicated in patients with significant renal insufficiency.

The dosage for urinary tract infection in adults is 100 mg orally taken four times daily. The drug should not be used to treat upper urinary tract infection. Oral nitrofurantoin can be given for months for the suppression of chronic urinary tract infection. It is desirable to keep urinary pH below 5.5, which greatly enhances drug activity. A single daily dose of nitrofurantoin, 100 mg, can prevent recurrent urinary tract infections in some women.

Anorexia, nausea, and vomiting are the principal side effects of nitrofurantoin. Neuropathies and hemolytic anemia occur in glucose-6-phosphate dehydrogenase deficiency. Nitrofurantoin antagonizes the action of nalidixic acid. Rashes, pulmonary infiltration and fibrosis, and other hypersensitivity reactions have been reported.

### **Methenamine Mandelate & Methenamine Hippurate**

Methenamine mandelate is the salt of mandelic acid and methenamine and possesses properties of both of these urinary antiseptics. Methenamine hippurate is the salt of hippuric acid and methenamine. Below pH 5.5, methenamine releases formaldehyde, which is antibacterial. Mandelic acid or hippuric acid taken orally is excreted unchanged in the urine, in which these drugs are bactericidal for some gram-negative bacteria when pH is less than 5.5.

Methenamine mandelate, 1 g four times daily, or methenamine hippurate, 1 g twice daily by mouth (children, 50 mg/kg/d or 30 mg/kg/d, respectively), is used only as a urinary antiseptic to suppress, not treat, urinary tract infection. Acidifying agents (eg, ascorbic acid, 4â€”12 g/d) may be given to lower urinary pH below 5.5. Sulfonamides should not be given at the same time because they may form an insoluble compound with the formaldehyde released by methenamine. Persons taking methenamine mandelate may exhibit falsely elevated tests for catecholamine metabolites.

### **DISINFECTANTS, ANTISEPTICS, & STERILANTS**

Disinfectants are strong chemical agents that inhibit or kill microorganisms (Table 50â€”1). Antiseptics are disinfecting agents with sufficiently low toxicity for host cells that they can be used directly on skin, mucous membranes, or wounds. Sterilants kill both vegetative cells and spores when applied to materials for appropriate times and temperatures. Some of the terms used in this context are defined in Table 50â€”2.

**Table 50â€”1 Activities of Disinfectants.**

	<b>Bacteria</b>		<b>Viruses</b>				<b>Other</b>		
	<b>Gram-positive</b>	<b>Gram-negative</b>	<b>Acid-Fast</b>	<b>Spores</b>	<b>Lipophilic</b>	<b>Hydrophilic</b>	<b>Fungi</b>	<b>Amebic Cysts</b>	<b>Prions</b>
Alcohols (isopropanol, ethanol)	HS	HS	S	R	S	V	...	...	R

HS, highly susceptible; S, susceptible; MS, moderately susceptible; R, resistant; V, variable; . . ., no data.

### **Table 50-2 Commonly Used Terms Related to Chemical and Physical Killing of Microorganisms.**

<b>Antisepsis</b>	Application of an agent to living tissue for the purpose of preventing infection
<b>Decontamination</b>	Destruction or marked reduction in number or activity of microorganisms
<b>Disinfection</b>	Chemical or physical treatment that destroys most vegetative microbes or viruses, but not spores, in or on inanimate surfaces
<b>Sanitization</b>	Reduction of microbial load on an inanimate surface to a level considered acceptable for public health purposes
<b>Sterilization</b>	A process intended to kill or remove all types of microorganisms, including spores, and usually including viruses, with an acceptably low probability of survival
<b>Pasteurization</b>	A process that kills nonsporulating microorganisms by hot water or steam at 65-100°C

Disinfection prevents infection by reducing the number of potentially infective organisms by killing, removing, or diluting them. Disinfection can be accomplished by application of chemical agents or use of physical agents such as ionizing radiation, dry or moist heat, or superheated steam (autoclave, 120°C) to kill microorganisms. Often a combination of agents is used, eg, water and moderate heat over time (pasteurization); ethylene oxide and moist heat (a sterilant); or addition of disinfectant to a detergent. Prevention of infection also can be achieved by washing, which dilutes the potentially infectious organism, or by establishing a barrier, eg, gloves, condom, or respirator, which prevents the pathogen from entry into the host.

**Handwashing** is the most important means of preventing transmission of infectious agents from person to person or from regions of high microbial load, eg, mouth, nose, or gut, to potential sites of infection. Soap and warm water efficiently and effectively remove bacteria. Skin disinfectants along with detergent and water are usually used preoperatively as a surgical scrub for surgeons' hands and the patient's

surgical incision.

Evaluation of effectiveness of antiseptics, disinfectants, and sterilants, although seemingly simple in principle, is very complex. Factors in any evaluation include the intrinsic resistance of the microorganism, the number of microorganisms present, mixed populations of organisms, amount of organic material present (eg, blood, feces, tissue), concentration and stability of disinfectant or sterilant, time and temperature of exposure, pH, and hydration and binding of the agent to surfaces. Specific, standardized assays of activity are defined for each use. Toxicity for humans also must be evaluated. The Environmental Protection Agency (EPA) regulates disinfectants and sterilants and the FDA regulates antiseptics.

Users of antiseptics, disinfectants, and sterilants need to consider their short-term and long-term toxicity because they may have general biocidal activity and may accumulate in the environment or in the body of the patient or caregiver using the agent. Disinfectants and antiseptics may also become contaminated by resistant microorganisms—eg, spores, *P aeruginosa*, or *Serratia marcescens*—and actually transmit infection. Most topical antiseptics interfere with wound healing to some degree. Simple cleansing with soap and water is less damaging than antiseptics to wounds. Topical antibiotics with a narrow spectrum of action and low toxicity (eg, bacitracin and mupirocin) can be used for temporary control of bacterial growth and are generally preferred to antiseptics. Methenamine mandelate releases formaldehyde in a low antibacterial concentration at acid pH and can be an effective urinary antiseptic for long-term control of urinary tract infections.

Some of the chemical classes of antiseptics, disinfectants, and sterilants are described briefly in the text that follows. The reader is referred to the general references for descriptions of physical disinfection and sterilization methods.

## **ALCOHOLS**

The two alcohols most frequently used for antiseptics and disinfection are ethanol and isopropyl alcohol (isopropanol). They are rapidly active, killing vegetative bacteria, *Mycobacterium tuberculosis*, and many fungi and inactivating lipophilic viruses. The optimum bactericidal concentration is 60%–90% by volume in water. They probably act by denaturation of proteins. They are not used as sterilants because they are not sporicidal, do not penetrate protein-containing organic material, may not be active against hydrophilic viruses, and lack residual action because they evaporate completely. The alcohols are useful in situations in which sinks with running water are not available for washing with soap and water. Their skin-drying effect can be partially alleviated by addition of emollients to the formulation. Use of alcohol-based hand rubs has been shown to reduce transmission of nosocomial bacterial pathogens and is recommended by the Centers for Disease Control and Prevention (CDC) as the preferred method of hand decontamination. Alcohol-based hand rubs are ineffective against spores of *C difficile* and assiduous handwashing with a disinfectant soap and water is still required for decontamination after caring for a patient with infection from this organism.

Alcohols are flammable and must be stored in cool, well-ventilated areas. They must be allowed to evaporate before cautery, electrosurgery, or laser surgery. Alcohols may be damaging if applied directly to corneal tissue. Therefore, instruments such as tonometers that have been disinfected in alcohol should be rinsed with sterile water, or the alcohol should be allowed to evaporate before they are used.

## **CHLORHEXIDINE**

Chlorhexidine is a cationic biguanide with very low water solubility. Water-soluble chlorhexidine digluconate is used in water-based formulations as an antiseptic. It is active against vegetative bacteria

and mycobacteria and has moderate activity against fungi and viruses. It strongly adsorbs to bacterial membranes, causing leakage of small molecules and precipitation of cytoplasmic proteins. It is active at pH 5.5–7.0. Chlorhexidine gluconate is slower in its action than alcohols, but because of its persistence it has residual activity when used repeatedly, producing bactericidal action equivalent to alcohols. It is most effective against gram-positive cocci and less active against gram-positive and gram-negative rods. Spore germination is inhibited by chlorhexidine. Chlorhexidine digluconate is resistant to inhibition by blood and organic materials. However, anionic and nonionic agents in moisturizers, neutral soaps, and surfactants may neutralize its action. Chlorhexidine digluconate formulations of 4% concentration have slightly greater antibacterial activity than newer 2% formulations. Chlorhexidine 0.5% in 70% alcohol formulations are available in some countries. Chlorhexidine has a very low skin-sensitizing or irritating capacity. Oral toxicity is low because it is poorly absorbed from the alimentary tract. Chlorhexidine must not be used during surgery on the middle ear because it causes sensorineural deafness. Similar neural toxicity may be encountered during neurosurgery.

## HALOGENS

### Iodine

Iodine in a 1:20,000 solution is bactericidal in 1 minute and kills spores in 15 minutes. Tincture of iodine USP contains 2% iodine and 2.4% sodium iodide in alcohol. It is the most active antiseptic for intact skin. It is not commonly used because of serious hypersensitivity reactions that may occur and because of its staining of clothing and dressings.

### Iodophors

Iodophors are complexes of iodine with a surface-active agent such as **polyvinyl pyrrolidone (PVP; povidone-iodine)**. Iodophors retain the activity of iodine. They kill vegetative bacteria, mycobacteria, fungi, and lipid-containing viruses. They may be sporicidal upon prolonged exposure. Iodophors can be used as antiseptics or disinfectants, the latter containing more iodine. The amount of free iodine is low, but it is released as the solution is diluted. An iodophor solution must be diluted according to the manufacturer's directions to obtain full activity.

Iodophors are less irritating and less likely to produce skin hypersensitivity than tincture of iodine. They act as rapidly as chlorhexidine and have a broader spectrum of action, including sporicidal action, but they lack the persistent action of chlorhexidine.

### Chlorine

Chlorine is a strong oxidizing agent and universal disinfectant that is most commonly provided as a 5.25% **sodium hypochlorite** solution, a typical formulation for **household bleach**. Because formulations may vary, the exact concentration should be verified on the label. A 1:10 dilution of household bleach provides 5000 ppm of available chlorine. The CDC recommends this concentration for disinfection of blood spills. Less than 5 ppm kills vegetative bacteria, whereas up to 5000 ppm is necessary to kill spores. A concentration of 1000–10,000 ppm is tuberculocidal. One hundred ppm kills vegetative fungal cells in 1 hour, but fungal spores require 500 ppm. Viruses are inactivated by 200–500 ppm. Dilutions of 5.25% sodium hypochlorite made up in pH 7.5–8.0 tap water retain their activity for months when kept in tightly closed, opaque containers. Frequent opening and closing of the container reduces the activity markedly.

Because chlorine is inactivated by blood, serum, feces, and protein-containing materials, surfaces should be cleaned before chlorine disinfectant is applied. Undissociated hypochlorous acid (HOCl) is the active biocidal agent. When pH is increased, the less active hypochlorite ion,  $\text{OCl}^-$  is formed. When

hypochlorite solutions contact formaldehyde, the carcinogen *bis*-chloromethyl is formed. Rapid evolution of irritating chlorine gas occurs when hypochlorite solutions are mixed with acid and urine. Solutions are corrosive to aluminum, silver, and stainless steel.

Alternative chlorine-releasing compounds include **chlorine dioxide** and **chloramine T**. These agents retain chlorine longer and have a prolonged bactericidal action.

## PHENOLICS

**Phenol** itself (perhaps the oldest of the surgical antiseptics) is no longer used even as a disinfectant because of its corrosive effect on tissues, its toxicity when absorbed, and its carcinogenic effect. These adverse actions are diminished by forming derivatives in which a functional group replaces a hydrogen atom in the aromatic ring. The phenolic agents most commonly used are **o-phenylphenol**, **o-benzyl-p-chlorophenol**, and **p-tertiary amylphenol**. Mixtures of phenolic derivatives are often used. Some of these are derived from coal tar distillates, eg, cresols and xylenols. Skin absorption and skin irritation still occur with these derivatives, and appropriate care is necessary in their use. Detergents are often added to formulations to clean and remove organic material that may decrease the activity of a phenolic compound.

Phenolic compounds disrupt cell walls and membranes, precipitate proteins, and inactivate enzymes. They are bactericidal (including mycobacteria) and fungicidal and they are capable of inactivating lipophilic viruses. They are not sporicidal. Dilution and time of exposure recommendations of the manufacturer must be followed.

Phenolic disinfectants are used for hard surface decontamination in hospitals and laboratories, eg, floors, beds, and counter or bench tops. They are not recommended for use in nurseries and especially in bassinets, where their use has been associated with hyperbilirubinemia. Use of **hexachlorophene** as a skin disinfectant has caused cerebral edema and convulsions in premature infants and occasionally in adults.

## QUATERNARY AMMONIUM COMPOUNDS

The quaternary ammonium compounds ("quats") are cationic surface-active detergents. The active cation has at least one long water-repellent hydrocarbon chain, which causes the molecules to concentrate as an oriented layer on the surface of solutions and colloidal or suspended particles. The charged nitrogen portion of the cation has high affinity for water and prevents separation out of solution. The bactericidal action of quaternary compounds has been attributed to inactivation of energy-producing enzymes, denaturation of proteins, and disruption of the cell membrane. These agents are bacteriostatic, fungistatic, and sporicidal and also inhibit algae. They are bactericidal for gram-positive bacteria and moderately active against gram-negative bacteria. Lipophilic viruses are inactivated. They are not tuberculocidal or sporicidal, and they do not inactivate hydrophilic viruses. Quaternary ammonium compounds bind to the surface of colloidal protein in blood, serum, and milk and to the fibers in cotton, mops, cloths, and paper towels used to apply them, which can cause inactivation of the agent by removing it from solution. They are inactivated by anionic detergents (soaps), by many nonionic detergents, and by calcium, magnesium, ferric, and aluminum ions.

Quaternary compounds are used for sanitation of noncritical surfaces (floors, bench tops, etc). Their low toxicity has led to their use as sanitizers in food production facilities. The CDC recommends that quaternary ammonium compounds such as **benzalkonium chloride** *not* be used as antiseptics because several outbreaks of infections have occurred that were due to growth of *Pseudomonas* and other gram-negative bacteria in quaternary ammonium antiseptic solutions.

## **ALDEHYDES**

**Formaldehyde** and **glutaraldehyde** are used for disinfection or sterilization of instruments such as fiberoptic endoscopes, respiratory therapy equipment, hemodialyzers, and dental handpieces that cannot withstand exposure to the high temperatures of steam sterilization. They are not corrosive for metal, plastic, or rubber. These agents have a broad spectrum of activity against microorganisms and viruses. They act by alkylation of chemical groups in proteins and nucleic acids. Failures of disinfection or steri

**Note:** Large images and tables on this page may necessitate printing in landscape mode.

**Basic and Clinical Pharmacology** > Chapter 51. Clinical Use of Antimicrobial Agents >

## CASE STUDY

A 51-year-old alcoholic patient presents to the emergency department with fever, headache, and altered mental status for 12 hours. Vital signs are blood pressure 90/55 mm Hg, pulse 120/min, respirations 30/min, temperature 40°C [104°F] rectal. The patient is minimally responsive to voice and does not follow commands. Examination is significant for a right third cranial nerve palsy and nuchal rigidity. Laboratory results show a white blood cell count of 24,000/mm<sup>3</sup> with left shift, but other hematologic and chemistry values are within normal limits. An emergency CT scan of the head is normal. Blood cultures are obtained, and a lumbar puncture reveals the following cerebrospinal fluid (CSF) values: white blood cells 5000/mm<sup>3</sup>, red blood cells 10/mm<sup>3</sup>, protein 200 mg/dL, glucose 15 mg/dL (serum glucose 96 taken at same time). CSF Gram stain reveals gram-positive cocci in pairs. What is the most likely diagnosis in this patient? What organisms should be treated empirically? Are there other pharmacologic interventions to consider before initiating antimicrobial therapy?

## CLINICAL USE OF ANTIMICROBIAL AGENTS:

### INTRODUCTION

The development of antimicrobial drugs represents one of the most important advances in therapeutics, both in the control or cure of serious infections and in the prevention and treatment of infectious complications of other therapeutic modalities such as cancer chemotherapy and surgery. However, evidence is overwhelming that antimicrobial agents are vastly overprescribed in outpatient settings in the United States, and the availability of antimicrobial agents without prescription in many developing countries has facilitated the development of resistance already severely limited therapeutic options in the treatment of life-threatening infections. Therefore, the clinician should first determine whether antimicrobial therapy is warranted for a given patient. The specific questions one should ask include the following:

1. Is an antimicrobial agent indicated on the basis of clinical findings? Or is it prudent to wait until such clinical findings become apparent?

2. Have appropriate clinical specimens been obtained to establish a microbiologic diagnosis?
3. What are the likely etiologic agents for the patient's illness?
4. What measures should be taken to protect individuals exposed to the index case to prevent secondary cases, and what measures should be implemented to prevent further exposure?
5. Is there clinical evidence (eg, from clinical trials) that antimicrobial therapy will confer clinical benefit for the patient?

Once a specific cause is identified based on specific microbiologic tests, the following further questions should be considered:

1. If a specific microbial pathogen is identified, can a narrower-spectrum agent be substituted for the initial empiric drug?
2. Is one agent or a combination of agents necessary?
3. What are the optimal dose, route of administration, and duration of therapy?
4. What specific tests (eg, susceptibility testing) should be undertaken to identify patients who will not respond to treatment?
5. What adjunctive measures can be undertaken to eradicate the infection? For example, is surgery feasible for removal of devitalized tissue or foreign bodies or drainage of an abscess into which antimicrobial agents may be unable to penetrate? Is it possible to decrease the dosage of immunosuppressive therapy in patients who have undergone organ transplantation? Is it possible to reduce morbidity or mortality due to the infection by reducing host immunologic response to the infection (eg, by the use of corticosteroids for the treatment of severe *Pneumocystis jiroveci* pneumonia or meningitis due to *Streptococcus pneumoniae*)?

## **EMPIRIC ANTIMICROBIAL THERAPY**

Antimicrobial agents are frequently used before the pathogen responsible for a particular illness or the susceptibility to a particular antimicrobial agent is known. This use of antimicrobial agents is called empiric (or presumptive) therapy and is based on experience with a particular clinical entity. The usual justification for empiric therapy is the hope that early intervention will improve the outcome; in the best cases, this has been established by placebo-controlled, double-blind prospective clinical trials. For example, treatment of febrile episodes in neutropenic cancer patients with empiric antimicrobial therapy has been demonstrated to have impressive morbidity and mortality benefits even though the specific bacterial agent responsible for fever is determined for only a minority of such episodes.

Finally, there are many clinical entities, such as certain episodes of community-acquired

pneumonia, in which it is difficult to identify a specific pathogen. In such cases, a clinical response to empiric therapy may be an important clue to the likely pathogen.

Frequently, the signs and symptoms of infection diminish as a result of empiric therapy, and microbiologic test results become available that establish a specific microbiologic diagnosis. At the time that the pathogenic organism responsible for the illness is identified, empiric therapy is optimally modified to **definitive therapy**, which is typically narrower in coverage and is given for an appropriate duration based on the results of clinical trials or experience when clinical trial data is not available.

## **Approach to Empiric Therapy**

Initiation of empiric therapy should follow a specific and systematic approach.

### **FORMULATE A CLINICAL DIAGNOSIS OF MICROBIAL INFECTION**

Using all available data, the clinician should determine that there is anatomic evidence of infection (eg, pneumonia, cellulitis, sinusitis).

### **OBTAIN SPECIMENS FOR LABORATORY EXAMINATION**

Examination of stained specimens by microscopy or simple examination of an uncentrifuged sample of urine for white blood cells and bacteria may provide important etiologic clues in a very short time. Cultures of selected anatomic sites (blood, sputum, urine, cerebrospinal fluid, and stool) and nonculture methods (antigen testing, polymerase chain reaction, and serology) may also confirm specific etiologic agents.

### **FORMULATE A MICROBIOLOGIC DIAGNOSIS**

The history, physical examination, and immediately available laboratory results (eg, Gram stain of urine or sputum) may provide highly specific information. For example, in a young man with urethritis and a Gram-stained smear from the urethral meatus demonstrating intracellular gram-negative diplococci, the most likely pathogen is *Neisseria gonorrhoeae*. In the latter instance, however, the clinician should be aware that a significant number of patients with gonococcal urethritis have uninformative Gram stains for the organism and that a significant number of patients with gonococcal urethritis harbor concurrent chlamydial infection that is not demonstrated on the Gram-stained smear.

### **DETERMINE THE NECESSITY FOR EMPIRIC THERAPY**

Whether or not to initiate empiric therapy is an important clinical decision based partly on experience and partly on data from clinical trials. Empiric therapy is indicated when there is a significant risk of serious morbidity if therapy is withheld until a specific pathogen is detected by the clinical laboratory.

In other settings, empiric therapy may be indicated for public health reasons rather than for demonstrated superior outcome of therapy in a specific patient. For example, urethritis in a young sexually active man usually requires treatment for *N gonorrhoeae*

and *Chlamydia trachomatis* despite the absence of microbiologic confirmation at the time of diagnosis. Because the risk of noncompliance with follow-up visits in this patient population may lead to further transmission of these sexually transmitted pathogens, empiric therapy is warranted.

### **INSTITUTE TREATMENT**

Selection of empiric therapy may be based on the microbiologic diagnosis or a clinical diagnosis without available microbiologic clues. If no microbiologic information is available, the antimicrobial spectrum of the agent or agents chosen must necessarily be broader, taking into account the most likely pathogens responsible for the patient's illness.

### **Choice of Antimicrobial Agent**

Selection from among several drugs depends on **host factors** that include the following: (1) concomitant disease states (eg, AIDS, neutropenia due to the use of cytotoxic chemotherapy; severe chronic liver or kidney disease) or the use of immunosuppressive medications; (2) prior adverse drug effects; (3) impaired elimination or detoxification of the drug (may be genetically predetermined but more frequently is associated with impaired renal or hepatic function due to underlying disease); (4) age of the patient; (5) pregnancy status; and (6) epidemiologic exposure (eg, exposure to a sick family member or pet, recent hospitalization, recent travel, occupational exposure, or new sexual partner).

**Pharmacologic factors** include (1) the kinetics of absorption, distribution, and elimination; (2) the ability of the drug to be delivered to the site of infection; (3) the potential toxicity of an agent; and (4) pharmacokinetic or pharmacodynamic interactions with other drugs.

Knowledge of the **susceptibility** of an organism to a specific agent in a hospital or community setting is important in the selection of empiric therapy. Pharmacokinetic differences among agents with similar antimicrobial spectrums may be exploited to reduce the frequency of dosing (eg, ceftriaxone may be conveniently given once every 24 hours). Finally, increasing consideration is being given to the cost of antimicrobial therapy, especially when multiple agents with comparable efficacy and toxicity are available for a specific infection. Changing from intravenous to oral antibiotics for prolonged administration can be particularly cost-effective.

Brief guides to empiric therapy based on presumptive microbial diagnosis and site of infection are given in Tables 51-1 and 51-2.

### **Table 51-1 Empiric Antimicrobial Therapy Based on Microbiologic Etiology.**

<b>Suspected or Proven Disease or Pathogen</b>	<b>Drugs of First Choice</b>	<b>Alternative Drugs</b>
--	------------------------------	--------------------------

**Gram-negative cocci (aerobic)**

<i>Moraxella (Branhamella) catarrhalis</i>	TMP-SMZ, <sup>1</sup> cephalosporin (second- or third-generation) <sup>2</sup>	Quinolone, <sup>3</sup> macrolide <sup>4</sup>
<i>Neisseria gonorrhoeae</i>	Ceftriaxone, cefixime	Spectinomycin, azithromycin
<i>Neisseria meningitidis</i>	Penicillin G	Chloramphenicol, ceftriaxone, cefotaxime

**Gram-negative rods (aerobic)**

<i>E coli, Klebsiella, Proteus</i>	Cephalosporin (first- or second-generation), <sup>2</sup> TMP-SMZ <sup>1</sup>	Quinolone, <sup>3</sup> aminoglycoside <sup>5</sup>
<i>Enterobacter, Citrobacter, Serratia</i>	TMP-SMZ, <sup>1</sup> quinolone, <sup>3</sup> carbapenem <sup>6</sup>	Antipseudomonal penicillin, <sup>7</sup> aminoglycoside, <sup>5</sup> cefepime
<i>Shigella</i>	Quinolone <sup>3</sup>	TMP-SMZ, <sup>1</sup> ampicillin, azithromycin, ceftriaxone
<i>Salmonella</i>	Quinolone, <sup>3</sup> ceftriaxone	Chloramphenicol, ampicillin, TMP-SMZ <sup>1</sup>
<i>Campylobacter jejuni</i>	Erythromycin or azithromycin	Tetracycline, quinolone <sup>3</sup>
<i>Brucella species</i>	Doxycycline + rifampin or aminoglycoside <sup>5</sup>	Chloramphenicol + aminoglycoside <sup>5</sup> or TMP-SMZ <sup>1</sup>
<i>Helicobacter pylori</i>	Proton pump inhibitor + amoxicillin + clarithromycin	Bismuth + metronidazole + tetracycline + proton pump inhibitor
<i>Vibrio species</i>	Tetracycline	Quinolone, <sup>3</sup> TMP-SMZ <sup>1</sup>
<i>Pseudomonas</i>	Antipseudomonal	Antipseudomonal penicillin ±

<i>aeruginosa</i>	penicillin ± aminoglycoside <sup>5</sup>	quinolone, <sup>3</sup> cefepime, ceftazidime, antipseudomonal carbapenem <sup>6</sup> or aztreonam ± aminoglycoside <sup>5</sup>
<i>Burkholderia cepacia</i> (formerly <i>Pseudomonas cepacia</i> )	TMP-SMZ <sup>1</sup>	Ceftazidime, chloramphenicol
<i>Stenotrophomonas maltophilia</i> (formerly <i>Xanthomonas maltophilia</i> )	TMP-SMZ <sup>1</sup>	Minocycline, ticarcillin-clavulanate, tigecycline, ceftazidime, quinolone <sup>3</sup>
<i>Legionella</i> species	Azithromycin or quinolone <sup>3</sup>	Clarithromycin, erythromycin
<b>Gram-positive cocci (aerobic)</b>		
<i>Streptococcus pneumoniae</i>	Penicillin <sup>8</sup>	Doxycycline, ceftriaxone, antipseudomonal quinolone, <sup>3</sup> macrolide, <sup>4</sup> linezolid
<i>Streptococcus pyogenes</i> (group A)	Penicillin, clindamycin	Erythromycin, cephalosporin (first-generation) <sup>2</sup>
<i>Streptococcus agalactiae</i> (group B)	Penicillin (± aminoglycoside <sup>5</sup> )	Vancomycin
<i>Viridans</i> streptococci	Penicillin	Cephalosporin (first- or third-generation), <sup>2</sup> vancomycin
<i>Staphylococcus aureus</i> β-Lactamase- negative	Penicillin	Cephalosporin (first-generation), <sup>2</sup> vancomycin
β-Lactamase- positive	Penicillinase-resistant penicillin <sup>9</sup>	As above
Methicillin-resistant	Vancomycin	TMP-SMZ, <sup>1</sup> minocycline, linezolid, daptomycin, tigecycline

<i>Enterococcus</i> species <sup>10</sup>	Penicillin ± aminoglycoside <sup>5</sup>	Vancomycin ± aminoglycoside <sup>5</sup>
---	--	--

**Gram-positive rods (aerobic)**

<i>Bacillus</i> species (non-anthraxis)	Vancomycin	Imipenem, quinolone, <sup>3</sup> clindamycin
---	------------	---

<i>Listeria</i> species	Ampicillin (± aminoglycoside <sup>5</sup> )	TMP-SMZ <sup>1</sup>
-------------------------	---	----------------------

<i>Nocardia</i> species	Sulfadiazine, TMP-SMZ <sup>1</sup>	Minocycline, imipenem, amikacin, linezolid
-------------------------	------------------------------------	--

**Anaerobic bacteria**

Gram-positive (clostridia, <i>Peptococcus</i> , <i>Actinomyces</i> , <i>Peptostreptococcus</i> )	Penicillin, clindamycin	Vancomycin, carbapenem, <sup>6</sup> chloramphenicol
--	-------------------------	--

<i>Clostridium difficile</i>	Metronidazole	Vancomycin, bacitracin
------------------------------	---------------	------------------------

<i>Bacteroides fragilis</i>	Metronidazole	Chloramphenicol, carbapenem, <sup>6</sup> β-lactam-β-lactamase-inhibitor combinations, clindamycin
-----------------------------	---------------	--

<i>Fusobacterium</i> , <i>Prevotella</i> , <i>Porphyromonas</i>	Metronidazole, clindamycin, penicillin	As for <i>B fragilis</i>
---	--	--------------------------

**Mycobacteria**

<i>Mycobacterium tuberculosis</i>	Isoniazid + rifampin + ethambutol + pyrazinamide	Streptomycin, moxifloxacin, amikacin, ethionamide, cycloserine, PAS, linezolid
-----------------------------------	--	--

*Mycobacterium leprae*

Multibacillary	Dapsone + rifampin + clofazimine
----------------	----------------------------------

Paucibacillary	Dapsone + rifampin
----------------	--------------------

***Mycoplasma pneumoniae***

Tetracycline, erythromycin	Azithromycin, clarithromycin, quinolone <sup>3</sup>
----------------------------	--

### **Chlamydia**

<i>C trachomatis</i>	Tetracycline, azithromycin	Clindamycin, ofloxacin
<i>C pneumoniae</i>	Tetracycline, erythromycin	Clarithromycin, azithromycin
<i>C psittaci</i>	Tetracycline	Chloramphenicol
<b>Spirochetes</b>		
<i>Borrelia recurrentis</i>	Doxycycline	Erythromycin, chloramphenicol, penicillin
<i>Borrelia burgdorferi</i>		
Early	Doxycycline, amoxicillin	Cefuroxime axetil, penicillin
Late	Ceftriaxone	
<i>Leptospira</i> species	Penicillin	Tetracycline
<i>Treponema</i> species	Penicillin	Tetracycline, azithromycin, ceftriaxone

### **Fungi**

<i>Aspergillus</i> species	Voriconazole	Amphotericin B, itraconazole, caspofungin
<i>Blastomyces</i> species	Amphotericin B	Itraconazole, fluconazole
<i>Candida</i> species	Amphotericin B, echinocandin <sup>11</sup>	Fluconazole, itraconazole, voriconazole
<i>Cryptococcus</i>	Amphotericin B ± flucytosine (5-FC)	Fluconazole, voriconazole
<i>Coccidioides immitis</i>	Amphotericin B	Fluconazole, itraconazole, voriconazole, posaconazole
<i>Histoplasma capsulatum</i>	Amphotericin B	Itraconazole
<i>Mucoraceae</i> ( <i>Rhizopus</i> , <i>Absidia</i> )	Amphotericin B	Posaconazole
<i>Sporothrix schenckii</i>	Amphotericin B	Itraconazole

<sup>1</sup>Trimethoprim-sulfamethoxazole (TMP-SMZ) is a mixture of one part trimethoprim plus five parts sulfamethoxazole.

<sup>2</sup>First-generation cephalosporins: cefazolin for parenteral administration; cefadroxil or cephalexin for oral administration. Second-generation cephalosporins: cefuroxime for

parenteral administration; cefaclor, cefuroxime axetil, cefprozil, for oral administration. Third-generation cephalosporins: ceftazidime, cefotaxime, ceftriaxone for parenteral administration; cefixime, cefpodoxime, ceftibuten, cefdinir, cefditoren for oral administration. Fourth-generation cephalosporin: cefepime for parenteral administration. Cephamycins: cefoxitin and cefotetan for parenteral administration.

<sup>3</sup>Quinolones: ciprofloxacin, gemifloxacin, levofloxacin, moxifloxacin, norfloxacin, ofloxacin. Norfloxacin is not effective for the treatment of systemic infections. Gemifloxacin, levofloxacin, and moxifloxacin have excellent activity against pneumococci. Ciprofloxacin and levofloxacin have good activity against *Pseudomonas aeruginosa*.

<sup>4</sup>Macrolides: azithromycin, clarithromycin, dirithromycin, erythromycin.

<sup>5</sup>Generally, streptomycin and gentamicin are used to treat infections with gram-positive organisms, whereas gentamicin, tobramycin, and amikacin are used to treat infections with gram-negatives.

<sup>6</sup>Carbapenems: doripenem, ertapenem, imipenem, meropenem. Ertapenem lacks activity against enterococci, *Acinetobacter*, and *Pseudomonas aeruginosa*.

<sup>7</sup>Antipseudomonal penicillin: piperacillin, piperacillin/tazobactam, ticarcillin/clavulanic acid.

<sup>8</sup>See footnote 3 in Table 51 for guidelines on the treatment of penicillin-resistant pneumococcal meningitis.

<sup>9</sup>Parenteral nafcillin or oxacillin; oral dicloxacillin.

<sup>10</sup>There is no regimen that is reliably bactericidal for vancomycin-resistant enterococcus for which there is extensive clinical experience; daptomycin has bactericidal activity in vitro. Regimens that have been reported to be efficacious include nitrofurantoin (for urinary tract infection); potential regimens for bacteremia include daptomycin, linezolid, and dalfopristin/quinupristin.

<sup>11</sup> Echinocandins: anidulafungin, caspofungin, micafungin.

**Table 51 Empiric Antimicrobial Therapy Based on Site of Infection.**

Presumed Site of Infection	Common Pathogens	Drugs of First Choice	Alternative Drugs
<b>Bacterial endocarditis</b>			
Acute	<i>Staphylococcus aureus</i>	Vancomycin + gentamicin	Penicillinase-resistant penicillin <sup>1</sup> + gentamicin

Subacute	<i>Viridans</i> streptococci, enterococci	Penicillin + gentamicin	Vancomycin + gentamicin
<b>Septic arthritis</b>			
Child	<i>H influenzae</i> , <i>S aureus</i> , $\beta$ -hemolytic streptococci	Ceftriaxone	Ampicillin-sulbactam
Adult	<i>S aureus</i> , Enterobacteriaceae	Cefazolin	Vancomycin, quinolone
<b>Acute otitis media, sinusitis</b>	<i>H influenzae</i> , <i>S pneumoniae</i> , <i>M catarrhalis</i>	Amoxicillin	Amoxicillin-clavulanate, cefuroxime axetil, TMP-SMZ
<b>Cellulitis</b>	<i>S aureus</i> , group A streptococcus	Penicillinase-resistant penicillin, cephalosporin (first-generation) <sup>2</sup>	Vancomycin, clindamycin, linezolid, daptomycin
<b>Meningitis</b>			
Neonate	Group B streptococcus, <i>E coli</i> , <i>Listeria</i>	Ampicillin + cephalosporin (third-generation)	Ampicillin + aminoglycoside, chloramphenicol, meropenem
Child	<i>H influenzae</i> , pneumococcus, meningococcus	Ceftriaxone or cefotaxime $\hat{A}\pm$ vancomycin <sup>3</sup>	Chloramphenicol, meropenem
Adult	Pneumococcus, meningococcus	Ceftriaxone, cefotaxime	Vancomycin + ceftriaxone or cefotaxime <sup>3</sup>
<b>Peritonitis due to ruptured viscus</b>	Coliforms, <i>B fragilis</i>	Metronidazole + cephalosporin (third-generation), piperacillin/tazobactam	Carbapenem, tigecycline
<b>Pneumonia</b>			
Neonate	As in neonatal meningitis		
Child	Pneumococcus, <i>S</i>	Ceftriaxone,	Ampicillin-sulbactam

<p>Adult (community-acquired)</p>	<p><i>aureus, H influenzae</i>  Pneumococcus, <i>Mycoplasma, Legionella, H influenzae, aureus, C pneumonia, coliforms</i></p>	<p>cefuroxime, cefotaxime  <b>Outpatient:</b> Macrolide,<sup>4</sup> amoxicillin, tetracycline</p>	<p><b>Outpatient:</b> Quinolone</p>
		<p><b>Inpatient:</b> Macrolide<sup>4</sup> + cefotaxime, ceftriaxone, ertapenem, or ampicillin</p>	<p><b>Inpatient:</b> Doxycycline + cefotaxime, ceftriaxone, ertapenem, or ampicillin; respiratory quinolone<sup>5</sup></p>
<p><b>Septicemia</b> <sup>6</sup></p>	<p>Any</p>	<p>Vancomycin + cephalosporin (third-generation) or piperacillin/tazobactam or imipenem or meropenem</p>	
<p><b>Septicemia with granulocytopenia</b></p>	<p>Any</p>	<p>Antipseudomonal penicillin + aminoglycoside; ceftazidime; cefepime; imipenem or meropenem; consider addition of systemic antifungal therapy if fever persists beyond 5 days of empiric therapy</p>	

<sup>1</sup>See footnote 9, Table 51â€1.

<sup>2</sup>See footnote 2, Table 51â€1.

<sup>3</sup>When meningitis with penicillin-resistant pneumococcus is suspected, empiric therapy with this regimen is recommended.

<sup>4</sup>Erythromycin, clarithromycin, or azithromycin (an azalide) may be used.

<sup>5</sup>Quinolones used to treat pneumococcal infections include levofloxacin, moxifloxacin, and gemifloxacin.

<sup>6</sup>Adjunctive immunomodulatory drugs such as drotrecogin-alfa can also be considered for patients with severe sepsis.

## ANTIMICROBIAL THERAPY OF INFECTIONS WITH KNOWN ETIOLOGY

### INTERPRETATION OF CULTURE RESULTS

Properly obtained and processed specimens for culture frequently yield reliable information about the cause of infection. The lack of a confirmatory microbiologic diagnosis may be due to the following:

1. Sample error, eg, obtaining cultures after antimicrobial agents have been administered, or contamination of specimens sent for culture
2. Noncultivable or slow-growing organisms (*Histoplasma capsulatum*, *Bartonella* or *Brucella* species), in which cultures are often discarded before sufficient growth has occurred for detection
3. Requesting *bacterial* cultures when infection is due to other organisms
4. Not recognizing the need for special media or isolation techniques (eg, charcoal yeast extract agar for isolation of legionella species, shell-vial tissue culture system for rapid isolation of cytomegalovirus)

Even in the setting of a classic infectious disease for which isolation techniques have been established for decades (eg, pneumococcal pneumonia, pulmonary tuberculosis, streptococcal pharyngitis), the sensitivity of the culture technique may be inadequate to identify all cases of the disease.

## **GUIDING ANTIMICROBIAL THERAPY OF ESTABLISHED INFECTIONS**

### **Susceptibility Testing**

Testing bacterial pathogens in vitro for their susceptibility to antimicrobial agents is extremely valuable in confirming susceptibility, ideally to a narrow-spectrum nontoxic antimicrobial drug. Tests measure the concentration of drug required to inhibit growth of the organism (**minimal inhibitory concentration [MIC]**) or to kill the organism (**minimal bactericidal concentration [MBC]**). The results of these tests can then be correlated with known drug concentrations in various body compartments. Only MICs are routinely measured in most infections, whereas in infections in which bactericidal therapy is required for eradication of infection (eg, meningitis, endocarditis, sepsis in the granulocytopenic host), MBC measurements occasionally may be useful.

### **Specialized Assay Methods**

#### **BETA-LACTAMASE ASSAY**

For some bacteria (eg, *Haemophilus* species), the susceptibility patterns of strains are similar except for the production of  $\beta$  lactamase. In these cases, extensive susceptibility testing may not be required, and a direct test for  $\beta$  lactamase using a chromogenic  $\beta$ -lactam substrate (nitrocephin disk) may be substituted.

#### **SYNERGY STUDIES**

Synergy studies are in vitro tests that attempt to measure synergistic, additive, indifferent, or antagonistic drug interactions. In general, these tests have not been

standardized and have not correlated well with clinical outcome. (See section on Antimicrobial Drug Combinations for details.)

## **MONITORING THERAPEUTIC RESPONSE: DURATION OF THERAPY**

The therapeutic response may be monitored microbiologically or clinically. Cultures of specimens taken from infected sites should eventually become sterile or demonstrate eradication of the pathogen and are useful for documenting recurrence or relapse. Follow-up cultures may also be useful for detecting superinfections or the development of resistance. Clinically, the patient's systemic manifestations of infection (malaise, fever, leukocytosis) should abate, and the clinical findings should improve (eg, as shown by clearing of radiographic infiltrates or lessening hypoxemia in pneumonia).

The duration of definitive therapy required for cure depends on the pathogen, the site of infection, and host factors (immunocompromised patients generally require longer courses of treatment). Precise data on duration of therapy exist for some infections (eg, streptococcal pharyngitis, syphilis, gonorrhea, tuberculosis, and cryptococcal meningitis). In many other situations, duration of therapy is determined empirically. For serious infections, continuing therapy for 7–10 days after the patient has become afebrile is a good rule of thumb. For recurrent infections (eg, sinusitis, urinary tract infections), longer courses of antimicrobial therapy or surgical intervention are frequently necessary for eradication.

### **Clinical Failure of Antimicrobial Therapy**

When the patient has an inadequate clinical or microbiologic response to antimicrobial therapy selected by in vitro susceptibility testing, systematic investigation should be undertaken to determine the cause of failure. Errors in susceptibility testing are rare, but the original results should be confirmed by repeat testing. Drug dosing and absorption should be scrutinized and tested directly using serum measurements, pill counting, or directly observed therapy.

The clinical data should be reviewed to determine whether the patient's immune function is adequate and, if not, what can be done to maximize it. For example, are adequate numbers of granulocytes present and are HIV infection, malnutrition, or underlying malignancy present? The presence of abscesses or foreign bodies should also be considered. Finally, culture and susceptibility testing should be repeated to determine whether superinfection has occurred with another organism or whether the original pathogen has developed drug resistance.

## **ANTIMICROBIAL PHARMACODYNAMICS**

The time course of drug concentration is closely related to the antimicrobial effect at the site of infection and to any toxic effects. Pharmacodynamic factors include pathogen

susceptibility testing, drug bactericidal versus bacteriostatic activity, drug synergism, antagonism, and postantibiotic effects. Together with pharmacokinetics, pharmacodynamic information permits the selection of optimal antimicrobial dosage regimens.

### **Bacteriostatic versus Bactericidal Activity**

Antibacterial agents may be classified as bacteriostatic or bactericidal (Table 51-3). For agents that are primarily bacteriostatic, inhibitory drug concentrations are much lower than bactericidal drug concentrations. In general, cell wall-active agents are bactericidal, and drugs that inhibit protein synthesis are bacteriostatic.

**Table 51-3 Bactericidal and Bacteriostatic Antibacterial Agents.**

<b>Bactericidal agents</b>	<b>Bacteriostatic agents</b>
Aminoglycosides	Chloramphenicol
Bacitracin	Clindamycin
$\beta$ -Lactam antibiotics	Ethambutol
Daptomycin	Macrolides
Isoniazid	Nitrofurantoin
Ketolides	Novobiocin
Metronidazole	Oxazolidinones
Polymyxins	Sulfonamides
Pyrazinamide	Tetracyclines
Quinolones	Tigecycline
Rifampin	Trimethoprim
Vancomycin	

The classification of antibacterial agents as bactericidal or bacteriostatic has limitations. Some agents that are considered to be bacteriostatic may be bactericidal against selected organisms. On the other hand, enterococci are inhibited but not killed by vancomycin, penicillin, or ampicillin used as single agents.

Bacteriostatic and bactericidal agents are equivalent for the treatment of most infectious diseases in immunocompetent hosts. Bactericidal agents should be selected over bacteriostatic ones in circumstances in which local or systemic host defenses are impaired. Bactericidal agents are required for treatment of endocarditis and other endovascular infections, meningitis, and infections in neutropenic cancer patients.

Bactericidal agents can be divided into two groups: agents that exhibit **concentration-dependent killing** (eg, aminoglycosides and quinolones) and agents that exhibit **time-dependent killing** (eg,  $\beta$ -lactams and vancomycin). For drugs whose killing action is concentration-dependent, the rate and extent of killing increase with increasing drug concentrations. Concentration-dependent killing is one of the pharmacodynamic factors responsible for the efficacy of once-daily dosing of aminoglycosides.

For drugs whose killing action is time-dependent, bactericidal activity continues as long as serum concentrations are greater than the MBC. Drug concentrations of time-dependent killing agents that lack a postantibiotic effect should be maintained above the MIC for the entire interval between doses.

### Postantibiotic Effect

Persistent suppression of bacterial growth after limited exposure to an antimicrobial agent is known as the postantibiotic effect (PAE). The PAE can be expressed mathematically as follows:

$$PAE = T - C$$

where T is the time required for the viable count in the test (in vitro) culture to increase tenfold above the count observed immediately before drug removal and C is the time required for the count in an untreated culture to increase tenfold above the count observed immediately after completion of the same procedure used on the test culture. The PAE reflects the time required for bacteria to return to logarithmic growth.

Proposed mechanisms include (1) slow recovery after reversible nonlethal damage to cell structures; (2) persistence of the drug at a binding site or within the periplasmic space; and (3) the need to synthesize new enzymes before growth can resume. Most antimicrobials possess significant in vitro PAEs ( $\geq 1.5$  hours) against susceptible gram-positive cocci (Table 51<sup>4</sup>). Antimicrobials with significant PAEs against susceptible gram-negative bacilli are limited to carbapenems and agents that inhibit protein or DNA synthesis.

**Table 51<sup>4</sup> Antibacterial Agents with In Vitro Postantibiotic Effects  $\geq 1.5$  Hours.**

#### Against gram-positive cocci

Aminoglycosides  
Carbapenems  
Cephalosporins  
Chloramphenicol  
Clindamycin

#### Against gram-negative bacilli

Aminoglycosides  
Carbapenems  
Chloramphenicol  
Quinolones  
Rifampin

Daptomycin	Tetracyclines
Ketolides	Tigecycline
Macrolides	
Oxazolidinones	
Penicillins	
Quinolones	
Rifampin	
Sulfonamides	
Tetracyclines	
Tigecycline	
Trimethoprim	
Vancomycin	

In vivo PAEs are usually much longer than in vitro PAEs. This is thought to be due to **postantibiotic leukocyte enhancement (PALE)** and exposure of bacteria to subinhibitory antibiotic concentrations. The efficacy of once-daily dosing regimens is in part due to the PAE. Aminoglycosides and quinolones possess concentration-dependent PAEs; thus, high doses of aminoglycosides given once daily result in enhanced bactericidal activity and extended PAEs. This combination of pharmacodynamic effects allows aminoglycoside serum concentrations that are below the MICs of target organisms to remain effective for extended periods of time.

## **PHARMACOKINETIC CONSIDERATIONS**

### **Route of Administration**

Many antimicrobial agents have similar pharmacokinetic properties when given orally or parenterally (ie, tetracyclines, trimethoprim-sulfamethoxazole, quinolones, chloramphenicol, metronidazole, clindamycin, rifampin, linezolid and fluconazole). In most cases, oral therapy with these drugs is equally effective, is less costly, and results in fewer complications than parenteral therapy.

The intravenous route is preferred in the following situations: (1) for critically ill patients; (2) for patients with bacterial meningitis or endocarditis; (3) for patients with nausea, vomiting, gastrectomy, or diseases that may impair oral absorption; and (4) when giving antimicrobials that are poorly absorbed following oral administration.

### **Conditions That Alter Antimicrobial Pharmacokinetics**

Various diseases and physiologic states alter the pharmacokinetics of antimicrobial agents. Impairment of renal or hepatic function may result in decreased elimination. Table

Table 51 lists drugs that require dosage reduction in patients with renal or hepatic insufficiency. Failure to reduce antimicrobial agent dosage in such patients may cause toxic effects. Conversely, patients with burns, cystic fibrosis, or trauma may have increased dosage requirements for selected agents. The pharmacokinetics of antimicrobials is also altered in the elderly, in neonates, and in pregnancy.

**Table 51 Antimicrobial Agents that Require Dosage Adjustment or Are Contraindicated in Patients with Renal or Hepatic Impairment.**

<b>Dosage Adjustment Needed in Renal Impairment</b>	<b>Contraindicated in Renal Impairment</b>	<b>Dosage Adjustment Needed in Hepatic Impairment</b>
Acyclovir, amantadine, aminoglycosides, aztreonam, cephalosporins, <sup>1</sup> clarithromycin, cycloserine, daptomycin, didanosine, doripenem, emtri-citabine, ertapenem, ethambutol, famciclovir, fluconazole, flucytosine, foscarnet, ganciclovir, imipenem, lamivudine, meropenem, penicillins, <sup>3</sup> quinolones, rimantadine, stavudine, telbivudine, telithromycin, tenofovir, terbinafine, trimethoprim-sulfamethoxazole, valacyclovir, vancomycin, zalcitabine, zidovudine	Cidofovir, methenamine, nalidixic acid, nitrofurantoin, sulfonamides (long-acting), tetracyclines <sup>2</sup>	Amprenavir, atazanavir, chloramphenicol, clindamycin, erythromycin, fosamprenavir, indinavir, metronidazole, rimantadine, tigecycline

<sup>1</sup>Except cefoperazone and ceftriaxone.

<sup>2</sup>Except doxycycline and possibly minocycline.

<sup>3</sup>Except antistaphylococcal penicillins (eg, nafcillin and dicloxacillin).

**Drug Concentrations in Body Fluids**

Most antimicrobial agents are well distributed to most body tissues and fluids. Penetration into the cerebrospinal fluid is an exception. Most do not penetrate uninfamed meninges to an appreciable extent. In the presence of meningitis, however, the cerebrospinal fluid concentrations of many antimicrobials increase (Table 51).<sup>6</sup>

**Table 51 Cerebrospinal Fluid (CSF) Penetration of Selected Antimicrobials.**

<b>Antimicrobial Agent</b>	<b>CSF Concentration (Uninflamed Meninges) as % of Serum Concentration</b>	<b>CSF Concentration (Inflamed Meninges) as % of Serum Concentration</b>
Ampicillin	2â€³	2â€³100
Aztreonam	2	5
Cefepime	0â€²	4â€³12
Cefotaxime	22.5	27â€³36
Ceftazidime	0.7	20â€³40
Ceftriaxone	0.8â€³1.6	16
Cefuroxime	20	17â€³88
Ciprofloxacin	6â€³27	26â€³37
Imipenem	3.1	11â€³41
Meropenem	0â€³7	1â€³52
Nafcillin	2â€³15	5â€³27
Penicillin G	1â€³2	8â€³18
Sulfamethoxazole	40	12â€³47
Trimethoprim	< 41	12â€³69
Vancomycin	0	1â€³53

### **Monitoring Serum Concentrations of Antimicrobial Agents**

For most antimicrobial agents, the relation between dose and therapeutic outcome is well established, and serum concentration monitoring is unnecessary for these drugs. To justify routine serum concentration monitoring, it should be established (1) that a direct relationship exists between drug concentrations and efficacy or toxicity; (2) that substantial interpatient variability exists in serum concentrations on standard doses; (3) that a small difference exists between therapeutic and toxic serum concentrations; (4) that the clinical efficacy or toxicity of the drug is delayed or difficult to measure; and (5) that an accurate assay is available.

In clinical practice, serum concentration monitoring is routinely performed on patients receiving aminoglycosides. Despite the lack of supporting evidence for its usefulness or need, serum vancomycin concentration monitoring is also widespread. Flucytosine serum concentration monitoring has been shown to reduce toxicity when doses are adjusted to maintain peak concentrations below 100 mcg/mL.

### **MANAGEMENT OF ANTIMICROBIAL DRUG TOXICITY**

Owing to the large number of antimicrobials available, it is usually possible to select an effective alternative in patients who develop serious drug toxicity (Table 51â€"1). However, for some infections there are no effective alternatives to the drug of choice. For example, in patients with neurosyphilis who have a history of anaphylaxis to penicillin, it is necessary to perform skin testing and desensitization to penicillin. It is important to obtain a clear history of drug allergy and other adverse drug reactions. A patient with a documented antimicrobial allergy should carry a card with the name of the drug and a description of the reaction. Cross-reactivity between penicillins and cephalosporins is less than 10%. Cephalosporins may be administered to patients with penicillin-induced maculopapular rashes but should be avoided in patients with a history of penicillin-induced immediate hypersensitivity reactions. The cross-reactivity between penicillins and carbapenems may exceed 50%. On the other hand, aztreonam does not cross-react with penicillins and can be safely administered to patients with a history of penicillin-induced anaphylaxis. For mild reactions, it may be possible to continue therapy with use of adjunctive agents or dosage reduction.

Adverse reactions to antimicrobials occur with increased frequency in several groups, including neonates, geriatric patients, renal failure patients, and AIDS patients. Dosage adjustment of the drugs listed in Table 51â€"5 is essential for the prevention of adverse effects in patients with renal failure. In addition, several agents are contraindicated in patients with renal impairment because of increased rates of serious toxicity (Table 51â€"5). See the preceding chapters for discussions of specific drugs.

Polypharmacy also predisposes to drug interactions. Although the mechanism is not known, AIDS patients have an unusually high incidence of toxicity to a number of drugs, including clindamycin, aminopenicillins, and sulfonamides. Many of these reactions, including rash and fever, may respond to dosage reduction or treatment with corticosteroids and antihistamines. Other examples are discussed in the preceding chapters and in Chapter 66.

## **ANTIMICROBIAL DRUG COMBINATIONS**

### **RATIONALE FOR COMBINATION ANTIMICROBIAL THERAPY**

Most infections should be treated with a single antimicrobial agent. Although indications for combination therapy exist, antimicrobial combinations are often overused in clinical practice. The unnecessary use of antimicrobial combinations increases toxicity and costs and may occasionally result in reduced efficacy due to antagonism of one drug by another. Antimicrobial combinations should be selected for one or more of the following reasons:

1. To provide broad-spectrum empiric therapy in seriously ill patients.
2. To treat polymicrobial infections (such as intra-abdominal abscesses, which

typically are due to a combination of anaerobic and aerobic gram-negative organisms, and enterococci). The antimicrobial combination chosen should cover the most common known or suspected pathogens but need not cover all possible pathogens. The availability of antimicrobials with excellent polymicrobial coverage (eg,  $\beta$ -lactamase inhibitor combinations or carbapenems) may reduce the need for combination therapy in the setting of polymicrobial infections.

3. To decrease the emergence of resistant strains. The value of combination therapy in this setting has been clearly demonstrated for tuberculosis.
4. To decrease dose-related toxicity by using reduced doses of one or more components of the drug regimen. The use of flucytosine in combination with amphotericin B for the treatment of cryptococcal meningitis in non-HIV-infected patients allows for a reduction in amphotericin B dosage with decreased amphotericin B-induced nephrotoxicity.
5. To obtain enhanced inhibition or killing. This use of antimicrobial combinations is discussed in the paragraphs that follow.

## **SYNERGISM & ANTAGONISM**

When the inhibitory or killing effects of two or more antimicrobials used together are significantly greater than expected from their effects when used individually, synergism is said to result. Synergism is marked by a fourfold or greater reduction in the MIC or MBC of each drug when used in combination versus when used alone. Antagonism occurs when the combined inhibitory or killing effects of two or more antimicrobial drugs are significantly less than expected when the drugs are used individually.

### **Mechanisms of Synergistic Action**

The need for synergistic combinations of antimicrobials has been clearly established for the treatment of enterococcal endocarditis. Bactericidal activity is essential for the optimal management of bacterial endocarditis. Penicillin or ampicillin in combination with gentamicin or streptomycin is superior to monotherapy with a penicillin or vancomycin. When tested alone, penicillins and vancomycin are only bacteriostatic against susceptible enterococcal isolates. When these agents are combined with an aminoglycoside, however, bactericidal activity results. The addition of gentamicin or streptomycin to penicillin allows for a reduction in the duration of therapy for selected patients with viridans streptococcal endocarditis. Some evidence exists that synergistic combinations of antimicrobials may be of benefit in the treatment of gram-negative bacillary infections in febrile neutropenic cancer patients and in systemic infections caused by *Pseudomonas aeruginosa*.

Other synergistic antimicrobial combinations have been shown to be more effective than monotherapy with individual components. Trimethoprim-sulfamethoxazole has been successfully used for the treatment of bacterial infections and *Pneumocystis jirovecii* (*carinii*) pneumonia.\*  $\beta$ -Lactamase inhibitors restore the activity of intrinsically active but

hydrolyzable  $\beta$ -lactams against organisms such as *S aureus* and *Bacteroides fragilis*. Three major mechanisms of antimicrobial synergism have been established:

1. **Blockade of sequential steps in a metabolic sequence:** Trimethoprim-sulfamethoxazole is the best-known example of this mechanism of synergy (see Chapter 46). Blockade of the two sequential steps in the folic acid pathway by trimethoprim-sulfamethoxazole results in a much more complete inhibition of growth than achieved by either component alone.
2. **Inhibition of enzymatic inactivation:** Enzymatic inactivation of  $\beta$ -lactam antibiotics is a major mechanism of antibiotic resistance. Inhibition of  $\beta$ -lactamase by  $\beta$ -lactamase inhibitor drugs (eg, sulbactam) results in synergism.
3. **Enhancement of antimicrobial agent uptake:** Penicillins and other cell wall-active agents can increase the uptake of aminoglycosides by a number of bacteria, including staphylococci, enterococci, streptococci, and *P aeruginosa*. Enterococci are thought to be intrinsically resistant to aminoglycosides because of permeability barriers. Similarly, amphotericin B is thought to enhance the uptake of flucytosine by fungi.

## Mechanisms of Antagonistic Action

There are few clinically relevant examples of antimicrobial antagonism. The most striking example was reported in a study of patients with pneumococcal meningitis. Patients who were treated with the combination of penicillin and chlortetracycline had a mortality rate of 79% compared with a mortality rate of 21% in patients who received penicillin monotherapy (illustrating the first mechanism set forth below).

The use of an antagonistic antimicrobial combination does not preclude other potential beneficial interactions. For example, rifampin may antagonize the action of anti-staphylococcal penicillins or vancomycin against staphylococci. However, the aforementioned antimicrobials may prevent the emergence of resistance to rifampin.

Two major mechanisms of antimicrobial antagonism have been established:

1. **Inhibition of cidal activity by static agents:** Bacteriostatic agents such as tetracyclines and chloramphenicol can antagonize the action of bactericidal cell wall-active agents because cell wall-active agents require that the bacteria be actively growing and dividing.
2. **Induction of enzymatic inactivation:** Some gram-negative bacilli, including enterobacter species, *P aeruginosa*, *Serratia marcescens*, and *Citrobacter freundii*, possess inducible  $\beta$ -lactamases.  $\beta$ -Lactam antibiotics such as imipenem, ceftioxin, and ampicillin are potent inducers of  $\beta$ -lactamase production. If an inducing agent is combined with an intrinsically active but hydrolyzable  $\beta$ -lactam such as piperacillin, antagonism may result.

\* *Pneumocystis jiroveci* is a fungal organism found in humans (*P carinii* infects animals)

that responds to antiprotzoal drugs. See Chapter 52.

## **ANTIMICROBIAL PROPHYLAXIS**

Antimicrobial agents are effective in preventing infections in many settings. Antimicrobial prophylaxis should be used in circumstances in which efficacy has been demonstrated and benefits outweigh the risks of prophylaxis. Antimicrobial prophylaxis may be divided into surgical prophylaxis and nonsurgical prophylaxis.

### **Surgical Prophylaxis**

Surgical wound infections are a major category of nosocomial infections. The estimated annual cost of surgical wound infections in the United States is \$1.5 billion.

The National Research Council (NRC) Wound Classification Criteria have served as the basis for recommending antimicrobial prophylaxis. NRC criteria consist of four classes (see National Research Council (NRC) Wound Classification Criteria).

#### **National Research Council (NRC) Wound Classification Criteria**

**Clean:** Elective, primarily closed procedure; respiratory, gastrointestinal, biliary, genitourinary, or oropharyngeal tract not entered; no acute inflammation and no break in technique; expected infection rate  $\leq$  2%.

**Clean contaminated:** Urgent or emergency case that is otherwise clean; elective, controlled opening of respiratory, gastrointestinal, biliary, or oropharyngeal tract; minimal spillage or minor break in technique; expected infection rate  $\leq$  10%.

**Contaminated:** Acute nonpurulent inflammation; major technique break or major spill from hollow organ; penetrating trauma less than 4 hours old; chronic open wounds to be grafted or covered; expected infection rate about 20%.

**Dirty:** Purulence or abscess; preoperative perforation of respiratory, gastrointestinal, biliary, or oropharyngeal tract; penetrating trauma more than 4 hours old; expected infection rate about 40%.

The Study of the Efficacy of Nosocomial Infection Control (SENIC) identified four independent risk factors for postoperative wound infections: operations on the abdomen, operations lasting more than 2 hours, contaminated or dirty wound classification, and at least three medical diagnoses. Patients with at least two SENIC risk factors who undergo clean surgical procedures have an increased risk of developing surgical wound infections and should receive antimicrobial prophylaxis.

Surgical procedures that necessitate the use of antimicrobial prophylaxis include contaminated and clean-contaminated operations, selected operations in which postoperative infection may be catastrophic such as open heart surgery, clean procedures

that involve placement of prosthetic materials, and any procedure in an immunocompromised host. The operation should carry a significant risk of postoperative site infection or cause significant bacterial contamination.

General principles of antimicrobial surgical prophylaxis include the following:

1. The antibiotic should be active against common surgical wound pathogens; unnecessarily broad coverage should be avoided.
2. The antibiotic should have proved efficacy in clinical trials.
3. The antibiotic must achieve concentrations greater than the MIC of suspected pathogens, and these concentrations must be present at the time of incision.
4. The shortest possible course—ideally a single dose—of the most effective and least toxic antibiotic should be used.
5. The newer broad-spectrum antibiotics should be reserved for therapy of resistant infections.
6. If all other factors are equal, the least expensive agent should be used.

The proper selection and administration of antimicrobial prophylaxis are of utmost importance. Common indications for surgical prophylaxis are shown in Table 51-7. Cefazolin is the prophylactic agent of choice for head and neck, gastroduodenal, biliary tract, gynecologic, and clean procedures. Local wound infection patterns should be considered when selecting antimicrobial prophylaxis. The selection of vancomycin over cefazolin may be necessary in hospitals with high rates of methicillin-resistant *S aureus* or *S epidermidis* infections. The antibiotic should be present in adequate concentrations at the operative site before incision and throughout the procedure; initial dosing is dependent on the volume of distribution, peak levels, clearance, protein binding, and bioavailability. Parenteral agents should be administered during the interval beginning 60 minutes before incision; administration up to the time of incision is preferred. In cesarean section, the antibiotic is administered after umbilical cord clamping. If short-acting agents such as cefoxitin are used, doses should be repeated if the procedure exceeds 3-4 hours in duration. Single-dose prophylaxis is effective for most procedures and results in decreased toxicity and antimicrobial resistance.

**Table 51-7 Recommendations for Surgical Antimicrobial Prophylaxis.**

Type of Operation	Common Pathogens	Drug of Choice
Cardiac (with median sternotomy)	Staphylococci, enteric gram-negative rods	Cefazolin
Noncardiac, thoracic	Staphylococci, streptococci, enteric	Cefazolin

	gram-negative rods	
Vascular (abdominal and lower extremity)	Staphylococci, enteric gram-negative rods	Cefazolin
Neurosurgical (craniotomy)	Staphylococci	Cefazolin
Orthopedic (with hardware insertion)	Staphylococci	Cefazolin
Head and neck (with entry into the oropharynx)	<i>S aureus</i> , oral flora	Cefazolin
Gastroduodenal (high-risk patients <sup>1</sup> )	<i>S aureus</i> , oral flora, enteric gram-negative rods	Cefazolin
Biliary tract (high-risk patients <sup>2</sup> )	<i>S aureus</i> , enterococci, enteric gram-negative rods	Cefazolin
Colorectal (elective surgery)	Enteric gram-negative rods, anaerobes	Oral erythromycin plus neomycin <sup>3</sup>
Colorectal (emergency surgery or obstruction)	Enteric gram-negative rods, anaerobes	Cefoxitin, cefotetan, or cefazolin + metronidazole
Appendectomy, non-perforated	Enteric gram-negative rods, anaerobes	Cefoxitin or cefazolin + metronidazole
Hysterectomy	Enteric gram-negative rods, anaerobes, enterococci, group B streptococci	Cefazolin or cefoxitin
Cesarean section	Enteric gram-negative rods, anaerobes, enterococci, group B streptococci	Cefazolin <sup>4</sup>

<sup>1</sup>Gastric procedures for cancer, ulcer, bleeding, or obstruction; morbid obesity; suppression of gastric acid secretion.

<sup>2</sup>Age > 60, acute cholecystitis, prior biliary tract surgery, common duct stones, jaundice, or diabetes mellitus.

<sup>3</sup>In conjunction with mechanical bowel preparation.

<sup>4</sup>Administer immediately following cord clamping.

Improper administration of antimicrobial prophylaxis leads to excessive surgical wound infection rates. Common errors in antibiotic prophylaxis include selection of the wrong antibiotic, administering the first dose too early or too late, failure to repeat doses during prolonged procedures, excessive duration of prophylaxis, and inappropriate use of broad-spectrum antibiotics.

## Nonsurgical Prophylaxis

Nonsurgical prophylaxis includes the administration of antimicrobials to prevent colonization or asymptomatic infection as well as the administration of drugs following colonization by or inoculation of pathogens but before the development of disease. Nonsurgical prophylaxis is indicated in individuals who are at high risk for temporary exposure to selected virulent pathogens and in patients who are at increased risk for developing infection because of underlying disease (eg, immunocompromised hosts). Prophylaxis is most effective when directed against organisms that are predictably susceptible to antimicrobial agents. Common indications and drugs for nonsurgical prophylaxis are listed in Table 51-8.

**Table 51-8 Recommendations for Nonsurgical Antimicrobial Prophylaxis.**

<b>Infection to Be Prevented</b>	<b>Indication(s)</b>	<b>Drug of Choice</b>	<b>Efficacy</b>
Anthrax	Suspected exposure	Ciprofloxacin or doxycycline	Proposed effective
Cholera	Close contacts of a case	Tetracycline	Proposed effective
Diphtheria	Unimmunized contacts	Penicillin or erythromycin	Proposed effective
Endocarditis	Dental, oral, or upper respiratory tract procedures <sup>1</sup> in at-risk patients <sup>2</sup>	Amoxicillin or clindamycin	Proposed effective
Genital herpes simplex	Recurrent infection ( $\geq$ 4 episodes per year)	Acyclovir	Excellent
Perinatal herpes simplex type 2 infection	Mothers with primary HSV or frequent recurrent genital HSV	Acyclovir	Proposed effective
Group B streptococcal	Mothers with cervical or vaginal GBS colonization and their	Ampicillin or penicillin	Excellent

(GBS) infection	newborns with one or more of the following: (a) onset of labor or membrane rupture before 37 weeks' gestation, (b) prolonged rupture of membranes (> 12 hours), (c) maternal intrapartum fever, (d) history of GBS bacteriuria during pregnancy, (e) mothers who have given birth to infants who had early GBS disease or with a history of streptococcal bacteriuria during pregnancy		
<i>Haemophilus influenzae</i> type B infection	Close contacts of a case in incompletely immunized children (< 48 months old)	Rifampin	Excellent
HIV infection	Health care workers exposed to blood after needle-stick injury	Tenofovir/emtricitabine $\hat{A}$ $\pm$ lopinavir/ritonavir	Good
	Pregnant HIV-infected women who are at $\geq$ 14 weeks of gestation Newborns of HIV-infected women for the first 6 weeks of life, beginning 8–12 hours after birth	HAART <sup>3</sup>	Excellent
Influenza A and B	Unvaccinated geriatric patients, immunocompromised hosts, and health care workers during outbreaks	Oseltamivir	Good
Malaria	Travelers to areas endemic for chloroquine-susceptible disease	Chloroquine	Excellent
	Travelers to areas endemic for chloroquine-resistant disease	Mefloquine, doxycycline, or atovaquone/proguanil	Excellent
Meningococcal infection	Close contacts of a case	Rifampin, ciprofloxacin, or ceftriaxone	Excellent
<i>Mycobacterium avium</i> complex	HIV-infected patients with CD4 count < 75/ $\mu$ L	Azithromycin, clarithromycin, or rifabutin	Excellent
Otitis media	Recurrent infection	Amoxicillin	Good
Pertussis	Close contacts of a case	Erythromycin	Excellent
Plague	Close contacts of a case	Tetracycline	Proposed

			effective
Pneumococemia	Children with sickle cell disease or asplenia	Penicillin	Excellent
<i>Pneumocystis jiroveci</i> pneumonia (PCP)	High-risk patients (eg, AIDS, leukemia, transplant)	Trimethoprim-sulfamethoxazole, dapsone, or atovaquone	Excellent
Rheumatic fever	History of rheumatic fever or known rheumatic heart disease	Benzathine penicillin	Excellent
Toxoplasmosis	HIV-infected patients with IgG antibody to <i>Toxoplasma</i> and CD4 count < 100/ $\mu$ L	Trimethoprim-sulfamethoxazole	Good
Tuberculosis	Persons with positive tuberculin skin tests and one or more of the following: (a) HIV infection, (b) close contacts with newly diagnosed disease, (c) recent skin test conversion, (d) medical conditions that increase the risk of developing tuberculosis, (e) age < 35	Isoniazid, rifampin, or pyrazinamide	Excellent
Urinary tract infections (UTI)	Recurrent infection	Trimethoprim-sulfamethoxazole	Excellent

<sup>1</sup>Prophylaxis is recommended for the following: dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa, invasive procedure of the respiratory tract that involves incision or biopsy of the respiratory mucosa, such as tonsillectomy and adenoidectomy.

<sup>2</sup>Prophylaxis should be targeted to those with the following risk factors: prosthetic heart valves, previous bacterial endocarditis, congenital cardiac malformations, cardiac transplantation patients who develop cardiac valvulopathy.

<sup>3</sup>Highly active retroviral therapy. See <http://www.hivatis.org/> for updated guidelines.

## CASE STUDY

The most likely diagnosis for this patient is *Streptococcus pneumoniae* meningitis, the most common bacterial cause of meningitis in adults. Other possible microbiologic etiologies include *Neisseria meningitidis*, *Listeria monocytogenes*, and enteric gram-negative bacilli. The use of dexamethasone has also been demonstrated to reduce mortality in adults with pneumococcal meningitis in conjunction with appropriate

antimicrobial therapy.

Basic and Clinical Pharmacology > Chapter 52. Antiprotozoal Drugs >

## CASE STUDY

A 5-year-old American girl presents with a 1-week history of intermittent chills, fever, and sweats. She had returned to the United States 2 weeks earlier after leaving the United States for the first time to spend 3 weeks with her grandparents in Nigeria. She received all standard childhood immunizations, but no additional treatment before travel, since her parents have returned to their native Nigeria frequently without medical consequences. Three days ago, the child was seen in an outpatient clinic and diagnosed with a viral syndrome. Examination reveals a lethargic child, with a temperature of 39.8°C (103.6°F) and splenomegaly. She has no skin rash or lymphadenopathy. Initial laboratory studies are remarkable for hematocrit 29.8%, platelets 45,000/mm<sup>3</sup>, and mildly elevated bilirubin and transaminases. A blood smear shows ring forms of *Plasmodium falciparum* at 1.5% parasitemia. What treatment should be started?

## TREATMENT OF MALARIA

Four species of plasmodium typically cause human malaria: *Plasmodium falciparum*, *P vivax*, *P malariae*, and *P ovale*. A fifth species, *P knowlesi*, is primarily a pathogen of monkeys, but has recently been recognized to cause illness, including severe disease, in humans in Asia. Although all of the latter species may cause significant illness, *P falciparum* is responsible for the majority of serious complications and deaths. Drug resistance is an important therapeutic problem, most notably with *P falciparum*.

## PARASITE LIFE CYCLE

Anopheline mosquito inoculates plasmodium sporozoites to initiate human infection (Figure 52-1). Circulating sporozoites rapidly invade liver cells, and exoerythrocytic stage tissue schizonts mature in the liver. Merozoites are subsequently released from the liver and invade erythrocytes. Only erythrocytic parasites cause clinical illness. Repeated cycles of infection can lead to the infection of many erythrocytes and serious disease. Sexual stage gametocytes also develop in erythrocytes before being taken up by mosquitoes, where they develop into infective sporozoites.

### Figure 52-1

Source: Katzung BG, Masters SB, Trevor AJ: *Basic & Clinical Pharmacology*, 11th Edition: <http://www.accessmedicine.com>

Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

Life cycle of malaria parasites. Only the asexual erythrocytic stage of infection causes clinical malaria. All effective antimalarial treatments are blood schizonticides that kill this stage.

(Reproduced, with permission, from Baird JK: Effectiveness of antimalarial drugs. *N Engl J M* 2005;352:1565.)

In *P falciparum* and *P malariae* infection, only one cycle of liver cell invasion and multiplication occurs, and liver infection ceases spontaneously in less than 4 weeks. Thus, treatment that eliminates erythrocytic parasites will cure these infections. In *P vivax* and *P ovale* infections, a dormant hepatic stage, the hypnozoite, is not eradicated by most drugs, and subsequent relapses can therefore occur after therapy directed against erythrocytic parasites. Eradication of both erythrocytic and hepatic parasites is required to cure these infections.

## DRUG CLASSIFICATION

Several classes of antimalarial drugs are available (Table 52-1 and Figure 52-2). Drugs that eliminate developing or dormant liver forms are called **tissue schizonticides**; those that act on erythrocytic parasites are **blood schizonticides**; and those that kill sexual stages and prevent transmission to mosquitoes are **gametocides**. No single available agent can reliably effect a **radical cure**, ie, eliminate both hepatic and erythrocytic stages. Few available agents are **causal prophylactic drugs**, ie, capable of preventing erythrocytic infection. However, all effective chemoprophylactic agents kill erythrocytic parasites before they increase sufficiently in number to cause clinical disease.

**Table 52-1 Major Antimalarial Drugs.**

Drug	Class	Use
Chloroquine	4-Aminoquinoline	Treatment and chemoprophylaxis of infection with sensitive parasites
Amodiaquine <sup>1</sup>	4-Aminoquinoline	Treatment of infection with some chloroquine-resistant <i>P falciparum</i> strains and in fixed combination with artesunate

Piperaquine <sup>1</sup>	Bisquinoline	Treatment of <i>P falciparum</i> infection in fixed combination with dihydroartemisinin
Quinine	Quinoline methanol	Oral and intravenous <sup>1</sup> treatment of <i>P falciparum</i> infections
Quinidine	Quinoline methanol	Intravenous therapy of severe infections with <i>P falciparum</i>
Mefloquine	Quinoline methanol	Chemoprophylaxis and treatment of infections with <i>P falciparum</i>
Primaquine	8-Aminoquinoline	Radical cure and terminal prophylaxis of infections with <i>P vivax</i> and <i>P ovale</i> ; alternative chemoprophylaxis for all species
Sulfadoxine-pyrimethamine (Fansidar)	Folate antagonist combination	Treatment of infections with some chloroquine-resistant <i>P falciparum</i> , including combination with artesunate; intermittent preventive therapy in endemic areas
Atovaquone-proguanil (Malarone)	Quinone-folate antagonist combination	Treatment and chemoprophylaxis of <i>P falciparum</i> infection
Doxycycline	Tetracycline	Treatment (with quinine) of infections with <i>P falciparum</i> ; chemoprophylaxis
Halofantrine <sup>1</sup>	Phenanthrene methanol	Treatment of <i>P falciparum</i> infections
Lumefantrine <sup>1</sup>	Amyl alcohol	Treatment of <i>P falciparum</i> malaria in fixed combination with artemether (Coartem)
Artemisinins (artesunate, artemether, <sup>1</sup> dihydroartemisinin <sup>1</sup> )	Sesquiterpene lactone endoperoxides	Treatment of <i>P falciparum</i> infections; oral combination therapies for uncomplicated disease; intravenous artesunate for severe disease

Structural formulas of antimalarial drugs.

**CHEMOPROPHYLAXIS & TREATMENT**

When patients are counseled on the prevention of malaria, it is imperative to emphasize measures to prevent mosquito bites (eg, with insect repellents, insecticides, and bed nets), because parasites are increasingly resistant to multiple drugs and no chemoprophylactic regimen is fully protective. Current recommendations from the Centers for Disease Control and Prevention (CDC) include the use of chloroquine for chemoprophylaxis in the few areas infested by only chloroquine-sensitive malaria parasites (principally the Caribbean and Central America west of the Panama Canal), mefloquine or Malarone\* for most other malarious areas, and doxycycline for areas with a very high prevalence of multidrug-resistant falciparum malaria (principally border areas of Thailand) (Table 52â€²2). CDC recommendations should be checked regularly (Phone: 770-488-7788; Internet: <http://www.cdc.gov/malaria>), because these may change in response to changing resistance patterns and increasing experience with new drugs. In some circumstances, it may be appropriate for travelers to carry supplies of drugs with them in case they develop a febrile illness when medical attention is unavailable. Regimens for self-treatment include new artemisinin-based combination therapies (see below), which are widely available internationally, though not yet available in the USA; quinine; Malarone; and mefloquine. Most authorities do not recommend routine terminal chemoprophylaxis with primaquine to eradicate

dormant hepatic stages of *P vivax* and *P ovale* after travel, but this may be appropriate in some circumstances, especially for travelers with major exposure to these parasites.

**Table 52-2 Drugs for the Prevention of Malaria in Travelers.<sup>1</sup>**

Drug	Use <sup>2</sup>	Adult Dosage <sup>3</sup>
Chloroquine	Areas without resistant <i>P falciparum</i>	500 mg weekly
Malarone	Areas with chloroquine-resistant <i>P falciparum</i>	1 tablet (250 mg atovaquone/100 mg proguanil) daily
Mefloquine	Areas with chloroquine-resistant <i>P falciparum</i>	250 mg weekly
Doxycycline	Areas with multidrug-resistant <i>P falciparum</i>	100 mg daily
Primaquine <sup>4</sup>	Terminal prophylaxis of <i>P vivax</i> and <i>P ovale</i> infections; alternative for primary prevention	52.6 mg (30 mg base) daily for 14 days after travel; for primary prevention 52.6 mg (30 mg base) daily

<sup>1</sup>Recommendations may change, as resistance to all available drugs is increasing. See text for additional information on toxicities and cautions. For additional details and pediatric dosing, see CDC guidelines (phone: 877-FYI-TRIP; <http://www.cdc.gov>). Travelers to remote areas should consider carrying effective therapy (see text) for use if they develop a febrile illness and cannot reach medical attention quickly.

<sup>2</sup>Areas without known chloroquine-resistant *P falciparum* are Central America west of the Panama Canal, Haiti, Dominican Republic, Egypt, and most malarious countries of the Middle East. Malarone or mefloquine are currently recommended for other malarious areas except for border areas of Thailand, where doxycycline is recommended.

<sup>3</sup>For drugs other than primaquine, begin 1–2 weeks before departure (except 2 days before for doxycycline and Malarone) and continue for 4 weeks after leaving the endemic area (except 1 week for Malarone). All dosages refer to salts.

<sup>4</sup>Screen for G6PD deficiency before using primaquine.

Multiple drugs are available for the treatment of malaria that presents in the USA (Table 52–3). Nonfalciparum infections and falciparum malaria from areas without known resistance should be treated with chloroquine. Vivax and ovale malaria should subsequently be treated with primaquine to eradicate liver forms. However, for *P vivax*, chloroquine-resistance is increasingly reported, and primaquine may fail to eradicate liver stages. Falciparum malaria from most areas is typically treated with oral quinine or intravenous quinidine, in either case plus doxycycline, or, for children, clindamycin. Other agents that are generally effective against resistant falciparum malaria include mefloquine and halofantrine, both of which have toxicity concerns at treatment dosages; Malarone, which may occasionally fail because of drug resistance; and artemisinin derivatives. The artemisinin derivatives are increasingly the international standard of care, but are not yet routinely available in the USA.

**Table 52–3 Treatment of Malaria.**

Clinical Setting	Drug Therapy <sup>1</sup>	Alternative Drugs
Chloroquine-sensitive <i>P falciparum</i> and <i>P malariae</i> infections	Chloroquine phosphate, 1 g, followed by 500 mg at 6, 24, and 48 hours <i>or</i> Chloroquine phosphate, 1 g at 0 and 24 hours, then 0.5 g at 48 hours	
<i>P vivax</i> and <i>P ovale</i> infections	Chloroquine (as above), then (if G6PD normal) primaquine, 52.6 (30 mg base) for 14 days	
Uncomplicated infections with chloroquine-resistant <i>P falciparum</i>	Quinine sulfate, 650 mg 3 times daily for 3–7 days <i>plus one of the following</i> Doxycycline, 100 mg twice daily for 7 days <i>or</i>	Malarone, 4 tablets (total of 1 g atovaquone, 400 mg proguanil) daily for 3 days <i>or</i> Mefloquine, 15 mg/kg once or 750 mg, then 500 mg in 6–8 hours <i>or</i>

	Clindamycin, 600 mg twice daily for 7 days	Coartem (coartemether 20 mg, lumefantrine 120 mg), 4 tablets twice daily for 3 days
Severe or complicated infections with <i>P falciparum</i> <sup>3</sup>	Artesunate, 2.4 mg/kg IV, every 12 hours for 1 day, then daily for two additional days; follow with 7 day oral course of doxycycline or clindamycin or full treatment course of mefloquine or Malarone <i>or</i> <sup>1</sup> Quinidine gluconate, <sup>2</sup> 10 mg/kg IV over 1–2 hours, then 0.02 mg/kg IV/min <i>or</i> <sup>1</sup> 15 mg/kg IV over 4 hours, then 7.5 mg/kg IV over 4 hours every 8 hours	Artemether, 3.2 mg/kg IM, then 1.6 mg/kg/d IM; follow with oral therapy as for artesunate

<sup>1</sup>All dosages are oral and refer to salts unless otherwise indicated. See text for additional information on all agents, including toxicities and cautions. See CDC guidelines (phone: 770-488-7788; <http://www.cdc.gov>) for additional information and pediatric dosing.

<sup>2</sup>Cardiac monitoring should be in place during intravenous administration of quinidine. Change to an oral regimen as soon as the patient can tolerate it.

\*Malarone is a proprietary combination formulation of atovaquone plus proguanil.

## CHLOROQUINE

Chloroquine has been the drug of choice for both treatment and chemoprophylaxis of malaria since the 1940s, but its usefulness against *P falciparum* has been seriously compromised by drug resistance. It remains the drug of choice in the treatment of sensitive *P falciparum* and other species of human malaria parasites.

### Chemistry & Pharmacokinetics

Chloroquine is a synthetic 4-aminoquinoline (Figure 52–2) formulated as the phosphate salt for oral use. It is rapidly and almost completely absorbed from the gastrointestinal tract, reaches maximum plasma concentrations in about 3 hours, and is rapidly distributed to the tissues. It has a very large apparent volume of distribution of 100–1000 L/kg and is slowly released from tissues and metabolized. Chloroquine is principally excreted in the urine with an initial half-life of 3–5 days but a much longer terminal elimination half-life of 1–2 months.

### Antimalarial Action & Resistance

#### ANTIMALARIAL ACTION

When not limited by resistance, chloroquine is a highly effective blood schizonticide. It is also moderately effective against gametocytes of *P vivax*, *P ovale*, and *P malariae* but not against those of *P falciparum*. Chloroquine is not active against liver stage parasites.

#### MECHANISM OF ACTION

Chloroquine probably acts by concentrating in parasite food vacuoles, preventing the biocrystallization of the hemoglobin breakdown product, heme, into hemozoin, and thus eliciting parasite toxicity due to the buildup of free heme.

#### RESISTANCE

Resistance to chloroquine is now very common among strains of *P falciparum* and uncommon but increasing for *P vivax*. In *P falciparum*, mutations in a putative transporter, PfCRT, have been correlated with resistance. Chloroquine resistance can be reversed by certain agents, including verapamil, desipramine, and chlorpheniramine, but the clinical value of resistance-reversing drugs is not established.

### Clinical Uses

#### TREATMENT

Chloroquine is the drug of choice in the treatment of nonfalciparum and sensitive falciparum malaria. It rapidly terminates fever (in 24–48 hours) and clears parasitemia (in 48–72 hours) caused by sensitive parasites. It is still used to treat falciparum malaria in some areas with widespread resistance, in particular much of Africa, owing to its safety, low cost, antipyretic properties, and partial activity, but continued use of chloroquine for this purpose is discouraged, especially in nonimmune individuals. Chloroquine has been replaced by other drugs, principally artemisinin-based combination therapies, as the standard therapy to treat falciparum malaria in most endemic countries. Chloroquine does not eliminate dormant liver forms of *P vivax* and *P ovale*, and for that reason primaquine must be added for the radical cure of these species.

### CHEMOPROPHYLAXIS

Chloroquine is the preferred chemoprophylactic agent in malarious regions without resistant falciparum malaria. Eradication of *P vivax* and *P ovale* requires a course of primaquine to clear hepatic stages.

### AMEBIC LIVER ABSCESS

Chloroquine reaches high liver concentrations and may be used for amebic abscesses that fail initial therapy with metronidazole (see below).

### Adverse Effects

Chloroquine is usually very well tolerated, even with prolonged use. Pruritus is common, primarily in Africans. Nausea, vomiting, abdominal pain, headache, anorexia, malaise, blurring of vision, and urticaria are uncommon. Dosing after meals may reduce some adverse effects. Rare reactions include hemolysis in glucose-6-phosphate dehydrogenase (G6PD)-deficient persons, impaired hearing, confusion, psychosis, seizures, agranulocytosis, exfoliative dermatitis, alopecia, bleaching of hair, hypotension, and electrocardiographic changes (QRS widening, T-wave abnormalities). The long-term administration of high doses of chloroquine for rheumatologic diseases (see Chapter 36) can result in irreversible ototoxicity, retinopathy, myopathy, and peripheral neuropathy. These abnormalities are rarely if ever seen with standard-dose weekly chemoprophylaxis, even when given for prolonged periods. Large intramuscular injections or rapid intravenous infusions of chloroquine hydrochloride can result in severe hypotension and respiratory and cardiac arrest. Parenteral administration of chloroquine is best avoided, but if other drugs are not available for parenteral use, it should be infused slowly.

### Contraindications & Cautions

Chloroquine is contraindicated in patients with psoriasis or porphyria, in whom it may precipitate acute attacks of these diseases. It should generally not be used in those with retinal or visual field abnormalities or myopathy. Chloroquine should be used with caution in patients with a history of liver disease or neurologic or hematologic disorders. The antidiarrheal agent kaolin and calcium- and magnesium-containing antacids interfere with the absorption of chloroquine and should not be co-administered with the drug. Chloroquine is considered safe in pregnancy and for young children.

### OTHER QUINOLINES

Amodiaquine is closely related to chloroquine, and it probably shares mechanisms of action and resistance with that drug. Amodiaquine has been widely used to treat malaria because of its low cost, limited toxicity, and, in some areas, effectiveness against chloroquine-resistant strains of *P falciparum*. Reports of toxicities of amodiaquine, including agranulocytosis, aplastic anemia, and hepatotoxicity, have limited use of the drug in recent years. However, recent reevaluation has shown that serious toxicity from amodiaquine is rare, and it may be used as a replacement for chloroquine in areas with high rates of resistance but limited resources. The most important current use of amodiaquine is in combination therapy. The World Health Organization (WHO) lists amodiaquine plus artesunate as a recommended therapy for falciparum malaria in areas with resistance to older drugs (Table 52-4). This combination is now available as a single tablet (ASAQ, Coarsucam) and is the first-line therapy for the treatment of uncomplicated falciparum malaria in many countries in Africa. Another combination, amodiaquine plus sulfadoxine-pyrimethamine, remains reasonably effective for the treatment of falciparum malaria in many areas with some resistance to the individual drugs, and WHO lists this combination as an interim alternative if artemisinin-containing therapies are unavailable. Chemoprophylaxis with amodiaquine is best avoided because of its apparent increased toxicity with long-term use.

**Table 52-4 WHO Recommendations for the Treatment of Falciparum Malaria.**

Regimen	Notes
Artemether-lumefantrine (Coartem, Riamet)	Coformulated; first-line therapy in many African countries
Artesunate-amodiaquine (ASAQ, Arsucam)	Coformulated; first-line therapy in many African countries
Artesunate-mefloquine	Standard therapy in parts of Southeast Asia
Artesunate-sulfadoxine-pyrimethamine	First-line therapy in some countries; efficacy low compared with other regimens in some areas
Amodiaquine-sulfadoxine-pyrimethamine	Less expensive; recommended as an interim option when efficacy established and other regimens are not available

World Health Organization: Guidelines for the Treatment of Malaria. World Health Organization. Geneva, 2006.

Piperaquine is a bisquinoline that was used widely to treat chloroquine-resistant falciparum malaria in China in the 1970s through the 1980s, but its use waned after resistance became widespread. Recently, piperaquine has been combined with

dihydroartemisinin in coformulated tablets (Artekin, Duocotexcin) that have shown excellent efficacy and safety for the treatment of falciparum malaria, without apparent drug resistance. Piperaquine has a longer half-life (~ 28 days) than amodiaquine (~ 14 days), mefloquine (~ 14 days), or lumefantrine (~ 4 days), leading to a longer period of post-treatment prophylaxis with dihydroartemisinin-piperaquine than with the other leading artemisinin-based combinations; this feature should be particularly advantageous in high transmission areas. Dihydroartemisinin-piperaquine is now the first-line therapy for the treatment of uncomplicated malaria in Vietnam.

## **QUININE & QUINIDINE**

Quinine and quinidine remain first-line therapies for falciparum malaria—especially severe disease—although toxicity may complicate therapy. Resistance to quinine is uncommon but may be increasing.

### **Chemistry & Pharmacokinetics**

Quinine is derived from the bark of the cinchona tree, a traditional remedy for intermittent fevers from South America. The alkaloid quinine was purified from the bark in 1820, and it has been used in the treatment and prevention of malaria since that time. Quinidine, the dextrorotatory stereoisomer of quinine, is at least as effective as parenteral quinine in the treatment of severe falciparum malaria. After oral administration, quinine is rapidly absorbed, reaches peak plasma levels in 1–3 hours, and is widely distributed in body tissues. The use of a loading dose in severe malaria allows the achievement of peak levels within a few hours. The pharmacokinetics of quinine varies among populations. Individuals with malaria develop higher plasma levels of the drug than healthy controls, but toxicity is not increased, apparently because of increased protein binding. The half-life of quinine also is longer in those with severe malaria (18 hours) than in healthy controls (11 hours). Quinidine has a shorter half-life than quinine, mostly as a result of decreased protein binding. Quinine is primarily metabolized in the liver and excreted in the urine.

### **Antimalarial Action & Resistance**

#### **ANTIMALARIAL ACTION**

Quinine is a rapid-acting, highly effective blood schizonticide against the four species of human malaria parasites. The drug is gametocidal against *P. vivax* and *P. ovale* but not *P. falciparum*. It is not active against liver stage parasites. The mechanism of action of quinine is unknown.

#### **RESISTANCE**

Increasing in vitro resistance of parasites from a number of areas suggests that quinine resistance will be an increasing problem. Resistance to quinine is already common in some areas of Southeast Asia, especially border areas of Thailand, where the drug may fail if used alone to treat falciparum malaria. However, quinine still provides at least a partial therapeutic effect in most patients.

### **Clinical Uses**

#### **PARENTERAL TREATMENT OF SEVERE FALCIPARUM MALARIA**

For many years, quinine dihydrochloride or quinidine gluconate have been the treatments of choice for severe falciparum malaria, although intravenous artesunate now provides an alternative for this indication. Quinine can be administered slowly intravenously or, in a dilute solution, intramuscularly, but parenteral preparations of this drug are not available in the USA. Quinidine has been the standard therapy in the USA for the parenteral treatment of severe falciparum malaria. The drug can be administered in divided doses or by continuous intravenous infusion; treatment should begin with a loading dose to rapidly achieve effective plasma concentrations. Because of its cardiac toxicity and the relative unpredictability of its pharmacokinetics, intravenous quinidine should be administered with cardiac monitoring. Therapy should be changed to an effective oral agent as soon as the patient has improved and can tolerate oral medications.

#### **ORAL TREATMENT OF FALCIPARUM MALARIA**

Quinine sulfate is appropriate first-line therapy for uncomplicated falciparum malaria except when the infection was transmitted in an area without documented chloroquine-resistant malaria. Quinine is commonly used with a second drug (most often doxycycline or, in children, clindamycin) to shorten quinine's duration of use (usually to 3 days) and limit toxicity. Quinine is less effective than chloroquine against other human malarias and is more toxic. Therefore, it is not used to treat infections with these parasites.

#### **MALARIAL CHEMOPROPHYLAXIS**

Quinine is not generally used in chemoprophylaxis owing to its toxicity, although a daily dose of 325 mg is effective.

#### **BABESIOSIS**

Quinine is first-line therapy, in combination with clindamycin, in the treatment of infection with *Babesia microti* or other human babesial infections.

### **Adverse Effects**

Therapeutic dosages of quinine and quinidine commonly cause tinnitus, headache, nausea, dizziness, flushing, and visual disturbances, a constellation of symptoms termed **cinchonism**. Mild symptoms of cinchonism do not warrant the discontinuation of therapy. More severe findings, often after prolonged therapy, include more marked visual and auditory abnormalities, vomiting, diarrhea, and abdominal pain. Hypersensitivity reactions include skin rashes, urticaria, angioedema, and bronchospasm. Hematologic abnormalities include hemolysis (especially with G6PD deficiency), leukopenia, agranulocytosis, and thrombocytopenia. Therapeutic doses may cause hypoglycemia through stimulation of insulin release; this is a particular problem in severe infections and in pregnant patients, who have increased sensitivity to insulin. Quinine can stimulate uterine contractions, especially in the third trimester. However, this effect is mild, and quinine and quinidine remain drugs of choice for severe falciparum malaria even during pregnancy. Intravenous infusions of the drugs may cause thrombophlebitis.

Severe hypotension can follow too-rapid intravenous infusions of quinine or quinidine. Electrocardiographic abnormalities (QT interval prolongation) are fairly common with intravenous quinidine, but dangerous arrhythmias are uncommon when the drug is administered appropriately in a monitored setting.

**Blackwater fever** is a rare severe illness that includes marked hemolysis and hemoglobinuria in the setting of quinine therapy for malaria. It appears to be due to a hypersensitivity reaction to the drug, although its pathogenesis is uncertain.

### **Contraindications & Cautions**

Quinine (or quinidine) should be discontinued if signs of severe cinchonism, hemolysis, or hypersensitivity occur. It should be avoided if possible in patients with underlying visual or auditory problems. It must be used with great caution in those with underlying cardiac abnormalities. Quinine should not be given concurrently with mefloquine and should be used with caution in a patient with malaria who has previously received mefloquine chemoprophylaxis. Absorption may be blocked by aluminum-containing antacids. Quinine can raise plasma levels of warfarin and digoxin. Dosage must be reduced in renal insufficiency.

### **MEFLOQUINE**

Mefloquine is effective therapy for many chloroquine-resistant strains of *P falciparum* and against other species. Although toxicity is a concern, mefloquine is one of the recommended chemoprophylactic drugs for use in most malaria-endemic regions with chloroquine-resistant strains.

### **Chemistry & Pharmacokinetics**
